Abstract: A previous study by [J. Lee, G. Long, and C. Jeung, J. Acoust. Soc. Am. **119**, S3332 (2006)] found that information at the onset or offset of modulation could be utilized for improved amplitude modulation (AM) depth discrimination in a continuous carrier condition (carrier presented 250 ms earlier and later than the modulator). In this study, the relative contribution of information at the onset or offset of the modulation was examined with an onset-fringe carrier condition (carrier begins 250 ms earlier than the modulator) and an offset-fringe condition (carrier ends 250 ms later than the modulator). The results suggest that modulation information at the onset might be utilized more than at the offset.

1. Introduction

Lee and Bacon (1997) studied the duration effect on amplitude modulation (AM) depth discrimination with a gated sinusoidal carrier condition (modulation begins and ends with the carrier). AM depth discrimination was found to be influenced by the number of modulation cycles. There was a critical duration of four cycles of modulation in which a dramatic threshold improvement (more than factor of 2) was observed when the stimulus duration increased from a shorter duration to this critical duration; only a slight or no improvement of threshold was observed when the stimulus duration exceeded this critical duration for modulation rates of 10, 20, 40, and 80 Hz. Lee and Bacon (1997) compared AM detection data (Sheft and Yost, 1990) with their AM depth discrimination data and found that AM detection lacks the critical duration effect observed in AM depth discrimination. In contrast, AM detection thresholds were found to decrease gradually with increasing duration from 25 to 400 ms. It should be noted, however, that Sheft and Yost (1990) used the noise carrier whose total duration was 51.2 ms longer (due to 25.6 ms rise/fall time) than modulation duration, while Lee and Bacon (1997) used a gated sinusoidal carrier. This difference between stimuli led to the study of Lee *et al.* (2006) in which both AM detection and AM depth discrimination were measured with the same stimulus conditions.

Lee *et al.* (2006) measured AM detection and AM depth discrimination with gated and continuous noise carrier conditions as a function of the number of modulation cycles. In the continuous noise carrier condition, the carrier was presented 250 ms earlier and 250 ms later than the modulator. A difference in thresholds between gated and continuous carrier conditions was observed for lower modulation rates of 10, 20, 40, and 80 Hz at less than four modulation cycles.

The critical duration of four cycles of modulation was observed for both AM detection and AM depth discrimination (for both standard depths of 0.1 and 0.4) in the gated carrier

[a)]A portion of this study was presented at the American Auditory Society meeting, 2007.

condition for lower modulation rates (10, 20, 40, and 80 Hz). For these lower modulation rates, there was a significant improvement in **both** AM detection and AM depth discrimination thresholds in the continuous carrier condition at fewer than four cycles of modulation. Thresholds were similar for both gated and continuous carrier conditions for modulation cycles greater than four. These results suggest that a difference in stimulus gating may have caused the absence of a critical duration effect in AM detection observed from the comparison of data from Sheft and Yost (1990) and Lee and Bacon (1997). For the gated carrier condition, shaping the onset/offset of stimuli with rise/fall times might reduce modulation information at the onset/offset, which might result in a dramatic change in threshold for a smaller number of modulation cycles. Therefore, the presence of a critical duration effect appears to be the result of gating differences.

In the continuous carrier condition used in Lee *et al.* (2006), the carrier was presented before and after the modulator. Therefore, it is impossible to determine from their data whether it was the modulation information at onset or offset of the modulator that was being used in the AM detection/discrimination task. The goal of the present study was to determine whether the onset or offset of modulation information is responsible for the observed improvement in AM depth discrimination at fewer than four cycles of modulation for lower modulation rates (10, 20, 40 and 80 Hz) in the continuous carrier condition. Four carrier conditions were compared: Gated (carrier gated on and off with the modulator), Onset/offset-fringe (carrier gated on 250 ms before modulator onset and gated off 250 ms after modulator offset), Offset-fringe (carrier gated on with the modulator and gated off 250 ms after modulator offset), and Onset-fringe (carrier gated on 250 ms before modulator onset and gated off with the modulator). For the purposes of this study, the continuous carrier condition of Lee *et al.* (2006) will be referred to as the onset/offset-fringe condition to make a clear distinction from the continuous carrier condition of Sheft and Yost (1990), where the wideband noise carrier was continuously on.

If it is the onset information of the modulator that contributes to the improved AM depth discrimination at fewer than four cycles of modulation, then the expected findings are: (1) the thresholds of the onset-fringe carrier condition will be lower than those of the offset-fringe carrier condition; (2) the thresholds of the onset-fringe and onset/offset-fringe carrier conditions will be similar or the same; (3) the thresholds of the gated carrier and offset-fringe carrier conditions will be similar or the same.

2. Methods

2.1 Subjects

Three normal hearing subjects participated in this study. Their ages ranged from 21 to 41. The subjects were paid for their participation.

2.2 Stimuli

Sinusoidally amplitude modulated noise was used as the stimulus throughout this experiment. The carrier was broadband noise low-pass filtered at 10,000 Hz.

Equation (1) defines the stimuli where A is the amplitude, m is the standard modulation depth, Δm is the change in the modulation depth, f_m is the modulation rate, and θ is the phase of modulation.

$$s(t) = A\{1 + [(m + \Delta m)\cos(2\pi f_m t + \theta)]\}X[\text{noise}], \quad (1)$$

Modulation frequencies of 10, 20, 40, or 80 Hz with a standard modulation depth of 0.1 were used. The phase of modulation was randomly chosen between trials. The onset and offset of all stimuli were shaped by a cosine-squared function resulting in a rise/fall time of 5 ms. The number of cycles for each modulation frequency was as follows: 2, 4, or 8 for 10 Hz; 2, 4, 8, or 16 for 20 Hz; 2, 4, 8, 16, or 32 for 40 Hz; 2, 4, 8, 16, 32, or 64 for 80 Hz. The overall level for each interval was randomized between 65 and 71 dB sound pressure level to ensure that depth discrimination was not based on a change in overall level due to modulation. The Tucker-Davis Technologies (TDT) system 3 was used to generate the stimuli with a 20 kHz sampling rate. Experiments were controlled by SykoFizX software. Four carrier conditions

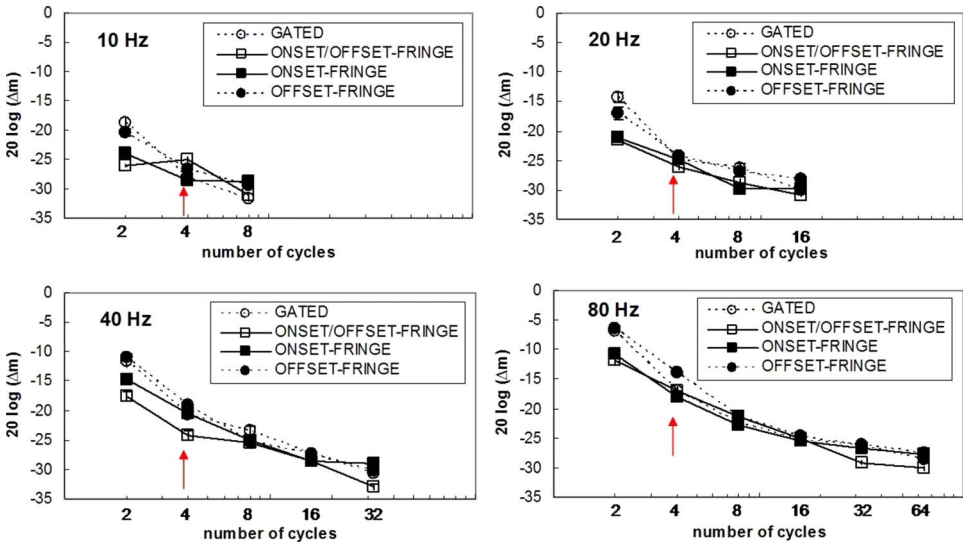

Fig. 1. (Color online) AM depth discrimination thresholds with gated (open circle), onset/offset-fringe carrier (open square), onset-fringe (closed square), and offset-fringe (closed circle) conditions were plotted as a function of the number of modulation cycles for $fm = 10$, 20, 40, and 80 Hz. These are the mean thresholds for three subjects. The standard errors are plotted and the size of symbols are smaller than the size of symbols.

were compared: Gated (carrier gated on and off with the modulator), onset/offset-fringe (carrier gated on 250 ms before modulator onset and gated off 250 ms after modulator offset), offset-fringe (carrier gated on with the modulator and gated off 250 ms after modulator offset), and onset-fringe (carrier gated on 250 ms before modulator onset and gated off with the modulator).

2.3 Procedure

AM depth discrimination thresholds were determined by a two alternative forced choice paradigm. The psychophysical task was to determine which interval contained the amplitude modulated sound with greater depth of modulation. The "standard" stimulus had a modulation depth of 0.1, and the "signal" stimulus had a modulation depth of $0.1+\Delta m$. The Δm was varied using a 3-down 1-up adaptive procedure (79.4% correct). The step size for the modulation depth change was 2 dB and was reduced to 1 dB after three reversals, and the trials were continued until obtaining seven reversals. The threshold for each run was an average of the final four reversals in the run. For each condition, three threshold estimations were averaged for the final threshold calculation if the standard deviation of the three threshold estimations was smaller than 3 dB. Additional threshold estimations were performed if the standard deviation was equal to or larger than 3 dB until the standard deviation was smaller than 3 dB, but the maximum number of threshold estimations did not exceed five.

Subjects were seated in a sound treated booth and listened to the stimuli through Sennheiser HD 250 linear II earphones. All stimuli were monaurally presented. Subject's responses were obtained with a push button response box with two buttons corresponding to two intervals. Practice trials were given before every run began and lasted until the subjects indicated that they understood the task. Correct answer visual feedback was provided after each response.

3. Results

All data in the figures are the mean of three subjects with standard error. In many cases, the standard error bars are smaller than the symbols. Figure 1 shows AM depth discrimination thresholds as a function of the number of modulation cycles for gated (open circles), onset/offset-fringe carrier (open square), onset-fringe (closed square), and offset-fringe (closed circle) conditions. Each panel represents different modulation rates. For a given modulation

rate, a two-way repeated analysis of variance (carrier type *x* number of cycles) indicated the main effect of carrier type is dependent on the number of modulation cycles since there is a significant interaction between the carrier type and the number of cycles ($p < 0.01$) for all modulation rates. Additional multiple comparison analysis (Holm–Sidak method) indicated that thresholds of gated and onset/offset-fringe conditions were not significantly different for four or greater number of cycles for all modulation rates except at 40 Hz for four modulation cycles, but the onset/offset-fringe condition thresholds were significantly better than those of the gated condition for two modulation cycles for all modulation rates ($p < 0.05$). Thresholds tend to increase as the number of modulation cycles decreases ($p < 0.025$) for all modulation rates. This finding is consistent with the results of Lee *et al.* (2006).

Comparison analysis of onset-fringe and offset-fringe conditions indicated that thresholds were not significantly different for four or greater number of cycles for all modulation rates except at 80 Hz for four modulation cycles, but the onset-fringe condition thresholds were significantly better than those of the offset-fringe condition for two modulation cycles for all modulation rates ($p < 0.05$).

Thresholds of offset-fringe and gated conditions were not significantly different for all modulation cycles for all modulation rates except at 20 Hz for two modulation cycles and at 80 Hz for four modulation cycles. Also, thresholds of onset-fringe and onset/offset-fringe conditions were not significantly different for all modulation cycles for all modulation rates except at 40 Hz for two and four modulation cycles.

Overall, at two modulation cycles, thresholds were better for conditions in which modulation information at the onset was well preserved (onset-fringe and onset/offset-fringe carrier) than for conditions in which modulation information at onset was distorted by the gating function (gated carrier and offset-fringe carrier). This supports our hypothesis that the modulation information at onset may contribute to better AM depth discrimination.

4. Discussion

For AM depth discrimination, conditions that included an unmodulated carrier prior to the modulator (onset-fringe and onset/offset-fringe carrier) had lower thresholds at two modulation cycles, resulting in gradual threshold improvement with increasing number of modulation cycles, than other conditions without an unmodulated carrier prior to the modulator (offset-fringe and gated carrier), resulting in an abrupt threshold improvement with increasing modulation cycles from two to four. Similar findings have been reported in studies with AM sounds (Sheft and Yost, 1990; Viemeister, 1979) and with recognition of syllables (Ainsworth and Meyer, 1994)

Sheft and Yost (1990) found that AM detection thresholds were reduced by the addition of 500 ms of carrier prior to the onset of modulation (fringe condition), which is similar to our onset-fringe condition. Their continuous condition (wideband noise carrier continuously on) produced lower thresholds than both gated and fringe conditions. This is different from the data reported here, which showed no significant difference between onset-fringe and onset/offset-fringe carrier conditions. Note, however, that their continuous carrier condition differs from our onset/offset-fringe condition. Our onset/offset-fringe had only 250 ms of noise present before and after the modulation, while their continuous carrier condition had a non-stop continuous carrier throughout the trials.

Viemeister (1979) measured AM detection for a gated and a continuous carrier condition (wideband noise carrier that was continuously on). Thresholds were found to be lower for the continuous carrier condition than for the gated carrier condition at low modulation rates (64 Hz and lower), while thresholds were similar across the two carrier conditions at higher modulation rates. The threshold difference between gated and continuous carrier conditions was larger for shorter stimulus durations. Viemeister speculated that improved thresholds for the continuous carrier condition at lower modulation rates may be due to a slow (100–200 ms) adaptation process occurring in the gated carrier condition. Short-term adaptation might reduce sensitivity to the modulation if the initial neural response to the onset of the stimulus is larger

relative to the change in neural response produced by the sinusoidal modulation. This reduced sensitivity effect is larger near carrier onset and will be more apparent for shorter durations; the first cycles of low frequency modulation would be masked.

Ainsworth and Meyer (1994) showed improved recognition of plosive syllables for a condition where noise was presented continuously (subjects were exposed to the noise at least 1 min before the task started), but this improved recognition was not present for a condition where noise was gated with syllables. They suggested that this may be the result of cochlear nerve fiber adaptation to the noise. Adaptation results in an increased dynamic range (increased saturation threshold) of the nerve fiber and could be the cause of improved recognition of syllables in continuous noise conditions (similar to our onset-fringe and onset/offset-fringe carrier conditions).

Therefore, it is possible that the improved AM depth discrimination at the shorter durations (usually corresponding to modulation cycles less than four) for the onset-fringe and onset/offset-fringe carrier condition in our study might be due to auditory nerve fibers' adaptation to the preceding noise. Another possible explanation is that unmodulated noise presented prior to the modulation could help preserve modulation information at the onset since the onset of modulation portion would not be shaped by the rise/fall time.

Abstract: Orthotropic plates support flexural waves with wavenumbers that depend on their angle of propagation. The present work investigates the effect of fluid loading on this angular dependence, and finds that the effect is relatively small for typical composite plate materials in contact with water. This finding results from an analytical model of the fluid-loaded plate, in which the plate is modeled by classical laminated plate theory and the fluid is modeled as an ideal acoustic fluid. The resulting dispersion relation is a tenth-order polynomial in the flexural wavenumber. Direct numerical solution, as well as analysis at frequencies below coincidence, reveals that the angular dependence of wavenumber is magnified but not significantly distorted by the addition of fluid loading.

1. Introduction

The bending rigidity of a composite plate may easily vary by an order of magnitude in its principal directions, even for classical composite materials. When the plate is *in vacuo*, this naturally causes substantial variations in the flexural wavenumber as the direction of wave propagation varies. The present work is concerned with the effects of fluid loading on these variations. Understanding this effect is expected to provide insights into the structural acoustics of finite orthotropic plates (Anderson and Bratos-Anderson, 2005), curved orthotropic structures (Ghinet and Atalla, 2005), and musical instrument models that involve thin orthotropic structures (Derveaux *et al.*, 2003).

Previous work by Fay (1948) on the propagation of flexural waves in fluid-loaded isotropic plates provides a foundation for the present work. Fay found that the dispersion relation for flexural waves involves a tenth-order polynomial in wavenumber. Further analysis at frequencies below coincidence revealed the existence of an unattenuated flexural wave that propagates with a subsonic sound speed. Fahy (1989) provided a simplified dispersion relationship below coincidence in which the effective mass of the fluid-loaded plate is a sum of the plate mass and the mass of a fluid whose volume is determined by the flexural wavenumber.

The present work derives the dispersion relation for a fluid-loaded orthotropic plate, following the derivation for the isotropic plate given by Fahy wherever possible. Next, a convenient method is presented for numerically computing the coefficients of the resulting tenth-order polynomial. The method involves the convolution of various polynomial coefficients, which avoids extensive algebraic manipulation. At frequencies below coincidence, a simplified dispersion relationship is found that is similar to that provided by Fahy. Examples involving classic composite materials indicate that the plate mass competes with the fluid mass for parameters of practical interest.

 © 2008 Acoustical Society of America

2. Dispersion relation

We begin by considering the equation of motion for an infinite orthotropic plate in contact with an acoustic fluid on one side (Leissa, 1969),

$$D_x\frac{\partial^4 w}{\partial x^4}+2D_{xy}\frac{\partial^4 w}{\partial x^2\,\partial y^2}+D_y\frac{\partial^4 w}{\partial y^4}+\rho_s h\frac{\partial^2 w}{\partial t^2}=f, \tag{1}$$

where w is the normal displacement and the coordinates x and y lie in the plane of the plate. This equation assumes that the plate thickness, h, is small relative to a flexural wavelength. The variables D_x and D_y represent the flexural stiffness of the plate in the x and y directions, respectively, and D_{xy} represents the "bending-torsional stiffness" of the plate (Anderson and Bratos-Anderson, 2005). Note that some authors, such as Timoshenko and Woinowsky-Krieger (1959), define the variable D_{xy} differently.

Derivation of the dispersion relation for the fluid-loaded orthotropic plate will follow a similar derivation by Fahy for isotropic plates, in which wave impedances for the plate and fluid act in mechanical parallel. Substitution of traveling wave representations for displacement and applied traction, $w=\Re\{W\exp[i(\omega t-k_x x-k_y y)]\}$ and $f=\Re\{F\exp[i(\omega t-k_x x-k_y y)]\}$, into Eq. (1) yields the wave impedance of the plate

$$Z_p=\frac{F}{i\omega W}=\frac{D_x k_x^4+2D_{xy}k_x^2k_y^2+D_y k_y^4-\rho_s h\omega^2}{i\omega}. \tag{2}$$

Similarly, substitution of a pressure field of the form $p=\Re\{P\exp[i(\omega t-k_x x-k_y y-k_z z)]\}$ into Euler's equation yields the acoustic wave impedance of the fluid,

$$Z_{fl}=\frac{P}{i\omega W}=\frac{\rho_0\omega}{k_z}, \tag{3}$$

and the acoustic wave equation provides a relationship between the wavenumbers,

$$k_0^2=k_x^2+k_y^2+k_z^2. \tag{4}$$

Finally, the dispersion relations are obtained by adding the impedances that are in mechanical parallel in the absence of excitation, $Z_p+Z_{fl}=0$, or

$$(k_0^2-k_x^2-k_y^2)(D_x k_x^4+2D_{xy}k_y^2k_x^2+D_y k_y^4-\rho_s h\omega^2)^2-(i\rho_0\omega^2)^2=0. \tag{5}$$

This polynomial is fifth order in k_x^2 when k_y^2 is specified. Only one of the roots represents a traveling flexural wave that is unattenuated when damping is not present. This wave is the sole focus for the remainder of this paper. For discussions of the other four roots, in the context of isotropic plates, the reader is referred to the paper by Fay.

In numerical simulations, it is convenient to numerically compute the coefficients of this polynomial by convolving vectors of coefficients whenever two polynomials are multiplied. This allows Eq. (5) to be written as $p(k_x^2)=0$, where $p(k_x^2)$ is a fifth-order polynomial in k_x^2. Its vector of coefficients, $\mathbf{p}$, is given by

$$\mathbf{p}=\mathbf{p}_1*\mathbf{p}_2*\mathbf{p}_2+\mathbf{p}_3, \tag{6}$$

where $*$ denotes a convolution defined by

$$(\mathbf{p}*\mathbf{q})_k=\sum_j \mathbf{p}_j\mathbf{q}_{k+1-j}. \tag{7}$$

The vectors are obtained by inspection of Eq. (5),

$$\mathbf{p}_1=\begin{bmatrix}-1 & (k_0^2-k_y^2)\end{bmatrix}. \tag{8}$$

$$\mathbf{p}_2=\begin{bmatrix}D_x & 2D_{xy}k_y^2 & (D_y k_y^4-\rho_s h\omega^2)\end{bmatrix}. \tag{9}$$

$$\mathbf{p}_3 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & -(i\rho_0\omega^2)^2 \end{bmatrix}. \tag{10}$$

In this way, the coefficients $\mathbf{p}_1 - \mathbf{p}_3$ are computed from the above equations and the polynomial coefficients are computed from Eq. (6). This avoids extensive algebraic manipulations to analytically solve for the coefficients of the polynomial.

3. Low frequency approximation

In this section, we investigate flexural wave dispersion at low frequencies, where the inertia of the fluid dominates its compressibility. For simplicity in the derivation, let a coordinate x' be defined in the propagation direction of a flexural wave in an orthotropic plate. Since the displacement is independent of all other orthogonal coordinates, the equation of motion of the plate with fluid loading on one side assumes the form

$$D_{x'} \frac{\partial^4 w}{\partial (x')^4} + \rho_s h \frac{\partial^2 w}{\partial t^2} = f, \tag{11}$$

where $D_{x'}$ is algebraically related to D_x, D_y, and D_{xy}, as well as the angle between x and x'. Details of this relationship are given by Leissa (1969) [see Eq. (9.25) and following text].

Assuming a traveling wave of the form

$$w = \Re\{W \exp[i(\omega t - k_{x'} x')]\}, \tag{12}$$

and following the derivation in the previous section results in the dispersion

$$(k_0^2 - k_{x'}^2)(k_{x'}^4 D_{x'} - \rho_s h \omega^2)^2 - (i\rho_0 \omega^2)^2 = 0. \tag{13}$$

Introducing the low-frequency approximation

$$k_0 \ll k_{x'} \tag{14}$$

simplifies the dispersion relation in Eq. (13) to

$$D_{x'} k_{x'}^4 - \omega^2 h \left(\rho_s + \frac{\rho_0}{k_{x'} h} \right) = 0, \tag{15}$$

which has the same form as the corresponding result for the isotropic plate given in Fahy.

As in the case of the isotropic plate, the fluid loading represents an added mass that is inversely proportional to the fluid-loaded wavenumber. Larger flexural wavelengths will be increased by smaller amounts. For this reason, fluid loading is expected to make flexural waves less directive in orthotropic plates. The overall magnitude of this effect will depend on the relative values of ρ_s and $\rho_0/(k_{x'} h)$. Noting that classical plate theory is generally valid when $k_{x'} h < 1$ leads to the expectation that the fluid mass will often dominate the plate mass at low frequencies, as noted by Fahy.

Table 1. Material properties of graphite-epoxy, taken from Yuan and Hsieh (1998).

E_x	138 GPa
E_y	8.9 GPa
E_z	8.9 GPa
G_{xy}	5.176 GPa
G_{xz}	5.176 GPa
G_{yz}	2.89 GPa
ν_{xy}	0.3
ν_{xz}	0.3
ν_{yz}	0.54
ρ	1600 kg/m^3

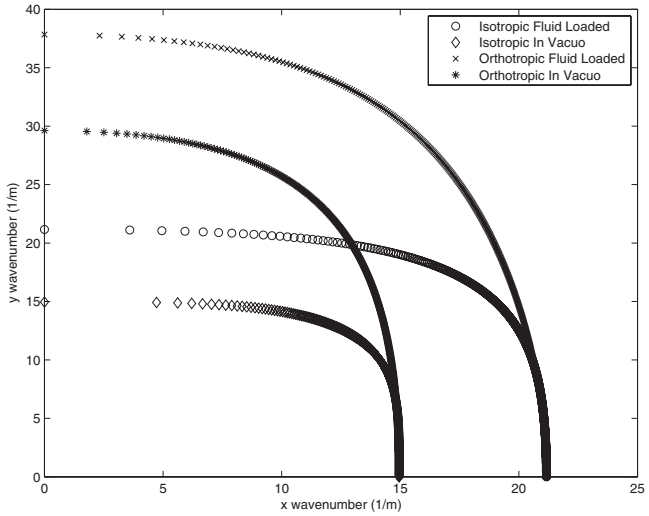

Fig. 1. Dispersion of flexural waves in a graphite-epoxy plate of thickness $h=0.01$ m, at 1 kHz.

4. Numerical results

The effects of fluid loading were numerically investigated for a plate constructed of graphite-epoxy with thickness $h=0.01$ m. Material properties are given in Table 1. Note that this material is at least an order of magnitude stiffer in the x direction than in the other directions. The fluid was taken as water with a sound speed $c_0=1500$ m/s and density $\rho_0=1$ kg/m^3. The wave number k_x corresponding to the propagating flexural wave was numerically computed from Eq. (5) for chosen values of k_y.

Results for a graphite-epoxy plate at frequencies of 1 kHz and 10 kHz are shown in Figs. 1 and 2. For comparison, results for the *in vacuo* case are plotted, as well as results for a similar isotropic plate whose properties are assumed to be those of the orthotropic plate in the x direction. These figures indicate a general magnification of the orthotropic wavenumbers due to

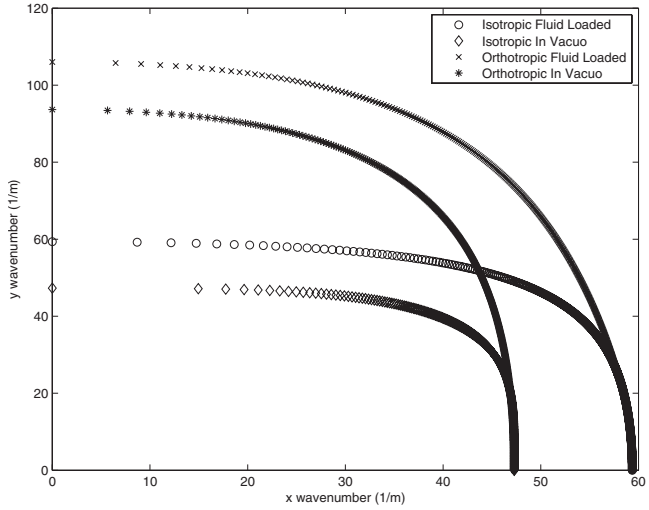

Fig. 2. Dispersion of flexural waves in a graphite-epoxy plate of thickness $h=0.01$ m, at 10 kHz.

Table 2. Percent increase in flexural wavenumber due to the addition of fluid loading to a composite plate.

	Case	% Increase in k_x	% Increase in k_y
1 kHz	Isotropic	41.54	41.54
	Orthotropic	41.54	27.73
10 kHz	Isotropic	25.56	25.56
	Orthotropic	25.56	13.19

fluid loading, however the variation with propagation angle is not significantly distorted when compared to the isotropic plate. This finding was more closely investigated in Table 2, which contains the percent increase in the flexural wavenumber due to fluid loading. This table supports the general conclusion that, for the cases studied, fluid loading does not distort the angular dependence of the flexural wave.

5. Summary

An analysis of the propagating flexural wave in a fluid-loaded orthotropic plate has been developed in order to better understand the effects of fluid loading. A method for numerically computing the coefficients of the resulting polynomial allows for direct calculation of the polynomial coefficients and hence the wavenumber. This work is expected to be important in numerically computing dispersion relations for more complicated geometries, such as cylindrical shells, where analytical derivation of the dispersion relation is difficult or impossible. When a single propagation angle is considered, this work shows that the equation of motion has the same form as that of an isotropic plate. This result reveals the underlying physics of flulid loading, particularly in the low-frequency regime where the fluid is primarily inertial and is likely to compete with the plate inertia.

Reviewers of Manuscripts, 2007

Each year the Journal endeavors to publish a list of all the persons who reviewed manuscripts during the preceding year. Such a list is a compendium of names supplied by the Associate Editors. Because our peer review system depends strongly on the continuing anonymity of the reviewers, the Journal publishes these names in alphabetical order without identification of the associate editors who provided the names and without identification of the papers they reviewed. The primary reason for the publication of the list is to express the Journal's gratitude to its reviewers. Reviewing a paper is often a very time consuming and demanding task, and the anonymity requirement yields no professional recognition to those who generously provide their time to help the Associate Editors decide which papers should be published and to give constructive criticisms to the authors. The Journal is justifiably proud of this list, which includes a goodly proportion of all the researchers and eminent authorities in acoustics and related fields. In a compendium of this length, omissions and errors are inevitable. If anyone notices such, please send the corrections and missing names via e-mail or regular mail to either Elaine Moran (asa@aip.org) or Allan Pierce (adp@bu.edu).

USA Meetings Calendar

Listed below is a summary of meetings related to acoustics to be held in the U.S. in the near future. The month/year notation refers to the issue in which a complete meeting announcement appeared.

2008

29 June–4 July	Joint Meeting of the Acoustical Society of America, European Acoustics Association and the Acoustical Society of France, Paris, France [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].
28 July–1 Aug	9th International Congress on Noise as a Public Health Problem (Quintennial meeting of ICBEN, the International Commission on Biological Effects of Noise). Foxwoods Resort, Mashantucket, CT [Jerry V. Tobias, ICBEN 9, Post Office Box 1609, Groton CT 06340-1609, Tel. 860-572-0680; Web: www.icben.org. E-mail: icben2008@att.net]
10–14 Nov	156th Meeting of the Acoustical Society of America, Miami, FL [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].

2009

18–22 May	157th Meeting of the Acoustical Society of America, Portland, OR [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].

Cumulative Indexes to the Journal of the Acoustical Society of America

Ordering information: Orders must be paid by check or money order in U.S. funds drawn on a U.S. bank or by Mastercard, Visa, or American Express credit cards. Send orders to Circulation and Fulfillment Division, American Institute of Physics, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2270. Non-U.S. orders add $11 per index. Some indexes are out of print as noted below.

Volumes 1–10, 1929–1938: JASA, and Contemporary Literature, 1937–1939. Classified by subject and indexed by author. Pp. 131. Price: ASA members $5; Nonmembers $10.
Volumes 11–20, 1939–1948: JASA, Contemporary Literature and Patents. Classified by subject and indexed by author and inventor. Pp. 395. Out of Print.
Volumes 21–30, 1949–1958: JASA, Contemporary Literature and Patents. Classified by subject and indexed by author and inventor. Pp. 952. Price: ASA members $20; Nonmembers $75.
Volumes 31–35, 1959–1963: JASA, Contemporary Literature and Patents. Classified by subject and indexed by author and inventor. Pp. 1140. Price: ASA members $20; Nonmembers $90.
Volumes 36–44, 1964–1968: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 485. Out of Print.
Volumes 36–44, 1964–1968: Contemporary Literature. Classified by subject and indexed by author. Pp. 1060. Out of Print.
Volumes 45–54, 1969–1973: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 540. Price: $20 (paperbound); ASA members $25 (clothbound); Nonmembers $60 (clothbound).
Volumes 55–64, 1974–1978: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 816. Price: $20 (paperbound); ASA members $25 (clothbound); Nonmembers $60 (clothbound).
Volumes 65–74, 1979–1983: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 624. Price: ASA members $25 (paperbound); Nonmembers $75 (clothbound).
Volumes 75–84, 1984–1988: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 625. Price: ASA members $30 (paperbound); Nonmembers $80 (clothbound).
Volumes 85–94, 1989–1993: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 736. Price: ASA members $30 (paperbound); Nonmembers $80 (clothbound).
Volumes 95–104, 1994–1998: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 632, Price: ASA members $40 (paperbound); Nonmembers $90 (clothbound).
Volumes 105–114, 1999–2003: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 616, Price: ASA members $50; Nonmembers $90 (paperbound).

ACOUSTICAL STANDARDS NEWS

Susan B. Blaeser, Standards Manager
ASA Standards Secretariat, Acoustical Society of America, 35 Pinelawn Rd., Suite 114E, Melville, NY 11747 [Tel.: (631) 390-0215; Fax: (631) 390-0217; e-mail: asastds@aip.org]

George S.K. Wong
Acoustical Standards, Institute for National Measurement Standards, National Research Council, Ottawa, Ontario K1A 0R6, Canada [Tel.: (613) 993-6159; Fax: (613) 990-8765; e-mail: george.wong@nrc.ca]

American National Standards (ANSI Standards) developed by Accredited Standards Committees S1, S2, S3, and S12 in the areas of acoustics, mechanical vibration and shock, bioacoustics, and noise, respectively, are published by the Acoustical Society of America (ASA). In addition to these standards, ASA publishes Catalogs of Acoustical Standards, both National and International. To receive copies of the latest Standards Catalogs, please, contact Susan B. Blaeser.
Comments are welcomed on all material in Acoustical Standards News.
This Acoustical Standards News section in JASA, as well as the National and International Catalogs of Acoustical Standards, and other information on the Standards Program of the Acoustical Society of America, are available via the ASA home page: http://asa.aip.org.

Accredited Standards Committees S1, Acoustics; S2, Mechanical Vibration and Shock; S3, Bioacoustics; S3/SC 1, Animal Bioacoustics; and S12, Noise will meet in conjunction with the 156th meeting of the Acoustical Society of America in Miami, FL, during the week of **10 November 2008**. The U.S. TAGs to ISO/TC 43, ISO/TC 43/SC 1, ISO/TC 108 and its subcommittees, and IEC/TC 29 will also meet during the Standards Plenary meeting. Specific meeting dates and times will be announced soon.

Note that there will be NO standards committee meetings in Paris in June 2008.

Standards Meetings Calendar—International

8–12 September 2008 - Oslo, Norway
• ISO/TC 108/SC 4, Human exposure to mechanical vibration and shock

3–7 November 2008 - St. Louis, MO, USA
• ISO/TC 108, Mechanical vibration, shock and condition monitoring

• ISO/TC 108/SC 3, Use and calibration of vibration and shock measuring instruments

• ISO/TC 108/SC 6, Vibration and shock generating systems

Standards News From The United States

American National Standards - Call for Comment on Proposals Listed

This section solicits comments on proposed new American National Standards and on proposals to revise, reaffirm, or withdraw existing standards. The dates listed in parentheses are for information only.

ASA (ASC S1) (Acoustical Society of America)

REAFFIRMATIONS

BSR/ASA S1.14-1998 (R200x), Recommendations for Specifying and Testing the Susceptibility of Acoustical Instruments to Radiated Radio-Frequency Electromagnetic Fields (reaffirmation and redesignation of ANSI S1.14-1998 (R2003))

Provides recommendations for specifying and testing the susceptibility of acoustical instruments to radiated radio-frequency electromagnetic fields. It does not contain recommendations regarding the susceptibility of an instrument to conducted electromagnetic fields, or recommendations to limit the emission of electromagnetic fields from instruments. It covers two ranges of radio frequencies for the carrier signal: 25 MHz to 500 MHz, and an extended range from 25 MHz to 1 GHz. (March 10, 2008)

ASA (ASC S12) (Acoustical Society of America)

REAFFIRMATIONS

BSR/ASA S12.8-1998 (R200x), Methods for Determining the Insertion Loss of Outdoor Noise Barriers (reaffirmation and redesignation of ANSI S12.8-1998 (R2003))

Adopts insertion loss - the difference between acoustical levels before and after a noise-barrier installation - as the basis for evaluating the acoustical effectiveness of an outdoor noise barrier. Methods are provided to determine the insertion loss of outdoor noise barriers at selected receiver locations and under conditions of interest. It covers insertion loss determination, by measurement or by the combination of measurement and prediction, for outdoor noise barriers of all types. (April 7, 2008)

BSR/ASA S12.9-Part 2-1992 (R200x), Quantities and Procedures for Description and Measurement of Environmental Sound - Part 2: Measurement of Long-Term, Wide-Area Sound (reaffirmation and redesignation of ANSI S12.9-Part 2-1992 (R2003))

Describes recommended procedures for measurement of long-term, time-average environmental sound outdoors at one or more locations in a community for environmental assessment or planning for compatible land uses and for other purposes such as noise prediction validation and regulation. Its purpose is to provide for a commonality for measurement of outdoor environmental sound as it may affect people in and around dwellings. (April 7, 2008)

BSR/ASA S12.9-Part 3-1993 (R200x), Quantities and Procedures for Description and Measurement of Environmental Sound - Part 3, Short-Term Measurements with an Observer Present (reaffirmation and redesignation of ANSI S12.9-Part 3-1993 (R2003))

Describes recommended procedures for measurement of short-term, time-average environmental sound outdoors at one or more locations in a community for environmental assessment or planning for compatible land uses and for other purposes such as demonstrating compliance with a regulation. These measurements are distinguished by the requirement to have an observer present. Methods are given to correct the measured levels for the influence of background sound. (April 7, 2008)

 0001-4966/2008/123(5)/2454/4/$23.00 © 2008 Acoustical Society of America

REVISIONS

BSR S12.9/Part 6-200x, Quantities and Procedures for Description and Measurement of Environmental Sound - Part 6: Methods for Estimation of Awakenings Associated with Noise Events Heard in Homes (revision of ANSI S12.9-Part 6-2000 (R2005))

Defines noise levels that are associated with sleep disturbance in home settings in which people are familiar with the neighborhood noise environment. Sleep "disturbance" is restricted to behaviorally confirmed awakening, as demonstrated by pressing a button upon awakening. Noise levels are quantified as indoor sound exposure levels of events occurring less than 5 minutes prior to the awakening. The Standard further assumes a population of normal hearing individuals with no sleep disorders. (February 25, 2008)

BSR/ASA S12.2-200x, Criteria for Evaluating Room Noise (revision and redesignation of ANSI S12.2-1995 (R1999))

Provides three primary methods for evaluating room noise: a survey method that employs the A-weighted sound level; an engineering method that employs expanded noise criteria (NC) curves; and a method for evaluating low frequency fluctuating noise using room noise criterion (RNC) curves. (March 31, 2008)

HI (Hydraulic Institute)

REVISIONS

BSR/HI 9.6.4-200x, Rotodynamic Pumps for Vibration Measurements and Allowable Values (revision of ANSI/HI 9.6.4-2000)

Applies to the evaluation of vibration on rotodynamic pump applications absorbing more than 2 kw (3 hp) and of the types as indicated within the standard. This standard pertains to evaluation of vibration when the vibration measurements are made on nonrotating parts (hearing housing vibration). The general evaluation criteria are included for acceptance tests in field environments or at the manufacturer's test facility, as appropriate and as defined in the standard. (March 17, 2008)

CALL FOR MEMBERS

AHAM (Association of Home Appliance Manufacturers)

BSR/AHAM AC-2-2006 (R200x), Method for Sound Testing of Portable Household Electric Room Air Cleaners (reaffirmation of ANSI/AHAM AC-2-2006)

ARI (Air-Conditioning and Refrigeration Institute)

BSR/ARI 575-200x, Method of Measuring Machinery Sound Within an Equipment Space (new standard)

ASA (ASC S12) (Acoustical Society of America)

BSR/ASA S12.10/Part 2-200x, Declared Noise Emission Values of Information Technology and Telecommunications Equipment (new standard)

HI (Hydraulic Institute)

BSR/HI 9.1-9.5-200x, Pump - General Guidelines for Types, Definitions, Application, Sound Measurement and Decontamination (revision of ANSI/HI 9.1-9.5-2000)

BSR/HI 9.6.4-200x, Rotodynamic Pumps for Vibration Measurements and Allowable Values (revision of ANSI/HI 9.6.4-2000)

Project Initiation Notification System (PINS)

ANSI Procedures require notification of ANSI by ANSI-accredited standards developers (ASD) of the initiation and scope of activities expected to result in new or revised American National Standards (ANS). Early notification of activity intended to reaffirm or withdraw an ANS is optional. The mechanism by which such notification is given is referred to as the PINS process. For additional information, see clause 2.4 of the ANSI Essential Requirements: Due Process Requirements for American National Standards. Following is a list of proposed actions and new ANS that have been received recently from ASDs.

AHAM (Association of Home Appliance Manufacturers)

BSR/AHAM AC-2-2006 (R200x), Method for Sound Testing of Portable Household Electric Room Air Cleaners (reaffirmation of ANSI/AHAM AC-2-2006)

Establishes a method to determine the sound rating of portable household electric room air cleaners. The sound rating is comprised of a set of sound levels that include: (1) Overall A-weighted sound power level (Lwa) and (2) Loudness level in SONES. Established in the standard are definitions, tests, calculations, ratings, and minimum data requirements for published ratings and conformance conditions. Project Need: To reaffirm the existing standard. Stakeholders: Manufacturers, consumer groups, general interest.

ARI (Air-Conditioning and Refrigeration Institute)

BSR/ARI 575-200x, Method of Measuring Machinery Sound Within an Equipment Space (new standard)

Applies to water chilling systems, pumps and similar operating machines and parts thereof, which, for reasons of size or operating characteristics, are more practically evaluated in situ. Project Need: To establish a uniform method of measuring and recording the Sound Pressure Level of machinery installed in a mechanical equipment space. Stakeholders: Manufacturers, engineers, installers, contractors and users.

BSR/ARI 1140-200x, Sound Quality Evaluation Procedures for Air-Conditioning and Refrigeration Equipment (new standard)

This standard applies to factory-made, residential and commercial air conditioning as well as transport refrigeration equipment. Project Need: To establish sound quality evaluation procedures for air conditioning and refrigeration equipment and to provide definitions; test requirements; sound quality evaluation procedures; minimum data requirements for Published Ratings; and conformance conditions. Stakeholders: Manufacturers, engineers, installers, contractors and users.

ASA (ASC S12) (Acoustical Society of America)

BSR/ASA S12.10/Part 2-200x, Declared Noise Emission Values of Information Technology and Telecommunications Equipment (new standard)

Defines how to calculate and disclose two noise emission specification values: the declared A-weighted sound power level [LWAd] and the declared A-weighted sound pressure level [LpAm (a mean value)] at the operator or bystander positions. The declared sound power level enables 3rd party verification of the specifications, and permits consistent comparison of IT equipment by consumers, purchasing agencies, etc. Project Need: To create an American National Standard to govern noise emission declaration for IT products. Stakeholders: Information technology and telecommunications equipment manufacturers and purchasers.

HI (Hydraulic Institute)

BSR/HI 9.1-9.5-200x, Pump - General Guidelines for Types, Definitions, Application, Sound Measurement and Decontamination (revision of ANSI/HI 9.1-9.5-2000)

Applies to all industrial/commercial pumps including rotodynamic, rotary, and reciprocating types. It includes types, definitions, design and application, airborne sound measurement and decontamination. Project Need: To improve and update the existing ANSI/HI standard with latest content. Stakeholders: Pump manufacturers, specifiers, purchasers, and pump users.

Final actions on American National Standards

The standards actions listed below have been approved by the ANSI Board of Standards Review (BSR) or by an ANSI-Audited Designator, as applicable.

ASME (American Society of Mechanical Engineers)

REAFFIRMATIONS

ANSI/ASME Y32.18-1972 (R2008), Symbols for Mechanical and Acoustical Elements as Used in Schematic Diagrams (reaffirmation of ANSI/ASME Y32.18-1972 (R2003))

ASTM (ASTM International)

New Standards

ANSI/ASTM F1334-2008, Test Method for Determining A-Weighted Sound Power Level of Vacuum Cleaners (new standard)

ATIS (Alliance for Telecommunications Industry Solutions)

REAFFIRMATIONS

ANSI T1.518-1998 (R2008), Objective Measurement of Telephone Band Speech Quality Using Measuring Normalizing Blocks (MNBs) (reaffirmation of ANSI T1.518-1998 (R2003))

SCTE (Society of Cable Telecommunications Engineers)

New Standards

ANSI/SCTE 24-23-2007, BV32 Speech Codec Specification for Voice over IP Applications in Cable Telephony (new standard)

STANDARDS NEWS FROM ABROAD

(Partially derived from *ANSI Standards Action*, with appreciation)

Newly Published ISO and IEC Standards

Listed here are new and revised standards recently approved and promulgated by ISO - the International Organization for Standardization – and IEC – the International Electrotechnical Commission.

ISO Standards

PERFORMANCE OF HOUSEHOLD ELECTRICAL APPLIANCES (TC 59)

IEC 60704-2-13 Amd.1 Ed. 1.0 b:2008, Amendment 1 - Household and similar electrical appliances - Test code for the determination of airborne acoustical noise - Part 2-13: Particular requirements for range hoods

ENVIRONMENTAL CONDITIONS, CLASSIFICATION AND METHODS OF TEST (TC 104)

IEC 60068-2-27 Ed. 4.0 b:2008, Environmental testing - Part 2-27: Tests - Test Ea and guidance: Shock

MECHANICAL VIBRATION AND SHOCK (TC 108)

ISO 18434-1:2008, Condition monitoring and diagnostics of machines - Thermography - Part 1: General procedures

ISO 18436-3:2008, Condition monitoring and diagnostics of machines - Requirements for qualification and assessment of personnel - Part 3: Requirements for training bodies and the training process

ISO 21289:2008, Mechanical vibration and shock – Parameters to be specified for the acquisition of vibration data

IEC Standards

IEC 61196-1-325 Ed. 1.0 b:2008, Coaxial communication cables – Part 1-325: Mechanical test methods - Aeolian vibration

ISO and IEC Draft International Standards

ISO

ACOUSTICS (TC 43)

ISO/DIS 13474, Acoustics - Framework for calculating a distribution of sound exposure levels of impulsive sound events for purposes of environmental noise assessment

MECHANICAL VIBRATION AND SHOCK (TC 108)

ISO 13091-1/DAmd1, Mechanical vibration - Vibrotactile perception thresholds for the assessment of nerve dysfunction - Part 1: Methods of measurement at the fingertips - Amendment 1

ISO/DIS 22266-1, Mechanical vibration - Torsional vibration of rotating machinery - Part 1: Land-based steam and gas turbine generator sets in excess of 50 MW

SMALL CRAFT (TC 188)

ISO/DIS 14509-3, Small craft - Airborne sound emitted by powered recreational craft - Part 3: Sound assessment using calculation and measurement procedures

IEC

61F/737/FDIS, IEC 60745-2-12-A1 Ed 2.0: Hand-held motor-operated electric tools - Safety - Part 2-12: Particular requirements for concrete vibrators

104/448/FDIS, IEC 60068-2-27 Ed. 4.0: Environmental testing – Part 2-27: Tests - Test Ea and guidance: Shock

104/456/FDIS, IEC 60068-2-64 Ed. 2.0: Environmental testing – Part 2-64: Tests - Test Fh: Vibration, broadband random and guidance

Information Concerning:

Proposed Foreign Government Regulations

Call For Comment

U.S. manufacturers, exporters, regulatory agencies and standards developing organizations may be interested in proposed foreign technical regulations issued by Member countries of the World Trade Organization (WTO). In accordance with the WTO Agreement on Technical Barriers to Trade (TBT Agreement), Members are required to report proposed technical regulations that may significantly affect trade to the WTO Secretariat in Geneva, Switzerland. In turn, the Secretariat disseminates the information to all WTO Members. The purpose of this requirement is to provide global trading partners with an opportunity to review and comment on the regulations before they become final.

The National Center for Standards and Certification Information (NCSCI) at the National Institute of Standards and Technology (NIST) distributes these proposed foreign technical regulations to U.S. stakeholders via an online service, Notify U.S. Notify U.S. is an e-mail and Web service that allows interested U.S. parties to register, obtain notifications, and read full texts of regulations from countries and for industry sectors of interest to them. To register for Notify U.S., please go to Internet URL: http://www.nist.gov/notifyus/ and click on "Subscribe."

NCSCI is the WTO TBT Inquiry Point for the U.S. and receives all notifications and full texts of regulations to disseminate to U.S. Industry. For further information, please contact: NCSCI, NIST 100 Bureau Drive, Gaithersburg, MD 20899-2160; Telephone: (301) 975-4040; Fax: (301) 926-1559; E-mail: ncsci@nist.gov or notifyus@nist.gov.

International Organization for Standardization (ISO)

Call for International (ISO) Secretariat ISO/TC 86/SC 7 – Testing and Rating of Commercial Refrigerated Display Cabinets

ANSI has been advised The Air Conditioning and Refrigeration Institute (ARI) wishes to serve as delegated ANSI Secretariat for the above ISO subcommittee that was relinquished by the British Standards Institute (BSI). This SC is covered by the scope of the main Technical Committee (ISO/TC 86), having the following scope: Standardization in the fields of refrigeration and air conditioning, including terminology, mechanical safety, methods of testing and rating equipment, measurement of sound levels, refrigerant and refrigeration lubricant chemistry, with consideration given to environmental protection. The scope includes factory-assembled air conditioners (cooling), heat pumps, dehumidifiers, refrigerants, and refrigerant reclaiming and recycling equipment as well as other devices, components and equipment such as humidifiers, ventilation equipment, and automatic controls used in air conditioning and refrigeration systems that are not covered by other ISO technical committees. Anyone wishing to comment on the delegation of the International Secretariat to ARI please contact Henrietta Scully, ANSI, via e-mail, hscully@ansi.org.

These reviews of books and other forms of information express the opinions of the individual reviewers and are not necessarily endorsed by the Editorial Board of this Journal.

Fundamentals of Voice Quality Engineering in Wireless Networks

Avi Perry

Cambridge University Press, 2006, 377 pp. Price: $90.00 (hardcover), ISBN: 0-521-85595-0

This book provides an excellent, practical, overview over the complete field of voice quality problems as encountered in wireless networks. Perry uses down to earth, sometimes nontechnical, descriptions to go over every aspect of voice quality, which sometimes leads to wordiness for those who are technically skilled in the field. However, it makes the book accessible for the larger field of nonexperts who want to gain insight into this topic, which has an ever-increasing impact on our daily telecommunication. The first two words of the title "Fundamentals Of" may be a little misleading because the fundamentals of voice quality itself are not worked out properly. Maybe the next issue of the book can take this criticism into account. The first part of the book, called "Voice-quality foundations," does not fulfill its promise, it should start with an ideal voice link as defined by the ITU (1 m air path) and then define the different aspects of conversational quality, listening quality (how do I perceive the other?), talking quality (how do I perceive my own voice?), and interaction quality (can we interrupt each other and what happens when we both talk?). Also the coding should be treated more fundamentally, Perry fails to make a distinction between redundancy and irrelevancy. Furthermore some ITU-T recommendations are not well treated (P.800, P.563, P.835, G.107, G.114).

The second part of the book, "Applications," gives an excellent overview of problems related to echo and noise problems and provides insights that go well beyond wireless networks. In fact most of the text can be applied to Voice over IP (VoIP) where the basic problems are more or less the same as in the wireless world, i.e., a longer end-to-end delay and consequently a need for more advanced (acoustic) echo canceling. Clear descriptions of both electric and acoustic echo problems are given in different network configurations. The impact of noise, noise reduction schemes, and level control are dealt with from a practical point of view and provide many useful discussion points that are very relevant in the operation of wireless networks. A minor point is that the reader may get a too optimistic view of the performance of noise suppressors/echo cancelers after reading part two.

The third part of the book deals with "Wireless architectures," where the voice quality topics are worked out and different architectures are discussed. It is well written with clear explanations of the relations between the architecture and voice quality problems for both mobile to fixed and mobile to mobile calls. An extra chapter devoted to the impact of radio parameters like RxQual, BLER, handover problems may be a good idea for the next issue.

Part four, "A network operator's guide for selecting, appraising and testing a voice-quality systems," provides many detailed tests for assessing voice-quality systems with a focus on the ITU-T recommendations G.160, G.167, and G.168 regarding objective testing. Also PESQ and other objective speech quality measurement systems are discussed and a warning is given not to rely on objective measurements too much. A nice list of different subjective tests that have to be carried out in the assessment of echo cancelers in order to have insight into their performance in "live" networks is given. Very useful are the subjective tests that relate to double talk conditions where especially the noise contrast and noise switching distortions are causing severe degradations in modern mobile and VoIP networks. This list should be used by anyone that is involved in designing and testing cancelers and by operators who want to have an idea of what their customers are experiencing.

Finally the remainder of the book provides a useful trouble-shooting overview where one can start with a voice-quality-related complaint and find a possible set of underlying technical problems and work toward a solution from that.

So overall Perry has succeeded to provide an excellent practical overview that is a good starting point for anyone in the field who needs a global picture on voice quality problems in wireless networks.

43.30.Vh METHOD AND APPARATUS FOR CORRELATION SONAR

Anthony L. Scoca, assignors to *Lockheed Martin Corporation*
13 November 2007 (Class 367/89); filed 6 January 2006

Incredibly, the authors assert that it is non-obvious that using extra receivers might just improve target velocity estimation.—GFE

7,289,389

43.30.Wi RESOLVING DIRECTIONAL INFORMATION IN SONAR ARRAYS

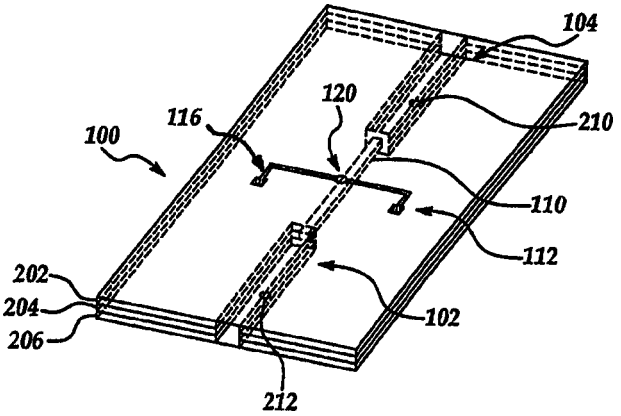
Rory Niland, *assignor to Sonartech Atlas Pty Limited*
30 October 2007 (Class 367/103); filed in Australia 4 September 2003

A formulaic recipe of using beamforming, the MUSIC algorithm, and expectation-maximization to improve the resolution of directional information, in that order, has been seized upon.—GFE

7,286,442

43.30.Yj METHOD AND APPARATUS FOR SEISMIC DATA ACQUISITION

Clifford H. Ray *et al.*, assignors to *Fairfield Industries, Incorporated*
23 October 2007 (Class 367/15); filed 25 October 2005



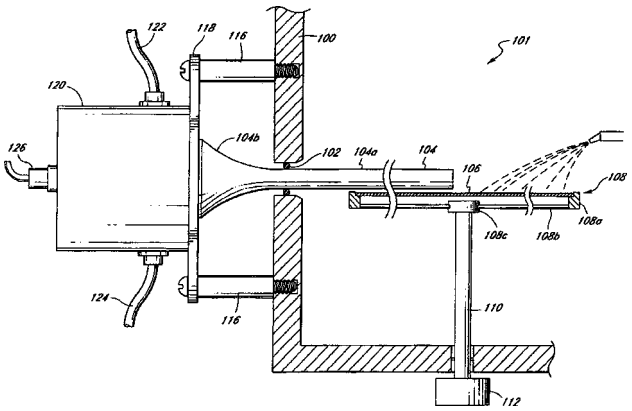
The involved details of one specific underwater seismic array are described.—GFE

7,304,732

43.35.Ud MICROELECTROMECHANICAL RESONANT PHOTOACOUSTIC CELL

Ronald G. Polcawich and Paul Pellegrino, assignors to *United States of America as represented by the Secretary of the Army*
4 December 2007 (Class 356/246); filed 19 November 2003

The authors describe a very simple MEMS cell constructed to allow a laser beam to pass through in one direction and contain a piezoelectric film microphone on another face. It is claimed that this planar geometry increases sensitivity to the photoacoustic interaction of light with the gas contained within. The cell as drawn is open to the air, so that the cavity inside is being used as an open-open resonant tube. The authors describe this arrangement as beneficial for trace gas monitoring of the atmosphere (as in waste gas monitoring, chemical warfare agent detection, etc.) It is claimed that the use of a MEMS cell allows for higher modulation frequencies and consequently higher detection sensitivities than in larger cavities. This seems counterintuitive, since the sensitivity of such microphones is rather poor, and the Q of any such small cavities must be low due to disadvantageous surface to volume area ratios. It would seem that the authors never actually built and tried such a device.—JAH



7,268,469

43.35.Zc TRANSDUCER ASSEMBLY FOR MEGASONIC PROCESSING OF AN ARTICLE AND APPARATUS UTILIZING THE SAME

Mario E. Bran, assignor to *Akrion Technologies, Incorporated*
11 September 2007 (Class 310/328); filed 15 March 2006

An ultrasonic cleaner **101** for semiconductor wafers is claimed comprising rod **104**–**104a** vibrating in its longitudinal mode at a megasonic (unspecified) frequency and in close proximity to wafer **106** on turntable

108–**108c**. Cleaning medium is sprayed onto the surface of rotating wafer **106**, moving cleaning droplets to and under the vibrating rod to be dispersed to clean surface **106**. Sprayed media may be various liquids and gases as well as dry ice snow.—AJC

7,289,038

43.38.Ar UNDERWATER SOUND RADIATION APPARATUS

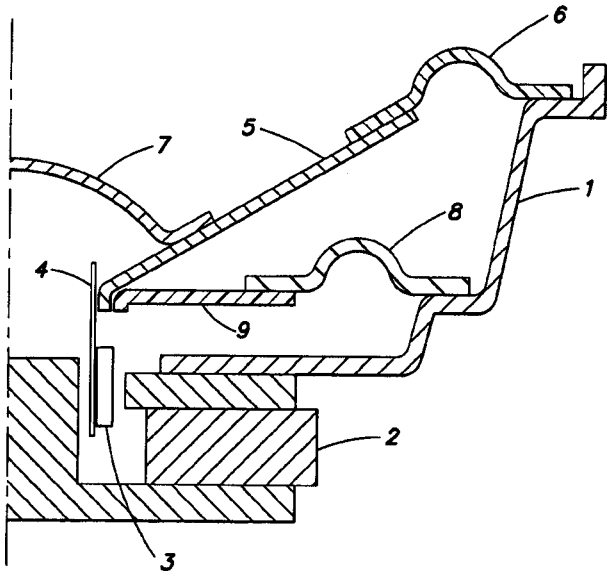
Takayuki Watanabe and Shinji Kishinaga, assignors to *Yamaha Corporation*
30 October 2007 (Class 340/850); filed in Japan 13 July 2001

Anything can be patented these days; including the well-known idea of coupling a transducer to a wall or hull to increase the effective size of the radiation surface.—GFE

7,289,388

43.60.Cg ESTIMATION OF BACKGROUND NOISE AND ITS EFFECT ON SONAR RANGE ESTIMATION

Nathan Intrator *et al.*, assignors to *Brown University*
30 October 2007 (Class 367/100); filed 8 June 2004



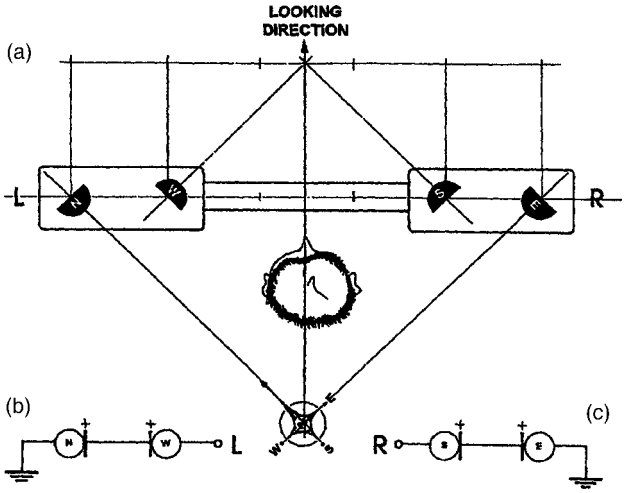
The straight-from-the-textbook method of measuring signal-to-noise ratio in different frequency bands via cross correlation is sadly nabbed.—GFE

7,292,707

43.38.Dv LOUDSPEAKER

Leonard Kreitmeier and Jürgen Ringlstetter, assignors to *Harman Becker Automotive Systems GmbH*
6 November 2007 (Class 381/398); filed in Germany 25 April 2001

For both cone type and flat panel loudspeakers with an electrodynamic drive, a "second bead" **8** is used instead of a conventional spider centering



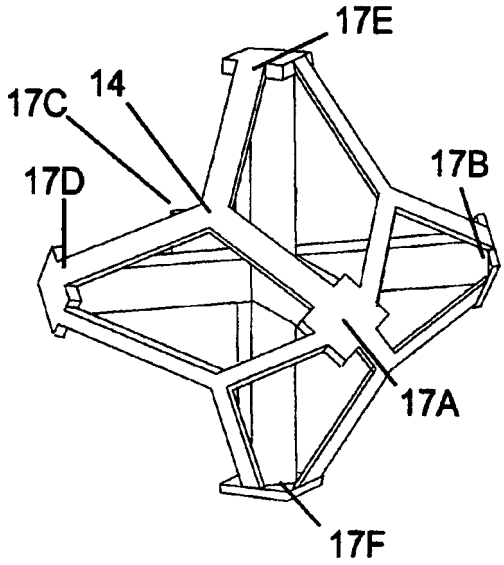
device. Multiple centering "beads" can be used.—NAS

7,263,034

43.38.Hz RESONATOR DEVICE AND CIRCUITS FOR 3-D DETECTION/RECEIVING SONIC WAVES, EVEN OF A VERY LOW AMPLITUDE/ FREQUENCY, SUITABLE FOR USE IN CYBERNETICS

Daniele Ramenzoni, Fidenza, Italy
28 August 2007 (Class 367/188); filed in Italy 18 March 2002

In rambling text, the author claims a transducer array for listening purposes operating at any frequency over a very wide range ("diapason") whose composite beam can be steered. Left transducers **N**–**W** (2.1 –10.8 cm apart) and right transducers **S**–**E** (also 2.1–10.8 cm apart) are arranged on line **L**–**R** spaced by 44 cm or less when operated in air. The pairs are connected in opposition as indicated in Figs. 1(b) and 1(c). Beam



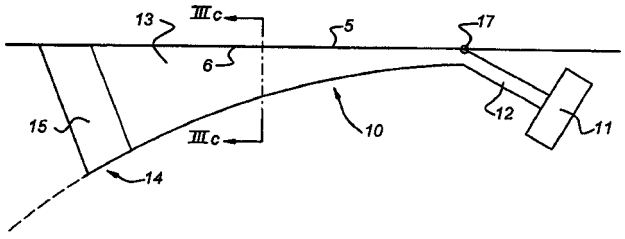
steering is provided by a variable resistor connected across **N** and one across **E**, while a fixed capacitor is connected across **W** and another across **S**. The resultant signals can be heard with earphones. Controlled directivity (beam steering) is claimed. It is also claimed that this transducer arrangement can be used to create and steer ultrasonic beams for therapeutic purposes in air and in liquid media in which case the spacings are increased (for water) by a factor of 4.395.—AJC

7,292,503

43.38.Hz MULTI PISTON ELECTRO-MECHANICAL TRANSDUCTION APPARATUS

Alexander L. Butler and John L. Butler, assignors to *Image Acoustics, Incorporated*
6 November 2007 (Class 367/163); filed 3 May 2004

Lever arm assembly **14** with piezoelectric drivers located below the square junctions **17** is surrounded by a spherical cover. This provides a



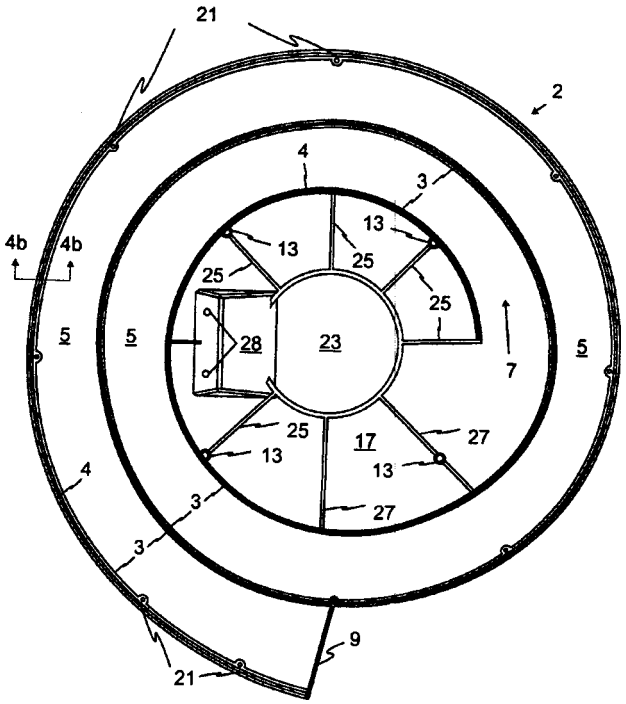
compact transducer that can find use in underwater applications. The patent also describes circular and cylindrical implementations using similar arrangements.—NAS

7,268,467

43.38.Ja ACOUSTIC TRANSDUCER

Gerard Hendrik Josephus De Vries, assignor to *Duran Audio B.V.*
11 September 2007 (Class 310/328); filed in Netherlands 14 February 2002

A high intelligibility loudspeaker assembly **10** for vehicle tunnels and multi-story parking lots is claimed. To avoid back-surface reflected waves that cause beam scalloping and delayed echoes, the speaker driver **11**–**12** is placed at the backing surface **5**. A surface **14** is added that parallels back surface **5** before widening to exit aperture **13**. In this way, the wave reflected



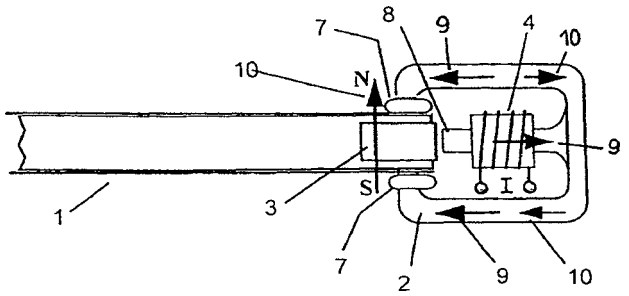
from the back surface **5** is not delayed in time. Both the direct and reflected waves **15** emerge in phase. The angular extent parallel to back surface **5** can be narrow, viz. 30 degrees as for a tunnel, or it can be a full 360 degrees, as for the ceiling of a multi-story parking lot.—AJC

7,284,638

43.38.Ja LOUDSPEAKER LOW PROFILE QUARTER WAVELENGTH TRANSMISSION LINE AND ENCLOSURE AND METHOD

Joseph Y. Sahyoun, Redwood City, California
23 October 2007 (Class 181/156); filed 8 May 2006

This reviewer thought that a transmission line design is used to completely absorb the rear wave from a driver in an enclosure. Here it is not and so appears to be more like a reflex or ported enclosure. Among the benefits



claimed for the design are reduced resistance to air flow (specifically exhale vs. inhale) as well as lower turbulence in the port, er, line. The design is also the enclosure.—NAS

7,302,077

43.38.Ja ELECTROMAGNETIC DRIVER FOR A PLANAR DIAPHRAGM LOUDSPEAKER

Wolfgang Bachmann *et al.*, assignors to *Harman/Becker Automotive Systems GmbH*
27 November 2007 (Class 381/412); filed in Germany 23 November 2000

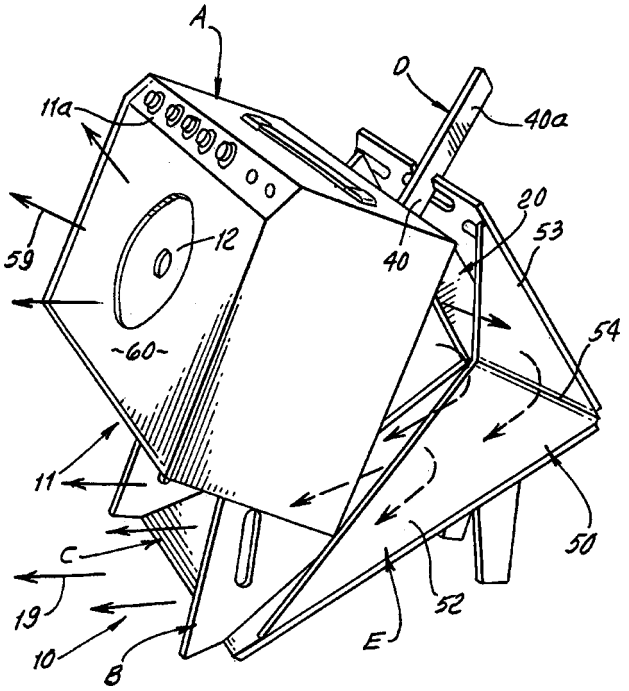
The patent is a continuation of U.S. Patent No. 7,158,651 which described a kind of see-saw electromagnetic driver for a planar loudspeaker. In this variant, magnet **3** is embedded in an edge of planar diaphragm **1**. Flux generated by voice coil **4** flows through clamp-shaped armature **9**, causing

the magnet and the plate to vibrate. The patent argues that the push-pull arrangement causes the difference in forces to be proportional to the coil current.—GLA

7,292,423

43.38.Ja ACOUSTIC/UNDERWATER SIGNALING DEVICE

Andres Etchenique, Miami, Florida
6 November 2007 (Class 361/134); filed 6 June 2005



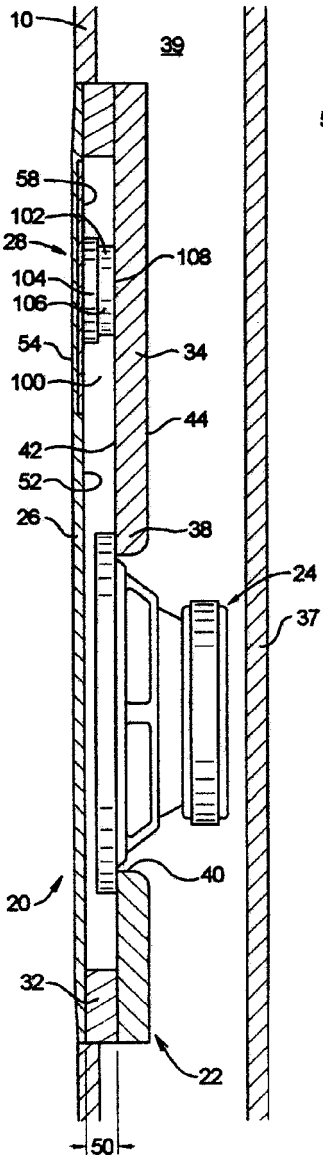
An underwater emergency siren is proposed. It is mechanical in nature and intended to be hand powered.—GFE

7,296,653

43.38.Ja SOUND CONTROL APPARATUS

Harold N. Smith, Jr. and Harold N. Smith III, both of Spring, Texas
20 November 2007 (Class 181/155); filed 7 January 2005

This patent describes a collapsible stand for an open-back musical instrument loudspeaker. When in use, sound from the rear is chaneled



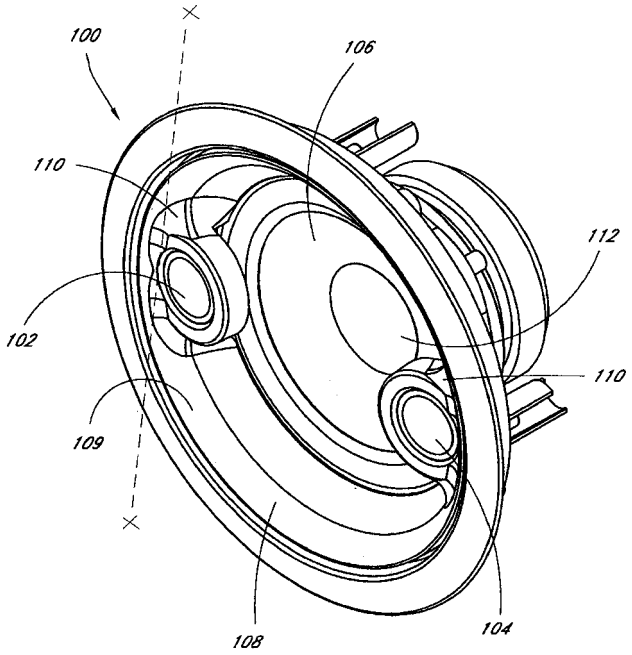
through a scoop-shaped reflector assembly, "…whereby control of ultimate sound effect is realized."—GLA

7,292,702

43.38.Ja IN-WALL SPEAKER SYSTEM METHOD AND APPARATUS

Paul N. Hagman, assignor to *Dimensional Communications, Incorporated*
6 November 2007 (Class 381/345); filed 28 April 2004

Radiating panel **26** has a high frequency area **58** that can be different in both thickness and laminations from low frequency "reciprocating" area **56**. Low frequency driver **26** is spaced a bit from panel **26** by frame **32**,



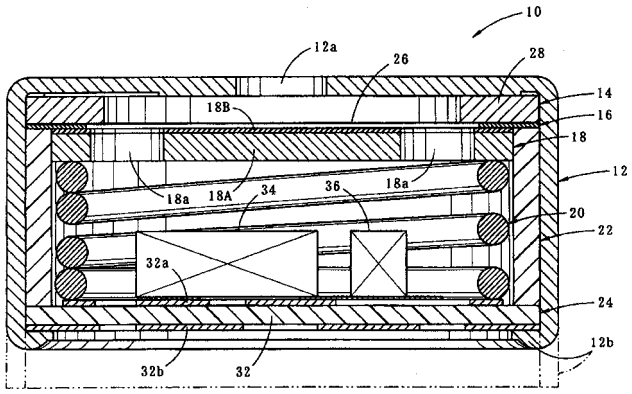
forming a chamber of sorts with back panel **34**, while high frequency drivers **102** are in contact with area **58**. Drivers **102** are NXT or similar drivers. A crossover network is also described.—NAS

7,302,061

43.38.Ja DUAL-TWEETER LOUDSPEAKER

Dean M. Rivera, assignor to *KSC Industries Incorporated*
27 November 2007 (Class 381/1); filed 12 December 2002

A non-coaxial two-way loudspeaker incorporates two tweeters **102**, **104** spaced as far apart as possible. When used as one speaker of a stereo



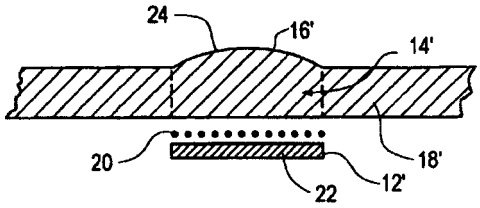
pair this geometry is said to provide improved imaging. Alternatively, the assembly can serve as a unitized stereo ceiling speaker in which the tweeters reproduce high frequencies from left and right channels, respectively. This is a continuation of earlier U.S. Design Patent No. 476,313.—GLA

7,287,327

43.38.Kb ELECTRET CAPACITOR MICROPHONE AND METHOD FOR PRODUCING THE SAME

Motoaki Ito and Kentaro Yonehara, assignors to *Star Micronics Company, Limited*
30 October 2007 (Class 29/886); filed in Japan 28 December 2001

Diaphragm material **26** is stretched under tension and bonded to ring **28** and assembled as shown into electret microphone assembly **10**. If the diaphragm tension is too high, the stiffness may be higher than desired and sensitivity suffers. The patent describes a process of first heating the ring/diaphragm, before assembly, for some time at certain temperatures (below



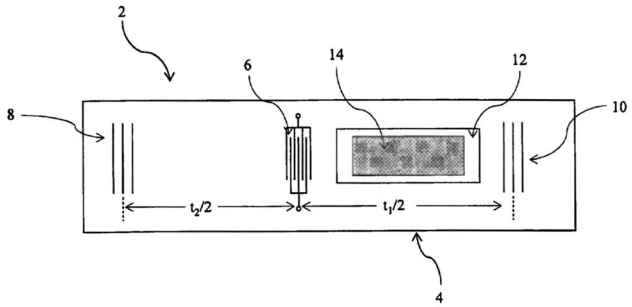
the melting point but above the second transition point of the thermoplastic material), sort of like annealing, and heated maybe more than once, to reduce the stiffness to a point where sensitivity is increased, but above the point where the diaphragm can "crinkle." This annealing-like process is widely used in the manufacture of tweeter diaphragms.—NAS

7,265,746

43.38.Rh ACOUSTIC WAVE TOUCH DETECTION CIRCUIT AND METHOD

Terence J. Knowles *et al.*, assignors to *Illinois Tool Works Incorporated*
4 September 2007 (Class 345/173); filed 4 June 2003

A touch sensor (switch) is claimed where raised portion **16** resonates at a vibrating frequency unique to its thickness **14** and mass. Transducer **12** may be an electromagnetic acoustic transducer (EMAT) comprising magnet



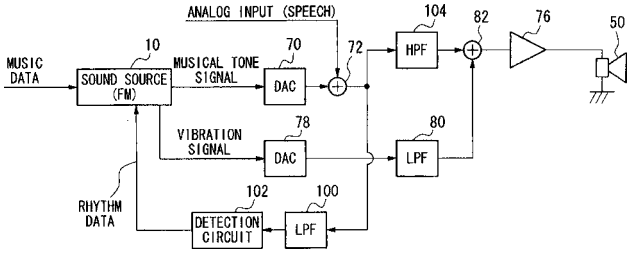
22 and winding **20**. A finger touching raised surface **24** will damp the resonant amplitude of the acoustic wave in resonator volume **14**, subsequently detected as evidence of the touch, and may be used for signal and command purposes.–AJC

7,268,662

43.38.Rh PASSIVE SAW-BASED HYDROGEN SENSOR AND SYSTEM

Jacqueline H. Hines and Leland P. Solie, assignors to *Applied Sensor Research & Development Corporation*
11 September 2007 (Class 338/34); filed 19 January 2006

A hydrogen gas concentration sensor **2** is claimed where palladium film **14** is arranged as a nano-cluster layer on siloxane monolayer **12**. Atmospheric hydrogen will absorb into palladium **14**, increasing its electrical conductivity which in turn slows down a surface acoustical wave (SAW) launched from fingers **12**. A SAW launched from **12** will be further delayed



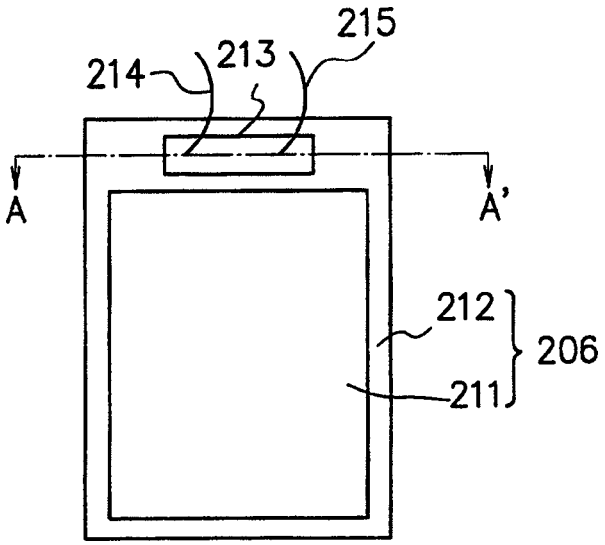
as it travels to and from reflector **10**, while a SAW from **6** to reflector **8** will not be further delayed. This sensor detects hydrogen in the atmosphere in concentrations from 25 ppm to 2% with a response time of a millisecond, is reversible and is operable at room temperatures.—AJC

7,301,094

43.38.Si DEVICE FOR DRIVING VIBRATION SOURCE

Masao Noro *et al.*, assignors to *Yamaha Corporation*
27 November 2007 (Class 84/645); filed in Japan 22 October 1999

Yamaha engineers have discovered a ghastly flaw in the evolution of the cellular telephone. Some current models can be set to notify the user of an incoming call using both sound (a custom ring melody) and vibration simultaneously. The problem is that the vibration and the music are not



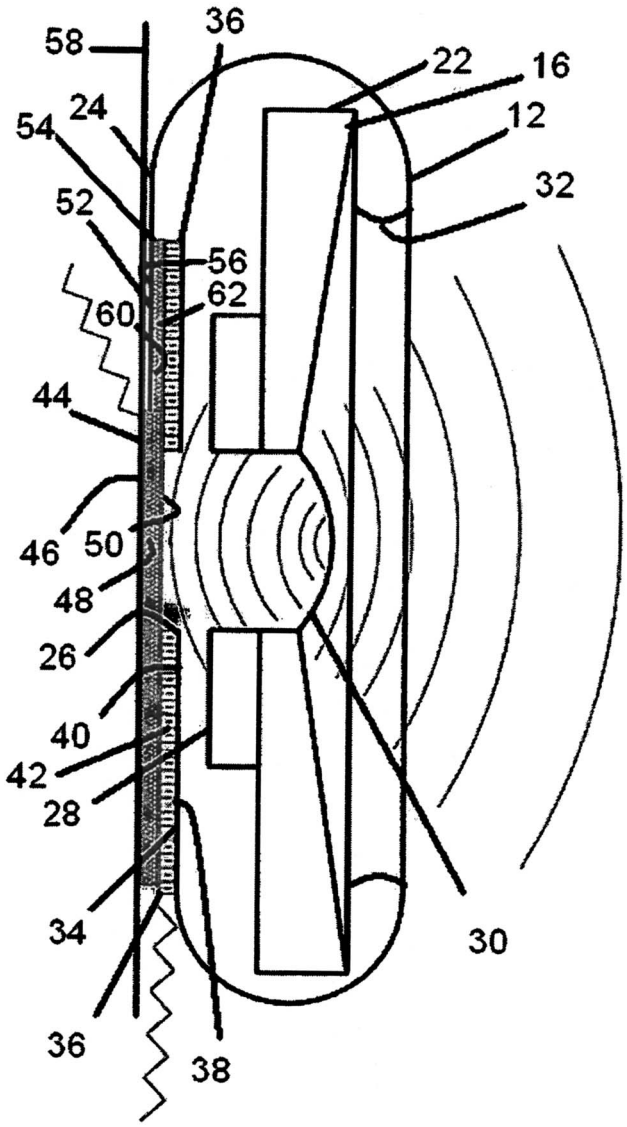
correlated, giving the user, "... a feeling of wrongness." How can this unacceptable oversight be corrected with minimal additional circuitry? The patent discloses a possible solution.—GLA

7,305,248

43.38.Si ELECTRONIC DEVICE

Ukyo Mori, assignor to *NEC Corporation*
4 December 2007 (Class 455/550.1); filed in Japan 28 November 2000

A transparent cover over the display panel of this cellular telephone also serves as a planar loudspeaker. This is hardly a new idea, and the patent



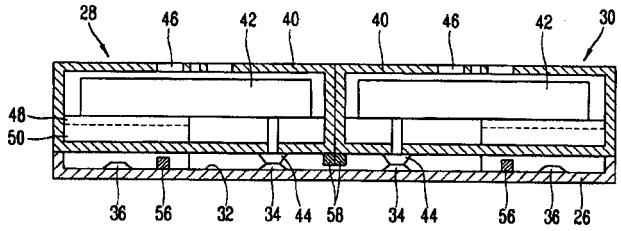
claims are restricted to a particular implementation involving a transparent section, a colored section, a planar voice coil, a resilient member, and two magnets.—GLA

7,308,108

43.38.Si HELMET-MOUNTED INTERCOMMUNICATIONS AND ENTERTAINMENT SYSTEM

William E. Davis, *Xenia*, **Ohio**
11 December 2007 (Class 381/376); filed 11 April 2005

Some motorcycle helmets include a microphone and headphone for two-way communication while riding. Instead of a conventional headphone, the inventor proposes enclosing a small loudspeaker in a padded fabric pouch that can be easily removed and reinstalled. This arrangement is said to optimize sonic performance, "…while eliminating the need for venting



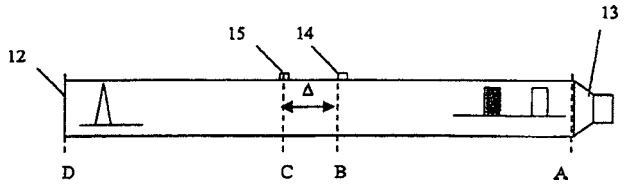
tubes or other cumbersome methods of properly porting a speaker for acoustic performance."—GLA

7,299,078

43.38.Vk MOBILE TERMINAL

Byung Jin Ahn, assignor to *LG Electronics Incorporated*
20 November 2007 (Class 455/575.4); filed 3 May 2004

Trying to reproduce surround sound from a cellular telephone may be a hopeless quest but inventors are nonetheless doing their best. In this example, left and right speakers are mounted on little extension sliders to



increase the distance between them. This is not a new idea, but apparently it has not previously been applied to cell phones.—GLA

7,266,992

43.40.Le REMOTE PIPELINE ACOUSTIC INSPECTION

Mohammad N Shamout *et al.*, assignors to *The Victoria University of Manchester*
11 September 2007 (Class 73/40.5A); filed in United Kingdom 30 November 2001

A pipe network inspection system is claimed where a sound pulse is introduced at **13-A** into one end of the pipe network while receiving transducers, **14**, **15**, etc., are inserted at various remote **B**–**C**, etc. locations along the pipe or pipe network. Received sound pulses and pulse echoes are analyzed by comparing them with a time-shifted reference pulse. Echo pulses

can arise from pipe transitions, by blockages by leaks and by pipe terminations **12-D**. The author claims a signal time shift and subtraction process to identify leaks and blockages.—AJC

7,289,391

43.40.Le NARROWBAND PHASE DIFFERENCE MEASUREMENT TECHNIQUE FOR SONAR APPLICATIONS

Byron W. Tietjen and Thaddeus J. Kurpiewski, assignors to *Lockheed Martin Corporation*
30 October 2007 (Class 367/125); filed 12 November 2004

In the this-will-never-work-in-real-life category, the authors plan to measure the phase difference between acoustic pulses at different frequencies in order to estimate the impedance (and thereby composition) of ocean bottom clutter.—GFE

7,296,654

43.40.Tm TUNABLE STACKED PLATE VIBRATION ISOLATOR

Morris S. Berman, assignor to *United States of America as Represented by the Secretary of the Army*
20 November 2007 (Class 181/207); filed 29 September 2004

This isolator, intended for the protection of electrical systems of projectiles and the like, consists of a stack of circular metal plates that are held together by a clamping arrangement. Damping results from friction between the plates and depends on their surface finish; the damping action may be adjusted by adjustment of the clamping force.—EEU

7,296,786

43.40.Tm COMPOSITE BUSHING HAVING DUAL DAMPING CAPABILITY

Erich Hees, assignor to *Honda Motor Company, Limited*
20 November 2007 (Class 267/293); filed 23 November 2004

This bushing in essence consists of an outer metal tube in the middle of which there is located a small metal tube, with a resilient connection between the two tubes. In a bushing according to this patent the resilient connection is provided by wedges of different resilient materials, so that the assembly has different stiffnesses in different radial directions.—EEU

7,299,698

43.40.Tm VIBRATION TEST MODULE HAVING CONTROLLABLE VIBRATION ATTRIBUTES

Gregg K. Hobbs, Westminster, Colorado
27 November 2007 (Class 73/649); filed 10 February 2005

The module to which this patent refers is a frame that is to be mounted on a shaker and that supports a test object. The support frame is provided with an array of spring-supported masses whose springs can be adjusted to change the natural frequencies of the spring-mass systems. Adjustment of the resonances of these systems permits one to shape the spectra of the vibrations to which the test article is exposed.—EEU

7,303,184

43.40.Tm ISOLATOR MOUNT FOR SHOCK AND VIBRATION MITIGATION

Bruce Bower and Gareth Knowles, both of Williamsport, Pennsylvania
4 December 2007 (Class 267/136); filed 12 September 2006

Equipment mounts, intended for shipboard use, consist of brackets made of a series of layers. In a typical mount the outer layers are relatively thick and of a material that can withstand repeated deflection. Sandwiched between these outer layers and bonded to these are thin layers capable of dissipating energy; these layers may consist of rare earth elements or alloys, ferromagnetic shape alloys, magnetic shape memory alloys, or super-elastic alloys.—EEU

7,306,082

43.40.Tm PASSIVE DAMPING OF VIBRATIONS IN A SUPPORT STRUCTURE

Ka Shing Kenny Kwan *et al.*, assignors to *ASM Technology Singapore PTE Limited*
11 December 2007 (Class 188/378); filed 8 April 2003

A component, such as one that supports devices that are rapidly repositioned in a microelectronics manufacturing machine, is subject to considerable accelerations. Damping of such components is desirable in order to suppress vibrations that may interfere with manufacturing accuracy. Damping of a device-supporting component is achieved according to this patent by introducing cylindrical cavities in the component and filling these at least partially with a composite material, such as butyl rubber loaded with carbon particles.—EEU

7,299,120

43.40.Vn METHOD FOR REDUCING JUDDERING VIBRATIONS

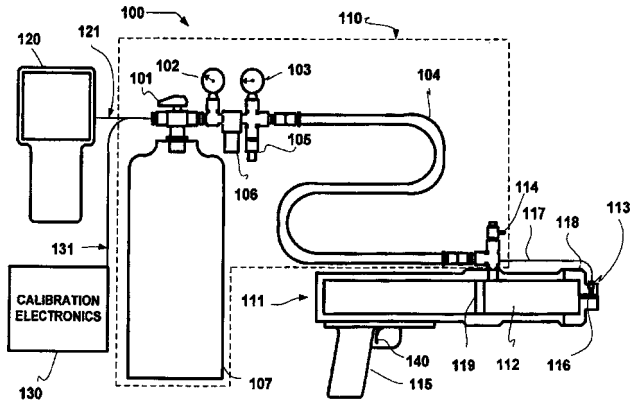
Boris Serebrennikov, assignor to *LuK Lamellen und Kupplungsbau Beteiligungs KG*
20 November 2007 (Class 701/67); filed in Germany 12 September 2002

This patent pertains to vibrations in the drive train of motor vehicles. As stated in the patent document, "juddering vibrations are…in particular vibrations of the transmission input against the vehicle." The system described here detects such vibrations and automatically adjusts an electronic clutch to suppress these.—EEU

7,299,141

43.40.Vn SYSTEM AND METHOD FOR CONTROLLING VIBRATION

Raymond Chin, assignor to *Hewlett-Packard Development Company, L.P.*
20 November 2007 (Class 702/56); filed 5 December 2002



The vibrations of a drive cage that houses a number of data transfer devices are monitored and compared to a known standard. If the standard is exceeded, the data transfer rate of one or more of these devices is reduced and/or some of the devices are turned off in order to reduce the vibrations produced by these devices.—EEU

7,266,986

43.40.Yq PORTABLE SYSTEM FOR MEASURING DYNAMIC PRESSURE IN SITU AND METHOD OF EMPLOYMENT THEREFOR

Fred D. Shirley *et al.*, assignors to *The United States of America as represented by the Secretary of the Army*
11 September 2007 (Class 73/1.57); filed 18 November 2004

A backpack portable blast sensor dynamic calibrator is claimed where a controlled volume of pressurized gas is delivered to the input port of that sensor. Gases such as helium (fastest rise time), nitrogen or air are used. Pressure gauge **102** shows supply tank pressure and gauge **103** shows applied pressure, typically under 150 psi. The operator presses nozzle **116** to

the blast sensor input port, then pulls trigger **140** to release the gas charge **112** by moving **119** rearward to remove a poppet valve plunger (not shown) from blocking gas flow into nozzle **116**. Reference transducer **113** sends a pressure signal **117**–**121** for display and for archiving via **131** to microprocessor **130**.—AJC

7,308,368

43.40.Yq METHOD AND APPARATUS FOR VIBRATION DETECTION, METHOD AND APPARATUS FOR VIBRATION ANALYSIS, LITHOGRAPHIC APPARATUS, DEVICE MANUFACTURING METHOD, AND COMPUTER PROGRAM

Haico Victor Kok *et al.*, assignors to *ASML Netherlands B.V.*
11 December 2007 (Class 702/56); filed 15 September 2004

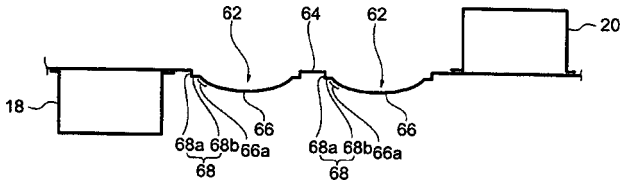
A lithographic apparatus is a machine that applies a desired pattern onto a target portion of a substrate. The pattern typically is provided by

radiation that passes through a patterning structure or by a beam that is made to scan along the substrate. Vibrations that may disturb the image produced by such a process are detected by projecting a test image onto the substrate and measuring its temporal intensity variations.—EEU

7,294,218

43.50.Fe COMPOSITE MATERIAL WITH IMPROVED STRUCTURAL, ACOUSTIC AND THERMAL PROPERTIES

Enamul Haque *et al.*, assignors to *Owens Corning Intellectual Capital, LLC*
13 November 2007 (Class 156/148); filed 18 November 2004



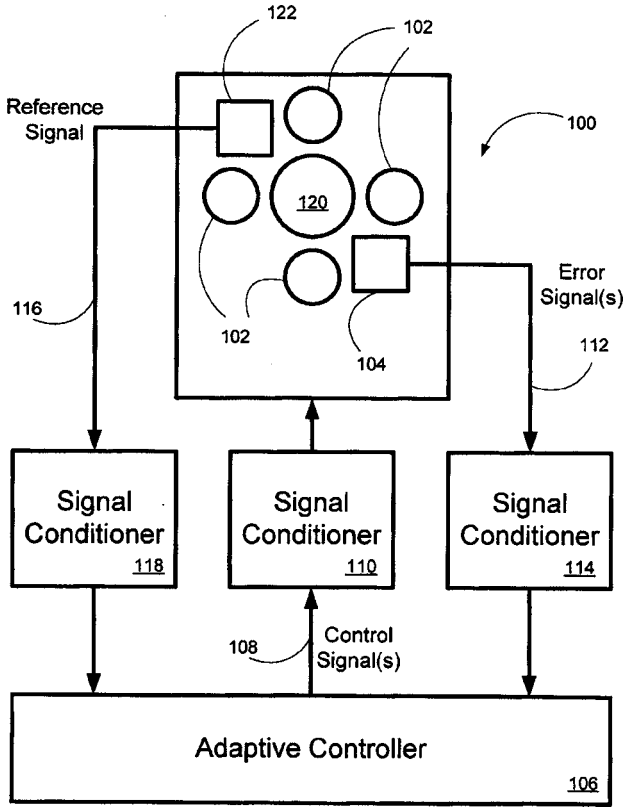
A method to produce multilayer acoustic and thermal insulation is put forth.—GFE

7,270,366

43.50.Gf AUTOMOTIVE FLOOR PANEL STRUCTURE

Takanobu Kamura *et al.*, assignors to *Mazda Motor Corporation*
18 September 2007 (Class 296/193.07); filed in Japan 11 November 2003

Reduction of noise emitted by vehicle floor panel **62**–**68** is claimed. Offending sound results from vibrations transferred from the car body **18**–**20** to floor panel **62**–**68**. Vibration arising from a 160 Hz suspension resonance and a 250 Hz tire cavity resonance that transmit to the floor panel can cause those panels to radiate sound into the vehicle cabin. Such sound radiation is reduced by forming the panel surface into at least two adjacent



segments **62**, having predetermined stiffnesses. Bends of convex shape **62** and circular platform **66**, **68**-**a**-**b** stiffen both panel segments so as to not have a 1×1 resonance around 160 Hz, while also having a 1×2 resonance at 250 Hz. The 1×1 panel mode acts as a non-resonant stiff mass at 160 Hz, while the 1×2 panel mode has plus and minus phases which will cancel the sound radiated to a remote distance from that panel.—AJC

7,272,234

43.50.Ki MULTI-CHANNEL ACTIVE CONTROL SYSTEM AND METHOD FOR THE REDUCTION OF TONAL NOISE FROM AN AXIAL FAN

Scott D. Sommerfeldt and Kent L. Gee, assignors to *Brigham Young University*
18 September 2007 (Class 381/71.11); filed 4 April 2003

Reduction of tonal noise emission from small fans, etc. is claimed where error microphone **104** is placed in the near field of sound from noise source **120**. Loudspeakers **102** are placed as close as possible to, and in the near field of, source **120**. A blade passage sensor **122** provides a synchronizing signal for feed-forward control. Signal conditioning **106**–**118** provides separate and phased drives for each speaker **102** to implement noise

cancellation. Noise reduction of 19 dBA is reported for a fan fundamental of 370 Hz plus harmonics up to 1480 Hz.—AJC

7,296,977

43.55.Ti DAMPING MATERIAL, DAMPING ARRANGEMENT AND METHOD FOR DESIGNING A DAMPING ARRANGEMENT

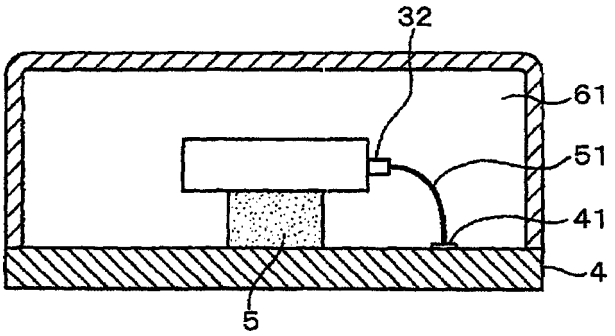
Laurent Bonnet, assignor to *General Electric Company*
20 November 2007 (Class 416/230); filed in the European Patent Office 17 November 2004

This laminate for damping vibrations is comprised of a soft viscoelastic layer (elastomer based) and a stiff constrained layer (steel or aluminum, for example). It is attached in stripes oriented in an orthogonal grid to a vibrating element like a wind turbine.—CJR

7,297,407

43.55.Ti GLASS LAMINATES FOR REDUCTION OF SOUND TRANSMISSION

Jerrel C. Anderson, assignor to *E. I. du Pont de Nemours and Company*
20 November 2007 (Class 428/441); filed 19 September 2005



This patent describes a sound damping laminate that has at least three separate polymer layers. The laminate provides improved sound damping and transmission loss performance in glazing to be used in buildings or vehicles.—CJR

7,304,413

43.58.Hp PIEZOOSCILLATOR

Kenji Kasahara, assignor to *Nihon Dempa Kogyo Company, Limited*
4 December 2007 (Class 310/326); filed in Japan 10 August 2005

Referring to the figure, the author describes the temperature controlled crystal oscillator that he devised, which is isolated inside a case that can be temperature controlled. In addition, the crystal is mounted on a "buffer material" such as silicone gel or "…rubber, sponge, fiber, form material,

spring or the like can be used other than the previously-described gel." OK, so this person has just described and patented 50-year-old technology that is present in every watch and digital trinket made since then. The existence of this patent is a perfect example of how broken the patent review system is.—JAH

7,299,678

43.58.Wc SENSOR APPARATUS

Eric Atherton, assignor to *Baker Hughes Incorporated*
27 November 2007 (Class 73/24.06); filed in United Kingdom 27 March 2000

This patent discloses the use of tuning forks and other vibrational resonators as frequency-domain transducers for physical properties of the environment, such as temperature, pressure, and magnetic field. The advantage of doing this, it is claimed, is that many transducers can be chained on a single-conductor cable and operated at different frequencies. The electronics can all be situated at the interrogating end of the single-conductor cable, and thereby the sensors can be allowed to operate at temperatures well above the limit for active electronics. Although the author is primarily describing applications of this type of sensor in a borehole deep underground, it appears that it would also be useful in undersea monitoring operations. There are no specifics given of the sensor construction (both vibrating wires and tuning forks are mentioned), so little can be said about the validity of the chaining concept except that it requires either low-impedance sensors in series or high-impedance sensors in parallel.—JAH

7,289,796

43.60.Dh MOBILE COMMUNICATIONS TERMINAL DEVICE AND METHOD FOR IDENTIFYING INCOMING CALL FOR USE WITH THE SAME

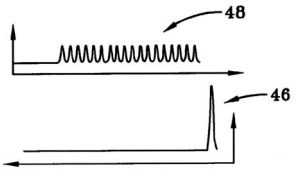
Kazuhiro Kudoh, assignor to *NEC Corporation*
30 October 2007 (Class 455/415); filed in Japan 6 July 2000

Somehow, the idea of customized ringtones was claimed again.—GFE

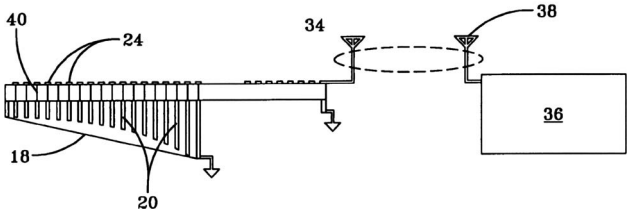
7,289,390

43.60.Fg ULTRASONIC TRANSMITTING/RECEIVING APPARATUS AND SCANNING SONAR EMPLOYING SAME

Yasushi Nishimori *et al.*, assignors to *Furuno Electric Company, Limited*
30 October 2007 (Class 367/103); filed 19 July 2004



The well-known concept of multi-beam sonar at different frequencies is put forth again. Maybe that's what "employing same" means?—GFE

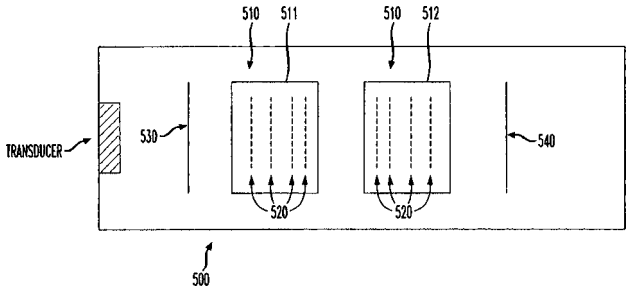


7,263,892

43.60.Qv PASSIVE TIRE PRESSURE SENSOR AND METHOD

Kent Bryant Pfeifer *et al.*, assignors to *The Goodyear Tire & Rubber Company*
4 September 2007 (Class 73/715); filed 23 January 2006

A transponding tire pressure gauge **34** is claimed. Sensor **18**–**34** receives a rf interrogation pulse **48** via antenna **34** whose energy is converted to a surface acoustic wave (SAW) in its substrate. This wave travels the length of that substrate and is reflected by any reflector **24** that is shorted by any contact **20** to cover **18**. The reflected SAW returns to the antenna with



modulation **44**. Tire air pressure will depress cover **18** over a sealed cavity, to progressively touch contacts **20**. Delay time from the interrogation pulse to the reflected pulse **44** is progressively shortened by increased tire air pressures. Interrogation transceiver **38**–**36** and its processor convert this pulse time delay into a tire pressure alert signal to the driver.—AJC

7,264,149

43.60.Qv SAW IDENTIFICATION TAG DISCRIMINATION METHODS

Clinton S. Hartmann, Dallas, and John C. Bellamy, Coppell, both of Texas
4 September 2007 (Class 235/375); filed 15 September 2004

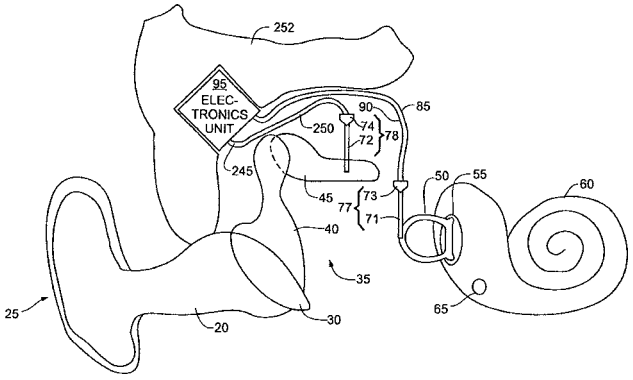
An error correcting radio frequency identification (RFID) tag is claimed for use in environments already rich in 2.8 GHz industrial, scientific and medical (ISM) signals, such as near a local area network (LAN) and microwave ovens. Surface acoustic wave (SAW) substrate **510** includes a transducer section, a start pulse reflector **530**, identical data encoder sections **511** and **512**, and a final reflector **540**. The subsequent pulse train received by an external interrogator (not shown) will contain two identical payload

pulse trains with an intervening pause. Improved discrimination is achieved for the desired RFID signal when in an environment rich in ISM radiation.—AJC

7,265,662

43.60.Qv APPARATUS AND METHOD FOR INSPECTING CONTAINERS

Paul Belanger, assignor to *Praxair Technology, Incorporated*
4 September 2007 (Class 340/521); filed 17 March 2005



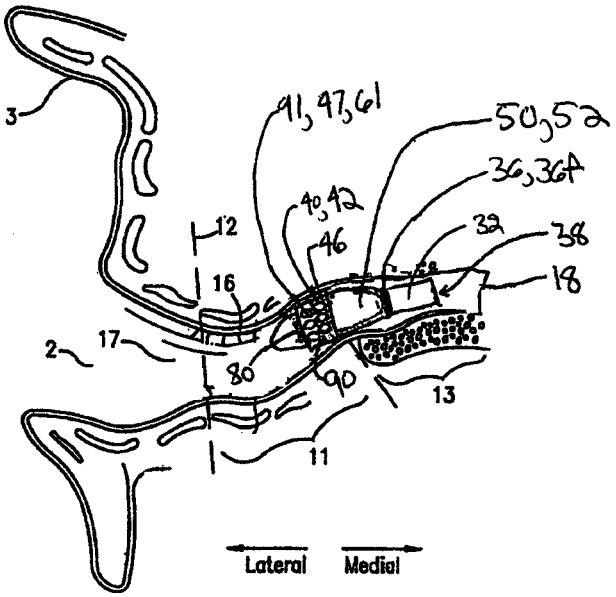
A system for inspecting empty pressurized gas storage cylinders prior to refilling is claimed using optical (video camera), sound and odor sensors. A microphone in the vicinity of the cylinder receives sound resulting from an impact by the operator or automatic impact device. The subsequent ring sound frequencies and other parameters are processed via a fast Fourier transform (FFT) or wavelet. These results are compared with database values to determine whether that cylinder is acceptable for refill.—AJC

7,297,101

43.66.Ts METHOD AND APPARATUS FOR MINIMALLY INVASIVE PLACEMENT OF SENSING AND DRIVER ASSEMBLIES TO IMPROVE HEARING LOSS

Johann J. Neisz *et al.*, assignors to *Envoy Medical Corporation*
20 November 2007 (Class 600/25); filed 17 January 2006

An implantable hearing system is mounted in the middle ear without performing mastoid surgery. By cutting a portion of the tympanic membrane, a trans-canal approach is used to mount the sensing/driver assembly



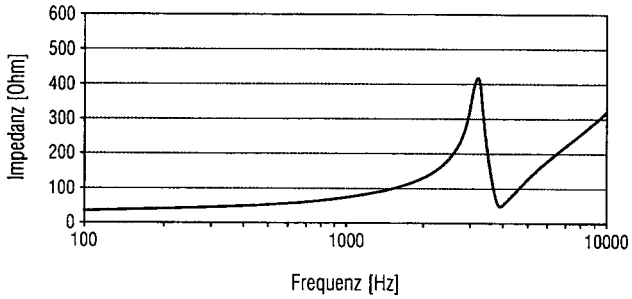
and secure it to a bone within the middle ear space. Leads from the electronics are coupled to the sensing/driver assembly through the skin near the ear canal.—DAP

7,298,857

43.66.Ts EXTENDED WEAR CANAL DEVICE WITH COMMON MICROPHONE-BATTERY AIR CAVITY

Adnan Shennib *et al.*, assignors to *Insound Medical, Incorporated*
20 November 2007 (Class 381/324); filed 7 February 2005

A deeply-fitting hearing device consists of a receiver assembly designed for location in the bony portion of the ear canal, a battery assembly hooked to the receiver assembly, and a microphone assembly that is attached to the battery assembly and oriented to prevent ingress of ear canal debris.



The microphone and battery assemblies are coupled to an air cavity, which may provide an air reservoir. A sealing retainer around the microphone or receiver assemblies helps to prevent acoustic feedback.—DAP

11 December 2007 (Class 600/443); filed 2 September 2004

A number of time-gain compensation functions are obtained, each from a separate set of echo signals, and the compensation functions are applied automatically without user intervention.—RCW

LETTERS TO THE EDITOR

This Letters section is for publishing (a) brief acoustical research or applied acoustical reports, (b) comments on articles or letters previously published in this Journal, and (c) a reply by the article author to criticism by the Letter author in (b). Extensive reports should be submitted as articles, not in a letter series. Letters are peer-reviewed on the same basis as articles, but usually require less review time before acceptance. Letters cannot exceed four printed pages (approximately 3000–4000 words) including figures, tables, references, and a required abstract of about 100 words.

Influence of vehicle color on loudness judgments (L)

Daniel Menzel[a] and Hugo Fastl
Arbeitsgruppe Technische Akustik, MMK, Technische Universität München, München, Germany

Ralf Graf and Jürgen Hellbrück
Arbeits-, Umwelt- und Gesundheitspsychologie, Katholische Universität Eichstätt-Ingolstadt, Eichstätt, Germany

(Received 18 October 2007; revised 7 February 2008; accepted 11 February 2008)

This experiment investigates the effect of images of differently colored sports cars on the loudness of a simultaneously perceived car sound. Still images of a sports car, colored in red, light green, blue, and dark green, were displayed to subjects during a magnitude estimation task. The sound of an accelerating sports car was used as a stimulus. Statistical analysis suggests that the color of the visual stimulus may have a small influence on loudness judgments. The observed loudness differences are generally equivalent to a change in sound level of about 1 dB, with maximum individual differences of up to 3 dB. © *2008 Acoustical Society of America.*

I. INTRODUCTION

Loudness plays an important role in sound-quality engineering and sound design. While loudness perception depends primarily on physical properties of the sound field, loudness judgments may also be influenced by nonacoustical factors (Blauert and Jekosch, 1997). For example, Namba *et al.* (1997) examined interior vehicle sounds and found that subjects tended to avoid extreme categorical ratings of loudness when a video of the scenery surrounding the driving car was presented. Thus loud sounds were rated softer, while soft sounds were rated louder. Dynamic visual information was also found to affect semantic differential ratings in a study reported by Suzuki *et al.* (2000). Different environmental sounds had to be rated with and without corresponding video sequences. The "volume" factor, which included adjectives such as powerful, loud, and noisy, had smaller loadings when there was additional visual stimulation. The influence of apparent size on the loudness of trucks was studied by Höger and Greifenstein (1988). In an eleven-point categorical scaling task, the sound accompanied by the video sequence of a small truck frequently was judged as being softer than the same sound combined with the video of a big truck.

Patsouras *et al.* (2002) and Rader *et al.* (2004) reported that the color of passenger trains may influence magnitude estimates of loudness. Still images which were electronically edited to show a bright red train caused subjects to give higher ratings when asked for the loudness of the sound of a passing train, while light-green trains elicited lower loudness judgments compared to purely auditory presentation. A summary of these and other studies concerning influences of visual stimulation on loudness estimation is given in Fastl (2004).

These phenomena of audio-visual interactions may also be of interest in the field of automotive design, especially regarding the typical bright red color of premium sports cars. It is expected that red cars cause an overestimation of loudness compared to cars of other colors.

II. EXPERIMENT

A. Stimuli

The picture of a British sports car (Aston Martin V8) was chosen as visual stimulus. Its dark-green (DG) color was digitally modified, so that in addition to the original color the images of a red (R), blue (B), and light-green (G) vehicle were available for the experiment (see Fig. 1). The images were shown on a 19 in. CRT computer monitor, with a viewing distance of 0.7 m. The monitor was positioned outside a soundproof booth and was visible through a window. The subjects were seated inside the booth and were instructed to keep their eyes focused on the image throughout the experiment.

The sound of an accelerating sports car with a duration of 4 s was used as auditory stimulus. It was presented diotically through calibrated electrodynamic headphones (Beyer

[a]Electronic mail: menzel@tum.de

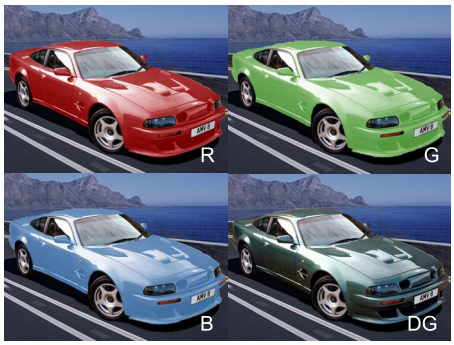

FIG. 1. (Color online) The four images used as visual stimuli. The original color of the car, a dark green, is depicted on the lower right-hand side.

DT 48), using a free field equalizer as described by Fastl and Zwicker (2007). To minimize memory effects during loudness judgments four different sound levels were chosen [L_{AFmax}=90,86,82, and 78 dB(A)].

B. Listeners

Sixteen subjects (four female, twelve male), aged 22 to 62 years (median 26 years), participated in the experiment. All had normal hearing, as verified by pure-tone audiometric measurements.

C. Procedure

Each subject participated in two sessions. Written instructions (in German) were given which informed the subjects that they were about to rate the perceived loudness of sounds accompanying the images of sports cars. They were told to do so by giving arbitrary positive numbers that correspond to perceived loudness ratios. In each session, all possible combinations of auditory and visual stimuli were presented four times in random order. At the beginning, a short training sequence was inserted consisting of four randomly chosen stimulus combinations. The subjects then judged the loudness of the sounds via free magnitude estimation, entering their answers on a computer keyboard. This resulted in 64 loudness ratings per subject per session.

D. Results

The data for each subject were normalized relative to the median of the ratings given for the dark-green image at 90 dB(A). The median rating of each stimulus combination across the four repetitions was then calculated and used in the following analysis.

Figure 2 shows a summary of the results. The median and interquartile ranges of each stimulus pair over all subjects are depicted. Regarding the median values, it seems that in most cases the sounds associated with images of red or dark-green vehicles were rated louder than those combined with light-green or blue ones.

To test the significance of these findings, a three-way repeated measures analysis of variance with session (1 and 2), level [90, 86, 82, and 78 dB(A)], and color (R, G, B, and DG) as within-subject factors was performed, which showed a significant interaction between session and color

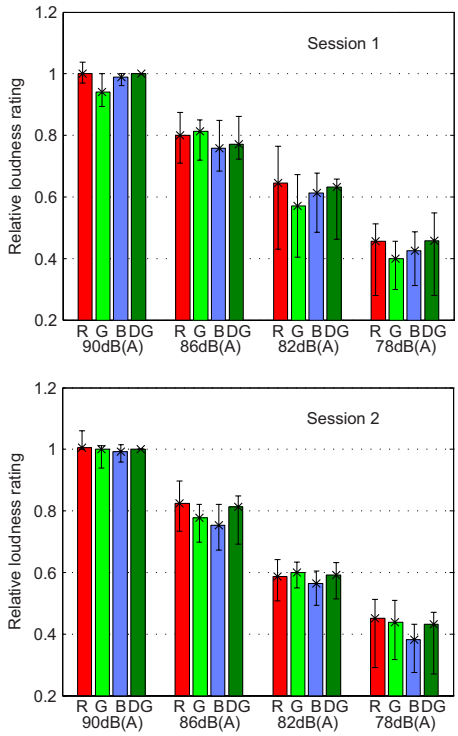

FIG. 2. (Color online) Median relative loudness ratings with interquartile ranges, grouped by level and normalized relative to the stimulus pair 90 dB(A)/DG.

[$F(3,45)=2.82$, $p<0.05$]. Therefore, the two sessions were analyzed separately using a two-way repeated measures analysis of variance with level [90, 86, 82, and 78 dB(A)] and color (R, G, B, and DG) as within-subject factors. Apart from the expected highly significant main effect of level [Session 1: $F(3,45)=222.24$, $p<0.0001$; Session 2: $F(3,45)=204.34$, $p<0.0001$], a significant main effect of color [Session 1: $F(3,45)=3.71$, $p<0.05$; Session 2: $F(3,45)=3.33$, $p<0.05$] was found, indicating that subjects were influenced in their loudness judgment by the color of the visual stimuli. No significant interaction (sound level by color) was found in either session ($p>0.05$).

To further investigate the influence of the visual conditions, a post-hoc comparison was performed using Scheffé's procedure. As can be seen in Table I, significant differences only occurred in Session 1 between the stimuli R and G ($p<0.05$) and in Session 2 between R and B ($p<0.05$). In both

TABLE I. Mean differences (D) between visual conditions. Critical differences (D_{crit}) were calculated according to Scheffé (α=0.05). Significant differences are marked with an asterisk.

	Session 1		Session 2	
	D	D_{crit}	D	D_{crit}
R-G	0.0359	0.0343*	0.0171	0.0331
R-B	0.0164	0.0343	0.0345	0.0331*
R-DG	0.0044	0.0343	0.0088	0.0331
G-B	−0.0195	0.0343	0.0174	0.0331
G-DG	−0.0316	0.0343	−0.0083	0.0331
B-DG	−0.0120	0.0343	−0.0257	0.0331

cases, sounds heard during the presentation of a red car produced higher loudness ratings. All other color combinations failed to reach statistical significance.

The mean difference between visual conditions R and G corresponds to a change in sound level of about 1 dB. Some subjects, however, seemed to be more strongly influenced by different colors and showed larger equivalent level differences of up to 3 dB.

III. CONCLUSIONS

In this experiment, small differences in magnitude estimates of loudness were found depending on visual stimulation by images of differently colored sports cars. These differences are equivalent to a change in sound level of about 1 dB, with maximum observed differences of 3 dB. Previous research concerning color influences on loudness was confirmed: Still images of red vehicles seem to elicit higher loudness ratings compared to light-green or blue vehicles. Similar tendencies were observed for dark green.

As light green and blue are rather untypical colors for sports cars, a tentative explanation could involve the degree to which the image displayed to the subjects gives the impression of a typical sports car. The general real life experience is that sports cars have certain visual and acoustical attributes, which separate them from "normal" cars. On the one hand, sports cars are usually built to reach high speeds, which requires for example a streamlined design and a powerful engine. On the other hand, certain colors like bright red are traditionally associated with premium sports cars. A visual stimulus that looks like a sports car (streamlined body structure, bright red color) thus could cause subjects to assume the vehicle possesses a powerful and therefore loud engine, which in turn could lead to higher loudness ratings. To test this hypothesis, other visual features of the vehicle apart from color could be modified to give the impression of more or less sportive cars. For example, race numbers on the door could suggest a professional racing car (with a corresponding powerful engine), and thus might influence loudness judgment even more. An additional questionnaire could give insight into introspection of the subjects, for example whether a particular vehicle during the experiment was identified as a sports car or not. A similar case of differences in loudness judgments caused by visual expectations was described by Aylor and Marks (1976).

There is evidence that the red/loud combination can raise physiological arousal and induce the perception of excitement (Wolfson and Case, 2000). Such a feeling of excitement may contribute to an overestimation of loudness.

On the conservation of momentum for a sound pulse reflecting from a pressure-release boundary (L)

A. G. Voronovich[a)]
Physical Science Division, NOAA/Earth System Research Laboratory, 325 Broadway, Boulder, Colorado 80305

(Received 9 August 2007; revised 8 February 2008; accepted 8 February 2008)

When a "massless" one-dimensional sound pulse (mass of a sound pulse is defined as an integral of the perturbation of density over the pulse length) reflects from a pressure-release boundary, its momentum changes sign. This obviously violates momentum conservation. However, in contrast to the case of an unbounded medium, calculation of the momentum in a bounded region includes a second-order term as well. Apparently, the second-order correction to the linear solution ensures momentum conservation in this case. The purpose of this Letter is to find a concrete form of this second-order correction. It appears that, as a result of the nonlinear interaction of the pulse with a pressure-release boundary, the latter experiences second-order net shift. This leads to the generation of a massive second-order rarefaction pulse whose momentum is directed opposite to the direction of propagation of the pulse itself. Appearance of this pulse ensures total momentum conservation.

I. INTRODUCTION

Momentum of a wave motion in a one-dimensional (1D) case in an unbounded fluid is

$$P = \int_{-\infty}^{\infty} (\rho_0 + \rho)\varphi_x dx = \rho_0 \Delta\varphi + \int_{-\infty}^{\infty} \rho\varphi_x dx, \tag{1}$$

where ρ_0 and $\rho(x,t)$ are equilibrium density and its variation, respectively, $\varphi(x,t)$ is velocity potential, and $\Delta\varphi=\varphi(+\infty,t)-\varphi(-\infty,t)$ is total variation of the potential across the wave. If in the initial moment of time $\Delta\varphi=0$, then the jump of the potential will be equal to zero always, and to calculate momentum up to the lowest, (i.e., second) order value it is sufficient to substitute into the second term in Eq. (1) a linear solution. In the 1D case linear solution can be represented as a superposition of the right- and left-propagating pulses. At a later time when both pulses separate and do not overlap, one can easily find with the help of Eq. (11) that

$$P = \frac{E_+}{c_0} - \frac{E_-}{c_0}, \tag{2}$$

where E_+, E_- is an energy of the right- and left-propagating pulses, respectively. A similar situation takes place in the three-dimensional case as well.[1] Now let us assume that at $x=0$ there is a pressure-release boundary. After reflection from the boundary direction of the propagation and hence the momentum of the pulse changes without action of an external force. This obviously violates momentum conservation. However, now in Eq. (1) one has $\Delta\varphi=\varphi(\xi,t)$, where ξ is coordinate of the boundary, and momentum conservation can be ensured if after reflection due to nonlinear effects the reflected pulse acquires a second-order "tail" so that in Eq. (1) $\Delta\varphi\neq 0$. The purpose of this Letter is to find details of this process using second-order analysis.

Second-order solution of the 1D motion of an ideal compressible fluid was, of course, calculated for different purposes in numerous works. A review and detailed analysis of many situations related to this classical problem can be found, in particular, in relatively recent work.[2] However, the case of a pressure-release boundary was not considered there. The issue of momentum conservation for the sound pulse reflecting from a pressure-release boundary in the works known to the author has not been clarified yet.

In Sec. II we will present a solution of the problem in the form convenient for our analysis, and in Sec. III we will provide physical interpretation of the results.

II. CALCULATION

The equations of the adiabatic motion of an ideal fluid in 1D read:

$$\varphi_t + \tfrac{1}{2}\varphi_x^2 + w(\tilde{\rho}) - w(\rho_0) = 0, \tag{3}$$

$$\tilde{\rho}_t + (\tilde{\rho}\varphi_x)_x = 0, \tag{4}$$

where $\tilde{\rho}$ is a total density and $w(\tilde{\rho})$ is an enthalpy. We will consider a solution of these equations in a weakly nonlinear case up to the second-order terms only. In this case one can use for the enthalpy power expansion;

$$\frac{w(\tilde{\rho}) - w(\rho_0)}{c_0^2} = \frac{\tilde{\rho} - \rho_0}{\rho_0} + \alpha\left(\frac{\tilde{\rho} - \rho_0}{\rho_0}\right)^2 + \cdots, \tag{5}$$

where c_0 is an unperturbed sound speed and α is a constant coefficient determined by the equation of state. Since $dw = d\tilde{p}/\tilde{\rho}$ for the total pressure $\tilde{p}$ we obtain a similar expansion,

a)Electronic mail: alexander.voronovich@noaa.gov

$$\frac{\tilde{p}-p_0}{\rho_0 c_0^2}=\frac{\tilde{\rho}-\rho_0}{\rho_0}+\left(\alpha+\frac{1}{2}\right)\left(\frac{\tilde{\rho}-\rho_0}{\rho_0}\right)^2+\cdots, \tag{6}$$

where

$$\alpha=\frac{1}{2}\left(\frac{\rho_0 d^2\tilde{p}}{c_0^2 d\tilde{\rho}^2}-1\right)_{\rho=\rho_0}=\frac{1}{2}\left(\frac{\rho}{c^2}\frac{dc^2}{d\rho}-1\right)_{\rho=\rho_0}. \tag{7}$$

For the ideal gas with the equation of state $\tilde{p}/p_0=(\tilde{\rho}/\rho_0)^\gamma$ one finds $\alpha=\gamma/2-1$. Now we can rewrite Eqs. (3) and (4) to the accuracy of the second-order terms as follows:

$$\varphi_t+\frac{1}{2}\varphi_x^2+c_0^2\frac{\rho}{\rho_0}+\alpha c_0^2\left(\frac{\rho}{\rho_0}\right)^2=0, \tag{8}$$

$$\rho_t+\rho_0\varphi_{xx}+(\rho\varphi_x)_x=0, \tag{9}$$

where $\rho=\tilde{\rho}-\rho_0$. Differentiating Eq. (9) with respect to t and using Eq. (8) we obtain

$$\varphi_{tt}-c_0^2\varphi_{xx}=\frac{c_0^2}{\rho_0}(\rho\varphi_x)_x-\left(\frac{1}{2}\varphi_x^2+\frac{\alpha c_0^2}{\rho_0^2}\rho^2\right)_t. \tag{10}$$

In the linear approximation the right-hand side of Eq. (10) can be neglected. Let us consider the first-order solution in the form of a right-propagating pulse,

$$\varphi^{(1)}=f\left(t-\frac{x}{c_0}\right),\quad \rho^{(1)}=-\frac{\rho_0}{c_0^2}f'\left(t-\frac{x}{c_0}\right). \tag{11}$$

We will assume that function f is smooth and differs from zero at $0<t<T$ only. Let us calculate the second-order solution assuming the following initial conditions:

$$\varphi^{(2)}|_{t=0}=0,\quad \rho^{(2)}|_{t=0}=0. \tag{12}$$

It follows from Eqs. (8) and (12) that

$$\varphi_t^{(2)}|_{t=0}=-\frac{1}{c_0^2}\left(\frac{1}{2}+\alpha\right)\left[f'\left(-\frac{x}{c_0}\right)\right]^2. \tag{13}$$

Calculating the right-hand side of Eq. (10) in terms of the first-order values Eq. (11) we find:

$$\varphi_{tt}^{(2)}-c_0^2\varphi_{xx}^{(2)}=-\frac{1}{c_0^2}\left(\frac{3}{2}+\alpha\right)\frac{\partial}{\partial t}\left[f'\left(t-\frac{x}{c_0}\right)\right]^2. \tag{14}$$

One can easily check by inspection that the solution of Eqs. (12)–(14) is as follows:

$$\varphi^{(2)}=F(x,t)=-\frac{1}{2c_0^2}\left(\frac{3}{2}+\alpha\right)t\left[f'\left(t-\frac{x}{c_0}\right)\right]^2+\frac{1}{2c_0^2}\left(\frac{1}{4}-\frac{\alpha}{2}\right)\int_{-t-x/c_0}^{t-x/c_0}[f'(\tau)]^2 d\tau. \tag{15}$$

The original equations are invariant under substitution $x\to -x$; hence, one can replace in Eqs. (11) and (15) x by $-x$ and obtain a similar solution for the left-propagating pulse.

Let us now impose on our problem the pressure-release boundary condition $\tilde{p}|_{x=\xi(t)}=p_0$ or

$$\rho|_{x=\xi(t)}=0, \tag{16}$$

where $\xi(t)$ is the coordinate of the boundary which, apparently, satisfies

$$\xi_t=\varphi_x(\xi,t). \tag{17}$$

Now in the first approximation we have

$$\varphi^{(1)}=f\left(t-\frac{x}{c_0}\right)-f\left(t+\frac{x}{c_0}\right), \tag{18}$$

$$\rho^{(1)}=-\frac{\rho_0}{c_0^2}f'\left(t-\frac{x}{c_0}\right)+\frac{\rho_0}{c_0^2}f'\left(t+\frac{x}{c_0}\right), \tag{19}$$

$$\xi^{(1)}=-\frac{2}{c_0}f(t). \tag{20}$$

The solution Eqs. (18)–(20) represents a pulse which propagates from the region of negative x to the right and after reflection from the pressure-release boundary at $x=0$ changes its polarity.

Substituting into the right-hand side of Eq. (10) expressions (18) and (19) we obtain squares of the terms associated with the arguments $(t-x/c_0)$ and $(t+x/c_0)$ and a cross-product term. In Eq. (13) the cross-product term is absent, since the original pulse and its mirror image at $t=0$ do not overlap. According to this the second-order solution can now be represented as follows:

$$\varphi^{(2)}=F(x,t)+F(-x,t)-G(x,t)+Q\left(t+\frac{x}{c_0}\right), \tag{21}$$

where $F(x,t)$ is given by Eq. (15). Function G here is due to the cross-product term; it is a solution of

$$G_{tt}-c_0^2G_{xx}=\frac{1-2\alpha}{c_0^2}\frac{\partial}{\partial t}\left[f'\left(t-\frac{x}{c_0}\right)f'\left(t+\frac{x}{c_0}\right)\right], \tag{22}$$

satisfying the initial conditions $G=G_t=0$, $t=0$;

$$G(x,t)=\frac{1-2\alpha}{4c_0^2}\frac{\partial}{\partial t}\left[f\left(t-\frac{x}{c_0}\right)f\left(t+\frac{x}{c_0}\right)\right]. \tag{23}$$

Function G is even with respect to x and differs from zero only at $0<t<T$.

Apparently, Q in Eq. (21) is a solution of the homogeneous wave equation representing a second-order, left-propagating pulse. We will assume that Q turns to zero for negative arguments so that this term does not contribute to the initial condition (12) at $x<0$. The appearance of function Q is due to the necessity to satisfy boundary condition (17) at second order:

$$\rho^{(2)}|_{x=0}=-\rho_x^{(1)}|_{x=0}\xi^{(1)}=4\frac{\rho_0}{c_0^4}f''(t)f(t). \tag{24}$$

Calculating second-order terms in Eq. (8) at $x=0$ taking into account Eqs. (21) and (24) and integrating over time we find:

$$c_0^2Q(t)=\left(\frac{3}{2}+\alpha\right)t[f'(t)]^2-\left(\frac{7}{2}+\alpha\right)f(t)f'(t)+\left(\frac{7}{4}+\frac{\alpha}{2}\right)\int_0^t[f'(\tau)]^2 d\tau. \tag{25}$$

Now, let us evaluate total shift of the boundary in the second order [the first-order shift according to Eq. (20), equals, of course, zero]. From Eq. (17) we find:

$$\xi^{(2)}(\infty)=\int_0^\infty \varphi_x^{(2)}(0,t)dt+\int_0^\infty \varphi_{xx}^{(1)}(0,t)\xi^{(1)}(t)dt. \tag{26}$$

According to Eq. (18), $\varphi_{xx}^{(1)}(0,t)=0$. The sum of the first three terms in Eq. (21) is an even function of x, whence

$$\xi^{(2)}(\infty)=\int_0^\infty \varphi_x^{(2)}(0,t)dt=\int_0^\infty \frac{Q'(t)}{c_0}dt=\frac{Q(\infty)}{c_0}$$
$$=\frac{1}{c_0^3}\left(\frac{7}{4}+\frac{\alpha}{2}\right)\int_0^\infty [f'(\tau)]^2 d\tau \tag{27}$$

(actually integration here and in similar integrals to follow proceeds within the finite limits $0<\tau<T$). Thus, in the second order the boundary generally experiences positive shift (if $\alpha>-7/2$, what should normally be the case).

III. INTERPRETATION

Consider a linear pulse propagating to the right which shape is given by Eq. (11). Let us introduce a "mass" of the pulse,

$$M=\int_{-\infty}^\infty \rho dx=-\frac{\rho_0}{c_0^2}\int_{-\infty}^\infty f'\left(t-\frac{x}{c_0}\right)dx=\frac{\rho_0}{c_0}\Delta\varphi, \tag{28}$$

where

$$\Delta\varphi=\varphi(+\infty)-\varphi(-\infty) \tag{29}$$

is total change of the potential across the pulse. For the left-propagating pulse we will similarly find:

$$M=-\frac{\rho_0}{c_0}\Delta\varphi. \tag{30}$$

The total momentum of the right-propagating pulse is

$$P=\int_{-\infty}^\infty (\rho_0+\rho)\varphi_x dx=\rho_0\Delta\varphi+\frac{\rho_0}{c_0^2}\int_{-\infty}^\infty [f'(\tau)]^2 d\tau.$$

In the general case one thus obtains

$$P=\pm\left(Mc_0+\frac{\rho_0}{c_0^2}\int_{-\infty}^\infty [f'(\tau)]^2 d\tau\right), \tag{31}$$

where the plus or minus sign is related to the right- or left-propagating wave, respectively.

According to our assumption for the original pulse one has $\Delta\varphi=0$ and hence the mass of the original pulse is zero: $M=0$. At the initial moments of time: $0<t\ll T$, when one can assume that the reflected pulse did not appear yet, the second-order potential according to Eq. (15) is

$$\varphi^{(2)}=F(x,t)=-\frac{1}{2c_0^2}\left(\frac{3}{2}+\alpha\right)t\left[f'\left(t-\frac{x}{c_0}\right)\right]^2$$
$$+\frac{1}{2c_0^2}\left(\frac{1}{4}-\frac{\alpha}{2}\right)\int_{-t-x/c_0}^0 [f'(\tau)]^2 d\tau$$
$$+\frac{1}{2c_0^2}\left(\frac{1}{4}-\frac{\alpha}{2}\right)\int_0^{t-x/c_0} [f'(\tau)]^2 d\tau. \tag{32}$$

The first term here is due to the intrinsic nonlinearity of the process of propagation and describes steepening of the wave profile. The initial conditions given by Eq. (12) are chosen such that the wave motion at the initial moments of time corresponds to the right-propagating linear solution up to the second-order terms. One obtains proper solution by adding to the first term in Eq. (32) two second-order pulses which have the same mass

$$M_0=-\frac{\rho_0}{2c_0^3}\left(\frac{1}{4}-\frac{\alpha}{2}\right)\int_0^\infty [f'(\tau)]^2 d\tau, \tag{33}$$

but propagate in the opposite directions. These two massive pulses compensate the extra sources of mass, but do not introduce extra momentum. In other words, the two auxiliary pulses in Eq. (32) ensure required distribution of the initial second-order pressure and velocity fields at $t=0$. Since amplitude of these pulses is of second order already, one does not need to take into account for them nonlinear effects, and these pulses propagate to the second-order accuracy without changing shape.

Now let us consider how the solution looks at $x<0$ for sufficiently large moments of time $t>T$, when the process of interaction of the pulse with the boundary is completed. Equation (21), taking into account Eq. (25), gives

$$\varphi^{(2)}=\frac{1}{c_0^2}\left(\frac{3}{2}+\alpha\right)\left(\frac{t}{2}+\frac{x}{c_0}\right)\left[f'\left(t+\frac{x}{c_0}\right)\right]^2$$
$$-\frac{1}{c_0^2}\left(\frac{7}{2}+\alpha\right)f'\left(t+\frac{x}{c_0}\right)f\left(t+\frac{x}{c_0}\right)+\frac{1}{2c_0^2}\left(\frac{1}{4}\right.$$
$$\left.-\frac{\alpha}{2}\right)\int_{-t-x/c_0}^0 [f'(\tau)]^2 d\tau-\frac{1}{2c_0^2}\left(\frac{1}{4}-\frac{\alpha}{2}\right)$$
$$\times\int_0^{t+x/c_0} [f'(\tau)]^2 d\tau+\frac{2}{c_0^2}\int_0^{t+x/c_0} [f'(\tau)]^2 d\tau \tag{34}$$

(strictly speaking the solution for $\varphi^{(2)}$ at $t>T$ also includes a constant term which is of no consequence for the motion picture and was dropped). The first two terms in Eq. (34) represent the process of the steepening of the wave profile due to the nonlinearity of the process of pulse propagation. The third term in Eq. (34) represents the same left-propagating pulse as in Eq. (32); this pulse does not interact with the boundary and remains unchanged. The fourth term in Eq. (34) corresponds to the right-propagating pulse in Eq. (32) which was reflected from the pressure-release boundary and for this reason changed its polarity and hence sign of the mass. Since direction of propagation of this pulse has also changed, its momentum did not change, and total momentum of the two auxiliary pulses remains zero as it was at the initial moment. However, in Eq. (34) there is an additional left-propagating pulse corresponding to the last term in this equation. This pulse has a negative mass

$$M_*=-2\frac{\rho_0}{c_0^3}\int_0^\infty [f'(\tau)]^2 dt. \tag{35}$$

Note that the mass does not depend of the equation of state related to coefficient α in Eq. (5). In the case of rigid boundary which does not move the nonlinear effects lead to the

appearance of the radiation pressure.[2] In the case of the pressure-release boundary which cannot support the excess of pressure, the nonlinearity results in the second-order net shift of the boundary. However, total mass should be conserved, and shift of the boundary results in the appearance of the rarefaction pulse. From Eqs. (18) and (20) it is easy to see that after a right-propagating pulse of mass M_0 reflects from a pressure-release boundary, the boundary experiences in the linear approximation a net shift $\xi(\infty)=2M_0/\rho_0$. Similarly, a second-order, left-propagating pulse with mass M_* will produce a second-order shift—M_*/ρ_0. It is easy to see that the sum of these two shifts does correspond to the total shift given by Eq. (27),

$$\rho_0\xi^{(2)}(\infty)=2M_0-M_*. \tag{36}$$

According to Eq. (31) momentum of the left-propagating pulse with mass M_* is

$$P_*=-M_*c_0=2\frac{\rho_0}{c_0^2}\int_0^\infty [f'(\tau)]^2d\tau \tag{37}$$

[the second term in Eq. (31) is in this case of fourth order and has to be neglected]. The pulse propagates to the left, however its momentum is directed to the right since $M_*<0$. Together with the negative momentum of the reflected original pulse, momentum P_* ensures overall momentum conservation in the case of a pressure-release boundary:

$$\frac{\rho_0}{c_0^2}\int_0^\infty [f'(\tau)]^2d\tau=-\frac{\rho_0}{c_0^2}\int_0^\infty [f'(\tau)]^2d\tau+P_*. \tag{38}$$

The shape of this pulse is given by the last term in Eq. (34). If we assume that the initial pulse is narrow band with some envelope having final support, then the second-order pulse under consideration can be considered as a superposition of a high-frequency pulse with double carrier frequency and zero mass and a low-frequency massive pulse with the local amplitude of the velocity proportional to the square of the amplitude of the velocity in the original pulse. In the absence of dispersion (the case considered here) the low- and high-frequency pulses will be always superimposed. However, in the presence of a weak dispersion these two pulses will eventually separate.

It is interesting to compare the cases of a pressure-release and a rigid boundary which corresponds to the boundary condition $\varphi_x(0,t)=0$. In the latter case the second terms in the first-order solution given by Eqs. (18) and (19) change signs and it becomes $\xi^{(1)}=0$. Correspondingly, the second-order solution for the potential is given in this case by Eq. (21) with the sign of the third term (G) changed and the last term (Q) absent. Apparently, the boundary condition is satisfied in this case since $\varphi^{(2)}$ is an even function of x. Solution at small t, of course, coincides with Eq. (32), and at $t>T$ solution given by Eq. (34) as simple calculation shows has to be modified as follows. The first two terms in Eq. (34) are replaced by

$$-\frac{1}{2c_0^2}\left(\frac{3}{2}+\alpha\right)t\left[f'\left(t+\frac{x}{c_0}\right)\right]^2, \tag{39}$$

the fouth term changes sign (since corresponding pulse reflects now from rigid boundary), and the last term disappears. The total change of the momentum now becomes

$$\Delta P=\frac{\rho_0}{c_0^2}\int_0^\infty [f'(\tau)]^2d\tau-\left(-\frac{\rho_0}{c_0^2}\int_0^\infty [f'(\tau)]^2d\tau-2M_0c_0\right)$$
$$=\frac{\rho_0}{c_0^2}\left(\frac{7}{4}+\frac{\alpha}{2}\right)\int_0^\infty [f'(\tau)]^2d\tau. \tag{40}$$

The momentum change depends now on the equation of state. Using Eq. (6) one can check that

$$\Delta P=\int_0^\infty (\tilde{p}-p_0)_{x=0}dt, \tag{41}$$

as it should be according to Newton's second law.[2] It is interesting to note that the total momentum change in the case of the pulse reflected from the rigid boundary and the total shift of the pressure-release boundary according to Eqs. (40) and (27) are related as follows:

$$\Delta P=\rho_0c_0\xi^{(2)}. \tag{42}$$

A possible interpretation of this observation was suggested during the reviewing process. If one assumes that the radiation pressure on the right-hand side of Eq. (41) appearing in the case of a rigid boundary can be converted into the second-order velocity of the boundary in a pressure-release case through the medium impedance ρ_0c_0 according to the standard relation:

$$(\tilde{p}-p_0)_{x=0}=\rho_0c_0\dot{\xi}, \tag{43}$$

then Eq. (42) immediately follows from Eq. (41).

IV. CONCLUSION

When a sound pulse is reflected from a pressure-release boundary, the boundary experiences a second-order shift. This results in the appearance of a second-order massive rarefaction pulse whose momentum, which is also of the second order, is directed opposite to the direction of its propagation. Momentum of this pulse ensures overall momentum conservation. Its energy, however, is a fourth-order value; thus presence of this pulse does not violate energy conservation.

Thus, interaction of the massless sound pulses with the boundaries which are allowed to move can result in the appearance of the second-order massive pulses, and total variation of the potential across the wave will become nonzero: the situation which cannot arise as a result of nonlinear interactions in the unbounded fluid.

The high-frequency dispersion coefficient for the Rayleigh velocity in a vertically inhomogeneous anisotropic half-space (L)

A. L. Shuvalov[a)]
Laboratoire de Mécanique Physique, Université Bordeaux 1, UMR CNRS 5469, F-33405 Talence Cedex, France

(Received 22 October 2007; revised 14 January 2008; accepted 8 February 2008)

For an arbitrary anisotropic half-space with continuous vertical variation of material properties, an explicit closed-form expression for the coefficient B of high-frequency dispersion of the Rayleigh velocity $v_R(\omega)\approx v_R^{(0)}(1+B/\omega)$ is derived. The result involves two matrices, one consisting of the surface-traction derivatives in velocity and the other of its Wentzel–Kramers–Brillouin coefficients, which are contracted with an amplitude vector of the Rayleigh wave in the reference homogeneous half-space. The "ingredients" are routinely defined through the fundamental elasticity matrix and its first derivative, both taken at $v=v_R^{(0)}$ and referred to the surface.

I. INTRODUCTION

Inspecting the effect of surface curvature or continuous material inhomogeneity on the high-frequency Rayleigh wave is among the basic probing means in seismology. Theoretical analysis of this problem is commonly based on the well-established methods of the Wentzel–Kramers–Brillouin (WKB) expansion and ray theory.[1–4] A powerful though arduous technique has been developed for deriving the amplitude of Rayleigh wave in a three-dimensional inhomogeneous half-space with an arbitrary shape of the boundary.[5,6] A simpler case of a planar boundary and one-dimensional (1D) vertical inhomogeneity is often encountered in nondestructive testing of solids with a pronounced near-surface variation of material properties into the depth. In this case, the high-frequency dispersion of the velocity of Rayleigh wave is to the leading order inversely proportional to frequency, which is notably slower than an exponential falloff of the Rayleigh-velocity dispersion in materials with a buried continuous inhomogeneity or with a piecewise homogeneous (multilayered) structure. This feature may therefore be used for detecting and investigating a continuous inhomogeneity developing under the surface, see Refs. 7–9 and the bibliographies therein.

A simple model describing the case of 1D vertical inhomogeneity is as follows. Given is a half-space $y\geqslant 0$ with real nondispersive density $\rho(y)$ and elasticity coefficients $c_{ijkl}(y)$, which depend only on y and have nonzero first derivative in y at the traction-free planar surface $y=0$. Appealing to the Berry phase simplified for the case of 1D inhomogeneity in hand (Refs. 5 and 6), or directly using the WKB expansion of surface traction in powers of inverse frequency ω (Ref. 10) readily shows that the leading-order dispersion of the Rayleigh velocity at high ω is of the form

$$v_R(\omega)\approx v_R^{(0)}\left(1+\frac{B}{\omega}\right), \tag{1}$$

where B is real, $v_R^{(0)}$ is the Rayleigh velocity in a "reference" homogeneous half-space with constant ρ and c_{ijkl} equal to the surface values $\rho(0)$ and $c_{ijkl}(0)$ in the actual inhomogeneous material. The dependence (1) describes either a continuous high-frequency extent of the lowest curve of the dispersion spectrum if the half-space has no bulk-wave channels slower than $v_R^{(0)}$, or a sequence of exponentially close segments of successive branches if otherwise.[10] The high-frequency dispersion coefficient B for isotropic materials has been derived in Ref. 10, and the result may be written as follows:

$$B=v_R^{(0)}\frac{b_1}{b_2}:\quad b_1=(q_L+q_T)\left[\frac{4(\rho c_T^2)'}{\rho v_R^{(0)2}}-\frac{\rho'}{\rho}\right]+\frac{(1-q_T^2)q_L}{2-q_T^2}\frac{c_T'}{c_T}+\frac{(1-q_L^2)q_T}{2-q_L^2}\frac{c_L'}{c_L}-\frac{2(1+q_T^2)}{q_L+q_T}\times\left[\frac{(\rho c_T^2)'}{\rho c_T^2}\left(1+\frac{(1+q_T^2)(3+q_T^2)}{2(1-q_T^2)}\right)-\frac{\rho'}{\rho}\right],$$

$$b_2=2(1-q_T^2)\left(\frac{q_L}{q_T}+\frac{q_T}{q_L}\frac{c_T^2}{c_L^2}-1-q_T^2\right), \tag{2}$$

where $q_{L,T}=\sqrt{1-v^2/c_{L,T}^2}$, $c_L^2=c_{11}/\rho$, $c_T^2=c_{44}/\rho$, and the prime denotes a derivative with respect to y at $y=0$. Equation (2) has been used in Ref. 7 (with a notation $v_R^{(\infty)}$ in place of $v_R^{(0)}$) for comparing the leading-order asymptotics (1) with an exact dispersion curve computed numerically for a given profile of vertical inhomogeneity. A good accuracy of approximation has been observed in a rather broad high-frequency range.

An explicit form (2) of the coefficient B given in Ref. 10 for isotropic materials is fairly lengthy, and explicit expressions of Ref. 5 for an anisotropic body are further unwieldy

even when these are reduced to the case of 1D inhomogeneity. The motivation of this letter is to present a closed-form solution for the high-frequency dispersion of Rayleigh velocity in a vertically inhomogeneous half-space of unrestricted anisotropy. The result amounts to a ratio of Hermitian forms of two 3×3 matrices of surface traction perturbations in v and ω^{-1} contracted with a vector of partial amplitudes of the Rayleigh wave in the "reference" homogeneous half-space.

II. BACKGROUND

The wave-propagation problem for a vertically inhomogeneous half-space $y\geqslant0$ maintaining zero traction $\sigma_{iy}=0$ at the surface $y=0$ with a normal $\mathbf{n}$ is considered in the transform domain $(\mathbf{k}_\parallel,y,\omega)$, where $\mathbf{k}_\parallel=k\mathbf{m}$ is orthogonal $\mathbf{n}$. The factor $e^{i(k\mathbf{m}\cdot\mathbf{r}-\omega t)}$ is suppressed hereafter. The governing equation of motion may be written as the first-order ordinary differential system of six equations

$$\left[\mathbf{Q}(y)-\frac{d}{dy}\right]\boldsymbol{\eta}(y)=\mathbf{0}, \tag{3}$$

where the state vector $\boldsymbol{\eta}(y)$ is a column of scalar multiples of displacement and traction vectors. An optional explicit form of the 6×6 matrix of system coefficients $\mathbf{Q}(y)$ can always be arranged so that

$$[\mathbf{TQ}(y)]^T=\mathbf{TQ}(y), \tag{4a}$$

$$\mathbf{Q}(y)=-\mathbf{Q}^*(y), \tag{4b}$$

where the superscript T and the asterisk mean transpose and complex conjugated, and $\mathbf{T}$ is a matrix with zero diagonal and identity off-diagonal 3×3 blocks. The system matrix $\mathbf{Q}(y)$ is composed of material coefficients $\rho(y)$, $c_{ijkl}(y)$ and also involves any two of dispersion parameters ω, k and $v=\omega/k$ (see Sec. III). At the same time, the eigenvectors $\boldsymbol{\xi}_\alpha(y)$ and eigenvalues $q_\alpha(y)$ of $\mathbf{Q}(y)$ are nondispersive in the sense that it is always possible to define $\boldsymbol{\xi}_\alpha(y)$ and $q_\alpha(y)$ for any fixed y as a function of v and as ω or k times function of v, respectively. For example, bearing in mind Eq. (4b), the eigenvalues of $\mathbf{Q}(y)$ can be introduced as $ikp_\alpha(y,v)$. Let $\hat{v}(y)$ be the threshold velocity, below which all $p_\alpha(y,v)$ at a given y are complex.

Denote the eigenspectrum of, specifically, $\mathbf{Q}(0)$ at the surface $y=0$ as follows:

$$[\mathbf{Q}(0)-ikp_\alpha\mathbf{I}]\boldsymbol{\xi}_\alpha=\mathbf{0},\quad \boldsymbol{\xi}_\alpha=(\mathbf{u}_\alpha\,\mathbf{f}_\alpha)^T,\quad \alpha=1,\ldots,6, \tag{5}$$

with p_α and $\boldsymbol{\xi}_\alpha$ understood as taken at $y=0$. Hence $\mathbf{u}_\alpha e^{ikp_\alpha y}$ and $\mathbf{f}_\alpha e^{ikp_\alpha y}$ are scalar multiples of displacements and tractions of partial modes in the reference homogeneous half-space [the one with constant $\rho=\rho(0)$ and $c_{ijkl}=c_{ijkl}(0)$]. Adopting the normalization $\boldsymbol{\xi}_\alpha\cdot\mathbf{T}\boldsymbol{\xi}_\alpha=1$ ensures that $\boldsymbol{\xi}_\alpha=\boldsymbol{\xi}_\alpha(v)$. Introduce the 6×6 matrix $\boldsymbol{\Xi}=\boldsymbol{\Xi}(v)$ whose columns are $\boldsymbol{\xi}_\alpha$. Note the identity

$$\boldsymbol{\Xi}^T\mathbf{T}=\boldsymbol{\Xi}^{-1}, \tag{6}$$

following from Eq. (4a) and incorporating the above-presented normalization. Assume hereafter that $v<\hat{v}(0)$, whence $p_\alpha(v)$ are complex and therefore complex conjugated. Let $\mathrm{Im}\,p_a(v)>0$ for $a=1,2,3$. Hence

$$\boldsymbol{\Xi}(v)=\begin{pmatrix}\hat{\mathbf{u}}(v) & \hat{\mathbf{u}}^*(v)\\ \hat{\mathbf{f}}(v) & \hat{\mathbf{f}}^*(v)\end{pmatrix}, \tag{7}$$

where the 3×3 matrices $\hat{\mathbf{u}}=\|u_{ia}\|$ and $\hat{\mathbf{f}}=\|f_{ia}\|$ involve displacements and tractions of the three partial modes $a=1,2,3$ decreasing into the depth of the reference homogeneous half-space. Denote the Rayleigh velocity in this homogeneous half-space by $v_R^{(0)}$ [see Eq. (1)] and introduce the abbreviated notations

$$\mathbf{u}_{0a}=\mathbf{u}_a(v_R^{(0)}),\quad \hat{\mathbf{u}}_0=\hat{\mathbf{u}}(v_R^{(0)}),\quad \mathbf{f}_{0a}=\mathbf{f}_a(v_R^{(0)}),$$

$$\hat{\mathbf{f}}_0=\hat{\mathbf{f}}(v_R^{(0)}). \tag{8}$$

The boundary condition $\sigma_{iy}=0$ at the surface $y=0$ implies that

$$\hat{\mathbf{f}}_0\mathbf{C}_0=0\Rightarrow\det\hat{\mathbf{f}}_0=0, \tag{9}$$

where $\mathbf{C}_0=(C_{01},C_{02},C_{03})^T$ is a vector of amplitudes of partial modes defined up to a constant scalar A. Denote the Rayleigh-wave displacement at $y=0$ in the reference homogeneous half-space by $\mathbf{u}_{0R}=\hat{\mathbf{u}}_0\mathbf{C}_0(=\Sigma_{a=1}^3C_{0a}\mathbf{u}_{0a})$. By virtue of Eqs. (6) and (9),

$$\mathbf{u}_{0R}^T\hat{\mathbf{f}}_0^*=\mathbf{0}, \tag{10a}$$

$$\hat{\mathbf{f}}_0^T\mathbf{u}_{0R}=\mathbf{C}_0. \tag{10b}$$

Hence $\mathbf{u}_{0R}=A(\mathbf{f}_{0a}^*\times\mathbf{f}_{0b}^*)$ and

$$\mathbf{C}_0=A([\mathbf{f}_{0a}^*\mathbf{f}_{0b}^*\mathbf{f}_{01}],[\mathbf{f}_{0a}^*\mathbf{f}_{0b}^*\mathbf{f}_{02}],[\mathbf{f}_{0a}^*\mathbf{f}_{0b}^*\mathbf{f}_{03}])^T, \tag{11a}$$

$$\mathbf{C}_0\cdot\mathbf{C}_0=0, \tag{11b}$$

where $[\cdot]$ is a mixed product and $a\neq b$ are any two of three modal numbers 1,2,3, unless the sagittal plane spanned by the vectors $\mathbf{m}$ and $\mathbf{n}$ is a symmetry plane. If it is, so that the Rayleigh wave is polarized in the sagittal plane $(\mathbf{m},\mathbf{n})$ and consists in the reference homogeneous half-space of two partial modes, say $a=1,2$, then $\mathbf{f}_{01}\|\mathbf{f}_{02}$, $\mathbf{u}_{0R}=A(\mathbf{f}_{01}^*\times\mathbf{f}_{03}^*)$, and, by Eq. (11b), $\mathbf{C}_0=A(1,\pm i)^T$, where $\pm$ is associated with an optional sign of a normalization constant supplied for each eigenvector in Eq. (5) by the condition $\boldsymbol{\xi}_\alpha\cdot\mathbf{T}\boldsymbol{\xi}_\alpha=1$.

Fundamentals of the surface-wave theory for homogeneous anisotropic solids are encompassed and referenced in Refs. 11 and 12. Details of the outlined state-vector formalism in vertically inhomogeneous materials may be found in Ref. 13.

III. THE COEFFICIENT OF HIGH-FREQUENCY DISPERSION

Let us proceed from specifying the high-frequency assumption. It is supposed to enable the WKB expansion and its truncation at the first-order term, also to free the consideration from possible turning points, and to allow a half-space model which discards a lower boundary. Denote by δ_1 and δ_2 typical values of, respectively, the first and second derivatives in y of $\rho(y)/\rho(0)$ and $c_{ijkl}(y)/c_{ijkl}(0)$ taken at $y=0$. Let $[0,y_c]$ be the depth range, within which there is no turning points and no abrupt boundaries with a jump of ma-

terial properties. The former implies that $v_R^{(0)} < \hat{v}(y)$ and hence that the eigenvalues $ikp(y,v)$ of $\mathbf{Q}(y)$ satisfy $\mathrm{Im}\, p_a(y, v_R^{(0)}) > 0$ $(a=1,2,3)$ for $y \leq y_c$. In these terms, we assume in the following that

$$\exp\left(-2\frac{\omega}{v_R^{(0)}}\int_0^{y_c} \mathrm{Im}\, p_a(y, v_R^{(0)})dy\right) \ll v_R^{(0)}\frac{\delta_1}{\omega} \ll v_R^{(0)2} \times \frac{\delta_2}{\omega^2} \ll 1. \tag{12}$$

Neglecting small exponential terms due to Eq. (12), the dispersion equation for the Rayleigh velocity in an inhomogeneous material at high frequency is

$$\det \hat{\mathbf{F}}(v,\omega) = 0, \tag{13}$$

where the columns of the 3×3 matrix $\hat{\mathbf{F}}(v,\omega)$ are the WKB expansions of "traction parts" of three partial solutions $\boldsymbol{\eta}_a(y)$ of Eq. (3) taken at $y=0$ and assuredly decreasing into the depth for $y \leqslant y_c$.

Seeking the solution of Eq. (13) in the form (1), we insert

$$\hat{\mathbf{F}}(v,\omega) = \hat{\mathbf{f}}(v) + \hat{\delta\mathbf{f}}(v_R^{(0)},\omega), \quad \hat{\mathbf{f}}(v) = \hat{\mathbf{f}}_0 + (d\hat{\mathbf{f}}/dv)_{v_R^{(0)}}\Delta v,$$

$$\hat{\delta\mathbf{f}}(v_R^{(0)},\omega) = \frac{1}{i\omega}(\hat{\mathbf{f}}_0\tilde{\mathbf{W}} + \hat{\mathbf{f}}_0^*\hat{\mathbf{W}}),$$

$$(d\hat{\mathbf{f}}/dv)_{v_R^{(0)}} = \frac{i}{v_R^{(0)}}(\hat{\mathbf{f}}_0\tilde{\mathbf{S}} + \hat{\mathbf{f}}_0^*\hat{\mathbf{S}}), \tag{14}$$

where the first-order WKB correction is introduced in its common form keeping i in $\hat{\delta\mathbf{f}} \sim (i\omega)^{-1}$, and the constant factor in the definition of $d\hat{\mathbf{f}}/dv$ is adjusted for convenience. Linearizing Eq. (13) in small $\Delta v = v - v_R^{(0)}$ and ω^{-1} leads us to the (approximate) equality

$$\frac{\Delta v}{v_R^{(0)}}\,\mathrm{trace}(\hat{\bar{\mathbf{f}}}_0\hat{\mathbf{f}}_0^*\hat{\mathbf{S}}) = \frac{1}{\omega}\,\mathrm{trace}(\hat{\bar{\mathbf{f}}}_0\hat{\mathbf{f}}_0^*\hat{\mathbf{W}}), \tag{15}$$

where $\hat{\mathbf{S}}$ and $\hat{\mathbf{W}}$ are Hermitian: $\hat{\mathbf{S}}=\hat{\mathbf{S}}^+$ and $\hat{\mathbf{W}}=\hat{\mathbf{W}}^+$ (see the following).

Next we note that the adjugate matrix $\hat{\bar{\mathbf{f}}}_0$ corresponds to $\hat{\mathbf{f}}_0$ with $\det \hat{\mathbf{f}}_0 = 0$ [see Eq. (9)], so that $\hat{\bar{\mathbf{f}}}_0\hat{\mathbf{f}}_0 = \hat{\mathbf{f}}_0\hat{\bar{\mathbf{f}}}_0 = \mathbf{I}\det\hat{\mathbf{f}}_0 = 0$ and therefore $\hat{\bar{\mathbf{f}}}_0$ is a dyadic product $\otimes$ of two vectors. The left vector is equal (up to an arbitrary factor A) to $\mathbf{C}_0$ according to the first half of Eq. (9), while the right vector is equal to $\mathbf{u}_R^*$ according to Eq. (10a). Hence, with reference to Eq. (10b),

$$\hat{\bar{\mathbf{f}}}_0\hat{\mathbf{f}}_0^* = (\mathbf{C}_0 \otimes \mathbf{u}_{0R}^*)\hat{\mathbf{f}}_0^* = \mathbf{C}_0(\mathbf{u}_{0R}^{*T}\hat{\mathbf{f}}_0^*) = \mathbf{C}_0\mathbf{C}_0^{*T}. \tag{16}$$

Plugging Eq. (16) into Eq. (15) yields Eq. (1) with the sought dispersion coefficient B in the form

$$B = \frac{\mathbf{C}_0^* \cdot \hat{\mathbf{W}}\mathbf{C}_0}{\mathbf{C}_0^* \cdot \hat{\mathbf{S}}\mathbf{C}_0} = \frac{\sum_{a=1}^3 W_{aa}|C_a|^2 + 2\,\mathrm{Re}\sum_{a,b=1;a>b}^3 W_{ab}C_a^*C_b}{\sum_{a=1}^3 S_{aa}|C_a|^2 + 2\,\mathrm{Re}\sum_{a,b=1;a>b}^3 S_{ab}C_a^*C_b}. \tag{17}$$

If the sagittal plane $(\mathbf{m},\mathbf{n})$ is a symmetry plane, then Eq. (17), with $a,b=1,2$ corresponding to the in-plane polarized modes, reduces to

$$B = \frac{W_{11} + W_{22} \mp 2\,\mathrm{Im}\, W_{12}}{S_{11} + S_{22} \mp 2\,\mathrm{Im}\, S_{12}}, \tag{18}$$

where the optional sign is inverse to that in $\mathbf{C}_0 \| (1, \pm i)^T$ [see the comment following Eq. (11)].

Let us now define an explicit form of the matrix $\hat{\mathbf{S}}$ of traction derivatives in v and the matrix $\hat{\mathbf{W}}$ of WKB coefficients, which are introduced in Eq. (14) and which appear in the resulting expressions (17) and (18). To do so, we need to specify an optional definition of the system matrix $\mathbf{Q}(y)$ of Eq. (3). The two most convenient and broadly used definitions, which enable a factorization of $\mathbf{Q}(y)$ with respect to one of the dispersion parameters, are the Stroh formulation $\mathbf{Q}(y,k,v) = ik\mathbf{N}_S(y,v)$ and the Thomson–Haskell formulation $\mathbf{Q}(y,\omega,v) = i\omega\mathbf{N}_{TH}(y,v)$, where

$$\mathbf{N}_S = \begin{pmatrix} \mathbf{N}_1 & \mathbf{N}_2 \\ \mathbf{N}_3 - \rho v^2\mathbf{I}_{(3)} & \mathbf{N}_1^{\mathrm{T}} \end{pmatrix},$$

$$\mathbf{N}_{TH} = \begin{pmatrix} s\mathbf{N}_1 & -\mathbf{N}_2 \\ -v^{-2}\mathbf{N}_3 + \rho\mathbf{I}_{(3)} & s\mathbf{N}_1^T \end{pmatrix},$$

$$\mathbf{N}_1 = -(nn)^{-1}(nm), \quad \mathbf{N}_2 = -(nn)^{-1},$$

$$\mathbf{N}_3 = (mm) - (mn)(nn)^{-1}(nm), \tag{19}$$

with $(ab) \equiv a_i c_{ijkl} b_l$ for $\mathbf{a},\mathbf{b}=\mathbf{m}$ or $\mathbf{n}$ (see Refs. 11–13 for the details). The matrix $\mathbf{N}$ is often called the fundamental elasticity matrix. Note that $\mathbf{N}_S \neq v\mathbf{N}_{TH}$, i.e., its two above formulations imply different (up to scalar factors) definitions of the state vector $\boldsymbol{\eta}$ in Eq. (3) and of the eigenvector $\boldsymbol{\xi}$ in Eq. (5). The eigenvalue problem (5) for the fundamental elasticity matrix taken at $v = v_R^{(0)}$ may be specialized correspondingly as

$$\left[\mathbf{N}_S(0, v_R^{(0)}) - p_{0\alpha}\mathbf{I}\right]\boldsymbol{\xi}_{0\alpha}^{(S)} = \mathbf{0}$$

or

$$\left[\mathbf{N}_{TH}(0, v_R^{(0)}) - \frac{p_{0\alpha}}{v_R^{(0)}}\mathbf{I}\right]\boldsymbol{\xi}_{0\alpha}^{(TH)} = \mathbf{0}, \tag{20}$$

where the both sets of eigenvectors $\boldsymbol{\xi}_{0\alpha} = (\mathbf{u}_{0\alpha}\,\mathbf{f}_{0\alpha})^T$ are normalized by the same condition $\boldsymbol{\xi}_{0\alpha} \cdot \mathbf{T}\boldsymbol{\xi}_{0\alpha} (= 2\mathbf{u}_{0\alpha} \cdot \mathbf{f}_{0\alpha}) = 1$, which renders the physical dimensions $1/\rho^{1/2}v$ and $\rho^{1/2}v$ to $\mathbf{u}_{0\alpha}^{(S)}$ and $\mathbf{f}_{0\alpha}^{(S)}$, and $1/(\rho v)^{1/2}$ and $(\rho v)^{1/2}$ to $\mathbf{u}_{0\alpha}^{(TH)}$ and $\mathbf{f}_{0\alpha}^{(TH)}$. In these terms, the components of matrices $\hat{\mathbf{S}}$ and $\hat{\mathbf{W}}$ are as follows:

$$S_{ab} = 2i\rho(0)v_R^{(0)2}\frac{\mathbf{u}_{0a}^{(S)*}\cdot\mathbf{u}_{0b}^{(S)}}{p_{0a}^{*}-p_{0b}} = 2i\rho(0)v_R^{(0)}\frac{\mathbf{u}_{0a}^{(TH)*}\cdot\mathbf{u}_{0b}^{(TH)}}{p_{0a}^{*}-p_{0b}}$$

$$= S_{ba}^{*},$$

$$W_{ab} = -v_R^{(0)}\frac{\boldsymbol{\xi}_{0a}^{(S)*}\cdot\mathbf{T}\left[\frac{d}{dy}\mathbf{N}_S(y,v_R^{(0)})\right]_{y=0}\boldsymbol{\xi}_{0b}^{(S)}}{(p_{0a}^{*}-p_{0b})^2} =$$

$$-\frac{\boldsymbol{\xi}_{0a}^{(TH)*}\cdot\mathbf{T}\left[\frac{d}{dy}\mathbf{N}_{TH}(y,v_R^{(0)})\right]_{y=0}\boldsymbol{\xi}_{0b}^{(TH)}}{(p_{0a}^{*}-p_{0b})^2} = W_{ba}^{*}, \quad (21)$$

where $a,b=1,2,3$ ($\mathrm{Im}\, p_{0a}>0$), and S_{ab} are physically dimensionless while W_{ab} are of dimension of frequency as they ought to be.

IV. SUMMARY

The high-frequency dispersion coefficient B in Eq. (1) is given by Eq. (17) or (18) as a ratio of Hermitian forms of the matrix $\hat{\mathbf{S}}$ of surface traction derivatives in v and of the matrix $\hat{\mathbf{W}}$ of the WKB coefficients incorporating the impact of inhomogeneity of material properties $\rho(y)$, $c_{ijkl}(y)$ via their first-order derivative taken with respect to y at the surface $y=0$. In the case of general anisotropy [Eq. (17)], these matrices are contracted with the vector $\mathbf{C}_0$ of partial amplitudes of the Rayleigh wave in the reference homogeneous half-space with constant $\rho=\rho(0)$ and $c_{ijkl}=c_{ijkl}(0)$. This result makes an evident physical sense linking the modal structure of the "zero-order" Rayleigh wave to the dispersive effect of inhomogeneity. The values of $\hat{\mathbf{S}}$, $\hat{\mathbf{W}}$, and $\mathbf{C}_0$ are defined by Eqs. (21) and (11) through the solutions p_{0a}, ξ_{0a} of the eigenvalue problem (20) for the fundamental elasticity matrix (19) taken at $v=v_R^{(0)}$ and $y=0$, and through its first derivative also taken at $y=0$.

A coupled pair of nonlinear parabolic equations is derived for the two components of the particle motion perpendicular to the axis of a shear wave beam in an isotropic elastic medium. The equations account for both quadratic and cubic nonlinearity. The present paper investigates, analytically and numerically, effects of cubic nonlinearity in shear wave beams for several polarizations: linear, elliptical, circular, and azimuthal. Comparisons are made with effects of quadratic nonlinearity in compressional wave beams. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2890739]

I. INTRODUCTION

The distinguishing feature of nonlinearity in shear waves is that it is primarily cubic rather than quadratic. A derivation of the nonlinear parabolic wave equation for shear wave beams in isotropic solids appeared in 1986.[1] Explicit expressions in terms of elastic moduli were presented for the coefficients of both the quadratic and cubic terms. The equation was solved by perturbation to demonstrate that while wavefront curvature introduces quadratic nonlinearity, it does not permit second harmonic generation directly by the fundamental. Rather, it was shown that the second harmonic is produced by interaction of the fundamental with the third harmonic generated by cubic nonlinearity.

A number of papers followed on wave propagation with cubic nonlinearity in nondispersive media. The 1987 paper by Lee-Bapty and Crighton[2] on plane waves develops a weak shock theory describing the discontinuities that form at both positive and negative gradients in the waveform. In the 1990s began a series of papers by Rudenko and co-workers on diffraction, self-focusing, and other effects in beams with cubic nonlinearity. For discussion of this body of work the reader is referred to two papers by Rudenko and Sapozhnikov[3,4] and the papers cited therein. The forms of the model equations used in these previous investigations restrict their application to nonlinear shear waves with linear polarization. A main purpose of the present investigation is to consider other types of polarization.

Our interest in nonlinear shear waves was motivated by experiments reported by Catheline *et al.*[5] that demonstrate clearly the harmonic generation and shock formation manifested by plane nonlinear shear waves propagating in soft tissue phantoms. The propagation speed of shear waves in soft tissue is extremely low, on the order of a few meters per second, making it relatively easy to generate disturbances with large acoustic Mach numbers. Catheline *et al.* reported a peak acoustic Mach number of 0.38, which is well in excess of acoustic Mach numbers ordinarily encountered with compressional waves. The close agreement they showed between measured waveforms containing shocks and numerical simulations based on a generalized Burgers equation confirmed that the nonlinearity was predominantly cubic.

The same group also reported measurements of elastic constants for soft tissue phantoms.[6] The enormous differences in the values of these constants for a given medium motivated development of a new expansion of the strain energy density in which the effects of shear deformation, which are associated with the small elastic constants, are separated from the effects of compressibility, which are associated with the large constants. The result is a much simplified expression for the strain energy density in nonlinear shear waves.[7] This new expansion was used to derive evolution equations for plane nonlinear shear waves in soft tissue-like media.[8]

In the present paper, the plane wave model[8] is extended to account for diffraction in nonlinear shear wave beams in arbitrary isotropic elastic media. Both components of the particle motion perpendicular to the beam axis are included to account for different polarizations of the beam, and not exclusively the linear polarization that is usually considered. A coupled pair of nonlinear parabolic wave equations is obtained that includes both quadratic and cubic nonlinearity. The present paper investigates, analytically and numerically, the effects of cubic nonlinearity in shear wave beams. Investigation of the quadratic nonlinearity is the subject of a future paper.

Selected results in the present paper have appeared previously in a conference proceedings.[9]

II. BASIC EQUATIONS

The general equation of motion in an elastic medium is[10]

$$\rho \frac{\partial^2 u_i}{\partial t^2} = \frac{\partial \sigma_{ik}}{\partial x_k}, \tag{1}$$

where ρ is the density of the material in its undeformed state, u_i are components of the particle displacement vector, and σ_{ik} is the stress tensor defined by

[a]Electronic mail: hamilton@mail.utexas.edu

 0001-4966/2008/123(5)/2488/8/$23.00 © 2008 Acoustical Society of America

$$\sigma_{ik} = \frac{\partial \mathcal{E}}{\partial(\partial u_i/\partial x_k)}. \tag{2}$$

The strain energy density $\mathcal{E}$ for an isotropic elastic medium may be expanded as follows:[1,7,10]

$$\mathcal{E} = \mu I_2 + \left(\tfrac{1}{2}K - \tfrac{1}{3}\mu\right)I_1^2 + \tfrac{1}{3}AI_3 + BI_1I_2 + \tfrac{1}{3}CI_1^3 + EI_1I_3 + FI_1^2I_2 + GI_2^2 + HI_1^4, \tag{3}$$

where the invariants

$$I_1 = \mathrm{tr}\,\mathbf{u} = u_{ii}, \quad I_2 = \mathrm{tr}\,\mathbf{u}^2 = u_{ik}u_{ki}, \quad I_3 = \mathrm{tr}\,\mathbf{u}^3 = u_{ik}u_{kl}u_{li}, \tag{4}$$

are defined in terms of the Lagrangian strain tensor

$$u_{ik} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i} + \frac{\partial u_l}{\partial x_i}\frac{\partial u_l}{\partial x_k}\right). \tag{5}$$

Here μ and K are the shear and bulk moduli, respectively; A, B, and C are the third-order elastic constants of Landau and Lifshitz;[10] E, F, G, and H are the fourth-order elastic constants introduced by Zabolotskaya[1] (but without the coefficient D in Zabolotskaya's expansion which, as explained elsewhere,[7] is not required).

To develop equations that describe the propagation of shear waves, the first step is to express the right-hand side of Eq. (1) explicitly in terms of particle displacement, retaining all terms through cubic order. The quadratic terms are given by Gol'dberg.[11] The expression for the cubic terms is rather long and therefore not presented here.

Next, we consider a shear wave beam that propagates in the x_3 direction and introduce the retarded time $\tau = t - x_3/c$, where $c = (\mu/\rho)^{1/2}$ is the small-signal wave speed. As usual, a reduced wave equation is sought by introducing a slow scale corresponding to the moving coordinate system. The following ordering scheme is employed, in which ϵ characterizes the amplitude of the particle displacement transverse to the beam axis:

$$u_1 = \epsilon U_1(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3, \tau), \quad u_2 = \epsilon U_2(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3, \tau), \quad u_3 = \epsilon^2 U_3(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3, \tau), \tag{6}$$

where $\tilde{x}_1 = \epsilon x_1, \tilde{x}_2 = \epsilon x_2$, and $\tilde{x}_3 = \epsilon^2 x_3$ are the slow-scale coordinates.

After substitution in Eq. (1) one obtains at leading (cubic) order in ϵ, for $i=1$,

$$\begin{aligned}\frac{2\mu}{c}\frac{\partial^2 U_1}{\partial \tilde{x}_3\,\partial\tau} &= \mu\left(\frac{\partial^2 U_1}{\partial \tilde{x}_1^2} + \frac{\partial^2 U_1}{\partial \tilde{x}_2^2}\right) + \left(K + \frac{\mu}{3}\right)\frac{\partial S}{\partial \tilde{x}_1} \\ &+ \frac{1}{c^2}\left(\mu + \frac{A}{4}\right)\left(\frac{\partial^2 U_m}{\partial\tau^2}\frac{\partial U_m}{\partial \tilde{x}_1} - \frac{1}{c}\frac{\partial^2 U_3}{\partial\tau^2}\frac{\partial U_1}{\partial\tau} + \frac{\partial^2 U_m}{\partial\tau^2}\frac{\partial U_1}{\partial \tilde{x}_m} - \frac{2}{c}\frac{\partial^2 U_1}{\partial\tau^2}\frac{\partial U_3}{\partial\tau} + 2\frac{\partial^2 U_1}{\partial \tilde{x}_m\,\partial\tau}\frac{\partial U_m}{\partial\tau}\right) \\ &+ \frac{1}{c^2}\left(K + \frac{\mu}{3} + \frac{A}{4} + B\right)\left(\frac{\partial^2 U_m}{\partial \tilde{x}_1\,\partial\tau}\frac{\partial U_m}{\partial\tau} + \frac{\partial S}{\partial\tau}\frac{\partial U_1}{\partial\tau}\right) + \frac{1}{c^2}\left(K - \frac{2\mu}{3} + B\right)S\frac{\partial^2 U_1}{\partial\tau^2} \\ &+ \frac{1}{c^4}\left(\frac{2\mu}{3} + \frac{K}{2} + \frac{A}{2} + B + G\right) \times \frac{\partial}{\partial\tau}\left\{\frac{\partial U_1}{\partial\tau}\left[\left(\frac{\partial U_1}{\partial\tau}\right)^2 + \left(\frac{\partial U_2}{\partial\tau}\right)^2\right]\right\},\end{aligned} \tag{7}$$

where $m=1,2$ is a summation index over components in the plane perpendicular to the x_3 axis, and

$$S = \frac{\partial U_1}{\partial \tilde{x}_1} + \frac{\partial U_2}{\partial \tilde{x}_2} - \frac{1}{c}\frac{\partial U_3}{\partial\tau}. \tag{8}$$

At leading order one also obtains for the divergence $\boldsymbol{\nabla}\cdot\mathbf{u} = \partial u_l/\partial x_l = \epsilon^2 S$. The result for $i=2$ is obtained by reversing the subscripts 1 and 2 in Eq. (7). For $i=3$, the leading order is quadratic in ϵ and one obtains

$$S = -\frac{1}{2c^2}\left(K + \frac{\mu}{3}\right)^{-1}\left(K + \frac{4\mu}{3} + \frac{A}{2} + B\right) \times \left[\left(\frac{\partial U_1}{\partial\tau}\right)^2 + \left(\frac{\partial U_2}{\partial\tau}\right)^2\right]. \tag{9}$$

Substitution of Eq. (9) in Eq. (7) and in the corresponding equation for U_2 yields, after reinstating the original coordinates and particle displacements, and using (x,y,z) in place of (x_1,x_2,x_3),

$$\frac{\partial^2 u_x}{\partial z\,\partial\tau} = \frac{c}{2}\nabla_\perp^2 u_x + \frac{1}{2c}\left(1 + \frac{A}{4\mu}\right)Q_{xy} + \frac{\beta}{3c^3}\frac{\partial}{\partial\tau}\left\{\frac{\partial u_x}{\partial\tau}\left[\left(\frac{\partial u_x}{\partial\tau}\right)^2 + \left(\frac{\partial u_y}{\partial\tau}\right)^2\right]\right\}, \tag{10}$$

$$\frac{\partial^2 u_y}{\partial z\,\partial\tau} = \frac{c}{2}\nabla_\perp^2 u_y + \frac{1}{2c}\left(1 + \frac{A}{4\mu}\right)Q_{yx} + \frac{\beta}{3c^3}\frac{\partial}{\partial\tau}\left\{\frac{\partial u_y}{\partial\tau}\left[\left(\frac{\partial u_x}{\partial\tau}\right)^2 + \left(\frac{\partial u_y}{\partial\tau}\right)^2\right]\right\}, \tag{11}$$

where $\nabla_\perp^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the Laplacian in the plane perpendicular to the beam axis, all quadratic terms are contained in

$$Q_{xy} = \frac{\partial^2 u_y}{\partial\tau^2}\frac{\partial u_y}{\partial x} + \frac{\partial^2 u_y}{\partial\tau^2}\frac{\partial u_x}{\partial y} + 2\frac{\partial^2 u_x}{\partial y\,\partial\tau}\frac{\partial u_y}{\partial\tau} - \frac{\partial^2 u_y}{\partial y\,\partial\tau}\frac{\partial u_x}{\partial\tau} - 2\frac{\partial^2 u_x}{\partial\tau^2}\frac{\partial u_y}{\partial y} - \frac{\partial^2 u_y}{\partial x\,\partial\tau}\frac{\partial u_y}{\partial\tau}, \tag{12}$$

and the coefficient of nonlinearity for the cubic terms is

$$\beta = \frac{3}{4\mu}\left(K + \tfrac{4}{3}\mu + A + 2B + 2G\right) - \frac{3}{4\mu}\frac{\left(K + \frac{4}{3}\mu + \frac{1}{2}A + B\right)^2}{K + \frac{1}{3}\mu}. \tag{13}$$

Equations (10) and (11) differ only by the reversal of x and y.

In the absence of the second term in Eq. (13), Eqs. (10) and (11) agree with Eq. (14) of Zabolotskaya.[1] The second

term in Eq. (13) is associated with cubic nonlinearity arising from quadratic nonlinearity due to the fact that the right-hand side of Eq. (8), by virtue of Eq. (9), is quadratic at leading order when expressed in terms of only transverse particle displacements. The absence of this contribution to the cubic nonlinearity in Eq. (14) of Ref. 1 was noted by Enflo *et al.*[12] but their expression corresponding to the second term in Eq. (13) differs from ours.

The origin of the second term in Eq. (13) is not connected with diffraction and can be understood from Gol'dberg's[11] Eqs. (6) and (7) for plane waves. Gol'dberg defines a quadratic nonlinearity coefficient $\gamma=K+\frac{4}{3}\mu+\frac{1}{2}A+B$, the square of which appears in Eq. (13). The longitudinal wave generated by the quadratic nonlinearity of a shear wave is proportional to γ, and the shear wave generated by interaction of the longitudinal wave with the original shear wave introduces another factor of γ, resulting in the coefficient γ^2 associated with this third-order process. The corresponding term derived by Enflo *et al.*[12] contains only one factor of γ.

For soft elastic media characterized by $\mu \ll K$, the second term in Eq. (13) is negligible relative to the first. This can be shown by making use of the following relations between the elastic constants for such media:[7,13] $A=O(\mu)$, $B=-K+O(\mu)$, and $G=\frac{1}{2}K+O(\mu)$. Substitution in Eq. (13) reveals that the first term is $O(1)$ and second term is $O(\mu/K)$. For soft tissue, with μ/K of order 10^{-5} and possibly smaller, the second term in Eq. (13) is insignificant. In this case, the elastic energy density can be expressed in a reduced form that depends on only three elastic constants,[7]

$$\mathcal{E}=\mu I_2+\tfrac{1}{3}AI_3+DI_2^2, \tag{14}$$

rather than the nine in Eq. (3), and all three constants are of the same order. This reduced equation for the energy density leads to[8]

$$\beta=\frac{3}{2}\left(1+\frac{\frac{1}{2}A+D}{\mu}\right) \tag{15}$$

in place of Eq. (13).

Enflo *et al.*[12] present a result similar to Eq. (10) for a shear wave beam that is linearly polarized in the x direction, but without the quadratic terms, and without the corresponding equation for u_y. While Q_{xy} and Q_{yx} vanish for plane waves, they do not for beams. For a source that is linearly polarized in the x direction, u_y and therefore Q_{xy} are in fact zero in the source plane. However, in Eq. (11) the first and last terms in Q_{yx} depend only on u_x, giving rise to a nonzero value of u_y due to quadratic nonlinearity. Simply stated, quadratic nonlinearity prevents the existence of a pure linearly polarized shear wave beam.

Cubic nonlinearity can be more pronounced than quadratic nonlinearity due to the quasiplanar nature of wavefronts in directional sound beams. In the present paper we consider only the effects of cubic nonlinearity.

In the absence of quadratic nonlinearity, one may introduce the particle velocities $v_x=\partial u_x/\partial\tau$ and $v_y=\partial u_y/\partial\tau$ in Eqs. (10) and (11) to obtain, following integration with respect to τ, the coupled equations

$$\frac{\partial v_x}{\partial z}=\frac{\beta}{3c^3}\frac{\partial}{\partial\tau}[v_x(v_x^2+v_y^2)]+\frac{\eta}{2\rho c^3}\frac{\partial^2 v_x}{\partial\tau^2}+\frac{c}{2}\int_{-\infty}^{\tau}(\nabla_\perp^2 v_x)d\tau', \tag{16}$$

$$\frac{\partial v_y}{\partial z}=\frac{\beta}{3c^3}\frac{\partial}{\partial\tau}[v_y(v_x^2+v_y^2)]+\frac{\eta}{2\rho c^3}\frac{\partial^2 v_y}{\partial\tau^2}+\frac{c}{2}\int_{-\infty}^{\tau}(\nabla_\perp^2 v_y)d\tau', \tag{17}$$

where the terms accounting for the shear viscosity η are introduced as for plane waves.[8] Without the diffraction and absorption terms, Eqs. (16) and (17) are the same as Eqs. (53) and (54) in Ref. 8. When the source functions are axisymmetric and can be expressed as $v_{x0}(r,t)$ and $v_{y0}(r,t)$, where $r=(x^2+y^2)^{1/2}$, it is evident that the radiated sound beam is axisymmetric, in which case $\nabla_\perp^2=\partial^2/\partial r^2+r^{-1}(\partial/\partial r)$.

Comparisons will be made with nonlinear compressional wave beams, which are described by the KZK equation for the particle velocity component in the z direction:

$$\frac{\partial v_z}{\partial z}=\frac{\beta_l}{c_l^2}v_z\frac{\partial v_z}{\partial\tau}+\frac{\delta}{2c_l^3}\frac{\partial^2 v_z}{\partial\tau^2}+\frac{c_l}{2}\int_{-\infty}^{\tau}(\nabla_\perp^2 v_z)d\tau'. \tag{18}$$

The subscript l is used to identify parameters that are specific to compressional waves. Here, $\tau=t-z/c_l$ is the retarded time, $c_l=[(K+\frac{4}{3}\mu)/\rho]^{1/2}$ the small-signal compressional wave speed, δ is a diffusivity that accounts for sound absorption due to both shear and bulk viscosity, and also heat condition, and

$$\beta_l=-\frac{3}{2}-\frac{A+3B+C}{K+\frac{4}{3}\mu} \tag{19}$$

is the coefficient of nonlinearity. The coefficient of nonlinearity for a liquid is $\beta_l=1+B_l/2A_l$, where B_l/A_l is the parameter of nonlinearity for liquids that is obtained from the equation of state relating the pressure and density.

III. LINEAR POLARIZATION

For beams that are linearly polarized along the x axis, $v_y=0$ and Eq. (16) reduces to

$$\frac{\partial v_x}{\partial z}=\frac{\beta}{c^3}v_x^2\frac{\partial v_x}{\partial\tau}+\frac{\eta}{2\rho c^3}\frac{\partial^2 v_x}{\partial\tau^2}+\frac{c}{2}\int_{-\infty}^{\tau}(\nabla_\perp^2 v_x)d\tau'. \tag{20}$$

Without the diffraction term, Eq. (20) reduces to Eq. (37) in Ref. 8. Equation (20) is formally equivalent to Eq. (18) for compressional wave beams apart from the cubic rather than quadratic nonlinearity. The linearized forms of the two equations thus possess the same Green's function, which may be used to compare the corresponding solutions for harmonic generation.

We begin by assuming a source condition with time dependence $e^{i\omega t}$ and write $v_x=v_{x1}+v_{x3}$, where $|v_{x3}|\ll|v_{x1}|$ and

$$v_{xn}(r,z,\tau) = \mathrm{Re}[w_{xn}(r,z)e^{in\omega\tau}]$$
$$= \tfrac{1}{2}w_{xn}(r,z)e^{in\omega\tau} + \text{c.c.}, \quad n = 1,3. \tag{21}$$

The integral solutions of Eq. (20) for the first and third harmonic are thus (see, e.g., Ref. 14, Chap. 8)

$$w_{x1}(r,z) = 2\pi\int_0^\infty w_{x1}(r',0)g_1(r,z|r',0)r'dr', \tag{22}$$

$$w_{x3}(r,z) = \frac{i\pi\beta k}{2c^2}\int_0^z\int_0^\infty w_{x1}^3(r',z')g_3(r,z|r',z')r'dr'dz', \tag{23}$$

where $k=\omega/c$ and the Green's function is

$$g_n(r,z|r',z') = \frac{ink}{2\pi(z-z')}J_0\left(\frac{nkrr'}{z-z'}\right)$$
$$\times\exp\left[-n^2\alpha(z-z') - \frac{ink(r^2+r'^2)}{2(z-z')}\right], \tag{24}$$

and where $\alpha=\eta\omega^2/2\rho c^3$ is the absorption coefficient at the source frequency. For a source with Guassian amplitude shading described by $w_{x1}(r,0)=v_0\exp(-r^2/a^2)$ the integrals yield

$$w_{x1}(r,z) = \frac{v_0}{1-iz/z_0}\exp\left(-\alpha z - \frac{r^2/a^2}{1-iz/z_0}\right), \tag{25}$$

$$w_{x3}(r,z) = \frac{\beta v_0^3 k z_0}{4c^2(1-iz/z_0)^2}\exp\left(-9\alpha z - \frac{3r^2/a^2}{1-iz/z_0}\right.$$
$$\left.-i6\alpha z_0\right)\{E_2[-i6\alpha z_0(1-iz/z_0)]$$
$$-(1-iz/z_0)E_2[-i6\alpha z_0]\}, \tag{26}$$

where $z_0=ka^2/2$ is the Rayleigh distance, and $E_2(\xi)$ is the exponential integral defined by $E_m(\xi)=\int_1^\infty e^{-\xi t}t^{-m}dt$ with $m=2$. Equation (25) is the same as the solution for a compressional wave.

To facilitate comparison of Eq. (26) with the corresponding solution for second-harmonic generation in a compressional wave beam[14] we set $\alpha=0$ to obtain[1]

$$w_{x3}(r,z) = \frac{i\beta v_0^3 kz}{4c^2(1-iz/z_0)^2}\exp\left(-\frac{3r^2/a^2}{1-iz/z_0}\right). \tag{27}$$

The amplitude along the axis of the beam in the near field ($z\ll z_0$) increases in proportion to z, just like the second harmonic in a compressional wave. In the far field ($z\gg z_0$), however, Eq. (27) describes a z^{-1} decay rate, as for a spherical wave in the linear approximation. In contrast, the second harmonic in a compressional wave decays as $z^{-1}\ln z$ in the far field,[14] which is slower than spherical spreading due to the unending transfer of energy from the fundamental in a lossless medium. When absorption is negligible, all harmonics in the shear wave beam decay as z^{-1} in the far field, whereas all harmonics in the compressional wave beam decay more slowly than z^{-1}.

The decay rate of nonlinear shear waves in the far field can be explained by replacing the absorption and diffraction terms in Eq. (20) with a term that accounts only for spherical spreading:

$$\frac{\partial v_x}{\partial z} + \frac{v_x}{z} = \frac{\beta}{c^3}v_x^2\frac{\partial v_x}{\partial\tau}. \tag{28}$$

Given a waveform $v_x=f(\tau)$ prescribed at some distance $z=z_0$ in the spherical wave field, the implicit solution describing evolution of the waveform prior to shock formation may be written in the form

$$v_x(z,\tau) = \frac{z_0}{z}v(z,\tau), \quad \text{where} \quad v = f\left[\tau + \frac{\beta}{c^3}v^2 z_0\left(1-\frac{z_0}{z}\right)\right]. \tag{29}$$

At distances $z\gg z_0$ the waveform ceases to depend on z, which is to say that no further nonlinear distortion of the waveform takes place. The particle velocity waveform $v_x(z,\tau)$ thus ultimately decays as z^{-1} without further change in shape. This phenomenon is referred to as waveform freezing. Spherical spreading does not cause waveform freezing in compressional waves.

When absorption is taken into account the behavior of nonlinearly generated harmonics in the far field is quite different. The asymptotic forms of Eqs. (25) and (26) are

$$w_{x1}(\theta,z) \sim iv_0z_0\frac{e^{-\alpha z}}{z}D(\theta)\exp\left(-\tfrac{1}{2}ikz\tan^2\theta\right), \tag{30}$$

$$w_{x3}(\theta,z) \sim \frac{\beta v_0^3 k z_0^3}{24\alpha c^2}\frac{e^{-3\alpha z}}{z^3}D^3(\theta)\exp\left(-\tfrac{3}{2}ikz\tan^2\theta\right), \tag{31}$$

where

$$D(\theta) = \exp\left[-\tfrac{1}{4}(ka\tan\theta)^2\right] \tag{32}$$

is the directivity function for a Gaussian beam in the linear approximation, and θ is the angle with respect to the beam axis, defined by $\tan\theta=r/z$. The third harmonic is seen to be proportional to the cube of the fundamental.

Because of the quadratic dependence of the absorption coefficient on frequency, all higher harmonics in a linearly polarized beam follow the trend $w_{xn}(\theta,z)\propto w_{x1}^n(\theta,z)$ in the far field.[14] This absorption law also permits far-field solutions to be used in combination with geometrical acoustics to obtain asymptotic solutions for harmonics when an analytic solution for the primary wave radiated by a particular source may be available only in the far field. Such is the case for radiation by a circular disk of radius a, the source condition for which is $w_{x1}(r,0)=v_0H(a-r)$, where H is the Heaviside unit step function. The far-field solutions for the fundamental and third harmonic in this case are given again by Eqs. (30) and (31), respectively, but with

$$D(\theta) = \frac{2J_1(ka\tan\theta)}{ka\tan\theta}. \tag{33}$$

IV. ELLIPTICAL POLARIZATION

For elliptical polarization, the x and y components of the particle velocity are in phase quadrature, and one may write the source condition in the form

$$v_x(r,0,t) = v_0\,\mathrm{Re}[f(r)e^{i\omega t}], \quad v_y(r,0,t) = sv_0\,\mathrm{Im}[f(r)e^{i\omega t}], \tag{34}$$

where s varies from zero for linear polarization along the x axis to unity for circular polarization. For a Gaussian amplitude shaded source with $f(r)=\exp(-r^2/a^2)$ one obtains, in place of Eq. (27),

$$w_{x3}(r,z) = \frac{i(1-s^2)\beta v_0^3 kz}{4c^2(1-iz/z_0)^2}\exp\left(-\frac{3r^2/a^2}{1-iz/z_0}\right), \tag{35}$$

$$w_{y3}(r,z) = \frac{s(1-s^2)\beta v_0^3 kz}{4c^2(1-iz/z_0)^2}\exp\left(-\frac{3r^2/a^2}{1-iz/z_0}\right), \tag{36}$$

with $v_{x3}(r,z,\tau)=\mathrm{Re}[w_{x3}(r,z)e^{i3\omega\tau}]$ and $v_{y3}(r,z,\tau)=\mathrm{Im}[w_{y3}(r,z)e^{i3\omega\tau}]$. The two components differ only by the factor $-is$, as do the corresponding components at the source frequency. This same ratio is not maintained for the third and higher harmonics when higher-order nonlinear interactions are taken into account. Numerical solutions reveal that the main differences arise in the relative phases of the harmonics in the frequency spectra of v_x and v_y. For weak or moderate nonlinearity, the relative amplitudes remain nearly the same.

Note that the third harmonic vanishes for circular polarization, $s=1$, which is the case considered next.

V. CIRCULAR POLARIZATION

Given the absence of third-harmonic generation for circular polarization, we seek a monofrequency solution in the form

$$v_x(r,z,\tau) = \mathrm{Re}[w(r,z)e^{i\omega\tau}], \quad v_y(r,z,\tau) = \mathrm{Im}[w(r,z)e^{i\omega\tau}]. \tag{37}$$

Since

$$v_x^2(r,z,\tau) + v_y^2(r,z,\tau) = |w(r,z)|^2, \tag{38}$$

the quantity $v_x^2+v_y^2$ is independent of time and may be removed from under the time derivatives in Eqs. (16) and (17). For a circularly polarized plane wave in a lossless medium, where $w=\mathrm{const}\equiv v_0$, the wave propagates as a small signal and the only effect of nonlinearity is to change the propagation speed from c to $(1+\beta v_0^2/3c^2)c$.[8] The amplitude w is not constant in a diffracting beam, and in particular it varies across the beam. Different parts of the beam thus propagate at different phase speeds according to the square of the local acoustic Mach number and the sign of the nonlinearity coefficient. Self-defocusing occurs for $\beta>0$ because the beam propagates faster along its axis than off axis. Conversely, self-focusing occurs for $\beta<0$.

The evolution equation for w is obtained by substituting Eq. (37) into either Eq. (16) or Eq. (17) to obtain

$$i\left(\frac{\partial w}{\partial z}+\alpha w\right) - \frac{1}{2k}\nabla_\perp^2 w + \frac{\beta k}{3c^2}|w|^2 w = 0, \tag{39}$$

which is a damped nonlinear Schrödinger equation. In the absence of damping it is the classical model equation for self-focusing of linearly polarized optical beams, and it has also been analyzed in connection with circularly polarized optical beams.[15] For a circularly polarized shear wave beam that is radiated by a Gaussian source into a lossless medium, wavefront curvature due to self-action in the near field becomes comparable with wavefront curvature due to diffraction for v_0/c of order $|\beta|^{-1/2}(ka)^{-1}$.

The main point to be made is that cubic nonlinearity in circularly polarized shear wave beams produces no harmonic generation and therefore no waveform distortion. Its only effect is to cause self-focusing or self-defocusing depending on the sign of β.

VI. AZIMUTHAL POLARIZATION

Azimuthal polarization, which produces a torsional wave beam, results from a source that exhibits only rotational motion about the z axis. For simplicity the source is assumed to be axisymmetric, such that in the cylindrical coordinates (r,ϕ,z) one obtains for the components of the particle velocity vector in the plane perpendicular to the z axis $v_r=0$ and $v_\phi=v_\phi(r,z,\tau)$. Then $v_x=-v_\phi\sin\phi$, $v_y=v_\phi\cos\phi$, $v_x^2+v_y^2=v_\phi^2$, and both Eqs. (16) and (17) yield

$$\frac{\partial v_\phi}{\partial z} = \frac{\beta}{c^3}v_\phi^2\frac{\partial v_\phi}{\partial\tau} + \frac{\eta}{2\rho c^3}\frac{\partial^2 v_\phi}{\partial\tau^2} + \frac{c}{2}\int_{-\infty}^{\tau}\left(\frac{\partial^2 v_\phi}{\partial r^2}+\frac{1}{r}\frac{\partial v_\phi}{\partial r}-\frac{v_\phi}{r^2}\right)d\tau'. \tag{40}$$

Equation (40) differs from Eq. (20) for linear polarization only by the addition of the term $-r^{-2}$ to the transverse Laplacian $\nabla_\perp^2=\partial^2/\partial r^2+r^{-1}(\partial/\partial r)$. Torsional waves are often more conveniently expressed in terms of the angular velocity in the medium, $\Omega=\partial\phi/\partial\tau$, for which $v_\phi=r\Omega$ and Eq. (40) becomes

$$\frac{\partial\Omega}{\partial z} = r^2\frac{\beta}{c^3}\Omega^2\frac{\partial\Omega}{\partial\tau} + \frac{\eta}{2\rho c^3}\frac{\partial^2\Omega}{\partial\tau^2} + \frac{c}{2}\int_{-\infty}^{\tau}\left(\frac{\partial^2\Omega}{\partial r^2}+\frac{3}{r}\frac{\partial\Omega}{\partial r}\right)d\tau'. \tag{41}$$

From Eq. (41) it is evident that nonlinearity vanishes along the axis of the beam.

We again consider third-harmonic generation, here with $v_\phi=v_{\phi1}+v_{\phi3}$ and

$$v_{\phi n}(r,z,\tau) = \mathrm{Re}[w_{\phi n}(r,z)e^{in\omega\tau}], \quad n=1,3. \tag{42}$$

The integral solutions of Eq. (40) for the fundamental and third harmonic are given by Eqs. (22) and (23) with the subscript x replaced everywhere by ϕ, and with

$$g_n(r,z|r',z') = -\frac{nk}{2\pi(z-z')}J_1\left(\frac{nkrr'}{z-z'}\right) \times \exp\left[-n^2\alpha(z-z') - \frac{ink(r^2+r'^2)}{2(z-z')}\right]. \tag{43}$$

Equation (43) differs from Eq. (24) by a multiplicative factor i and by J_1 in place of J_0. The corresponding Green's function for Eq. (41) is obtained by multiplying the right-hand side of Eq. (43) by r'/r.

The source condition is expressed in the form

$$\Omega(r,0,t) = \Omega_0 \,\mathrm{Re}[f(r)e^{i\omega t}], \tag{44}$$

such that $w_{\phi 1}(r,0)=\Omega_0 r f(r)$. We first take $f(r)=\exp(-r^2/a^2)$ and obtain for the angular velocity at the source frequency

$$W_1(r,z) = \frac{\Omega_0}{(1-iz/z_0)^2}\exp\left(-\alpha z - \frac{r^2/a^2}{1-iz/z_0}\right), \tag{45}$$

with $\Omega_n(r,z,\tau)=\mathrm{Re}[W_n(r,z)e^{in\omega\tau}]$. In the far field the decay rate associated with spherical spreading is z^{-2} rather than z^{-1}. This is a consequence of the dipole-like nature of the source, and therefore the entire field, because $v_{x,y}(r,\phi,z,\tau)=-v_{x,y}(r,\phi+\pi,z,\tau)$. For any pair of points that are symmetric with respect to the z axis, the particle velocity vectors in the (x,y) plane are equal in magnitude and opposite in direction.

The integral for the third harmonic does not appear to admit a closed-form solution for a Gaussian beam. However, as discussed at the end of Sec. III, an analytic solution for the primary wave in the far field is sufficient to determine the corresponding asymptotic solution for the third harmonic. We thus consider radiation from a circular disk of radius a, for which $f(r)=H(a-r)$ in Eq. (44). The solutions for the fundamental and third harmonic in the far field are found to be

$$W_1(\theta,z) \sim -\frac{1}{2}\Omega_0 z_0^2 \frac{e^{-\alpha z}}{z^2} D(\theta)\exp\left(-\tfrac{1}{2}ikz\tan^2\theta\right), \tag{46}$$

$$W_3(\theta,z) \sim -\frac{i\beta\Omega_0^3 z_0^5}{384\alpha c^2}\frac{e^{-3\alpha z}}{z^4}(ka\tan\theta)^2 D^3(\theta) \times \exp\left(-\tfrac{3}{2}ikz\tan^2\theta\right), \tag{47}$$

where the directivity function for the primary wave,

$$D(\theta) = \frac{8J_2(ka\tan\theta)}{(ka\tan\theta)^2}, \tag{48}$$

is normalized to be unity on axis.

Like the linear solution for a Gaussian torsional beam, Eq. (46) exhibits a $z^{-2}e^{-\alpha z}$ decay rate. Unlike the linear solution for a Gaussian beam, the directivity function is different from that for a linearly polarized beam radiated by a source with the same amplitude distribution [compare Eqs. (25) and (45), and then Eqs. (33) and (48)]. Due to the factor $(ka\tan\theta)^2$ multiplying $D^3(\theta)$, the third harmonic vanishes along the axis of the beam in the far field. The maximum amplitude of the third harmonic in the far field is located at the angle θ_0 where $ka\tan\theta_0=1.92$, for which $(ka\tan\theta_0)^2D^3(\theta_0)=1.41$.

Equations (31) and (47) may now be used to compare the maximum amplitudes in a linearly polarized beam and an azimuthally polarized beam. To relate the source amplitudes, the kinetic energies associated with translation and rotation of the disk are matched to obtain $\Omega_0=2^{1/2}v_0/a$, for which the far-field formulas yield $|w_{\phi 3}(\theta_0,z)/w_{x3}(0,z)|\sim 0.12$. In terms of harmonic generation, azimuthal polarization is thus significantly less efficient than linear polarization.

VII. SOLUTION ALGORITHMS

Numerical results are presented in Sec. VIII for shear wave beams radiated in the z direction by a circular disk of radius a. The source condition for elliptically polarized beams, including linearly and circularly polarized beams, is

$$v_x(r,0,t) = v_0 H(a-r)\cos\omega t, \qquad v_y(r,0,t) = sv_0 H(a-r)\sin\omega t. \tag{49}$$

Diffraction is characterized by the Rayleigh distance $z_0=ka^2/2$, nonlinearity by the plane wave shock formation distance $z_{\mathrm{sh}}=c^2/\beta k v_0^2$, and absorption by the length $z_{\mathrm{abs}}=1/\alpha$. In terms of these length scales, the two dimensionless parameters used to characterize solutions of Eqs. (16) and (17) are $A=z_0/z_{\mathrm{abs}}$ for absorption and $N=z_0/z_{\mathrm{sh}}$ for nonlinearity. For plane waves, the Gol'dberg number $\Gamma=Z_{\mathrm{abs}}/z_{\mathrm{sh}}$ is used.

The source condition for azimuthally polarized beams is

$$\Omega(r,0,t) = \Omega_0 H(a-r)\cos\omega t. \tag{50}$$

Since in this case the peak particle velocity in the source plane is $a\Omega_0$, the characteristic shock formation distance is taken to be $z_{\mathrm{sh}}=c^3/\beta\omega a^2\Omega_0^2$. The parameters N and A are otherwise defined as for elliptically polarized beams.

Comparisons are made with solutions of Eq. (18) for compressional wave beams, the source condition for which is

$$v_z(r,0,t) = v_{z0}H(a-r)\cos\omega t. \tag{51}$$

The parameters N, A, and Γ are defined as for shear waves, except with the shock formation distance given instead by $z_{\mathrm{sh}}=c_l/\beta k_l v_{z0}$, where $k_l=\omega/c_l$, because the nonlinearity is quadratic.

For linear polarization, Eq. (20) is solved using the time domain algorithm in Ref. 16 after a minor change is made in the nonlinearity subroutine to account for the cubic nonlinearity. Equation (41) is solved for azimuthal polarization, again with the algorithm in Ref. 16 but without the coordinate transformation. Also, in addition to the change in the nonlinearity subroutine, a minor change is required in the diffraction subroutine. For elliptical polarization, Eqs. (16) and (17) must be solved simultaneously. No implicit analytical solution was discovered for the nonlinearity time step, and a weighted essentially nonoscillatory scheme[17] was used in place of the time base transformation in Ref. 16.

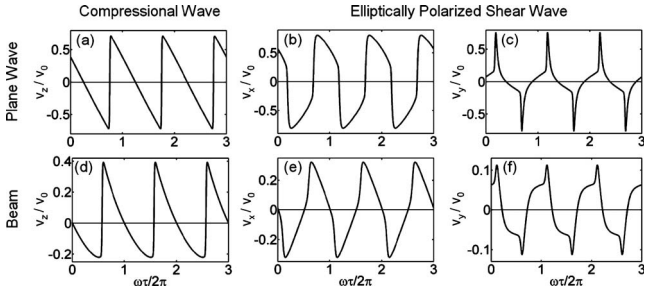

FIG. 1. Axial time waveforms in a compressional wave (first column, v_z) and an elliptically polarized shear wave with $s=0.25$ (second and third columns, v_x and v_y, respectively), both without diffraction [first row, (a)–(c)] and with diffraction [second row, (d)–(f)]. The distance for the plane waves is $z=3z_{sh}$ with $\Gamma=100$, and for the beams it is $z=3z_0$ with $N=1$ and $A=0.01$.

VIII. NUMERICAL RESULTS

Axial time waveforms are presented in Fig. 1 for a compressional wave (first column, v_z) and for an elliptically polarized shear wave with $s=0.25$ (second and third columns, v_x and v_y, respectively), both without diffraction [first row, Figs. 1(a)–1(c)] and with diffraction [second row, Figs. 1(d)–1(f)]. The distance for the plane waves is $z=3z_{sh}$ with $\Gamma=100$, and for the beams it is $z=3z_0$ with $N=1$ and $A=0.01$. The plane compressional waveform (a) has the classical sawtooth shape associated with quadratic nonlinearity. A distinctive feature of shear waves is that there are two shocks per period. In the y component, spikes appear at the locations where shocks appear in the x component. Effects of beam diffraction are illustrated in the lower row. Note that the waveform asymmetry in the compressional wave beam is absent from the shear wave beam. This is because the cubic nonlinearity generates only odd harmonics in the nonlinear shear wave, and any waveform that can be expressed as a Fourier series of odd harmonics is necessarily symmetric, regardless of the relative harmonic phase shifts introduced by diffraction. However, if the initial waveform contains even harmonics, diffraction will introduce some degree of waveform asymmetry in a nonlinear shear wave beam. Waveforms calculated for linear polarization are much the same as those shown in Figs. 1(b) and 1(e).

While unrelated to diffraction, the formation of secondary shocks was observed in simulations of elliptically polarized shear waves at high amplitude. Shown in Fig. 2 are waveforms at the three distances (a) $z=3z_{sh}$, (b) $10z_{sh}$, and (c) $15z_{sh}$ for an elliptically polarized plane wave with $s=0.25$ and $\Gamma=500$. In each frame, the velocity component v_x is on the top, v_y on the bottom. Note the small spikes that appear in v_x at $3z_{sh}$ (a). Their locations coincide with the large spikes in v_y. By $10z_{sh}$ (b) the spikes have evolved into small step shocks that have advanced in the waveform (to earlier retarded times, from right to left in the figure). By $15z_{sh}$ (c) the secondary shocks have disappeared. For sufficiently large Γ these secondary shocks may reappear.

Presented in Fig. 3 are harmonic beam patterns at $z=5z_0$ with $N=0.2$ and $A=0.01$ for (a) a compressional wave beam, and for the (b) x and (c) y components in an elliptically polarized shear wave beam with $s=0.25$. The beam

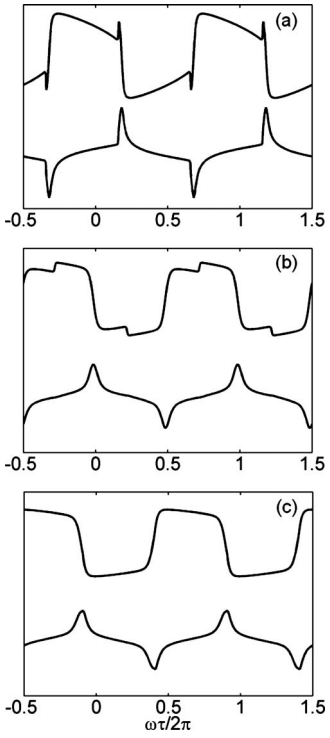

FIG. 2. Waveforms in an elliptically polarized plane wave with $s=0.25$ and $\Gamma=500$ at (a) $z=3z_{sh}$, (b) $10z_{sh}$, and (c) $15z_{sh}$. In each frame, the velocity component v_x is on the top, v_y on the bottom.

patterns for the even harmonics in the compressional wave are deemphasized by use of a lighter line weighting to facilitate comparison of the odd harmonics with those of the shear wave. As with compressional waves, the number of sidelobes in the nth harmonic beam pattern for the shear wave is n times the number in the beam pattern at the source frequency. This is not predicted by Eq. (31) for the third harmonic in the shear wave. The directivity function $D^3(\theta)$ indicates a beam pattern having the same number of sidelobes as at the source frequency, not three times as many. These additional sidelobes, also observed in the beam patterns for the compressional wave, are near-field effects that become less pronounced as either distance or absorption is increased.[14] For weak absorption, the far field for the nonlinearly generated harmonics is not reached until distances far beyond the Rayleigh distance z_0.

Results for an azimuthally polarized beam are presented in Fig. 4 for $N=3$ and $A=0.01$. Figure 4(a) shows harmonic beam patterns at $z=z_0$ for the source frequency and its third

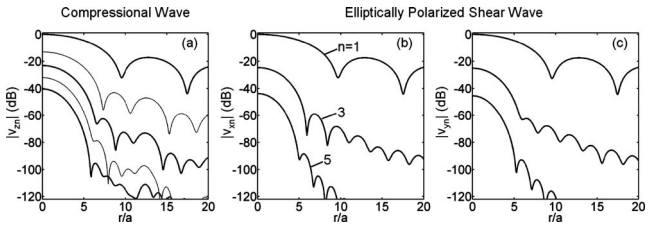

FIG. 3. Harmonic beam patterns at $z=5z_0$ with $N=0.2$ and $A=0.01$ for (a) a compressional wave beam, and for the (b) x and (c) y components in an elliptically polarized shear wave beam with $s=0.25$.

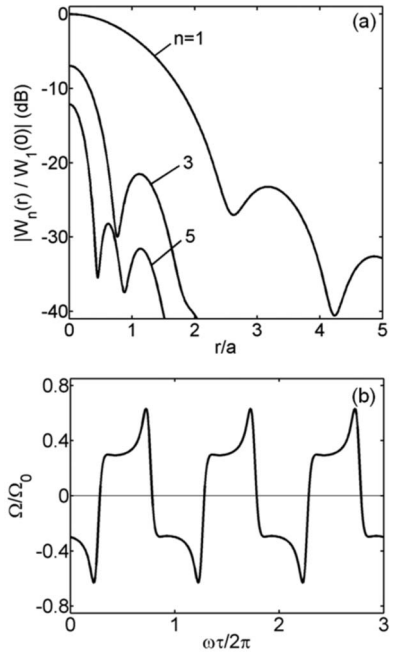

FIG. 4. (a) Harmonic beam patterns and (b) axial time waveform at $z=z_0$ in an azimuthally polarized beam with $N=3$ and $A=0.01$.

and fifth harmonics. Note that the levels of the third and fifth harmonics on the beam axis are maxima, not minima. The discrepancy with Eq. (47), which predicts zero for the amplitude of the third harmonic along the beam axis, is because the wave is not yet in the far field. Even though the nonlinear term in Eq. (41) is zero everywhere along the beam axis, harmonics generated nonlinearly off axis in the near field diffract into the axial region. Figure 4(b) shows the axial waveform at $z=z_0$. Like the waveforms in Figs. 1(e) and 1(f) for the elliptically polarized beam, the waveform in the azimuthally polarized beam is also symmetric.

IX. CONCLUSION

Effects of cubic nonlinearity in shear wave beams were analyzed for linear, elliptical, circular, and azimuthal polarizations, and comparisons were made with effects of quadratic nonlinearity in compressional wave beams. The coupled nonlinear evolution equations that were derived also include quadratic nonlinearity due to diffraction. Effects of quadratic nonlinearity, and the generation of longitudinal components in shear wave beams, are under investigation and will be reported in the future.

(Received 15 August 2007; revised 18 December 2007; accepted 26 December 2007)

Piezo-driven inkjet systems are very sensitive to air entrapment. The entrapped air bubbles grow by rectified diffusion in the ink channel and finally result in nozzle failure. Experimental results on the dynamics of fully grown air bubbles are presented. It is found that the bubble counteracts the pressure buildup necessary for the droplet formation. The channel acoustics and the air bubble dynamics are modeled. For good agreement with the experimental data it is crucial to include the confined geometry into the model: The air bubble acts back on the acoustic field in the channel and thus on its own dynamics. This two-way coupling limits further bubble growth and thus determines the saturation size of the bubble. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2835624]

I. INTRODUCTION

Drop-on-demand inkjet printing[1] has been and will be applied to many industrial applications,[2] which range from printing color filters for flat panel displays[3] to DNA microarrays.[4] Still, the most common application is the printing of text and graphics on paper. A small volume of ink is deposited on the paper in a very controlled way. The stability of the printing process is crucial, especially because the productivity and accuracy standards are continuously raised. The principle of a piezo printhead is a piezo element, which deforms an ink channel, thereby building up pressure at the nozzle.[5] One of the biggest challenges in piezo-acoustic printing is the entrapment of air bubbles.[6–8] They disturb the pressure buildup at the nozzle and lead to nozzle failure. Therefore, the monitoring of the printing process while printing is crucial.

Air entrapment at the nozzle can be detected by using the actuating piezo as a sensor.[8] An entrapped bubble has to be removed as quickly as possible to continue the printing process. However, waiting for the dissolution of the bubble is very time consuming and decreases the productivity of the printhead. Therefore, it is desirable to actively get rid of the air bubble. To accomplish this, first the bubble dynamics have to be understood. This article focuses on the dynamics of fully grown air bubbles where the jetting of droplets has completely broken down. The entrapped air bubble oscillates in the acoustic field. During bubble compression, gas is pressed out of the bubble, while during expansion dissolved gas enters into the bubble. For a large enough driving pressure the second effect dominates and a net growth of the air bubble results (rectified diffusion, see Refs. 9 and 10). Finally, the bubble reaches a dynamic equilibrium size.

The presence of an equilibrium radius signals the saturation: The bubble has become relatively large, thereby influencing the acoustic waves in the printhead, hence limiting its own oscillations and growth. During actuation, the bubble will then just remain in the ink channel oscillating around its equilibrium radius. By employing a glass connection channel and high speed imaging, the air bubble can be visualized and its dynamics can be resolved.

The dynamics of a bubble in a tube differ from the dynamics of a bubble in an infinite volume of liquid.[11,12] Due to the finite size of the ambient liquid, the natural frequency of oscillation usually decreases when the bubble becomes larger with respect to the pipe.[13,14,22] Qin *et al.*[15] showed that in some cases, the opposite occurs, indicating that the surrounding system and its behavior are relevant for the dynamics of the bubble. When the bubble touches the walls during expansion, the bubble can become nonspherical.[16,17] Cui *et al.*[18] found that for a bubble between two parallel plates, the acoustic field generated by the bubble is essential for the evolution of the bubble. For the saturated bubbles in an inkjet printhead, we find the two-way coupling effect, i.e., the backreaction of the bubble on the acoustic field, to be crucial, whereas for small bubbles this effect can be neglected.[19] To model the two-way coupling, the one-dimensional disk bubble model of Ref. 19 is extended to a fully coupled model. Moreover, the bubble itself is now modelled with a linearized Rayleigh–Plesset equation. We find that with such an extended model the experimental data can be described very well. The two-way coupling effect is found to be crucial. The pressure at the nozzle and the transfer function of

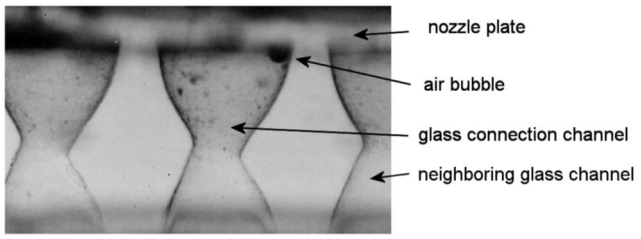

FIG. 1. The entrapped air bubble is trapped in the glass connection channel. When actuating, the fully grown air bubble will just remain oscillating in the channel. Note the position of the air bubble: due to the Bjerknes forces it is pushed against the glass walls. (The bubble is larger than its resonance size.) To the left and right of the channel with the bubble, the neighboring channels can be seen.

the velocity in the nozzle over the actuator voltage are changed significantly by the entrained air bubble.

The article is organized as follows: First, in Sec. II the details of the experimental setup are discussed. Next, in Sec. III, the experimental air bubble dynamics are presented. Section IV is devoted to the bubble model. For readability, some technical details of the model are separated in an appendix. The comparison between the experiments and the model is given in Sec. V. The paper ends with the conclusions and an outlook, Sec. VI.

II. EXPERIMENTAL SETUP

The setup consists of a side-shooter printhead,[19] developed by Océ Technologies. In this printhead, a 5 mm long rectangular ink channel is deformed by a piezo element, thereby generating acoustic waves in the channel. The waves result in a pressure and velocity field near the nozzle. To visualize the dynamics of the entrained air bubble, a glass connection channel was interposed between the ink channel and a glass nozzle plate, similar to Ref. 19. This channel has a length of 400 μm and an hourglass shape. The waist diameter is 80 μm and the maximum diameter 250 μm at the inlet and outlet. On top of the connection channel a glass nozzle plate is glued. The conical nozzles have a diameter of 30 μm at the exit and 50 μm at the inlet. The pulse applied to the printhead is trapezoidal lasting 8 μs (2 μs rise time, 4 μs plateau, and 2 μs fall time), with a repetition rate of 20 kHz.

After the bubble has been entrained, it is allowed to grow to its diffusive equilibrium. The droplet formation process has now ceased completely. The entrained air bubble is visualized by a Shimadzu HPV-1 high-speed camera (maximum frame rate of 1 Mfps) and a bright Olympus light source. The Shimadzu HPV-1 is capable of recording 100 frames and has an exposure time as short as 250 ns. A single frame showing the entrapped air bubble in the glass channel is depicted in Fig. 1. In this article we restrict ourselves to fully developed bubbles, so that the bubbles start every acoustic cycle with the same radius.

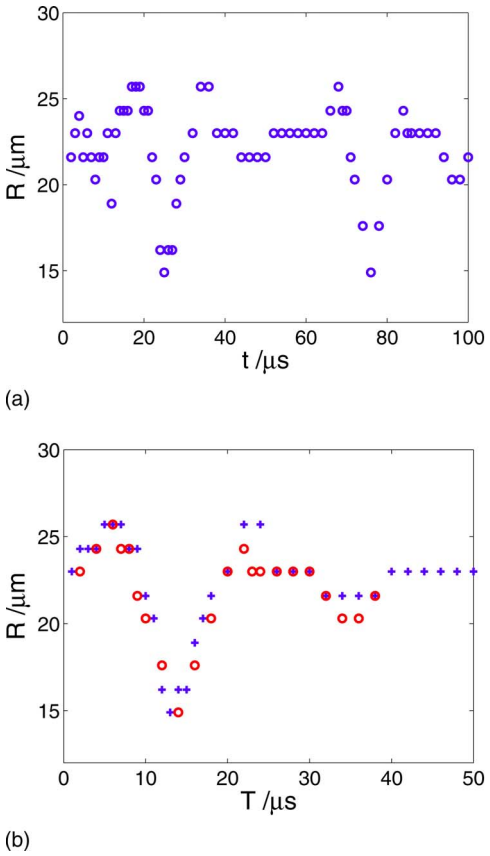

FIG. 2. (Color online) (a) Radius $R(t)$ of the entrained bubble actuated with 190 V as a function of time. The actuation frequency is 20 kHz. (b) To show the reproducibility of the bubble oscillations, the radius is plotted modulo its periodicity $T=1/f=50$ μs. The different cycles are denoted by different symbols.

III. EXPERIMENTAL RESULTS: BUBBLE OSCILLATIONS

For a driving voltage of 190 V, the radius of the bubble is plotted in Fig. 2(a). The equilibrium value was found to be $R_0=23$ μm, the minimum radius was 15 μm and the maximum radius was 26 μm. Two successive acoustic cycles (50 μs each) were captured by the camera with a frame rate of 1 Mfps. Plotting these acoustic cycles modulo the period $T=1/f=50$ μs shows the reproducibility of the oscillation, thereby confirming the assumption of a bubble in dynamical equilibrium, Fig. 2(b). The error in the data is caused by the assumed sphericity of the air bubble and by the limited resolution of the images. The error is estimated to be 2 μm in radius. Note that the expansion of the bubble is smaller than the compression. As we will see in the next section, this is due to the finite size of the ink channel. When reducing the actuating voltage to 120 V, we see a decrease in the saturation size of the air bubble, from $R_0=23$ μm to $R_0=18$ μm, see Fig. 3. The minimum bubble radius is now found to be13 μm, and its maximum is 22 μm.

Note the position of the air bubble: it is pushed against the nozzle plate. We attribute this to the flow field generated by the bubble oscillations. This flow field pulls the bubble toward the walls. This effect is called the secondary Bjerknes force.[20] Inspection of the obtained images reveals the bubble

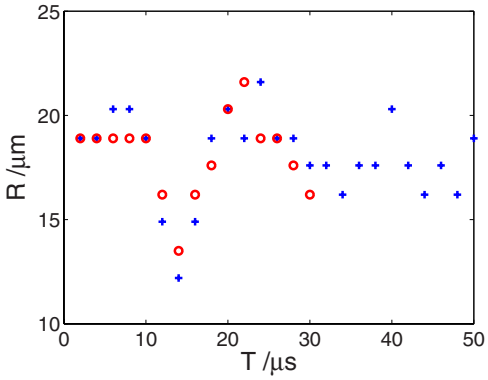

FIG. 3. (Color online) Radius $R(t)$ of the entrained bubble actuated with 120 V as a function of time. The actuation frequency is 20 kHz. Two acoustic cycles are displayed.

shape. When walls are nearby, the bubble oscillates nonspherically. After a large expansion, the shape of the bubble is nearly a quarter of a sphere that is bounded by the nozzle plate and the channel wall. When the bubble is compressed, it becomes nearly spherical. At lower actuation amplitudes, the bubble oscillations are more spherical. This is expected to be caused by a decrease in secondary Bjerknes force. By reducing the actuation voltage, the amplitude of the acoustic field is reduced, and so are the bubble oscillations. Therefore, when the bubble oscillations are decreasing, so is the secondary Bjerknes force that pulls the bubble toward the wall, resulting a less deformed bubble and a reduction of the error introduced by the assumed sphericity of the bubble.

The fast Fourier transform (FFT) is calculated to extract the frequencies present in the oscillations of the bubble, and is depicted in Fig. 4. To obtain a smooth spectrum, the bubble radius fluctuation $\Delta R(t)$ is padded with trailing zeros before calculating the FFT. At both the driving voltage of 120 V where $R_0=18$ μm, and at a driving voltage of 190 V

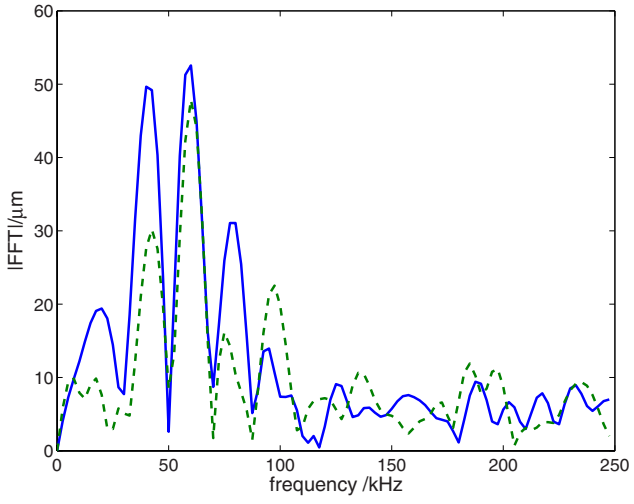

FIG. 4. (Color online) FFT of $\Delta R(t)$ for a driving voltage of 190 V, where the saturated ambient bubble radius is $R_0=23$ μm (solid), and for 120 V, where the saturated ambient bubble radius is $R_0=18$ μm (dashed): The largest maximum remains nearly unchanged at 60 kHz, whereas the second largest maximum at 40 kHz is larger at 190 V.

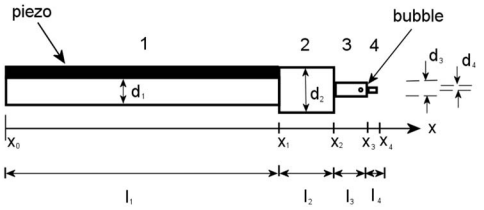

FIG. 5. A schematic overview of the ink channel. It is divided into four sections. Section I is the channel where the piezo is located. Section II is the standard connection channel. Section III is a representation of the glass connection channel, and section IV is the nozzle. The interfaces between the sections are positioned at, respectively, x_1, x_2, and x_3. The (undisturbed) diameters d_j for the four sections $j=1,2,3$, and 4 are $d_1=195$ μm, $d_2=250$ μm, $d_3=80$ μm, and $d_4=30$ μm, respectively.

where $R_0=23$ μm, the main frequency of the bubble oscillations is found to be 60 kHz.

IV. BUBBLE MODEL

A. Simplified geometry

To model the bubble oscillations in the ink channel, a one-dimensional model is used. The cylindrical channel is divided into four sections, see Fig. 5. Section 1 is the actuation channel, where the piezo is located. Section 2 is the standard connection channel. Section 3 is a model of the glass connection channel which we have included for visualization and section 4 is the nozzle. The interface between the sections is positioned at, respectively, x_1, x_2, and x_3. The channel acoustics, bubble dynamics, and nozzle flow are modeled. The bubble is located in the connection channel, and similar to the experiments it experiences the pressure at x_3 between the glass connection channel and the nozzle. The effect of the bubble on the channel acoustics is included in this model.

The channel acoustics is first treated section by section. Then the channel sections are coupled through the matching of interface conditions. The channel deformations are only represented by the cross-sectional variations.

B. Channel acoustics

The channel is actively deformed when applying a voltage to section 1, and passively by the pressure inside the channel. The channel cross-sectional area $A_j(x,t)$ of section j can be written as

$$A_j(x,t) = A_{0,j} + a_{a,j}(t) + a_{p,j}(x,t). \quad (1)$$

Here x is the spatial coordinate in the channel direction, $A_{0,j}$ is the undisturbed, equilibrium, cross-sectional area, $a_{a,j}(t)$ is the variation of cross-sectional area due to the actuator voltage V_j (obviously being nonzero only for section 1), and $a_{p,j}(x,t)$ is the passive deformation of the channel in response to the pressure, $P_j(x,t)$, inside the channel. Note that $a_{a,j}(t)$ is constant over a channel section. For frequencies below the Nyquist frequency $f_n=500$ kHz of the measurements, the wavelength $\lambda > 2.5$ mm is much larger than the channel radius $d_j < 250$ μm, so the radial component of the pressure gradient and velocity become negligible with

TABLE I. Parameters of the channel sections.

j	Section	α_j (V^{-1})	β_j ($m^2\,N^{-1}$)	d_j (μm)	$c_{\mathrm{eff,j}}$ ($m\,s^{-1}$)	l_j (μm)
1	Actuation channel	-3.43×10^{-6}	8.36×10^{-10}	195	803	5000
2	Connection channel	0	0	250	1250	1000
3	Glass connection	0	0	80	1250	149
4	Nozzle	0	0	30	1250	42

respect to the axial components. Linearize the channel deformations:

$$a_{a,j}(t) = \alpha_j V_j(t) A_{0,j}$$

$$a_{p,j}(x,t) = \beta_j P_j(x,t) A_{0,j} \tag{2}$$

with

$$\alpha_j = \frac{1}{A}\left(\frac{\partial A}{\partial V}\right)_P$$

$$\beta_j = \frac{1}{A}\left(\frac{\partial A}{\partial P}\right)_V \tag{3}$$

α_j, β_j, $A_{0,j}$, and $V_j(t)$, for $j=1,2,3,4$, are assumed to be constant over a channel section, α_j and β_j are calculated with a plane-strain calculation in the commercial solid mechanics model ANSYS by Océ Technologies B.V. Each channel section is characterized by the magnitude of these quantities, and the length l_j of the channel section. In Table I we have summarized the parameters characterizing the sections.

The wave equation for a deforming channel can be derived from the Navier–Stokes equation by a control volume analysis in the low reduced frequency approximation[21] where $R_c \ll \lambda$. Insert the linearized channel deformations, Eq. (2), into the wave equation for a deforming channel:

$$\partial_t^2 P_j = c_{\mathrm{eff},j}^2 \partial_x^2 P_j - \alpha_j \rho c_{\mathrm{eff},j}^2 \partial_t^2 V_j - c_{\mathrm{eff},j}^2 \frac{\mu}{A_{0,j}} \partial_x \oint_{\partial A_j} \partial_n u \, ds \tag{4}$$

where u is the axial velocity field, $\mu=0.01\ \mathrm{N\,m^{-2}\,s}$ is the viscosity, $\rho=1090\ \mathrm{kg\,m^{-3}}$ is the density of the ink, and $c_{\mathrm{eff},j}$ the effective phase velocity, which is given by

$$c_{\mathrm{eff},j} = \sqrt{\frac{c^2}{1+\beta_j c^2 \rho}} \tag{5}$$

where $c=1250\ \mathrm{m\,s^{-1}}$ is the velocity of sound in the ink. Equation (4) is linear, and can be solved in the frequency domain, so that in each channel section the pressure is given by

$$P_j(x,t) = p_{1,j} e^{i(\omega t - k_{1,j} x)} + p_{2,j} e^{i(\omega t - k_{2,j} x)} - \alpha_j c_{\mathrm{eff},j}^2 \rho v_j \tag{6}$$

where $p_{1,j}$ and $p_{2,j}$ are the amplitudes of the waves propagating in the negative and positive x direction, respectively. The driving voltage is $V_j = v_j e^{i\omega t}$, where v_j is the amplitude and ω is the angular frequency. Note again that only section I experiences direct driving, $v_1 \neq 0$, whereas sections II, III, and IV have $v_j=0$. The angular frequency ω ranges from $-2\pi\times10^7$ to $2\pi\times10^7\ \mathrm{rad\,s^{-1}}$. It is not to be confused with the drop-on-demand driving frequency $f_{\mathrm{DoD}}=5$ kHz, which is chosen such that the acoustic field is completely damped at the end of the acoustic cycle, $k_{1,j}$ and $k_{2,j}$ are the wave numbers of the waves propagating in the negative and positive x direction, respectively. Inserting the velocity profile of a cylindrical pipe given by Womersley[23] and dropping the $e^{i\omega t}$ term leads to

$$k_{n,j} = (-1)^n \frac{\omega}{c_{\mathrm{eff},j}} \left(1 + \frac{2\sqrt{i} J_1(\mathrm{Wo}_j i^{3/2})}{\mathrm{Wo}_j J_0(\mathrm{Wo}_j i^{3/2})}\right)^{-1/2} \quad (n \in \{1,2\}) \tag{7}$$

where $\mathrm{Wo}_j = 0.5 d_j \sqrt{\omega\rho\mu^{-1}}$ is the Womersley number. The functions J_0 and J_1 are the ordinary Bessel functions of the first kind, of zeroth and first order, respectively. With Eq. (7) substituted into Eq. (6) one finally obtains a general expression for the pressure $P_j(x,t)$ in section j.

The glass connection channel ($j=3$) and the nozzle ($j=4$) are not cylindrical but have a more complicated shape. However, both sections can be modeled by an equivalent cylindrical section, as shown in Appendices A and B. For the glass connection channel an equivalent diameter of $d_3=80\ \mu$m and an equivalent length of $l_3=148\ \mu$m are found. The conical nozzle is described by a cylinder of equivalent diameter $d_4=30\ \mu$m and equivalent length of $l_4=42\ \mu$m. Over most of their length, the radii of the real nozzle and glass connection channel are larger then the radii of the equivalent cylindrical sections. The equivalent lengths are chosen to keep the acoustic admittance constant. As the acoustic admittance is proportional to the ratio of the cross sectional area over the length of the cylinder, see the forthcoming Eq. (A8) the real lengths are also larger then the equivalent lengths.

The flow rate through the cylindrical nozzle is a function of the pressure drop over the nozzle in the frequency domain. The expression given by Womersley[23] for the amplitude of the volume flow rate q_j in a cylinder (the nozzle) is

$$q_j = p_j \frac{\pi d_j^2 i}{4 l_j \omega \rho} \left(1 - \frac{2 J_1(\mathrm{Wo}_j i^{3/2})}{i^{3/2} \mathrm{Wo}_j J_0(\mathrm{Wo}_j i^{3/2})}\right). \tag{8}$$

C. Matching the channel sections

We now have to match the pressure fields $P_j(x,t)$ for the different sections j. The boundary conditions at the ends of each section are continuity of pressure and flow. The pressure should be continuous at the matching positions x_1, x_2, x_3 (Fig. 5),

$$P_j(x_j) = P_{j+1}(x_j), \quad j = 1,2,3. \tag{9}$$

Moreover, continuity requires that the volume flow rate should also be continuous:

$$A_j u_j(x_j) = A_{j+1} u_{j+1}(x_j), \quad j = 1,2. \tag{10}$$

Here $u_j(x)$ is the velocity averaged over the cross section, $A_j(x_j)$. The effect of the bubble is included in the volume flow rate balance between section 3 and 4 where the bubble sits by explicitly considering the flux Q_b into the bubble,

$$A_3 u_3(x_3) = A_4 u_4(x_3) + Q_b \tag{11}$$

These boundary conditions together with equations (6) and (7) (the equation for the propagation of acoustic waves) provide a complete description of the channel acoustics.

D. Bubble volume oscillations

The behavior of spherical bubbles in large volumes is described by the Rayleigh–Plesset (RP) equation (see, e.g., Brennen[20])

$$R\ddot{R} + \frac{3}{2}\dot{R}^2 = \frac{1}{\rho}\left[\left(P_0 + \frac{2\sigma}{R_0} - P_v\right)\left(\frac{R_0}{R}\right)^{3\gamma} + P_v - \frac{2\sigma}{R} - \frac{4\mu\dot{R}}{R} - P_\infty(t)\right]. \tag{12}$$

Here $R(t)$ is the bubble radius, $\rho = 1090\ \mathrm{kg\ m^{-3}}$ is the ink density, σ is the surface tension, $\alpha = 0.028\ \mathrm{N\ m^{-1}}$, R_0 is the bubble radius at ambient pressure $P_0 = 101\,325\ \mathrm{N\ m^{-2}}$, $P_v = 2400\ \mathrm{N\ m^{-2}}$ is the vapor pressure, $\mu = 0.01\ \mathrm{N\ m^{-2}\ s}$ is the viscosity, and γ is the polytropic index. The bubble is assumed to oscillate isothermally, i.e., $\gamma = 1$. $P(t)$ is the pressure fluctuation caused by the actuator so that far from the bubble the pressure is

$$P_\infty(t) = P_3(x_3) = P_0 + P(t) + \Delta P(t). \tag{13}$$

Here $\Delta P(t)$ is the pressure disturbance caused by the bubble. This term can be neglected for bubbles in an infinite volume of liquid. In a channel however, this term is significant. It reflects the coupling between the channel acoustics and the bubble volume oscillations. The pressure $P_\infty(t)$ is the pressure at locations so far from the bubble, that the pressure due to the inertia of the radial flow field is negligible with respect to the imposed pressure fluctuations.

For small fluctuations of the driving pressure $P(t) \ll P_0$ and bubble radius $\Delta R(t) \ll R_0$ the RP equation, Eq. (12), can be linearized. The response of the bubble can be transformed to the frequency domain,

$$R(t) = \sum_{k=-\infty}^{\infty} r(\omega_k) e^{i\omega_k t}, \tag{14}$$

where $r(\omega)$ is the amplitude of the radius at frequency ω. Similarly,

$$P_\infty(t) = P_3(x_3) = \sum_{k=-\infty}^{\infty} p_3(\omega_k) e^{i\omega_k t}, \tag{15}$$

where $p_3(\omega)$ is the amplitude of the pressure at frequency ω at the position x_3. In the notation we suppress the explicit dependence on ω_k for compactness of formulation. Upon linearization, RP equation (12) becomes

$$-\omega^2 r = \frac{1}{R_0\rho}\left(-r\left(P_0 + \frac{2\sigma}{R_0} - P_v\right)\left(\frac{3\gamma}{R_0}\right) + r\frac{2\sigma}{R_0^2} - \frac{4\mu i\omega r}{R_0} - p_3\right). \tag{16}$$

The volume change of the bubble and thus the ink flow toward the position of the bubble center is:

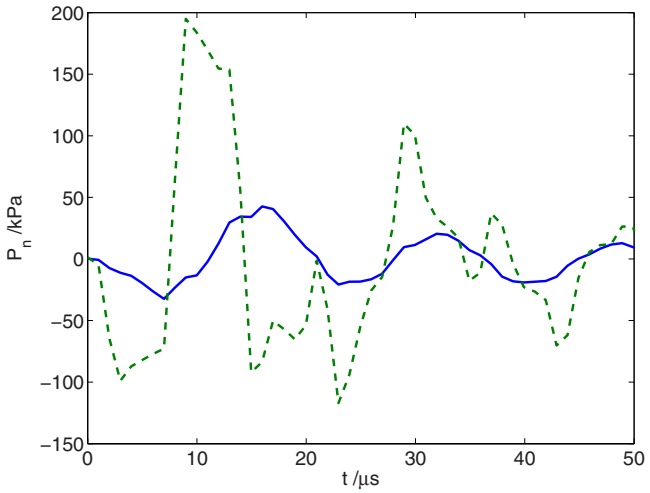

FIG. 6. (Color online) Pressure at the entrance of the nozzle $P_3(x_3)$ with (solid), and without (dashed) an entrained bubble of $R_0 = 23\ \mu\mathrm{m}$, as calculated by the model for a 2–4–2 pulse (2 μs rise time, 4 μs plateau, and 2 μs fall time), applied at 80 V. The pressure peak that starts at 10 μs would normally cause the formation of a droplet. With an entrained air bubble, this peak is reduced by a factor of four. The pressure reduction due to the bubble is strong enough to prevent the droplet formation.

$$Q_b(t) = -\frac{d}{dt}\left(\frac{4}{3}\pi R(t)^3\right) = \sum_{k=-\infty}^{\infty} q_b(\omega_k) e^{i\omega_k t}, \tag{17}$$

where $q_b(\omega)$ is the amplitude of the volume flow rate into bubble at frequency ω. Combining Eqs. (16) and (17) yields an expression for the amplitude of the volume flow rate:

$$q_b = -4\pi i p_3 R_0^2 \omega\left(R_0\rho\omega^2 - \left(P_0 + \frac{2\sigma}{R_0} - P_v\right)\left(\frac{3\gamma}{R_0}\right) + \frac{2\sigma}{R_0^2} - \frac{4\mu i\omega}{R_0}\right)^{-1}. \tag{18}$$

When inertia, vapor pressure, viscosity, and surface tension are neglected, Eq. (18) reduces to the expression for the disk bubble in de Jong *et al.*[19] This shows that the dynamics obtained for the disk bubble in Ref. 19 can be alternatively derived from the RP equation.

E. Model results

The model described in this section was developed to test the hypothesis that the two-way coupling between the bubble dynamics and channel acoustics is essential. The modification of the pressure fluctuation at the entrance of the nozzle by the bubble is significant, as shown in Fig. 6 for a bubble of $R_0 = 23\ \mu\mathrm{m}$, driven at 80 V.

The pressure fluctuations are reduced by a factor of 4 when a bubble is present. It is this pressure reduction which causes the nozzle to stop jetting droplets. Not only the pressure amplitude is reduced, also the higher frequencies in the signal are damped. This becomes evident when looking at the transfer function of the actuator voltage to the velocity in the nozzle, as shown in Fig. 7.

The velocity in the nozzle is reduced and the resonance peaks at 50 and 110 kHz are shifted to 20 and 60 kHz, respectively. Moreover, the higher frequencies are completely

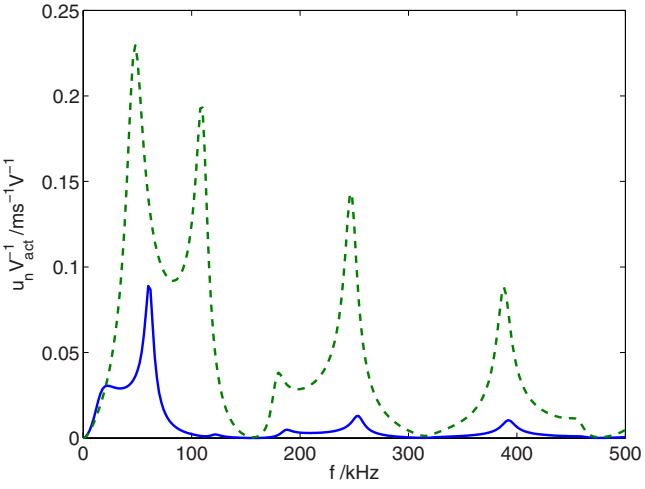

FIG. 7. (Color online) Transfer function amplitude of velocity in the nozzle over actuator voltage, with (solid) and without (dashed) an entrained bubble with a radius $R_0=23$ μm. Note the large reduction of the velocity, in particular at higher frequencies. The individual peaks are shifted as a result of the modification of the reflection at the nozzle. The bubble has a significant influence on the channel acoustics.

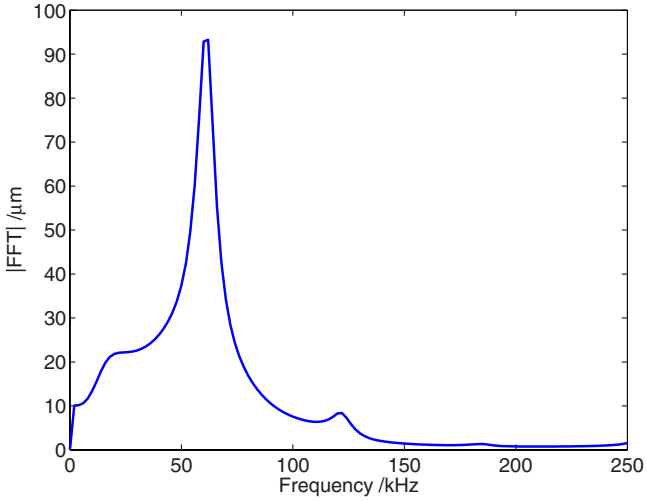

FIG. 9. (Color online) FFT calculated from the bubble oscillations for the case of Fig. 8 with two-way coupling. The main frequency is $f=60$ kHz. For this bubble radius, $R_0=23$ μm, the bubble reflects the acoustic waves in the ink channel. Therefore, the closed end (the nozzle) is replaced by an open end (the bubble).

damped by the air bubble. The zeros in the transfer function are not shifted as they are caused by the properties of section 1. The zeros occur at frequencies $f=nc_{\text{eff},1}l_1^{-1}$, where n is an integer.

The change in pressure fluctuation that the bubble experiences is accompanied by a change in bubble radius oscillation, as shown in Fig. 8. Here the bubble radius is shown, calculated with the described model, and calculated when neglecting the two-way coupling. Through the channel acoustics, the bubble loses energy, thus reducing the amplitude of the volume oscillations. When this effect is neglected, the bubble is driven beyond the linear regime, and the linearization is not justified. The bubble oscillations without two-way coupling were thus calculated with the full [nonlinear] RP equation, Eq. (12), driven by the pressure that would occur in the absence of a bubble, see Fig. 6. As seen in Fig. 8, the effect of the two-way coupling appears to be significant, and cannot be neglected.

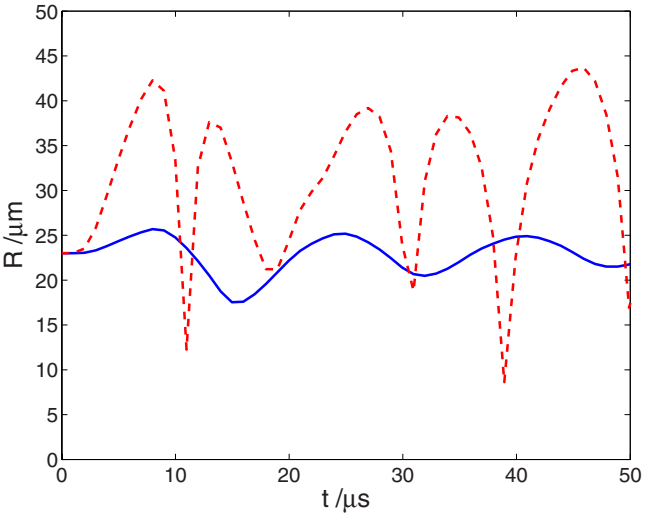

FIG. 8. (Color online) Bubble radius, neglecting the two-way coupling between bubble volume fluctuation and pressure (dashed), and with this two-way coupling taken into account (solid). The case with two-way coupling is calculated with the linearized analysis as described in the text for a trapezoidal 2–4–2 pulse and a driving of 80 V. The case where two-way coupling is neglected is calculated with the nonlinear Rayleigh–Plesset equation because in this case the bubble is driven beyond the linear regime. This is most evident in the violent collapse near $t=10$ μs, where the bubble is compressed within 3 μs from 48 to 10 μm.

The FFT is calculated from the oscillations of the $R_0=23$ μm, bubble and displayed in Fig. 9. The main frequency is 60 kHz. The same frequency is also found for the bubble of $R_0=18$ μm. This frequency does not depend on the bubble radius once it has reached a certain size. The reason for this is that once the bubble is large enough, it fully reflects the acoustic waves, acting like an open end of section 3 of the channel and decoupling it from the nozzle (section 4).

Air bubbles can be detected by monitoring the electric current through the piezo in the time domain, as it reacts to pressure fluctuations. This detection method has been described by de Jong *et al.*[8] The proposed model predicts the changes in this signal due to the entrained air bubble, as shown in Fig. 10, for the system considered by de Jong *et al.*[8] This printhead has an 8 mm actuation channel and a 50 μm trumpet shaped nozzle. A 5–6–3 (5 μs rise time, 6 μs plateau, and 3 μs fall time) trapezoidal pulse is employed, at a voltage of 44 V. The bubble is placed at the nozzle entrance, and has a radius of $R_0=23$ μm.

In the first part the piezo is deformed by the pulse. After $t=15$ μs, the piezo reacts to the pressure fluctuations in the ink channel. As our interest is focused on the acoustical signal from the piezo, the scale on the vertical axis is chosen such that the pressure change in the ink channel and its modification due to the bubble are resolved. The air bubble causes the signal to have a higher amplitude, a faster oscillation, and less high frequency fluctuation.

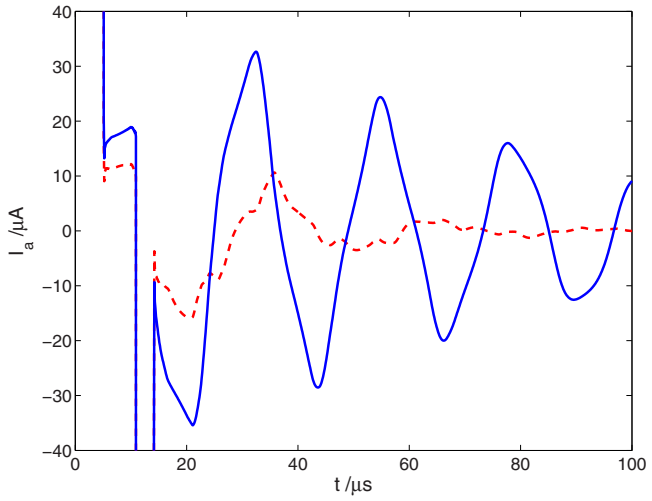

FIG. 10. (Color online) Piezo current with (solid) and without (dashed) an entrained air bubble of 23 μm radius. The printhead has an 8 mm actuation channel, a 50 μm trumpet shaped nozzle and is driven at 44 V with a 5–6–3 (5 μs rise time, 6 μs plateau, and 3 μs fall time) trapezoidal pulse. The signal is divided into two parts: first ($0<t<15$ μs), the piezo is deformed by a 44 V voltage, in the second part ($15<t<100$ μs), the piezo is only deformed by the pressure changes in the ink channel. Without a bubble, the piezo current is small after $t=50$ μs. The bubble however reflects the acoustic waves traveling toward the nozzle. As most damping is caused by the nozzle, the acoustic waves remain in the ink channel for a relatively long time.

V. COMPARISON BETWEEN MODEL AND EXPERIMENT

To compare the experimental data with the bubble model, the experimentally obtained equilibrium radius of the bubble is used in the model. A quantitative comparison can be seen in Fig. 11 for the 120 and the 190 V driving. As mentioned before, only the amplitude of the acoustic pressure for a driving of 190 V is adjusted to the pressure in the experiments so that for a bubble of $R_0=23$ μm the amplitude of the bubble oscillations fits to the experiment: The driving of 190 V in the experiments is found to be a driving of 80 V in the model. The difference in driving is assumed to be caused by the properties of the piezo, in particular the value of α_1. Upon adjusting this absolute size, a good agreement of the shape of the signal can be seen, showing the importance of the confined geometry in our printhead channel. In particular, the relatively small expansion of the bubble compared to its large compression is well captured. After about $t=30$ μs, the model slightly deviates from the experimental data. This is assumed to be due to the absence of thermal damping in the model, which is known to be relevant for bubbles of this size,[20] in particular in closed systems.[24]

The frequency spectrum (fast Fourier transform) is compared in Fig. 12. The bubble radius is $R_0=23$ μm in the experiments and in the model. The main frequency component found in the experiments is 60 kHz, as in the model.

VI. CONCLUSIONS AND OUTLOOK

When an air bubble is entrapped in the ink channel, it grows by rectified diffusion up to some saturation size. The oscillations of this bubble of saturated size are measured and

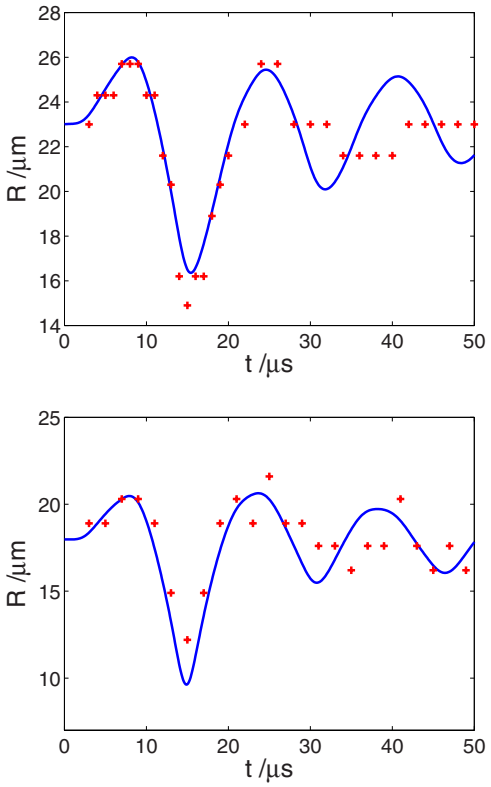

FIG. 11. (Color online) Comparison of the experimental bubble oscillations (crosses) with the numerical model (solid line). The air bubble of $R_0=23$ μm (top) and $R_0=18$ μm (bottom) is driven at 190 V (top) and at 120 V (bottom). The model driven at 80 V (top) and 51 V (bottom) captures the details of the initial expansion and the compression of the bubble. After $t=30$ μs, the model deviates from the bubble oscillations.

modeled. Due to the confined space the bubble acts back on the acoustic waves. This two-way coupling between the bubble and the channel acoustics results in the equilibrium size of the bubble. By employing a glass window the oscillations are measured with high speed imaging. The channel acoustics and bubble dynamics are modeled with a one-

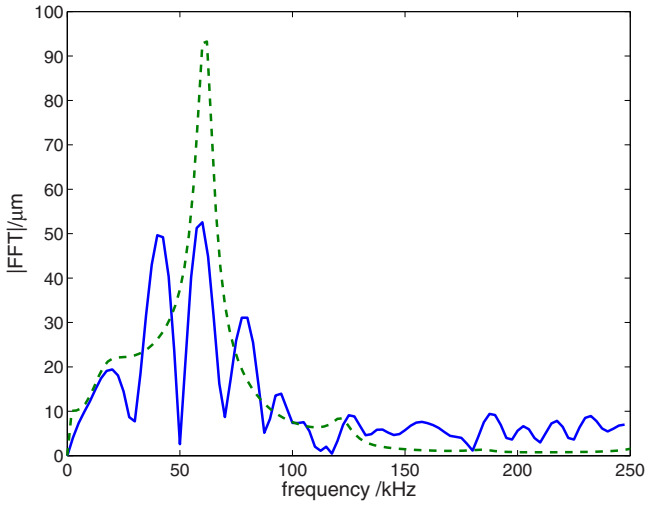

FIG. 12. (Color online) Fast Fourier transform (FFT) of the bubble oscillations in the experiments (dashed) and for the model (solid), for a bubble size of $R=23$ μm radius. The main frequency component at $f=60$ kHz agrees reasonably well.

dimensional model. This model incorporates coupling between the bubble and the ink channel. The bubble itself is modeled with a linearized Rayleigh-Plesset equation. It turns out that the confined geometry and therefore the two-way coupling is crucial. The result is a simple model that can be employed to study air bubble behavior and predict the effect of an entrapped air bubble on the acoustic field in the channel. In this way, air bubbles can be studied for different channel properties, $A_{0,j}$, l_j, α_j, β_j, and acoustic driving protocols.

APPENDIX A: NOZZLE REPRESENTATION

1. Conical nozzle representation

This appendix deals with the representation of the conical nozzle used in the experiments through the cylindrical nozzle that is employed in the model. A sketch of experimental nozzle and its cylindrical representation is shown in Fig. 13.

Two nozzle properties are important: the viscous friction on the walls, and the acoustic properties. The experimental nozzle can be described as a cylinder with an equivalent diameter and length. The equivalent diameter of the model nozzle, $d_4=2R_4$, is chosen equal to the minimum experimental nozzle diameter 30 μm in order to match the viscous friction in the nozzle. Now the correct equivalent length, l_4, has to be determined based on the acoustic properties.

The volume flow rate of ink through the nozzle, Q_n, is defined as

$$\int_{A_n} u_n dA = Q_n = \sum_{k=-\infty}^{\infty} q_n(\omega_k) e^{i\omega_k t}, \tag{A1}$$

where q_n is the amplitude of the volume flow rate through the nozzle.

The pressure can be obtained by integrating the linearized momentum equation over the axial coordinate

$$\partial_t u_j = \frac{-1}{\rho} \partial_x P_j \Rightarrow P_n(x) = P_n(x_3) + \int_{x_3}^{x} i\rho\omega \frac{q_n}{A_n(x)} dx. \tag{A2}$$

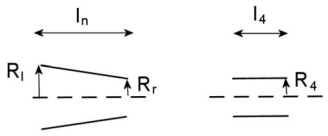

FIG. 13. (Left) Experimental nozzle, $R_l=25$ μm, $R_r=15$ μm, and $l_n=70$ μm. (Right) Cylindrical nozzle representation employed in the model, $R_4=15$ μm, and $l_4=42$ μm.

Transforming P_n to the frequency domain gives

$$P_n = \sum_{k=-\infty}^{\infty} p_n(\omega_k) e^{i\omega_k t}. \tag{A3}$$

After solving for the admittance (the volume flow divided by the pressure see, e.g., Refs. 25 and 26) and imposing zero pressure at the meniscus one gets

$$\frac{q_n}{p_n} = \frac{-1}{i\rho\omega \int_0^{l_n} \frac{1}{A_n(x)} dx}. \tag{A4}$$

Equation (A4) is a general solution depending on the geometry of the nozzle. This equation will now be evaluated for different nozzles and the glass connection channel.

The nozzle radius of the experimental conical nozzle is described by

$$R_n(x) = R_l\left(1 - \frac{x}{l_4}\right) + R_r \frac{x}{l_n}, \tag{A5}$$

where R_l is the entrance radius (25 μm), and R_r is the exit nozzle radius (15 μm). The length of the experimental nozzle is $l_n=70$ μm. Inserting Eq. (A5) into Eq. (A4) results in

$$\begin{aligned} \frac{q_n}{p_n} &= \frac{-\pi}{i\rho\omega \int_0^{l_n} \frac{1}{\left(R_l\left(1 - \frac{x}{l_n}\right) + R_r \frac{x}{l_n}\right)^2} dx} \\ &= \frac{-\pi R_l^2}{i\rho\omega l_n \int_0^1 \frac{1}{\left(1 + \left(\frac{R_r}{R_l} - 1\right)x\right)^2} dx}. \end{aligned} \tag{A6}$$

By evaluating the integral, the admittance of the experimental conical nozzle is obtained as

$$\frac{q_n}{p_n} = \frac{-\pi R_l R_r}{i\rho\omega l_n}. \tag{A7}$$

For the cylindrical nozzle of section 4, the admittance is

$$\frac{q_4}{p_n} = \frac{-\pi (R_4)^2}{i\rho\omega l_4}. \tag{A8}$$

If we now match the admittance of the experimental nozzle and the modeled cylinder, we can calculate the equivalent length l_4 of the nozzle based on the minimum radius, $1/2d_4=R_4=R_r=15$ μm:

$$\frac{q_4}{p_n} = \frac{-\pi (R_4)^2}{i\rho\omega l_4} = \frac{-\pi R_l R_r}{i\rho\omega l_n}. \tag{A9}$$

The equivalent length for the cylindrical nozzle is found to be:

$$l_4 = \frac{R_4^2}{R_l R_r} l_n = 42 \ \mu\text{m}. \tag{A10}$$

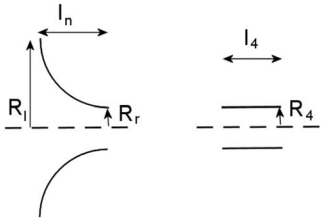

FIG. 14. (Left) Experimental nozzle, R_l=65 μm, R_r=15 μm, and l_n =50 μm. (Right) Cylindrical nozzle representation employed in the model, R_4=15 μm, and l_4=46 μm.

2. Trumpet shaped nozzle representation

The nozzle considered for the calculation of the electric current through the piezo in Fig. 10 is a trumpet shaped nickel nozzle. A sketch of the experimental nozzle and the nickel nozzle is depicted in Fig. 14.

We describe the radius of the trumpet-shape nozzle of Fig. 14 by

$$R_n(x) = R_l - l_n\sqrt{1-\left(1-\frac{x}{l_n}\right)^2}. \tag{A11}$$

The trumpet shaped nozzle is specified by two parameters: the nozzle length l_n=50 μm and the ratio $\lambda = R_l/l_n$ where R_l=65 μm is the entrance radius. The smallest radius is $R_n(l_n)=R_r=R_l-l_n=1/2d_4$=15 μm, and this is the radius at the meniscus. The radius is plotted as a function of x in Fig. 15.

Insert this nozzle shape into Eq. (A4) to obtain the admittance of the trumpet shaped nozzle:

$$\frac{q_n}{p_n} = \frac{-\pi l_n}{i\rho\omega}\frac{2(-1+\lambda^2)^{3/2}}{\pi + 2\arctan\left(\frac{1}{\sqrt{-1+\lambda^2}}\right) + 2\sqrt{-1+\lambda^2}}. \tag{A12}$$

This admittance is equal to the admittance of a cylindrical nozzle whose radius is equal to R_r and whose length is

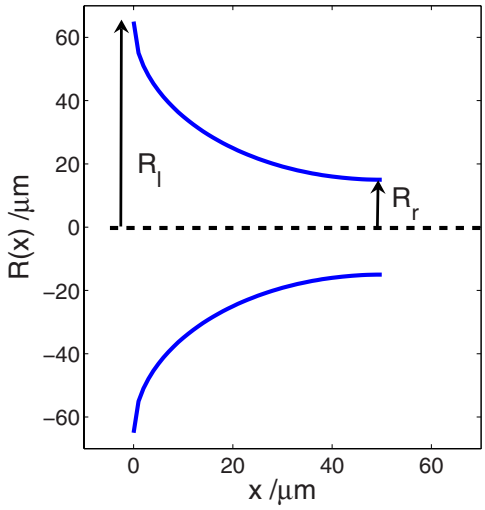

FIG. 15. (Color online) Approximation of the experimental nozzle radius.

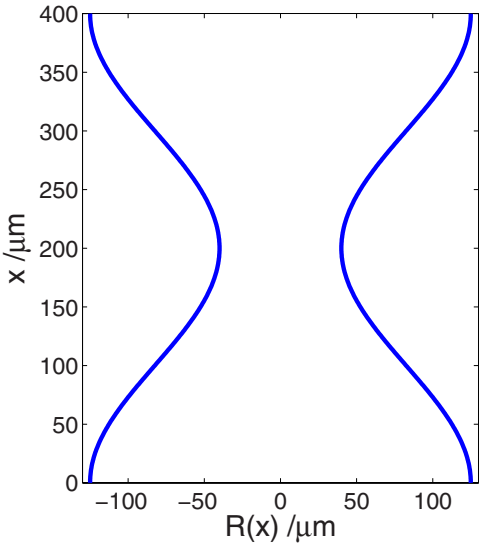

FIG. 16. (Color online) Approximation of the hour glass shape of Fig. 1.

$$l_4 = R_l\frac{1}{1+\sqrt{F}} \tag{A13}$$

with F equal to the second fraction on the right-hand side of Eq. (A12).

Therefore, the equivalent cylinder has a diameter of d_4 =30 μm and a length of l_4=46 μm.

APPENDIX B: GLASS CONNECTION CHANNEL REPRESENTATION

The method used to obtain equivalent cylindrical nozzles is also applied to the glass connection channel. The shape of the connection channel is approximately:

$$R_c(x) = R_{\max} - (R_{\max} - R_{\min})\left(\sin\frac{\pi x}{l_g}\right)^2, \tag{B1}$$

where l_g is the length of the glass connection channel, $R_{\max}$ is the maximum channel radius, and $R_{\min}$ is the minimum channel radius. The approximated shape of Eq. (B1) is plotted in Fig. 16.

Insert the channel cross-sectional area based on this radius into Eq. (A4) to obtain:

$$\frac{q_g}{p_g} = \frac{-\pi R_{\max}^2}{i\omega\rho l_g}\frac{2(1-\kappa)^{3/2}}{2-\kappa}, \tag{B2}$$

where p_g is the amplitude of the pressure drop over the glass connection channel, q_g is the amplitude of the volume flow rate through the glass connection channel, and

$$\kappa = \frac{R_{\max}-R_{\min}}{R_{\max}} = \frac{125\times10^{-6}-40\times10^{-6}}{125\times10^{-6}} = 0.68. \tag{B3}$$

The equivalent cylindrical connection channel with diameter d_3=80 μm has a length of l_3=149 μm. The admittance of the glass connection channel and the conical nozzle can be compared to obtain an estimate of the relative influence of the connection channel. The conical nozzle is approximated by a cylindrical nozzle of d_4=15 μm, and equivalent length of l_4=42 μm. The maximum glass channel

radius is $R_{max}=125\ \mu m$ and the channel length is $l_g=400\ \mu m$. The pressure drop ratio is $p_g/p_n=0.5$. The pressure drop over the connection channel is significant, with respect to the pressure drop over the nozzle.

(Received 14 June 2007; revised 13 November 2007; accepted 31 January 2008)

Plunging surf is a known generator of infrasound, though the mechanisms have not been clearly identified. A model based on collective bubble oscillations created by demise of the initially entrained air pocket is examined. Computed spectra are compared to infrasound data from the island of Kauai during periods of medium, large, and extreme surf. Model results suggest that bubble oscillations generated by plunging waves are plausible generators of infrasound, and that dynamic bubble plume evolution on a temporal scale comparable to the breaking wave period may contribute to the broad spectral lobe of dominant infrasonic energy observed in measured data. Application of an inverse model has potential to characterize breaking wave size distributions, energy, and temporal changes in seafloor morphology based on remotely sensed infrasound.

I. INTRODUCTION

Oceanic ambient noise arises from a diverse set of geophysical, biological, and mechanical sources. This paper focuses on characterization of infrasound (1–20 Hz) produced from ocean waves breaking on coastlines-surf. Wave breaking processes are important contributors to the acoustic ambient field. Above roughly 500 Hz breathing-mode oscillation of individual air bubbles entrained by breaking waves constitute an important underwater sound source,[1] while at frequencies below 500 Hz it has been shown that collective bubble oscillations are significant generators of acoustic power.[2–6] In the infrasonic band known contributors include turbulence, machinery, and wave-wave interactions.[7,8] Analysis of oceanic infrasound by Nichols (1986) led to speculation that breaking waves could be capable sources,[9] followed by McCreery and Duennebier (1993) who postulated that hydroacoustic energy in the 0.5–10 Hz band might be attributed to coastal wave breaking.[10] It has been shown that near surface infrasonic sources can couple with insignificant power loss into the atmosphere,[11] and several studies have verified surf as a persistent and significant source of atmospheric infrasound.[12–15]

The type of breaking wave exerts a large influence on the generation of low frequency sound. Wave tank observations by Loewen and Melville revealed that plunging waves generate low frequency ($f>20$ Hz) energy correlated with breaking, while spilling waves do not.[5] Likewise, measurement of individual coastal breaking waves by Garcés *et al.* found that plunging waves were effective infrasonic sources ($f<20$ Hz), whereas spilling breakers were not.[16] Plunging waves are characterized by an overturning jet (or wall) of water which plunges forward of the wave and completely encloses a pocket of air (the tube, or barrel), while spilling breakers collapse into a bore of foam. Therefore, one can speculate that the unique water jet impact and enclosed vortex generation of plunging waves are candidate mechanisms for infrasound generation.

Even though specific generation mechanisms for surf infrasound have not been clearly identified, the foregoing observations suggest several likely sources: hydraulic impact of the plunging wave jet,[17] oscillations of the plunging wave jet-splash cycle,[18] impulse pressure "bounce back" from hydraulic impacts on elastic bodies (cliffs, reefs, seafloor),[19] multiple coherent vortex structure generation under the wave,[20] breathing-mode oscillation of the initially enclosed air volume,[5] and the collective oscillation of the collapsing bubble plume,[16,21]

Regarding the collective oscillation mechanism as a low frequency source, Carey speculated "If the spatial distribution of bubbles is related to the vorticity distribution, then the noise due to collective oscillations should have frequencies determined by the size of the vorticities".[22] The primary aim of this paper is to investigate the collective bubble oscillation mechanism as a potential generator of infrasound from plunging surf with sufficient energy and spatial scales. A model is developed in which bubble plume distributions are estimated from breaking wave spectra. Plume oscillations and temporal evolution lead to an estimate of acoustic radiation frequency as a function of breaking wave frequency, which is transformed into a relative acoustic amplitude spectrum. Model results are compared to field data and some inferences regarding bubble plume evolutions are presented.

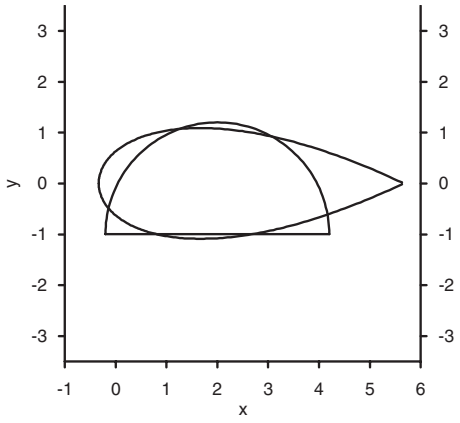

FIG. 1. Longuet-Higgins cubic vortex function compared to a semicylindrical cross section.

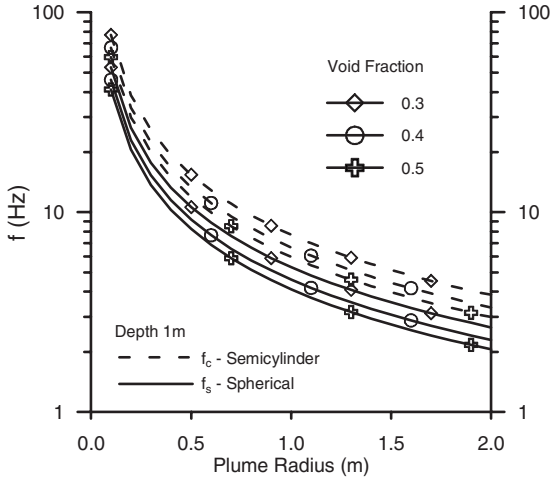

FIG. 2. Lowest eigenfrequency of collective bubble oscillation.

II. LOW FREQUENCY SOUND GENERATION FROM BUBBLE OSCILLATIONS

Wave breaking results in subsurface air entrainment which leads to both individual[5] as well as collective bubble oscillations,[2,4] each capable of generating low frequency acoustic radiation. According to Loewen and Melville, the low frequency sound produced by plunging waves contains two components.[5] The first is detected at the time of breaking and is attributed to "volumetric pulsation of the cylinder of pure air (100% void fraction) entrapped by the plunging wave crest." The second, which initiates some fraction of a wave period, later occurs when "the cylinder of pure air breaks up to form a bubble plume." It was noted by Loewen and Melville that the second component is a "slightly lower frequency signal" than the first.

Field observation and experiments indicate that the cross section of initial air entrainment by plunging waves is typically asymmetric.[5,23,24] Longuet-Higgins expressed the cross-section of the initial air volume in terms of a parametric cubic function with a shape resembling a teardrop (see Fig. 1).[23] Experimental work by Loewen and Melville found it convenient to model the bubble plume as a semicylindrical horizontal tube parallel to the crest of the wave.[5] As a comparison, Fig. 1 plots the Longuet-Higgins vortex function along with a semicylindrical cross section that has a radius the same dimension as the maximum vortex height.

Based on wave tank experiments Loewen and Melville fitted an empirical expression for the lowest eigenfrequency (see Fig. 2) of the semicylindrical horizontal bubble plume[5]

$$f_c \approx \frac{1}{2.5R_B}\sqrt{\frac{P_o}{\beta\rho}}, \tag{1}$$

where the range of approximation encompassed a plume radius R_B less than 1 m, and air volume fraction β less than 0.1. P_o denotes the ambient pressure and ρ the density of water. This expression is similar to that of the lowest eigenfrequency of a spherical cloud of radius R reported by Carey in Ref. 4

$$f_s = \frac{1}{2\pi R}\sqrt{\frac{3\gamma P_o}{\beta\rho}}, \tag{2}$$

where γ is the adiabatic ratio of specific heat. Comparison of Eqs. (1) and (2) reveals that $f_c \approx 1.45 f_s$, indicating that the asymmetric plume has a higher fundamental resonance than the spherical plume.

Using β values in the range measured by Deane,[24] $\gamma = 1$ (isothermal conditions, bubble surface tension is neglected), $P_o = 111{,}145$ Pa (depth 1 m) and $\rho = 1000$ kg/m^3, results of Eqs. (1) and (2) are shown in Fig. 2. These results indicate that for plunging breakers which produce approximately semicylindrical bubble clouds with characteristic radii larger than about 1/2 m, infrasonic generation from collective bubble oscillation is plausible.

III. ACOUSTIC MODEL

The model relies on a breaking wave spectrum to estimate the distribution of bubble plume sizes, which is transformed into an acoustic radiation spectrum. Considering only the entrained air oscillations, the model can be represented with a series of functional transformations applied to the deepwater wave spectrum.

Model input consists of a deepwater ocean wave spectrum $S(\omega)$ (Fig. 3), which can be constructed from wave

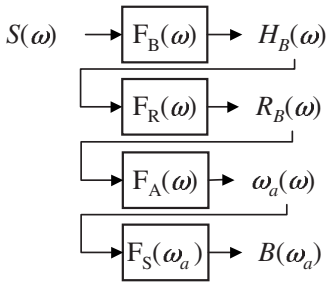

FIG. 3. Schematic of the acoustic transformation model: ω is the deepwater ocean wave frequency, ω_a the acoustic radiation frequency, S the deepwater wave spectrum, H_B the breaking wave height spectrum, R_B the bubble cloud characteristic length distribution and B the amplitude spectrum of acoustic radiation.

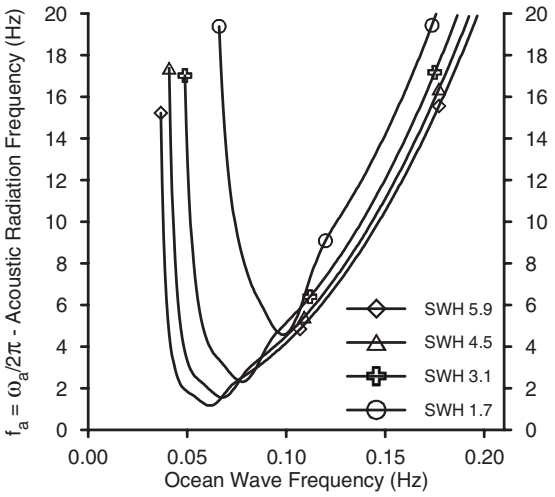

FIG. 4. Radiation frequencies of collective bubble oscillation from Eq. (6) versus the deepwater wave frequency for spectra with SWH of 1.7, 3.1, 4.5 and 5.9 m.

growth models applied to atmospheric weather conditions, or applied directly from observed ocean data buoys. The nonlinear transformation $F_B(\omega)$ produces a breaking wave height spectrum $H_B(\omega)$, which will depend on local bathymetry. $F_B(\omega)$ can be obtained from a breaker height index derived from empirical data,[25] or from a hydrodynamic wave model.[26] The breaking wave spectrum is then converted to a spectrum of bubble cloud characteristic lengths, $R_B(\omega)$, by the function $F_R(\omega)$ which can be modeled from data relating bubble cloud distributions to breaking wave height[27] and temporal evolution of plume dynamics.[6] The bubble cloud dimension is transformed into spectrum of acoustic radiation frequencies, $\omega_a(\omega)$ (see Fig. 4), based on the nonlinear transformation $F_A(\omega)$ which accounts for the radiation characteristics of the bubble plume.[5] Note that the deepwater wave frequency is denoted by ω, while the acoustic radiation frequency is denoted ω_a. Finally, the nonlinear distribution of radiation frequencies is summed and scaled across the acoustic frequency spectrum to estimate the acoustic radiation spectrum $B(\omega_a)$. Figure 3 is a schematic diagram of the model.

A. Breaking wave height spectrum

In the current model we employ the JONSWAP spectrum[28] as the deepwater wave generator, although other suitable distributions can be used. Median values of JONSWAP spectrum parameters were used (peak enhancement factor $\gamma=3.3$, peak width factor $\sigma=0.08$.) Model input consists of wind speed and fetch, from which the deepwater wave spectrum $S(\omega)$ is computed.

The function $F_B(\omega)$ transforms the deepwater wave spectrum into a breaking wave spectrum: $H_B(\omega)=F_B(S(\omega))$. One way to quantify the transition from deepwater-to-breaking wave height is with the breaker height index $h_B=H_B/H_o$ where H_B is the breaking wave height and H_o the deepwater wave height.[25] The breaker height index depends on beach slope and the incident wave steepness H_o/L_o, where L_o is the wavelength, and can be described with a power law of the form

$$h_B = c(H_o/L_o)^{-d} \tag{3}$$

with parameters $c=0.5784$, $d=0.23925$ for a beach slope of 1/10, and $c=0.5403$, $d=0.21618$ for a beach slope of 1/50.

Given a deepwater wave spectrum and slope of the beach where breaking will occur, a breaker height spectrum can be estimated by multiplying the deepwater spectrum with the corresponding breaker height index at each frequency.

$$H_B(\omega) = h_B(\omega) \cdot S(\omega) \tag{4}$$

With an estimate of the breaking wave spectrum at hand, the next step is to relate the breaking wave distribution to bubble cloud dimensions.

B. Bubble plume distribution

Application of Eq. (1) to estimate the acoustic spectrum of collective bubble radiation requires specification of the bubble plume radius, R_B, for each wave of the spectrum. Based on similarity between the Longuet-Higgins vortex function and a semicylinder of comparable scale (Fig. 1), the model assumes that the vortex height H_v, can be used as an approximation to the semicylindrical radius of Eq. (1). We therefore seek a variable, C_H, which scales the breaking wave height into an equivalent vortex height as shown in Eq. (5).

$$R_B(\omega) = H_v(\omega) = C_H \cdot H_B(\omega). \tag{5}$$

Mead and Black quantified ratios of vortex to breaking height at 26 surf locations,[27] from which we compute a mean value of $C_H=0.37$. The model estimate of initially entrained vortex height is therefore specified as: $H_v(\omega)=0.37 \cdot H_B(\omega)$.

C. Bubble radiation

The model assumes that the fundamental frequency f_c specified in Eq. (1) scales to plume dimensions larger than $R_B \approx 1$ m. This assumption is based on the scale invariance observed between Eqs. (1) and (2) in Fig. 2 as R exceeds 1 m. A spectrum of acoustic radiation frequencies associated with each incident breaking wave frequency can then be computed by combination of Eqs. (1) and (5):

$$\omega_a(\omega) = \frac{2\pi}{2.5H_v(\omega)}\sqrt{\frac{P_o}{\beta\rho}}. \tag{6}$$

Equation (6) does not quantify the spectral amplitude of radiation, rather, it defines a mapping between an incident breaking wave frequency and an estimate of the frequency of radiation of the collapsing vortex. Estimates of relative spectral amplitude are addressed in the next section.

To examine the evolution of bubble radiation with changes in wave group energy, Fig. 4 plots radiation frequencies of Eq. (6) for ocean wave spectra with deepwater significant wave heights of 1.7, 3.1, 4.5 and 5.9 m. As ocean wave group energy increases, with a corresponding increase in dominant wavelength and height, the acoustic radiation

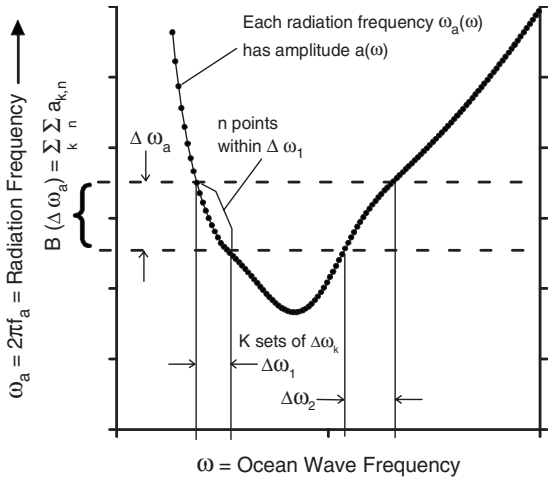

FIG. 5. Schematic of multiple contributions to bubble spectrum ω_a from ocean waves of different frequencies ω.

frequencies deepen into lower values. Thus we expect acoustic radiation spectra to exhibit stronger low frequency energy as incident ocean wave energy increases. One can also observe that the acoustic radiation broadens, covering a wider range of incident wave frequencies. This suggests that as incident wave energy increases, the acoustic radiation spectrum should also broaden around its main energy lobe.

D. Spectral amplitude estimates

The acoustic radiation frequencies of the model are computed from Eq. (6), we seek to transform this spectrum of radiation frequencies (such as shown in Fig. 4 where $\omega_a = 2\pi f_a$) into a spectrum of acoustic radiation amplitude, $B(\omega_a)$. The task is to identify the amplitude coefficient, B, associated with each acoustic radiation frequency ω_a.

It is clear from the nonlinear nature of $\omega_a(\omega)$ in Fig. 4 that bubble oscillations induced from multiple ocean wave frequencies can contribute to a single value of ω_a, and therefore B. This reflects the fact that for a given wave spectra, there can exist two frequencies with the same wave height. To account for these multiple sources, denote the acoustic radiation amplitude coefficient from each of k contributing ocean wave frequency as $a_k(\omega)$. In relation to Fig. 4 there are two contributing ocean waves at most values of ω_a, so that values of k are 1 and 2.

From an engineering perspective, there are a finite number of points in the spectra ω_a and B, and we denote the analysis binwidth of each component of B as $\Delta\omega_a$. Within each $\Delta\omega_a$ we designate the number of points for each of the k components as n. With an assumption of superposition, the discrete value of B within each analysis binwidth is given by

$$B(\Delta\omega_a) = \sum_k \sum_n a_{k,n}. \tag{7}$$

Figure 5 depicts the application of Eq. (7) to a representative radiation frequency spectrum $\omega_a(\omega)$.

Failure of superposition would arise from destructive interference between multiple, independent sources radiating at ω_a. However, the ocean wave periods and temporal persistence of the bubble plumes are an order of magnitude greater than the periods of ω_a. Given detector integration windows which are significantly greater than the wave period, it can be assumed that phase components are uniformly distributed and the amplitudes will be additive.

It is likely that a is a multiparametric function not just dependent on ω, but also a function of wave energy, site-specific wave breaking parameters such as beach slope, and other factors. Ideally, an estimate of the amplitude could be made from a low frequency acoustic model which considers both the bubble oscillation mechanics and the source-receiver transfer functions. For example, in the ocean layer the low frequency bubble oscillation models of Oguz[29] or Means[30] might assess the integrated behavior of the bubble plumes, while an additional aeroacoustic transfer function would be needed to model the atmospheric propagation to the infrasonic sensors. However, application of such models is beyond the scope of the present effort, and, it is useful to assess to what extent a simple first-order model can provide a robust and efficient estimator of breaking wave energy from remotely monitored infrasound. Here we make the assumption that $a(\omega)$ decays according to a simple $1/f$ scaling

$$a_n = A_n / f_{a_n}, \tag{8}$$

where A is a coefficient which can be used to describe the amplitude factors derived from higher order models such as those by Oguz[29] and Means,[30] and which can account for corrections due to the density of points summed in $\Delta\omega_a$. The discrete magnitude coefficients of B are then specified by

$$B(\Delta\omega_a) = \sum_k \sum_n A_{k,n} / f_{a_{k,n}}. \tag{9}$$

In the current model, $A \equiv 1$, and consequently this model is incapable of predicting absolute spectrum levels, it is limited to characterization of cutoff frequencies and spectral shape.

E. Bubble plume evolution

Bubble plumes from breaking ocean waves are known to persist for time scales on the order of seconds to tens of seconds. Given the dynamic environment in which the plumes are formed, and the unbalanced nature of the forces, plumes can evolve significantly within relatively short time scales (fractions of wave period). Two of the primary changes are a decrease in plume entrained air fraction, β, and an increase in plume cross-sectional area. Other important features include the horizontal and vertical velocities of the plume.

Lamarre and Melville[6] quantified plume dynamics in wavetank measurements and reported statistical moments of plume evolution. The mean void fraction as a function of time exhibited a nearly linear decrease for approximately one-half wave period after breaking. Based on their results, we have applied the following relationship to model the void fraction evolution:

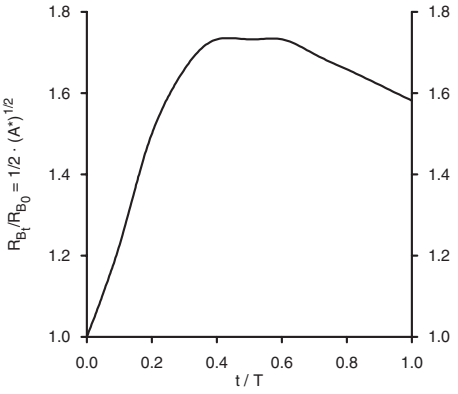

FIG. 6. Approximate evolution of plume cross-sectional area.

$$\beta(t) = \beta(0) - \frac{0.56t}{T};\ t \leqslant \frac{T}{2}, \tag{10}$$

where T is the wave period and $\beta(0)$ the initial air void fraction.

The bubble plume cross-sectional area normalized by the initial volume per unit width $(A*)$ was also reported as a function of time. It exhibited a nearly linear increase for the first several tenths of wave period after breaking, then tended to flatten out, and eventually decrease after times comparable to a wave period. There was considerable scatter in the data for times greater than about 0.2 T.

Equation (5) defines the initial bubble plume radius $R_B(\omega,t=0)$ as a function of breaking wave height. To model the evolution of plume radius, R_B is modulated with the relative radius length scale $\sqrt{A*}/2$

$$R_B(\omega,t) = \frac{\sqrt{A*(t)}}{2} R_B(\omega,t=0). \tag{11}$$

Values of $R_B(\omega,t)$ are then applied in Eq. (6) as the vortex height H_v to model time-varying plume growth. Figure 6 plots the evolution of the relative plume radius $\sqrt{A*}/2$, where values of $A*$ were taken from Ref. 6.

IV. KAUAI DATA

Figure 7 plots atmospheric infrasound recorded at a nearshore inland location on the island of Kauai during periods of moderate, high and extreme surf over the period March 4–March 10, 2005.[12] The spectra are parameterized in terms of significant wave height (SWH) measured from seafloor mounted pressure sensors offshore the surf zone. As the SWH increases there is a general increase in sound level, a shift to lower frequencies of the dominant energy, and a broadening of the dominant energy lobe. These observations are consistent with expectations of spectral evolution suggested by the computed radiation frequency spectra of Fig. 4.

Signal processing of the raw infrasound data collected at Kauai used an integration window of $\tau=3600$ s to estimate the spectral levels presented in Fig. 7. Since the model is based on transformation of radiation frequencies derived from a complete breaking wave distribution, model predictions are relevant only if the data window has sufficient length to sample a significant proportion of wavenumbers

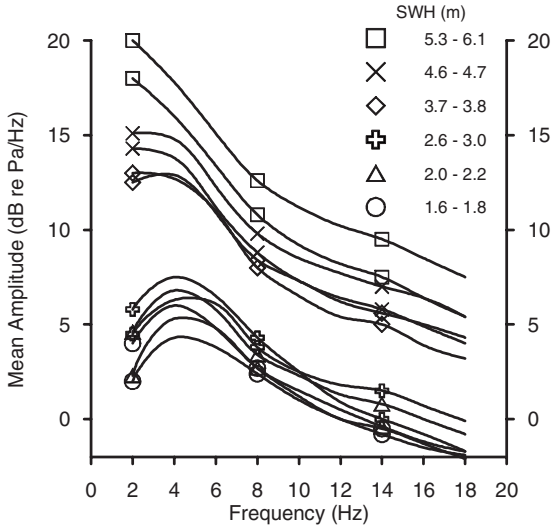

FIG. 7. Atmospheric infrasound from waves breaking at Polihale, Kauai.

represented in the breaking wave distribution. Most of the energy in the ocean wave spectra are contained in the 0.05–0.1 Hz bands, with dominant frequencies in the range 0.06–0.09 Hz corresponding to periods of 11–17 s. The long integration windows of the Kauai data allow for over 150 events with a period of 20 s, and therefore are deemed appropriate for model comparison.

V. MODEL RESULTS

This section presents comparisons of model results with measured data. Parameters used in model runs are as follows:

1. Slope of the breaking wave seafloor $m=0.06$.
2. Initial plume void fraction $\beta_0=0.35$, consistent with measured values by Deane.[24]
3. Initial vortex breaking height ratio $C_H=0.37$, from Sec. III B, Eq. (5).
4. Radiation spectrum (f_a) amplitude analysis binwidth $\Delta\omega_a=0.5$ Hz.

In default mode the model assumes that bubble plumes are static, there is a single bubble distribution that is summed in Eq. (9) to estimate the spectral shape. The model is capable of including contributions from additional bubble distributions according the evolution Eqs. (10) and (11). With this dynamic plume option, the void fraction values are decreased according to Eq. (10), and the plume effective radius is increased according to Eq. (11). Contributions for additional plumes in Eq. (9) are evaluated at fractional wave periods $t/T=0.1,0.2,0.3,0.4,0.5$.

Figure 8 plots results of Eq. (9) corresponding to deep-water significant wave heights of 1.8, 2.1, 2.4, 2.8, 3.7 and 4.6 m. Since the model computes only relative spectral levels, a bias term has been added to each computed spectrum to match the 10 Hz value of observed data.

Concerning the medium to large scale surf (SWH 1.8–2.4 m) represented in Fig. 8, characterization of the dominant infrasonic frequency is reasonable. This indicates that the presumed bubble oscillation mechanism is a candi-

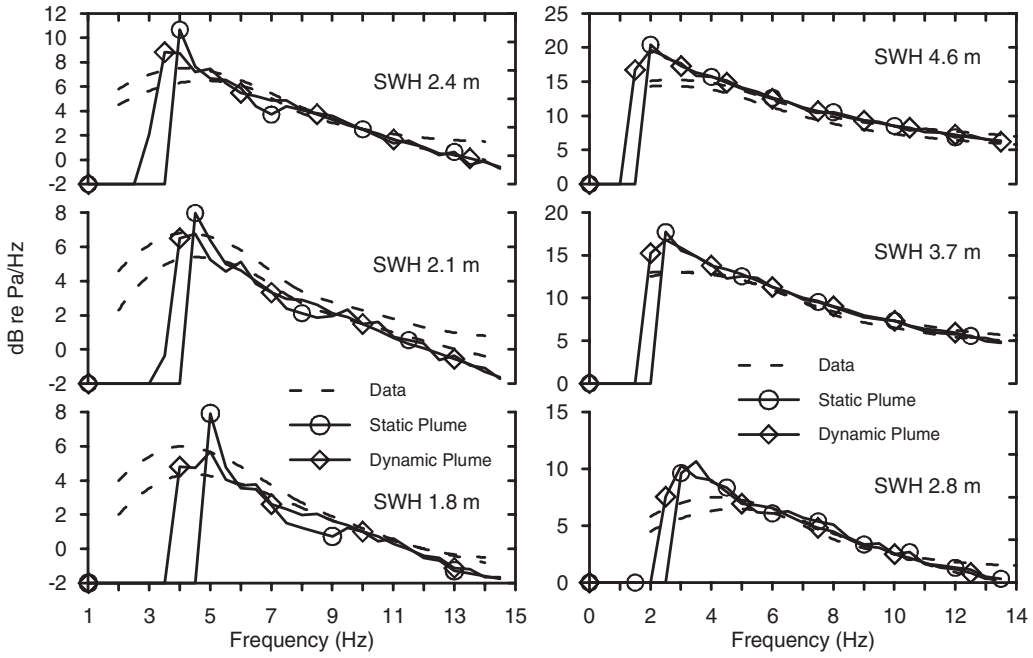

FIG. 8. Modeled infrasound spectra for ocean wave spectra with SWH of 1.8, 2.1, 2.4, 2.8, 3.7, 4.6 m compared to Kauai data.

date mechanism for generation of surf infrasound. It is also observed that the dynamic plume approximation has a broader main lobe, and lower cutoff frequency than the static plume, which is consistent with a larger sample of plume distributions that grow in size as the plume evolves. This result suggests that dynamic plume evolution is a significant factor contributing to the broad spectral lobes of dominant energy observed in field data.

Model results for the large and extreme surf conditions (SWH $>$ 2.5 m) estimate spectral shapes similar to the data, again with a slightly broader, lower frequency main energy lobe with the dynamic plume approximation. Prominence of the main energy lobe diverging from the spectral shape of the observed data may indicate that at these large spatial scales and energies the collective bubble oscillation mechanism is not a dominant contributor to infrasound generation. In this regime, the impact mechanisms may play a larger role.

VI. DISCUSSION

It has been recognized that remotely sensed infrasound has potential to provide "useful insight into coastal processes and permit an assessment of wave energy distribution in the littoral zone".[31] Indeed, Aucan *et al.* demonstrated that the bandpassed time series envelope of atmospheric infrasound generated by plunging surf can be used to estimate the dominant breaking wave period.[32] As an extension, we propose that based on an infrasound model such as that described above, an inverse model could be used to estimate a breaking wave height spectrum $H_B(\omega)$ from a measured infrasound spectrum $B(\omega_a)$.

Not only can an estimate of $H_B(\omega)$ be obtained, but one should also be able to estimate the bubble plume size distribution $R_B(\omega)$. Lamarre and Melville[33] found that dissipation of breaking ocean wave energy by air entrainment against buoyancy can account for up to 50% of the dissipated energy. Therefore, with an estimate of the initial wave energy spectrum and the entrained air volumes, the wave energy dissipated in breaking might be estimated. The residual could provide an estimate of the wave energy available for runup on the shore.

Another potential assessment of littoral dynamics is long term monitoring of surf zone bathymetric changes. Since bathymetry is a key variable in determination of the breaking wave spectrum, it is conceivable that parametric model fits to long term infrasonic monitoring could characterize seafloor morphology over times cales of days to months.

VII. CONCLUSION

A simple, functional transformation model of infrasound generated by collective bubble oscillations from collapsing air pockets entrained by plunging surf has been developed. The model is limited to estimation of relative spectral shape and cutoff frequencies since the amplitude coefficients of radiating spectral components are not quantified. Application of low frequency models which characterize the amplitude distributions, and source-receiver transfer functions[29,30] have potential to remove this limitation. Nonetheless, the model captures the observed characteristics of surf infrasound which include migration of dominant infrasonic energy to lower frequencies as ocean wave energy increases, and a broadening of the infrasonic energy distribution across the main lobe.

The model matches dominant infrasound frequencies and spectral shape reasonably well for medium to large scale surf, which may indicate that collective bubble oscillations are effective generators of surf infrasound. Further, it is suggested that dynamic plume evolution between breaking events is crucial to produce the observed broad spectral lobe around the dominant frequency of infrasonic energy. At the large and extreme scales of wave breaking, for example

when breaking wave heights exceed roughly 5 m, the model overestimates the relative amplitude of the lowest frequency components of the infrasound. This may indicate that at these larger spatial scales and energies the collective bubble oscillation mechanism is less important. In this regime hydrodynamic sources such as jet impact, vortex generation, impulse pressure bounce back, impact reverberations, as well as the massive bores of foam which persist shoreward of the plunging surf zone are potential contributors.

Estimation of acoustic radiation spectra from deepwater ocean wave spectra (forward model) constitutes a nonlinear transformation. Inversion of this model, for example with a neural network or other nonlinear state estimator, has potential to characterize surf-zone hydraulic and geomorphic dynamics based on remote infrasound sensing. In particular, it is suggested that the breaking wave height distribution, wave energy dissipation, wave energy runup potential, and long term bathymetric dynamics could be assessed.

ACKNOWLEDGMENT

The authors thank Dr. Robert M. Kennedy for his thoughtful review of the manuscript and suggestions which served to improve the paper.

(Received 30 October 2007; revised 11 February 2008; accepted 24 February 2008)

The multilevel fast multipole algorithm (MLFMA) is extended to solve for acoustic wave scattering by very large objects with three-dimensional arbitrary shapes. Although the fast multipole method as the prototype of MLFMA was introduced to acoustics early, it has not been used to study acoustic problems with millions of unknowns. In this work, the MLFMA is applied to analyze the acoustic behavior for very large truncated ground with many trenches in order to investigate the approach for mitigating gun blast noise at proving grounds. The implementation of the MLFMA is based on the Nyström method to create matrix equations for the acoustic boundary integral equation. As the Nyström method has a simpler mechanism in the generation of far-interaction terms, which MLFMA acts on, the resulting scheme is more efficient than those based on the method of moments and the boundary element method (BEM). For near-interaction terms, the singular or near-singular integrals are evaluated using a robust technique, which differs from that in BEM. Due to the enhanced efficiency, the MLFMA can rapidly solve acoustic wave scattering problems with more than two million unknowns on workstations without involving parallel algorithms. Numerical examples are used to demonstrate the performance of the MLFMA with report of consumed CPU time and memory usage. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2897048]

I. INTRODUCTION

Fast multipole method (FMM) was introduced by Rokhlin to rapidly calculate Coulombic potentials for a large-scale particle system.[1] Later on, it was generalized by Greengard[2] to seek fast numerical solutions for two-dimensional and three-dimensional (3D) Laplace equations in particle simulations. This method was mainly applied to particle simulations in astrophysics and molecular dynamics at the beginning.[3,4] Later, it was extended to acoustic wave problem that follows from Helmholtz equation.[5] In electromagnetics (EM), it received intensive studies, and was extended to a multilevel scheme, known as multilevel fast multipole algorithm (MLFMA), in 1994.[6–8] The most distinctive feature of the method is the rapid evaluation of the matrix-vector multiply useful in an iterative method for solving a matrix equation. Also, the matrix elements are never explicitly stored except for those near-interaction entries, leading to a matrix-free scheme, where the memory requirement is dramatically reduced. In the iterative methods, the speed bottleneck is the matrix-vector multiply, which requires $\mathcal{O}(N^2)$ costs, where N is the number of unknowns in the matrix equation.

MLFMA wisely decomposes each element of the matrix, which represents the far interaction between a source point and a field point, into radiation pattern, translator, and receiving pattern. The matrix-vector multiply is then performed in three stages within a multilevel tree structure. The decomposition of a matrix element, which is the matrix representation of the Green's function, is based on the addition theorem.[9] The radiation pattern, translator, and receiving pattern can be constructed in advance and stored with much less memory. Due to the use of the multilevel tree structure, the diagonalization of the translation operator, and the interpolation or anterpolation for wave expansions at different levels, MLFMA can reduce the original $\mathcal{O}(N^2)$ complexity, both in CPU time and in memory usage, to a $\mathcal{O}(N \log N)$ complexity. This is a significant difference in computational costs when N is very large.

MLFMA has been widely used in solving EM integral equations.[10] With the help of supercomputers, the very large problems with 10–30 million unknowns have been solved.[11–14] Although FMM dealt with acoustic wave problems very early,[5] the development of the method in acoustics has been relatively slow,[15–19] compared with that in EM. Recently, there is a growing interest in the acoustic applications of MLFMA.[20–25] In Refs. 20 and 21, the authors considered scattering by multiple spheres based on the spherical harmonic expansion for the scattered fields. As semianalytical formulas instead of boundary integral equation (BIE) are used, the generation of matrix elements is simple. The scheme is not suitable for solving the scattering by arbitrarily shaped objects, although it has been demonstrated to solve

[a]Electronic mail: meisongt@uiuc.edu
[b]Currently on leave from UIUC to serve at The University of Hong Kong.

problems involving up to 10^4 spheres (about one million unknowns). In fact, the scheme is different from the BIE-based MLFMA, which we developed in this work. In Refs. 22–25, however, MLFMA together with BIE is applied to solve for acoustic scattering by 3D arbitrarily shaped scatterers, but the implementation is based on BEM.

We modify MLFMA for solving acoustic wave scattering by very large objects with 3D arbitrary shapes. In the studies for mitigating gun blast noise at proving grounds, we design a trench structure in the ground to block the propagation of sound wave. The simulation for acoustic wave scattering by such a structure requires solving a very large matrix equation resulting from acoustic BIE. MLFMA is then used to accelerate the solution process and fast solutions for problems with millions of unknowns can be obtained on workstations without involving parallel algorithms. Unlike the work in Refs. 21–25, our MLFMA is based on the Nyström method to form matrix elements. This is also different from the MLFMA implementation in EM, which is mainly based on the method of moments (MOM) with Rao-Wilton-Glisson (RWG) basis[26] to create matrix entries.

The Nyström method is an efficient numerical tool in solving integral equations.[27] Initially, this method was designed for solving integral equations with regular kernels. In recent years, it has been used to solve for the integral equations derived from Helmholtz equations for wave radiation and propagation problems.[28–31] Such integral equations include singular integral kernels related to the Green's function and special treatments are needed for self and near interaction terms. The Nyström method uses a collocation or point-matching process and wisely selects the quadrature points of a quadrature rule as the source points and observation points to transform an integral equation into a matrix equation. The matrix elements for far interactions are simply the direct evaluation of integrands. Due to its elegance, the Nyström method is simpler than MOM and BEM in incorporating MLFMA—this is also the first time that Nyström method is used with our version of MLFMA. However, the Nyström method usually has a lower accuracy than MOM for the same discretization of geometry with the same density of unknowns and the number of unknowns will dramatically increase if improving the accuracy by using a higher-order quadrature rule. For the near interaction terms of matrix in the MLFMA implementation, the original Nyström method is recalled and we derive very simple and efficient formulas for the singular or near-singular integrations of the acoustic BIE kernel. This technique is different from the regularization of singularity in BEM. Numerical examples from the simulation for mitigating gun blast noise show that the proposed MLFMA has a robust performance in solving for the acoustic wave scattering by very large and complex structures. A typical problem with one million unknowns can be solved within two days on a Dell Precision 690 machine using 5 GB memory. This machine has two dual-core 3.0 GHz CPU with 16 GB RAM, but we only employ one of CPU's as the series algorithm is utilized. All calculations in this work are realized on it.

II. IMPLEMENTATION OF MLFMA FOR ACOUSTIC BIE

MLFMA is described in the Appendix which factorizes Green's function, and hence, the matrix element that describes the interaction between a source point and a field point. In this section, we will describe the use of MLFMA for expediting the solution of the acoustic BIE.

A. Acoustic BIE

For EM wave scattering, the governing equation is a vector integral equation with the vector current as the unknown function, and MOM with RWG basis may be the appropriate method incorporating MLFMA. In contrast, acoustic wave scattering is represented by a scalar BIE,[32] i.e.

$$p^i(\mathbf{r}) + \int_S \left[\frac{\partial g(\mathbf{r},\mathbf{r}')}{\partial n'} p(\mathbf{r}') - g(\mathbf{r},\mathbf{r}') \frac{\partial p(\mathbf{r}')}{\partial n'} \right] dS' = \frac{1}{2} p(\mathbf{r}), \quad \mathbf{r} \in S, \tag{1}$$

where p is the pressure field, $g(\mathbf{r},\mathbf{r}')=e^{ikR}/(4\pi R)$ is the 3D Green's function, which is the same as that in EM, and $\hat{n}'$ is the outward unit normal vector on the surface S of a scatterer. The superscript i on p denotes the incident wave and $R=|\mathbf{r}-\mathbf{r}'|$ represents the distance between a field point (or observation point) $\mathbf{r}$ and a source point $\mathbf{r}'$. If we incorporate the impedance boundary condition[33]

$$\frac{\partial p(\mathbf{r}')}{\partial n'} - \eta p(\mathbf{r}') = 0, \tag{2}$$

where $\eta=i\omega\rho/z_s$ and z_s is the surface impedance, the previous BIE becomes

$$\frac{1}{2} p(\mathbf{r}) - \int_S G_0(\mathbf{r},\mathbf{r}') p(\mathbf{r}') dS' = p^i(\mathbf{r}), \quad \mathbf{r} \in S, \tag{3}$$

where $G_0=(\hat{n}'\cdot\nabla'-\eta)g(\mathbf{r},\mathbf{r}')$. Note that the previous BIE may have the possible internal resonance problem which refers to the nonuniqueness of the solution when the frequency of incident wave coincides with the resonance frequency of a cavity with the same shape as that of the scatter.[34] This problem can only be removed completely by using different BIEs, such as the combined Helmholtz integral equation formulation[35] or the Burton and Miller formulation.[36] We do not meet the internal resonance problem even using the BIE (1) in the solution because our iteration process converges normally. If the resonant frequency is approached or touched, the system matrix will be near-singular or singular and the iteration, which is very sensitive to the conditioning of the matrix, will tend to be divergent.

B. Radiation and receiving patterns

Due to the scalar property of the previous acoustic BIE, BEM, or the Nyström method may be more appropriate than MOM to combine with MLFMA in order to accelerate the solution. If the Nyström method with a one-point quadrature rule is used (the higher-order quadrature rules can be used,

but the number of unknowns will dramatically increases), the corresponding terms in the matrix equation in Eq. (A1) will be

$$A_{ji} = -\int_{\Delta S_i} dS' G_0(\mathbf{r}_j, \mathbf{r}'),$$

$$b_j = p^i(\mathbf{r}_j) \tag{4}$$

and a_i is the unknown pressure field at the centroid of the ith triangle patch ΔS_i. We do not include the identity or constant term (1/2) of the BIE in A_{ji} here because it belongs to the near terms (diagonal terms) and the matrix element here only represents the far interaction between a field point and a source point, which MLFMA works on. Using Eq. (A2) for the factorization of the Green's function, the integral kernel can be written as

$$G_0(\mathbf{r}_j - \mathbf{r}_i) = \frac{1}{4\pi}\int d^2\hat{k}(-\hat{n}' \cdot i\mathbf{k} - \eta) e^{i\mathbf{k}\cdot(\mathbf{r}_{jm} - \mathbf{r}_{im'})} \cdot \alpha_{mm'}(\mathbf{k}, \mathbf{r}_{mm'}). \tag{5}$$

With the previous kernel, the radiation and receiving patterns are

$$V_{sm'i}(\hat{k}) = \int_{\Delta S_i} dS' e^{-i\mathbf{k}\cdot(\mathbf{r}' - \mathbf{r}_{m'})}(-\hat{n}' \cdot i\mathbf{k} - \eta), \quad \mathbf{r}' \in \Delta S_i,$$

$$V_{fmj}(\hat{k}) = \frac{1}{4\pi} e^{i\mathbf{k}\cdot\mathbf{r}_{jm}} \tag{6}$$

and the translator is the same as Eq. (A3). We will implement Eq. (A2) based on Eq. (6) for far interactions and the solution process will be accelerated dramatically. The far interaction or well-separated interaction is defined as the interaction between a field point $\mathbf{r}_j$ and a source point $\mathbf{r}_i$ whose separation is at least one box at the same level.[10]

The previous integral over $\hat{k}$ is evaluated by the Gaussian quadrature rule with $Q=2L^2$ points, where L is the truncated number of the summation series in the translator in Eq. (A3). The use of the quadrature rule results in

$$A_{ji} = -\sum_{q=1}^{Q} V_{fjm}(\hat{k}_q) \cdot \alpha_{mm'}(\mathbf{k}_q, \mathbf{r}_{mm'}) \cdot V_{sm'i}(\hat{k}_q) = \mathbf{V}_{jm} \cdot \bar{\alpha}_{mm'} \cdot \mathbf{V}_{m'i}, \tag{7}$$

where

$$\mathbf{V}_{jm} = [w_1 V_{fjm}(\hat{k}_1), w_2 V_{fjm}(\hat{k}_2), \ldots, w_Q V_{fjm}(\hat{k}_Q)],$$

$$\bar{\alpha}_{mm'} = \mathrm{diag}\{\alpha_{mm'}(\mathbf{k}_1, \mathbf{r}_{mm'}), \alpha_{mm'}(\mathbf{k}_2, \mathbf{r}_{mm'}), \ldots, \alpha_{mm'}(\mathbf{k}_Q, \mathbf{r}_{mm'})\},$$

$$\mathbf{V}_{m'i} = [V_{sm'i}(\hat{k}_1), V_{sm'i}(\hat{k}_2), \ldots, V_{sm'i}(\hat{k}_Q)]^T, \tag{8}$$

and $w_1, w_2, \ldots, w_Q$ are the weights of the quadrature rule. We will store the previous vectors and matrix with an efficient manner in the preprocessing stage and they are used in each matrix-vector multiply in the iterative process.

C. Nyström method

In solving the boundary integral equation, we need to transform it into an algebraic matrix equation first. If the integral kernel is regular, the Nyström method directly replaces the numerical integration over a small patch with a summation under an appropriate quadrature rule, i.e.,

$$\int_{\Delta S} f(\mathbf{r}, \mathbf{r}') u(\mathbf{r}') dS' = \sum_{j=1}^{P} w_j f(\mathbf{r}, \mathbf{r}'_j) u(\mathbf{r}'_j), \tag{9}$$

where ΔS is the small patch, $f(\mathbf{r}, \mathbf{r}')$ is the integral kernel, $u(\mathbf{r}')$ is the unknown function, P is the number of quadrature points and w_j is the weights of the quadrature rule. The small patch usually represents a flat triangle in the discretization of the geometry and the quadrature rule has different choices.[37] This direct replacement will result in a very simple process to generate matrix elements when a collocation procedure is performed on the field point $\mathbf{r}$. The process is just the direct evaluation of the integrand multiplied by the weights at quadrature points and the unknown coefficients are chosen as the values of unknown function at quadrature points.

However, in wave physics, the integral kernel is related to Green's function which is not regular in the self and near interactions and a special treatment or local correction is needed.[28–30] We develop a very simple and efficient local correction scheme for EM[31,38] that can also be used for acoustic problems. We will implement the scheme to generate those self and near interaction terms in MLFMA.

D. Near terms

The near terms in MLFMA are calculated by the original numerical methods on which the solution of BIE is based without MLFMA acceleration. One usually employs MOM with RWG basis in EM and utilizes BEM in acoustics. Here we use the Nyström method to generate the near terms. The near terms include the self-interaction terms in which the source point and field point reside in the same triangle patch, and the near-interaction terms in which the source point and field point are located at different but nearby triangle patches. The acoustic BIE includes two kernels which are the Green's function itself and its gradient. The integral related to the Green's function itself has a week singularity which can be easily handled[38,39] and we will not deal with it here. The integral with the gradient of the Green's function has a $1/R^2$ singularity on which the special care should be taken. In a Cartesian coordinate system, the gradient of the Green's function becomes

$$\nabla g(\mathbf{r}, \mathbf{r}') = g_x\hat{x} + g_y\hat{y} + g_z\hat{z} = c_0(x - x')\hat{x} + c_0(y - y')\hat{y} + c_0(z - z')\hat{z}, \tag{10}$$

where

$$c_0 = \frac{(ikR - 1)}{4\pi R^3} e^{ikR}. \tag{11}$$

In Eq. (10), (x, y, z) and (x', y', z') are the coordinates of the field point and the source point on a triangle patch. If we create a local coordinate system on the source triangle patch plane whose origin is the projection of the field point on the

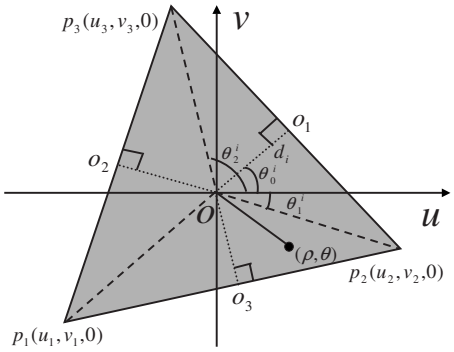

FIG. 1. Local coordinate system on a triangle patch plane.

plane, as shown in Fig. 1, then the three components of the gradient can be written as

$$g_u = c_0(-u); \quad g_v = c_0(-v); \quad g_w = c_0 w_0, \tag{12}$$

where $R=\sqrt{u^2+v^2+w_0^2}$. The source point is located at $(u,v,0)$ on the triangle patch and the field point is located at $(0,0,w_0)$ in the local coordinate system now. If we expand the exponential term in the Green's function into a series form

$$e^{ikR} = \sum_{m=0}^{\infty} \frac{(ik)^m}{m!} R^m \approx \sum_{m=0}^{M} \frac{(ik)^m}{m!} R^m, \tag{13}$$

which converges very rapidly (M is small) for near and self interaction terms as R is small, then the most singular integrals included in those three components of gradient will be

$$I_1 = \int_{\Delta S} \frac{u}{R^3} dS; \quad I_2 = \int_{\Delta S} \frac{v}{R^3} dS; \quad I_3 = \int_{\Delta S} \frac{w_0}{R^3} dS. \tag{14}$$

Other integrals are either regular or with a weak singular kernel of $1/R$ which are easily handled. By referring to Fig. 1, which includes a polar coordinate system (ρ,θ) for a source point on the triangle patch and $R=\sqrt{\rho^2+w_0^2}$, the first integral above can be written as

$$\begin{aligned} I_1 &= \int_{\Delta S} \frac{u}{R^3} dS = \sum_{i=1}^{3} \int_{\theta_1^i}^{\theta_2^i} d\theta \cos\theta \int_0^{d_\theta^i} \frac{\rho^2 d\rho}{(\rho^2+w_0^2)^{3/2}} \\ &= \sum_{i=1}^{3} \left[\int_{\theta_{10}^i}^{\theta_{20}^i} d\phi \frac{-d_i \cos(\phi+\theta_0^i)}{\sqrt{d_i^2 + w_0^2 \cos^2\phi}} + \int_{\theta_{10}^i}^{\theta_{20}^i} d\phi \cos(\phi \right. \\ &\quad + \theta_0^i) \ln(d_i + \sqrt{d_i^2 + w_0^2 \cos^2\phi}) - \int_{\theta_{10}^i}^{\theta_{20}^i} d\phi \cos(\phi \\ &\quad \left. + \theta_0^i) \ln(\cos\phi) \right] = \sum_{i=1}^{3} (I_{1a}^i + I_{1b}^i + I_{1c}^i), \end{aligned} \tag{15}$$

where $d_\theta^i = d_i/\cos(\theta-\theta_0^i)$, $\theta_{10}^i = \theta_1^i - \theta_0^i$, $\theta_{20}^i = \theta_2^i - \theta_0^i$. The first and third integrals above can be found analytically,[40] i.e.

$$\begin{aligned} I_{1a}^i &= -\frac{d_i}{w_0} \{\cos\theta_0^i [\arcsin(s_0 a_2^i) - \arcsin(s_0 a_1^i)] \\ &\quad + \sin\theta_0^i [\ln(w_0 b_2^i + \sqrt{d_i^2 + (w_0 b_2^i)^2}) \\ &\quad - \ln(w_0 b_1^i + \sqrt{d_i^2 + (w_0 b_1^i)^2})]\}, \end{aligned}$$

$$\begin{aligned} I_{1c}^i &= t_0[(1+a_2^i)\ln(1+a_2^i) - (1+a_1^i)\ln(1+a_1^i) \\ &\quad - (1-a_2^i)\ln(1-a_2^i) + (1-a_1^i)\ln(1-a_1^i) - 2(a_2^i \\ &\quad - a_1^i)] + \sin\theta_0^i [b_2^i \ln(b_2^i) - b_1^i \ln(b_1^i) - b_2^i + b_1^i], \end{aligned} \tag{16}$$

where $t_0=0.5\cos\theta_0^i$, $s_0=w_0/\sqrt{d_i^2+w_0^2}$, $a_1^i=\sin\theta_{10}^i$, $a_2^i=\sin\theta_{20}^i$, $b_1^i=\cos\theta_{10}^i$, and $b_2^i=\cos\theta_{20}^i$. The second integral I_{1b}^i is never singular no matter how the field point is close to the triangle patch, so it can be integrated numerically. We can use a similar way to handle I_2. For I_3, it is easy to show that

$$\begin{aligned} I_3 &= \int_{\Delta S} \frac{w_0}{R^3} dS = w_0 \sum_{i=1}^{3} \int_{\theta_1^i}^{\theta_2^i} d\theta \int_0^{d_\theta^i} \frac{\rho d\rho}{(\rho^2+w_0^2)^{3/2}} \\ &= t_1 \sum_{i=1}^{3} [\theta_2^i - \theta_1^i - \arcsin(s_0 a_2^i) + \arcsin(s_0 a_1^i)], \end{aligned} \tag{17}$$

where $t_1=\text{sign}(w_0)$. When the field point is inside the triangle patch, we can take a limit of $w_0 \to 0$ to obtain

$$I_1 = \sum_{i=1}^{3} [(\sin\theta_2^i - \sin\theta_1^i)\ln(d_i) - I_A \cos\theta_0^i + I_B \sin\theta_0^i],$$

$$I_2 = \sum_{i=1}^{3} [(\cos\theta_1^i - \cos\theta_2^i)\ln(d_i) - I_B \cos\theta_0^i - I_A \sin\theta_0^i],$$

$$I_3 = 0, \tag{18}$$

where

$$\begin{aligned} I_A &= 0.5\{(1+a_2^i)[\ln(1+a_2^i) - 1] - (1+a_1^i)[\ln(1+a_1^i) \\ &\quad - 1] - (1-a_2^i)[\ln(1-a_2^i) - 1] + (1-a_1^i)[\ln(1-a_1^i) \\ &\quad - 1]\}, \end{aligned}$$

$$I_B = b_2^i[1 - \ln(b_2^i)] - b_1^i[1 - \ln(b_1^i)]. \tag{19}$$

The formulas in Eq. (18) may not be necessary as the dot product of the unit normal vector with the gradient of the Green's function on a self-patch will vanish. We present these formulas for completeness, and also they may be useful for underwater acoustics in which a different BIE is employed.

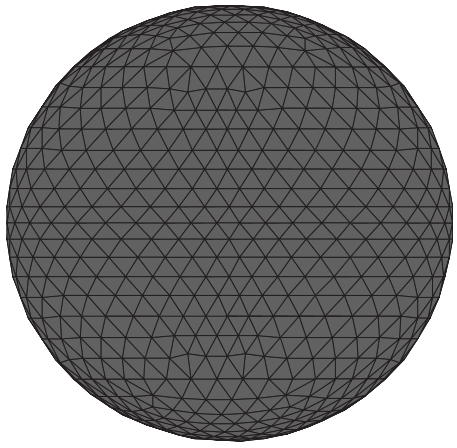

FIG. 2. A meshed sphere surface.

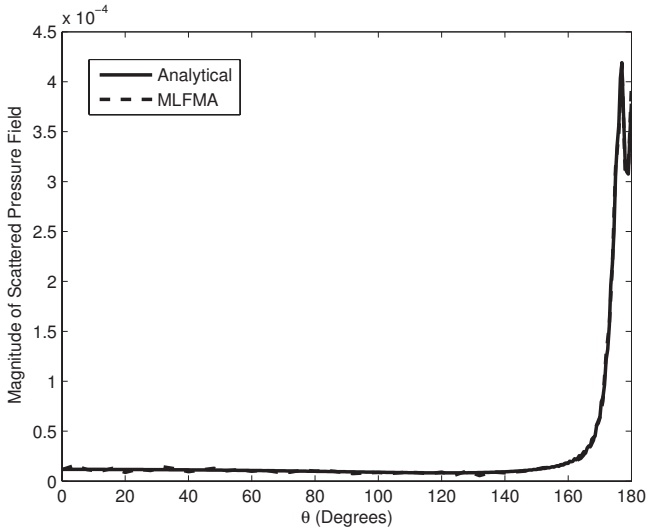

FIG. 3. Magnitude of scattered pressure field at the $r=50a$ principal cut, $a=20\lambda$ and $\eta=10-10i$.

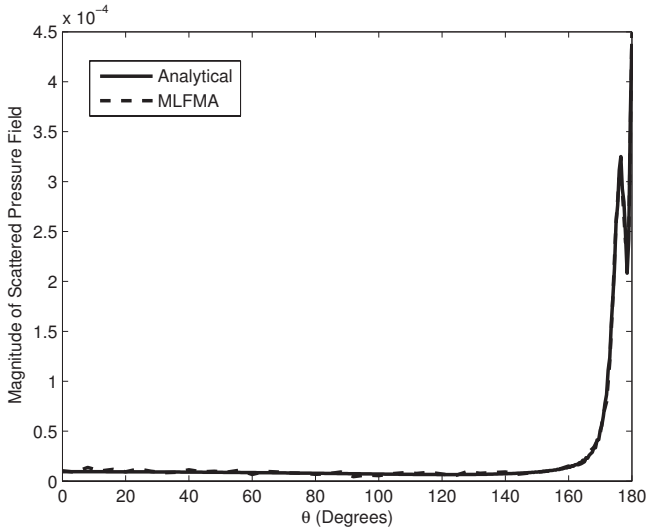

FIG. 5. Magnitude of scattered pressure field at the $r=50a$ principal cut, $a=25\lambda$ and $\eta=10-10i$.

III. NUMERICAL RESULTS

We use the developed MLFMA with the generalized minimal residual method as the iterative solver to solve for the acoustic wave scattering by very large scatterers. We first consider the scattering by a sphere so that the solutions can be verified by comparing with the corresponding analytical solutions. The sphere has a large radius $a=20\lambda$, 25λ, and 30λ, respectively, where λ is the wavelength in free space, and is meshed with flat triangle patches as illustrated in Fig. 2. The surface status of the sphere is characterized by the value of η and the incident wave is generated by a normalized point source located at $(0,0,10a)$ with a frequency $f=1700$ Hz. The propagation medium is the air with a standard acoustic velocity $c=340$ m/s.

Figures 3–6 show the scattered pressure fields along the principal cut ($\phi=0°$ and $\theta=0° \sim 180°$) at the $r=50a$ surface. Figure 7 is a zoom-in plot for the details between $\theta=160°$ and 180° for the $a=30\lambda$ case. We can see that the solutions are very close to the corresponding analytical solutions. Table I summarizes the CPU time T (s) and memory usage M (GB) for solving these large problems, where N is the number of unknowns. It is seen from the table that solving a one million unknown problem only consumes about 16 h when the stopping error of the iteration is set up 10^{-5}.

After validating the code, we apply it to solve for the acoustic wave scattering by large trench structures which are needed in the design for mitigating gun blast noise. Figures 8 illustrates a meshed trench structure embedded in a circularly truncated ground (top view) and 9 defines the geometrical sizes for each trench. We assume that the ground and trench surfaces are rigid, so $\eta=0$ here. The trenches are concentrically shaped and the entire structure is a body of revolution (BOR), but we treat it as a full 3D geometry and the solutions are compared with those obtained from BOR formulas

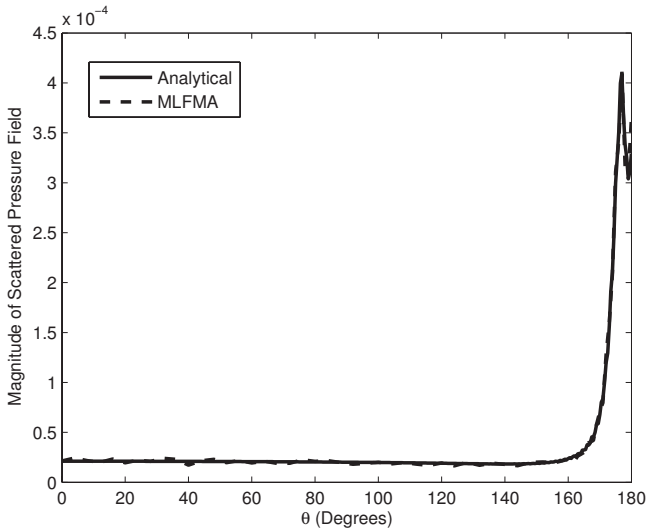

FIG. 4. Magnitude of scattered pressure field at the $r=50a$ principal cut, $a=20\lambda$ and $\eta=10$.

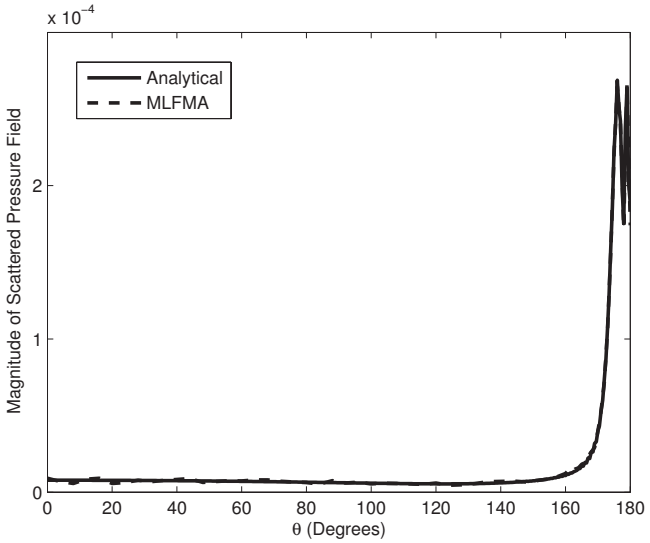

FIG. 6. Magnitude of scattered pressure field at the $r=50a$ principal cut, $a=30\lambda$ and $\eta=10-10i$.

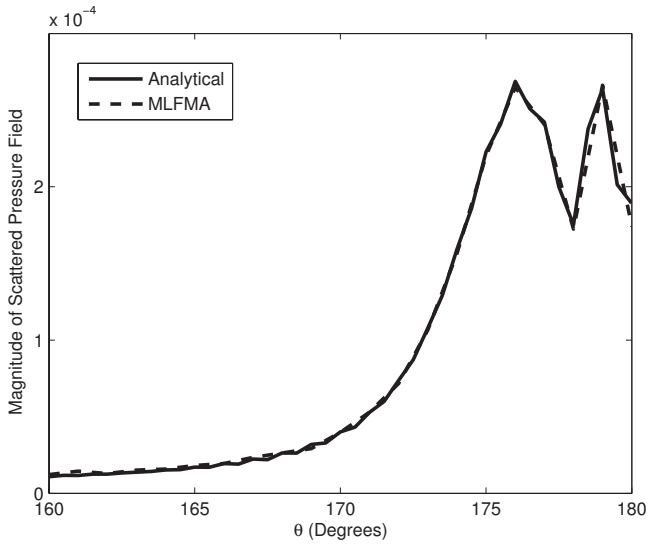

FIG. 7. Zoom-in plot for the magnitude of scattered pressure field at the $r=50a$ principal cut, $a=30\lambda$ and $\eta=10-10i$.

we developed previously. This can make sure the correctness of the solutions when lacking analytical solutions to compare with. In the calculations, we choose the frequency of the incident wave generated by a point source as $f=20$ Hz, which is close to the central frequency of a large-caliber gun blast noise, and the wave velocity as $c=350$ m/s.[41] The point source is located at a location above the ground center with a height of $h=0.1\lambda$. The truncated radius of the ground is chosen as $r_g=20\lambda$, which is large enough for the previous specific point source.[42] The trench geometry has a width of $w=0.1\lambda$, a periodicity of $t=0.2\lambda$ and a depth of $d=0.25\lambda$. The distance between the ground center and the inner wall of the first trench is $r_0=0.2\lambda$.

Figures 10–13 depict the radiation patterns (RP) or excess attenuations (EA) for the trench structures when the number of concentric trenches is $K=1$, 5, 10, and 50, respectively. RP or EA is defined as[43]

$$\mathrm{RP}=\mathrm{EA}=20\log_{10}\left|\frac{p(\mathbf{r})}{p_0(\mathbf{r})}\right|\mathrm{dB}, \tag{20}$$

where p is the total pressure field (with scatterer) and p_0 is the free-space pressure field (without scatterer) at an observation point $\mathbf{r}$. The observation points are located at the principal cut defined by $\theta=0°-90°$ and $\phi=0°$ and 180° on the sphere surface of $|\mathbf{r}|=2000$ m. It can be seen that the solutions based on MLFMA are close to those obtained from BOR formulas and also the propagation of acoustic wave is suppressed along the ground surface as the number of trenches increases. Figure 14 presents the comparison of radiation patterns when the larger truncated sizes of ground

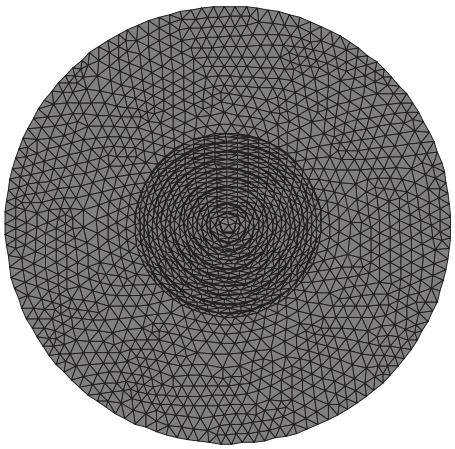

FIG. 8. A meshed trench structure embedded in a truncated ground (top view).

$r_g=30\lambda$ and 40λ with 50 trenches are chosen and it is clear that $r_g=20\lambda$ is large enough. Table II gives the CPU times and memory usage for running these cases, where K is the number of trenches. For the cases with more than 2 million unknowns in the two tables, we believe that they are the largest cases in acoustics that numerical solvers have solved without resorting to parallel algorithms and supercomputers. It should be noted that the commercial software IDEAS we employed to generate meshes in this work usually cannot generate more than one million triangular meshes. If more than one million triangular meshes are needed for a geometry, we have to generate coarse meshes using IDEAS first, and then refine these meshes by dividing a triangle into three smaller triangles. The three smaller triangles are formed by connecting three vertices with the centroid of the larger triangle. As such a refinement is based on the coarse IDEAS meshes, the small difference between three curves in Fig. 14 may be caused by the disagreement of geometrical approximation of the coarse IDEAS meshes between three cases.

IV. CONCLUSION

MLFMA is extended to solve for acoustic wave scattering by very large objects with 3D arbitrary geometries. In the implementation, We first use the Nyström method to generate

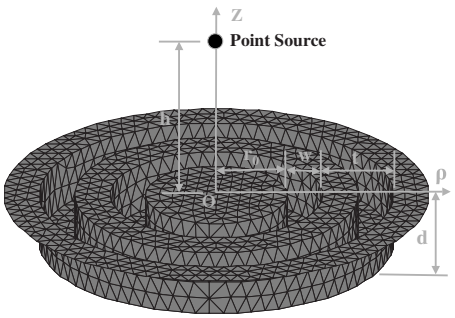

FIG. 9. Geometrical parameters of the trench structure, in which r_0 is the distance between the ground center and the inner wall of the first trench, w and d are the width and depth of each trench, respectively, and t is the periodicity of trenches. The ground width between two neighboring trenches is $t-w$.

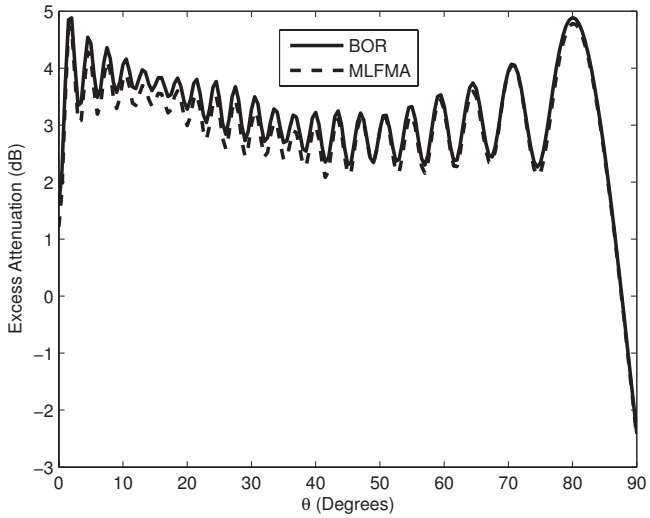

FIG. 10. Radiation pattern for the truncated ground with 1 trench.

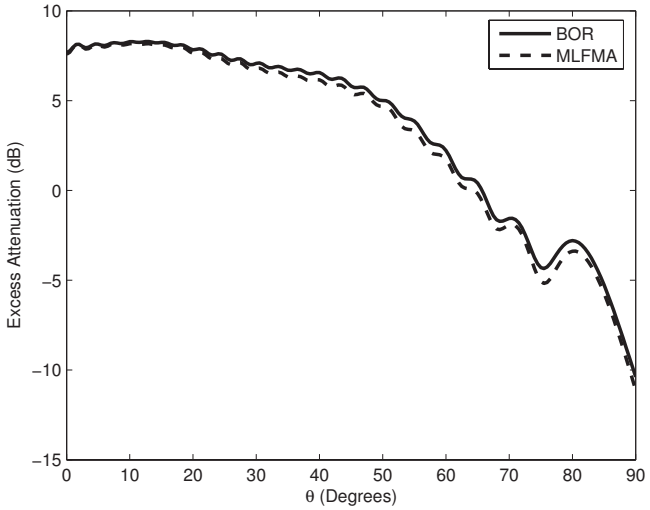

FIG. 12. Radiation pattern for the truncated ground with 10 trenches.

matrix equations. Due to the elegance of the Nyström method, i.e., the direct evaluation of integrands for far-interaction terms, the resulting radiation patterns and receiving patterns are more efficient compared with those in the BEM based fast multipole algorithm, which has been implemented in acoustics. Also, we develop a simple and efficient evaluation technique for those singular or near-singular integrals appearing in near terms. The technique is different from the singularity regularization used in BEM. The numerical examples from the simulations for mitigating gun blast noise have demonstrated the robustness of the proposed MLFMA. The fast solution for the problems with more than 2 million unknowns can be obtained on a workstation without involving parallel algorithms.

APPENDIX: MLFMA

The description of MLFMA can be found in details in many publications, such as Ref. 10. To facilitate the description of the proposed MLFMA in acoustics, we present a brief introduction for the algorithm here. In the iterative solution of matrix equation, the bottleneck is the matrix-vector multiply which requires $\mathcal{O}(N^2)$ operations in each iteration. MLFMA changes the computing strategy of the matrix-vector product for far-interaction terms by using the addition theorem for the Green's function and an inverted tree structure in the calculation. The inverted tree structure is illustrated in Fig. 15 and we have three stages, i.e., aggregation, translation, and disaggregation for calculating the far interaction between the grouped source points and field points. The aggregation process represented by β^t (vector) is to calculate the radiation pattern of the outgoing field from the source points. The translation process is characterized by $\bar{\alpha}$ (matrix) and is used to convert the outgoing waves to incoming waves. The disaggregation process denoted by β (vector) is to calculate the receiving pattern of the incoming field for

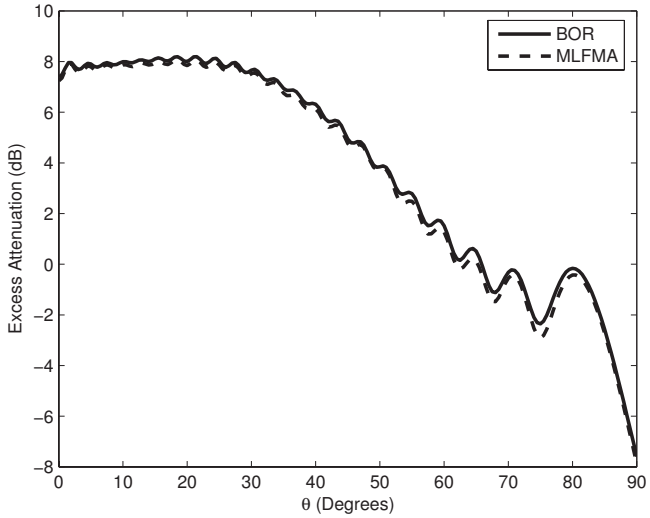

FIG. 11. Radiation pattern for the truncated ground with 5 trenches.

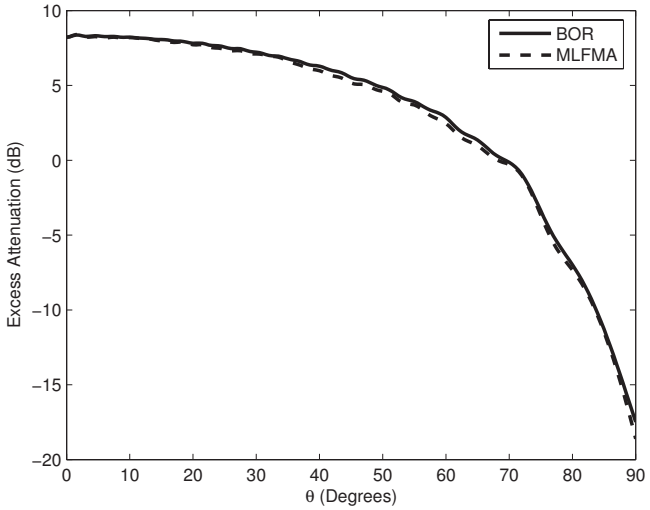

FIG. 13. Radiation pattern for the truncated ground with 50 trenches.

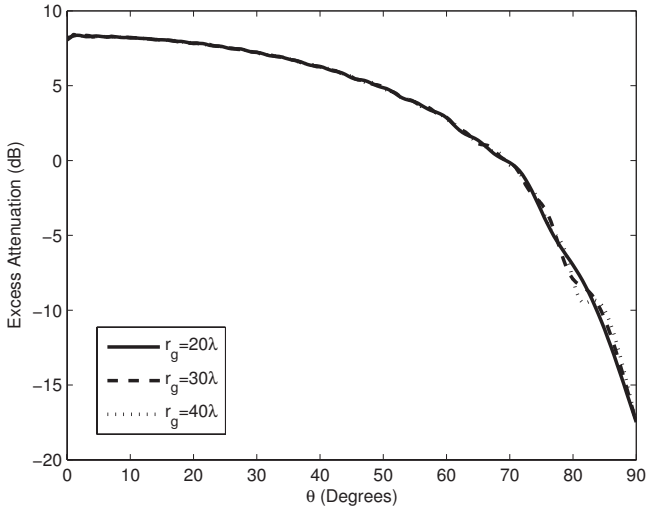

FIG. 14. Comparison of radiation patterns for different truncated sizes of ground with 50 trenches.

desired field points. In the multi-level version, the above is augmented by interpolation and anterpolation between levels.[6,7]

Consider a typical matrix equation

$$\sum_{i=1}^{N} A_{ji} a_i = b_j, \quad j = 1, \ldots, N, \tag{A1}$$

where N is the total number of unknowns after discretizing an integral equation, b_j is the known excitation in a wave equation, a_i is the unknown coefficient to be solved, and A_{ji} is the matrix element. In wave physics, the matrix element A_{ji} is related to the scalar Green's function which can be expanded as[15]

$$\frac{e^{ikr_{ji}}}{r_{ji}} = \int d^2\hat{k} e^{i\mathbf{k}\cdot(\mathbf{r}_{jm}-\mathbf{r}_{im'})} \alpha_{mm'}(\mathbf{k}, \mathbf{r}_{mm'}), \tag{A2}$$

where

$$\alpha_{mm'}(\mathbf{k}, \mathbf{r}_{mm'}) = \frac{ik}{4\pi} \sum_{l=0}^{L} i^l (2l+1) h_l^{(1)}(kr_{mm'}) P_l(\hat{r}_{mm'} \cdot \hat{k}) \tag{A3}$$

is the translator. Here, we have chosen $\mathbf{r}_m$ and $\mathbf{r}_{m'}$ as the centers of the mth and m'th groups in which the field point $\mathbf{r}_j$ and source point $\mathbf{r}_i$ reside, respectively. Also, $\mathbf{r}_{jm}$ denotes the distance vector from the field point to its group center, $\mathbf{r}_{im'}$ denotes the distance vector from the source point to its group center, and $\mathbf{r}_{mm'}$ denotes the distance vector from the field group center to source group center. Usually the integral kernels in wave integral equations will include the gradient operation on the scalar Green's function. The expansion for integral kernels can be obtained by simply replacing the gradient ∇ in space domain with multiplication of $i\mathbf{k}$ in the $\hat{k}$-domain in Eq. (A2). Thus the matrix element in Eq. (A1) can be written as

$$A_{ji} = \int d^2\hat{k} V_{fmj}(\hat{k}) \cdot \alpha_{mm'}(\mathbf{k}, \mathbf{r}_{mm'}) V_{sm'i}(\hat{k}), \tag{A4}$$

where

$$V_{fmj}(\hat{k}) = e^{i\mathbf{k}\cdot\mathbf{r}_{jm}},$$

$$V_{sm'i}(\hat{k}) = \int_{\Delta S_i} dS' e^{-i\mathbf{k}\cdot\mathbf{r}_{im'}} f(\hat{k}), \tag{A5}$$

are the receiving pattern and radiation pattern, respectively. Note that we do not include a basis function in the radiation pattern and a testing function in the receiving pattern as we do in MOM. In the previous, $f(\hat{k})$ denotes the $\hat{k}$-domain representation for the operation acting on the scalar Green's function in the integral kernels.

For the multilevel implementation, the outgoing wave expansions in the radiation pattern are calculated at the finest level and then the expansions for higher levels are obtained by interpolation. Similarly, the anterpolation or transpose interpolation is used to get the incoming wave expansion at a lower level from that at its parent level in the receiving pattern. The interpolation or anterpolation is recognized as one of the key techniques for reducing costs in MLFMA.

(Received 2 August 2007; revised 29 February 2008; accepted 29 February 2008)

The hydrodynamic pressure fluctuations that occur on the solid surface beneath a turbulent boundary layer are a common source of flow noise. This paper reports multipoint surface pressure fluctuation measurements in water beneath a high-Reynolds-number turbulent boundary layer with wall injection of air to reduce skin-friction drag. The experiments were conducted in the U.S. Navy's Large Cavitation Channel on a 12.9-m-long, 3.05-m-wide hydrodynamically smooth flat plate at freestream speeds up to 20 m/s and downstream-distance-based Reynolds numbers exceeding 200×10^6. Air was injected from one of two spanwise slots through flush-mounted porous stainless steel frits ($\sim$40 μm mean pore diameter) at volume flow rates from 17.8 to 142.5 l/s per meter span. The two injectors were located 1.32 and 9.78 m from the model's leading edge and spanned the center 87% of the test model. Surface pressure measurements were made with 16 flush-mounted transducers in an "L-shaped" array located 10.7 m from the plate's leading edge. When compared to no-injection conditions, the observed wall-pressure variance was reduced by as much as 87% with air injection. In addition, air injection altered the inferred convection speed of pressure fluctuation sources and the streamwise coherence of pressure fluctuations.

I. INTRODUCTION

[1]Pressure fluctuations produced on solid surfaces by turbulent flow are an important engineering concern as they are known to be a source of unwanted vibration, interior and exterior noise, and even structural fatigue—in extreme cases—in transportation systems. Thus, understanding and quantifying hydrodynamic pressure fluctuations is of interest for engineering design of watercraft. In addition, since wall-pressure fluctuations are directly related to the structure of boundary layer turbulence, changes in these fluctuations may yield insight into boundary-layer skin-friction drag-reduction mechanism(s). Thus, quantifying the modifications to wall-pressure fluctuations in a gas-laden liquid turbulent boundary layer (TBL) is a potentially important step prior to implementation of gas injection as a skin-friction drag-reduction technique for liquid flow over a solid surface.

Wall-pressure fluctuations beneath a TBL have been extensively studied and are well documented for single-phase gas or liquid flows. Reviews of single-phase wall-pressure-fluctuation research can be found in Bull (1996) and Keith *et al.* (1992). Likewise, skin-friction drag reduction by gas injection, herein termed bubble drag reduction (BDR), has been the focus of a number of experimental investigations; a review of BDR research can be found in Merkle and Deutsch (1992). However, scarcely any literature exists for wall-pressure fluctuations in liquid TBL flows with skin-friction drag reduction by gas injection, though two studies of an alternative skin-friction reduction technique (Brungart *et al.*, 2000; Barker, 1973) report pressure fluctuations beneath a polymer modified TBL. Brungart *et al.* simultaneously measured wall-pressure fluctuations and skin-friction reduction beneath the TBL on an axisymmetric body, 89 mm in diameter and 632 mm in length, in a polyethylene oxide (PEO) ocean at flow speeds up to 10.7 m/s. Spectral levels were reduced in proportion to the observed level of skin-friction drag reduction. Likewise, with the addition of dilute PEO solutions, Barker observed reductions in wall-pressure fluctuations as well as in the radiated noise from the TBL of a rotational flow apparatus. In contrast, no wall-pressure-fluctuation data have yet been reported for bubble-laden TBL flows even though local skin-friction drag reductions exceeding 80% have been experimentally observed for BDR.

While the mechanism(s) of BDR is (are) not yet fully understood, the phenomenon is associated with the modification of turbulent fluctuations and a reduced momentum exchange in the near-wall region (Merkle and Deutsch, 1992). Lumley (1977) reported that the presence of bubbles acts to increase the local viscosity in the buffer region of the TBL, resulting in a thickening of the viscous sublayer and a reduction in the near-wall velocity gradient. While measur-

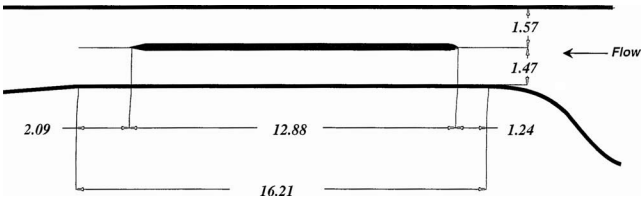

FIG. 1. Elevation side view of the test section geometry with the test model mounted slightly below the test section centerline. Dimensions are in meters.

ing shear stress indirectly with hot-film anemometry during BDR, Pal *et al.* (1989) observed suppressions in skin friction fluctuation levels, as well as reduction in the mean skin friction. Based on these prior findings, it is not surprising that similar suppressions of wall-pressure fluctuations were found in the study reported here.

This paper presents the results of a large scale BDR experiment designed to examine skin-friction drag reduction at large scales and high-Reynolds numbers on a hydrodynamically smooth surface when air was injected through the surface at one of two locations downstream of the surface's leading edge. A variety of data were gathered, but only skin-friction drag reduction and dynamic wall-pressure measurements are discussed herein. Wall-pressure fluctuations were observed with an array of dynamic pressure sensors flush mounted on the test model surface. Modifications to the spectral levels, and hence root-mean-square (rms) levels, convection velocities, and streamwise coherence of the wall pressure are reported for various levels of skin-friction drag reduction for a variety of freestream liquid speeds and gas injection rates. The remainder of this paper is divided into three sections that describe the experimental methods used in collecting and reducing the measurements, the results and their relationship to the no-injection or base line flow, and the conclusions drawn from this investigation.

II. EXPERIMENTAL METHODS

The experiments were conducted at the U.S. Navy's William B. Morgan Large Cavitation Channel (LCC), the world's largest low-turbulence (<0.5% free stream turbulence) recirculating water tunnel. The dimensions of the LCC test section are 16 m (length) and 3.05×3.05 m^2 (width and height). Details of the LCC test facility can be found in Etter *et al.* (2005).

The test model was a 12.9-m-long, 3.05-m-wide, and 18-cm-thick rigid flat plate. It spanned the entire width of the LCC test section and produced 6% blockage. The leading edge of the model was a 4:1 ellipse and the trailing edge was a 15° full-angle truncated wedge. A distributed roughness trip consisting of 120 μm particles embedded in epoxy was added near the leading edge. The trip spanned the entire test model and started 2.5 cm from the leading edge and extended 25.4 cm downstream. The model was positioned slightly below the vertical centerline of the LCC test section with the working surface facing downward, as shown in Fig. 1. The working surface was polished 304 stainless steel yielding a rms surface roughness, $k < 0.4$ μm, sufficiently small to be considered hydrodynamically smooth, even at the highest water-flow test speed, ~20 m/s. Figure 2 shows the location of the air injectors, skin-friction drag balances, and the dynamic-pressure transducer array. The downstream coordinate x has its origin ($x=0$) at the leading edge of the model.

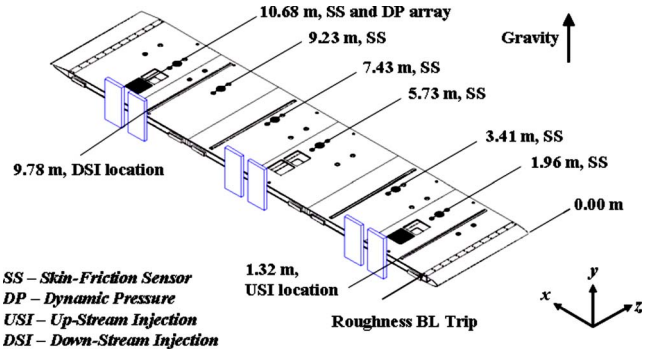

FIG. 2. (Color online) Schematic of the test model's working surface with the two air injectors and instrumental suite layout. Air injectors were located 1.32 and 9.78 m from the model leading edge and the six skin-friction drag balances span the model length. The dynamic pressure sensor array was located 10.68 m from the model leading edge and the velocity profile measurements were made at that location using a laser-Doppler velocimetry system.

Three test speeds, 6.6, 13.2, and 19.9 m/s, were investigated. These speeds were measured in the freestream with a laser-Doppler velocimetry system at the streamwise location of the dynamic pressure array. Boundary layer growth caused a slight favorable pressure gradient and freestream acceleration (<2.5%) along the length of the model. This flow acceleration, in terms of a dimensionless acceleration parameter K, is less than 10^{-9} for all freestream test speeds, where

$$K = \frac{\nu}{U_\infty^2}\frac{dU_\infty}{dx}, \tag{1}$$

where U_∞ is the freestream flow speed and ν is the kinematic viscosity of the fluid. Patel (1965) reported that the classical TBL log law remains unaltered for $K < 1.6 \times 10^{-6}$; therefore, the results presented herein are presumed to approach that of a zero-pressure-gradient TBL.

A. Skin-friction drag balances

Average skin-friction measurements were made at six streamwise locations using floating-plate-type force balances. Skin-friction drag reduction, calculated from measurements made at the same streamwise location as the transducer array using the furthest downstream balance ($x = 10.68$ m), is reported with the dynamic pressure measurements. Table I provides the base line (no-injection) skin-friction shear stresses, τ_w, local Reynolds numbers, and other TBL parameters measured with a laser-Doppler velocimetry system at the streamwise location of the dynamic pressure array. The force balances were designed at the Applied Research Laboratory of Pennsylvania State University. The floating elements of the force balances were polished stainless steel disks 15.2 cm in diameter and 0.79 cm thick, and each element was attached to a beryllium copper load cell instrumented with a full wheat-stone bridge of semiconductor strain gauges (model ESU-025-500, MSI Sensors®). The

TABLE I. Local base line (no-injection) Reynolds numbers, shear stress, and turbulent-boundary-layer parameters at the streamwise location of the dynamic pressure sensor array.

Parameter description	Symbol	Values		
Local freestream speed	U_∞	6.6 m/s	13.2 m/s	19.9 m/s
Downstream distance Reynolds number	Re_x ($\times 10^{-6}$)	69	139	209
Momentum thickness Reynolds number	Re_Θ ($\times 10^{-3}$)	66	126	186
Single-phase flow wall shear stress	τ_w (Pa)	37	136	292
Shear velocity$=(\tau_w/\rho)^{1/2}$	u_τ (m/s)	0.193	0.369	0.541
99% boundary layer thickness	δ_{99} (mm)	108	102	101
Boundary layer displacement thickness	δ (mm)	12.8	11.9	11.6
Boundary layer momentum thickness	θ (mm)	10.0	9.5	9.3

load cell and floating element were mounted in a stainless steel housing, which contained an eight-point leveling system to position the floating-plate flush with the housing. The gap between the floating element and the surrounding housing was measured to be 60 ± 20 μm. The balances were calibrated with a suction cup affixed to the floating element, a tensioning cable, and a precision load cell mounted on a translation stage.

B. Dynamic pressure sensors

Wall-pressure fluctuations were measured with 16 flush-mounted dynamic pressure sensors (model 138M101, PCB Piezotronics®) with a nominal sensitivity of 50 mV/psi, a low frequency cutoff of 1.6 Hz, and a resonant frequency greater than 300 kHz (leading to a rise time of less than 2 μs). The sensors had circular sensing surfaces with a diameter $d=5.6$ mm. The nominal factory-specified sensor calibration was used in the data processing. The sensors were connected to a multichannel excitation and signal-conditioning amplifier (model series 481, PCB Piezotronics®), and their signals were amplified with a gain of 150 and low-pass filtered at 4765 Hz. Each amplified and filtered signal was digitized at 10 kHz for a period of 20 s. The dynamic pressure sensors were flush mounted in a single "L-shaped" array located 10.7 m from the test model's leading edge (9.4 m from the upstream air injector and 0.9 m from the downstream air injector). The sensors were logarithmically spaced in each direction with the array spanning 27 cm in the streamwise direction and 40 cm in the cross-stream direction, as shown in Fig. 3.

C. Air injection

For the BDR experiments, air was injected through one of two spanwise air injectors located at $x=1.32$ m and $x=9.78$ m, designated upstream injection (USI) and downstream injection (DSI), respectively. Filtered air was delivered to the active injector through a symmetrical delivery manifold that fed 40 evenly spaced ports on the back of the injector housing. The air-flow rate was regulated with five mass flow meters (Sierra Instruments, model 840N3-0-0V1-S1-MP) each supplying eight of the 40 injector ports. Three layers of perforated brass plates with 0.5 mm diameter holes and 33% open area served to create a pressure drop in the injector that evenly distributed the air across the injector span. A cross-sectional schematic of the air injectors is shown in Fig. 4. They consisted of a contracting slot inclined at a mean angle of 25° with respect to the model surface, a full-angle contraction of 10°, and a final layer of sintered stainless steel with mean pore diameter of 40 μm (Mott Corporation®). The air injectors spanned the center 2.65 m

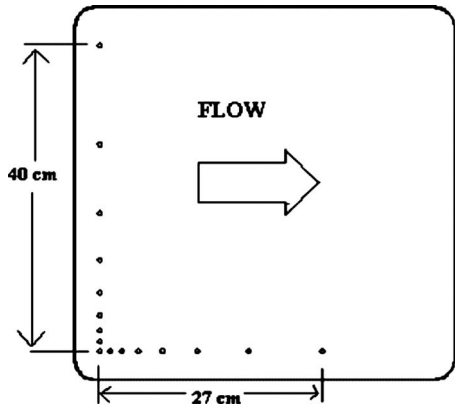

FIG. 3. Layout of the dynamic pressure sensor array located 10.7 m from the leading edge of the test model with the circles corresponding to locations of the dynamic pressure sensors. The array spanned 40 cm in the cross-stream direction and 27 cm in the spanwise direction.

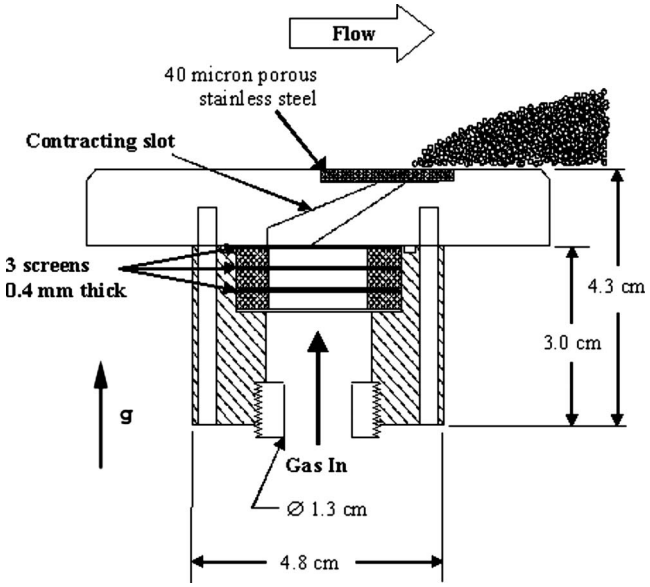

FIG. 4. Cross-sectional schematic of the air injectors that spanned the center 2.65 m of the test model. The air inlet consisted of 40–1.27 cm ID ports along the injector span, which supplied a manifold that spanned the entire injector length.

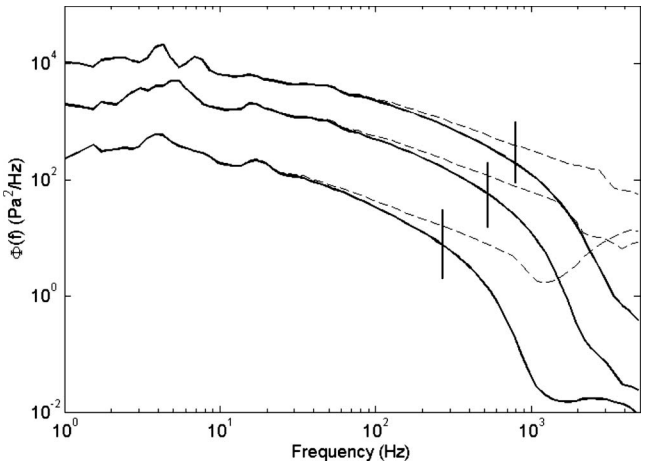

FIG. 5. Dimensional pressure spectra for single-phase flow at the three test speeds. The solid lines are the measured spectra and the dashed lines are the spectra after correction for sensor-size attenuation (Corcos, 1963). The vertical lines represent f_c, given in Table II, above which sensor size limitations become significant.

(87%) of the test model surface. *In situ* visual observations of bubble clouds, near and far from the injector, suggested that the air injection scheme had sufficient spanwise uniformity for these tests. Average-flux-based void fractions within the bubbly TBL were in the 1%–20% range with bubbles distributed in size between 200 and 700 μm (see Sanders *et al.*, 2006).

D. Test procedures

Air was injected at four nominal flow rates: 100, 200, 400, and 800 SCFM (standard cubic feet per minute) ranging from 17.8 to 142.5 l/s per meter of injector span. Dynamic pressure data acquisition was initiated once the skin-friction drag balances showed that force levels had reached steady state. At the lower air injection rates, the LCC test section static pressure could be maintained near the desired 138 kPa (absolute) so the true volumetric-flow rates were ~38% less than the specified volumetric-flow rates (given in SCFM above). However, at the highest injection rate (800 SCFM), a steady rise in test section pressure occurred during the injection process to a maximum of 240 kPa. Ignoring surface tension effects, this static pressure rise would cause bubble volume and void fraction to decrease by ~40% and bubble diameters to decrease by ~17%. Further details of the BDR experiment are reported in Sanders *et al.* (2006).

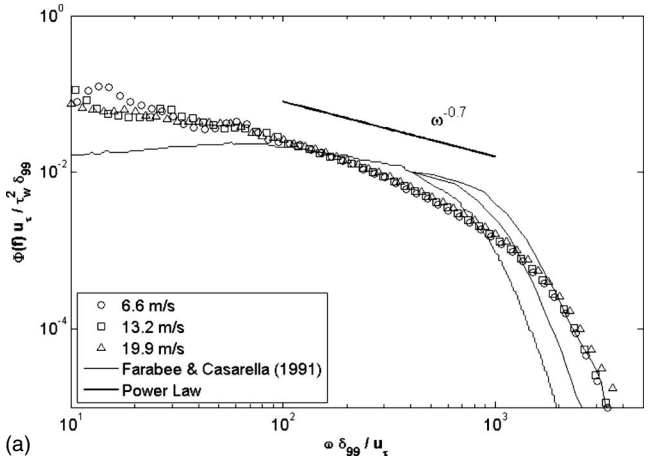
III. RESULTS

A. Base line spectra

The base line pressure spectra are shown in Fig. 5 (solid lines) in dimensional form for the three test speeds. The spectra presented are the average of the 16 sensors used in the experiment. Sensor-to-sensor differences in the base line flow pressure variance were less than 50%. When sensitivity differences between sensors are taken into account, variance differences are reduced to ~30%. Small unintended surface-flushness differences between sensors are the likely cause of the remaining variance differences. Unfortunately, further investigation of the observed variance differences became impossible once the experiment was disassembled. Thus, the experimental uncertainty of any single spectral measurement reported here is $\pm 10\log_{10}(1.3) \approx \pm 1$ dB. Wherever possible, results were averaged across sensors to further reduce this uncertainty, and, for clarity, the spectra were smoothed using a 1/20th decade top hat filter. The pressure spectra, $\Phi(\omega)$, presented herein are of the single-sided form.

TABLE II. Sensor size limitations and attenuation frequencies.

Freestream flow speed	6.6 m/s	13.2 m/s	19.9 m/s
Wall unit, l^+ (μm)	5.16	2.70	1.84
Sensor size, $d^+=d/l^+$	1100	2100	3000
Attenuation frequency, f_c	270 Hz	530 Hz	800 Hz



$$P_{\text{rms}}^2 = \int_0^\infty \Phi(\omega)d\omega, \tag{2}$$

$$\Phi(\omega) = \frac{1}{2\pi}\Phi(f), \tag{3}$$

where P_{rms}^2 is the pressure variance, and $\omega=2\pi f$ is the temporal frequency.

Unfortunately, the pressure spectra contain three types of noise: background tunnel noise, model vibration noise, and electrical noise. The first is most prevalent at low frequencies (below 10 Hz or so). Unfortunately, it was not separately quantified for these experiments. However, it does not dominate the measurements below 10 Hz because air injection was observed to alter pressure spectra in this frequency range. Model vibration noise covered much of the same frequency range as the pressure spectra but its spectral level was determined to be two or three orders of magnitude lower based on the separate test-surface acceleration measurements and the manufacturer-specified acceleration sensitivity for the pressure transducers. Similarly, broadband electrical noise levels were typically four or more decades below pressure spectrum levels. This is illustrated in Fig. 5 where the electrical noise spectral level is apparent as the nearly flat portion of the 6.6 m/s spectrum at frequencies above 1 kHz. In the results presented here, no noise reduction schemes have been implemented.

In addition, the pressure spectra are limited by the size of the transducer's sensing surface (d=diameter) relative to the inner TBL length scale, $l^+=\nu\sqrt{\rho/\tau_w}$, where ρ is the fluid density, which results in a suppression of the high-frequency fluctuations levels. The $d^+=d/l^+$ values of the sensors are presented in Table II for the three nominal flow speeds. Also listed in Table II is an estimated roll-off frequency, f_c, where the spectrum is attenuated by 50% due to the size of the sensor. Above this frequency, signal attenuation rapidly increases with frequency. According to prior work by Corcos (1963), this roll-off frequency occurs at $2\pi f_c d/U_c \sim 2.0$, where U_c is the convection velocity, which is approximately 70% of the freestream velocity, U_∞. The dashed lines in Fig. 5 show the spectra that have been corrected for sensor size

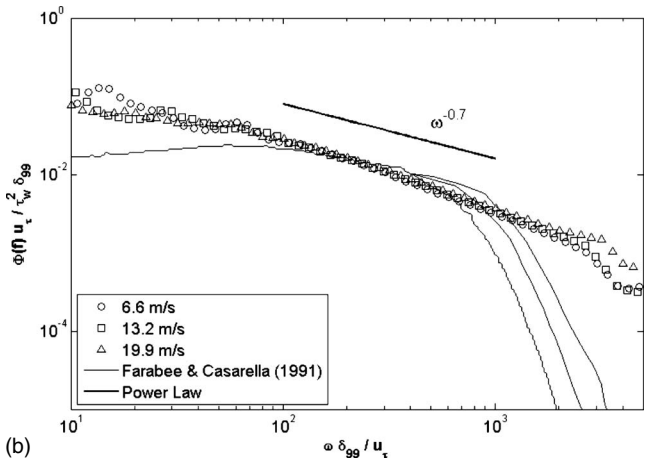


FIG. 6. Base line (single-phase) spectra scaled with outer flow variables for the three test speeds, (a) uncorrected for sensor size attenuation and (b) corrected for sensor size attenuation (Corcos 1963). Thin solid curves correspond to results obtained by Farabee and Casarella (1991), and the bold solid line has a slope of −0.7, as suggested by Goody (2004).

attenuation following the technique employed by Corcos. The short vertical lines mark f_c for each spectrum in this figure.

B. Base line TBL flow scaling

Work done by Farabee and Casarella (1991) identifies three frequency ranges for pressure fluctuation scaling: (1) a low frequency range, $\omega\delta^*/U_\infty \leqslant 0.03$; (2) a high frequency range, $\omega\nu/u_\tau^2 \geqslant 0.3$; and (3) a midfrequency range, $0.05 < \omega\delta^*/U_\infty < 10$, where δ^* is the boundary layer displacement thickness and $u_\tau = \sqrt{\tau_w/\rho}$ is the shear velocity. In this experiment, the low frequency range is possibly corrupted by background tunnel noise, and the high frequency range is largely lost because of finite-sensor-size attenuation. Therefore, the appropriate scaling range for the present data is the midfrequency range. Keith *et al.* (1992) and Brungart *et al.* (2000) have shown good collapse of data with mixed variable scaling: $\omega\delta^*/U_\infty$ and $\Phi U_\infty/\tau_w^2\delta^*$. Here, the data are scaled with outer variables and compared to the results of Farabee and Casarella (1991) in Fig. 6(a) without sensor size correction and in Fig. 6(b) with this correction. Table I provides the scaling parameters. The pressure spectra from these

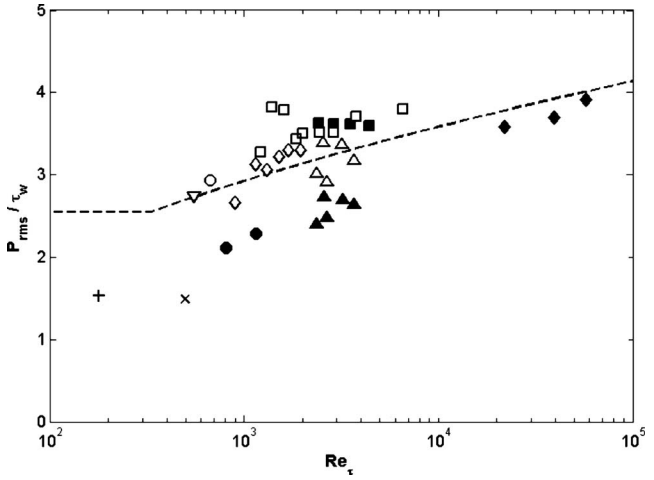

FIG. 7. Base line scaled rms pressure fluctuations for the current experiment, plotted as solid diamonds, along with other investigations compiled by Farabee and Casarella (1991). The dashed line corresponds to a scaling law purposed by Farabee and Cassarella.

two experiments collapse well from $10^2 < \omega\delta_{99}/u_\tau < 10^3$ when the current results are corrected for sensor-size attenuation. This is the spectral region where the most important changes occur when air is injected into the boundary layer. The lack of collapse outside this zone is a likely result of sensor-size limitations, imperfections in the sensor size corrections, and the higher Reynolds numbers of the present experiments compared to that of Farabee and Casarella. Note also that because the ratio of sensor size to boundary layer thickness (d/δ_{99}) is comparable between the current experiments (0.05) and those of Farabee and Casarella (0.03), the spectra from the two experiments in Fig. 6(a) are not as different as might be anticipated. More recently, Goody (2004) proposed a spectral scaling that includes the effects of Reynolds number. It suggests that pressure spectra should follow $\omega^{-0.7}$ in the midfrequency range (i.e., the bandwidth of interest in this study). Given the approximation inherent in the sensor-size correction, an $\omega^{-0.7}$ power law is close to that shown by the current corrected spectra [see Fig. 6(b)].

Scaling of the rms pressure fluctuation, P_{rms}, from different experiments has proven to be challenging due to the low frequency facility-specific noise contamination, high frequency attenuation due to the sensor size, and the dependence of wall-pressure fluctuations on Reynolds number. Results compiled in Farabee and Casarella (1991) illustrate this problem. For the current experiments, P_{rms} has been obtained by numerically integrating the pressure spectra corrected for sensor attenuation from 1 Hz, the lower frequency limit shown in Fig. 5, to the frequency where the sensor-size-induced attenuation is 99%. The potentially noisy frequency range from 1 to 10 Hz contributes only about 10% of the pressure variances. Figure 7 shows P_{rms}/τ_w from the investigations compiled by Farabee and Casarella along with the results from the current experiment plotted versus $\text{Re}_\tau = u_\tau\delta_{99}/\nu$. Also shown is the empirical scaling law proposed by Farabee and Casarella. Although the current results fall slightly below the proposed scaling law, they do confirm an overall trend of increasing P_{rms} with increasing Reynolds number.

For the present purposes, the results shown in Figs. 6 and 7 serve to validate the base line flow results via comparisons to prior higher-resolution, lower-Reynolds-number experiments. Thus, the effects of BDR on wall-pressure fluctuations are presented in the remainder of this manuscript by direct comparisons of BDR and single-phase flow results without the potential distractions associated with dimensionless scaling and sensor-size corrections. Given the importance of τ_w in the scaling of wall-pressure fluctuations and the large variations in τ_w that occur in BDR flows, presentation and comparisons of unscaled and uncorrected spectra are appropriate here for quantifying bubbly flow induced changes in wall-pressure fluctuations.

C. Spectral modifications during BDR

BDR wall-pressure spectra are compared to the base line spectra in Fig. 8. For reference, the skin-friction drag reduction (%DR at $x=10.68$ m), given by Eq. (4), is provided in the legends, where τ_w' is the BDR skin friction and τ_w is the base line skin friction.

$$\%\mathrm{DR} = \left(1 - \frac{\tau_w'}{\tau_w}\right) \times 100. \tag{4}$$

In the BDR spectra, an increase is observed in both the low ($f<10$ Hz) and the high ($f>1000$ Hz) frequency ranges. The low frequency spectral increase may be a result of the intermittency of an air film over the test model surface, which only occurs at the highest levels of skin-friction drag reduction, typically found at high air injection rates and lower freestream velocities. The high frequency spectral increase is likely associated with either (i) acoustic noise generated during the air injection process or (ii) the pressure fluctuations from small bubbles passing over the plate surface. Unfortunately, air injection measurements without flow in the LCC test section were not performed to readily discriminate between these two possibilities, and the complicated spatial filtering necessary to separate acoustic and convective noise sources for $f>1000$ Hz was not attempted.

Compared to the base line measurements, wall-pressure spectra in BDR flows were suppressed over a frequency range of at least a decade, and this range of reduction shifted upward in frequency with increasing freestream velocity. In general, the magnitude of this spectral suppression increases with increasing levels of skin-friction drag reduction, which agrees with the findings of Brungart *et al.* (2000) for polymer-based skin-friction drag reduction. In contrast, Brungart *et al.* observed reductions in spectral levels over the entire measured frequency range. However, this spectral suppression difference may be a result of differences in background noise in the two experiments. The injection of air in the current experiments audibly increased the background noise outside the water tunnel; presuming this was true inside the tunnel as well, air injection noise is likely the cause of the increase in BDR spectral levels at frequencies above 1 or 2 kHz seen in Fig. 8. There was no active injection system in the investigation of Brungart *et al.* (2000); thus, the suppression of pressure fluctuations in both types of skin-friction-drag-reduced flows may have common elements.

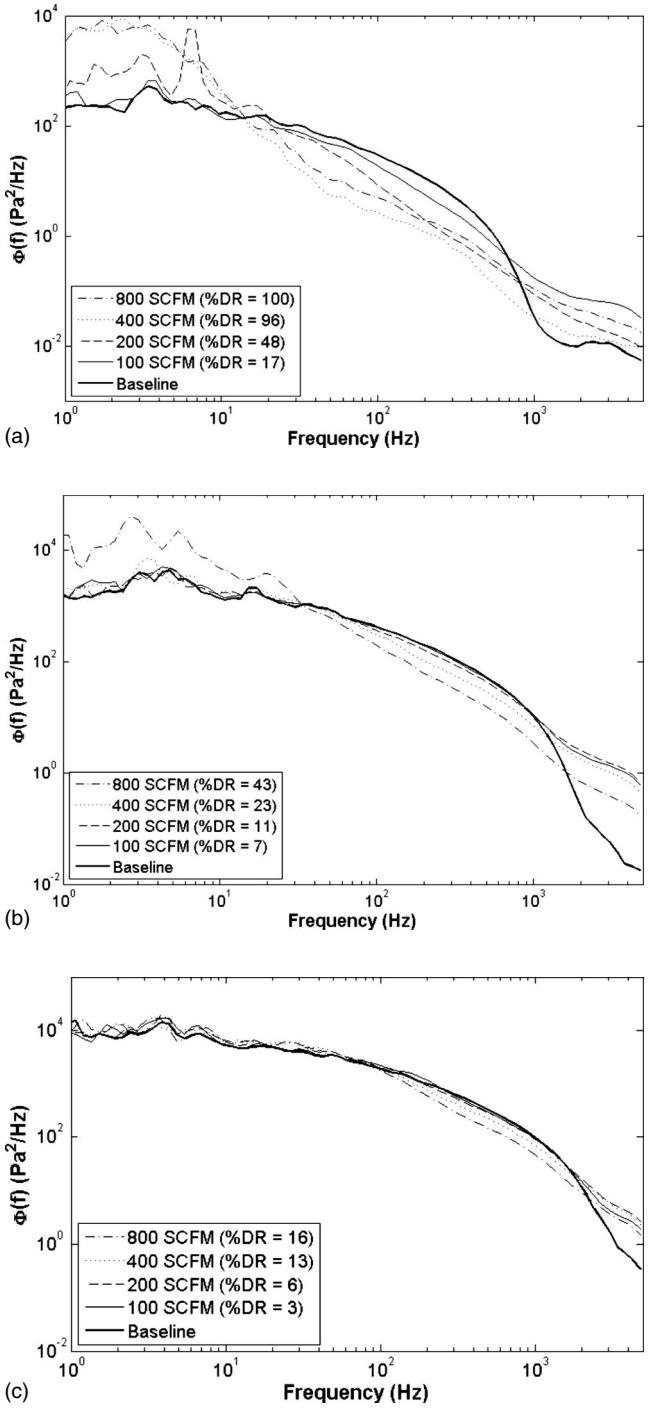

FIG. 8. Bubble modified pressure spectra for all air injection rates tested at (a) 6.6 m/s USI (b) 13.2 m/s DSI and (c) 19.9 m/s DSI. Also shown in the legend are the corresponding %DR measured by the skin-friction-drag balances at the same downstream location ($x=10.68$ m).

D. Reduction in mean-square pressure fluctuations

The ratio of pressure variance with bubbles, ${P'_{\mathrm{rms}}}^2$ to that of the baseline flow, P_{rms}^2 is plotted versus the reduction in skin friction, τ_w'/τ_w, in Fig. 9 for all the BDR measurements. The ${P'_{\mathrm{rms}}}^2$ values were computed by integrating the spectra over the frequency range where the spectral reductions occurred. This approach nearly eliminates the influence of high and low frequency noises in the BDR results, but it may also bias the results by under-reporting the ${P'_{\mathrm{rms}}}^2$ values. Also

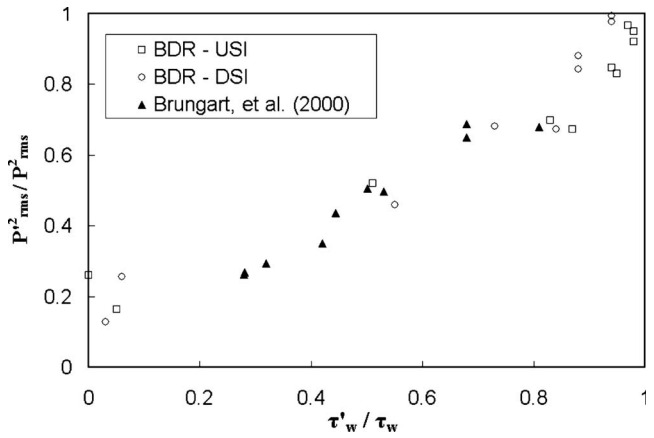

FIG. 9. Comparison of mean-square pressure fluctuations and skin-friction reductions during BDR. Also shown for comparison are data obtained from Brungart *et al.* (2000) where polymer was used to reduce the skin-friction drag.

shown in Fig. 9 are the results of the polymer skin-friction drag-reduction experiments of Brungart *et al.* (2000). The two data sets agree well with a simple linear trend with some additional scatter in the present data.

E. Convection velocity

The apparent convection velocity, U_c, of pressure fluctuations can be determined from the cross spectrum, Φ_{12}, of a streamwise sensor pair, as defined in Eq. (5), where ζ is the spacing between sensors and $\theta(\omega,\zeta)$ is the cross-spectrum phase defined in Eq. (6).

$$U_c(\omega,\zeta) = -\frac{\omega\zeta}{\theta(\omega,\zeta)}, \tag{5}$$

$$\theta(\omega,\zeta) = \tan^{-1}\left(\frac{\mathrm{Im}(\Phi_{12})}{\mathrm{Re}(\Phi_{12})}\right). \tag{6}$$

Figure 10 shows U_c/U_∞ for BDR at 13.2 and 19.9 m/s. The lower frequencies show an increase whereas the higher frequencies show a decrease in U_c relative to the base line results. The magnitude of these effects increases with increasing air injection rate and the corresponding skin-friction drag reduction achieved. The decrease in convection velocity at high frequencies indicates that the near-wall pressure fluctuations are moving slower with air injection and that the near-wall velocity gradient is decreased relative to the base line. The hydrodynamic BDR results reported in Sanders *et al.* (2006) put near-wall bubble velocities at 0.50–0.65 of U_∞; the present results at frequencies above about 300 Hz agree with this finding.

F. Streamwise coherence

A streamwise array of sensors can be used to measure the coherence of the pressure fluctuations as they are convected downstream. The coherence, $\Gamma(\omega,\zeta)$, given in Eq. (7), is a measure of the evolution and/or decay of the pressure fluctuations at frequency ω over a distance ζ. Here, Φ_{12} is the cross spectrum between a streamwise sensor pair, and Φ_{11}, Φ_{22} are the autospectra of each sensor.

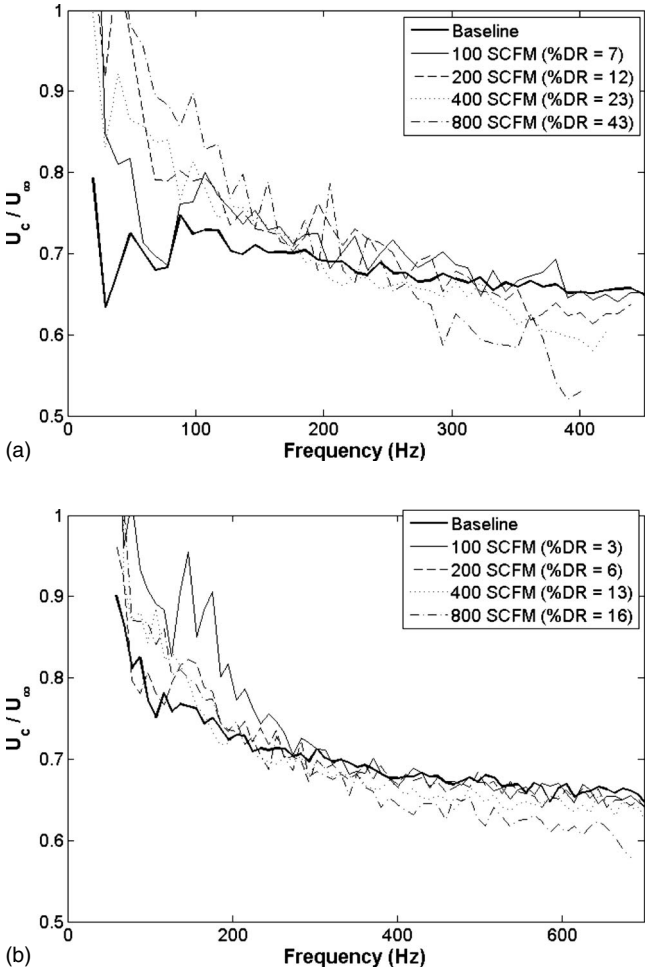

FIG. 10. Bubble modified convection velocity scaled using the freestream velocity for all air injection rates at (a) 13.2 m/s DSI and (b) 19.9 m/s DSI. The bold solid lines correspond to the base line (single-phase) convection velocity results.

$$\Gamma(\omega,\zeta) = \frac{|\Phi_{12}(\omega,\zeta)|}{\sqrt{\Phi_{11}\Phi_{22}}}. \tag{7}$$

The normalization shown in Eq. (7) prevents Γ from being significantly impacted by sensor size limitations. An empirical model for the decay of Γ, proposed by Corcos (1963),

$$\Gamma(\omega,\zeta) = \exp\left(-C_1\left|\frac{\omega\zeta}{U_c}\right|\right), \tag{8}$$

is based on a nondimensional spacing, $\omega\zeta/U_c$, and an empirical decay constant, C_1. The existing literature reports values of C_1 ranging from 0.10 to 0.19. Brooks and Hodgson (1981) reported a slight Reynolds number dependence for C_1, with C_1 decreasing with increasing Reynolds number. This agrees with the base line results from the present experiment, where $0.10 < C_1 < 0.12$ with the highest and lowest C_1 values corresponding to 6.6 and 19.9 m/s, respectively.

The base line coherence from two test speeds, 6.6 and 19.9 m/s, are given in Fig. 11 as a function of nondimensional spacing, $\omega\zeta/U_c$, with the corresponding empirical decay functions. Five sensor pair spacings, ranging from 2.0 to 9.1 cm, are shown. The data follow the exponential decay function reasonably well with the exception of the lowest

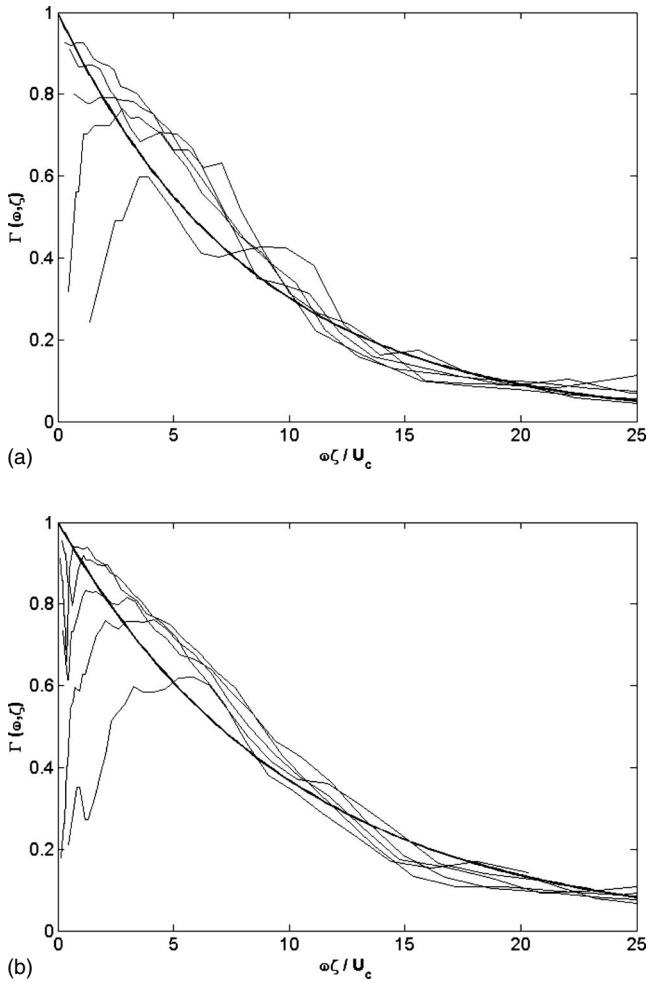

FIG. 11. Base line (single-phase) coherence and empirical decay model for five sensor pairings at two test speeds: (a) 6.6 m/s with C_1=0.12 and (b) 19.9 m/s with C_1=0.10.

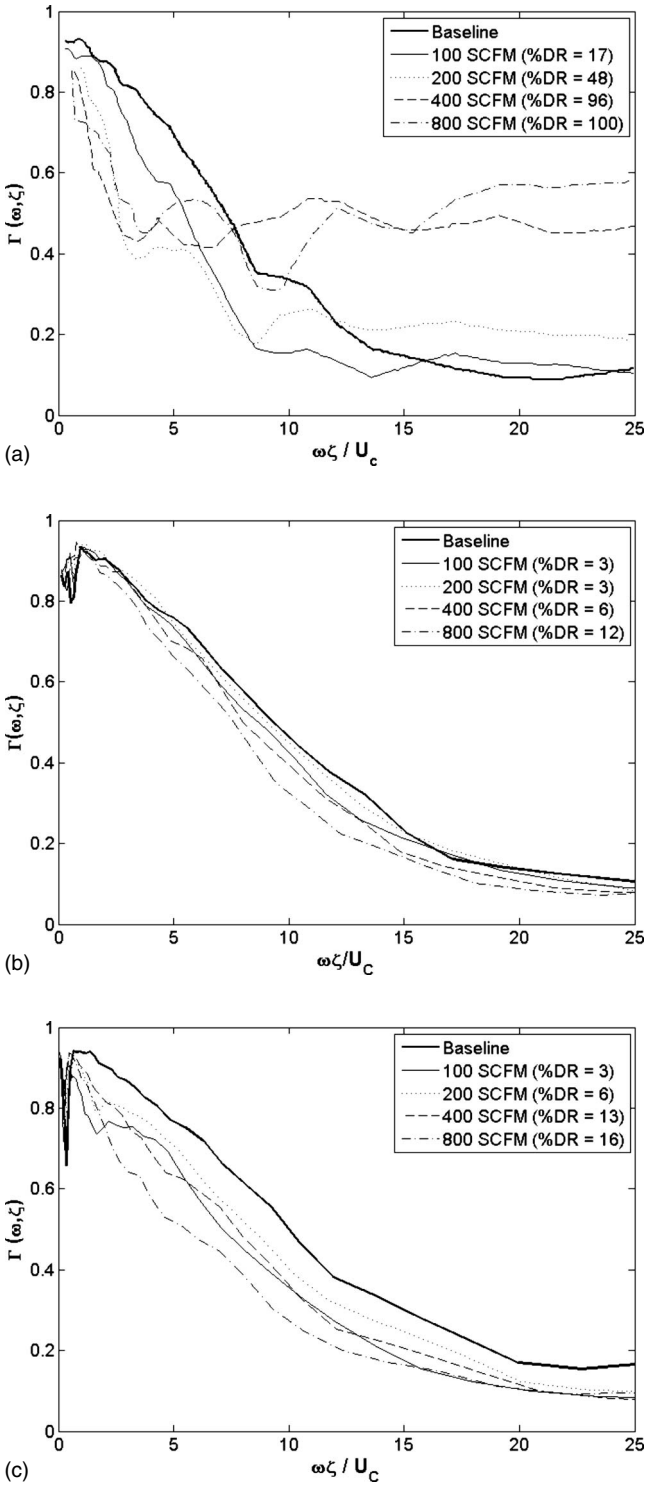

FIG. 12. Bubble modified streamwise coherence for a single sensor pair spacing (ζ=2.00 cm) and all air injection rates at (a) 6.6 m/s USI, (b) 13.2 m/s USI, and (c) 19.9 m/s DSI.

frequencies, where Γ peaks and then decreases or behaves erratically as $\omega\zeta/U_c$ approaches zero. This effect is a result of a breakdown of the similarity scaling embodied by $\omega\zeta/U_c$ for any finite sensor spacing as frequency approaches zero. This breakdown has been observed in other experiments (see Farabee and Casarella, 1991). To smooth the coherence results, the convection velocity, U_c, used to scale the coherence measurements in Figs. 11–13 was determined from a simple analytic form, $U_c/U_\infty = A\ \ln(B \cdot f)$, that was least-squares fit to the data for each flow condition shown in Fig. 10. Here, A and B are the fit constants and f is the frequency in hertz. In addition, the coherence spectra were postprocessed with a 1/20th decade top hat bandpass filter.

The coherence of surface pressure fluctuations during BDR is plotted in Fig. 12 for the three test speeds and all air injection rates. For clarity, results for only a single sensor pair spacing, ζ=2.00 cm, are shown in this figure. Relative to the base line, the coherence is typically suppressed over the entire frequency range shown and this suppression increases with increasing air injection rate. This observation implies that bubbles decrease the longevity of pressure sources within the boundary layer. The two exceptions to this observation are at the highest injection rates (400 and 800 SCFM) at 6.6 m/s, where a full or partial air film formed over the test surface. Here, the low frequency coherence is reduced, but the coherence at higher frequencies is elevated relative to the base line and it remains nearly constant at approximately 0.50. The reason for these changes is the different flow morphology. When a full or partial air layer forms, multiple irregularly shaped flat air pockets, with a thickness of ~1 cm and minimum horizontal dimension of δ(~10 cm) or greater, form and move downstream while

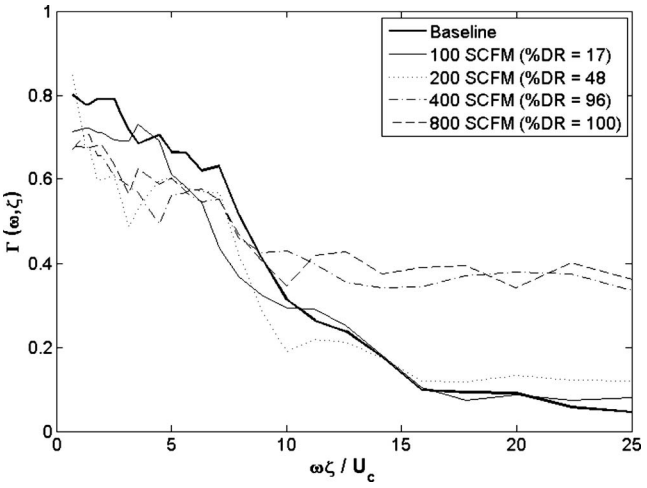

FIG. 13. Bubble modified streamwise coherence at 6.6 m/s with a single sensor pair spacing (ζ=4.6 cm) and all air injection rates.

slowly changing shape. As the air-flow rate increases, these air pockets merge and eventually form a complete air film. Thus, the enhanced high-frequency coherence in the 400 and 800 SCFM results in Fig. 12(a) can likely be attributed to passage of air-pocket edges over the pressure sensors. The decreased low frequency coherence is probably due to the air pockets altering or destroying large-scale base line TBL structures.

As a check of the similarity scaling of frequency and sensor spacing, BDR results from 6.6 m/s are provided in Fig. 13 for a sensor spacing of ζ=4.6 cm. A comparison of Figs. 12(a) and 13 shows that the differences are comparable (or nearly so) to differences in the single-phase coherence results at difference sensor spacings (see Fig. 11). Thus, the similarity variable $\omega\zeta/U_c$ appears to be equally valid in both single-phase and BDR TBL flows, even when a full or partial air layer forms. Hence, both turbulence- and bubble-originated pressure fluctuation sources move and evolve downstream in a similar manner.

IV. CONCLUSIONS

The data presented here show how the injection of air from the wall beneath a TBL modifies the spectra, coherence, and convection velocity of wall-pressure fluctuations. From this investigation, the following conclusions can be drawn. (1) rms pressure fluctuations without air injection have a Reynolds number dependence that is in good agreement with the scaling law proposed by Farabee and Casarella (1991). (2) With the injection of air, wall-pressure spectra are suppressed in the midfrequency range, approximately from $20 < \omega\delta/u_\tau < 2000$, where δ and u_τ are drawn from the equivalent single-phase base line boundary layer. However, air injection leads to increases in spectral levels above and below this range, likely caused by bubbles or pockets of air passing over the model surface and/or acoustic noise from the air injection process. In dimensional terms, the frequency range of this suppression shifts to slightly higher frequencies with increasing freestream velocity. The magnitude of this suppression increases monotonically with increasing skin-friction drag reduction. (3) Mean-square pressure fluctuations in BDR flows are reduced nearly in proportion to the reduction in skin friction, both relative to that measured in single-phase flow. (4) The convection velocity of pressure fluctuations above $\omega\delta/u_\tau \sim 50$ decreases with air injection, indicating that the pressure source terms for these frequencies are in a slower moving region of the flow. This convection velocity decrease becomes more apparent with increasing air injection rate. (5) The streamwise coherence of pressure fluctuations decreases during BDR, except when there is sufficient air to create an air layer between the liquid flow and the plate surface. (6) Comparisons of the base line coherence and the BDR coherence suggest that the usual frequency-distance similarity variable is equally valid when bubbles are present and when bubbles are absent.

(Received 29 June 2007; revised 4 February 2008; accepted 24 February 2008)

Despite significant recent advances in numerical methodologies for simulating rough-surface acoustic scattering, their applicability has been constrained by the limitations of state-of-the-art computational resources. This has been particularly true in high-frequency applications where the sheer size of the full-wave simulations render them impractical, and engineering processes must therefore rely on asymptotic models [e.g., Kirchhoff approximation (KA)]. However, the demands for high precision can make the latter inappropriate, thus efficient, error-controllable methodologies must be devised. This paper presents a computational strategy that combines the virtues of rigorous solvers (error control) with those of high-frequency asymptotic models (frequency-independent computational costs). These methods are based on *high-order* "boundary perturbations," which display high precision and unparalleled efficiency. This is accomplished by incorporating asymptotic phase information to effect a significant decrease in computational effort, simultaneously retaining the full-wave nature of the approach. The developments of this contribution are constrained to configurations that preclude multiple scattering; it is further explained how the schemes can be made applicable to general scattering scenarios, though implementation details are left for future work. Even for single-scattering configurations, the approach presented here gives significant gains in accuracy when compared to asymptotic theories (e.g., KA) with modest additional computational cost. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2897104]

I. INTRODUCTION

The significant advances in high-performance algorithms and hardware that have been attained over the last three decades have had a substantial impact on the classical engineering and design paradigm of repeated physical experimentation, interpretation, and modification in the most varied applications. Those relating to wave dynamics (e.g., acoustic, electromagnetic, elastic), such as in remote sensing,[1] nondestructive testing,[2] or imaging,[3] for instance, have increasingly relied on *numerical* simulations to accelerate assessment and/or prototyping projects. The success of such strategies has, in turn, provided further impetus to continue to migrate towards virtual experimentation and it has thus enhanced the need for evermore efficient and accurate simulators. These needs are, however, challenged by the increasing complexity of the processes to be numerically represented, which continuously test the limits of state-of-the-art computational methodologies and platforms. In the context of wave propagation these complexities can arise from that of the geometrical arrangement, from the intrinsic oscillations of the field quantities, or from both. Current simulation capabilities allow for the treatment of complicated geometries with a high degree of detail and accuracy. It is thus the requirement to resolve field quantities on the scale of the wavelength of oscillation that typically limits the applicability of advanced simulation schemes, and that consistently results in the need to abandon these in favor of approximate (high-frequency) asymptotic theories.

In this paper we introduce a family of numerical algorithms that are designed to overcome these limitations, simultaneously avoiding the inaccuracies that arise (at finite frequencies) from asymptotic solutions, such as those based on the classical Kirchhoff approximation[4] (KA) or on its corrected versions.[5–8] The schemes we present are based on *high-order* "boundary perturbations" (see, e.g., Refs. 9–16, and references cited therein) and can therefore be made to approximate the exact solution of full-wave scattering models to within any prescribed accuracy. As in classical implementations of these methods, the procedures we introduce here display a high degree of precision (owing to their spectral nature), and efficiency [stemming from the use of accelerated evaluations, e.g., based on fast-Fourier transforms (FFTs)]. In contrast with the classical approach, however, these characteristics are attained here, simultaneously avoiding the need to discretize the fields on the scale of the wavelength.

The basic observation that allows for such discretizations, and the consequent reduction in computational cost, relates to the possibility of predetermining the manner in

a)Electronic mail: nicholls@math.uic.edu
b)Electronic mail: reitich@math.umn.edu

which field quantities oscillate. More precisely, asymptotic high-frequency theories (e.g., geometrical acoustics) can be used *a priori* to predict the *phase* of the fields and, thus, to reduce the number of unknowns through its extraction, leaving only a slowly oscillatory modulation to be found. In the simplest case of impenetrable scatterers and wherein waves do not undergo multiple reflections, for instance, this phase takes on a particularly uncomplicated form, given by that of the incoming radiation on the surface of the obstacles and by the classical law of reflection away from these. This idea of phase extraction has been extensively used in the design of low-order analytical scattering theories (see, e.g., Refs. 5, 8, and 17–20) and, more recently, in the solution of integral equation formulations.[21–25] Here, in contrast, we explain how this can be incorporated into classical boundary perturbation algorithms to allow for efficient solutions of arbitrary accuracy.

Unlike low-order theories, the schemes we present here produce solutions that actually converge to that of the full-wave model. In fact, this characteristic also contrasts our approach with the high-order solutions of Refs. 21–23, which can be shown to be only asymptotic. Our methodology is perhaps most closely related to the work in Refs. 24 and 25, which introduces a *rigorous* approach to the numerical solution of high-frequency scattering problems based on the idea of phase extraction. This latter work is concerned with bounded scatterers for which an integral equation solver is designed to produce solutions with any prescribed accuracy in frequency-independent computational times. To this end, and in addition to the extraction of the phase, the work introduces suitable numerical mechanisms for a high-order treatment of the resulting singular and high-frequency integration problems, as well as of shadowing transitions[24] and multiple scattering effects.[25] Although a similar approach, based on integral equations, is certainly viable for the case we consider here of infinite (periodic) rough surfaces, the alternative perturbative procedures we advocate display some distinct advantages. In particular, for instance, these latter methodologies obviate the need to deal with the complications brought about by the corresponding Green's function (related to cost of its evaluation[26]), which are exacerbated at high frequencies, or with those related to the evaluation of oscillatory integrals.[25]

Although the derivations that follow apply to every boundary perturbation approach, for the sake of definiteness we shall detail these for two particularly popular schemes, namely the "field expansions" (FE) method of Bruno and Reitich[9–11] (a high-order, analytically continued version of the classical Rayleigh–Rice theory[27,28]); and the "operator expansion" (OE) method of Milder and co-worker[29–33] [based on perturbative expansions of the Dirichlet–Neumann Operator (DNO)]. In this initial contribution we constrain our developments to configurations that preclude multiple scattering, and are thus readily comparable with classical high-frequency approximations (e.g., KA). Extensions to cases wherein the effects of multiple scattering are significant can be attained through an iterative procedure that successively accounts for secondary reflections.[25] The numerical implementation of this procedure, however, is significantly more complicated (as it does, for instance, require the development of an accurate geometrical acoustics solver) and it is thus left for future work.

With these considerations, the rest of the paper is organized as follows: First, and for the sake of completeness, in Sec. II we recall the governing equations of rough surface scattering. Then, in Sec. III, we introduce the high-frequency versions of the OE and FE approaches that incorporate (single scattering) phase information to greatly reduce the number of degrees of freedom that are necessary to approximate the solution to any given accuracy. In Sec. IV we display results of numerical simulations which substantiate these claims and which show, in particular, that the approach can deliver significantly improved results when compared to classical asymptotic theories (e.g., KA) at a very modest additional computational cost. Finally, our conclusions follow in Sec. V.

II. GOVERNING EQUATIONS

The problem we consider is the scattering of time-harmonic acoustic waves from an impenetrable infinite surface which, for simplicity, is "sound soft" (our methods are easily modified to deal with other boundary conditions). We will consider the general three-dimensional case with crossed periodic gratings having shape represented by $y=g(x_1,x_2)$ where $g(x_1+d_1,x_2+d_2)=g(x_1,x_2)$ for periods d_1 and d_2.

If an incident plane wave,

$$v_i(x_1,x_2,y) = e^{i(\alpha x_1+\beta x_2-\gamma y)},$$

isonifies the surface, then this problem is governed by the Helmholtz equation with quasiperiodic lateral boundary conditions and a pressure release boundary condition at the scatterer, i.e.,

$$\Delta v + k^2 v = 0, \quad y > g(x_1,x_2), \tag{1a}$$

$$v(x_1,x_2,g(x_1,x_2)) = -v_i(x_1,x_2,g(x_1,x_2)) =: \xi(x_1,x_2), \tag{1b}$$

$$v(x_1+d_1,x_2+d_2,y) = e^{i(\alpha d_1+\beta d_2)} v(x_1,x_2,y), \tag{1c}$$

where v is the scattered field, ξ will denote the boundary data, and $k^2=\alpha^2+\beta^3+\gamma^2$. To specify a unique solution of Eq. (1) we need a boundary condition at infinity; this is given by an upward propagating condition,[34] which states that all scattered waves are "outgoing." It can be shown[15,16] that this can be explicitly enforced in the near-field with a "transparent boundary condition" at a hyperplane $y=a>\max|g|$. More precisely, Eq. (1) is equivalent to

$$\Delta v + k^2 v = 0, \quad g(x_1,x_2) < y < a, \tag{2a}$$

$$v(x_1,x_2,g(x_1,x_2)) = \xi(x_1,x_2), \tag{2b}$$

$$\partial_y v(x_1,x_2,a) - T[v(x_1,x_2,a)] = 0, \tag{2c}$$

$$v(x_1+d_1,x_2+d_2,y) = e^{i(\alpha d_1+\beta d_2)} v(x_1,x_2,y), \tag{2d}$$

where

$$T[\psi] := \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} (i\gamma_{p_1,p_2}) \hat{\psi}_{p_1,p_2} e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2)},$$

and

$$\alpha_{p_1} = \alpha + (2\pi/d_1)p_1, \quad \beta_{p_2} = \beta + (2\pi/d_2)p_2,$$

$$\gamma_{p_1,p_2} = \sqrt{k^2 - \alpha_{p_1}^2 - \beta_{p_2}^2}, \tag{3}$$

and $\mathrm{Im}\{\gamma_{p_1,p_2}\} \geq 0$. In this formula we have used the (generalized) Fourier series representation for quasiperiodic functions:

$$\psi(x_1,x_2) = \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} \hat{\psi}_{p_1,p_2} e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2)}. \tag{4}$$

Once computed, we can use the scattered field v to realize any of several near- and far-field quantities of interest. In the present context we will consider the normal derivative of the field at the surface of the scatterer:

$$\nu(x_1,x_2) := [\nabla v \cdot N_g]_{y=g},$$

where $N_g = (\partial_{x_1} g, \partial_{x_2} g, -1)^T$ is an exterior normal to the physical domain of the problem. As the "input" to our problem is the Dirichlet data ξ and the "output" is the Neumann information ν, this map is oftentimes called the DNO,[15,16] or Dirichlet-to-Neumann map.[35,36] We will denote this DNO by

$$G(g)[\xi] := [\nabla v \cdot N_g]_{y=g}$$
$$= [-\partial_y v + (\partial_{x_1} g)\partial_{x_1} v + (\partial_{x_2} g)\partial_{x_2} v]_{y=g}. \tag{5}$$

We note that knowledge of the DNO is exactly equivalent to that of the full solution to the scattering problem (2), as the field at any point can be readily recovered from this and the boundary pressure via Green's identities.

III. BOUNDARY PERTURBATION METHODS

The power and simplicity of boundary perturbation (BP) methods are based upon viewing the complicated problem domain as a perturbation of a much simpler one where the solution is trivial to compute. In the present context we view the shape of the grating, g, as a perturbation of a flat configuration, $g = \varepsilon f$ where, at the outset, ε will be small. Based upon this identification, one makes expansions of the form, e.g.,

$$v(x_1,x_2,y,\varepsilon) = \sum_{n=0}^{\infty} v_n(x_1,x_2,y)\varepsilon^n,$$

$$G(\varepsilon f)[\xi] = \sum_{n=0}^{\infty} G_n(f)[\xi]\varepsilon^n, \tag{6}$$

which can subsequently be shown to be *strongly convergent* under quite general conditions.[16,37] Additionally, these solutions can typically be continued analytically[16,38] so that, in fact, ε can be chosen quite large (provided that it remains real). In a numerical implementation this fact can be used to advantage if a suitable analytic continuation technique, such as Padé approximation,[39] is utilized. As we shall see, this combination of ideas leads to algorithms with quite remarkable properties of reliability, cost-effectiveness, and high-order accuracy.

A. Field expansions

The derivation of the FE method (originally named the "Method of Variation of Boundaries"[9–11]) begins with the expansion of the field, v:

$$v = v(x_1,x_2,y,\varepsilon) = \sum_{n=0}^{\infty} v_n(x_1,x_2,y)\varepsilon^n.$$

Upon insertion into Eq. (2) and evaluation at matching powers of ε, we realize the following system of equations to be solved:

$$\Delta v_n + k^2 v_n = 0, \quad 0 < y < a, \tag{7a}$$

$$v_n(x_1,x_2,0) = P_n(x_1,x_2), \tag{7b}$$

$$\partial_y v_n(x_1,x_2,a) - T[v_n(x_1,x_2,a)] = 0, \tag{7c}$$

$$v_n(x_1+d_1,x_2+d_2,y) = e^{i(\alpha d_1 + \beta d_2)} v_n(x_1,x_2,y), \tag{7d}$$

where

$$P_n(x_1,x_2) = \delta_{n,0}\xi(x_1,x_2) - \sum_{l=0}^{n-1} F_{n-l}(x_1,x_2)\partial_y^{n-l} v_l(x_1,x_2,0),$$

and

$$F_l(x_1,x_2) := \frac{f(x_1,x_2)^l}{l!}.$$

We recall that solutions v_n of Eqs. (7a), (7c), and (7d) can be written as

$$v_n(x_1,x_2,y) = \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} d_{p_1,p_2} e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2 + \gamma_{p_1,p_2} y)}, \tag{8}$$

c.f. Eq. (3). Given that ξ can be expressed as

$$\xi(x_1,x_2) = \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} \hat{\xi}_{p_1,p_2} e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2)},$$

c.f. Eq. (4), Eq. (7b) delivers a recursion formula for the $d_{p_1,p_2,n}$:

$$d_{p_1,p_2,n} = \delta_{n,0}\hat{\xi}_{p_1,p_2} - \sum_{l=0}^{n-1} \sum_{q_1=-\infty}^{\infty} \sum_{q_2=-\infty}^{\infty} F_{n-l,p_1-q_1,p_2-q_2} (i\gamma_{q_1,q_2})^{n-l} d_{q_1,q_2,l}, \tag{9}$$

where the coefficients F_{l,p_1,p_2} are defined by

$$F_l(x_1,x_2) =: \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} F_{l,p_1,p_2} e^{i((2\pi/d_1)p_1 x_1 + (2\pi/d_2)p_2 x_2)}.$$

To compute the DNO, Eq. (5), we note that

$$\sum_{n=0}^{\infty} G_n(f)[\xi]\varepsilon^n = G(\varepsilon f)[\xi]$$

$$= [-\partial_y v + (\varepsilon\partial_{x_1} f)\partial_{x_1} v + (\varepsilon\partial_{x_2} f)\partial_{x_2} v]_{y=\varepsilon f}$$

$$= \sum_{n=0}^{\infty} \varepsilon^n \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} (-i\gamma_{p_1,p_2} + (\varepsilon\partial_{x_1} f) i\alpha_{p_1} + (\varepsilon\partial_{x_2} f) i\beta_{p_2}) \times d_{p_1,p_2,n} e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2 + \gamma_{p_1,p_2}\varepsilon f)}.$$

From this we deduce that

$$G_n(f) = \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} \left(-\sum_{l=0}^{n} F_{n-l} (i\gamma_{p_1,p_2})^{n-l+1} d_{p_1,p_2,l} + \sum_{l=0}^{n-1} F_{n-l-1}((\partial_{x_1} f)(i\alpha_{p_1}) + (\partial_{x_2} f)(i\beta_{p_2})) \times (i\gamma_{p_1,p_2})^{n-l-1} d_{p_1,p_2,l} \right) e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2)}. \tag{10}$$

B. High frequency field expansions

As we shall see in Sec. IV A, the FE method we have just described is not particularly well suited for high-frequency simulations. If the Fourier–Taylor coefficients $d_{p_1,p_2,n}$ from Eq. (9) are truncated after $N_{x_1} \times N_{x_2}$ Fourier modes and N Taylor terms, then the FE method has quite modest time $[\mathcal{O}(N_{x_1} \log(N_{x_1}) N_{x_2} \log(N_{x_2}) N)]$ and memory $[\mathcal{O}(N_{x_1} N_{x_2} N)]$ requirements. However, *all* features of the scattered field must be resolved to realize an accurate solution and, for this, the number of Fourier terms $N_{x_1} \times N_{x_2}$ *must* scale like $k \times k$.

However, the technique of phase extraction[5,8,19,21,22] gives us insight into how one can create a FE method which is specially designed for high-frequency calculations. In the present context, and in the absence of multiple scattering, it can be shown (see, e.g., Refs. 24 and 40) that

$$v(x_1,x_2) = e^{i(\alpha x_1 + \beta x_2 - \gamma g(x_1,x_2))} \mu(x_1,x_2), \tag{11}$$

where μ is a "slowly varying" envelope whose variations *do not* accentuate with increasing frequency. Note that this implies, in particular, that a uniformly accurate representation of μ can be attained with a number of degrees of freedom that is independent of the wave number k. Motivated by this realization we factor the *field*

$$v(x_1,x_2,y) = e^{i(\alpha x_1 + \beta x_2 - \gamma y)} w(x,y)$$

and substitute this into Eq. (2), which delivers

$$\Delta w + 2i(\alpha,\beta,-\gamma)\cdot\nabla w = 0, \quad g(x) < y < a, \tag{12a}$$

$$w(x_1,x_2,g(x_1,x_2)) = -1, \tag{12b}$$

$$w(x_1+d_1,x_2+d_2,y) = w(x_1,x_2,y). \tag{12c}$$

For the condition at the artificial boundary $y=a$, c.f. Eq. (2c), we begin with the calculation:

$$v(x_1,x_2,a) = e^{i(\alpha x_1+\beta x_2)} e^{-ia\gamma} w(x_1,x_2,a)$$

$$= e^{-ia\gamma} e^{i(\alpha x_1+\beta x_2)} \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} \tilde{d}_{p_1,p_2} \times e^{i((2\pi/d_1)p_1 x_1 + (2\pi/d_2)p_2 x_2)}$$

$$= e^{-ia\gamma} \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} \tilde{d}_{p_1,p_2} e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2)},$$

where

$$\tilde{d}_{p_1,p_2} := \frac{1}{d_1 d_2} \int_0^{d_1} \int_0^{d_2} w(x_1,x_2,a) \times e^{-i((2\pi/d_1)p_1 x_1 + (2\pi/d_2)p_2 x_2)} dx_1 dx_2$$

is the (p_1,p_2)th Fourier coefficient of $w(x_1,x_2,a)$. Now, applying the operator T:

$$T[v(x_1,x_2,a)] = e^{-ia\gamma} T\left[\sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} \tilde{d}_{p_1,p_2} e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2)} \right]$$

$$= e^{-ia\gamma} \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} (i\gamma_{p_1,p_2}) \tilde{d}_{p_1,p_2} \times e^{i(\alpha_{p_1} x_1 + \beta_{p_2} x_2)}$$

$$= e^{i(\alpha x_1+\beta x_2)} e^{-ia\gamma} \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} (i\gamma_{p_1,p_2}) \tilde{d}_{p_1,p_2} \times e^{i((2\pi/d_1)p_1 x_1 + (2\pi/d_2)p_2 x_2)}.$$

Finally, Eq. (2c) gives

$$0 = \partial_y v(x_1,x_2,a) - T[v(x_1,x_2,a)]$$

$$= \left(\partial_y w(x_1,x_2,a) - \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} (i\gamma_{p_1,p_2} + i\gamma) \tilde{d}_{p_1,p_2} \times e^{i((2\pi/d_1)p_1 x_1 + (2\pi/d_2)p_2 x_2)} \right) e^{i(\alpha x_1+\beta x_2)} e^{-ia\gamma},$$

and we realize

$$\partial_y w(x_1,x_2,a) - T_0[w(x_1,x_2,a)] = 0, \tag{13}$$

where, for a *periodic* function $\zeta(x_1,x_2)$,

$$T_0[\zeta(x_1,x_2)] := \sum_{p_1=-\infty}^{\infty} \sum_{p_2=-\infty}^{\infty} (i\gamma_{p_1,p_2} + i\gamma) \times \hat{\zeta}_{p_1,p_2} e^{i((2\pi/d_1)p_1 x_1 + (2\pi/d_2)p_2 x_2)}. \tag{14}$$

Again, it can be shown that the (factored) field w can be expanded in a convergent Taylor series

$$w = w(x_1,x_2,y,\varepsilon) = \sum_{n=0}^{\infty} w_n(x_1,x_2,y)\varepsilon^n.$$

These w_n must satisfy

$$\Delta w_n + 2i(\alpha,\beta,-\gamma)\cdot\nabla w_n = 0, \quad 0 < y < a, \tag{15a}$$

$$w_n(x_1,x_2,0) = Q_n(x_1,x_2), \tag{15b}$$

$$\partial_y w_n(x_1,x_2,a) - T_0[w_n(x_1,x_2,a)] = 0, \tag{15c}$$

$$w_n(x_1+d_1,x_2+d_2,y) = w_n(x_1,x_2,y), \tag{15d}$$

where

$$Q_n(x_1,x_2) = -\delta_{n,0} - \sum_{l=0}^{n-1} F_{n-l}(x_1,x_2)\partial_y^{n-l} w_l(x_1,x_2,0).$$

Solutions of Eqs. (15a), (15c), and (15d) are given by

$$w_n(x_1,x_2,y) = \sum_{p_1=-\infty}^{\infty}\sum_{p_2=-\infty}^{\infty} b_{p_1,p_2,n} e^{(i\gamma_{p_1,p_2}+i\gamma)y} \times e^{i((2\pi/d_1)p_1x_1+(2\pi/d_2)p_2x_2)},$$

so that Eq. (15b) gives

$$b_{p_1,p_2,n} = -\delta_{n,0}\delta_{p_1,0}\delta_{p_2,0} - \sum_{l=0}^{n-1}\sum_{q_1=-\infty}^{\infty}\sum_{q_2=-\infty}^{\infty} F_{n-l,p_1-q_1,p_2-q_2} \times (i\gamma_{q_1,q_2}+i\gamma)^{n-l} b_{q_1,q_2,l}, \tag{16}$$

c.f. Eq. (9).

To compute the DNO we recall our factorization, Eq. (11), of the "fast" surface velocity ν as the product of an oscillatory term and a "slow" surface velocity μ. In terms of the slow field, w, we can write

$$\begin{aligned}\mu(x_1,x_2) &= e^{i(-\alpha x_1-\beta x_2+\gamma g(x_1,x_2))}\nu(x_1,x_2) = e^{i(-\alpha x_1-\beta x_2+\gamma g(x_1,x_2))}[-\partial_y v + (\partial_{x_1} g)\partial_{x_1} v + (\partial_{x_2} g)\partial_{x_2} v]_{y=g} = e^{i(-\alpha x_1-\beta x_2+\gamma g(x_1,x_2))}\\ &\times[(i\gamma)e^{i(\alpha x_1+\beta x_2-\gamma y)}w - e^{i(\alpha x_1+\beta x_2-\gamma y)}\partial_y w + (\partial_{x_1} g)(i\alpha)e^{i(\alpha x_1+\beta x_2-\gamma y)}w + (\partial_{x_2} g)(i\beta)e^{i(\alpha x_1+\beta x_2-\gamma y)}w\\ &+ (\partial_{x_1} g)e^{i(\alpha x_1+\beta x_2-\gamma y)}\partial_{x_1} w + (\partial_{x_2} g)e^{i(\alpha x_1+\beta x_2-\gamma y)}\partial_{x_2} w]_{y=g} = [(i\gamma)w - \partial_y w + (\partial_{x_1} g)(i\alpha)w + (\partial_{x_2} g)(i\beta)w + (\partial_{x_1} g)\partial_{x_1} w\\ &+ (\partial_{x_2} g)\partial_{x_2} w]_{y=g}.\end{aligned}$$

Now, if the w depends analytically upon ε then so will

$$\tilde{G}(\varepsilon f)[\psi(x_1,x_2)] := e^{i(-\alpha x_1-\beta x_2+\gamma\varepsilon f(x_1,x_2))} \times G(\varepsilon f)[e^{i(\alpha x_1+\beta x_2-\gamma\varepsilon f(x_1,x_2))}\psi(x_1,x_2)], \tag{17}$$

where $\psi\equiv -1$ corresponds to plane-wave scattering, i.e., $\tilde{G}(\varepsilon f)[-1]=\mu(x)$. Thus

$$\begin{aligned}\sum_{n=0}^{\infty}\tilde{G}_n(f)\varepsilon^n &= \tilde{G}(\varepsilon f)[-1]\\ &= [(i\gamma)w - \partial_y w + ((\varepsilon\partial_{x_1} f)(i\alpha) + (\varepsilon\partial_{x_2} f)\\ &\times(i\beta))w + (\varepsilon\partial_{x_1} f)\partial_{x_1} w + (\varepsilon\partial_{x_2} f)\partial_{x_2} w]_{y=g}\\ &= \sum_{n=0}^{\infty}\varepsilon^n\sum_{p_1=-\infty}^{\infty}\sum_{p_2=-\infty}^{\infty}[i\gamma - (i\gamma_{p_1,p_2}+i\gamma)\\ &+ (\varepsilon\partial_{x_1} f)i\alpha + (\varepsilon\partial_{x_2} f)i\beta + (\varepsilon\partial_{x_1} f)i(2\pi/d_1)p_1\\ &+ (\varepsilon\partial_{x_2} f)i(2\pi/d_2)p_2]\\ &\times b_{p_1,p_2,n} e^{i((2\pi/d_1)p_1x_1+(2\pi/d_2)p_2x_2+(\gamma+\gamma_{p_1,p_2})\varepsilon f)}.\end{aligned}$$

From this we have

$$\begin{aligned}\tilde{G}_n(f) = \sum_{p_1=-\infty}^{\infty}\sum_{p_2=-\infty}^{\infty}\Bigg(&\sum_{l=0}^{n} F_{n-l}(i\gamma)(i\gamma_{p_1,p_2}+i\gamma)^{n-l} b_{p_1,p_2,l}\\ &- \sum_{l=0}^{n} F_{n-l}(i\gamma_{p_1,p_2}+i\gamma)^{n-l+1} b_{p_1,p_2,l}\\ &+ \sum_{l=0}^{n-1} F_{n-l-1}[(\partial_{x_1} f)(i\alpha) + (\partial_{x_2} f)(i\beta)](i\gamma_{p_1,p_2}\\ &+ i\gamma)^{n-l-1} b_{p_1,p_2,l} + \sum_{l=0}^{n-1} F_{n-l-1}[(\partial_x f)i((2\pi/d_1)p_1)\\ &+ (\partial_{x_2} f)i(2\pi/d_2)p_2](i\gamma_{p_1,p_2}+i\gamma)^{n-l-1} b_{p_1,p_2,l}\Bigg).\end{aligned} \tag{18}$$

To reconstruct the DNO we simply multiply each of the $\tilde{G}_n$ by the factor $\exp(i(\alpha x_1+\beta x_2-\gamma g(x_1,x_2)))$.

C. Operator expansions

The OE method of Milder and co-worker[29–33] is a somewhat different approach than the FE algorithm as it endeavors to compute, given Dirichlet data, *only* the normal derivative (the DNO). Of course, as we mentioned, if the full field is desired then an appropriate integral can be used to recover this. To specify this OE algorithm we begin with the observation that the function

$$u_p(x,y) = e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2+\gamma_{p_1,p_2}y)}$$

satisfies Eqs. (2a), (2c), and (2d). Recalling the definition of the DNO, Eq. (5), and, again, setting $g(x_1,x_2)=\varepsilon f(x_1,x_2)$, we observe that

$$\begin{aligned} &G(\varepsilon f)[e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2+\gamma_{p_2,p_2}\varepsilon f(x_1,x_2))}] \\ &\quad = (-i\gamma_{p_1,p_2}+\varepsilon(\partial_{x_1}f)(i\alpha_{p_1})+\varepsilon(\partial_{x_2}f) \\ &\qquad \times(i\beta_{p_2}))e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2+\gamma_{p_1,p_2}\varepsilon f(x_1,x_2))}. \end{aligned} \tag{19}$$

Our goal is to, once again, take advantage of the analyticity properties of the DNO to find the Neumann data. This requires a formula for the nth term in the expansion of the DNO, G_n, c.f. Eq. (6), as applied to a generic quasiperiodic function $\xi(x_1,x_2)$. Making use of the representation

$$\xi(x_1,x_2) = \sum_{p_1=-\infty}^{\infty}\sum_{p_2=-\infty}^{\infty}\hat{\xi}_{p_1,p_2}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}, \tag{20}$$

c.f. Eq. (4), it suffices to find a formula for G_n applied to a single harmonic $\exp(i(\alpha_{p_1}x_1+\beta_{p_2}x_2))$. For this we use Eq. (19):

$$\begin{aligned} &\left(\sum_{n=0}^{\infty}\varepsilon^n G_n(f)\right)\left[e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}\sum_{n=0}^{\infty}F_n(i\gamma_{p_1,p_2})^n\varepsilon^n\right] \\ &\quad = (-i\gamma_{p_1,p_2}+\varepsilon(\partial_{x_1}f)(i\alpha_{p_1})+\varepsilon(\partial_{x_2}f) \\ &\qquad \times(i\beta_{p_2}))e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}\sum_{n=0}^{\infty}F_n(i\gamma_{p_1,p_2})^n\varepsilon^n, \end{aligned}$$

where, again, $F_l := f^l/l!$. At order ε^0 we find

$$G_0[e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}] = -i\gamma_{p_1,p_2}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)},$$

which, using Eq. (20), gives

$$\begin{aligned} G_0[\xi] &= -i\gamma_D\xi \\ &:= \sum_{p_1=-\infty}^{\infty}\sum_{p_2=-\infty}^{\infty}(-i\gamma_{p_1,p_2})\hat{\xi}_{p_1,p_2}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}, \end{aligned}$$

and defines the order-one Fourier multiplier G_0. At order ε^n, $n\geq 1$, we have

$$\begin{aligned} &G_n(f)[e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}] \\ &\quad = -F_n(i\gamma_{p_1,p_2})^{n+1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}+[(\partial_{x_1}f)F_{n-1}(i\alpha_{p_1}) \\ &\quad + (\partial_{x_2}f)F_{n-1}(i\beta_{p_2})](i\gamma_{p_1,p_2})^{n-1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)} \\ &\quad - \sum_{l=0}^{n-1}G_l(f)[F_{n-l}(i\gamma_{p_1,p_2})^{n-l}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}]. \end{aligned}$$

We can simplify the first two terms

$$\begin{aligned} R_n &:= -F_n(i\gamma_{p_1,p_2})^{n+1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}+(\partial_{x_1}f)F_{n-1}(i\alpha_{p_1}) \\ &\quad \times(i\gamma_{p_1,p_2})^{n-1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}+(\partial_{x_2}f)F_{n-1}(i\beta_{p_2}) \\ &\quad \times(i\gamma_{p_1,p_2})^{n-1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)} \\ &= \{-F_n(i\gamma_{p_1,p_2})^2+(\partial_{x_1}f)F_{n-1}(i\alpha_{p_1}) \\ &\quad +(\partial_{x_2}f)F_{n-1}(i\beta_{p_2})\}(i\gamma_{p_1,p_2})^{n-1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)} \end{aligned}$$

with the observation that, as $\alpha_{p_1}^2+\beta_{p_2}^2+\gamma_{p_1,p_2}^2=k^2$, we have

$$\begin{aligned} R_n &= \{F_nk^2+F_n(i\alpha_{p_1})^2+F_n(i\beta_{p_2})^2+(\partial_{x_1}f)F_{n-1}(i\alpha_{p_1}) \\ &\quad +(\partial_{x_2}f)F_{n-1}(i\beta_{p_2})\}(i\gamma_{p_1,p_2})^{n-1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}. \end{aligned}$$

Rewriting this using differential operators and the product rule we realize

$$\begin{aligned} R_n &= \{F_nk^2+F_n\partial_{x_1}^2+F_n\partial_{x_2}^2+(\partial_{x_1}f)F_{n-1}\partial_{x_1} \\ &\quad +(\partial_{x_2}f)F_{n-1}\partial_{x_2}\}(i\gamma_D)^{n-1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)} \\ &= \{F_nk^2+\partial_{x_1}F_n\partial_{x_1}+\partial_{x_2}F_n\partial_{x_2}\}(i\gamma_D)^{n-1}e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2)}, \end{aligned}$$

resulting in

$$\begin{aligned} G_n(f)[\xi] &= k^2F_n(i\gamma_D)^{n-1}\xi+\partial_{x_1}F_n\partial_{x_1}(i\gamma_D)^{n-1}\xi \\ &\quad +\partial_{x_2}F_n\partial_{x_2}(i\gamma_D)^{n-1}\xi-\sum_{l=0}^{n-1}G_l(f)[F_{n-l}(i\gamma_D)^{n-l}\xi], \end{aligned} \tag{21}$$

where we have again used Eq. (20).

D. High frequency operator expansions

In a manner similar to that outlined in Sec. III B we can design a high-frequency OE method by making use of factorization (11). For this "high frequency operator expansions" (HFOE) method we wish to work directly with the DNO, however, now it should be scaled by the incident radiation so that it is slowly varying. Again, our goal is to find a formula for the nth term in the expansion acting on an *arbitrary* function. However, our surface function is the *periodic*, factored (slowly varying) incident radiation

$$\psi(x_1,x_2) := e^{i(-\alpha x_1-\beta x_2+\gamma g(x_1,x_2))}\xi(x_1,x_2) = -1.$$

Of course, this has a trivial Fourier series

$$\psi(x_1,x_2) = \hat{\psi}_{0,0}e^{i(0x_1+0x_2)} = (-1)e^{i(0x_1+0x_2)},$$

but we find it convenient to find the action of the nth term in the expansion of the reduced DNO applied to a general Fourier mode $\exp(i((2\pi/d_1)p_1x_1+(2\pi/d_2)p_2x_2))$.

As before, c.f. Eq. (17), we claim that $\tilde{G}(\varepsilon f)$ depends analytically upon ε, so that

$$\tilde{G}(\varepsilon f) = \sum_{n=0}^{\infty}\tilde{G}_n(f)\varepsilon^n.$$

To derive an explicit recurrence for the operators $\tilde{G}_n(f)$, we set

$$\psi(x_1,x_2) = e^{i((2\pi/d_1)p_1x_1+(2\pi/d_2)p_2x_2+\gamma g(x_1,x_2)+\gamma_{p_1,p_2}g(x_1,x_2))}. \tag{22}$$

Using this and the definition, Eq. (17), we find

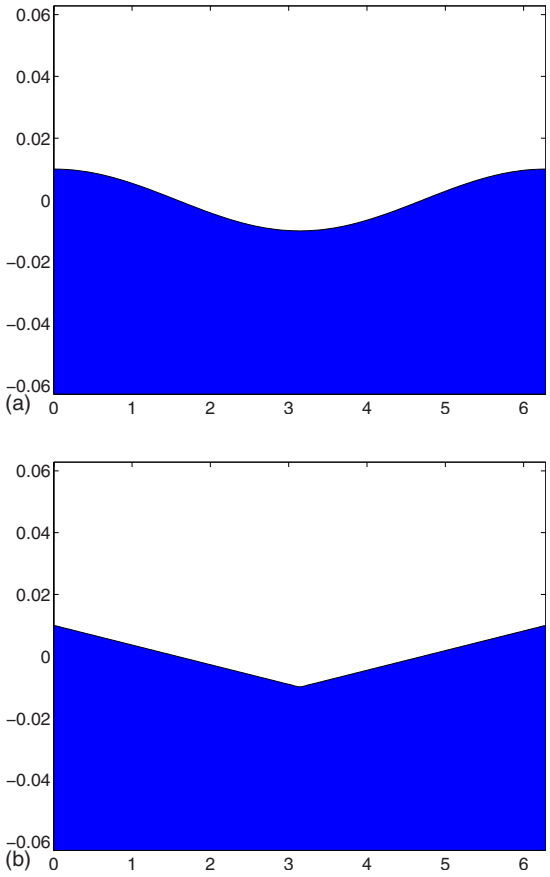

FIG. 1. (Color online) Plots of the two-dimensional profiles $f_s(x)=\cos(x)$, Eq. (24a), and $f_{L,40}$, Eq. (25).

$$\tilde{G}(g)[\psi] = e^{i(-\alpha x_1-\beta x_2+\gamma g(x_1,x_2))} \times G(g)[e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2+\gamma_{p_1,p_2}g(x_1,x_2))}] = e^{i(-\alpha x_1-\beta x_2+\gamma g(x_1,x_2))}[-\partial_y v(x_1,x_2,y) + (\partial_{x_1}g)\partial_{x_1}v(x_1,x_2,y) + (\partial_{x_2}g)\partial_{x_2}v(x_1,x_2,y)]_{y=g},$$

as the Dirichlet data, Eq. (22), we provide to G gives rise to the exact solution:

$$v(x_1,x_2,y) = e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2+\gamma_{p_1,p_2}y)}.$$

Continuing,

$$\tilde{G}(\varepsilon f)[\psi] = e^{i(-\alpha x_1-\beta x_2+\gamma\varepsilon f(x_1,x_2))}(-i\gamma_{p_1,p_2} + (\varepsilon\partial_{x_1}f)(i\alpha_{p_1}) + (\varepsilon\partial_{x_2}f)(i\beta_{p_2}))e^{i(\alpha_{p_1}x_1+\beta_{p_2}x_2+\gamma_{p_1,p_2}\varepsilon f(x_1,x_2))} = (-i\gamma_{p_1,p_2} + (\varepsilon\partial_{x_1}f)(i\alpha_{p_1}) + (\varepsilon\partial_{x_2}f)(i\beta_{p_2})) \times e^{i(2\pi/d_1)p_1x_1+i(2\pi/d_2)p_2x_2+(i\gamma_{p_1,p_2}+i\gamma)\varepsilon f(x_1,x_2)},$$

c.f. Eq. (19). Expanding as we did in the previous section:

$$\left(\sum_{n=0}^{\infty}\varepsilon^n\tilde{G}_n(f)\right)\left[e^{i((2\pi/d_1)p_1x_1+(2\pi/d_2)p_2x_2)}\sum_{n=0}^{\infty}F_n(i\gamma_{p_1,p_2} + i\gamma)^n\varepsilon^n\right] = (-i\gamma_{p_1,p_2} + \varepsilon(\partial_{x_1}f)(i\alpha_{p_1}) + (\varepsilon\partial_{x_2}f) \times i\beta_{p_2}))e^{i((2\pi/d_1)p_1x_1+(2\pi/d_2)p_2x_2)} \times\sum_{n=0}^{\infty}F_n(i\gamma_{p_1,p_2}+i\gamma)^n\varepsilon^n,$$

we find that, at order zero,

$$\tilde{G}_0[\psi] = -(i\gamma_D)\psi,$$

and at order $n\geq 1$,

$$\tilde{G}_n[\psi] = -F_n(i\gamma_D)(i\gamma_D+i\gamma)^n\psi + (\partial_{x_1}f)F_{n-1}(i\alpha_D)(i\gamma_D+i\gamma)^{n-1} \times\psi + (\partial_{x_2}f)F_{n-1}(i\beta_D)(i\gamma_D+i\gamma)^{n-1}\psi - \sum_{l=0}^{n-1}\tilde{G}_l[F_{n-l}(i\gamma_D+i\gamma)^{n-l}\psi]. \quad (23)$$

IV. NUMERICAL TESTS

In this section we illustrate the superior accuracy one can realize with our new algorithms with cost *independent* of the frequency. We begin with a series of numerical tests in two dimensions, Sec. IV A, where we consider gratings which are invariant in one direction and the incident field is aligned precisely so that this invariant direction can be ignored. This configuration can be simulated with the algorithms outlined earlier by simply setting $\beta=0$, setting $d=d_1$, $x=x_1$, etc. In Sec. IV B we consider the full three-dimensional problem and show that our general conclusions are unchanged.

A. Two-dimensional tests

To test the usefulness of the two new algorithms, high-frequency field expansion (HFFE) and high frequency operator expansion (HFOE), outlined previously we will use them

TABLE II. Relative error in FE, OE, HFFE, and HFOE algorithms (all with $N_x=16$) vs perturbation order N for the cosine profile, Eq. (24a), as compared to a highly resolved TFE simulation ($N_x=1024$, $N_y=64$, $N=28$); frequency is $(\alpha=10,\gamma=10)$.

to compute the induced normal surface velocity for two scatterers with very different smoothness. For simplicity we assume the period to be $d=2\pi$, and we consider the following profiles:[15,16] A sinusoid

$$f_s(x)=\cos(x), \tag{24a}$$

and a nondifferentiable ("Lipschitz") function

$$f_L(x)=\begin{cases}-(2/\pi)x+1, & 0\le x\le \pi\\ (2/\pi)x-3, & \pi\le x\le 2\pi.\end{cases} \tag{24b}$$

For our simulations we point out that f_L admits an infinite Fourier series expansions:[15]

$$f_L(x)=\sum_{r=1}^{\infty}\frac{8}{\pi^2(2r-1)^2}\cos((2r-1)x),$$

which, in our numerical simulations, we will truncate after P terms:

$$f_{L,P}(x)=\sum_{r=1}^{P/2}\frac{8}{\pi^2(2r-1)^2}\cos((2r-1)x); \tag{25}$$

please see Fig. 1 for depictions of, Eqs. (24a) and (25) ($P=40$).

Of course, for a generic profile there is no exact closed-form solution to the problem of plane-wave scattering by a grating so we resort to an alternative method to produce an "exact solution" with which we can compare. For this purpose we use the reliable, high-order "transformed field expansion" (TFE) method[16,41] for very large and/or very rough scatterers. For all of the two-dimensional simulations we present, a highly resolved reference solution was produced using this TFE algorithm with $N_x=1024$ (horizontal) Fourier modes, $N_y=64$ (vertical) Chebyshev coefficients, and $N=28$ Taylor orders; see Ref. 16 for a complete description of this method and these numerical parameters. These reference solutions can be shown to attain relative accuracies of the order of 10^{-10} which certainly suffice for our demonstration purposes. In this context then this becomes the smallest realizable "error," though the actual solutions we compute can be significantly more accurate when compared to the actual exact solution.

TABLE V. Relative error in HFFE and HFOE algorithms summed via Taylor and Padé algorithms (all with $N_x=32$) vs perturbation order N for the cosine profile, Eq. (24a), as compared to a highly resolved TFE simulation ($N_x=1024$, $N_y=64$, $N=28$); frequency is ($\alpha=100, \gamma=100$).

In Tables I–III we display results of FE, HFFE, OE, and HFOE simulations of plane-wave scattering from the sinusoidal profile, Eq. (24a), with $\varepsilon=0.01$ (to exclude the possibility of multiple reflections) for $(\alpha,\gamma)=(1,1)$, $(10,10)$, and (100,100), respectively. To exemplify the capabilities of our new methods, in all of these simulations we fix the number of Fourier modes at $N_x=16$ and study our solutions as the Taylor order is varied among $N=0$, 2, 4, 6, and 8. In this, and all future simulations, we have summed these Taylor series using Padé approximation[39] although, as the order N is quite small, the accuracy gains were typically modest.

In Table I we see that all four algorithms realize the optimal errors with respect to the TFE solution (of the order of 10^{10}) by perturbation order $N=6$ which is to be expected as this solution for $(\alpha,\gamma)=(1,1)$ is not very oscillatory. However, for this discretization, the FE and OE algorithms produce inaccurate results for $(\alpha,\gamma)=(10,10)$ and (100,100). Of course, this is not surprising as these algorithms attempt to resolve quite oscillatory functions with only $|r|<N_x/2=8$ modes. By contrast, as our new HFFE/HFOE methods simulate the *slowly* varying envelope μ, we notice *uniformly* excellent convergence behavior for all choices of (α,γ) where accuracies of 10^{-9} or 10^{-10} are always achieved with $N=8$ perturbation orders. For this final frequency we also display a plot of the slow, $\mu(x)$, and fast, $\nu(x)$, surface velocities in Fig. 2. From this we can clearly see how our new approach delivers such superior accuracy as the slowly changing function $\mu(x)$ can easily be represented with $N_x=16$ which is obviously insufficient for the highly oscillatory $\nu(x)$.

In Table IV we display results of FE, HFFE, OE, and HFOE simulations of plane-wave scattering from the sinusoidal profile, Eq. (24a), with various values of ε, $N_x=16$, $N=8$, and $(\alpha,\gamma)=(100,100)$. The results in this table exemplify the broad range of applicability of our scheme within the setting of single scattering configurations. To determine the limits of our new approach, a simple geometrical acoustics calculation is needed to determine the first appearance of multiple reflection for the given incidence and grating shape. For instance, in the present case of the sinusoidal profile, Eq. (24a), and incident radiation $\alpha=\gamma$ we have determined that multiple reflections occur once $\varepsilon\approx0.36$. By contrast, for the same profile but *normal* incidence, $\alpha=0$, we found that secondary reflections occur at $\varepsilon\approx0.82$.

TABLE VII. Relative error in FE, OE, HFFE, and HFOE algorithms (all with $N_x=256$) vs perturbation order N for the Lipschitz profile, Eq. (25), as compared to a highly resolved TFE simulation ($N_x=1024$, $N_y=64$, $N=28$); frequency is $(\alpha=10,\gamma=10)$.

10	4.05×10^{-11}	4.1×10^{-11}	6.97×10^{-11}	4.1×10^{-11}
12	4.05×10^{-11}	4.1×10^{-11}	6.99×10^{-11}	4.1×10^{-11}

In Table V we display results which illustrate the stabilizing effect which Padé summation can have on our algorithm. We again consider scattering from the cosine profile with incident radiation of frequency $(\alpha,\gamma)=(100,100)$, but now focus on the largest value of ε presented thusfar ($\varepsilon=0.1$) and compare, for values of the Taylor order $N=0,\ldots,12$ (for a slightly larger $N_x=32$ to avoid aliasing), the convergence of our high-frequency methods (HFFE and HFOE) with both Taylor and Padé summation. We see that through six orders all four calculations produce roughly the same precision, however, beyond eight orders the results from Taylor summation begin to deteriorate. This is particularly true for the HFOE algorithm, and highlights the advantageous properties of Padé summation even within the disk of convergence of these Taylor series.

We now present calculations for the Lipschitz profile, Eq. (25), (with $\varepsilon=0.01$) which features Fourier series which decay very slowly (as r increases). Due to this extremely slow decay we found it necessary to choose $N_x=256$ before our high-frequency algorithms gave uniformly good results. For this reason, the unmodified algorithms (FE and OE) were quite competitive up to $(\alpha,\gamma)=(10,10)$ (see Tables VI and VII). However, once the frequency reached (α,γ)

TABLE IX. Relative error in Kirchhoff Approximation for cosine, Eq. (24a) and Lipschitz profiles, Eq. (25), as compared to a highly resolved TFE simulation ($N_x=1024$, $N_y=64$, $N=28$).

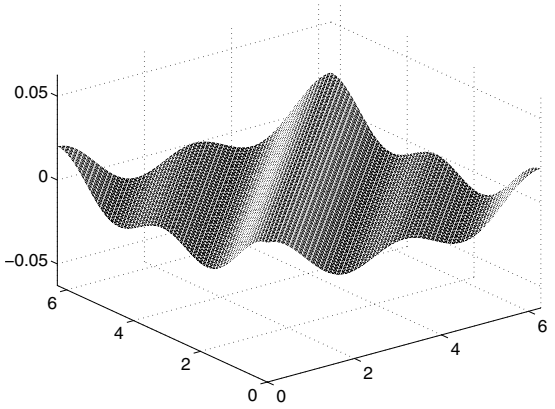

FIG. 3. Plot of the three-dimensional profile $f_r^{(3)}(x_1,x_2)$, Eq. (26).

$=(100,100)$ our specially designed algorithms were clearly superior, see Table VIII. Again, the range of applicability of our algorithm is determined by the onset of multiple scattering events which, we have calculated, to set in at $\varepsilon \approx 0.42$ for $\alpha=\gamma$ and $\varepsilon \approx 0.91$ for normal incidence, $\alpha=0$.

Finally, we make a comparison of our new methods to the KA for these configurations. The results are summarized in Table IX and show that, while the KA does give improved results as the frequency is increased, it never approaches the accuracy of our new HFFE/HFOE algorithms.

B. Three-dimensional test

We now present a set of illustrative numerical simulations to show that the HFFE and HFOE algorithms again deliver highly accurate solutions with very few degrees of freedom even in the three-dimensional case of scattering by a crossed grating. For this set of experiments we consider the three-dimensional smooth profile:

$$f_r^{(3)}(x_1,x_2) = \cos(x_1 - x_2) + \cos(2x_1 - 2x_2), \tag{26}$$

which is 2π periodic in both the x_1 and x_2 directions, and choose $\varepsilon=0.01$ to avoid multiple reflections (see Fig. 3). Again, we will use all four algorithms to compute the normal derivative of the field at the surface of the scatterer and compare this with a highly resolved TFE simulation, again accurate to around 10^{-10} ($N_{x_1}=128$, $N_{x_2}=128$, $N_y=64$, $N=28$). We display results of these simulations with $N_{x_1}=32$, $N_{x_2}=32$, and Taylor orders $N=0$, 2, 4, 6, and 8 in Tables X–XII for $(\alpha,\beta,\gamma)=(1,1,1)$, $(10,10,10)$, and $(100,100,100)$, respectively.

TABLE X. Relative error in FE, OE, HFFE, and HFOE algorithms (all with $N_{x_1}=32$ and $N_{x_2}=32$) vs perturbation order N for the three dimensional smooth profile, Eq. (26), as compared to a highly resolved TFE simulation ($N_{x_1}=128$, $N_{x_2}=128$, $N_y=64$, $N=28$); frequency is $(\alpha=1,\beta=1,\gamma=1)$.

8	5.3×10^{-5}	5.56×10^{-11}	5.3×10^{-5}	5.56×10^{-11}

For a relatively small frequency, $(\alpha,\beta,\gamma)=(1,1,1)$, all four algorithms work very well, c.f. Table X. However, at the more moderate frequency $(\alpha,\beta,\gamma)=(10,10,10)$ the standard FE/OE methods become disadvantaged and can only resolve the normal derivative of the field to 10^{-5}, see Table XI. Finally, once we reach the relatively high frequency $(\alpha,\beta,\gamma)=(100,100,100)$ the FE/OE approaches produce inaccurate results while the HFFE and HFOE methods produce solutions which are accurate to 10^{-10}.

To close, we note, for sake of comparison, that the KA delivers solutions with errors 0.065 260 7, 0.010 607 6, 0.000 975 237 for $(\alpha,\beta,\gamma)=(1,1,1)$, $(10,10,10)$, and $(100,100,100)$, respectively. Again, these errors are decreasing as the frequency is increased, but the KA solution cannot compete with the ones that HFFE/HFOE produce.

V. CONCLUSIONS

In this paper we have shown how asymptotic phase information can be incorporated into high-order boundary perturbation methods to produce numerical algorithms for acoustic scattering, which are error controllable with frequency-independent computational cost. A detailed specification has been given for two particularly popular boundary perturbation schemes, the "field expansions" method, based on perturbative expansions of the pressure, and the "operator expansion" method which works with expansions of the relevant Dirichlet–Neumann operator. Of particular note, these new methods *never* produce significantly worse results than the original FE/OE recursions, regardless of the frequency. Therefore it appears that these high-frequency schemes are to be recommended for *all* configurations where FE and OE are applicable. Also, provided that we have properly resolved the profile, there is *always* a smallest frequency for which these

new methods are significantly more accurate than the standard FE/OE algorithms. Further, for frequencies larger than this critical value the FE/OE recursions become unreliable, whereas our new procedures produce consistently accurate results. In this first contribution we have restricted our descriptions and numerical results to geometries which do not generate multiple reflections. However, we have discussed how these single-reflection methods can be rendered applicable to multiple scattering configurations, though we leave the specification and implementation to future work.

(Received 4 June 2007; revised 25 February 2008; accepted 3 March 2008)

The author has proposed a modified gap stiffness model, which is incorporated into the Biot model; the resultant model is called the BIMGS model. By using this model, it is theoretically demonstrated that the frame bulk modulus is dependent on frequency [M. Kimura, "Frame bulk modulus of porous granular marine sediments," J. Acoust. Soc. Am. **120**, 699–710 (2006)]. In this study, the modified gap stiffness model is reinvestigated and approximated expressions are derived for low- and high-frequency ranges. In particular, experimental validation of the BIMGS model is carried out. First, for glass beads and beach sands, the modified gap stiffness at a high frequency is experimentally obtained as a function of the grain size. Second, by using the measured values of the longitudinal wave velocities in the glass beads with two types of alcohol-water-mixed liquids, it is validated that the frame bulk modulus is a linear function of the fluid bulk modulus and that the frame bulk modulus is dependent on frequency, which can be derived from the BIMGS model. Finally, for applying the BIMGS model, it is shown that the reported velocity dispersion and the frequency dependence of attenuation, which cannot be explained by using the Biot-Stoll model with a constant frame bulk modulus, can be explained.

I. INTRODUCTION

Velocity dispersion in marine sediments is one of the important subjects that remains unresolved in the field of sediment acoustics.[1,2] The reported velocity dispersion is greater than the dispersion calculated by using the Biot-Stoll model with a constant frame bulk modulus.[1,3,4] Among the 13 physical parameters that are required by the Biot-Stoll model,[5–10] the value of the frame bulk modulus is one of the most difficult to estimate.[11] The author has proposed the BIMGS model (a modified gap stiffness model incorporated into the Biot model),[12] which is an improved version of Chotiros and Isakson's model.[13] In this model, the frame bulk modulus is the summation of the frequency-independent Hertz-Mindlin term and the frequency-dependent modified gap stiffness term, whose relaxation frequency is a function of the bulk modulus, viscosity of the fluid, and aspect ratio. That is, the frame bulk modulus in the BIMGS model is predicted to begin from a low-frequency asymptotic value and increase toward a high-frequency asymptotic value. Thus, the BIMGS model has been theoretically proposed. However, experimental validation of the model has not been carried out.

In this study, the BIMGS model is reinvestigated and approximated expressions are derived for the modified gap stiffness at low- and high-frequency ranges. In particular, the BIMGS model is experimentally validated. First, the modified gap stiffness at a frequency considerably higher than the relaxation frequency of it is experimentally obtained as a function of the grain size by using the measured results of the longitudinal wave velocities in the glass beads with 4 different kinds of grain sizes and 85 kinds of beach sands. In the BIMGS model, the frame bulk modulus at a high frequency is a linear function of the fluid bulk modulus, and the frame bulk modulus is dependent on frequency. The longitudinal wave velocities are measured in glass beads with two types of alcohol-water-mixed liquids with different viscosities and with different weight concentrations. Two types of alcohols—ethanol and methanol—with almost the same bulk moduli and with different ratios of the bulk modulus to the viscosity were used. By using these data sets, the BIMGS model was experimentally validated. Finally, for an application of the BIMGS model, it is shown that the reported velocity dispersion and the frequency dependence of the attenuation, which cannot be explained by using the Biot-Stoll model with a constant frame bulk modulus, can be explained by using this model.

In Sec. II, the BIMGS model will be reinvestigated and the expressions for the modified gap stiffness for low- and high-frequency ranges will be derived. In Sec. III, the modified gap stiffness at a high frequency will be experimentally obtained as a function of the grain size for glass beads and beach sands. Moreover, it will be experimentally validated that the frame bulk modulus is a linear function of the fluid bulk modulus and the frame bulk modulus is dependent on frequency. In Sec. IV, by using the BIMGS model, it will be shown that the reported velocity dispersion and the frequency dependence of attenuation can be explained. Finally, the paper will be concluded in Sec. V.

II. THE BIMGS MODEL

The BIMGS model has been developed by the author.[12] This model describes the acoustic relaxation due to the local fluid flow[14–16] in the gap between the grains. A porous grain contact has an effective normal stiffness. The effective normal stiffness k_n is the sum of the elastic stiffness of the solid-to-solid contact (contact stiffness) k_c and the effective stiffness of the contact gap (modified gap stiffness) k_g; this can be expressed as follows:

$$k_n = k_c + k_g. \tag{1}$$

The modified gap stiffness k_g is expressed as

$$k_g = \frac{\pi a^2 K_f}{h_0}\left(1 - \frac{1}{\frac{\kappa a}{2}\frac{J_0(\kappa a)}{J_1(\kappa a)}}\right), \tag{2}$$

where a denotes the contact radius, h_0 is the initial value of the gap separation distance, K_f is the fluid bulk modulus, and J_0 and J_1 are the Bessel functions of the first kind of the zeroth and first orders, respectively. κa is defined as follows:

$$\kappa a = \sqrt{-j2\pi\frac{f}{f_r}}, \tag{3}$$

where f_r is the relaxation frequency of the modified gap stiffness that is dependent on the bulk modulus K_f, viscosity η of the pore fluid, and the aspect ratio $\alpha(=h_0/a)$ as follows:[17]

$$f_r = \frac{1}{12}\frac{K_f}{\eta}\alpha^2. \tag{4}$$

The normalized modified gap stiffness k_{gn} is expressed as

$$k_{gn} = \frac{k_g}{k_{g\infty}} = 1 - \frac{1}{\frac{\kappa a}{2}\frac{J_0(\kappa a)}{J_1(\kappa a)}}\left(k_{g\infty} = \frac{\pi a^2 K_f}{h_0}\right). \tag{5}$$

The frequency characteristics of the normalized modified gap stiffness k_{gn} were investigated for low- and high-frequency ranges. At low frequencies $(f<2f_r)$, the normalized modified gap stiffness k_{gn} given in Eq. (5) can be approximated to the Maxwell model as follows:

$$k_{gn} = \frac{0.76}{1 - j\frac{f_r}{f}} \quad (f < 2f_r). \tag{6}$$

At high frequencies $(f>2f_r)$, the subsequent approximated expression

$$k_{gn} = 1 - \frac{0.925}{\left(\frac{\sqrt{\pi\frac{f}{f_r}}}{2} + \frac{1}{8}\right) + j\left(\frac{\sqrt{\pi\frac{f}{f_r}}}{2} - \frac{1}{8}\right)} \quad (f > 2f_r) \tag{7}$$

can be obtained by using the approximated expressions for the Bessel functions of the first kind of the zeroth and first orders[18] and fitting the coefficients of these equations for obtaining a better agreement between the approximated and exact values. A spring and dashpot model can be written for the modified gap stiffness k_g in each frequency range in Fig. 1. From this figure, it is observed that the Maxwell model can be applied for $f<2f_r$, that is, the loss factor is purely resistive. The factor of 0.76 in Eq. (6) appears in the BIMGS model for $f<2f_r$, under conditions in which the modified gap stiffness is normalized by that at an infinite frequency. However, the Maxwell model cannot be applied for $f>2f_r$. For $f>2f_r$, the frequency-dependent dashpot is replaced in parallel to the frequency-dependent spring k_η and dashpot η_g', that is, the loss factor is not purely resistive. The viscosity decreases and the elasticity increases with the frequency. At an infinite frequency, there is only the spring $k_{g\infty}(=\pi a^2 K_f/h_0)$, which means that the fluid has no time to flow in and out and the only compliant part of the gap is the bulk modulus of the fluid in the gap. The calculated results obtained by using the approximated equations [Eqs. (6) and (7)] are shown in Fig. 2. From this figure, it is observed that the calculated results obtained by using the approximated and exact equations are almost the same. The modified gap

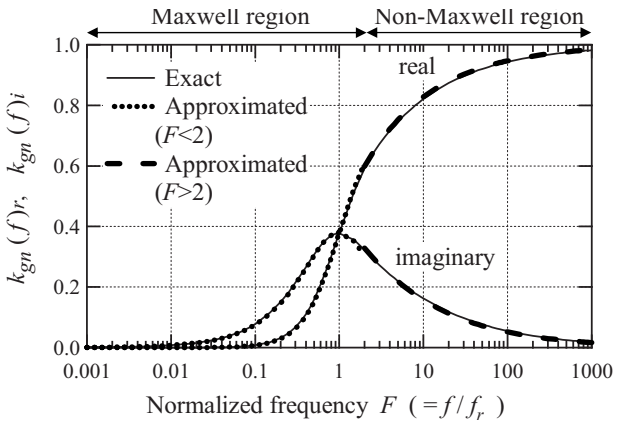

FIG. 2. Frequency dependence of the real and imaginary parts of the normalized exact and an approximated modified gap stiffness.

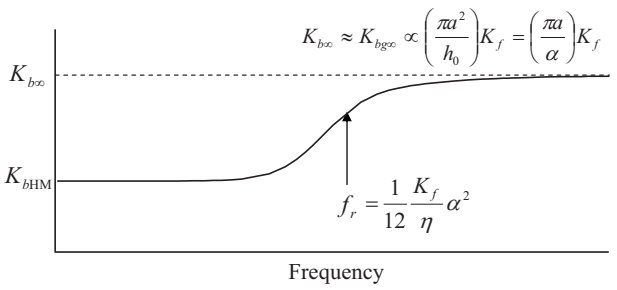

FIG. 3. Conceptual diagram of the frequency characteristics of the frame bulk modulus.

stiffness model is similar to the Maxwell model at a low frequency, except for the difference between the coefficients. However, the gap stiffness model is considerably different from the Maxwell model at high frequencies ($f > 2f_r$). In the Biot model with grain contact squirt flow and shear drag (BICSQS) model[13] in which the Maxwell model was used for the frame bulk modulus, there are no explicit physical parameters for the frame bulk modulus. On the contrary, there are some explicit physical parameters such as the bulk modulus, viscosity of the fluid, contact radius, and gap separation distance (or aspect ratio) for determining the frame bulk modulus in the BIMGS model.

The frame bulk modulus K_b is determined by the contact stiffness $k_c(\propto r)$ and gap stiffness k_g by using the following equation:[12]

$$K_b = \frac{C_n(1-\beta)}{12\pi r}(k_c + k_g) = \sqrt[3]{\frac{C_n^2(1-\beta)^2\mu_r^2}{18\pi^2(1-\sigma_r)^2}P} + \frac{C_n(1-\beta)}{12\pi r}k_g = K_{b\mathrm{HM}} + K_{bg}(f) = K_{b\mathrm{HM}} + (K_{b\infty} - K_{b\mathrm{HM}})k_{gn}, \tag{8}$$

where β denotes the porosity, C_n is the coordination number, r is the grain radius, μ_r is the shear modulus of the grain, σ_r is Poisson's ratio of the grain, and P is the hydrostatic confining pressure. Here, $K_{b\mathrm{HM}}$ is the frequency-independent term (Hertz-Mindlin term) and $K_{bg}(f)$ is the frequency-dependent term (gap stiffness term). A conceptual diagram of the frequency characteristics for the frame bulk modulus is shown in Fig. 3. In this figure, it is observed that the frame bulk modulus is predicted to begin from a low-frequency asymptotic value, $K_{b\mathrm{HM}}$, and increase toward a high-frequency asymptotic value, $K_{b\infty}$. The transition occurs over a frequency range that is approximately centered around the relaxation frequency.

III. VALIDATION OF THE BIMGS MODEL

A. Grain-size dependence of the modified gap stiffness of water-saturated glass beads and beach sands at a high frequency

The modified gap stiffness at a frequency considerably higher than the relaxation frequency of it cannot be theoretically determined as a function of the grain size. This relationship is experimentally studied by using the measured results of the longitudinal wave velocities in the glass beads with 4 different kinds of grain sizes and 85 kinds of beach sands at a high frequency by the author.[12]

The frame bulk modulus at a frequency considerably higher than the relaxation frequency of the modified gap stiffness can be approximated to

$$K_{b\infty} \approx K_{bg\infty} = \frac{C_n(1-\beta)}{12\pi r}k_{g\infty} = \frac{C_n(1-\beta)}{12\pi r}\frac{\pi a^2 K_f}{h_0}, \tag{9}$$

because the modified gap stiffness term at a high frequency $K_{bg\infty}(f)$ (the order of 10^9 Pa) is considerably higher than the Hertz-Mindlin term $K_{b\mathrm{HM}}$ (the order of 10^7 Pa). Therefore, the gap stiffness at a high frequency is expressed as follows:

$$k_{g\infty} = \frac{12\pi r}{C_n(1-\beta)}K_{bg\infty}. \tag{10}$$

The author measured the longitudinal wave velocities in 4 kinds of water-saturated glass beads with different grain sizes and 85 kinds of beach sands at the frequency of 500 kHz.[12] The grain size for a lowest ϕ is 0.78 mm and the wavelength at 500 kHz is approximately 4.0 mm. The ratio of the grain size to the wavelength at 500 kHz is about 1–5. Therefore, the grain sizes of most glass beads and sands are much smaller as compared to the wavelength at 500 kHz. The frame bulk modulus at a high frequency can be inverted by using the Biot model and the values of the longitudinal wave velocity and other Biot parameters, except the frame bulk modulus.[12] Subsequently, the modified gap stiffness at a high frequency is derived from the values of the frame bulk modulus at a high frequency $K_{bg\infty}$, grain radius r, porosity β, and coordination number C_n, which is expressed as[19,20]

$$C_n = 24.00\exp[-2.547\beta] - 0.3731. \tag{11}$$

The modified gap stiffness at a high frequency as a function of the grain size is shown in Fig. 4. Figures 4(a) and 4(b) show 4 kinds of water-saturated glass beads and 85 kinds of water-saturated beach sands, respectively. These figures show the strong grain-size dependence of the modified gap stiffness. The empirical equations of the modified gap stiffness at a high frequency as a function of the grain size are obtained as follows:

$$\log k_{g\infty} = 6.87 - 0.457\phi \rightarrow k_{g\infty} = (7.41 \times 10^6)d_m^{\,1.52} \quad \text{(for water-saturated glass beads)} \tag{12}$$

and

$$\log k_{g\infty} = 7.03 - 0.520\phi \rightarrow k_{g\infty} = (1.07 \times 10^7)d_m^{\,1.73} \quad \text{(for water-saturated beach sands, } N = 85\text{)}. \tag{13}$$

The difference between the results for the glass beads and sands shown in Fig. 4 and that between the empirical relationships in Eqs. (12) and (13) appears to exist due to the difference in the grain-size distribution of the sand and the shape of sand grains. From Eqs. (12) and (13), the following equations are obtained:

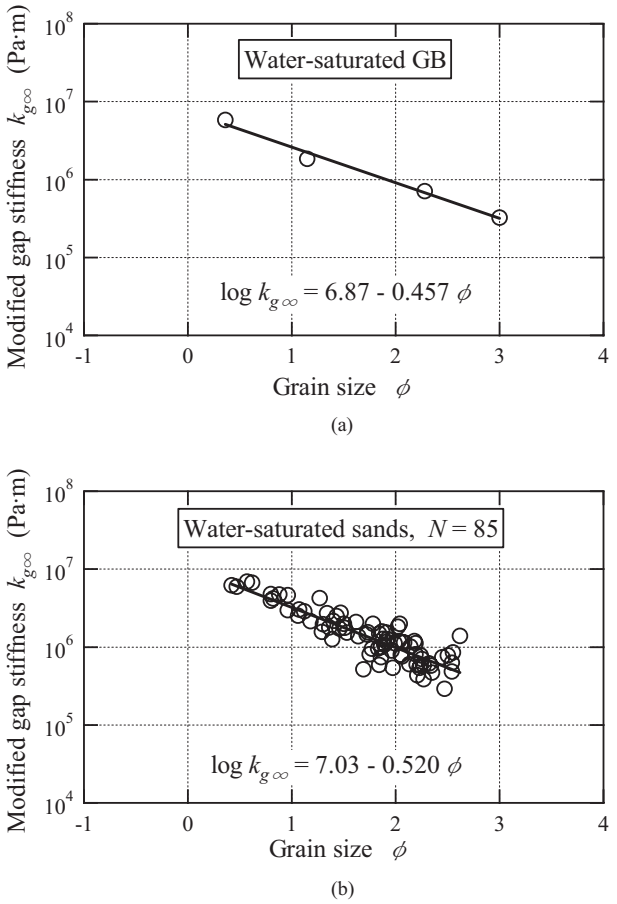

FIG. 4. Modified gap stiffness at a high frequency $k_{g\infty}$ as a function of the grain size ϕ for (a) water-saturated glass beads with 4 kinds of the grain sizes and (b) 85 kinds of water-saturated beach sands derived by the author's data.

$$\frac{a^2}{h_0} = \frac{a}{\alpha} \propto d_m^{1.52} \quad \text{(for water-saturated glass beads)} \quad (14)$$

and

$$\frac{a^2}{h_0} = \frac{a}{\alpha} \propto d_m^{1.73} \quad \text{(for water-saturated beach sands, } N = 85\text{)}. \quad (15)$$

Equations (14) and (15) indicate that the ratio of the gap radius to the aspect ratio exhibits grain-size dependence. In the future, it is necessary to investigate the grain-size dependence of the contact radius and the aspect ratio, separately.

Finally, the following equation can be obtained by using Eqs. (9), (12), and (13):

$$K_{bg\infty} \propto d_m^{0.52} \quad \text{(for water-saturated glass beads)} \quad (16)$$

and

$$K_{bg\infty} \propto d_m^{0.73} \quad \text{(for water-saturated beach sands, } N = 85\text{)}. \quad (17)$$

Thus, the frame bulk moduli of water-saturated glass beads as well as beach sands at a high frequency are expected to increase with the grain size.

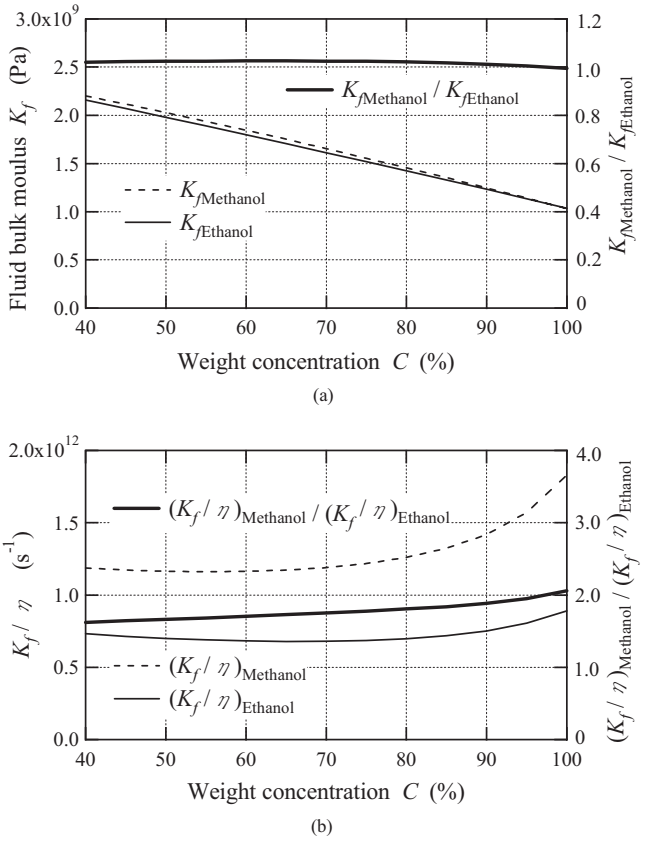

FIG. 5. (a) Fluid bulk modulus and (b) the ratio of the fluid bulk modulus to the viscosity of the mixed liquid as functions of the weight concentration of methanol and ethanol.

B. Fluid bulk modulus and frequency dependence of the frame bulk modulus

In the BIMGS model, the maximum value of the frame modulus is dependent on the contact radius a, gap separation distance h_0, and fluid bulk modulus K_f. Further, the relaxation frequency is dependent on the bulk modulus and viscosity η of the pore fluid and the aspect ratio α. Thus, the maximum value of the frame bulk modulus is a linear function of the fluid bulk modulus under the condition of the constant value of a^2/h_0, and the frequency characteristics of the frame bulk modulus are dependent on the relaxation frequency. Measurements of the frequency dependence of the frame bulk modulus using pore fluids with different bulk moduli and viscosities are necessary in order to confirm the validity of the BIMGS model. In this study, the glass beads saturated with two types of alcohols, ethanol- and methanol-water-mixed liquids, possessing a grain size of 0.192 mm were used for the measurements. The fluid bulk modulus and the viscosity of the alcohol-water-mixed liquid are dependent on the weight concentration of the alcohol. A liquid mixture of ethanol and water or methanol and water with a weight concentration ranging from approximately 50% to 100% was used for the pore fluids. The fluid bulk modulus and the ratio of the fluid bulk modulus to the viscosity of the mixed liquid as a function of the weight concentration are shown in Fig. 5. From this figure, it is observed that the relationships between the fluid bulk modulus and the weight concentration for methanol and ethanol are almost identical. However, the re-

lationships between the ratio of the fluid bulk modulus to the viscosity and the weight concentration for both the cases are considerably different. Therefore, it is expected that the maximum values of the frame bulk modulus are almost the same for both the mixed liquids; however, the relaxation frequencies are different in both the cases.

The author measured the longitudinal wave velocity in the glass beads saturated with the alcohol-water-mixed liquid by the time-of-flight method, which was also used in the previous measurements.[12] In the 500 kHz measurements, piezoelectric transducers with a resonance frequency of 500 kHz and a diameter of 2.54 cm were used for transmitting and receiving signals. A five-cycle sine wave pulse with a frequency of 500 kHz was used as the transmitting wave form. For the measurements, the depth was set to 30 mm in order to obtain the same stress condition. The external stress was hydrostatic.

The propagation distance was 40.2 mm. The longitudinal wave velocity is obtained by using the following equation:

$$c_l = c_w = \frac{1}{1 - \frac{\Delta t c_w}{d}} \rightarrow c_l = c_w \frac{1}{1 - \frac{\Delta t c_w}{d}} \tag{18}$$

where c_w(=1483 m/s) is the velocity in water at a temperature of 20 °C, d is the propagation distance, and $\Delta t = t_w - t_l$ (t_l, t_w=28.75 μs: propagation time in the sample and water at a temperature of 20 °C, respectively). For the measurements in the liquid-saturated samples, the removal of air in the sample is important. The alcohol-water-mixed liquid, which was degassed by vacuum deaeration for an hour, was poured into the vessels, and then the glass beads were carefully poured into the liquid little by little. The sample was deaerated again in the vacuum chamber for an hour. The measurements were conducted at a temperature of 20 °C in a constant temperature bath. The experimental vessel in which a sample was placed was vibrated by a vibrator for densely packing the sample. In the 50 kHz measurements, piezoelectric transducers with a resonance frequency of 50 kHz and a diameter of 3.8 cm were used for transmitting and receiving signals. A single-cycle sine wave pulse with a frequency of 50 kHz was used as the transmitting wave form. The depth for the measurement was again set as 30 mm and the external stress was hydrostatic. The propagation distance was 40.5 mm. The longitudinal wave velocity is obtained by using Eq. (18). In this case, the propagation time in water at a temperature of 20 °C, t_w, was 29.02 μs. The method used for deaeration was similar to that in the case of the 500 kHz measurements. The measurements were conducted at a temperature of 20 °C in a constant temperature bath. The experimental vessel in which a sample was placed was vibrated by a vibrator for densely packing the sample.

The measured results of the longitudinal wave velocity in the glass beads saturated with the alcohol-water-mixed liquid by the author are shown in Fig. 6. The frequencies for the measurements were 500 and 50 kHz. From Fig. 6, it is observed that the velocities at the frequency of 500 kHz are greater than those at 50 kHz for both the samples of glass

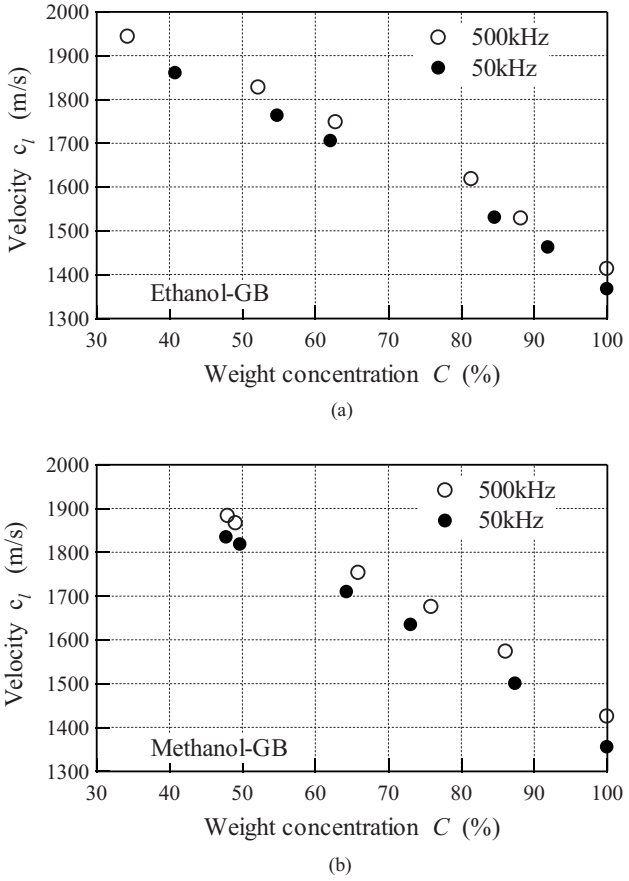

FIG. 6. Measured results of the longitudinal wave velocity in glass beads (GB) saturated with (a) ethanol- and (b) methanol-water-mixed liquids at the frequencies of 500 and 50 kHz by the author.

beads saturated with the alcohol-water-mixed liquid, and the velocities increase with a decrease in the weight concentrations for all the cases. The frame bulk modulus at a high frequency can be inverted by using the Biot model and the values of the longitudinal wave velocity and other Biot parameters, except the frame bulk modulus.[12] The inverted frame bulk modulus at 500 kHz as a function of the fluid bulk modulus by using the author's data is shown in Fig. 7. From this figure, it is observed that the frame bulk modulus is a linear function of the fluid bulk modulus for both the samples of glass beads saturated with the alcohol-water-mixed liquid. According to the BIMGS model, the maximum value of the frame bulk modulus is approximated, as shown in the following equation:

$$K_{bg\infty} \propto \frac{\pi a^2}{h_0} K_f. \tag{19}$$

The value of a^2/h_0 is considered to be a constant because the frame structure of the glass beads saturated with the alcohol-water-mixed liquid is considered to be the same for all the cases. Therefore, the results shown in Fig. 7 (K_b=0.748K_f for ethanol glass beads (GB) and K_b=0.781K_f for methanol GB) are consistent with those of the BIMGS model. The inverted frame bulk modulus at 50 kHz together with that at 500 kHz as a function of the fluid bulk modulus by using the author's data is shown in Fig. 8. In this figure, it is observed that the frame bulk modulus for ethanol GB at the frequency

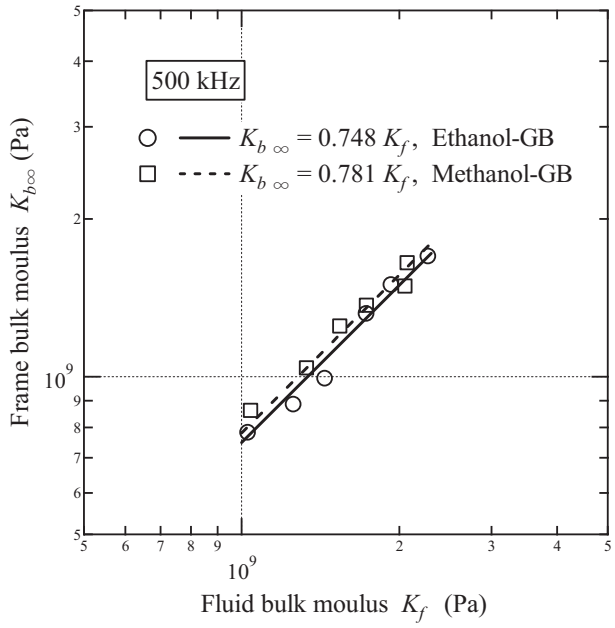

FIG. 7. Inverted frame bulk moduli at the frequency of 500 kHz as a function of the fluid bulk modulus for the glass beads with the ethanol- and methanol-water-mixed liquids by using the author's data.

of 50 kHz is larger than that for methanol GB. This is due to the difference in the ratios of the fluid bulk modulus to the viscosity. This ratio of ethanol is smaller than that of methanol. Therefore, the relaxation frequency for ethanol GB is lower than that for methanol GB. The frequency dependence of the frame bulk modulus for alcohol saturated glass beads with weight concentrations of 60%, 75%, and 90% inverted by using the author's data is shown in Fig. 9. In this figure, the circles and squares indicate the inverted values of the frame bulk modulus for both the samples of glass beads saturated with the alcohol-water-mixed liquid at 500 and 50 kHz,

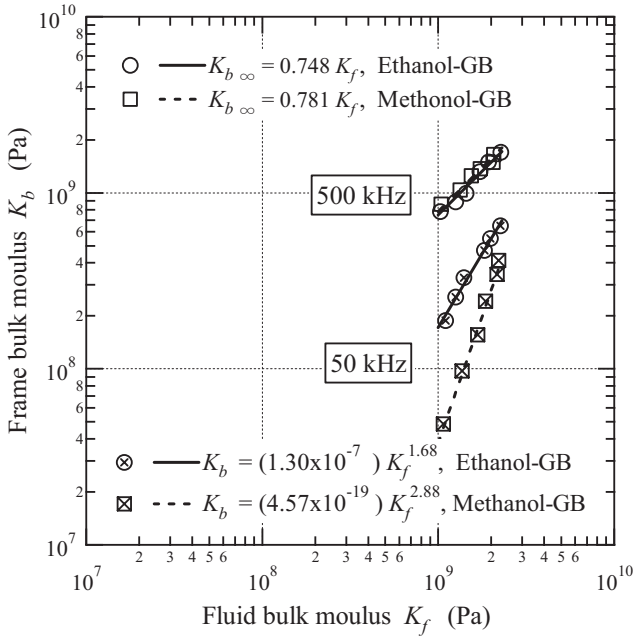

FIG. 8. Inverted frame bulk modulus at the frequencies of 500 and 50 kHz as a function of the fluid bulk modulus for the glass beads with the ethanol- and methanol-water-mixed liquids by using the author's data.

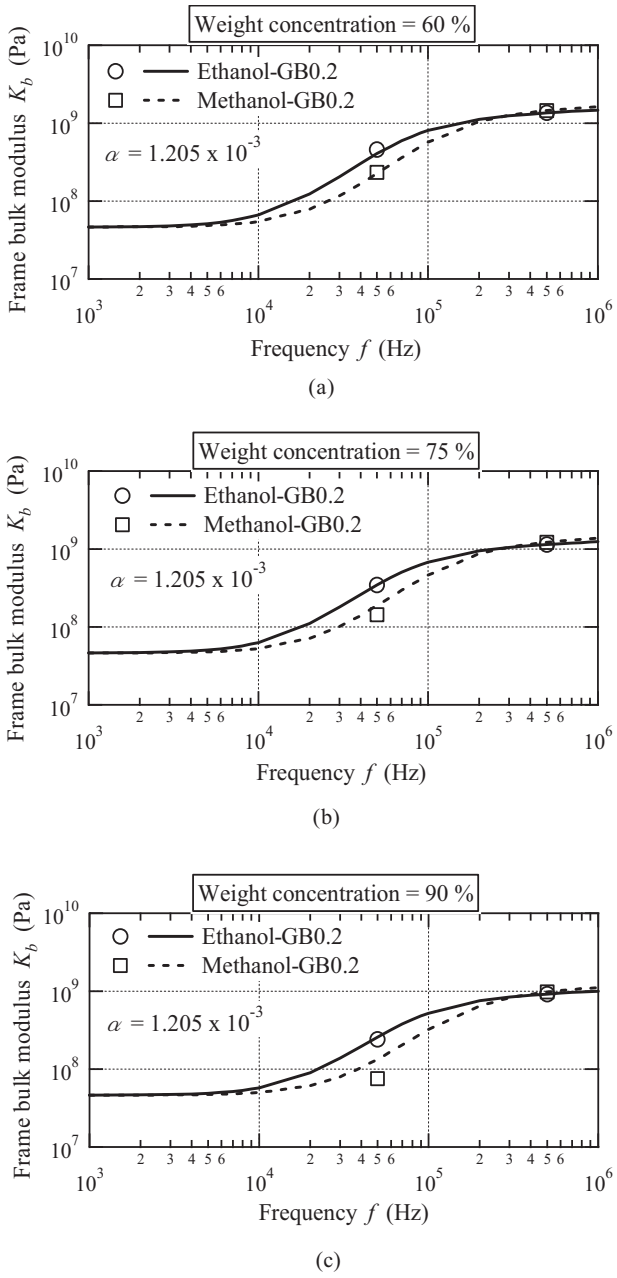

FIG. 9. Frequency dependence of the frame bulk modulus for the ethanol- and the methanol-saturated glass beads with the weight concentrations of 60%, 75%, and 90%. The circles and squares indicate the inverted values of the frame bulk modulus for the glass beads saturated with alcohol-water-mixed liquids at 500 and 50 kHz, respectively, by using the author's data. respectively. The solid and broken lines indicate the calculated curves for the glass beads saturated with the ethanol- and methanol-water-mixed liquids with an aspect ratio α value of 1.205×10^{-3}, respectively. This value of the aspect ratio was selected by fitting the inverted values of the frame bulk modulus to the calculated values for the glass beads saturated with the ethanol-water-mixed liquid with a weight concentration of 75% at the frequencies of 500 and 50 kHz. The values of the parameters used in the calculation are shown in Table I. In Fig. 9, it is shown that the frame bulk modulus is constant at a low frequency, gradually increases

at an intermediate frequency, and again becomes constant at a high frequency, as shown in Fig. 3. The inverted values of the frame bulk moduli are almost consistent with the calculated values. The frame bulk modulus of ethanol GB at 50 kHz is larger than that of methanol GB. This is because the relaxation frequency of ethanol GB is lower than that of methanol GB due to the difference in the values of K_f/η, as shown in Fig. 5.

IV. APPLICATIONS OF THE BIMGS MODEL

A. Velocity dispersion in air-saturated glass beads

First of all, the air-saturated case was investigated. The measured results of the frequency dependence of the longitudinal wave velocity in air-saturated glass beads with a grain size of 1.84 mm, which were obtained by Nomura *et al.*,[22] are shown in Fig. 10. A large velocity dispersion is observed in this figure. This dispersion cannot be explained by using a classical contact theory such as the Hertz-Mindlin model because there is no dispersion in the case of the Hertz-Mindlin model, as observed in Fig. 10. On the contrary, good agreement between the measured and calculated results can be achieved by using the BIMGS model. The values of the parameters used in the calculation are shown in Table II. This result implies that the elasticity of the air in the gap between the grains plays an important role in the determination of the frame bulk modulus, even in the case of air-saturated glass beads. In the author's previous study, the large grain-size dependence of the longitudinal wave velocity in air-saturated glass beads was obtained.[12] The velocity significantly increases with the grain size. First of all, it was assumed that this increase is due to the effect of some residual moisture at the grain contacts. Then, the velocity in the glass beads was measured after drying to remove the moisture. However, the results obtained were the same as those obtained before drying. Next, the velocity measurements were carried out in a vacuum chamber. The velocity decreases with the removal of air. The grain-size dependence in the vacuum-saturated case is relatively small (Fig. 8 in Ref. 12). From the above results, it is considered that the large velocity dispersion in Fig. 10 occurs due to the effect on the elasticity of air in the gap between the grains in the BIMGS model.

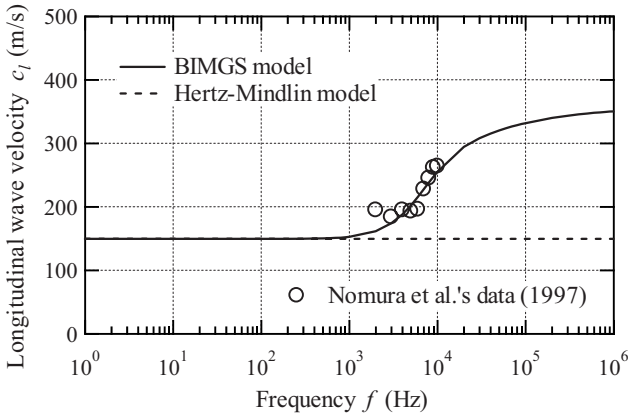

FIG. 10. Longitudinal wave velocity as a function of frequency for air-saturated glass beads with a diameter of 1.84 mm. The open circles indicate the data by Nomura *et al.* (Ref. 22), the broken line indicates the calculated result using the Hertz-Mindlin model, and the solid line indicates the calculated results using the BIMGS model for $K_{bHM}=2.70\times10^7$ Pa, $K_{bg\infty}=1.64\times10^8$ Pa, and $\alpha=3.76\times10^{-3}$.

B. Velocity dispersion in water-saturated marine sediments

1. Turgut and Yamamoto's data

We investigate some velocity dispersion data that have been reported.[2,23,24] We begin by investigating Turgut and Yamamoto's data.[23] In their data, it is observed that there is a large dispersion at frequencies ranging from 1 to 27 kHz, as shown in Fig. 11. It is not possible to explain the dispersion data by using the Biot-Stoll model with a constant frame bulk modulus. If the calculated value of the velocity is adjusted to the measured value at a lower frequency by using a frame bulk modulus of 2.40×10^7 Pa, the measured and calculated values are found to be considerably different at a higher frequency, as shown in Fig. 11. On the contrary, if the calculated value of the velocity is adjusted to the measured value at a higher frequency by using a frame bulk modulus of 7.00×10^8 Pa, both the values are found to be considerably different at a lower frequency. Subsequently, the BIMGS model is applied for analyzing the dispersion data. The values of the parameters used for calculating the longitudinal wave velocity are shown in Table III. In Fig. 11, the calculated results obtained by using the BIMGS model are almost consistent with the measured results. Further, the frequency dependence of the attenuation is shown in Fig. 12. It includes Turgut and Yamamoto's data[23] and the calculated results. In this figure, it is observed that the calculated results obtained by using the BIMGS model are relatively consistent with the measured results.

2. SAX99 and SAX04 data

The SAX99 data obtained by Williams *et al.* provide excellent velocity dispersion and attenuation information.[2] Several researchers have measured velocity dispersion over a frequency range of 125 Hz–400 kHz and attenuation over a frequency range of 2.6–400 kHz for sand sediments. Almost all the physical parameters for the Biot-Stoll model could be obtained by *in situ* and laboratory measurements. The SAX99 dispersion data are shown in Fig. 13.[2] In this figure, a large dispersion is observed at frequencies ranging from 125 Hz to 400 kHz. At frequencies ranging from 1.7 to 400 kHz, the calculated results obtained by using the Biot-Stoll model with a constant frame bulk modulus is consistent with the measured results. However, an agreement between the calculated and measured results could not be obtained at low frequencies such as 125 and 400 Hz, which are indicated by the circles. The measured velocity is considerably low as compared to the calculated velocity obtained by using the Biot-Stoll model with a constant frame bulk modulus. Next, we attempted to adjust the fluid bulk modulus to match the measured results to the calculated results at a low frequency.[13] In this case, a good agreement could not

be obtained at a high frequency. Moreover, another SAX04 dispersion data set obtained by Hines *et al.*[24] is shown in Fig. 14 in conjunction with the SAX99 dispersion data set.[2] Further, a large dispersion occurs in the frequency range from 600 Hz to 20 kHz. We attempted to apply the BIMGS model to these dispersion data. Excellent agreement was achieved

between the measured SAX99 data and the calculated results with an aspect ratio of 0.75×10^{-4}. Further, the calculated result with an aspect ratio of 2.25×10^{-4} agrees relatively well with the SAX04 dispersion data. Several researches measured velocity and attenuation by some different methods; however, the data were obtained at a common location. Then, the author used the values of the Biot parameters for the SAX99 data, which were similar to the parameters used by Williams.[2] The environmental characteristics of the SAX04 data were assumed to be slightly different from those of the SAX99. However, the Biot parameters for the SAX04 data could not be obtained. Therefore, the author used the same values of the parameters for the SAX04 data as those used for the SAX99 data. Further, in order to match the data, two kinds of aspect ratios were used for the calculations for the SAX99 and SAX04 data. The values of the parameters used for calculating the longitudinal wave velocity are shown in Table IV. The measured attenuation as a function of the frequency[2] is shown in Fig. 15. The results calculated by using the BIMGS model ($\alpha=0.75\times10^{-4}$) almost agree with the measured results at frequencies ranging from 20 to 50 kHz. At frequencies below 10 kHz, the calculated values are larger than the measured values, which are similar to the values calculated for the Biot-Stoll model with a constant frame bulk modulus. On the other hand, at frequencies above 100 kHz, the values calculated by using the BIMGS model ($\alpha=2.25\times10^{-4}$) relatively agree with the measured values. Further investigations are required to understand the frequency dependence of the attenuation.

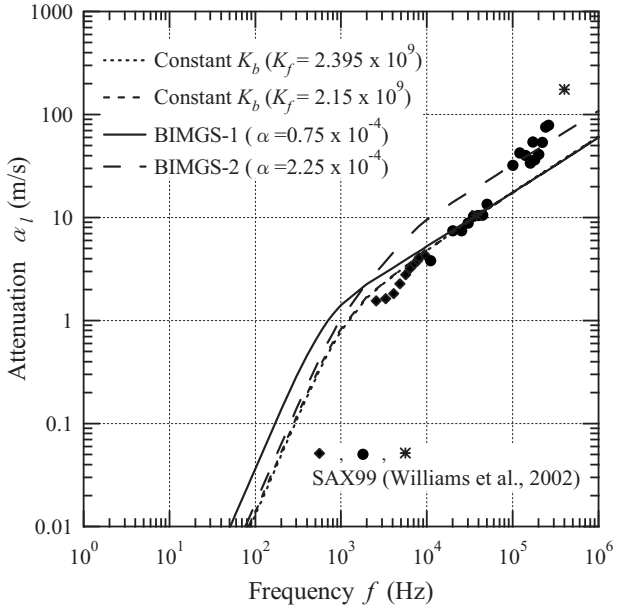

FIG. 15. Attenuation as a function of frequency for water-saturated marine sediments. Symbols indicate SAX99 data (Ref. 2) and the dotted and the broken lines indicate the calculated result using the Biot-Stoll model with constant frame bulk moduli such as $K_f=2.395\times10^9$ and 2.15×10^9 Pa, respectively. The solid line indicates the calculated results using the BIMGS model for $K_{b\mathrm{HM}}=4.61\times10^7$ Pa, $K_{bg\infty}=1.24\times10^9$ Pa, and $\alpha=0.75\times10^{-4}$. The dashed and double-dotted lines indicate the calculated results using the BIMGS model for $K_{b\mathrm{HM}}=4.61\times10^7$ Pa, $K_{bg\infty}=1.31\times10^9$ Pa, and $\alpha=2.25\times10^{-4}$.

V. CONCLUSIONS

In this study, the BIMGS model was reinvestigated and approximated expressions were derived for the modified gap stiffness at low- and high-frequency ranges. In particular, the BIMGS model was experimentally validated. First, the modified gap stiffness at a frequency considerably higher than the relaxation frequency of it was experimentally obtained as a function of the grain size by using the measured results of the longitudinal wave velocities in the glass beads with 4 different kinds of grain sizes and 85 kinds of beach sands. From the measured results, the gap stiffness at a high frequency was derived as a function of the grain size, that is, $k_{g\infty}=(7.41\times10^6)d_m^{1.52}$ for water-saturated glass beads and $k_{g\infty}=(1.07\times10^7)d_m^{1.73}$ for water-saturated beach sands. Moreover, it was validated that the modified gap stiffness at a high frequency is a linear function of the fluid bulk modulus and that the frame bulk modulus is dependent on frequency. Further, it was shown that the frame bulk modulus of ethanol-GB at 50 kHz was larger than that of methanol GB. This was because the relaxation frequency of ethanol GB was larger than that of methanol GB due to the difference in the values of K_f/η. Finally, for an application of the BIMGS model, it was shown that the reported velocity dispersion and the frequency dependence of the attenuation data, which were obtained from Turgut and Yamamoto's data and the SAX99 and SA04 data, could be explained.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. Nicholas P. Chotiros of the Applied Research Laboratories, the University of Texas at Austin, for his valuable suggestions. The author is grateful to Professor Nicholas G. Pace and Dr. John C. Osler for presenting a proceedings and some papers to us. The author also thanks Ms. Nodoka Jinbo, who was a student in the School of Marine Science and Technology, Tokai University, during the year 2005, for her assistance in conducting the experiments.

APPENDIX

There are typographical errors in Eqs.(23) and (26) in Ref. 12. The corrected equations are as follows.

The normalized gap stiffness k_{gn} is expressed as follows:

$$k_{gn}=1-\frac{1}{\frac{\kappa a}{2}\frac{J_0(\kappa a)}{J_1(\kappa a)}}, \tag{23}$$

$$k_{gMn}=\frac{1}{1-j\frac{f_{rM}}{f}}. \tag{26}$$

Fitting data, but poor predictions: Reverberation prediction uncertainty when seabed parameters are derived from reverberation measurements

Charles W. Holland[a)]
Applied Research Laboratory, The Pennsylvania State University, State College, Pennsylvania 16804

(Received 10 December 2007; revised 19 February 2008; accepted 20 February 2008)

For many decades, researchers have been developing inverse techniques for estimating seabed parameters from reverberation data, notably scattering strength. Generally, the angular dependence of the scattering kernel is unknown and is either solved for or assumed fixed. In either case, agreement is typically quite good between the measured reverberation and that modeled (by fitting scattering parameters). However, what are the resulting uncertainties in a reverberation prediction if the ocean or geometry changes? The main results of the paper are that (1) these prediction uncertainties are surprisingly large, of order 10 dB at 10 km and thus (2) traditional/current methods for reverberation inversion should be augmented, mitigating the large prediction uncertainties by an additional measurement. Several options for additional measurements are discussed.

I. INTRODUCTION

Predicting acoustic reverberation in a shallow water waveguide is an important problem for facilitating operation of active sonar. One of the quantities of interest is the predicted time decay of the received signal, sometimes called diffuse reverberation. Contributions to diffuse reverberation can originate from the sea surface, the ocean volume (i.e., bubbles or biologics), or the seabed (interface and/or subbottom structure). In shallow water regions, it is often the seabed that controls the reverberation decay and in this paper we focus on the seabed contributions to diffuse reverberation at low to midfrequencies (nominally 500–5000 Hz).

In order to predict diffuse reverberation in situations where the seabed contributions dominate, the seabed scattering kernel and the reflection coefficient (or equivalently the geoacoustic parameters) must be known. In an area without prior measurements, these are generally poorly known, thus predictions of diffuse reverberation in forward areas are expected to be quite poor. Ostensibly, one way to improve this state of affairs is to conduct long-range reverberation measurements in areas of interest and invert for the reflection coefficient and scattering kernel. Such measurements can be performed in a survey mode, or alternatively by using the very sonar system for which one wishes to make a prediction (this latter method is sometimes called "through the sensor" or "rapid environmental assessment"). Due to the considerable potential of such methods, a significant amount of work has been done on the inverse problem, i.e., to estimate the scattering kernel and/or reflection coefficient from reverberation data (e.g., Refs. 1–10, not intended to be exhaustive).

The objective of this paper is not to explore another inverse method, but rather to quantify the uncertainties in reverberation prediction that remain after a survey measurement (beyond this point we make no distinction between survey methods and rapid environmental assessment or through the sensor methods, since the uncertainties discussed here arise from all these methods). One of the reasons it is useful to study uncertainty is because it can help identify particular parameters that tend to drive the uncertainty; measurement assets can then be focused on those particular parameters. The total uncertainty of the reverberation prediction depends upon a variety of factors, including the uncertainty in the seabed parameters and how well the ocean environment (sound speed profiles, air–sea roughness, biologics, bubbles, etc.) is known during the survey measurement. However, here we ignore the latter uncertainties and ask "what are the prediction uncertainties if the ocean (above the seabed) is perfectly known?"[11]

After a brief review of the theory of reverberation in a waveguide (Sec. II), a simple example is provided to illuminate the issues associated with the large prediction uncertainties. Section III then explores more realistic examples of how uncertainties in the scattering kernel lead to reverberation prediction uncertainties. These uncertainties are examined under various environmental conditions in order to both determine the environmental dependencies and provide insight into ways of mitigating those uncertainties. Sediment reflection coefficient uncertainties (addressed in Sec. IV) are shown to have a smaller impact on the total uncertainty than scattering kernel uncertainty. The principal findings are discussed and summarized in the final section.

II. THEORY

In a range-independent waveguide with an arbitrary sound speed profile, the incoherent monostatic reverberation can be written (e.g., Refs. 12 and 13)

[a)]Electronic mail: holland-cw@psu.edu

$$I = I_0 \frac{4\gamma c\tau}{r\ 2} \int_0^{\theta_c} \int_0^{\theta_c} R(\theta_H)^{2r/r_c(\theta)} \frac{\cos\theta}{r_c(\theta)\sin\theta_H} M(\theta_H, \phi_H)$$

$$\times R(\phi_H)^{2r/r_c(\phi)} \frac{\cos\phi}{r_c(\phi)\sin\phi_H} d\theta d\phi, \quad (1)$$

where I_0 is the source intensity; r is range; r_c is cycle distance; γ is the horizontal beamwidth of the source or receiver; c is the sound speed; τ is pulse length; θ_c is the critical angle; R is the magnitude of the seabed plane wave pressure reflection coefficient; H is water depth; and M is the seabed scattering kernel which depends upon source and receiver vertical angles, θ and ϕ. The subscript H indicates angles at depth H, i.e., at the water–seabed interface.

The main assumptions are that: there are many modes, i.e., $kH \sin\theta_c/\pi \gg 1$, where k is the wave number; the receiver is many water depths from the source, i.e., $r/H \gg 1$; the single scatter approximation is valid, i.e., that there is only reflection at each forward bounce and only one scatter back to the receiver; and geometric dispersion can be ignored (typically has a small effect, less than about 1 dB). Lloyd mirror effects (i.e., when source/receiver are close to the boundaries) are ignored and source receiver are assumed to be omnidirectional. Finally, we impose certain assumptions about the environment: that the sea surface is a flat pressure release boundary; the water column is lossless; and that the scattering arises only from the seabed and is independent of azimuth. The environmental assumptions, the omnidirectionality for source/receiver, and proximity to the boundary (e.g., Ref. 14) could be easily removed, but are not limiting for this study.

Although R and M in Eq. (1) are completely general, it is helpful for the goals of the study to treat them simply, in a way that can be readily parametrized. With this in mind, consider a sediment half-space with a reflection coefficient calculated from nominal geoacoustic properties (see Table I) and an empirical scattering kernel,

$$M(\theta, \phi) = \mu \sin^m(\theta) \sin^m(\phi) \quad (2)$$

with a scattering strength parameter μ and an angular dependence parameter m (reciprocity requires the incoming and outgoing angle dependence to be identical). We could easily consider more complicated models, i.e., with layers and scattering arising from the subbottom volume and/or various layer roughnesses, but this level of detail may obscure the main points of the paper without changing the conclusions. What is important here is that the R and M are reasonably realistic,[15] even if simple. We also state up front that since we do not expect Eq. (2) to be representative of all possible scattering kernels, our estimates of reverberation uncertainties will not necessarily represent upper bounds.

TABLE I. Geoacoustic model for the case where geoacoustic properties (or equivalently the seabed reflection coefficient) are known *a priori* (see Figs. 1–5).

Sound speed (m/s)	Attenuation (dB/m/kHz)	Density (g/cm^3)
1600	0.5	1.8

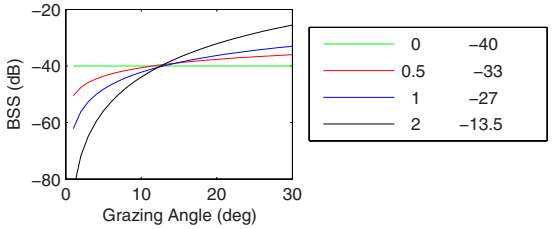

FIG. 1. (Color online) Various scattering kernels used in the study [the backscattering strength $\mathrm{BSS} = 10\log M(\theta, \theta)$]. The parameters m and $10\log\mu$ [see Eq. (2)] are given in the first and second columns of the legend, respectively.

In addition to simple scattering kernels, we also consider simple, i.e., linear, sound speed profiles (SSP) in the water column.

III. UNCERTAINTIES ASSOCIATED WITH THE SCATTERING KERNEL

We assume in this section that the ocean environment including the seabed reflection coefficient (or equivalently the geoacoustic properties) is perfectly known, except for the scattering kernel. Thus, the only uncertainties are due to the unknown seabed scattering kernel. An unbiased monostatic reverberation "survey" measurement is made and those data are employed to estimate the seabed parameters μ and m, Eqs. (1) and (2). Our intent is to determine the impact of the environmental uncertainties associated with estimating those parameters on the prediction of reverberation at future times (i.e., different sound speed profile and/or geometry).

The fundamental issues that lead to uncertainties are that (1) there is a limited angular range over which the scattering kernel can be observed and (2) there are many possible scattering kernels that can fit the observations (e.g., Ref. 16). For sake of argument, consider a situation where the reverberation is only sensitive to a single angle, say at 13°. In this case, any one of the scattering kernels in Fig. 1 could be used to accurately model the reverberation data (all the scattering kernels have the same value at 13°). Imagine for example that the true scattering kernel had a dependence of $m=0.5$, but that the model used to fit the data assumed $m=2$. Now consider the same seafloor region, but the sound speed profile and/or the source/receiver depths have changed so that the reverberation is only sensitive to scattering at 7°. The reverberation (using the scattering strength parameters derived from the measurements) would underpredict the true reverberation by 8 dB (the difference in scattering strengths between the two models at 7°).

This is a simplistic example. Generally, reverberation probes a distribution of angles (an exception would be a single propagating mode). The shape of the angular distribution is a function of the reflection coefficient, the SSP, the source–receiver depths and range. In the following, the bias errors associated with the unknown scattering kernel are examined using Eq. (1) for more realistic situations than the above-noted example. The cycle distance is obtained by ray theory, and the integral is evaluated numerically using Simpson's rule. The integrand, in general, is very well behaved, i.e., smoothly varying. Some care though is required in prop-

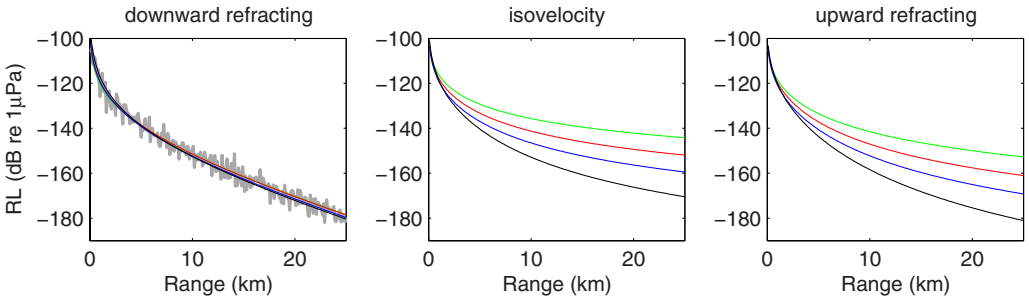

FIG. 2. (Color online) Reverberation predictions ($RL=10\log I$) for various sound speed profiles. The leftmost plot shows synthetic survey reverberation "data" (gray line) along with fits to the data using four scattering kernels shown in Fig. 1. The center and right-hand plots show reverberation predictions using the same scattering kernels under different sound speed profiles. The sound speed gradients from left to right are −0.3, 0, and 0.2. In the simulation the water depth is 100 m, sediment properties are given in Table I, and source/receiver depths are 10 m.

erly sampling the integrand for upward refracting cases at angles near the onset when the ray first interacts with the seabed.[17]

In Secs. III A and III B we consider bias errors if the sound speed profile during the survey measurement is (a) downward refracting and (b) isovelocity.

A. Bias errors in reverberation prediction: Downward refracting in survey

Consider a reverberation survey measurement conducted with a downward refracting profile with a gradient of $-0.3\ \mathrm{s}^{-1}$. Water depth is 100 m and the seabed properties are given in Table I. "Measured" (synthetic) data are shown in the gray line of Fig. 2(a) which were generated using $m=0.5$ summed with a zero-mean Gaussian distribution with a standard deviation of 3 dB. The synthetic data here and in the following sections are not frequency specific, but could apply to any frequency in the band of interest. A common method is to fit the data assuming a particular scattering kernel. Here we fit the data [Fig. 2(a)] using the four (out of an infinite number of possible) scattering kernels shown in Fig. 1. Note that all of the scattering kernels (see Table II) fit the data approximately equally well.

We can understand the reason why the ostensibly disparate scattering kernels fit the data by considering the angular distribution of the scattered intensity [i.e., the integrand of Eq. (1)]. The angular distribution depends somewhat on range,[18] but is approximately a truncated Gaussian with the main contributions around 13° [see Fig. 3(a)]. Since the scattering kernels all have similar levels near this angle (Fig. 1), the reverberation is also nearly the same [Fig. 2(a)] and in the absence of other information, it would be impossible to distinguish which (if any) of the models was the "correct" one. This is a specific example of the fundamental issue discussed previously, i.e., there is often a limited range of angles probed in reverberation measurements and thus many scattering kernels can be made to fit the data.

TABLE II. Scattering kernel possibilities for the case where geoacoustic properties (or equivalently the seabed reflection coefficient) are known *a priori*, but the scattering kernel is unknown (see Figs. 1–5).

m	$10\log(\mu)$
0	−40
0.5	−33
1	−27
2	−13.5

If the ocean and the source–receiver geometry were constant for all time, obviously each one of the four seabed parameter solutions would predict the reverberation equally well and there would be no need to inquire which one was correct. In reality (at least for database considerations), it is important to make predictions under changing ocean (SSPs) and geometries. At first blush one might be tempted to calculate the uncertainty associated with the reverberation prediction, simply by using the uncertainty associated with the estimate of μ. The uncertainty associated with any one of the scattering kernels would be a few decibels, and thus, one might conclude the total estimated prediction uncertainty would be a few decibels (the scattering strength parameter is a simple multiplier to the intensity). However, this method of predicting uncertainty severely underestimates the true uncertainties. The predicted uncertainties must take into account a wide variety of possible parametrizations, e.g., scattering kernels. This is done in the following paragraphs, showing how the predicted uncertainties evolve under changing ocean profiles and changing geometries.

1. Bias errors due to changing sound speed profile

Figure 2(b) shows reverberation predictions if the sound speed profile changed to isovelocity. The difference in the various curves is a measure of the prediction uncertainty associated with the uncertainty of the scattering kernels chosen. Recalling that the correct underlying scattering dependency was $m=0.5$; if it were erroneously assumed $m=1$ (Lambert's law) the resulting prediction would be 7 dB too low at 20 km. If one assumed $m=2$ or $m=0$, the resulting predictions at 20 km would be 16 dB too low or 7 dB too high, respectively. Figure 2(c) shows the bias errors if the SSP changes from downward to upward refracting where the results are similar (i.e., large bias errors) to the isovelocity case. The key point is that even with a reverberation measurement, the bottom properties that were extracted from it might only be useful when the SSP was similar to that of the original measurement, unless there was supplemental information about the nature of the scattering kernel.

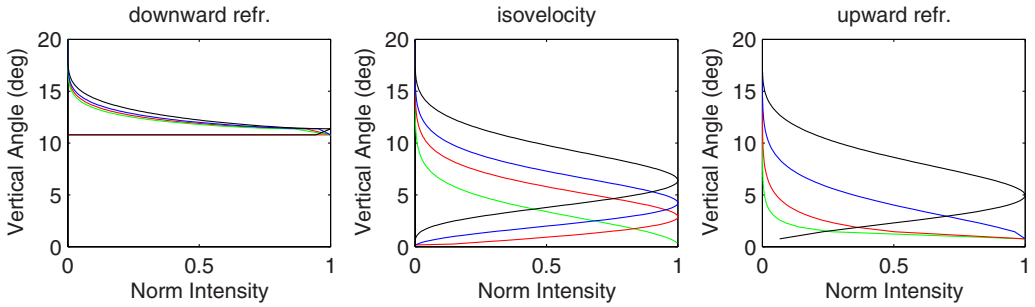

FIG. 3. (Color online) Vertical angle distributions for the reverberation of Fig. 2 at 10 km, normalized to the maximum value.

2. Bias errors due to changing source–receiver depths

Bias errors are also expected for changes in source–receiver depths (since the angular distribution on the seabed is a function of source–receiver depth). For example, the impact of changes in the source–receiver depths (monostatic) on the reverberation is shown in Fig. 4. The total spread in biases at 20 km at 90 m depth is about 12 dB. More complicated and larger errors due to changes in sound speed profile and source–receiver depths are possible. We wish first, though, to show the order of magnitude effects that might occur for separate environment and geometry changes.

It is of interest to quantify the bias error bounds as a function of sound speed gradient and source–receiver depth (see Fig. 5). Bias error bounds are defined here as the difference in reverberation from $m=0$ and $m=2$ at 10 km. The range of 10 km is somewhat arbitrary while the bounds of m are based on observations, theory, and current practice. At the upper end, $m=2$ is predicted at low angles by perturbation theory;[19] and is also observed in data at higher angles (e.g., Ref. 20, Fig. 25, Site 3, 10°–20° at 1200 Hz, 1800 Hz, where $m\sim 1.8$). For the lower bound, $m=0$ was chosen because theory predicts that the scattering can be approximately independent of angle over limited angle regions (e.g., see Fig. 4 of Ref. 21); it is also observed in data in some angular regimes (e.g., Ref. 20, Fig. 25, Site 2, below 1800 Hz) and $m=0$ is used in some reverberation inversion approaches (e.g., Refs. 1, 5, and 8).

Examining first the black line of Fig. 5(a) (same sediment parameters of Fig. 2), note that as the SSP changes from that applicable during the observation (in this case downward refracting), the errors rapidly increase to peak at isovelocity and then are roughly constant. We can understand this behavior by appealing to Figs. 3 and 1. As the sound speed gradient increases (away from that in the survey measurement, $-0.3\ \mathrm{s}^{-1}$), the dominant angles at the seabed decrease, and the difference in the respective scattering kernels increase (see Fig. 1). For the isovelocity profile, the angles are in the neighborhood of zero degrees grazing. For increasing gradients (i.e., upward refracting), the angles change but not substantially—hence the relatively constant bias errors.

How do the errors depend on the reflection coefficient (or geoacoustic properties)? The gray line of Fig. 5 shows the bias errors where sediment attenuation is reduced by a factor of 5. The bias errors as a function of changing SSP [Fig. 5(a)] are smaller for the less lossy seabed, though the overall shape of the two curves are similar. The smaller bias errors are due to the fact that with smaller reflection losses, the angular distribution at the bottom is broader and pushed toward higher angles (see Fig. 6). Both of these effects when considered in view of the scattering kernels (Fig. 1) tend to reduce the total error. In other words, the scattering kernels integrated over the angular distribution of Fig. 6 have less disparity than the scattering kernels integrated over the narrower angular distribution of Fig. 3. Increasing/decreasing the sediment sound speed has a similar effect, i.e., decreasing/increasing bias errors, but maintaining the overall shape of the curve.

The sensitivity of bias errors to source-receiver depth is shown in Fig. 5(b). Note that errors monotonically increase with distance away from the survey measurement geometry. Also note that the sensitivity is the same for both geoacoustic models. This is because the angular distribution is not very sensitive to differences in the geoacoustic models. The sensitivity of the bias errors to source–receiver depth is greatest for the downward refracting environment [see Fig. 5(c)].

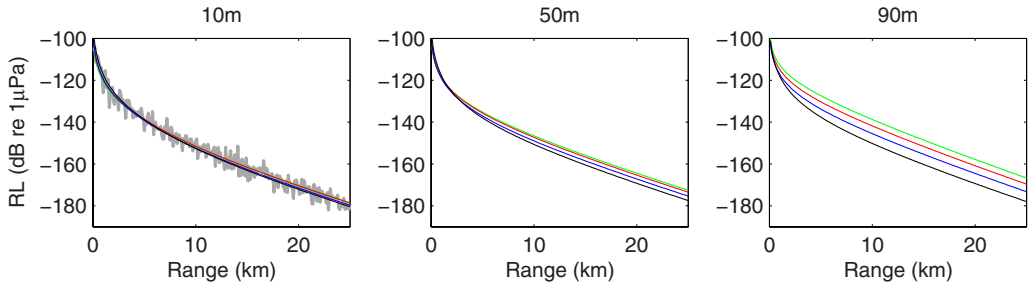

FIG. 4. (Color online) Reverberation for the four scattering kernels shown in Fig. 1 for various source–receiver depths; sound speed gradient is $-0.3\ \mathrm{s}^{-1}$.

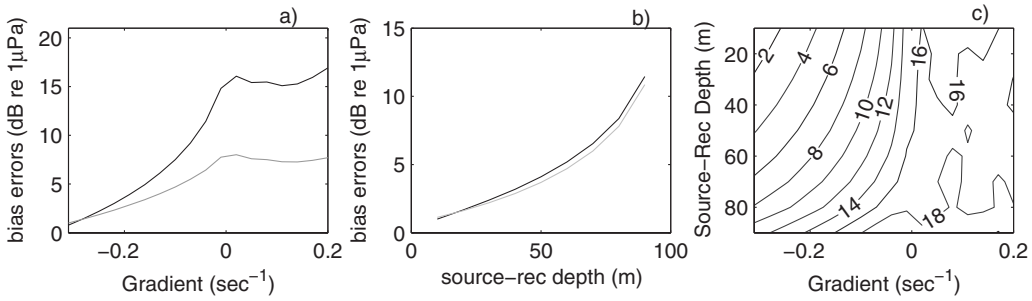

FIG. 5. Sensitivity of bias error bounds at 10 km range to: (a) sound speed gradient; (b) source–receiver depth; and (c) gradient and source–receiver depth (contours are bias errors in decibels). The black lines are errors where geoacoustic properties are given in Table I line; the gray lines are for an environment with a lower sediment attenuation (0.1 dB/m/kHz). Error bounds increase monotonically with range.

B. Bias errors in reverberation prediction: Isovelocity in survey

What happens if the survey measurement is conducted in isovelocity rather than in downward refracting conditions? "Measured" (synthetic) data from isovelocity conditions are shown in the gray line of Fig. 7 along with four scattering kernels that fit the data.

One salient point is that for isovelocity conditions there is a greater difference in the decay rates of the reverberation for the four scattering kernels than for downward refracting case [compare Fig. 7(a) with Fig. 2(a)]. Thus, if reverberation was measured over the entire 25 km as shown in Fig. 7, it would clearly be possible to eliminate several of the scattering kernels just based on the different decay rates. Imagine for the moment, however, because of high ambient noise and/or limited dynamic range, that reverberation could only be measured over ranges of 5–9 km. Over this limited range, all of the scattering kernels fit the data roughly equally well. In this case, the bias error bounds are very similar to those shown in Fig. 5(a) (with a shift in the curves so that the bias error of 0 is at isovelocity). If reverberation data were obtained over the entire range, and one could narrow the range of possible scattering kernel to say $0.5 \leqslant m \leqslant 1$, the error bounds at 10 km would be reduced from ~12 to ~4 dB. For the isovelocity case, the bias errors are zero with respect to changing source–receiver geometry since the incoherent field is independent of depth (except within a few wavelengths of the boundaries).

What happens if the survey measurement is conducted in upward refracting conditions? The results for the upward refracting case are similar to the isovelocity case, with the main difference being that the reverberation decay is even more distinct for the four scattering kernels. Thus, for a given set of reverberation versus range observations, and a perfectly known ocean with a smooth surface, the upward refracting case provides the greatest opportunity to minimize bias errors from the unknown scattering kernel. Also, the sensitivity of the bias errors to source–receiver depth is smaller than the downward refracting case.

In summary, the unknown scattering kernel can lead to substantial uncertainties in predicting reverberation for changing ocean conditions and/or changing source–receiver geometries. Bias errors as large as 10–18 dB were shown for simple, but not unrealistic cases.

IV. UNCERTAINTIES ASSOCIATED WITH THE REFLECTION COEFFICIENT

We now consider the case where the seabed scattering kernel is known, but the geoacoustic properties (or R) are unknown. Before examining specific cases, we point out that the range of reflection coefficients below the critical angle (supporting waveguide propagation) is much smaller than the range of scattering strengths at low angles. Thus, one might expect that the impact of an unknown reflection coefficient would tend to be less severe than the impact of an unknown scattering kernel. While we shall see that this is indeed the case, we note that while differences in R tend to be modest, those differences do get raised to the power $2r/r_c$ [see Eq. (1), where r/r_c is the number of bounces to the scattering patch] and so in principle might be significant.

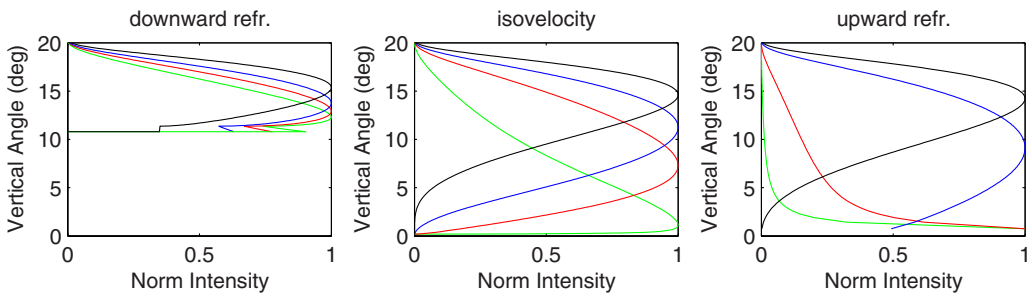

FIG. 6. (Color online) Normalized vertical angle distribution for the reverberation with attenuation of 0.1 dB/m/kHz. Note that the distributions include higher angles than in Fig. 3 due to less loss per bounce.

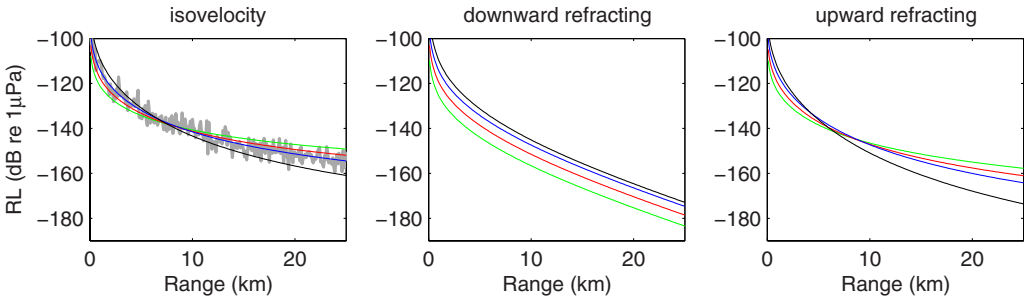

FIG. 7. (Color online) Reverberation predictions for various sound speed profiles. The leftmost plot shows synthetic survey reverberation data (gray line) along with fits to the data using four scattering kernels shown in Fig. 1. The center and right-hand plots show reverberation predictions using the same scattering kernels under different sound speed profiles. The sound speed gradients from left to right are 0, −0.3, and 0.2. In the simulation the water depth is 100 m, sediment properties are given in Table I, and source/receiver depths are 10 m.

A. Bias errors due to changed sound speed profile: Downward refracting in survey

In order to gain some insight, we examine a few specific cases. Three different reflection coefficients (corresponding to three geoacoustic models, see Table III) are shown in Fig. 8 that have similar levels at 13°. In our downward refracting environment with a gradient of $-0.3\ s^{-1}$, we expect [from Fig. 3(a)] that since the reverberation is dominated by angles near 13°, that the reverberation for all three reflection coefficients would be similar. The results of Fig. 9(a) show that indeed this is the case. Let us consider, as before, that any one of these curves could be a fit to a survey measurement. We are now interested in the uncertainties that occur if we make a prediction for a different SSP. The results of Figs. 9(b) and 9(c) indicate that the reverberation levels are similar for the three reflection coefficients under other SSPs; in other words, the uncertainty associated with the unknown reflection coefficient is rather small, on the order of a few decibels and nearly independent of range.

Why does uncertainty in the reflection coefficient (Fig. 9) lead to so much less uncertainty in reverberation than uncertainty in the scattering kernel (Fig. 2)? The answer is straightforward, inasmuch as the angles at the seabed for isovelocity and upward refracting sound speed profiles are all lower than that for the survey measurement (Fig. 3) and from Fig. 8 it is observed that the reflection coefficients are similar below 13°. Another way to say this is that the long-range reverberation in the mode stripping regime is not very sensitive to the individual geoacoustic properties, it is only sensitive to the slope of the reflection coefficient with angle (e.g., Refs. 2 and 22). Thus, there are an infinite number of reflection coefficients (or geoacoustic models) that could be used to fit the observations.

TABLE III. Three sediment half-space possibilities for the case when the scattering kernel is known *a priori* but the geoacoustic properties (or reflection coefficient) are unknown (see Figs. 8 and 9).

Sound speed (m/s)	Attenuation (dB/m/kHz)	Density (g/cm^3)
1600	0.5	1.8
1547	0.14	1.5
1670	1.0	2.0

It should be noted that the small uncertainties shown here do not necessarily represent the full range of possible uncertainties. For example, in fitting the data here we have assumed the "correct" parametrization, i.e., a half-space. If one were to assume, for example, that there was a sediment layer or layers, then the range of uncertainties associated with changing SSPs does indeed increase. However, some limited modeling (not shown) indicates modest and not dramatic increases in uncertainty, and much smaller uncertainties than seen for the scattering kernel in Sec. III.

The effect of changing geometry is similar to that of changing SSP, that is, the uncertainties are modest (a few decibels). The results here were calculated for a specific scattering kernel ($m=0.5$ and $10\log\mu=-33$ dB), however, the conclusions here are not sensitive to the particular scattering kernel chosen.

B. Bias errors due to changed sound speed profile: Isovelocity in survey

Since the reflection coefficients tend to be similar at low angles when fit to data, it does not matter very much whether the survey measurement is performed in downward refracting, isovelocity, or upward refracting conditions. All lead to similar (and modest) uncertainties.

However, we do comment that in the case where there is only a limited observation in range of the reverberation, the uncertainties could be significant. For example, consider a survey measurement of reverberation (isovelocity conditions) where because of noise and/or limited dynamic range, only ranges of 9–13 km could be observed. In this case, any

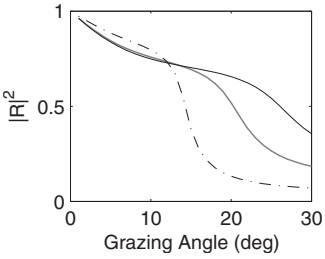

FIG. 8. Plane wave intensity reflection coefficients with similar levels at 13°. The geoacoustic models are in Table III [row 1 (gray line), row 2 (dash-dot), and row 3 (black)].

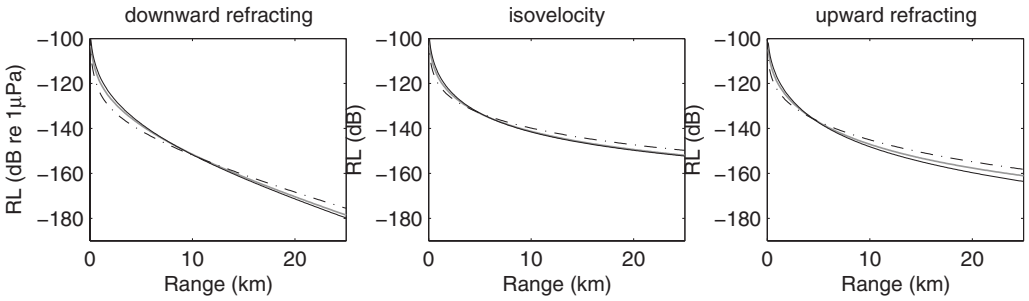

FIG. 9. Reverberation predictions for various sound speed profiles. The leftmost plot shows reverberation with the three reflection coefficients shown in Fig. 8 (with same line styles). The center and right-hand plots show reverberation predictions under different sound speed profiles. The sound speed gradients from left to right are −0.3, 0, and 0.2. In the simulation the water depth is 100 m, the sediment properties are provided in Table III, and source/receiver depths are 10 m.

one of the reflection coefficient curves of Fig. 10(d) could be made to fit the observations of Fig. 10(b). If predictions were made then under, say, downward refracting conditions [Fig. 10(a)], the errors at 10 km are about 6 dB.

C. Uncertainties associated with the reflection coefficient and the scattering kernel

In Sec. III, we showed that there was some advantage to conducting the survey measurement in an upward refracting or near isovelocity sound speed profiles when only the scattering kernel is unknown. Downward refracting gave the largest errors. It is of interest to determine whether this is true when both the scattering kernel and the reflection coefficient are unknown.

Fig. 11(a) shows fits to reverberation "data" for an upward refracting case in which both the scattering kernel and the reflection coefficient are unknown. The geoacoustic properties and scattering kernels are given in Table V. All of the sediment models fit the data reasonably well. If the SSP changes to downward refracting ($-0.3\ s^{-1}$), the predictions are shown in Fig. 11(b) where a very large spread in values (~60 dB at 10 km) is apparent. Thus, it is clear that if both the scattering kernel and reflection coefficient are unknown, there is no advantage to a particular SSP for the survey measurement.

Without attempting a complete treatment of prediction uncertainties in the case where both the scattering kernel and reflection coefficient are unknown, it suffices it to say that the error bounds can be quite large, many tens of decibels.

V. DISCUSSION AND CONCLUSIONS

A. Predicted uncertainties are large

The first and perhaps most important conclusion is that even in instances where a reverberation measurement is conducted, reverberation prediction uncertainties can be large when the sound speed profile changes or the source–receiver depths are different from that in the measurement. Uncertainties in reverberation prediction may be up to 18 dB at 10 km even when a measurement exists and everything is perfectly known about the ocean except the scattering kernel (which is obtained by fitting the data). Lossy bottoms (which have the

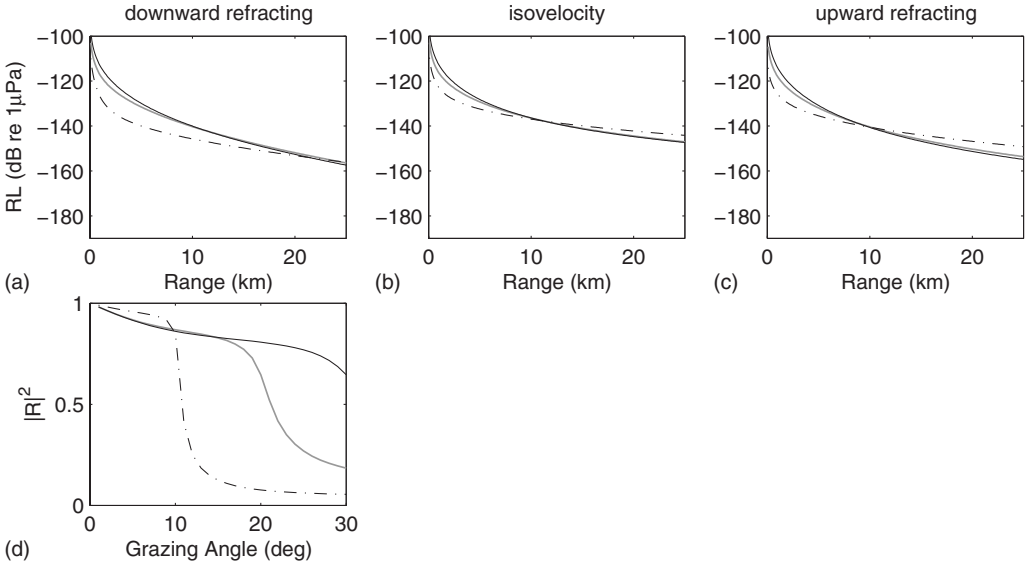

FIG. 10. (a)–(c) Reverberation predictions under various sound speed profiles and (d) reflection coefficients. The geoacoustic models for the reflection coefficients are given in Table IV.

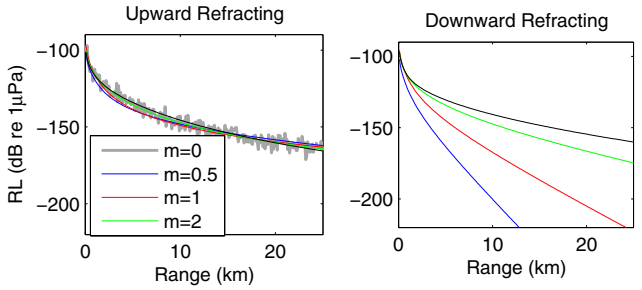

FIG. 11. (Color online) Example of no *a priori* knowledge of the scattering kernel or the reflection coefficient. "Synthetic" data (gray line) is compared with four scattering kernels (m=0, 0.5, 1, and 2) and variable reflection coefficients (see Table V) under upward refracting conditions in the left-hand plot. The right-hand plot shows predictions for the same four models if the sound speed profile changed to downward refracting ($-0.3\ s^{-1}$).

largest target echo-to-reverberation levels[22]) will generally have the largest bias errors from an unknown scattering kernel.

In realistic cases, the uncertainties are likely to be larger than predicted here since uncertainties, in the SSP, sea surface conditions, source/receiver calibrations, and seabed geoacoustic properties are not included in the order 10 dB uncertainties mentioned earlier. As an example, it was shown that uncertainties from lack of knowledge of both the scattering kernel and seabed geoacoustic properties can be very large (60 dB at 10 km). Thus our uncertainty bounds may underestimate the true uncertainties. It is the purpose here, however, to show order of magnitude uncertainties.

While we have used empirical models to quantify the order of magnitude bias errors that can occur, these same bias errors also occur for physics-based models when the underlying scattering kernel is unknown. Recalling the underlying cause that leads to the large uncertainties (a limited angular window to sample the scattering kernel), it does not matter whether the inverse approach assumes a fixed scattering kernel (e.g., Refs. 1, 3, 5, 6, and 8) or a variable scattering law including physics-based models (e.g., Refs. 2, 4, 7, 9, and 10). All of these approaches suffer from uncertainties in extrapolating from the angular window of observation to another angular window, which might be governed by a completely different scattering mechanism (see, e.g., Ref. 23, where low angles are controlled by volume scattering and intermediate angles by subbottom interface scattering).

B. Mitigating uncertainties

Reverberation prediction uncertainties of order 10 dB may be so large for some applications that the prediction is rendered of little value. Here we explore various ways to reduce the uncertainty. Given that the fundamental problem is a limited sampling of the scattering kernel in a reverberation measurement, the general idea in mitigation is to expand the angular sampling window (at the seabed). Various methods for accomplishing this are given in the following.

TABLE IV. Three sediment half-space possibilities for the case when the scattering kernel is known *a priori* but the geoacoustic properties (or reflection coefficient) are unknown (see Fig. 10).

Sound speed (m/s)	Attenuation (dB/m/kHz)	Density (g/cm^3)
1600	0.25	1.8
1525	0.02	1.5
1750	0.8	2.0

TABLE V. Geoacoustic models and scattering kernels for the case in which both the scattering kernel and the geoacoustic properties are unknown (Fig. 11).

Sound speed (m/s)	Attenuation (dB/m/kHz)	Density (g/cm^3)	m	$10\log(\mu)$

1600	1.5	1.8	0.5	−25
1600	0.5	1.8	1	−22
1600	0.25	1.8	2	−12

1. Mitigation of uncertainties by exploiting the sound speed profile

One possibility is to conduct the experiment during upward refracting or near isovelocity SSP. In the case of known seabed reflection coefficient, measuring reverberation over as large as possible range extent in an upward refracting profile offers the best chance for determining the correct scattering kernel from the data themselves. Strongly downward refracting profiles tend to lead to the largest bias errors (most difficult to distinguish various scattering kernels from the data themselves), with decreasing bias errors from decreasing sound speed gradients. Two caveats should be mentioned. First, in upward refracting cases, there is much greater likelihood for scattering from the sea surface, so it may actually become more difficult to determine the relative contributions of sea surface and seabed contributions. Second, if both the scattering kernel and the reflection coefficient are unknown, the bias errors might still be large (uncertainties of 60 dB at 10 km exist in the above–presented example) for the upward refracting or isovelocity case. Also note that, for some applications, waiting for a different SSP may be impractical.

2. Mitigation of uncertainties by multiple diverse reverberation measurements

Multiple reverberation measurements under diverse conditions permit the angular dependence of the scattering kernel (and also R) to be probed more widely. For example, reverberation in diverse SSPs or using diverse source–receiver depths in a single profile could reduce these uncertainties (also noted in Ref. 10). Generally, the greater disparity between the SSP or source–receiver depths for each measurement, the greater reduction in uncertainties will ensue (effectively probing the scattering over wider angular regions). However, it should be noted that in isovelocity (or near isovelocity) conditions, exploiting different source–receiver depths will not reduce the uncertainties, since in this case the reverberation is independent of source–receiver depth. Note again that in some cases, waiting for a diverse SSP may be impractical.

Another possibility is to exploit source–receiver vertical directionality[9] to probe the scattering kernel. That is, by ju-

dicious choice of directionality, one might be able to control the angles at the seabed and hence probe a wider angular window of the scattering kernel. If the directionality resides solely in the receiver, it might be possible to accomplish this with a single measurement.

3. Mitigation of uncertainties by measurement of the scattering kernel

Given that the prediction uncertainties tend to be dominated by scattering strength uncertainties (as opposed to reflection coefficient uncertainties), it suggests that measurement resources should be invested most heavily in measuring the scattering kernel directly. Perhaps the most obvious approach is to use the reverberation at short times when the reverberation is dominated by direct paths to the seabed (e.g., Ref. 24). However, the challenges include difficulty in isolating low angle scattering contributions (for which significant source–receiver directionality is required), the requirement to know geometry and source/receiver beampatterns accurately, and a large dynamic range (or adjustable gains). This is not to say that using a system designed for long-range reverberation cannot be used to measure short range scattering, it is only to say that considerable care is required.

Alternatively, the scattering kernel can be measured at low angles using techniques specifically designed for direct path (e.g., Refs. 20 and 25) measurements. Fortunately, uncertainties in vertically bistatic angular dependence have a minor impact on the uncertainties of the predicted reverberation,[26] therefore a measurement of backscatter is sufficient. The backscattering must be measured, however, over the range of angles that contribute to reverberation. For example, in shallow water this means angles below the critical angle.

There is evidence that scattering strength may be relatively constant over large areas in some environments (e.g., Ref. 27). Therefore, a promising strategy in a survey sense would be to use directional reverberation to determine provinces (i.e., areas where the scattering kernel appears to be reasonably constant in space) and then conduct a few direct path backscattering measurements to reduce reverberation prediction uncertainties.

C. Uncertainty estimation

In addition to the need for making an additional measurement to reduce or mitigate the large uncertainties, it would be useful for reverberation inversion approaches to report the estimated reverberation prediction uncertainties. A simple way might be similar to Fig. 5(c), where the range of sound speed profiles could be tailored to the particular area.

A straightforward, but potentially incorrect approach to estimating the uncertainties would be to simply propagate the uncertainties of the fitted seabed parameters. This would only be correct if the inverse problem is parametrized sufficiently broadly, including all possibilities for the seabed properties (for which the forward predictions are sensitive). For example, it is clear that the angular dependence of the scattering kernel has a large impact on prediction uncertainties. In the (not uncommon) case of assuming a fixed angular dependence in the inverse problem, the prediction of reverberation uncertainty must include a wide parametrization, allowing for other angular dependencies.

VI. SUMMARY

Reverberation measurements, either in a survey or through the sensor operation can be a powerful tool for reducing uncertainties in performance prediction for active systems. However, we have shown here that for current inversion methods where reverberation (and sometimes propagation) is inverted for seabed parameters, the remnant uncertainties even after the measurement can be quite large, of order 10 dB at 10 km, increasing with increasing range. These uncertainties are due to uncertainty in the scattering kernel, which generally cannot be obtained uniquely from long-range reverberation. Prediction uncertainties from the reflection coefficient (when the scattering kernel was known) were shown to be much smaller. However, in practice, when there are uncertainties in both the scattering kernel and the geoacoustic properties, the uncertainties can be much greater, several tens of decibels. Since the errors tend to depend most heavily on the (generally unknown) angular dependence of the scattering kernel, several methods were briefly explored for reducing the uncertainties. These methods allow a wider angular sampling of the scattering kernel than a single reverberation measurement.

In summary, the main points of the paper are as follows:

(1) Reverberation prediction uncertainties can be large, order 10 dB, even in the presence of high quality reverberation measurements at the same location, and ostensibly small uncertainties of the fitted seabed parameters.
   (a) Prediction uncertainties tend to be largest when there is a limited time/range window over which the observations are made.
   (b) However, increase of the range window does not necessarily guarantee a reduction in the prediction uncertainties (a case in point is for a downward refracting environment, see Fig. 2)

(2) Current methods for reverberation inversion should be modified, mitigating the large prediction uncertainties by at least one of the following:
   (a) Making independent measurements of the scattering kernel (backscattering strength is sufficient) from the critical angle to as low an angle as practical;
   (b) Conducting the reverberation measurements in isovelocity or upward refracting environments (or multiple sound speed profiles), if the angular dependence of the reflection coefficient is well known, and the scattering at the sea surface is negligible compared to the bottom scattering;
   (c) Conducting the reverberation measurements using multiple source/receiver depths, if the sound speed profile is not isovelocity or nearly isovelocity.

(3) Results for reverberation inversion should be accompanied by estimates of reverberation prediction uncertainty.

Optimization of transmitting beam patterns of a conformal transducer array

Zhengyao He[a] and Yuanliang Ma
Institute of Acoustic Engineering, Northwestern Polytechnical University, Xi'an, 710072, China

(Received 11 September 2007; revised 14 January 2008; accepted 22 February 2008)

A method is presented to calculate the driving-voltage weighting vector of a conformal array of underwater acoustic transmitting transducers to obtain a low-sidelobe beam pattern based on the measured receiving array manifold. The relationship among three quantities is given, which are, respectively, the radiated acoustic field, the measured receiving array manifold matrix and the driving-voltage weighting vector of the transducer array. Then, the driving-voltage weighting vector of the array is calculated using the optimization method to obtain a low-sidelobe transmitting beam pattern. At the frequency of 12.5 kHz, the receiving array manifold matrix of a 27-element conformal array is measured in an anechoic water tank. The driving-voltage weighting vector of the array is calculated using the proposed method. In addition, the computer simulation and experiments are carried out. The results agree well and show that the proposed method can obtain a low-sidelobe transmitting beam pattern and at the same time provide the largest amplitude of pressure in the axial direction when the maximum amplitude of the driving voltages of the array elements keeps unchanged. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2897046]

I. INTRODUCTION

A low-sidelobe transmitting beam pattern and large radiated pressure amplitude of the mainlobe is always expected in an underwater acoustic transmitting transducer array of active sonar and autonomous underwater vehicle (AUV).[1] In the research of the radiated acoustic field of compact transducer arrays, the mutual interactions among elements must be considered.[2–4] In the conformal array of our research, the volume of the array is small with compact elements, and it is needed to transmit broadband signal. Consequently, the interactions among elements in the conformal array are definitely significant.[5] On the other side, the radiated acoustic field of the array may be greatly influenced by the baffle with a certain impedance boundary condition.[6] Diffraction is caused by the baffle when the conformal array transmits and receives acoustic signals. Thus, the diffraction constant is necessary to be considered when the transmitting beam pattern of the conformal array is controlled.

There is some preliminary research about the influence of the baffle and mutual interactions among elements on the performance of the transducer array. Carson[7] utilized the equivalent circuit principle to select appropriate tuning capacitors to control the vibration velocity of the transducer array. Audoly[8] adopted the improved Helmholtz boundary integral equation method[9] to calculate the acoustic radiation and mutual interactions of the 8-element and 32-element planar array set in the finite baffle. But, the above-mentioned research only analyzed how the baffle and mutual interactions greatly influenced the transmitting performance of the transducer array, yet they did not propose such methods that could reduce the influence in order to control the transmitting beam pattern and obtain a high transmitting source level. He and Ma[10] utilized the boundary element model to calculate the radiated acoustic field of the transducer array, and adopted optimization method to control the transmitting beam pattern of the array. However, a relatively big error existed when this theoretical calculation method was used practically. The experimental results were not very satisfactory when the transducer number in the array increases.

When the received signals of the conformal array of our research are processed by beam forming, the measured receiving array manifold of the array, which is composed of the receiving response of each element in the array including both amplitude and phase responses,[11] can be used to optimize the beam pattern of received signals. In the investigation of the conformal array, the acoustic reciprocity principle may be used. The basic concept of the acoustic reciprocity principle was given by Foldy and Primakoff[12] and Bobber[13] in detail. When the transducer array transmits acoustic signals, the array may be influenced by the baffle, the mutual interactions among elements, etc. When it receives acoustic signals, the array may also be influenced by these factors. Therefore, an idea emerges that the measured receiving array manifold may be used to calculate the driving-voltage weighting vector of the conformal array. Thus, comparing with the results using the theoretical model,[10] the error may decrease and the performance may increase.

In this paper, a new method is proposed to calculate the driving-voltage weighting vector of the conformal array based on the measured receiving array manifold in order to obtain a low-sidelobe transmitting beam pattern and good transmitting performance. Further, an experiment has been conducted to demonstrate the correctness and validity of the proposed method in an anechoic water tank.

II. TRANSMITTING AND RECEIVING DIFFRACTION CONSTANTS OF TRANSDUCER

The concept of the transmitting and receiving diffraction constants[12] is given in the following. Assume that the surface vibration velocity of the transducer is uniform. Place a transducer with a volume velocity U in a free field, producing a pressure p in the far field at a distance d. Place a simple source with a volume velocity U_s at the point with the distance d, producing an average blocked pressure $\bar{p}_b$ on the transducer and a free-field pressure p_f at the transducer location. Then, the receiving diffraction constant of the transducer is

$$D = \frac{\bar{p}_b}{p_f}. \tag{1}$$

From the acoustic reciprocity theorem, it leads to

$$\frac{p}{U} = D\left(\frac{\omega\rho}{4\pi d}\right), \tag{2}$$

where ω is the sound wave angular frequency and ρ is the density of the medium.

Substitute a simple source for the transducer with the same volume velocity U, then the pressure at the point with the distance d is

$$p_0 = \left(\frac{\omega\rho}{4\pi d}\right)U. \tag{3}$$

From Eqs. (2) and (3), we can get

$$\frac{p}{p_0} = D. \tag{4}$$

The transmitting diffraction constant of the transducer is calculated by Eq. (4), which is the ratio of the pressure produced by a transducer at a remote point in a free field to the pressure produced at the same point when a simple source with the same volume velocity is substituted for the transducer. It is numerically equal to the receiving diffraction constant of the transducer. The transmitting diffraction constant D of the transducer can be calculated by the boundary element model. The transmitting and receiving diffraction constants include not only amplitude but also phase. Let the initial phase of the vibration velocity of the transducer when transmitting signals be zero and that of the simple source when receiving signals be zero. Then, according to the acoustic reciprocity principle, the phases of the transmitting and receiving diffraction constants are the same.

III. TRANSMITTING AND RECEIVING EQUIVALENT CIRCUITS OF TRANSDUCER

The transmitting and receiving equivalent circuits of the transducer are introduced in this section, which is preparation for the transmitting beam pattern optimization of the transducer array in the next section. Suppose that the transducers in the array are all piston transducers. The transmitting equivalent circuit of one transducer is shown in Fig. 1. C_0 is the static capacitance. n is the electromechanical transfer ratio, Z_m is the mechanical impedance, and Z_s is the radiation impedance. These parameters may be obtained by different models or by experiments.[14,15] E is the prescribed voltage on the transducer, I, I_0, and I_d are the electric currents in different branches, F is the mechanical force, and v is the vibration velocity of the transducer.

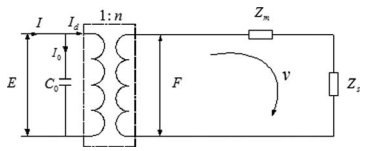

FIG. 1. Transmitting equivalent circuit of the transducer.

In the array composed of L identical transducers, the mechanical impedance of the transducers are all assumed to be Z_{m0}. Then, the mutual impedance matrix of the array can be written as

$$\mathbf{Z} = \begin{bmatrix} Z_{m0}+z_{11} & z_{12} & \cdots & z_{1L} \\ z_{21} & Z_{m0}+z_{22} & \cdots & z_{2L} \\ \vdots & \vdots & \vdots & \vdots \\ z_{L1} & z_{L2} & \cdots & Z_{m0}+z_{LL} \end{bmatrix}, \tag{5}$$

where z_{ii} is the self-radiation impedance of the ith transducer and z_{ij} is the mutual radiation impedance between the ith and jth transducer. Then, the driving voltage and the vibration velocity of the array satisfy the following relationship:

$$\mathbf{V} = n\mathbf{Z}^{-1}\mathbf{E}, \tag{6}$$

where n is the electromechanical transfer ratio of the transducers, $\mathbf{Z}$ is the mutual impedance matrix of the array, $\mathbf{E}$ is the column vector of the driving voltage, and $\mathbf{V}$ is the column vector of the vibration velocity of the array.

The receiving equivalent circuit of the transducer is shown in Fig. 2. F represents the mechanical force, which is exerted on the surface of the transducer by the free-field pressure p_f, D is the receiving diffraction constant, S is the surface area, Z_s is the radiation impedance, Z_m is the mechanical impedance, and Z_e is the electrical impedance when the vibration velocity is zero. According to the acoustic reciprocity principle, the mechanical impedance and radiation impedance of the transducer when receiving signals are the same as those when transmitting signals. n_r is the electromechanical transfer ratio when receiving signals, and v is the vibration velocity caused by the incident sound wave. The previous satisfies the following relationship:

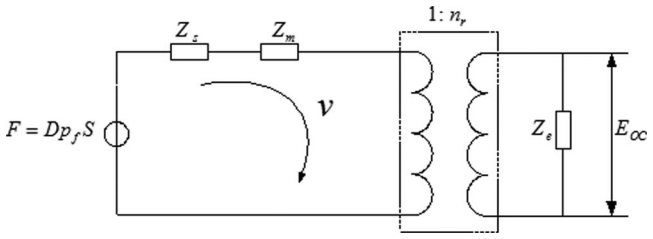

FIG. 2. Receiving equivalent circuit of the transducer.

$$F = Dp_f S = (Z_s + Z_m)v. \tag{7}$$

When the transducer receives signals, the open-circuit output voltage is

$$E_{OC} = n_r v, \tag{8}$$

where n_r is the electromechanical transfer ratio of the transducer when receiving signals and v is the vibration velocity of the transducer.

In the transducer array, the mutual impedance matrix when receiving signals is the same as that of transmitting, which is also $\mathbf{Z}$. Then, the mechanical force vector on the array exerted by the incident sound wave and the resultant vibration velocity vector of the array satisfy

$$\mathbf{F} = \mathbf{ZV}. \tag{9}$$

Using the transmitting and receiving equivalent circuits of the transducer and array introduced earlier, the relationship of the following quantities can be derived, which are, respectively, the driving voltage, diffraction constants, element mutual interactions, vibration velocity, and the receiving open-circuit voltage, and then the transmitting beam pattern of the transducer array can be optimized in the next section.

IV. TRANSMITTING BEAM PATTERN OPTIMIZATION PRINCIPLE OF THE TRANSDUCER ARRAY

Now, the transmitting beam pattern optimization principle of the transducer array is derived as follows. From Eqs. (3) and (4), the radiated acoustic pressure and vibration velocity of the transducer satisfy

$$p = Dp_0 = \frac{\omega \rho S}{4\pi d} Dv, \tag{10}$$

where S is the radiation surface area of the transducer, d is the distance between the far-field point and the equivalent acoustic center of the radiation area on the transducer, and D is the transmitting diffraction constant, including both amplitude and phase.

Suppose that the transducer array is composed of L transducers, the radiated acoustic pressure of the array is to be calculated. We uniformly divide the circle at a certain distance from the center of the array in the radiated acoustic field into M field points. The lines connecting these field points and the array center denote M directions of the radiated acoustic field. Assume that the transmitting diffraction constant of the jth transducer of the array in the ith direction is D_{ij}. Then, the transmitting diffraction constants of L transducers in M directions can form the constant matrix $\mathbf{D}$, which is

$$\mathbf{D} = \begin{bmatrix} D_{11} & D_{12} & \cdots & D_{1L} \\ D_{21} & D_{22} & \cdots & D_{2L} \\ \vdots & \vdots & \vdots & \vdots \\ D_{M1} & D_{M2} & \cdots & D_{ML} \end{bmatrix}. \tag{11}$$

From Eq. (6) and Eqs. (10) and (11), we can obtain the radiated acoustic pressure of the transducer array

$$\mathbf{P}_Q = \frac{n\omega\rho S}{4\pi d} \mathbf{DZ}^{-1}\mathbf{E}, \tag{12}$$

where $\mathbf{P}_Q$ denotes the vector constituted by the sound pressure in the M directions on the circle in the radiated far-field of the array.

When the transducer array receives acoustic signals, according to the acoustic reciprocity principle, the matrix of the receiving diffraction constant is the same as that of the transmitting diffraction constant, which is also determined by Eq. (11). Assume that the incident pressure p_f of each element in each direction is the same, and the surface area S of each transducer is also the same. From Eqs. (7)–(9) and Eq. (11), when the transducer array receives signals, the open-circuit output voltage is

$$\mathbf{E}_{OC} = n_r p_f S \cdot \mathbf{Z}^{-1}\mathbf{D}^T, \tag{13}$$

where $\mathbf{E}_{OC}$ is a $L \times M$ matrix, denoting the response to the far-field plane wave of L elements in M directions of the transducer array when receiving acoustic signals, including amplitude and phase responses, that is, $\mathbf{E}_{OC}$ is the receiving array manifold matrix of the transducer array, which can be obtained by experimental measurements. Because the mutual impedance matrix $\mathbf{Z}$ of the array is a symmetrical matrix, we can get

$$(\mathbf{Z}^{-1})^T = (\mathbf{Z}^T)^{-1} = \mathbf{Z}^{-1}. \tag{14}$$

Transposing the matrices on the two sides of Eq. (13) and substituting Eq. (14) into it, we get

$$(\mathbf{E}_{OC})^T = n_r p_f S \cdot \mathbf{DZ}^{-1}. \tag{15}$$

From Eq. (15), we obtain:

$$\mathbf{DZ}^{-1} = \frac{1}{n_r p_f S}(\mathbf{E}_{OC})^T. \tag{16}$$

Substituting Eq. (16) into Eq. (12) gives:

$$\mathbf{P}_Q = \frac{\omega\rho n}{4\pi d n_r p_f}(\mathbf{E}_{OC})^T\mathbf{E}. \tag{17}$$

Equation (17) relates the radiated acoustic field of the array with the measured receiving array manifold and the driving-voltage vector. Where $\mathbf{P}_Q$ is a $M \times 1$ vector, $(\mathbf{E}_{OC})^T$ is a $M \times L$ matrix, $\mathbf{E}$ is a $L \times 1$ vector, L denotes L elements of the array, and M denotes M directions on the circle in the radiated far field of the array. When the receiving array manifold matrix $\mathbf{E}_{OC}$ of the array is obtained by experimental measurements, the driving-voltage weighting vector of the array can be calculated by the optimization method to control the transmitting beam pattern of the array.

It is necessary to carry out the beam control for the transducer array in order to obtain a low-sidelobe transmitting beam pattern. Because the maximum amplitude of the driving voltages of the transducers in the array is limited, the result of the beam control may reduce the pressure amplitude in the axial direction of the array. For the purpose of making the transmitting source level of the array as high as possible, it needs to provide the largest pressure amplitude in the axial direction when the maximum amplitude of the driving voltages of the array elements keeps unchanged. That is, we

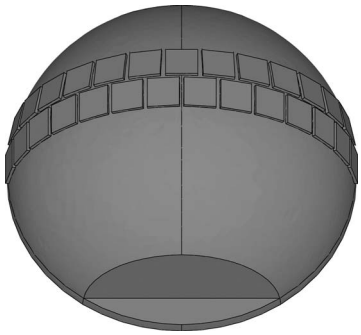

FIG. 3. Structure diagram of the conformal array which consists of 27 piston transducers and a hemispherical baffle.

make the maximum modulus of the driving-voltage weighting vector be minimum, simultaneously producing the same amplitude of pressure in the axial direction of the array and at the same time imposing constraints on the sidelobes of the transmitting beam pattern. Because what is to be calculated is the normalized vector, the coefficient $\omega\rho n/4\pi dn_r p_f$ in Eq. (17) can be left out of the calculation. It leads to the following optimization problem:

$$\begin{aligned} &\min_{\mathbf{W}_E} \mu \\ &\text{subject to} \quad \mathbf{E}_{\mathrm{OC}}(\theta_0)^T \mathbf{W}_E = 1 \\ &\qquad\qquad |\mathbf{W}_E(j)| \le \mu, \quad j = 1,2,\ldots,L \\ &\qquad\qquad |\mathbf{E}_{\mathrm{OC}}(\theta_s)^T \mathbf{W}_E| \le \delta_s, \quad \forall\, \theta_s \in \Theta_{\mathrm{SL}}, \end{aligned} \tag{18}$$

where $\mathbf{W}_E$ is the driving-voltage weighting vector of the array, μ is a nonnegative real variable, L is the transducer number of the array, θ_0 is the mainlobe direction, θ_s is the sidelobe direction, Θ_{SL} is the sidelobe regions which includes a number of directions, and δ_s controls the sidelobe level of the transmitting beam pattern. $\mathbf{E}_{\mathrm{OC}}(\theta_0)$ and $\mathbf{E}_{\mathrm{OC}}(\theta_s)$ are, respectively, the receiving array manifold vectors in θ_0 and θ_s directions, which can all be obtained by experimental measurements.

The optimization problem (18) can be solved by means of the optimization algorithm of the second-order cone programming.[16,17] Then, the required driving-voltage weighting vector $\mathbf{W}_E$ of the array is calculated. The practical driving voltage exerted on the transducers in the array is obtained by normalizing the calculated weighting vector, that is, the weighting vector is divided by the maximum modulus of the vector, and then multiplied by a voltage factor which must be less than the maximum voltage that can be exerted on the transducers of the array.

V. SIMULATION COMPUTATION

The structure diagram of the conformal array is shown in Fig. 3. This conformal array consists of 27 piston transducers. It is set in two arc lines of a hemispherical baffle. The cover board is on the underside of the baffle. The surface of the hemispherical baffle is made of rubber, the two sides of the baffle are of organic glass, and the cover board is of aluminum. The 27-element array is divided into two rows. The first row is in the middle. The left and right side of two rows are symmetrical. The first row consists of 14 transducers from a1 to a14. The second row consists of 13 transducers from b1 to b13. The distance between two adjacent transducers of the first row is 0.0452 m, and that of the second row is 0.0453 m. The angle between the planes of the first and second rows passing the hemispherical center is 12°. The radius of the hemispherical baffle is $r=0.216$ m. The radiation surface of each piston transducer is rectangular with the length $a=0.04$ m and width $b=0.04$ m. The sound frequency is $f=12.5$ kHz, speed underwater is $c=1500$ m/s and wavelength is $\lambda=0.12$ m. An experiment has been carried out to measure the receiving array manifold matrix of the conformal array in the anechoic water tank. The response of each element to the plane-wave acoustic signals, including amplitude and phase responses, is measured in the range of ±135° from the main axial direction of the array with the interval 3°, in this way, the receiving array manifold matrix of the conformal array is obtained. Then, two methods are used to calculate the driving-voltage weighting vector of the array. One is the conventional beam-forming method in which the weighting vector is calculated by phase compensation according to the geometrical positions of the elements using the plane-wave model.[18] The other is the proposed method in this paper, which uses Eq. (18) to calculate the weighting vector of the array. Figures 4–7 are, respectively, the radiated sound pressure amplitude and directivity of the 27-element conformal array calculated by simulation when the beam scan angles are 0° and 84°. The solid line represents the weighting vector calculated by the proposed method with the sidelobe level constrained to −20 dB. The dotted line represents the weighting vector calculated by the conventional beam-forming method with the plane-wave model. Then, the radiated acoustic pressure of the array is calculated by Eq. (17). The ordinates of Figs. 4 and 6 represent the radiated acoustic pressure amplitude of the array divided by the axial maximum pressure amplitude when the weighting vector is obtained by the conventional beam-forming method and the

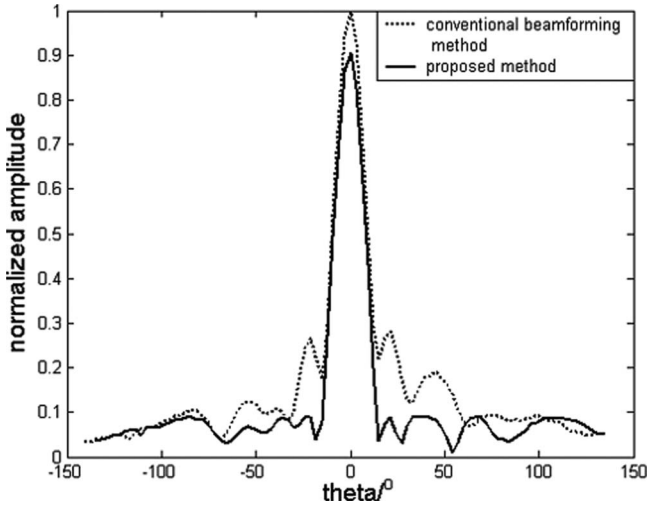

FIG. 4. Radiated sound pressure amplitude of the 27-element conformal array calculated by simulation of two weighting methods when the beam scan angle is 0°, where the pressure amplitude is divided by the axial maximum pressure amplitude when the weighting vector is obtained by the conventional beam-forming method. Revealed is the difference of the maximum amplitude in the axial direction of two weighting methods.

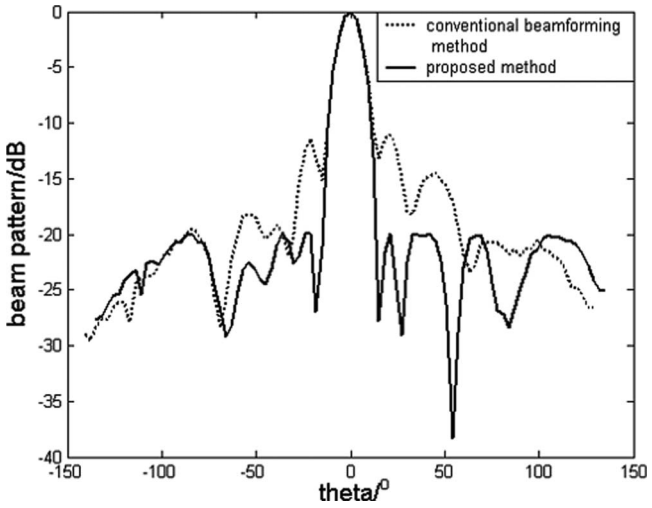

FIG. 5. Radiated sound pressure directivity of the 27-element conformal array calculated by simulation when the beam scan angle is 0°, in which the maximum value is normalized to 0 dB.

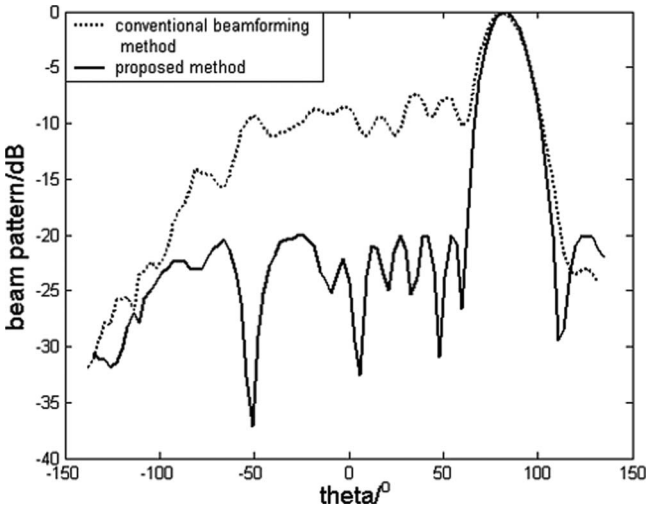

FIG. 7. Radiated sound pressure directivity of the conformal array calculated by simulation when the beam scan angle is 84°, in which the maximum value is normalized to 0 dB.

beam scan angle is 0°. Figures 4–7 show that the proposed method can control the sidelobes of the transmitting beam pattern of the conformal array and can obtain a low-sidelobe level. When the beam scan angles are 0° and 84°, using the proposed method, the highest sidelobe levels of the beam patterns of simulation are both −20 dB, whereas using the conventional beam-forming method, the highest sidelobe levels are, respectively, −11 and −7.3 dB. On the other hand, because the proposed method imposes constraints on the sidelobe level of the beam pattern, the maximum pressure amplitude of the mainlobe may reduce comparing with that of the conventional beam-forming method. However, the proposed approach can provide the largest pressure amplitude in the axial direction of the array when the maximum amplitude of the driving voltages of the array elements remains the same, simultaneously satisfying the sidelobe constraints. Corresponding to Figs. 4 and 6, using the proposed method, comparing with the conventional beam-forming method, the maximum pressure amplitude does not reduce much, with the reduction amounts of 0.87 and 0.3 dB, respectively. Because of the acoustic diffraction caused by the baffle and the element radiation directivity of each transducer in the array, the axial maximum pressure amplitude of the array, when the beam scan angle is in the side direction, may be lower compared to that in the main direction. The attainable beam scan angle of the conformal array of our research is broad, thus, the axial maximum pressure amplitude, when the beam scan angle is in the side direction 84°, does not reduce much compared with that in the main direction 0°, and the reduction amount is 3.2 dB. The simulation results show that the proposed approach can obtain a low-sidelobe transmitting beam pattern, and provide the largest pressure amplitude in the axial direction of the array when the maximum amplitude of the driving voltages of the array elements keeps unchanged.

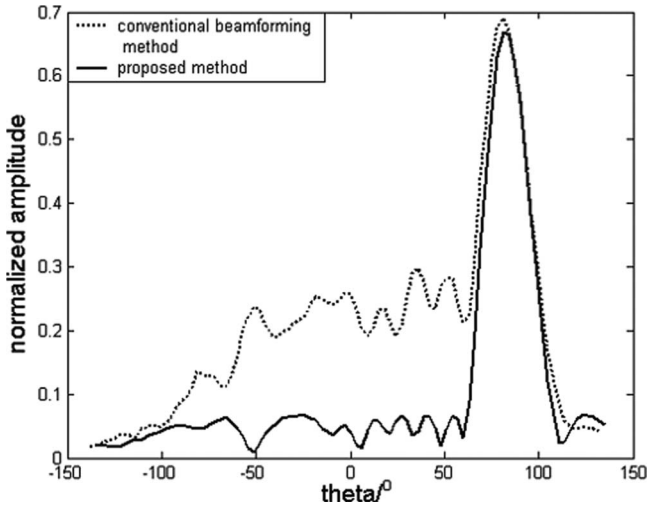

FIG. 6. Radiated sound pressure amplitude of the conformal array calculated by simulation when the beam scan angle is 84°. Pressure amplitude is divided by the axial maximum pressure amplitude when the weighting vector is obtained by the conventional beam-forming method and the beam scan angle is 0°. Revealed is the difference of the maximum amplitude in the axial direction of two weighting methods and two beam scan angles.

VI. EXPERIMENTAL RESULTS

An experiment has been conducted to measure the radiated acoustic pressure directivity of the conformal array in an anechoic water tank. The working frequency is $f=12.5$ kHz. The maximum driving voltage exerted on the transducers is 4 V, i.e., the normalized driving-voltage weighting vector calculated by Eq. (18) is multiplied by the voltage factor 4 V. Figures 8–11 are, respectively, the measured radiated sound pressure amplitude and directivity of the 27-element conformal array when the beam scan angles are 0° and 84°. The meanings represented by the solid and dotted lines in Figs. 8–11 are the same as those in Figs. 4–7. The ordinates of Figs. 8 and 10 represent the measured radiated acoustic pressure amplitude of the array divided by the axial maximum pressure amplitude when the weighting vector is calculated by the conventional beam-forming method and the beam scan angle is 0°. From Figs. 8–11, it is shown that the

measured results are consistent with the simulation results in Sec. V. Obviously, the proposed method can obtain a low-sidelobe transmitting beam pattern. Using the proposed method, the highest sidelobe levels of the measured beam patterns are, respectively, −17.1 and −13.9 dB when the beam scan angles are 0° and 84°. Although using the conventional beam-forming method, the highest sidelobe levels of the measured beam patterns are −13.9 and −6.6 dB, respectively. It is shown that the highest sidelobe levels are greatly reduced using the proposed method, compared to the conventional beam-forming method. There are some differences between the experimental and simulation results due to the measurement errors. On the other hand, similar to the simulation results, because the proposed method imposes constraints on the sidelobe level of the beam pattern, the maximum pressure amplitude of the mainlobe may be reduced compared to that of the conventional beam-forming method. The proposed method can provide the largest pressure amplitude in the axial direction of the array when the maximum amplitude of the driving voltages of the array elements are kept unchanged, and at the same time satisfying the sidelobe constraints. Corresponding to Figs. 8 and 10, by use of the proposed method contrasting with the conventional beam-forming method, the maximum pressure amplitude does not reduce much, with reduction amounts of 1.13 and 0.29 dB, respectively. From the experimental results, it is also shown that the attainable beam scan angle of the conformal array is broad, and the axial maximum pressure amplitude, when the beam scan angle is in the side direction 84°, does not reduce much compared to that in the main

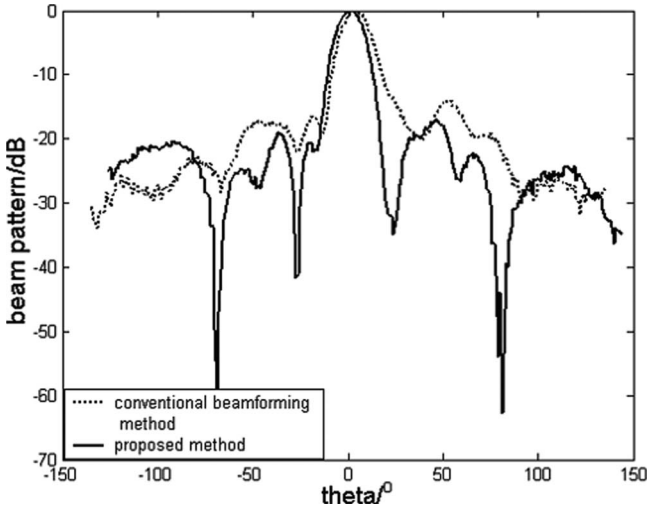

FIG. 9. Measured radiated sound pressure directivity of the 27-element conformal array when the beam scan angle is 0°, in which the maximum value is normalized to 0 dB.

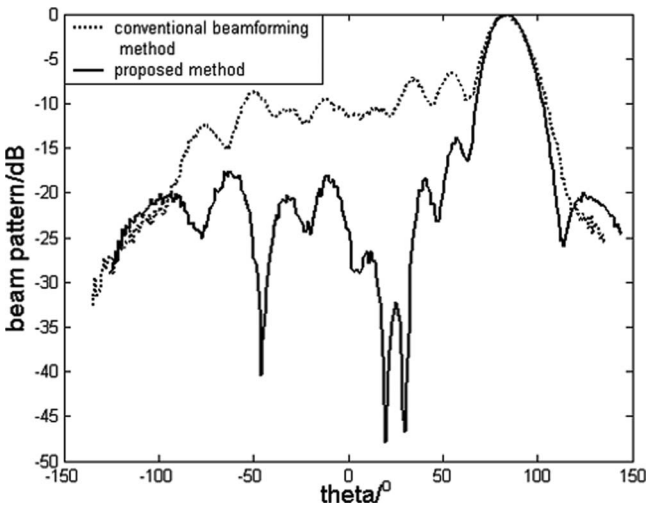

FIG. 11. The measured radiated sound pressure directivity of the conformal array when the beam scan angle is 84°, in which the maximum value is normalized to 0 dB.

direction 0°, with the reduction amount of 3.12 dB. It can be seen that the experimental results are greatly consistent with the simulation results, which verifies that the proposed method is valid and practical.

VII. CONCLUSIONS

In this paper, a new method is proposed to calculate the driving-voltage weighting vector of the conformal array based on the measured receiving array manifold in order to control the sidelobe of the transmitting beam pattern. According to the acoustic reciprocity principle, the relationship between the transmitting and receiving diffraction constants is given. The relationship among three quantities is presented, which are, respectively, the radiated acoustic field, the measured receiving array manifold, and the driving-voltage weighting vector of the transducer array. At last, the driving-voltage weighting vector of the array is calculated using the optimization method. The simulation results show that the proposed method can be adopted to calculate the driving-voltage weighting vector of the conformal array to obtain a low-sidelobe transmitting beam pattern and provide the largest pressure amplitude in the axial direction of the array when the maximum amplitude of the driving voltages of the array elements remains unchanged. An experiment has been carried out to measure the radiation directivity of the conformal array in the anechoic water tank and its results demonstrate that our method is valid and practical. There are still some differences between the experimental and simulation results due to measurement errors. The performance of the proposed method may be more perfect when the experimental measurements are more accurate.

(Received 28 June 2007; revised 15 January 2008; accepted 15 February 2008)

Successful processing of materials by powder sintering relies on the creation of strong interparticle bonds. During certain critical stages of the sintering process, the medium may be modeled as two phases consisting of the particles and a surrounding matrix. Ultrasonic methods have been proposed as a potential tool for monitoring such sintering processes. Thus, an understanding of the propagation and scattering of elastic waves in two-phase solids is of fundamental importance to these monitoring techniques. In this article, expressions for the ultrasonic attenuations are developed based on the spatial statistics of the density and Lamé parameters of the material constituents under assumptions of statistical homogeneity and statistical isotropy. The formulation is based on the solution of the elastodynamic Dyson equation within the limits of the first-order smoothing approximation. Since the geometric two-point correlation function plays a central role in the model, numerical models are developed using Voronoi polycrystals surrounded by a matrix of different material properties. The spatial statistics of the medium are extracted from these models. The results presented suggest new ultrasonic techniques may be developed to extract multiple correlation lengths for such two-phase microstructures. © *2008 Acoustical Society of America.*

I. INTRODUCTION

Sintered metals and ceramics are very important in modern manufacturing. Many construction and engineering materials are produced by sintering of different crystal powders in mechanical engineering, energetics, metal-working industries, instrument making and electronics. An increased understanding of the sintering process would lead to intelligent process control, greater reliability of the production process, and improved quality of the end products. Therefore, continuous real-time monitoring of the microstructure evolution is necessary. More importantly, such monitoring techniques will provide valuable information for modeling sintering processes. Most current monitoring techniques are not *in situ* techniques. Ultrasonic and eddy current techniques have great potential for direct measurements during processing. However, eddy current techniques are limited to information predominantly about the material near the specimen surface.[1] Ultrasonic methods can provide information about the interior microstructure due to the penetration of ultrasonic waves and are capable of inspecting the sintering process at high temperatures.[2,3] However, the main difficulty with such ultrasonic techniques is the theoretical framework necessary to make the measurements quantitative.

The propagation and scattering of elastic waves through random medium has received considerable attention.[4,5] The basic premise of these analyses is to treat the material properties as random variables and use statistical methods to analyze the wave propagation. Most of those statistical theories require information about the spatial statistics of the microstructure to predict the macroscopic properties of heterogeneous materials. The model of Stanke and Kino[6] clearly established that the two-point correlation function is important for the attenuation within the second-order perturbation theory. Furthermore, the exponential correlation function used by Stanke and Kino for statistically isotropic, polycrystalline media is widely adopted in many works due to its simplicity.[7–11] The validity of this geometric autocorrelation function in polycrystalline media was examined by Man *et al.*[12] They found that the exponential formula fails to represent the correlation function for the grain boundary structure of a commercial aluminum alloy and that an alternative function is necessary. Such information will provide valuable insight for modeling the microstructure of complex materials during sintering processes.

In this article, the propagation and scattering of ultrasound in partially sintered materials is examined using a two-phase model consisting of the polycrystals and a surrounding matrix. The theory based on a stochastic, elastic wave model presented by Turner and Anugonda[10] is extended to study the attenuation of elastic waves in two-phase materials. The medium is assumed to be statistically homogeneous and statistically isotropic. The spatial statistics of the microstructure, also known as geometric correlation functions, are numerically evaluated and investigated. The attenuation of longitudinal and transverse elastic wave is presented in terms of the statistics of the density and Lamé parameters of the materials. The influence of correlation functions on the resulting attenuations is discussed.

II. STATISTICS OF MATERIAL PROPERTIES

The derivations for scattering attenuation rely on information regarding the statistics of the microstructure. Explicit expressions for the attenuation of longitudinal and transverse elastic waves used in this article are based upon the general description discussed by Turner and Anugonda.[10] In that work, the solution for the wave vector in the heterogeneous medium is based on the Dyson equation derived for the elastodynamic case. The Dyson equation was solved within the limits of the first-order smoothing approximation[13] for which the dimensionless combination of material fluctuation, bare wave number and correlation length must be smaller than unity. For more details, the reader may wish to refer to previous work using this approach.[9,10,14]

The spatial statistics of material properties are presented in this section. The material density, ρ, and Lamé parameters, λ and μ, are assumed to vary spatially and to have the form

$$\rho(\mathbf{x}) = \bar{\rho}[1 + \delta\rho(\mathbf{x})],$$

$$\lambda(\mathbf{x}) = \bar{\lambda}[1 + \delta\lambda(\mathbf{x})],$$

$$\mu(\mathbf{x}) = \bar{\mu}[1 + \delta\mu(\mathbf{x})], \tag{1}$$

where the over-bar terms are the average quantities and terms with δ represent a dimensionless measure of the spatial fluctuations about the average. It is assumed that the fluctuations are small and that the material properties are locally isotropic. The second-order statistics of the fluctuations are also required. The covariance of the density is given by

$$R_{\rho\rho}(\mathbf{x}-\mathbf{y}) = \langle \delta\rho(\mathbf{x})\delta\rho(\mathbf{y})\rangle. \tag{2}$$

The assumptions of statistical homogeneity and statistical isotropy imply that the correlation functions depend only on the distance, r, between the two positions. Thus

$$R_{\rho\rho}(\mathbf{x}-\mathbf{y}) = R_{\rho\rho}(|\mathbf{x}-\mathbf{y}|) = R_{\rho\rho}(r). \tag{3}$$

Autocorrelations of Lamé parameters, $R_{\lambda\lambda}$ and $R_{\mu\mu}$, as well as the cross correlation between different parameters $R_{\rho\lambda}$, $R_{\rho\mu}$, and $R_{\lambda\mu}$ can be defined in a similar manner.

For a material consisting of two uniform phases, a general and convenient description of the spatial variation is supplied by introducing the characteristic function[15]

$$\chi_1(\mathbf{x}) = \begin{cases} 1, & \text{if } x \in \Omega_1, \\ 0, & \text{otherwise}, \end{cases} \tag{4}$$

of the region Ω_1 occupied by phase "1." The complement Ω_2 is occupied by phase "2," and obviously, its characteristic function is $\chi_2(\mathbf{x}) = 1 - \chi_1(\mathbf{x})$. Starting from the definition of Eq. (3)

$$R_{\rho\rho}(r) = \frac{\langle(\rho(\mathbf{x}) - \bar{\rho})(\rho(\mathbf{y}) - \bar{\rho})\rangle}{\bar{\rho}^2}. \tag{5}$$

The density may then be described in terms of the characteristic functions

$$\rho(\mathbf{x}) = \rho_1\chi_1(\mathbf{x}) + \rho_2\chi_2(\mathbf{x}) \tag{6}$$

and

$$\bar{\rho} = \rho_1\langle\chi_1(\mathbf{x})\rangle + \rho_2\langle\chi_2(\mathbf{x})\rangle, \tag{7}$$

where ρ_1 and ρ_2 are the densities of phase "1" (grains) and "2" (matrix). After substitution into Eq. (5), we have

$$R_{\rho\rho}(r) = \frac{(\rho_1 - \rho_2)^2[\langle\chi_1(\mathbf{x})\chi_1(\mathbf{y})\rangle - \eta_1^2]}{\bar{\rho}^2}, \tag{8}$$

where $\eta_1 = \langle\chi_1(\mathbf{x})\rangle$ is the volume fraction of phase "1." The two-point correlation function $S_1 = \langle\chi_1(\mathbf{x})\chi_1(\mathbf{y})\rangle$ is noted as the probability that $\mathbf{x}$ and $\mathbf{y}$ are both in phase "1." As a result, the covariance reduces to the two-point moment[16] $M_2 = \langle\chi_1(\mathbf{x})\chi_1(\mathbf{y})\rangle - \eta_1^2$. For any statistically homogeneous medium, this two-point correlation moment, M_2, should be positive-definite such that its Fourier transform must be positive.[16,17] Similar derivations apply to the covariance of Lame parameters, $R_{\lambda\lambda}$ and $R_{\mu\mu}$, as well as the cross correlations between different parameters, $R_{\rho\lambda}$, $R_{\rho\mu}$, and $R_{\lambda\mu}$.

The spatial Fourier transform of the covariance is given by

$$\tilde{R}(\mathbf{p}) = \frac{1}{(2\pi)^3}\int d^3r R(\mathbf{r})e^{i\mathbf{p}\cdot\mathbf{r}}, \tag{9}$$

where $\mathbf{p}$ is the wave vector.

The general expressions of scattering attenuations from Turner and Anugonda[10] may then be simplified for the case of two-phase materials using the two-point correlation function. In the next section, the two-point correlation function is estimated from numerical simulations. The attenuations are then derived in terms of the two-point correlation function.

III. CORRELATION FUNCTION

The numerical models of the two-phase materials are constructed using Voronoi polycrystals surrounded by a matrix. This type of model allows the matrix structure to have different properties from the grain structure as dictated by typical sintering problems. Voronoi polycrystals are widely used in numerical analysis of many engineering problems. These models have been shown to model closely polycrystalline metals, ceramics and microstructures of many materials.[18–20] In Fig. 1, a Voronoi polycrystal diagram is created using a Voronoi tessellation,[21] demonstrating the two-phase geometry. A normal distribution of Voronoi nuclei is used such that the scattering theories assume uniform grain size, which is the average diameter D of the grains. The thickness of the matrix d is also assumed uniform. Various combinations of grain size and thickness of interface can be created as needed. Thus, the microstructural and statistical information of the medium may be obtained from such models.

Once such a model is created, the two-point correlation function can be measured in five steps: (i) Choose two random points $\mathbf{x}$ and $\mathbf{y}$ separated by a distance r repeatedly throughout the model; (ii) judge whether the points are inside grains or matrix; (iii) calculate $\delta\rho(\mathbf{x})$, $\delta\rho(\mathbf{y})$ for each point, and then calculate the covariance $\langle\delta\rho(\mathbf{x})\delta\rho(\mathbf{y})\rangle$ using the

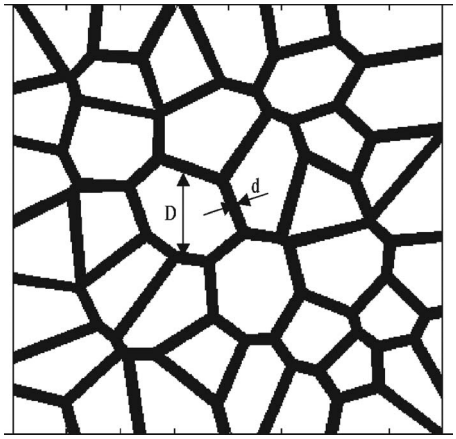

FIG. 1. Two-phase model using Voronoi polycrystals, with the grain diameter (size) D and the thickness of the matrix d.

definition of the ensemble average; (iv) average the covariance from different realizations of numerical models (here 100 realizations proved sufficient to obtain converged correlation behavior); (v) deduce the two-point correlation function $S_1=\langle\chi_1(\mathbf{x})\chi_1(\mathbf{y})\rangle$ using Eq. (8). Example correlation statistics of density from 100 realizations for a model of size 2.5 mm by 2.5 mm by 2.5 mm, grain size 0.8 mm, interface thickness 0.1 mm, are shown in Fig. 2. Note the step size Δr used was 0.006 mm for this result.

Although the two-point correlation function can be acquired directly from numerical simulations, the use of an analytical form is more helpful in evaluation of attenuation. The proper mathematical forms of these functions can allow us to investigate the details of the microstructure and therefore obtain the attenuation of ultrasound in the materials of interest. The use of appropriate forms of the two-point correlation functions has been investigated by Torquato and Stell,[22–26] Corson,[27,28] and Cule and Torquato,[29] to name a few. The exponential formula of the correlation function in Stanke and Kino's macroscopically isotropic model has been widely adopted in the studies of ultrasound attenuation in polycrystalline solids. They chose the following spatial autocorrelation function[6]

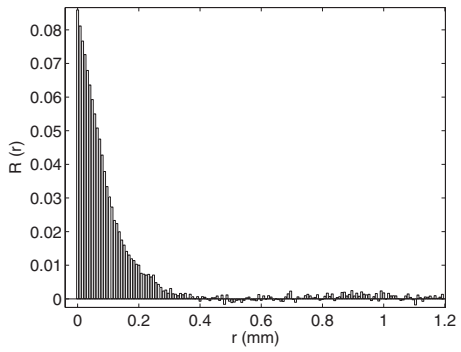

FIG. 2. Histogram of covariance from 100 realizations for a model of size 2.5 mm by 2.5 mm by 2.5 mm, grain size 0.8 mm, interface thickness 0.1 mm.

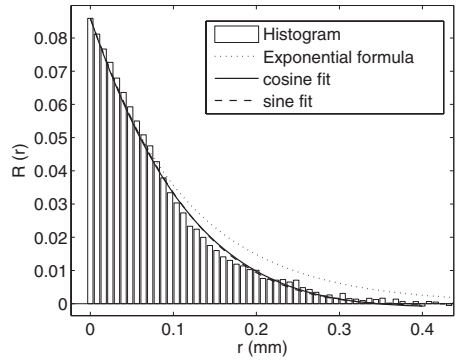

FIG. 3. Least squares fits to the measured data with the exponential formula and other models of correlation functions.

$$W(r) = e^{-r/L}, \tag{10}$$

which corresponds to the normalized two-point moment $\langle\chi_1(\mathbf{x})\chi_1(\mathbf{y})\rangle-\eta_1^2$ in our case. However, as shown in Fig. 3, this exponential formula is not valid to represent the numerical histogram data measured in the two-phase model. As mentioned above, this formula also failed for the geometric autocorrelation function in the grain boundary structure of a commercial aluminum alloy.[12] Therefore, finding a suitable formula for the two-phase medium is necessary. For a statistically homogeneous, isotropic microstructure, Cule and Torquato,[29] Yeong and Torquato,[30] proposed the following two-point correlation functions, respectively:

$$S_1(r) = \eta_1^2 + \eta_1\eta_2 e^{-br}\frac{\sin(qr)}{qr} \tag{11}$$

and

$$S_1(r) = \eta_1^2 + \eta_1\eta_2 e^{-b'r}\cos(cr), \tag{12}$$

where b, q, and b', c are characteristic spatial scale parameters, and $\eta_2=1-\eta_1$ is the volume fraction of phase "2." A least squares fit to the measured data using these two correlation functions in Fig. 3 shows that both of them are suitable to represent the two-point correlation function of this two-phase model. Note that only the positive part before oscillation is considered for curve fitting due to the short-range order observed. Therefore, the correlation function for the two-phase model is given by

$$S(r) = \begin{cases} \eta_1^2 + \eta_1\eta_2 e^{\frac{-br\sin(qr)}{qr}} \text{ or } \eta_1^2 + \eta_1\eta_2 e^{-b'r}\cos(cr), & 0 \le r \le r_0, \\ 0, & r > r_0, \end{cases} \tag{13}$$

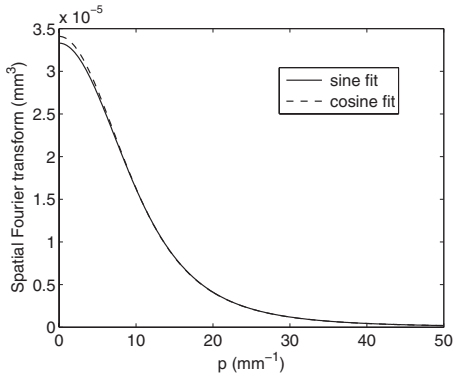

FIG. 4. Comparison of spatial Fourier transforms for the two correlation functions.

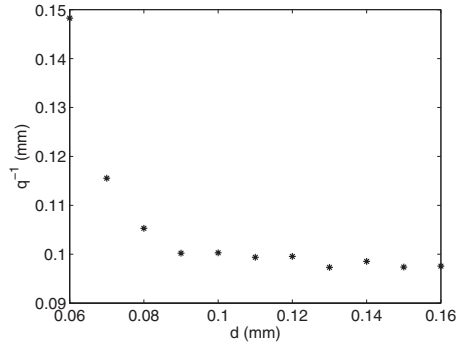

FIG. 6. Characteristic parameter q^{-1} vs. d for one combination of $D+d$ =0.83 mm.

where $r_0=\pi/q$ or $\pi/2c$ for models (11) and (12), respectively. The spatial Fourier transforms of the covariance obtained by curve fitting the histogram for both models are shown in Fig. 4. We found the difference between the two models is very small such that the attenuation results do not vary substantially. It is also found that the characteristic parameters in both models behave very similarly. Therefore, we conclude that both models provide good descriptions of the measured correlation functions. Here, only model (11) is used in the attenuation calculations that follow.

A least squares fit to the histogram of the measured two-point correlation function provides the two parameters b, q for the model given by Eq. (11). Note that there are also two independent parameters, grain size D and interface thickness d, for the two-phase geometry. Next the relationship between b, q and D, d is studied. Given a 2.5 mm by 2.5 mm by 2.5 mm cube, if we have the specified numbers of grains, the sum of $D+d$ is constant even when we change the thickness of the interface d. Figure 5 shows how b changes with the thickness d for the cube geometry with 80 grains, where $D+d=0.83$. The characteristic length scale b^{-1} appears to vary linearly with d. From Fig. 6, it seems q is a function of $(D+d)$ because it does not change significantly with d. Models with different numbers of grains are also created so that different values of $D+d$ are examined. A similar relationship between b^{-1} and d is observed in Fig. 7 for different combinations of $D+d$. However, from Fig. 8 the physical meaning of q is not clearly related with the geometric parameters, and is still under investigation. We also found out that these two models of correlation functions do not fit well to the histogram when the ratio of d/D is very small. Figure 9 shows the least squares fit to the histogram for the case of $d=0.03$, $D=0.80$. It is also seen that the exponential formula does not fit the data well. After investigation, it is believed that the ratio d/D needs to be larger than about 0.06 to apply the correlation function of Eq. (11).

The spatial Fourier transform of the two-point moment was then evaluated using numerical integration as

$$\tilde{S}(\mathbf{p}) = \frac{1}{(2\pi)^3}\int_0^{r_0}\int_0^{\pi}\int_0^{2\pi}\left(\eta_1\eta_2 e^{-br}\frac{\sin(qr)}{qr}\right) \times e^{-ipr\cos\theta}\sin\theta r^2 dr d\theta d\phi. \quad (14)$$

Expressions of attenuation for longitudinal and shear waves can then easily be obtained. In the next section, example numerical results and discussion are presented.

IV. EXAMPLE ATTENUATION RESULTS

Example results are presented for this two-phase model with known D and d. It is first assumed that the material properties are uncorrelated such that the cross correlations are zero ($R_{\rho\mu}=R_{\rho\lambda}=R_{\lambda\mu}=0$). In this case, the general expressions of scattering attenuations are given by[10]

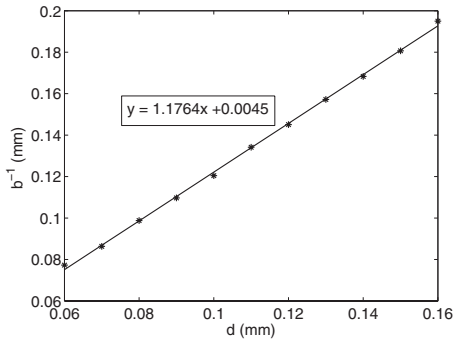

FIG. 5. Characteristic parameter b as a function of d for a 2.5 mm by 2.5 mm by 2.5 mm cubic model with 80 grains.

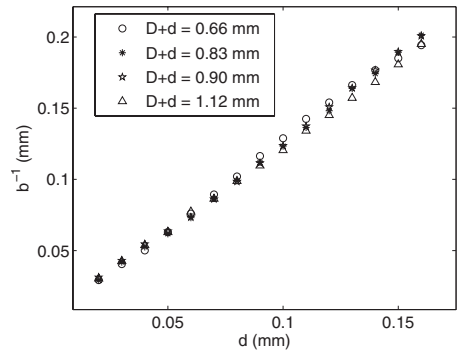

FIG. 7. Characteristic parameter b as a function of d for different combinations of $D+d$.

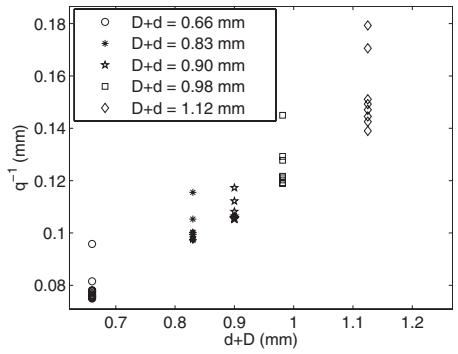

FIG. 8. Characteristic parameter q^{-1} in terms of $D+d$ for different combinations of $D+d$.

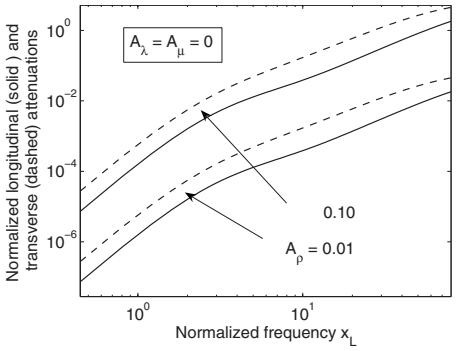

FIG. 10. Normalized longitudinal and transverse attenuations as a function of dimensionless frequency, $x_L=\omega D/c_L$, for density fluctuations only.

$$\alpha_{LL}=\frac{\pi^2\omega^4}{2c_L^4}\int_{-1}^{+1}\left\{\chi^2\tilde{R}_{\rho\rho}^{LL}(\chi)+\frac{(c_L^2-2c_T^2)^2}{c_L^4}\tilde{R}_{\lambda\lambda}^{LL}(\chi)+\frac{4c_T^4}{c_L^4}\chi^4\tilde{R}_{\mu\mu}^{LL}(\chi)\right\}d\chi, \tag{15}$$

$$\alpha_{LT}=\frac{\pi^2\omega^4}{2c_Lc_T^3}\int_{-1}^{+1}(1-\chi^2)\left\{\chi^2\tilde{R}_{\rho\rho}^{LT}(\chi)+\frac{(c_L^2-2c_T^2)^2}{c_L^4}\tilde{R}_{\lambda\lambda}^{LL}(\chi)+\frac{4c_T^2}{c_L^2}\chi^2\tilde{R}_{\mu\mu}^{LT}(\chi)\right\}d\chi,$$

$$\alpha_{TL}=\frac{1}{2}\left(\frac{c_T}{c_L}\right)^2\alpha_{LT},$$

$$\alpha_{TT}=\frac{\pi^2\omega^4}{4c_T^4}\int_{-1}^{+1}\{(\chi^2+1)\tilde{R}_{\rho\rho}^{TT}(\chi)+(1-3\chi^2+4\chi^4)\tilde{R}_{\mu\mu}^{TT}(\chi)\}d\chi,$$

where ω is the angular frequency. The $\tilde{R}$ terms are defined by

$$\tilde{R}^{ij}=\tilde{R}\left(\left|\frac{\omega}{c_i}\hat{\mathbf{p}}-\frac{\omega}{c_j}\hat{\mathbf{s}}\right|\right), \tag{16}$$

where i and j refer to the wave types, L or T (longitudinal or transverse). Here, $\hat{\mathbf{p}}$ defines the propagation direction and $\hat{\mathbf{s}}$ defines the scattered direction, with $\chi=\hat{\mathbf{p}}\cdot\hat{\mathbf{s}}=\cos\Phi$, where Φ is the angle between these directions. The correlation functions depend only on this angle due to the assumption of statistical isotropy. The final expressions for the total attenuations are given by[14]

$$\alpha_L=\alpha_{LL}+\alpha_{LT}, \tag{17}$$

$$\alpha_T=\alpha_{TL}+\alpha_{TT}. \tag{18}$$

For the two-phase material, since the material properties are assumed uncorrelated, from Eq. (8) the covariance can be written

$$R_{\tau\tau}(r)=A_\tau^2[S(r)-\eta_1^2], \tag{19}$$

where the subscript τ refers to the material parameters ρ, λ and μ. The contrast of the properties for the two phases is given by $A_\tau=(\tau_1-\tau_2)/\bar{\tau}$.

For the specific case shown here, the grain size and thickness of the matrix are chosen as $D=0.80$ mm and $d=0.10$ mm. The volume fraction of the grains is $\eta_1=0.684$. The parameters in the two-point correlation model are $b=8.09\ \text{mm}^{-1}$ and $q=8.90\ \text{mm}^{-1}$. The ratio of wave speed used here is $c_T/c_L=1/2$.

Numerical results of the attenuations are now presented. Figure 10 shows the normalized longitudinal $\alpha_L D$ and transverse attenuations $\alpha_T D$ as a function of dimensionless frequency, $x_L=\omega D/c_L$, for density fluctuations only ($A_\lambda=A_\mu=0$). The attenuations increase with the fourth power of frequency in the low frequency limit as expected. After a transition region, the attenuations scale with the square of frequency. The longitudinal attenuation is always smaller than the transverse attenuation as shown. It can be seen that the contrasts or fluctuations of material properties affect the ratio of the attenuations. Figure 11 shows the normalized longitudinal and transverse attenuations as a function of dimensionless frequency, x_L, for modulus fluctuations only ($A_\rho=0$). Similar results are seen as those in Fig. 10. From Eq. (15), attenuations of all material property fluctuations are just the sum of each component from these figures. Moreover, the contribution of density fluctuations to the attenuation weighs much more than modulus fluctuations for the same level of contrasts. All these results are in qualitative agreement with those of previous work.[10]

Finally, the influence of correlation functions is examined. Figure 12 is a plot of normalized longitudinal attenuations for $A_\rho=0.1$, $A_\lambda=A_\mu=0$ using the exponential formula

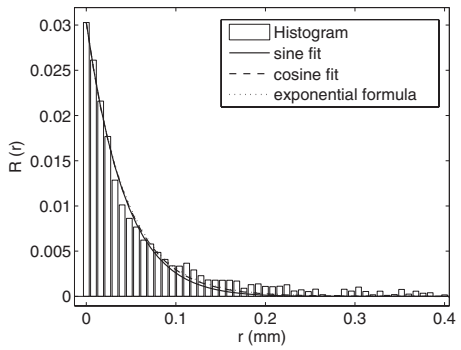

FIG. 9. Fitting of the correlation function for the model with a small ratio of d/D ($d=0.03, D=0.80$).

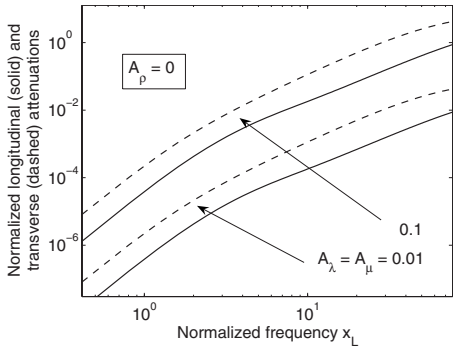

FIG. 11. Normalized longitudinal and transverse attenuations as a function of dimensionless frequency, x_L, for modulus fluctuations only.

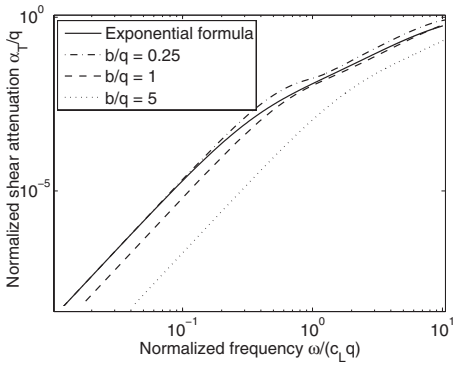

FIG. 13. Comparison of normalized transverse attenuations for $A_\rho=0.1$, $A_\lambda=A_\mu=0$ using exponential formula and Cule's correlation function.

and Cule and Torquato's model, respectively. Attenuations change with the ratio of b/q for this multiple parameter correlation model. When b/q is about 0.25, the attenuations of two models appear to have overlap in the low frequency range. However, as the frequency increases, the attenuations differ with each other. The results show that the multiple correlation lengths may not be detected at low frequencies. In this specific case, when the dimensionless frequency x_L is smaller than about 0.2, only one correlation length may be extracted. The most likely frequency range to extract both b and q is about $0.3<x_L<4$ as observed in this figure. Figure 13 is a plot of normalized transverse attenuations for different correlation functions. Similar results can be observed. The importance of extracting the correlation function from ultrasonic measurements has not been discussed before. All previous attenuation models use correlation functions with a single correlation length. The attenuation results presented here suggest that new ultrasonic techniques for characterization of multiple correlation parameters may be possible. The frequency to be used to extract the multiple correlation parameters may be determined based on the theoretical models developed here. In addition to the analysis presented here, numerical models for attenuation will also be necessary and will be investigated in subsequent work.

V. SUMMARY

The propagation of elastic waves in a statistical homogeneous and statistical isotropic two-phase solid has been investigated. The theory was derived for the case of both density and Lamé parameters which varied spatially. A numerical method to determine directly the geometric spatial correlation function of the microstructure has been presented. The exponential formula used previously was not applicable for the two-phase model compared with the numerical data. However, the models of two-point correlation functions given by Eqs. (11) and (12) would provide a suitable setting for the two-phase microstructure. The characteristic parameters in these models were also examined. Using those two-point correlation functions, the final expressions of attenuation were given in terms of the spatial statistics of density and Lamé constants. As mentioned, the fluctuations must be small and the volume fraction of each phase must not be so high $(d/D>0.06)$ for the validity of the correlation function model. Influence of the correlation functions on attenuations was observed. The results show that extracting the multiple correlation lengths may only be feasible in a specific frequency range. The general formulation here can be directly related to sintered metals, concrete, and polycrystals with decorated grain boundaries for which previous models had difficulty explaining the experimental results.[31,32] These results should be very useful for nondestructive testing and materials characterization research despite the simplicity of the assumptions made.

(Received 8 August 2007; revised 2 January 2008; accepted 24 February 2008)

A new frequency-domain approach to photoacoustic tomography has recently been proposed, promising to overcome some of the shortcomings associated with the pulsed photoacoustic approach. This approach offers many of the benefits of pulsed photoacoustics but requires a different set of equations for modeling of the forward and inverse problems due to the longer time scales involved in the optical input signal. The theory of photoacoustic tomography with an optical input that is not necessarily a short pulse is considered in this paper. The full optical, thermal, and acoustic governing equations are derived. A transfer function approach is taken for the solution and analysis of this problem. The results and implications are compared with those of pulsed photoacoustics and traditional ultrasonic diffraction tomography. A Fourier diffraction theorem is also presented, which could be used as a basis for the development of tomographic imaging algorithms.

I. INTRODUCTION

In recent years, noninvasive laser-based diagnostic and imaging techniques have been proposed and developed. Photoacoustic signal generation is a new technique, which has demonstrated great potential for visualization of the internal structures and function of soft tissue. It has particularly shown great potential for small animal imaging.[1,2] With this technique, a short-pulsed laser source is used to irradiate the sample. The energy absorbed produces a small temperature rise, which induces a pressure inside the sample through thermal expansion. This pressure acts as an acoustic source and generates further acoustic waves, which can be detected by ultrasound transducers positioned outside the sample. As there is a large difference in optical absorption between blood and surrounding tissue, the ultrasound wave induced by the laser irradiation carries information about the optical absorption property of the tissue. This approach is thus suitable for the imaging of the microvascular system or for tissue characterization.

This imaging technique has contrast similar to that of pure optical imaging and spatial resolution similar to that of pure ultrasonic imaging. It therefore combines the advantages of two imaging modalities in a single modality. The issue of the strong scattering of light in media such as biological tissue is overcome and the ability of acoustic waves to travel long distances without significant distortion or attenuation is also exploited. Photoacoustic detection has shown concrete promise of imaging in turbid media at depths greater than the full thickness of skin.[3,4]

The potential for high contrast is the most potent advantage of the technique. The large variation in the optical absorption and scattering properties of different tissue constituents can be exploited. Sources of naturally occurring absorption contrast include chromophores—features that selectively absorb light at certain wavelengths—such as blood vessels, tumors, hemoglobin (and its various oxygenated states), melanin, beta-carotene, and lipids. Of all of these, hemoglobin is perhaps the most significant. It offers strong optical contrast at optical wavelengths giving the technique the potential to image blood vessels for directly assessing arterial disease or mapping the vasculature. It can also be exploited to detect abnormal tissue morphologies such as cancerous lesions and vascular lesions that are accompanied by changes in the surrounding vasculature and tissue oxygenation status.[5,6] For three-dimensional (3D) imaging, the achievable resolution depends not only on the experimental approach but also on the choice of image reconstruction algorithm.[7–14] Careful design and verification of tomographic algorithms are required to ensure stable, rapid, and artifact-free imaging. A good review of photoacoustic imaging is given in Ref. 12.

The general field of photoacoustic tomography has so far been based entirely on pulsed laser excitation and time-of-flight measurements of acoustic transients to determine the position and optical properties of subsurface chromophores.[4,7,8,15–17] The field has recently experienced rapid development due to promising results for subsurface measurements and imaging of turbid media.[2,18]

A novel Fourier-domain photothermoacoustic (FD-PTA) imaging methodology has recently emerged.[5,19] For FD-PTA, the acoustic wave is generated by periodic modulation of a laser. In general, frequency-domain approaches in place of time-domain approaches have been shown to yield higher signal-to-noise ratios in other imaging modalities.[20] In this paper, the term photothermoacoustic imaging will be used to denote photoacoustic imaging where a short pulse is not necessarily used. This may imply a frequency-domain approach with narrow-band lock-in amplifiers or a time-domain approach where the pulse used is not necessarily short enough

[a)]Electronic mail: nbaddour@uottawa.ca

to fulfil the assumptions upon which photoacoustic imaging is based. Thus, the data can be acquired either as a steady-state complex intensity with measurable amplitude and phase or as time-varying intensities as the response to an input pulse. With the restriction of a short pulse removed, there is a greater degree of flexibility in the choice of input optical excitation. With this higher degree of flexibility and control available over the distribution in space and time of the illuminating sources, the potential to design an optimal acquisition system in a realistic fashion presents itself. Such a design must be based on a proper theoretical analysis. This paper aims to consider the theoretical development of the necessary background upon which to base the tomography algorithms and/or experiment design.

The layout of the paper is as follows: in Sec. II, the governing equations are derived. Sections III–V present sign conventions, geometry, and some background mathematics. Sections VI and VII present the solution to the presented problem, based on the use of the first Born approximation. Section VIII includes necessary mathematical simplifications, whereas Sec. IX considers the Green function theorem for a general illumination function. Section X presents an analysis of the implications of the mathematical results. Sections XI–XIII present the Fourier diffraction theorem for this problem, both for a generalized illumination function and for a planar illumination function and consider the implications of this theorem on the achievable resolution of this approach to imaging. Section XIV concludes the paper.

II. GOVERNING EQUATIONS

Governing equations for the coupled photothermoacoustic problem are presented here and are culled from,[5,21,22] where the photonic, thermal, or acoustic phenemena are separately discussed. The equations presented here are assembled to represent a complete model consisting of the full coupled photonic, thermal, and acoustic phenomena and are presented in infinite space in order to allow a diffraction tomographic approach. The first equation is the equation for the diffuse photon density waves (DPDW) that describes the propagation of photons in turbid media. The second equation uses the DPDW wave as a source term to the heat equation and describes the thermal expansion of the turbid media. Finally, the thermal term is used as an inhomogeneous source term to the acoustic wave equation where the variable of interest is the acoustic displacement potential.

A. Light propagation in scattering media

The gold standard for describing light propagation in turbid media is the radiative transport equation. The radiative transport equation governs light propagation in random media such as clouds, fog, and biological tissues. It takes into account scattering and absorption due to inhomogeneities in the propagating medium. Understanding the optical response due to inhomogeneities inside a uniform absorbing and scattering medium is important for imaging purposes. A commonly used approximation to the transport theory is the diffusion approximation, which describes time and frequency dependent photon diffusion. This approximation is particularly appealing due to its inherent mathematical tractability. This approximation is valid in the regime of multiple scattering such that the wavelength of light is much smaller than the thickness of the medium.[6] In this approximation, the multiply scattered light intensity is described by the diffusion equation. The equation for the DPDW, which describes the photon density $\rho_d(\mathbf{r},t)$ in the solid due to incident energy intensity $S(\mathbf{r},t)$ (optical source function) is given in the time domain by

$$D\nabla^2\rho_d(\mathbf{r},t) - \frac{1}{c}\frac{\partial}{\partial t}\rho_d(\mathbf{r},t) - \mu_a\rho_d(\mathbf{r},t) = -S(\mathbf{r},t). \tag{1}$$

In the preceding equation, μ_a is the optical absorption coefficient (m^{-1}), c is the speed of light in the turbid medium (m/s), and D is the optical diffusion coefficient (m). The optical diffusion coefficient is defined as

$$D = \frac{1}{3(\mu_a + \mu_s')}, \tag{2}$$

where μ_s' is the reduced scattering coefficient (m^{-1}). The reduced scattering coefficient μ_s' is related to the scattering coefficient μ_s such that $\mu_s' = (1-g)\mu_s$ where g is the mean cosine of the scattering function $p(\theta)$ of the photon over all spatial directions described by the solid angle Ω. It can be considered to be an assymetry parameter for anisotropic multiple scattering and can be defined as

$$g = \frac{\int_{4\pi} p(\theta)\cos\,\theta\, d\Omega}{\int_{4\pi} p(\theta) d\Omega}. \tag{3}$$

Note that $-1 \leq g \leq 1$. Isotropic scattering is given by $g=0$. Net backward scattering implies negative values of g while net forward scattering implies positive values of g. Clearly the reduced scattering coefficient μ_s' becomes equal to the scattering coefficient μ_s only in the case of isotropic scattering when $g=0$.

The diffusion approximation to the radiative transport equation, as given in Eq. (1) is valid when the absorption coefficient μ_a is much smaller than the reduced scattering coefficient μ_s', or $\mu_a \ll \mu_s'$.[23] It should be noted that even when this condition is satisfied, the diffusion approximation breaks down when the point-scatterer source is near the boundaries of the turbid medium and in general may not be applicable near the surface of a turbid medium.[6] This topic is addressed in Ref. 6, where it is found that for a turbid medium such as skin, the near-surface ballistic "skin layer" is on the order of 7–50 μm thick. A concise review of the literature on this subject is also included in that reference. It is noted that for the work considered here, an infinite domain is used and thus boundary layer effects are not considered.

Taking the Fourier transform of the DPDW equation, we obtain the Helmholtz pseudowave equation in the frequency domain:

$$\nabla^2\Psi_d(\mathbf{r},\omega) + k_p^2\Psi_d(\mathbf{r},\omega) = -\frac{S(\mathbf{r},\omega)}{D}, \tag{4}$$

where $k_p^2 = -\mu_a/D - i\omega/cD$ and $\Psi_d(\mathbf{r},\omega) = F\{\rho_d(\mathbf{r},t); t\rightarrow\omega\}$ is the Fourier transform of $\rho_d(\mathbf{r},t)$.

B. Thermal propagation equation

The equation describing the temperature rise in the material that follows as a result of the generation of the photonic diffuse density wave is given by the heat equation:

$$\nabla^2 T(\mathbf{r},t) - \frac{1}{\alpha}\frac{\partial}{\partial t}T(\mathbf{r},t) = -\frac{\mu_a}{\kappa_s}\rho_d(\mathbf{r},t). \tag{5}$$

In the frequency domain, this equation becomes another Helmholtz pseudowave equation given by

$$\nabla^2 T(\mathbf{r},\omega) + k_t^2 T(\mathbf{r},\omega) = -\mu_a \frac{\Psi(\mathbf{r},\omega)}{\kappa_s}, \tag{6}$$

where $k_t^2 = -i\omega/\alpha$ and $\Psi = \Psi_d + \Psi_c$. In the previous equation, $\Psi = \Psi_d + \Psi_c$ is the total DPDW wave and is the sum of the diffuse and coherent photon density waves. The variable α is the thermal diffusivity of the material and κ_s is the thermal conductivity of the material.

C. Acoustic propagation equation

Finally, the acoustic displacement potential is described by the wave equation, leading to the Helmholtz equation in the frequency domain. The wave equation can be dealt with by introducing a displacement potential $\phi_s(\mathbf{r},t)$, which is related to the displacement vector by[24]

$$u(\mathbf{r},t) = \nabla \phi_s(\mathbf{r},t). \tag{7}$$

Only longitudinal waves are assumed to propagate and as a result $\nabla \times u(\mathbf{r},t) = 0$ and the displacement potential satisfies the wave equation

$$\nabla^2 \phi_s(\mathbf{r},t) - \frac{1}{c_s^2}\frac{\partial^2}{\partial t^2}\phi_s(\mathbf{r},\omega) = \frac{\kappa_s \beta_s}{\rho_s c_s^2} T(\mathbf{r},t). \tag{8}$$

Taking the Fourier transform of this equation leads to a Helmholtz equation in the frequency domain with the thermal term acting as a source term, yielding

$$\nabla^2 \phi_s(\mathbf{r},\omega) + k_s^2 \phi_s(\mathbf{r},\omega) = \frac{\kappa_s \beta_s}{\rho_s c_s^2} T(\mathbf{r},\omega), \tag{9}$$

where $k_s^2 = \omega^2/c_s^2$. The thermoelastic pressure in the solid is then obtained from the displacement potential by $P(\mathbf{r},t) = -\rho_s(\partial^2/\partial t^2)\phi_s(\mathbf{r},t)$, which in the frequency domain becomes $P(\mathbf{r},\omega) = \rho_s \omega^2 \phi_s(\mathbf{r},\omega)$. Here c_s is the speed of sound in the medium, ρ_s is the material density, and β_s is the coefficient of thermal expansion of the material. Although the partial differential equation describing the variations of pressure is not an additional equation as the same information is contained in the equation for the displacement potential, it is nevertheless instructive to examine the equation for pressure:

$$\nabla^2 P(\mathbf{r},t) - \frac{1}{c_s^2}\frac{\partial^2}{\partial t^2}P(\mathbf{r},t) = -\frac{\kappa_s \beta_s}{c_s^2}\frac{\partial^2}{\partial t^2}T(\mathbf{r},t). \tag{10}$$

It can immediately be seen that the acoustic pressure is governed by the second time derivative ("acceleration") of the temperature dependence. It is noted that acoustic inhomogeneities and acoustic absorption are not modeled in this formulation.

In the preceding equations k refers to the wave number and the subscript indicates which phenomena (photonic, thermal or acoustic) the wave number is referring to. Specifically, k_p refers to the wave number for the DPDW (photonic) equation, k_t refers to the thermal wave number, and k_s refers to the acoustic wave number. It should be noted that only the acoustic wave number is real, with the thermal and photonic wave numbers being complex quantities, hence the use of the term "pseudowave" equation to describe the resulting Helmholtz equation in order not to avoid confusion with the proper Helmholtz equation with, the real wave number.

In this paper, our main interest lies in reconstructing the inhomogeneous distributions of optical absorption. Further, it is assumed in this formulation that the only inhomogeneities present are in the optical absorption coefficient.

III. NOTATION AND SIGN CONVENTIONS

From the preceding section, it can be seen that the photonic, thermal, and acoustic wave numbers are defined by the squares of their quantities and arise as a result of taking the Fourier transform of the corresponding equation. In particular,

$$k_p^2 = -\frac{\mu_a}{D} - \frac{i\omega}{cD}, \quad k_t^2 = -\frac{i\omega}{\alpha}, \quad k_s^2 = \frac{\omega^2}{c_s^2} \tag{11}$$

In the rest of the paper, we will have great use of the wave numbers themselves, namely, k_p, k_s, and k_t, which are the square roots of the equations in Eq. (11). Each k will be written as the sum of a real and an imaginary part, so that $k_p = k_{pr} + ik_{pi}$ with k_{pr} denoting the real part of k_p and k_{pi} denoting the imaginary part of k_p. Similar notations will apply to the other k's. As there are two square roots in the previous equations, we will use the convention that a particular (photonic, thermal, acoustic) k is the square root of the corresponding k^2 such that the *imaginary* part of k is positive. Hence k_p is the square root of k_p^2 such that $k_{pi} > 0$ and so forth. This convention will be important in derivations in order to ensure boundedness of solutions.

It is noted that the variable ω is the Fourier frequency variable corresponding to time. The (temporal) Fourier transform is defined in the conventional way as

$$\hat{F}(\omega) = \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt, \tag{12}$$

with the inverse transform defined by

$$f(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \hat{F}(\omega) e^{i\omega t} d\omega. \tag{13}$$

The two-dimensional (2D) and 3D spatial Fourier transform of functions will be required and is defined as

$$\hat{F}_{3D}(\omega_x,\omega_y,\omega_z) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x,y,z) \times e^{-i\omega_x x} e^{-i\omega_y y} e^{-i\omega_z z} dx\, dy\, dz. \tag{14}$$

In this case $(\omega_x, \omega_y, \omega_z)$ are the spatial frequency variables in

the Fourier domain. We will also require use of a variable of the form

$$\gamma^2 = \omega_x^2 + \omega_y^2 - k^2. \tag{15}$$

We will adopt the convention that the subscript on γ indicates the subscript of the corresponding k. That is, we define $\gamma_p^2 = \omega_x^2 + \omega_y^2 - k_p^2$, $\gamma_t^2 = \omega_x^2 + \omega_y^2 - k_t^2$, and $\gamma_s^2 = \omega_x^2 + \omega_y^2 - k_s^2$. Similarly, the use of γ will be more frequent than γ^2 and thus a convention is required to indicate which square root is being used. We will write $\gamma = \gamma_r + i\gamma_i$ where this is defined as the square root of γ^2 such that $\gamma_r \geq 0$. Similar to the convention for k_s the subscripts for γ get carried over to real and imaginary parts so that, e.g., $\gamma_s = \gamma_{sr} + i\gamma_{si}$ can be written.

IV. GEOMETRY

As for standard acoustic diffraction tomography theory, we assume a background medium infinite in extent and an inhomogeneity structure of finite extent. The previously given equations for the scattered field are valid for all points outside the inhomogeneity and for arbitrary source–detector configurations. The assumption of an infinite domain is the simplest case for physical insight and can later be modified for different geometries. As it is also the assumption typically made for standard acoustic diffraction tomography, as well as for diffuse photonic wave tomography, this assumption will allow for straightforward comparisons.

We further specialize our formulation to the case where the acoustic wave is measured by a plane of detectors so that the acoustic wave is measured in the $z = z_d$ plane. We are thus interested in the Fourier transform of the wave measured in the $z = z_d$ plane.

V. FIRST BORN APPROXIMATION

For tomographic imaging purposes, our main interest lies in reconstructing the inhomogeneous distributions of optical absorption. We therefore consider the Helmholtz equation for the photon density wave:

$$(\nabla^2 + k_p^2(\vec{r}))\Psi_d(\vec{r},\omega) = 0. \tag{16}$$

We now write

$$k_p^2(\vec{r}) = k_{p_0}^2 n^2(\vec{r}), \quad n^2(\vec{r}) = \frac{\mu_{a_0}}{\mu_a(\vec{r})}, \tag{17}$$

where $k_{p_0}^2 = -\mu_{a_0}/D - i\omega/cD$ and μ_{a_0} is the optical absorption coefficient of the assumed homogeneous medium surrounding the object region Q and $n(\vec{r})$ is a measure of the variation of the values of the optical absorption coefficient in the object from that of the surrounding homogeneous (reference) region. In this development, it is assumed that the only inhomogeneities are in the optical absorption coefficient. It is also assumed that the object has finite size. This leads to

$$(\nabla^2 + k_{p_0}^2)\Psi_d(\vec{r},\omega) = -\frac{1}{D} o_a(\vec{r})\Psi_d(\vec{r},\omega), \tag{18}$$

where the object function is given by

$$o_a(\vec{r}) = \begin{cases} k_{p_0}^2(n^2(\vec{r}) - 1), & \vec{r} \in Q \\ 0, & \vec{r} \notin Q. \end{cases} \tag{19}$$

It is noted that the preceding exactly follows the development of the diffraction tomography problem with the wave equation, with the exception of the complex nature of the photonic wave vector. The effect of the inhomogeneities of the object region appears as a source term on the right-hand side of the Helmholtz equation (18), with $o_a(\vec{r})$ being the object function representing the inhomogeneities of the scattering object region Q. The object function is zero outside the object region and its nonzero value within the object region represents the ratio of optical absorption coefficients.

The DPDW field $\Psi_d(\vec{r},\omega)$ shall be considered to be the sum of two components, $\Psi_{d0}(\vec{r},\omega)$ and $\Psi_{ds}(\vec{r},\omega)$, namely,

$$\Psi_d(\vec{r},\omega) = \Psi_{d0}(\vec{r},\omega) + \Psi_{ds}(\vec{r},\omega). \tag{20}$$

The component $\Psi_{d0}(\vec{r})$ is known as the incident field (or equivalently the illumination function) and is the field present without any inhomogeneities. It is given by the solution to

$$(\nabla^2 + k_{p_0}^2(\vec{r}))\Psi_{d0}(\vec{r},\omega) = 0. \tag{21}$$

The component $\Psi_{ds}(\vec{r},\omega)$, known as the secondary field, will be that part of the total field that can be attributed solely to the inhomogeneities. Note that this term is often referred to as the scattered field, however, the term "secondary" will be used here to avoid confusion with the true scattered field in the optical sense. The secondary component of the field will necessarily have to satisfy

$$(\nabla^2 + k_{p_0}^2)\Psi_{ds}(\vec{r},\omega) = -\frac{1}{D} o_a(\vec{r})\Psi_d(\vec{r},\omega). \tag{22}$$

It should be noted that $\Psi_d(\vec{r},\omega)$ in the right-hand side of Eq. (22) is unknown. However, for small enough inhomogeneities, $\Psi_d(\vec{r},\omega)$ can be replaced with its free-space value $\Psi_{d0}(\vec{r},\omega)$, which itself can be found from Eq. (21). Replacing $\Psi_d(\vec{r},\omega)$ with $\Psi_{d0}(\vec{r},\omega)$ on the right-hand side of Eq. (21) is known as the first Born approximation. Hence, under the first Born approximation, the secondary component of the DPDW field must satisfy

$$(\nabla^2 + k_{p_0}^2)\Psi_{dB}(\vec{r},\omega) = -\frac{1}{D} o_a(\vec{r})\Psi_{d0}(\vec{r},\omega), \tag{23}$$

where $\Psi_{dB}(\vec{r},\omega)$ is used to denote the first Born approximation to the secondary DPDW field. Thus, $\Psi_d(\vec{r},\omega) = \Psi_{d0}(\vec{r},\omega) + \Psi_{dB}(\vec{r},\omega)$, with $\Psi_{d0}(\vec{r},\omega)$ and $\Psi_{dB}(\vec{r},\omega)$ given by Eqs. (21) and (23), respectively. In the rest of what follows, we will use k_p to denote k_{p_0} for ease of notation, as no explicit reference to k_{p_0} is needed once the first Born approximation has been made.

VI. SOLUTION TO THE FORWARD PROBLEM

The complete problem formulation starts with Eq. (21) for the illumination function (which is a DPDW) along with Eq. (23), the Born solution to the inhomogeneous DPDW problem. The solution to this is subsequently used as source

terms in Eq. (6), the solution of which is then further used in Eq. (9). Hence the full problem consists of Eq. (21) along with Eqs. (6), (9), and (23).

To begin, a general illumination function is considered. That is, the sequentially coupled equations, Eqs. (6), (9), and (23), are solved without (yet) specifying a form for the illumination function. Next, we proceed by taking the spatial Fourier transform of both sides of the equations, however only with respect to the x and y variables leaving the z variable untransformed. This gives

$$\frac{d^2}{dz^2}\Psi_{dB}(\omega_x,\omega_y,z) - \gamma_p^2\Psi_{dB}(\omega_x,\omega_y,z,\omega) = -\frac{1}{D}O_a(\omega_x,\omega_y,z)\Psi_{d0}(\omega_x,\omega_y,z,\omega), \tag{24}$$

where $\gamma_p^2=\omega_x^2+\omega_y^2-k_p^2$. Denote $O_a\Psi_{d0}(\omega_x,\omega_y,z) := O_a(\omega_x,\omega_y,z)\Psi_{d0}(\omega_x,\omega_y,z,\omega)$ for brevity. Similarly, the thermal and acoustic equations become

$$\frac{d^2}{dz^2}T(\omega_x,\omega_y,z,\omega) - \gamma_t^2 T(\omega_x,\omega_y,z,\omega) = -\frac{\mu_a}{\kappa_s}\Psi_{dB}(\omega_x,\omega_y,z,\omega), \tag{25}$$

$$\frac{d^2}{dz^2}\phi_s(\omega_x,\omega_y,z,\omega) - \gamma_s^2\phi_s(\omega_x,\omega_y,z,\omega) = -\frac{\kappa_s\beta_s}{\rho_s c_s^2}T(\omega_x,\omega_y,z,\omega), \tag{26}$$

where $\gamma_t^2=\omega_x^2+\omega_y^2-k_t^2$ and $\gamma_s^2=\omega_x^2+\omega_y^2-k_s^2$. Note that Eqs. (24)–(26) can be solved using the one-dimensional (1D) Green function with the appropriate γ as the wave vector. Hence,

$$\Psi_{dB}(\omega_x,\omega_y,z,\omega) = \int_{-\infty}^{\infty}\frac{1}{2\gamma_p}e^{-\gamma_p|z-z_p|}\times\left\{\frac{1}{D}O_a\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)\right\}dz_p. \tag{27}$$

The same Green function is also used to solve thermal equation (25) to give

$$T(\omega_x,\omega_y,z,\omega) = \int_{-\infty}^{\infty}\frac{1}{2\gamma_t}e^{-\gamma_t|z-z_t|}\frac{\mu_a}{\kappa_s}\Psi_{dB}(\omega_x,\omega_y,z_t,\omega)dz_t. \tag{28}$$

Using the expression in Eq. (27), this can be simplified to

$$T(\omega_x,\omega_y,z,\omega) = \frac{\mu_a}{4\kappa_s D\gamma_t\gamma_p}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}e^{-\gamma_t|z-z_t|}e^{-\gamma_p|z_t-z_p|}O_a\times\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)dz_p dz_t. \tag{29}$$

Finally, the 1D Green expansion can also be used to solve acoustic equation (26) to give

$$\phi_s(\omega_x,\omega_y,z,\omega) = \int_{-\infty}^{\infty}\frac{1}{2\gamma_s}e^{-\gamma_s|z-z_s|}\frac{\kappa_s\beta_s}{\rho_s c_s^2}T(\omega_x,\omega_y,z_s,\omega)dz_s. \tag{30}$$

The expression for T from Eq. (29) is substituted into Eq. (30) and the order of integration is switched, yielding

$$\phi_s(\omega_x,\omega_y,z,\omega) = \frac{-\mu_a\beta_s}{8\gamma_p\gamma_t\gamma_s D\rho_s c_s^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}e^{-\gamma_p|z_t-z_p|}\times e^{-\gamma_t|z_s-z_t|}e^{-\gamma_s|z-z_s|}O_a\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)dz_s\,dz_t\,dz_p. \tag{31}$$

Recalling that the pressure is given by $P(\vec{r},\omega)=\omega^2\rho_s\phi_s(\vec{r},\omega)$, the Fourier transform of the pressure detected in a plane is obtained

$$\begin{aligned}P(\omega_x,\omega_y,z,\omega) &= \frac{-\mu_a\beta_s k_s^2}{D}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{e^{-\gamma_p|z_t-z_p|}}{2\gamma_p}\times\frac{e^{-\gamma_t|z_s-z_t|}}{2\gamma_t}\frac{e^{-\gamma_s|z-z_s|}}{2\gamma_s}\\ &\quad\times O_a\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)dz_s\,dz_t\,dz_p\\ &= \frac{-\mu_a\beta_s k_s^2}{D}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\times g_p(z_t-z_p;\gamma_p)g_t(z_s-z_t;\gamma_t)g_s(z-z_s;\gamma_s)O_a\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)dz_s\,dz_t\,dz_p.\end{aligned} \tag{32}$$

In the integrand, the photonic, thermal and acoustic Green functions have been identified and labeled with the appropriate subscript, in keeping with the conventions of this paper. That is, for $i=p$, t, and s representing photonic, thermal and acoustic phenomena:

$$g_i(z;\gamma_i) = \frac{e^{-\gamma_i|z|}}{2\gamma_i}. \tag{33}$$

Equation (32) provides a good interpretation of the physics of the problem. In the Born approximation, the product of the object function and illumination function $O_a(x,y,z)\Psi_{d0}(x,y,z,t)$ can be considered as the input, with the only time dependence being in the incident diffuse photon density wave function. Let us refer to this product of object and illumination functions as the heterogeneity function. The system acts on this heterogeneity function input through the three Green functions. The system can be considered to be acting on the input with the photonic, followed by thermal, followed by acoustic Green function with the total system Green function being a product of the three. Essentially, we have

$$\begin{aligned}P(\omega_x,\omega_y,z,\omega) &= \frac{-\mu_a\beta_s k_s^2}{D}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\times g_{pts}(z,z_p,z_t,z_s;\gamma_p,\gamma_t,\gamma_s)O_a\\ &\quad\times\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)dz_s\,dz_t\,dz_p,\end{aligned} \tag{34}$$

where $g_{pts}(z,z_p,z_t,z_s;\gamma_p,\gamma_t,\gamma_s)=g_p(z_t-z_p;\gamma_p)g_t(z_s-z_t;\gamma_t)\times g_s(z-z_s;\gamma_s)$.

This is a convenient way of thinking of the effect of the system as any simplifications or alternative modeling assumptions can be directly reflected in the individual Green functions and it is known that the total system Green function, given by g_{pts}, will be a product of the three individual ones and thus any changes can be analyzed directly. Note that the total system Green function, g_{pts}, is a four-dimensional (4D) function of (z,z_p,z_t,z_s) and when integrated can be considered to be the sequential convolution of the Green functions for the three subsystems. The integrations are performed over z_p, z_t, and z_s to ultimately yield a function of z. The γ's are considered to be parameters in the Green function(s). Simplifying this expression for the total system Green function will now be considered.

VII. SIMPLIFYING THE INTEGRALS

The expression for the pressure as given in Eq. (32) can be simplified. Using Lemma 1 (derived in the Appendix), the following results are important.

Result 1

$$\int_{-\infty}^{\infty}\frac{e^{-\gamma_t|z_s-z_t|}}{2\gamma_t}\frac{e^{-\gamma_s|z-z_s|}}{2\gamma_s}dz_s = \int_{-\infty}^{\infty}g_t(z_s-z_t;\gamma_t)g_s(z-z_s;\gamma_s)dz_s = \frac{g_s(z-z_t;\gamma_s)}{(k_s^2-k_t^2)} + \frac{g_t(z-z_t;\gamma_t)}{(k_t^2-k_s^2)}. \tag{35}$$

Proof: This result follows directly from the application of Lemma 1, which is given in the Appendix.

Result 2

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{e^{-\gamma_p|z_t-z_p|}}{2\gamma_p}\frac{e^{-\gamma_t|z_s-z_t|}}{2\gamma_t}\frac{e^{-\gamma_s|z-z_s|}}{2\gamma_s}dz_s\,dz_t = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}g_p(z_t-z_p;\gamma_p)g_t(z_s-z_t;\gamma_t)g_s(z-z_s;\gamma_s)dz_s\,dz_t = \frac{g_s(z-z_p;\gamma_s)}{(k_s^2-k_t^2)(k_s^2-k_p^2)} + \frac{g_t(z-z_p;\gamma_t)}{(k_t^2-k_s^2)(k_t^2-k_p^2)} + \frac{g_p(z-z_p;\gamma_p)}{(k_p^2-k_s^2)(k_p^2-k_t^2)} \tag{36}$$

Proof: We write

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}g_p(z_t-z_p;\gamma_p)g_t(z_s-z_t;\gamma_t)g_s(z-z_s;\gamma_s)dz_s\,dz_t = \int_{-\infty}^{\infty}g_p(z_t-z_p;\gamma_p)\left[\int_{-\infty}^{\infty}g_t(z_s-z_t;\gamma_t)g_s(z-z_s;\gamma_s)dz_s\right]dz_t \tag{37}$$

and then invoke Result 1.

VIII. GREEN FUNCTION THEOREM FOR A GENERAL ILLUMINATION FUNCTION

Results 1 and 2 can be used to simplify Eq. (32) to give

$$P(\omega_x,\omega_y,z,\omega) = \frac{-\mu_a\beta_s k_s^2}{D}\int_{-\infty}^{\infty}O_a\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)\times\left[\frac{g_s(z-z_p;\gamma_s)}{(k_s^2-k_t^2)(k_s^2-k_p^2)} + \frac{g_t(z-z_p;\gamma_t)}{(k_t^2-k_s^2)(k_t^2-k_p^2)} + \frac{g_p(z-z_p;\gamma_p)}{(k_p^2-k_s^2)(k_p^2-k_t^2)}\right]dz_p. \tag{38}$$

Let us further define the following variables:

$$A_s := \frac{\mu_a^2k_s^2}{(k_s^2-k_t^2)(k_s^2-k_p^2)}, \tag{39}$$

$$A_t := \frac{\mu_a^2k_s^2}{(k_t^2-k_s^2)(k_t^2-k_p^2)}, \tag{40}$$

$$A_p := \frac{\mu_a^2k_s^2}{(k_p^2-k_s^2)(k_p^2-k_t^2)}. \tag{41}$$

With these new variables, Eq. (38) can be written as

$$P(\omega_x,\omega_y,z,\omega) = \frac{-\beta_s}{D\mu_a}\int_{-\infty}^{\infty}O_a\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)g_{pts}\times(z-z_p;\gamma_s,\gamma_p,\gamma_t)dz_p, \tag{42}$$

where $g_{pts}(z;\gamma_s,\gamma_p,\gamma_t)=A_pg_p(z;\gamma_p)+A_tg_t(z;\gamma_t)+A_sg_s(z;\gamma_s)$

It can be seen that this is now a one dimensional (1D) problem with the pressure being given by a convolution of the heterogeneity function with the system Green function. Further, it is also clear that the system Green function, which was formerly 4D and a *product* of the subsystem Green functions, is now 1D and a *sum* of the subsystem Green functions.

A. Interpretation as a convolution

Equation (42) can be interpreted as a convolution where it can be written as

$$P(\omega_x,\omega_y,z,\omega) = \frac{-\beta_s}{D\mu_a}[O_a\Psi_{d0}(\omega_x,\omega_y,z,\omega)] * g_{pts}\times(z;\gamma_s,\gamma_p,\gamma_t)(z). \tag{43}$$

Taking the Fourier transform with respect to z of both sides turns products into convolutions and convolutions into products, leading to

$$P(\omega_x,\omega_y,\omega_z,\omega) = \frac{-\beta_s}{D\mu_a}O_a * \Psi_{d0}(\omega_x,\omega_y,\omega_z,\omega)\cdot G_{pts}\times(\omega_x,\omega_y,\omega_z,\omega), \tag{44}$$

where, $G_{pts}(\omega_x,\omega_y,\omega_z,\omega)=A_pG_p(\omega_x,\omega_y,\omega_z,\omega)+A_t\times G_t(\omega_x,\omega_y,\omega_z,\omega)+A_sG_s(\omega_x,\omega_y,\omega_z,\omega)$

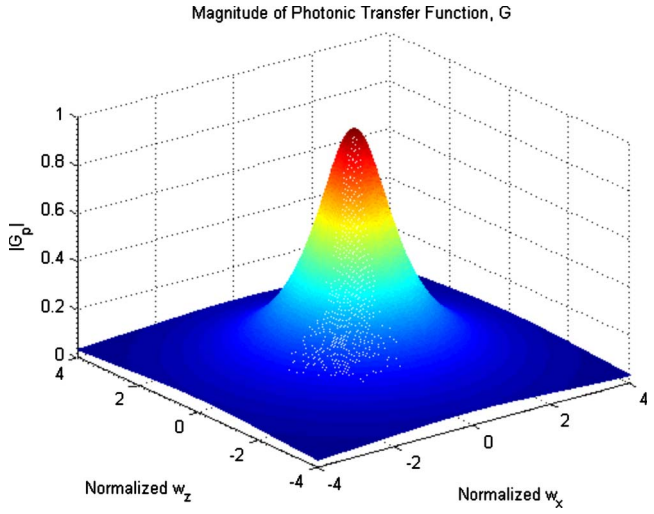

FIG. 1. (Color online) Photonic transfer function.

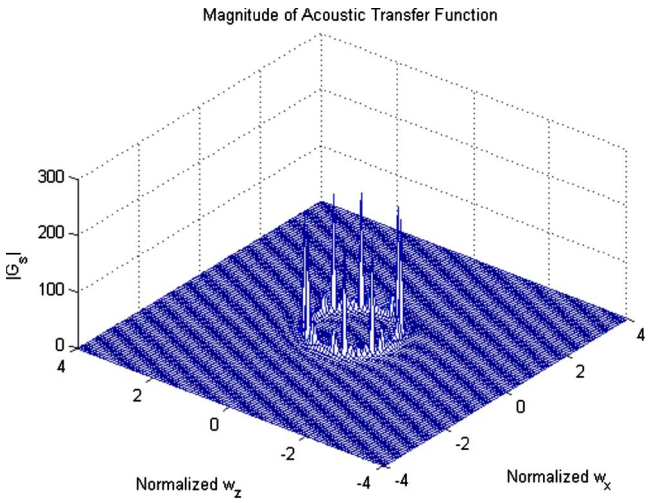

FIG. 3. (Color online) Acoustic transfer function.

The capital G is used to denote the full Fourier transform of each corresponding g function, for each of the photonic, thermal, and acoustic Green function. The form of each of these transfer functions is given by

$$G(\omega_x,\omega_y,\omega_z,\omega) = \mathbb{F}\left(\frac{e^{-\gamma_\omega|z|}}{2\gamma_\omega}\right) = \frac{2\gamma_\omega}{2\gamma_\omega}\frac{1}{\gamma_\omega^2+\omega_z^2} = \frac{1}{\omega_x^2+\omega_y^2+\omega_z^2-k^2}, \tag{45}$$

which is precisely the three-dimensional (3D) wave equation transfer function. In this form, it is easier to visualize the physical implications of the photonic, thermal, and acoustic transfer functions separately, as the combined transfer function is a sum of the three subsystem transfer functions. The magnitude of each transfer function is shown in Figs. 1–3, respectively. The transfer functions are 4D hypersurfaces in frequency space but have been plotted in Figs. 1–3 with $\omega_y = 0$ for clarity. In Figs. 1–3 each wave number in the denominator of the transfer function of the form of Eq. (45) has been normalized so that $|k| = 1$. Thus, the spatial frequencies displayed in the plots are normalized frequencies rather than true frequencies. To obtain the true frequency, each spatial frequency would have to be multiplied by the $|k|^2$ corresponding to that particular transfer function. The thermal transfer function dies off much more quickly in spatial frequency space than the photonic transfer function as the decay of both is primarily controlled by the exponent in the decaying exponential function. As the thermal wave number is smaller, the corresponding gamma exponent is larger for the thermal transfer function and thus the thermal transfer function goes to zero far more quickly than the photonic transfer function. As both the photonic and thermal wave numbers are complex, the corresponding transfer function reaches its maximum at $\omega_x = \omega_y = \omega_z = 0$ and then goes to zero for increasing spatial frequencies. Thus, the photonic and thermal transfer functions can be considered to be low-pass filters. However, the situation for the acoustic transfer function is not the same. The acoustic wave number is real, thus its transfer function, as given by Eq. (45) reaches a maximum when the denominator is zero. This would occur for $\omega_x^2 + \omega_y^2 + \omega_z^2 = k_s^2$. As illustrated in Fig. 3, in two dimensions this would be $\omega_x^2 + \omega_z^2 = k_s^2$, a circle in 2D spatial frequency space (and a sphere in 3D space). The variation in the heights of the spikes in Fig. 3 is an artifact of the discretization the Fourier space and not an inherent property of the transfer function. The acoustic transfer function can be considered to be a band-pass filter, with frequencies satisfying $\omega_x^2 + \omega_y^2 + \omega_z^2 = k_s^2$ passed on for detection.

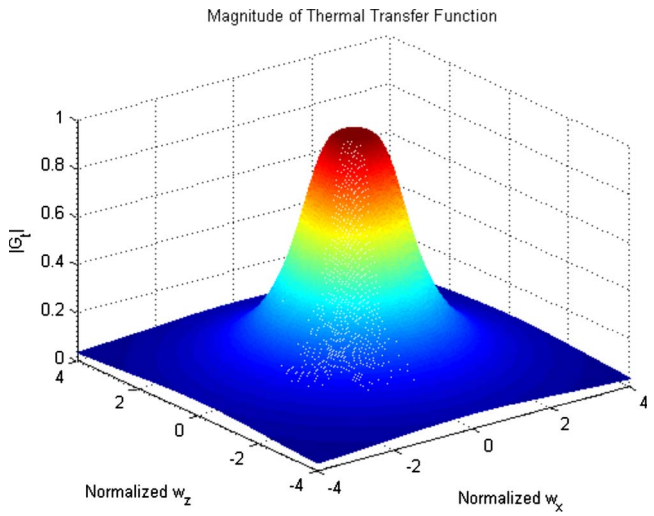

FIG. 2. (Color online) Thermal transfer function.

B. Block diagram and comparison with ultrasonic imaging

From Eq. (44), it can be seen that the detected pressure in Fourier frequency space (spatial and temporal) can be considered as a sequence of operations on the object (inhomogeneity) function. The object function is first convolved with the illumination function. This resulting function (termed the heterogeneity) function is then multiplied by the system transfer function. For the photothermoacoustics problem, this

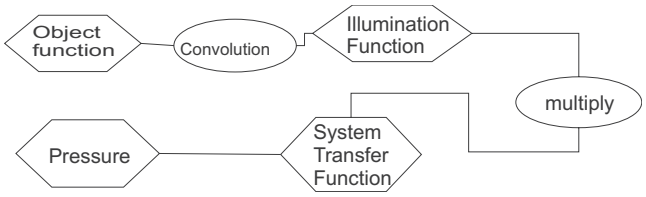

FIG. 4. Schematic of PTA process in the spatial and temporal frequency domain.

system transfer function is actually a sum of the three subsystem transfer functions. This process yields the pressure everywhere. This is shown schematically in Fig. 4. Clearly, the act of detecting the pressure on some surface is yet another transfer function, which acts on the resulting pressure function.

Viewing the photothermoacoustic process in the block diagram of Fig. 4 allows immediate comparison with the usual ultrasonic imaging modality. For traditional ultrasonic imaging, the inhomogeneity being imaged (i.e., the object function) represents inhomogeneities in the speed of sound in the object. In comparison, with PTA imaging, it is the inhomogeneities in the absorption coefficient of the tissue that are being imaged. The large variation in the optical absorption of different tissue constituents is thus expoited as these are the high-contrast inhomogeneities that are being imaged. For ultrasonic imaging, the illumination function is typically a plane-wave acoustic wave. This plane wave is a delta function in the spatial frequency domain and its convolution with the object function yields a shift of the object function in spatial Fourier space. In PTA imaging, the illumination function is a DPDW. Finally, the system transfer function for ultrasonic imaging is the acoustic transfer function alone, similar to the acoustic subsystem transfer function derived here. For PTA imaging, the system transfer function consists of the sum of the acoustic, photonic, and thermal transfer functions with the effect of each to be discussed shortly.

C. Comparison with pulsed photoacoustic imaging

In pulsed photoacoustic tomography, the pulse duration is so short that the thermal conduction time is greater than the thermoacoustic transit time and the effect of thermal conduction can be ignored.[25] The equation describing the resulting thermoacoustic pressure wave propagation is given by[12–14,25,26]

$$\nabla^2 p(\vec{r},t) - \frac{1}{c_s^2}\frac{\partial^2}{\partial t^2}p(\vec{r},t) = -\frac{\beta_s c_s}{C_p}\frac{\partial}{\partial t}H(\vec{r},t), \tag{46}$$

where C_p is the specific heat, H is the heating function defined as the thermal energy deposited by the energy source per time and volume, β_s is the coefficient of thermal volume expansion, and c_s is the speed of sound. The heating function can be written as the product of a spatial absorption function and a temporal illumination function of the rf source,

$$H(\vec{r},t) = I_0 o_a(\vec{r})\,\eta(t), \tag{47}$$

where I_0 is a scaling factor proportional to the incident radiation intensity and $o_a(\vec{r})$ describes the absorption properties of the medium—essentially the inhomogeneity whose image is sought. The function $\eta(t)$ describes the shape of the irradiating pulse and is a nonnegative function whose integration over time equals the pulse energy. Taking the Fourier transform with respect to time and the 3D Fourier transform with respect to space of Eq. (46) yields

$$P(\omega_x,\omega_y,\omega_z,\omega) = \frac{\beta I_0 i\omega}{C_p}\eta(\omega) \times O_a(\omega_x,\omega_y,\omega_z)G_s(\omega_x,\omega_y,\omega_z,\omega), \tag{48}$$

where

$$G_s(\omega_x,\omega_y,\omega_z,\omega) = \frac{1}{\omega_x^2+\omega_y^2+\omega_z^2-k_s^2} \tag{49}$$

is the acoustic transfer function. This can be directly compared with Eq. (43) for the full photo-thermo-acoustic problem. We see that there are several differences. First, the transfer functions are not the same. The pulsed photoacoustic problem yields the purely acoustic transfer function whereas the full photothermoacoustic problem has a transfer function, which is a sum of the acoustic, thermal, and photonic transfer functions. Second, for the pulsed photoacoustic problem, the system transfer function is directly multiplied with the object function. However, for the photothermoacoustic problem, the object function is first convolved with the illumination function before being multiplied by the system transfer function. As the choice of illumination function is somewhat under the control of the designer, it should be expected that the photothermoacoustic approach might yield greater ability to "probe" the object function and thus better imaging results.

IX. DIMENSIONAL ANALYSIS

The relative importance of acoustic, thermal, and photonic effects will be governed by three separate characteristic frequencies. To analyze the effects of acoustic, thermal, and photonic effects, let us define these characteristic frequencies as

$$\omega_s := \mu_a c_s =: \frac{1}{\tau_s}, \quad \omega_t := \mu_a^2\alpha =: \frac{1}{\tau_t}, \quad \omega_p := \mu_a c =: \frac{1}{\tau_p}. \tag{50}$$

The subscripts have been used along with this paper's convention of s,t, and p referring to acoustic, thermal, and photonic phenomena, respectively. Each characteristic frequency also defines a characteristic time, with this time defined as the inverse of the corresponding characteristic frequency. The time τ_s is the transit time of sound through the depth of light penetration. This is the time taken for stress to traverse the heated region. For frequencies $\omega > \omega_s$, or equivalently for times $t < \tau_s$, this condition is known as stress confinement.[12] For frequencies $\omega > \omega_t$, then heat conduction is considered to be negligible[25] as the thermal diffusion length is shorter than

the heating zone. Thus the time τ_t can be interpreted as a characteristic time scale for the heat dissipation of the absorbed photonic energy by thermal conduction.[12] It is a measure of the relative sizes of the depth of penetration of the diffuse photon density wave (heating zone) and the thermal diffusion length. This condition has been referred to as thermal confinement.[12] It follows that τ_s, τ_t, and τ_p can be interpreted as the times taken for acoustic, thermal, and photonic waves to traverse the depth of light penetration (the heating zone). Thermal and stress confinements are usually discussed in terms of time scales rather than frequencies. Generally, $\omega_p > \omega_s > \omega_t$.

In keeping with the work of Gusev and Karabutov,[25] we also define

$$\omega_\alpha = \frac{c_s^2}{\alpha} = \frac{\omega_s^2}{\omega_t}. \tag{51}$$

Gusev and Karabutov note that (Ref. 25, p. 16) the wave vector of the acoustic wave is much smaller than the wave vector of the thermal wave across the entire frequency range. This implies

$$\frac{\omega}{c_s} \ll \sqrt{\frac{\omega}{\alpha}} \rightarrow \frac{\omega\alpha}{c_s^2} \ll 1 \rightarrow \omega \ll \frac{\omega_s^2}{\omega_t} = \omega_\alpha. \tag{52}$$

This is simply the statement that the acoustic wavelength is much longer than the thermal wavelength, expressed in terms of input frequency and characteristic frequencies. It follows immediately from this statement that

$$\frac{k_s^2}{k_t^2} = \frac{\omega\alpha i}{c_s^2} = \frac{\omega\omega_t}{\omega_s^2} i \ll 1i, \tag{53}$$

where $i = \sqrt{-1}$, so that the magnitude of the ratio of the squared acoustic to thermal wave number is very small. Similarly,

$$\frac{k_p^2}{k_t^2} = -\frac{\mu_a \alpha i}{D\omega} + \frac{\alpha}{cD} = \frac{1}{\mu_a D}\left[\frac{\omega_t}{\omega_p} - \frac{\omega_t}{\omega} i\right] \approx \frac{-1}{\mu_a D}\frac{\omega_t}{\omega} i, \tag{54}$$

and can thus be considered as a measure of the degree of thermal confinement. If the input frequency $\omega \gg \omega_t$, then the magnitude of the ratios of the squared photonic to thermal wave number is very small (thermal confinement). Finally, we can also write

$$\frac{k_p^2}{k_s^2} = -\frac{\mu_a c_s^2}{D\omega^2} - \frac{i c_s^2}{cD\omega} = \frac{-\omega_s^2}{\omega^2}\left[1 + \frac{\omega}{\omega_p} i\right]\frac{1}{\mu_a D}. \tag{55}$$

This last ratio of squared wave numbers can be considered as a measure of the degree of stress confinement and in general cannot be considered to be a small quantity. In summary, we have that thermal confinement implies that k_p^2/k_t^2 is a small quantity and that stress confinement implies that k_p^2/k_s^2 is a small quantity. It is noted that both conditions can be expressed in terms of ratios of the appropriate wave numbers with thermal confinement involving the ratio of the photonic to thermal wave numbers and stress confinement involving the ratio of photonic to acoustic wave number.

Some typical examples of parameters are now given. From Ref. 12, it can be obtained that the absorption coefficients of the electric field in fat (low water content) and muscle (high water content) are about 0.1 and 0.9 cm^{-1}, respectively, at 3 GHz and about 0.03 and 0.25 cm^{-1}, respectively, at 300 MHz. Typical thermal diffusivity for most soft tissues is 1.4×10^{-3} cm^2/s. The speed of sound is 1.5 $\text{mm}/\mu\text{s}$. Telenkov *et al.* gives the thermal diffusivity of soft tissue as 0.11 mm^2/s.[27] Background optical properties are given as $\mu_a = 0.02$ cm^{-1} and $\mu_s' = 8.0$ cm^{-1}.[28] The speed of light in tissue, c, is on the order of 2×10^8 m/s.[29] Given these typical parameters, then $\omega_p = 2 \times 10^8$ s^{-1}, $\omega_s = 3 \times 10^3$ s^{-1}, and $\omega_t = 5.6 \times 10^{-7}$ s^{-1}. Given these numbers, it is easy to see that, in general, $\omega \gg \omega_t$ will be easily achieved whereas it is not necessarily true that $\omega > \omega_s$. Thus, in general, it follows that the magnitude of the ratio of the photonic and thermal wave numbers is very small and that the magnitude of the ratio of the acoustic and thermal wave number is also small. However, the ratio of photonic to acoustic wave number will depend on the frequency of the illumination function.

Based on the preceding analysis, the values of A_s, A_t, and A_p can be simplified. Using $\mu_a^2/k_s^2 = \omega_s^2/\omega^2$ and $\mu_a^2/k_t^2 = i\omega_t/\omega$, along with Eqs. (53) and (54), these can be rewritten as

$$A_t := \frac{-\omega_t^2/\omega_s^2}{(1 - k_s^2/k_t^2)(1 - k_p^2/k_t^2)} \approx -\frac{\omega_t^2}{\omega_s^2} \ll 1, \tag{56}$$

$$A_s := \frac{\omega_t i/\omega}{(k_s^2/k_t^2 - 1)(1 - k_p^2/k_s^2)} \approx -\frac{\omega_t i}{\omega}\frac{1}{(1 - k_p^2/k_s^2)}, \tag{57}$$

$$A_p := \frac{\omega_t i/\omega}{(k_p^2/k_s^2 - 1)(k_p^2/k_t^2 - 1)} \approx -\frac{\omega_t i}{\omega}\frac{1}{(k_p^2/k_s^2 - 1)} = -A_s. \tag{58}$$

Thus, the system Green function can now be written as

$$\begin{aligned} g_{pts}(z;\gamma_s,\gamma_p,\gamma_t) &= A_p g_p(z;\gamma_p) + A_t g_t(z;\gamma_t) + A_s g_s(z;\gamma_s) \\ &\approx A_s[g_s(z;\gamma_s) - g_p(z;\gamma_p)], \end{aligned} \tag{59}$$

and it follows that the thermal subsystem Green function has very little effect on the final output.

Stress confinement: As previously discussed, under the condition of stress confinement, k_p^2/k_s^2 becomes a small quantity. It then further follows that under stress confinement A_p and A_s simplify to

$$A_s = -\frac{\omega_t i}{\omega} = -A_p. \tag{60}$$

As previously discussed, A_t is considered small for most frequencies. The system Green function still has the same form as given by Eq. (59).

Near field and far field regions: It can be seen from Eq. (59) that the system Green function is a sum of photonic and acoustic Green functions. Recall that these functions are given by by the form,

$$g(z) = \frac{e^{-\gamma_\omega |z|}}{2\gamma_\omega}, \tag{61}$$

where γ_ω takes on the appropriate form for photonic and acoustic wave numbers and is an "effective" wave number. For acoustic waves, γ_ω is purely real for values of $k_s^2 < \omega_x^2 + \omega_y^2$ and thus decays exponentially. The Green function will approach zero for values of $|z|$ greater than about $5/\gamma_{\omega r}$—recalling that it is the real component of γ_ω that causes the decay in the Green function. As γ_s acts as an effective wave number, the inverse of γ_s behaves as an effective wavelength. For $k_s^2 > \omega_x^2 + \omega_y^2$, then γ_s is purely imaginary and thus does not decay. This is the "low-pass" version of the Green function as essentially only these lower spatial frequencies are propagated and the others are attenuated. More specifically, the acoustic Green function is really a band-pass function as spatial frequencies such that $\gamma_s = 0$, that is $\omega_x^2 + \omega_y^2 = k_s^2$, are the ones that are most highly selected, causing the denominator of the Green function to go to zero. The corresponding γ_ω for the DPDW is always complex and thus always has a decaying component. Hence, "far enough" away from a given inhomogeneity, only the acoustic contribution will remain as the photonic contribution to the system, as given in Eq. (59), will have completely decayed. As increasing spatial frequencies only serve to enhance the possible decay of the exponential term, the largest allowable z (before the Green function decays to zero) occurs at $\omega_x = \omega_y = 0$. It is the real part of k_p that dictates the rate of decay of the Green function. Recall that

$$k_p^2 = -\frac{\mu_a}{D} - \frac{i\omega}{cD}. \tag{62}$$

As the speed of light, c, is large, then for all but the highest of frequencies we can approximately write $k_p^2 = -\mu_a/D$ and thus $k_p = i\sqrt{\mu_a/D}$. For the typical values previously mentioned, $\sqrt{\mu_a/D} \approx 70\ \mathrm{m}^{-1}$ and it follows that the decay constant is roughly about 1.4 cm. If the detector is roughly within this order of magnitude or closer to the inhomogeneity then both the acoustic and photonic contributions to the final pressure should be considered. However, for distances about 4 to 5 times this far, then the photonic contribution becomes negligible and only the acoustic Green function plays a role. This distinction is of importance and should have an effect on any inversion algorithms employed.

X. GENERALIZED FOURIER DIFFRACTION THEOREM FOR GENERAL ILLUMINATION FUNCTION

Given the exponential functional form of the subsystem Green functions, Eq. (42) can be interpreted in terms of the Fourier transform. For a general Green function of the form $g(z - z_p) = e^{-\gamma_\omega |z - z_p|}/(2\gamma_\omega)$, we can write for any function h of space and temporal frequency:

$$\begin{aligned}
\int_{-\infty}^{\infty} h(\omega_x, \omega_y, z_p, \omega) \frac{e^{-\gamma_\omega |z - z_p|}}{2\gamma_\omega} dz_p &= \int_{-\infty}^{\infty} h(\omega_x, \omega_y, z_p, \omega) \frac{e^{-[\gamma_{\omega r} + i\gamma_{\omega i}]|z - z_p|}}{2\gamma_\omega} dz_p \\
&= \begin{cases} \dfrac{e^{-[\gamma_{\omega r} + i\gamma_{\omega i}]z}}{2\gamma_\omega} \displaystyle\int_{-\infty}^{\infty} h(\omega_x, \omega_y, z_p, \omega) e^{\gamma_{\omega r} z_p} e^{i\gamma_{\omega i} z_p} dz_p, & z > z_p \\ \dfrac{e^{[\gamma_{\omega r} + i\gamma_{\omega i}]z}}{2\gamma_\omega} \displaystyle\int_{-\infty}^{\infty} h(\omega_x, \omega_y, z_p, \omega) e^{-\gamma_{\omega r} z_p} e^{-i\gamma_{\omega i} z_p} dz_p, & z < z_p \end{cases} \\
&= \begin{cases} \dfrac{e^{-[\gamma_{\omega r} + i\gamma_{\omega i}]z}}{2\gamma_\omega} F_{3D}\{h(\vec{r}, \omega) e^{\gamma_{\omega r} z}\}\big|_{\omega_z = -\gamma_{\omega i}}, & z > z_p \quad \text{(transmission)} \\ \dfrac{e^{[\gamma_{\omega r} + i\gamma_{\omega i}]z}}{2\gamma_\omega} F_{3D}\{h(\vec{r}, \omega) e^{-\gamma_{\omega r} z}\}\big|_{\omega_z = \gamma_{\omega i}}, & z < z_p \quad \text{(reflection)}. \end{cases}
\end{aligned} \tag{63}$$

Here, F_{3D} denotes the 3D Fourier transform and it can be observed that each subsystem Green function has the effect of returning the 3D Fourier transform of the product of the heterogeneity function and a (decaying) exponential, evaluated on $\omega_z = \pm \gamma_{\omega i}$, weighted by appropriate factors. The positive sign is chosen for measurements in reflection and the negative sign for measurements in transmission. The weighting factor $e^{\pm[\gamma_{\omega r} + i\gamma_{\omega i}]z}/2\gamma_\omega$ is a constant for a fixed receiver plane and its form is very much reminiscent of the form of each subsystem Green function. In fact, as without loss of generality the inhomogeneity can be taken to be located at the origin, then the previous equation can be more compactly written as

$$\begin{aligned}
&\int_{-\infty}^{\infty} h(\omega_x, \omega_y, z_p, \omega) \frac{e^{-\gamma_\omega |z - z_p|}}{2\gamma_\omega} dz_p \\
&\quad = g_\omega(z) F_{3D}\{h(\vec{r}, \omega) e^{\gamma_{\omega r} |z|}\}\big|_{\omega_z = -\gamma_{\omega i}\, \mathrm{sgn}(z)},
\end{aligned} \tag{64}$$

where $g_\omega(z)$ is the appropriate (thermal, photonic or acoustic) Green function. Positive z's are chosen for transmission measurements and negative z's are chosen for reflection measurements. With respect to the convergence of the integrals in Eq. (63), it should be noted that the object function has finite

support, otherwise the basic premise of the Born approximation is no longer valid. With finite support, the integrals will converge, despite the presence of the exponential terms in the integrand.

Result: Applying the result of Eq. (63) on Eq. (42), we obtain the generalized Fourier diffraction theorem for the coupled PTA problem:

$$P(\omega_x,\omega_y,z,\omega)=\frac{-\beta_s}{D\mu_a}\int_{-\infty}^{\infty}O_a\Psi_{d0}(\omega_x,\omega_y,z_p,\omega)g_{pts}(z-z_p;\gamma_s,\gamma_p,\gamma_t)dz_p=\frac{-\beta_s}{D\mu_a}\sum_{\omega=p,t,s}A_\omega g_\omega(z)F_{3D}\times\{O_a\Psi_{d0}(\omega_x,\omega_y,z,\omega)e^{\gamma_{\omega r}|z|}\}\big|_{\omega_z=-\gamma_{\omega i}\,\mathrm{sgn}(z)}. \tag{65}$$

This Fourier diffraction theorem tells us that the spatial 2D Fourier transform of the measured response on a plane is proportional to the *sum* of three 3D Fourier transforms of the heterogeneity function (weighted with an exponential), evaluated at $\omega_z=\pm\gamma_{\omega i}$. The positive z is chosen for measurements in reflection and the negative z is chosen for measurements in transmission. The three separate 3D Fourier transforms are due to each of photonic, thermal, and acoustic generalized wave number, γ_ω. The γ has been defined as the square root of γ^2 such that the real part is positive, so that the exponential functions in front of the 3D Fourier transform are always well behaved at infinity.

XI. FOURIER DIFFRACTION THEOREM FOR PLANE-WAVE ILLUMINATION FUNCTION

We now specialize the Fourier diffraction theorem as derived earlier to the case of plane-wave illumination. Specifically, it is assumed that

$$\Psi_{d0}(\omega_x,\omega_y,z,\omega)=\Psi_{d0}(z,\omega)=e^{ik_p|z|}. \tag{66}$$

For plane-wave illumination, Eq. (65) becomes

$$P(\omega_x,\omega_y,z,\omega)=\frac{-\beta_s}{D\mu_a}\int_{-\infty}^{\infty}O_a(\omega_x,\omega_y,z)e^{ik_p|z|}g_{pts}(z-z_p;\gamma_s,\gamma_p,\gamma_t)dz_p=\frac{-\beta_s}{D\mu_a}\sum_{\omega=p,t,s}A_\omega g_\omega(z)F_{3D}\times\{o_a(\vec{r})e^{(\gamma_{\omega r}-k_{pi})|z|}\}\big|_{\omega_z=(-k_{pr}-\gamma_{\omega i})\mathrm{sgn}(z)}. \tag{67}$$

As $\gamma_{p/t/s}^2=\omega_x^2+\omega_y^2-k_{p/t/s}^2$, then the terms $g_\omega(z)$ in Eq. (67) always have a positive decaying component with the exception of $\gamma_s=\sqrt{\omega_x^2+\omega_y^2-k_s^2}$ when $\omega_x^2+\omega_y^2<k_s^2$. Hence for "large enough" z, the acoustic terms for which $\omega_x^2+\omega_y^2<k_s^2$ are propagated and the other terms are attenuated, effectively a low-pass filter. In this case, $\gamma_{si}=\sqrt{k_s^2-\omega_x^2-\omega_y^2}$, and the Fourier region of the 3D transform of $o_a(\vec{r})e^{(\gamma_{\omega r}-k_{pi})|z|}$ that is detected is where $\omega_z=\pm(k_{pr}+\gamma_{si})$ or $(\omega_z\pm k_{pr})^2=\gamma_{si}^2=k_s^2-\omega_x^2-\omega_y^2$, implying $(\omega_z\pm k_{pr})^2+\omega_x^2+\omega_y^2=k_s^2$. This last expression is for a sphere in 3D spatial frequency space, centered at $(0,0,\pm k_{pr})$ and of radius k_s and is the photothermoacoustic equivalent of the Fourier diffraction theorem as used in traditional ultrasonic detection.

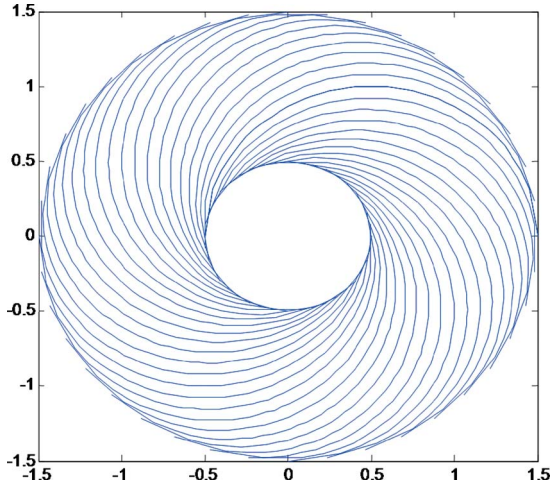

FIG. 5. (Color online) Rotated semicircle of radius 1, center at 0.5.

XII. FOURIER PLANE COVERAGE

As mentioned in the previous section, it can be seen that in the case of plane-wave illumination, the Fourier region is a hemisphere (depending on whether the detection is in transmission or reflection) centered at $(0,0,\pm k_{pr})$ and of radius k_s. It should be clear that the resolution with which the object can be imaged depends on how much of its Fourier transform can be measured. The Fourier plane coverage—the portion of the full 3D Fourier transform of the objection function that is obtained via measurement—is thus a good indicator of what it is theoretically possible to image. Further, as similar Fourier plane coverage results can be obtained or derived for both traditional ultrasonic imaging and pulsed photoacoustic imaging, different imaging modalities can be compared by comparing their Fourier plane coverage.

In particular, let us compare the Fourier plane coverage for the case of fixed frequency and multiple views. In other words, we compare the coverage of the object function if measurements are made at a specific frequency but the transmission/detection is made at various angles, eventually obtaining full 360° coverage of the subject.

For graphical simplicity, circles in the 2D Fourier plane rather than spheres in the 3D Fourier plane can be considered. For the ultrasonic case, this analysis is performed in Ref. 30. It can be observed that for the frequency domain photoacoustic modality, at fixed frequency and multiple views, the Fourier plane coverage is controlled by the location of the center of the circle, k_{pr} and the radius of the circle, k_s. By normalizing with k_s, the relevant quantities become the location of the center of the circle and the circle itself (of radius 1). As the view angle is changed, new information is obtained at a different location in the Fourier plane. The Fourier plane coverage for fixed frequency and multiple views is shown in Figs. 5–9. Various circle centers are shown. For Fig. 5, we see the Fourier coverage for a circle at center 0.5 and radius 1. It does not matter if the center is at (0,0.5) or (0.5, 0), etc. as these theoretical measurements are

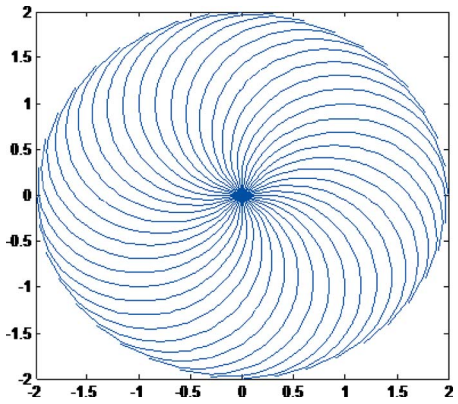

FIG. 6. (Color online) Rotated semicircle, radius 1, center at 1.

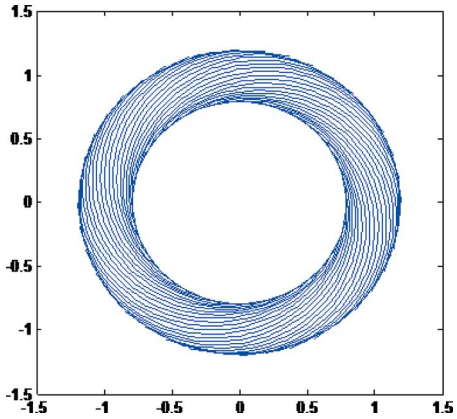

FIG. 8. (Color online) Rotated semicircle, radius 1, center at 0.2.

made through a full 360° rotation about the object. We see that this is essentially a band-pass filter for the object function as only information in an annulus type region of the Fourier plane is obtained. Figure 6 shows the Fourier coverage for a circle at center 1 and radius 1. This case corresponds to the ultrasonic case.[30] This case is a low-pass filter, in comparison with the band-pass filter of the previous case. The difference between the ultrasonic case and the photothermoacoustic case is that in the ultrasonic case, both the center of the circle and radius of the circle are controlled by k_s, whereas in the photothermoacoustic case, the center of the circle is controlled by k_{pr}, whereas the radius of the circle is controlled by k_s—two separate, although related, quantities. Figure 7 shows the case for a circle of radius 1, centered at 0. It can be shown that this corresponds to the pulsed photoacoustic case. In a way, this is an unreasonable comparison as in the case of pulse excitation more than one frequency would be present and thus it could be argued that the single-frequency-multiple-view scenario is unrealistic. However, for the sake of analysis we proceed with this case, in particular as this would also apply when k_{pr} is close to zero. We see that in this case, the band-pass filter narrows and essentially passes only those frequencies that are on the fixed circle. The Fourier coverage is minimal and in fact, no new information is gained by making measurements at various views. To gain more information about the rest of the Fourier plane, measurements would have to be made at additional frequencies, thus changing the radius of the circle. In Fig. 8, the case with center at 0.2 (a small center compared to radius) is demonstrated and it can be seen that this corresponds to a narrow band-pass filter. Clearly, the case where the center is at or close to zero is the limiting band-pass case. In Fig. 9, the case where the center is at 4, and thus greater than the radius of the circle (which is 1) is shown. This is again another band-pass case, although the location of the information on the Fourier plane is different. It can be seen from Fig. 9 that as the center of the circle starts to move away from the origin, additional measurements (more views) need to be made in order to "fill in" the information in the Fourier plane disk. In constrast, for the very narrow band-pass filters such those of Figs. 7 and 8, fewer views (measurements) need to be taken before all possible information at that frequency has been obtained. Hence, the higher k_{pr}, the more views need to be taken to fill in the Fourier disk and vice versa.

All of these simulations where done for the case of 40 views to achieve a full 360° rotation about the object. The smaller the center of the circle, as controlled by k_{pr}, the narrower the annulus of the band-pass filters. For small k_{pr}, less and less information is gained by making measurements at multiple views and the same frequency. In the limit of $k_{pr}=0$, additional views yield no new information, and measurements at different frequencies *must* be obtained in order to gain more information about the 3D Fourier transform of

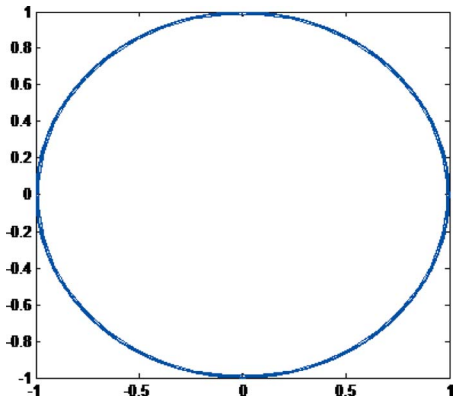

FIG. 7. (Color online) Rotated semicircles, radius 1, center at 0.

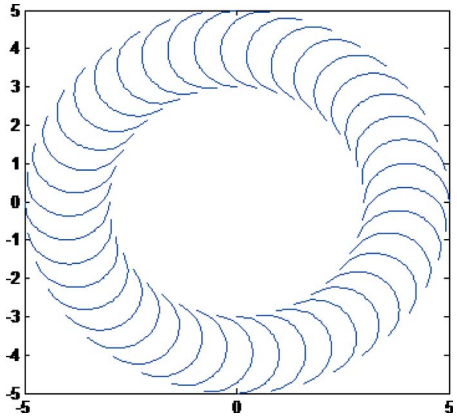

FIG. 9. (Color online) Rotated semicircle, radius 1, center at 4.

the object. The case where center and radius of the circle are equal corresponds to the traditional ultrasonic case and roughly speaking achieves best coverage of the Fourier plane *at a fixed frequency.* This case becomes a low-pass filter case in comparison with the band-pass filter of all the other cases. The power behind the photothermoacoustic modality is that the center and radius of the circle control the band-pass nature of the detection modality and these quantities are controlled by separate but related quantities, k_{pr} and k_s. Proper experiment design would be a matter of controlling the choice of frequencies and views in order to obtain coverage of the 3D Fourier transform of the object that is adequate for the intended application.

XIII. CONCLUSIONS

In conclusion, the governing equations for photoacoustic imaging were derived where a short input pulse is not assumed. The full coupled problem with diffuse photon density waves, thermal and acoustic waves was presented. It was shown that the forward problem could be interpreted as a convolution between the system transfer function and the heterogeneity function where the heterogeneity function is defined as the product of the object and illumination functions. Although truly a product of the three subsystem transfer function, the total system transfer function was eventually shown to be a sum of the three subsystem transfer function. Analysis of relative sizes of each showed that in general the thermal Green function can be neglected, whereas the photonic one may be negligible under certain circumstances. Finally, the preceding results led to a Fourier diffraction theorem for PTA imaging where the observed resulting pressure measured on a plane is shown to be a spherical slice of the 3D Fourier transforms of the object function. Fourier plane coverage was considered. It is expected that these findings will be useful in the design of experiments to ensure proper Fourier plane coverage and also as the basis of reconstruction algorithms for PTA imaging. Future work will extend these results to more general geometries and consider incorporating additional effects into the model.

APPENDIX

Define the following function:

$$f(z,z_t;\gamma_t,\gamma_s) := \int_{-\infty}^{\infty} e^{-\gamma_t|z_s-z_t|}e^{-\gamma_s|z-z_s|}dz_s. \tag{A1}$$

Note that z_s is a (dummy) integration variable and that (γ_t,γ_s) are parameters. We have used γ_t,γ_s in Eq. (A1) and we shall make use of their specific definition in what follows.

Lemma 1:

$$f(z,z_t;\gamma_t,\gamma_s) := \int_{-\infty}^{\infty} e^{-\gamma_t|z_s-z_t|}e^{-\gamma_s|z-z_s|}dz_s = \frac{2\gamma_t e^{-\gamma_s|z-z_t|}}{k_s^2-k_t^2} - \frac{2\gamma_s e^{-\gamma_t|z-z_t|}}{k_s^2-k_t^2}. \tag{A2}$$

Proof: As f is essentially a function of z and z_t, two possible cases need to be considered to evaluate the integral. In the first possible case, $z<z_t$, whereas in the second possible case, $z>z_t$. In the first case, if $z<z_t$, then f as given in Eq. (A1) can be written as

$$f(z,z_t;\gamma_t,\gamma_s) = \int_{-\infty}^{z} e^{-\gamma_t(z_t-z_s)}e^{-\gamma_s(z-z_s)}dz_s + \int_{z}^{z_t} e^{-\gamma_t(z_t-z_s)} \times e^{-\gamma_s(z_s-z)}dz_s + \int_{z_t}^{\infty} e^{-\gamma_t(z_s-z_t)}e^{-\gamma_s(z_s-z)}dz_s. \tag{A3}$$

This sum of integrals can be easily evaluated to give

$$f(z,z_t;\gamma_t,\gamma_s) = \frac{e^{-\gamma_t(z_t-z)}+e^{-\gamma_s(z_t-z)}}{\gamma_t+\gamma_s} + \frac{e^{-\gamma_s(z_t-z)}-e^{-\gamma_t(z_t-z)}}{\gamma_t-\gamma_s}. \tag{A4}$$

In the second case, if $z>z_t$, then f as given in Eq. (A1) can be written as

$$f(z,z_t;\gamma_t,\gamma_s) = \int_{-\infty}^{z_t} e^{-\gamma_t(z_t-z_s)}e^{-\gamma_s(z-z_s)}dz_s + \int_{z_t}^{z} e^{-\gamma_t(z_s-z_t)} \times e^{-\gamma_s(z-z_s)}dz_s + \int_{z}^{\infty} e^{-\gamma_t(z_s-z_t)}e^{-\gamma_s(z_s-z)}dz_s. \tag{A5}$$

This sum of integrals can similarly be easily evaluated to give

$$f(z,z_t;\gamma_t,\gamma_s) = \frac{e^{-\gamma_t(z-z_t)}+e^{-\gamma_s(z-z_t)}}{\gamma_t+\gamma_s} + \frac{e^{-\gamma_s(z-z_t)}-e^{-\gamma_t(z-z_t)}}{\gamma_t-\gamma_s}. \tag{A6}$$

Clearly, the preceding two cases can be summarized by use of the absolute value notation so that

$$\begin{aligned} f(z,z_t;\gamma_t,\gamma_s) &= \frac{e^{-\gamma_t|z-z_t|}+e^{-\gamma_s|z-z_t|}}{\gamma_t+\gamma_s} + \frac{e^{-\gamma_s|z-z_t|}-e^{-\gamma_t|z-z_t|}}{\gamma_t-\gamma_s} \\ &= \frac{2\gamma_t e^{-\gamma_s|z-z_t|}}{\gamma_t^2-\gamma_s^2} - \frac{2\gamma_s e^{-\gamma_t|z-z_t|}}{\gamma_t^2-\gamma_s^2} \\ &= \frac{2\gamma_t e^{-\gamma_s|z-z_t|}}{k_s^2-k_t^2} - \frac{2\gamma_s e^{-\gamma_t|z-z_t|}}{k_s^2-k_t^2}, \end{aligned} \tag{A7}$$

where we have made use of the definitions of γ so that $\gamma_t^2-\gamma_s^2=k_s^2-k_t^2$. The proof is complete.

(Received 29 November 2007; revised 27 February 2008; accepted 5 March 2008)

Most investigators emphasize the importance of detecting the reflected signal from the defect to determine if the pipe wall has any damage and to predict the damage location. However, often the small signal from the defect is hidden behind the other arriving wave modes and signal noise. To overcome the difficulties associated with the identification of the small defect signal in the time history plots, in this paper the time history is analyzed well after the arrival of the first defect signal, and after different wave modes have propagated multiple times through the pipe. It is shown that the defective pipe can be clearly identified by analyzing these late arriving diffuse ultrasonic signals. Multiple reflections and scattering of the propagating wave modes by the defect and pipe ends do not hamper the defect detection capability; on the contrary, it apparently stabilizes the signal and makes it easier to distinguish the defective pipe from the defect-free pipe. This paper also highlights difficulties associated with the interpretation of the recorded time histories due to mode conversion by the defect. The design of electro-magnetic acoustic transducers used to generate and receive the guided waves in the pipe is briefly described in the paper.

I. INTRODUCTION

Many catastrophic failures of gas and liquid transmission pipelines all over the world warrant more developments on reliable pipe inspection technology. A number of research papers have been published on various nondestructive evaluation techniques for early forecasting of the degradation process and for detecting existence of the mechanical defects in long pipelines. Cylindrical guided waves are useful for such defect detection and are becoming popular for pipe inspection.

Gazis[1,2] first analytically solved the harmonic wave propagation problem in an infinitely long elastic hollow cylinder. Greenspon[3,4] studied dispersion curves and displacement fields for an elastic cylindrical shell. Zemanek[5] presented numerical analyses of the frequency equation in an elastic cylinder. Some investigators[6,7] used guided wave modes for detecting wall thinning defects in cylindrical pipes. Cawley and co-workers[8–10] successfully used cylindrical guided waves for detecting crack and corrosion in pipes. Rose and co-workers[11,12] designed a special probe which can be used both as a transmitter and a receiver during the pipe inspection. Guo and Kundu[13,14] designed a new transducer holder mechanism for pipe inspection using cylindrical guided waves. Using those transducer holders, Na *et al.*[15–18] generated cylindrical guided waves in underwater pipes, concrete filled pipes, and steel bars embedded in concrete.

In most studies related to the pipe wall damage detection using guided waves investigators launched guided waves on the pipe and then let it propagate a long distance along the pipe before the wave is detected and analyzed. Received signal strengths are generally found to be different for defect-free and defective pipes. Thus comparing the received signal from a defect-free pipe one can conclude if the inspected pipe is defective. However, it will be shown in this paper that analysis and interpretation of the received signal from the defective pipe and detection of the small reflected signal from the defect are often not a trivial task. Difficulties associated with this interpretation and the technique to identify a defective pipe, even when the signal reflected from the defect is missed, are discussed below. In our experiment the guided wave is launched and recorded by electro-magnetic acoustic transducers (EMATs). One advantage of EMAT is that it does not need to be in direct contact with the pipe. Therefore, the pipe surface does not need to be very smooth and no coupling fluid between the transducer and the pipe is needed for launching the guided waves. It should be noted here that the ultrasonic piezoelectric transducers although preferred by many investigators, have a major shortcoming—they require either coupling fluids between the transducer and the pipe or a smooth pipe surface for the direct contact condition in the absence of any coupling medium.

II. EXPERIMENTAL INVESTIGATION

A. EMAT design

The electromagnetic field simulation program, "MAXWELL 2D" was used to model the optimal magnetic configu-

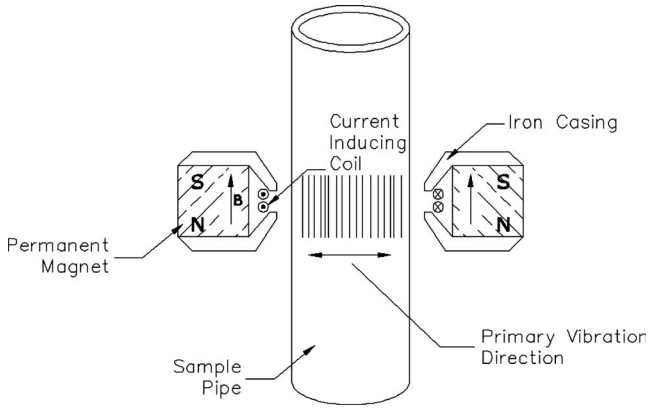

FIG. 1. Relative orientation of the electromagnetic acoustic transducer and the pipe. Note that the diagram shows the cross section of the EMAT which goes around the pipe.

ration for the EMAT. This finite element based program was used to create a two-dimensional model of the spatial distribution of the magnetic flux. The model of the EMAT is drawn on a two-dimensional plane which is intended for axisymmetric models. A typical drawing plane of the designed EMAT can be seen in Fig. 1, where the cross section is rotated about the axis of symmetry (z axis) in order to calculate the distribution of the magnetic induction.

Two shapes were considered for the EMAT design. The shape shown in Fig. 1 is the final shape used in the experiments. Note that this shape is different from the conventional EMAT design which uses only flat circular ferromagnetic disks. The conical shape of the disks of the EMAT shown in Fig. 1 increases the magnetic induction in the location of the coil. Computed results from the two designs are shown in Fig. 2. The simulation is based on the neodymium-iron-born (NdFeB) magnets with the outer and inner diameters equal to 60 and 20 mm, respectively, and the magnetization direction is along the positive Z axis. The magnetic induction distribution and the magnetic flux lines of the final design are shown in Figs. 3 and 4, respectively. Figure 5 shows the details of the EMAT assembly.

B. Specimens

Two different steel pipes—one is defect free and the second one is defective (dented)—are inspected. The two

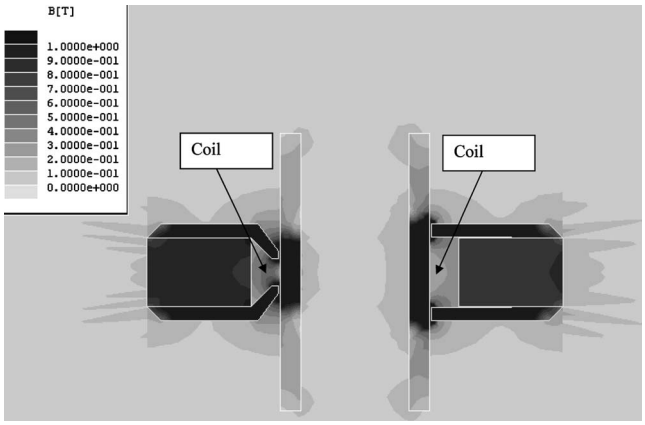

FIG. 2. Comparison of two designs of EMAT.

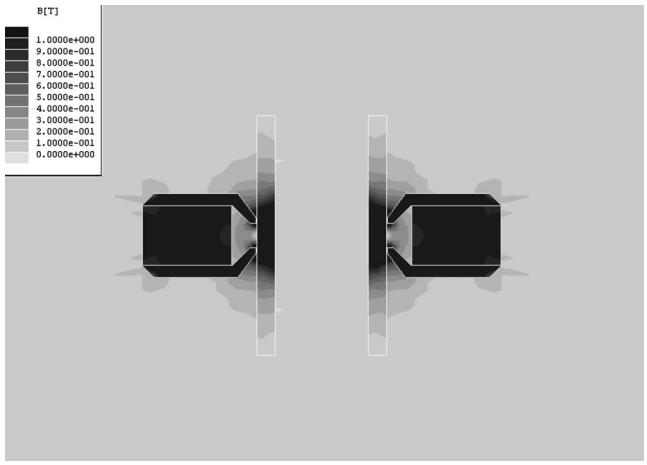

FIG. 3. Magnetic field distribution of the final EMAT design.

pipes have the same cross section; the outer and inner diameters of the pipes are 21.4 and 16.4 mm, respectively. The defect is fabricated by forming a dent (1 mm deep and 0.5 mm wide) along the circumference of a 6000-mm-long pipe. A dent is a localized depression or deformation in the pipe's cylindrical geometry resulting from an applied force.[17] Figure 6 shows the two pipes used in the experiment. These two pipes are denoted as (a) defect free and (b) defective pipes.

C. Experiment

Electromagnetic acoustic transducers (EMATs) were designed for exciting longitudinal wave modes in the pipe (see Fig. 1) as well as to receive the ultrasonic waves. EMATs were mounted on brass holders that helped to position the EMATs perpendicular to the pipe axis with a spacing of approximately 1 mm between the pipe wall and the EMAT. This position was fine tuned by small plastic screws in the brass holders (which were also the only points of contact between the entire EMAT system and the pipe). Figure 5 shows the details of the EMAT assembly. Digital oscilloscope TiePie Handyscope HS3 was used to generate chirp signals of varying frequencies controlled through the LABVIEW program written for this particular application. The signal generated by the transmitting EMAT propagated through the pipe and was received by the receiving EMAT. It was

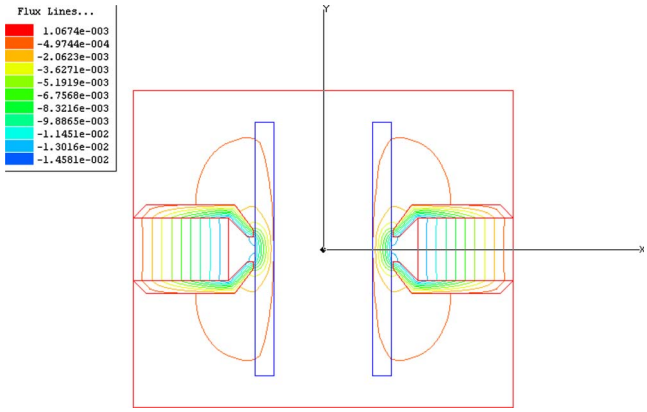

FIG. 4. (Color online) Flux line distribution of the final EMAT design.

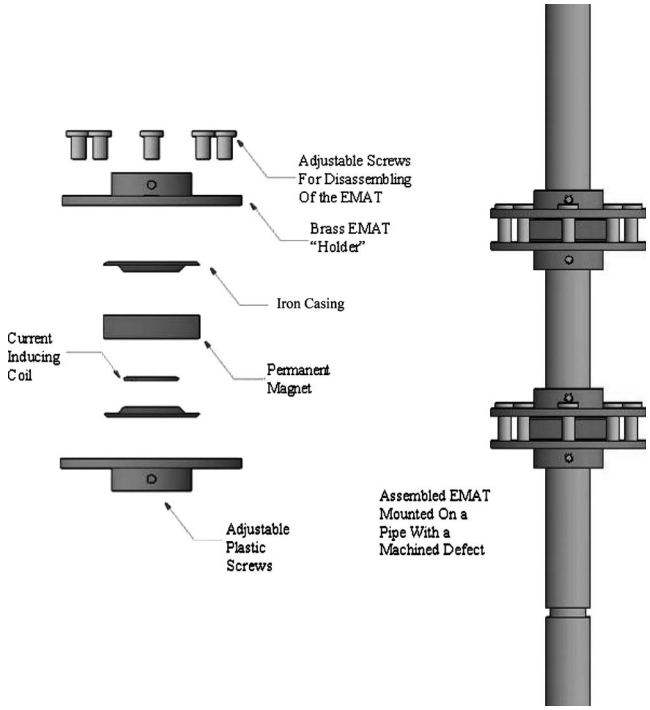

FIG. 5. Detailed diagram of the EMAT assembly.

then amplified by the Princeton Applied Research 113 Low Noise Preamplifier, digitized by the same Handyscope HS3 unit that was used to generate the signal, and displayed on the computer in the same LABVIEW program as a function of time, as well as a function of frequency. The signal strength for both time history and frequency spectrum was displayed in volts. The variation of the time versus signal strength is called time history or transient curve, and the variation of the signal amplitude versus frequency is called the spectral plots or the $V(f)$ curve. During the raw data collection, every time step was averaged by the program for at least 1024 times before being recorded to give a consistent value. Then it was analyzed in the new LABVIEW program created for the data analysis.

Figure 7 shows the experimental setup. The defect in the pipe is a total circumferential dent. EMAT to EMAT distance (dimension "b" in Fig. 7) is 2550 mm, EMAT to defect distance (dimension "d" in Fig. 7) is 250 mm, and the distance between the defect and the end of the pipe (dimension "c" in Fig. 7) is 1460 mm. A chirp signal with a frequency range of 100–150 kHz is sent to the transmitting EMAT. PAR 113 preamplifier has built-in low-pass and high-pass filters. The preamplifier amplifies signals in the frequency range

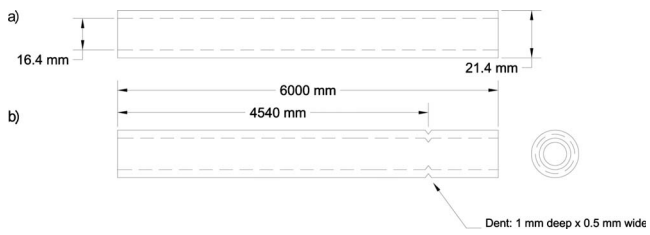

FIG. 6. Steel pipe specimens—(a) defect-free and (b) defective or dented pipe. Both pipes have the same inner and outer radii and length.

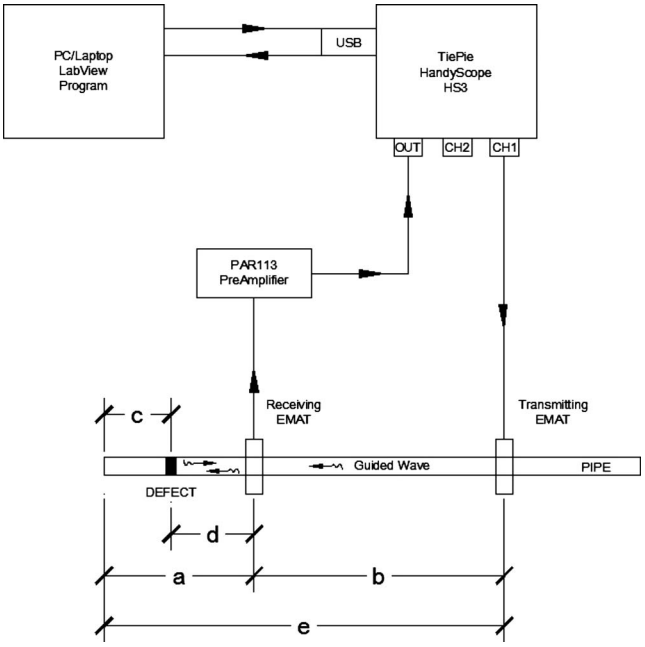

FIG. 7. Schematic of the experimental setup. Dimensions a, b, c, d and e are given in the text.

1–300 kHz. It magnifies the signal from the receiving EMAT ten thousand times. Excitation signal as well as the preamplifier setting stays the same for all experiments. Figure 8 shows the recorded time histories for the pipe with and without the defect. The first prominent peak is due to the radio frequency cross talk between the output and the input channels. Regions (1), (2), (3) and (4) marked in Fig. 8 are separately analyzed in the following section. Figures 9 through 12 show the $V(f)$ curves for Regions (1) through (4), respectively. The $V(f)$ curve for the entire recorded signal is plotted in Fig. 13.

III. ANALYSIS OF THE EXPERIMENTAL RESULTS

Time histories for defective and defect-free pipes shown in Fig. 8 clearly show significant differences. Therefore, the fabricated EMAT system used in this experiment is sensitive to the pipe wall defect. However, the time histories look very

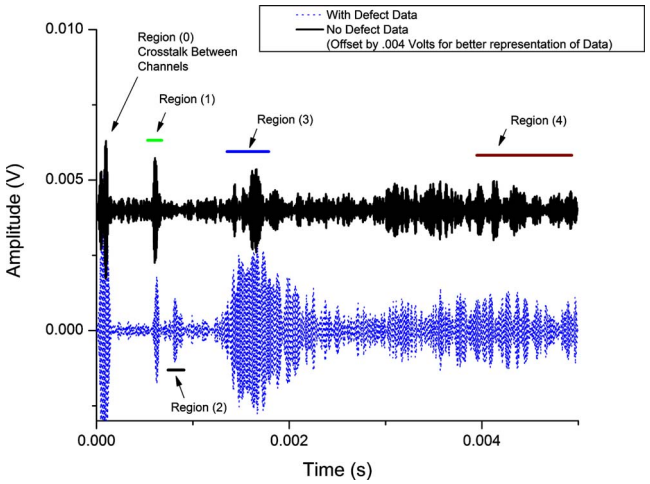

FIG. 8. (Color online) Recorded time histories for the defect-free and defective pipes.

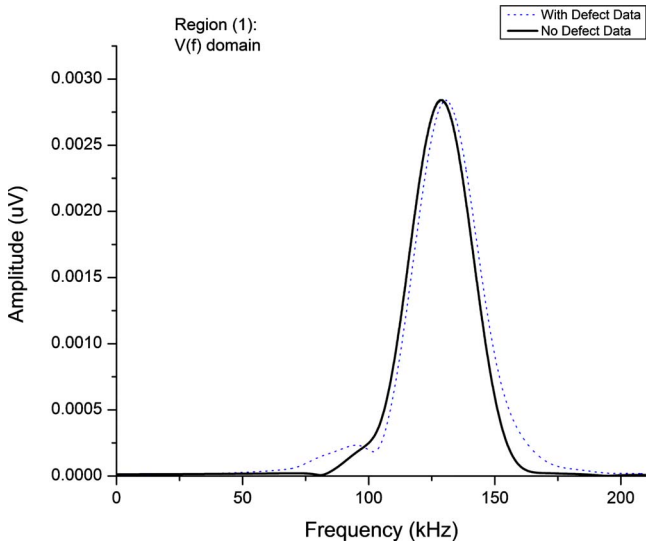

FIG. 9. (Color online) Spectral plots of Region 1 of the time histories shown in Fig. 8.

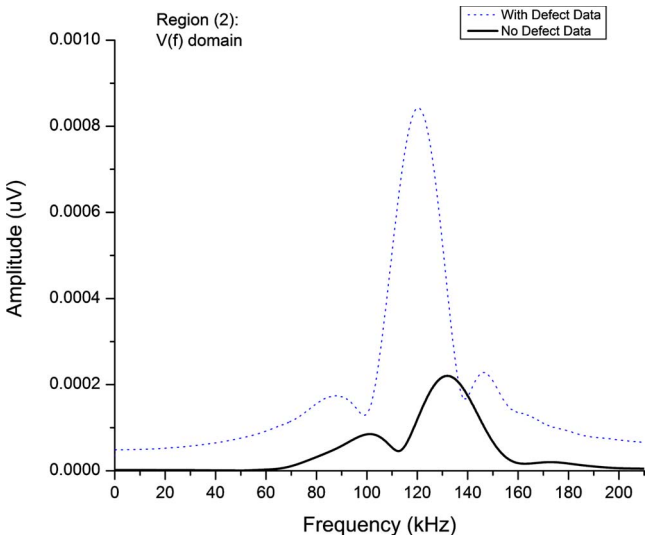

FIG. 10. (Color online) Spectral plots of Region 2 of the time histories shown in Fig. 8.

cumbersome and are not easy to interpret. The simple conclusion that can be drawn from these complicated plots is that the two time histories are significantly different. The first major peak [seen in Region (1)] in Fig. 8 appears at the same time in both time history plots. Spectral plots (see Fig. 9) of Region (1) show small differences between the defect-free and defective pipe signals. Therefore, this part of the signal must have been recorded before the wave encounters the defect and hence is not affected by the defect.

One clear distinction between these two time histories is that a relatively strong peak is observed in Region 2 for the defective pipe. Therefore, this peak must be the contribution of the defect. One can also observe a relatively strong packet of waves in the defective pipe signal in Region 3. To understand which peak corresponds to which guided wave mode, dispersion curves for the pipe are generated. Phase velocity and group velocity dispersion curves for $L(0,1)$ and $L(0,2)$ modes are shown in Fig. 14. Since the fabricated EMAT generates only the longitudinal wave modes in the frequency range 100–150 kHz, only $L(0,1)$ and $L(0,2)$ modes appear in the desired frequency range for the steel pipe considered here (P-wave speed=5.96 km/s, S-wave speed=3.26 km/s, density=7.932 gm/cm^3, outer diameter=21.4 mm and inner diameter=15.4 mm).

The group velocity of a propagating wave can be experimentally measured from the following equation

$$c_g(f) = \frac{s}{t}, \tag{1}$$

where group velocity c_g is a function of frequency f; s is the distance traveled by the wave and t is the time taken by the wave to travel the distance, s. Region 1 in Fig. 8 is where the first peak is observed. This peak corresponds to the wave traveling directly from the transmitting EMAT to the receiving EMAT. The time taken by this signal to travel a distance of 2550 mm is 0.524 ms (the distance between the cross talk region and Region 1 in Fig. 8) which gives the group velocity of 2.55/0.524=4.9 km/s. From Fig. 9, the dominant frequency at which this wave packet is propagating is found to be 130 kHz. Plotting these two values on the group velocity dispersion curves of Fig. 14, one can identify this wave mode as the $L(0,2)$ mode. Since $L(0,2)$ mode has higher velocity than $L(0,1)$ mode it arrives at the receiving EMAT first.

The peak in Region 2 of Fig. 8 appears only for the defective pipe. One can then conclude that this is the reflected signal from the defect. Since the distance between the receiving EMAT and the defect is 250 mm and the group velocity of $L(0,2)$ mode is 4.9 m/ms, the distance between the peaks of Regions 1 and 2 for the defective pipe should be 0.5/4.9 ms=0.102 ms if the wave travels twice the distance between the receiving EMAT and the defect as the L(0,2) mode. However, the measured time difference between these two peaks is found to be 0.189 ms in Fig. 8. This discrepancy can be explained in the following manner. If the wave travels from the EMAT to the defect as the $L(0,2)$ mode but returns to the EMAT as the slower $L(0,1)$ mode after being reflected by the defect, then the distance between the two peaks of Regions 1 and 2 should be greater than 0.102 ms. If the reflection by the defect causes mode conversion, then only such $L(0,2)$ to $L(0,1)$ mode conversion is possible.

The distance between the receiving EMAT and the defect is 250 mm. From Fig. 14 the group Velocity of $L(0,2)$ mode at 130 kHz is found to be 4.9 m/ms. Figure 10 shows that the peak value of the $V(f)$ curve for the defective pipe is between 110 and 120 kHz. At this frequency $L(0,1)$ mode has a group velocity of 1.8 m/ms. Therefore the total time taken by the wave to travel from the EMAT to the defect and back is

$$\frac{0.25}{4.9} + \frac{0.25}{1.8} = 0.051 + 0.138 = 0.189 \text{ ms}. \tag{2}$$

In Fig. 8, the time measured between Regions 1 and 2 is also found to be 0.189 ms. Therefore, it proves that the defect causes mode conversion. This problem can be reversed to calculate the distance of the defect from the EMAT, thus one

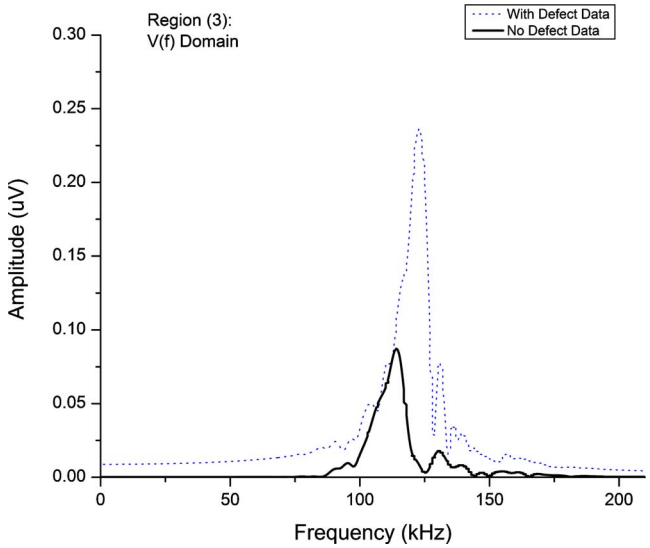

FIG. 11. (Color online) Spectral plots of Region 3 of the time histories shown in Fig. 8.

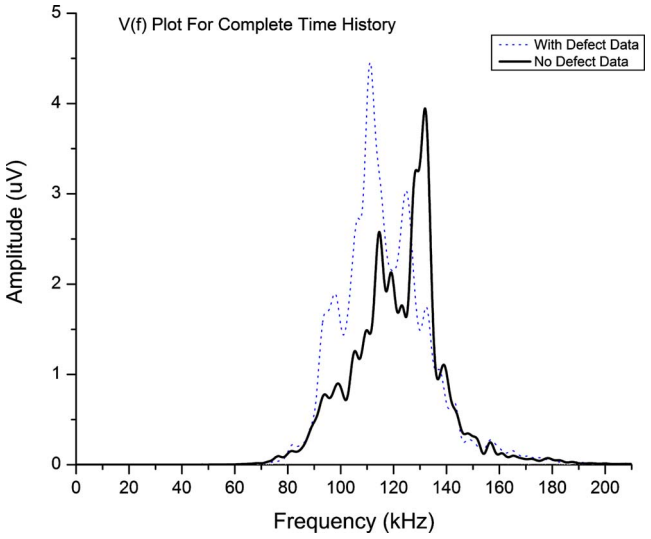

FIG. 13. (Color online) Spectral plots for the complete time histories of Fig. 8.

can predict the exact location of the defect in a pipe from the time of arrival of the reflected signal from the defect and knowing the modes of wave propagation between the receiving EMAT and the defect.

In the time history plots after Region 2, signals become quite complicated for defective and defect-free pipes after 1.4 ms time because $L(0,1)$ and $L(0,2)$ modes propagating directly from the transmitter to the receiver and those reflected from the pipe ends and the defect start overlapping. The recorded time history for the defective pipe appears to be more cumbersome because the defect causes mode conversion as well as reflection, transmission, and scattering of the ultrasonic energy. To investigate if any useful information can be extracted from the recorded signal beyond Region 2, frequency spectra of Regions 3, 4 and that of the complete and plotted in Figs. 11, 12, and 13, respectively.

Figure 11 shows that the spectral plot for the defective pipe is much greater than that for the defect-free pipe. The frequency corresponding to the highest peak is near 120 kHz for the defective pipe in both Figs. 10 and 11. Also, the peaks are higher for the defective pipe in both figures. However, the frequency corresponding to the highest peak for the defect-free pipe is close to 130 kHz in Fig. 10 and it is close to 115 kHz in Fig. 11. Clearly, the elastic waves generated by the defect have a strong influence on the time history signals in both Regions 2 and 3. Note that both have peaks near the same frequency (~120 kHz) and show much higher amplitude compared to that for the defect-free pipe. Therefore, even if someone misses the defect signal in Region 2 it is possible to identify the defective pipe from the spectral plots of Region 3.

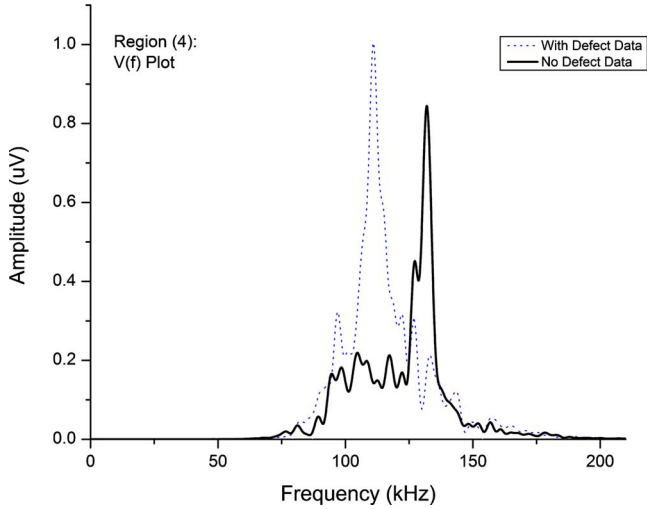

FIG. 12. (Color online) Spectral plots of Region 4 of the time histories shown in Fig. 8.

Next it is investigated if any consistent difference between the signals obtained from the defective and the defect-free pipes can be observed in the spectral plots from the time histories recorded well beyond the first arrivals of the reflected wave from the defect. With this goal in mind the $V(f)$ curves of Region 4 of Fig. 8 are plotted in Fig. 12. In Region 4, $L(0,1)$ and $L(0,2)$ modes and possibly some other modes generated by the defect strike the receiving EMAT multiple times after being reflected, transmitted, and scattered by the defect and the pipe boundaries multiple times. Therefore, in this region it is impossible to separately identify the contributions of different modes. However, the spectral plot shows a clear distinction between the defect-free and the defective pipe. The peak for the defective pipe is at 110 kHz while that for the defect-free pipe is at 130 kHz. The peak value for the defective pipe is also found to be slightly higher than that for the defective pipe. These two observations of Fig. 12 qualitatively agree with that in Fig. 10. Note that in Fig. 10 also a stronger peak at a lower frequency is observed for the defective pipe.

To investigate if this observation holds good if the spectral plots of the entire recorded time histories are compared, Fig. 13 is generated by taking the Fourier transform of the two time histories presented in Fig. 8. Note that although Figs. 12 and 13 are different, as one should expect, the strongest peak positions in both figures are observed at 110 kHz for the defective pipe and at 130 kHz for the defect-free

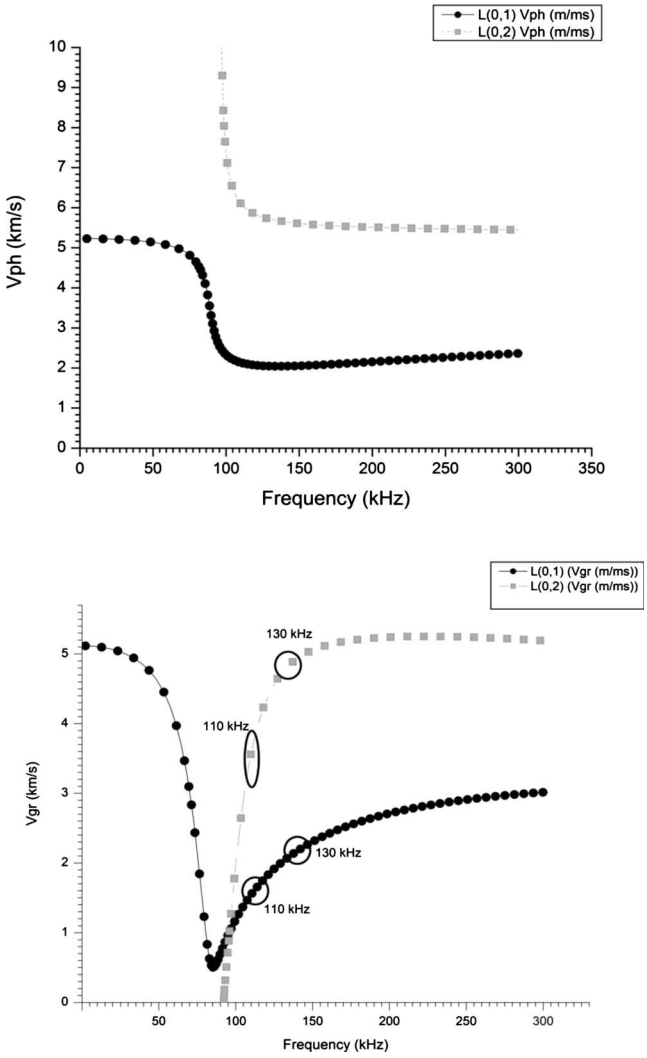

FIG. 14. Phase velocity (top) and group velocity (bottom) dispersion curves for the steel pipe.

pipe. The peak value for the defective pipe is stronger than that for the defect-free pipe in both figures. This is an important observation because it means that one can identify the defective pipe comparing the spectral plots of the complete time history (or that of the tail end, Region 4 of Fig. 8) without the need of pinpointing the exact position of the signal from the defect (Region 2 of Fig. 8) that may be hidden behind the noise level or other arriving modes for a different position of the defect or the receiving EMAT.

Justification of the frequency shift from 130 kHz for the defect-free pipe to 110 kHz for the defective pipe in Figs. 12 and 13 is given in the following. The mode conversion caused by the defect may explain this frequency shift. From the dispersion curves in Fig. 14, one can see that at frequencies greater than 100 kHz both $L(0,1)$ and $L(0,2)$ modes can exist in the pipe and that they have different phase and group velocities. Near 110 kHz, the curve for $L(0,2)$ mode has a steep slope that causes high dispersion. Therefore, the $L(0,2)$ mode traveling through the pipe near 110 kHz frequency is dispersed more than the $L(0,1)$ mode whose steep slope (high dispersion) is observed below 100 kHz. Therefore, if the defect generates $L(0,1)$ mode due to mode conversion then this mode can propagate multiple times through the pipe at 110 kHz without being significantly dispersed while the $L(0,2)$ mode at the same frequency decays sooner due to dispersion.

Identifying defective specimens by analyzing the reverberating tail end of the ultrasonic signal, also known as the diffuse ultrasonic signal,[19] has been attempted earlier. Michaels and Michaels[20] applied time domain differencing, spectrogram differencing, and local temporal coherence to diffuse ultrasonic waves in plates to identify defective plates in presence of temperature and environmental changes (wet and dry surface conditions). They found that time domain differencing and spectral analysis are generally ineffective in discriminating damage from environmental effects while local temporal coherence can successfully discriminate structural damage from both temperature change and modest change in the surface condition. Effect of the temperature and environmental change on the pipe damage detection capability using diffuse waves is currently under investigation. To the best of our knowledge this is the first attempt of using diffuse waves for pipe wall damage detection.

IV. CONCLUDING REMARKS

Longitudinal modes $L(0,1)$ and $L(0,2)$ of cylindrical guided waves have been generated and detected in a metal pipe by newly designed EMATs. Pipe dent could be easily detected by the EMAT.

In most guided wave based experiments one common question arises—what is the effect of reflection at the pipe ends on the defect detection capability? Often it is recommended that reflected waves from the pipe ends should be avoided as much as possible by truncating the signal right after the first arrival. However, in doing so slower modes are truncated. Also, often the small signal from the defect is hidden behind the other arriving modes and signal noise. To overcome the difficulties associated with identifying the small signal from the defect and truncating the signal right after the defect signal but before the arrival of the reflected signal from the pipe end, in this paper the signal is analyzed both before and well after different wave modes have propagated multiple times through the pipe. It is found that the defective pipe can be clearly identified by analyzing the signal well beyond the first arrival of the signal from the defect. Multiple reflections and scattering of the propagating wave modes by the pipe ends and the defects do not make the defect detection more difficult, on the contrary it apparently stabilizes the signal and consistent spectral plots clearly distinguish the defective pipe from the defect-free pipe. However, to predict the exact location of the defect the signal from the defect must be identified in the time history plots.

(Received 28 October 2007; revised 31 January 2008; accepted 15 February 2008)

The on-axis far-field pressure response of a circular membrane in an infinite baffle when driven by a uniformly distributed electrostatic force is calculated using two different trial functions for the surface velocity distribution. The first is an expansion based upon a solution to the free space wave equation in oblate spheroidal coordinates, which has already been derived in a previous paper [J. Acoust. Soc. Am. **120**(5), 2460–2477 (2006)], and the second is a membrane eigenfunction expansion (or Bessel series), which is rigorously derived in this letter. Although the latter can be used as a basis for calculating a number of different radiation characteristics such as the radiation impedance or directivity, etc., only the on-axis far-field sound pressure is considered here. The results are compared and discussed. © *2008 Acoustical Society of America.*

I. INTRODUCTION

In a previous paper,[1] the sound field of a circular membrane in an infinite baffle was calculated using a trial function for the surface velocity distribution based upon a solution to the free space wave equation in oblate spheroidal coordinates. No convergence problems were encountered because the chosen trial function has an inherent zero at the rim which matches the clamped rim boundary condition of the membrane. In a more recent paper,[2] the sound field of a shallow spherical shell was calculated, which differed from the membrane in that the surface velocity was non-zero at the rim. Initially, the authors tried using the spheroidal trial function, but encountered convergence problems because a very large number of terms were needed in the expansion in order to maintain the true non-zero velocity close to the rim where it is forced to zero by the trial function. Hence, an eigenfunction expansion based upon the solution to the wave equation of the shell itself was used instead. In this letter, this eigenfunction expansion method is retrospectively applied to the membrane and compared with the original spheroidal trial function. The authors originally obtained this result in order to verify the eigenfunction method before applying it to the shell. However, there are some differences in the derivations for the membrane and shell due to differences in their boundary conditions, as will be pointed out.

In Sec. II, both trial functions are presented in the form of summations with unknown coefficients. In Secs. III and IV, solutions to the free space and membrane wave equations respectively are given. In Sec. V, the solutions are then coupled and solved simultaneously in Sec. VI for the unknown trial function coefficients. Finally, in Sec. VII, expressions for the far-field sound pressure response are derived.

Electrostatic loudspeakers often have damping in the form of narrow sound holes in the electrodes which provide viscous losses in order to flatten what would otherwise be a highly modal response. The pressure response is calculated here without damping in order to obtain a response with strong modal features. This makes it easier to see whether the two calculation methods actually give the same results. Also, the lack of damping demonstrates more clearly the effect of coupling to the acoustic radiation load: Due to the radiation mass being considerably greater than the membrane mass, the modes are shifted downwards at low frequencies and the radiation resistance has a damping effect at high frequencies.

II. TRIAL FUNCTION

In the case of the membrane,[1] the following spheroidal trial function was used for the velocity distribution:

$$\tilde{u}_0(w_0) = \sum_{m=0}^{\infty} \tilde{A}_m \left(1 - \frac{w_0^2}{a^2}\right)^{m+(1/2)}, \tag{1}$$

where $\tilde{A}_m$ are the expansion coefficients (which have to be calculated), w_0 is the radial ordinate, and a is the radius of the membrane, as shown in Fig. 1. In the case of the shell,[2] an eigenfunction expansion was used instead, in order to guarantee convergence. A similar eigenfunction expansion can also be used as a trial function for a membrane as follows:

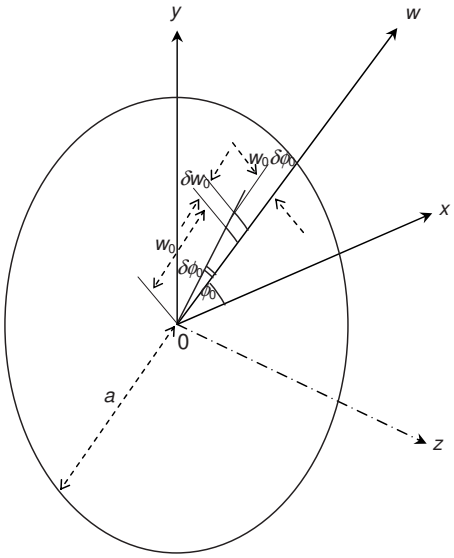

FIG. 1. Geometry of the membrane.

$$\tilde{u}_0(w_0) = \sum_{m=1}^{\infty} \tilde{A}_m J_0(\alpha_m w_0/a), \tag{2}$$

where α_m is the mth zero of $J_0(\alpha_m)$. However, this differs from the eigenfunction expansion for a shell in that a shell has bending stiffness which gives rise to a $I_0(\alpha_m w_0/a)$ term where I_0 is the Bessel function of the second kind. The shell also has a piston term which is proportional to the dome height. The uniform driving force is not expected to excite any axial modes, so only the 0th order Bessel function is included. Both of these trial functions satisfy the boundary condition of zero velocity at the rim of the membrane. The first is a solution to the wave equation for the surrounding medium to which the membrane is coupled and the second is a solution to the homogeneous wave equation for membrane itself. Only the latter is applied in this letter. In some ways, this method is slightly more direct because a set of simultaneous equations for the expansion coefficients is generated by simply equating the coefficients of $J_0(\alpha_n w/a)$ in the coupled equation. In the previous spheroidal derivation,[1] Eq. (1) was expanded as a Bessel series at one stage in order to generate the simultaneous equations. Both of these methods are fairly direct, though, and avoid the need for collocation or least squares minimization, which in turn leads to smaller errors and greater detail at high frequencies. Errors come mainly from the truncation of the expansion limits, as will be discussed.

III. SOLUTION TO THE FREE SPACE WAVE EQUATION

Using the King integral and doubling the amplitude due to the presence of the baffle, the pressure distribution is defined by

$$\tilde{p}(w,z) = 2\int_0^{2\pi}\int_0^a g(w,z|w_0,z_0) \times \frac{\partial}{\partial z_0}\tilde{p}(w_0,z_0)|_{z_0=0+} w_0 dw_0 d\phi_0, \tag{3}$$

where the Green's function is defined, in axisymmetric cylindrical coordinates, by

$$g(w,z|w_0,z_0) = \frac{i}{4\pi}\int_0^{\infty} J_0(\mu w)J_0(\mu w_0)\frac{\mu}{\sigma}e^{-i\sigma|z-z_0|}d\mu \tag{4}$$

and $\sigma=\sqrt{k^2-\mu^2}$, where k is the wave number given by $k=\omega/c=2\pi/\lambda$ and

$$\frac{\partial}{\partial z}\tilde{p}(w,z)|_{z=0\pm} = -ik\rho c\tilde{u}_0(w), \quad 0 \le w \le a, \tag{5}$$

where ρ is the density of air or any surrounding acoustic medium and c is the speed of sound in that medium. Inserting Eqs. (4) and (5) in Eq. (3) and integrating over the surface of the membrane while setting $z_0=0$ yields the sound pressure field as follows:

$$\tilde{p}(w,z) = ka\rho c\sum_{m=1}^{\infty}\tilde{A}_m\alpha_m J_1(\alpha_m) \times \int_0^{\infty}\frac{J_0(a\mu)J_0(\mu w)e^{-i\sigma z}}{(\alpha_m^2 - a^2\mu^2)\sigma}a\mu d\mu, \tag{6}$$

where the following identity[3] has been used:

$$\int_0^a J_0(\mu w_0)J_0(\alpha_m w_0/a)w_0 dw_0 = \frac{a^2}{\alpha_m^2 - a^2\mu^2}(\alpha_m J_0(a\mu)J_1(\alpha_m) - a\mu J_0(\alpha_m)J_1(a\mu)) \tag{7}$$

and taking into account that $J_0(\alpha_m)=0$. Let the power series coefficients $\tilde{A}_m$ be related to normalized dimensionless coefficients τ_m by

$$\tilde{A}_m = \tau_m\tilde{p}_I/(2\rho c), \tag{8}$$

where $\tilde{p}_I$ is the uniformly distributed driving pressure. Setting $z=0$ in Eq. (6) provides the surface pressure as follows:

$$\tilde{p}_+(w_0) = ka^2\frac{\tilde{p}_I}{2}\sum_{m=1}^{\infty}\tau_m\alpha_m J_1(\alpha_m)\int_0^{\infty}\frac{J_0(a\mu)J_0(\mu w_0)}{(\alpha_m^2 - a^2\mu^2)\sigma}\mu d\mu. \tag{9}$$

IV. SOLUTION TO THE MEMBRANE WAVE EQUATION

The solution[1] to the membrane wave equation $T(\nabla^2 - k_D^2)\tilde{\eta}(w) = \tilde{p}_+(w) - \tilde{p}_-(w) - \tilde{p}_I$, subject to the boundary conditions $\tilde{\eta}(a)=0$ and $\tilde{p}_+(w) = -\tilde{p}_-(w)$, is given by

$$\tilde{\eta}(w) = \frac{1}{T}\int_0^{2\pi}\int_0^a (2\tilde{p}_+(w_0) - \tilde{p}_I)G(w|w_0)w_0 dw_0 d\phi_0, \tag{10}$$

where $\nabla^2 = \partial^2/(\partial w^2) + w^{-1}\partial/(\partial w)$, $\tilde{\eta}(w)$ is the membrane deflection, T is the tension and k_D is the wave number of the membrane defined by $k_D=\omega\sqrt{\rho_D h/T}$, where ρ_D is the density

of the membrane and h is its thickness. The Green's function[4] for the membrane can be written suppressing the axial term in ϕ and ϕ_0 as follows:

$$G(w|w_0) = \frac{1}{\pi}\sum_{n=1}^{\infty} \frac{J_0(\alpha_n w/a)J_0(\alpha_n w_0/a)}{J_1^2(\alpha_n)(\alpha_n^2 - k_D^2 a^2)}, \quad 0 \le w \le a. \tag{11}$$

V. FORMULATION OF THE COUPLED PROBLEM

Substituting Eqs. (9) and (11) in Eq. (10) and equating the deflection with that given in Eq. (2) (where $\tilde{\eta}(w) = -i\tilde{u}_0(w)/kc$) leads to the following coupled equation (after integrating over the surface):

$$\frac{1}{\alpha_n J_1(\alpha_n)} = -i\tau_n \frac{\alpha_n^2 - k_D'^2 a^2}{4ka^2\rho c^2} T + ka\sum_{m=1}^{\infty} \tau_m \int_0^{\infty} \frac{\alpha_m \alpha_n J_0^2(a\mu) a\mu}{(\alpha_m^2 - a^2\mu^2)(\alpha_n^2 - a^2\mu^2)\sigma} d\mu, \tag{12}$$

which is obtained by equating the coefficients of $J_0(\alpha_n w/a)$ and again using the identity of Eq. (7) together with[5] $\int_0^a J_0(\alpha_n w_0/a) w_0 dw_0 = a^2 J_1(\alpha_n)/\alpha_n$.

VI. CALCULATION OF THE POWER SERIES COEFFICIENTS

A. Final set of simultaneous equations

From Eq. (12), the following set of M simultaneous equations in τ_m can be written

$$\sum_{m=1}^{M} {}_m\Psi_n(k_D' a, ka)\tau_m = 1, \quad n = 1,2,\ldots,M, \tag{13}$$

where ${}_m\Psi_n$ is an element of the mth column an nth row of the $M \times M$ matrix given by

$${}_m\Psi_n(k_D' a, ka) = \alpha_n J_1(\alpha_m)\left(-\frac{ika(\alpha_n^2 - k_D'^2 a^2)}{2\alpha^2(ka)}\delta_{mn} + \alpha_m \alpha_n I(k,m,n)\right), \tag{14}$$

where δ_{mn} is the Kronecker delta function and the infinite series limit has been truncated to order M. The dimensionless parameter α is the fluid-loading factor given by $\alpha(ka) = kac\sqrt{2a\rho/T}$. The integral $I(k,m,n)$ is defined by $I(k,m,n) = I_F(k,m,n) + iI_I(k,m,n)$, where

$$I_F(k,m,n) = ka\int_0^k \frac{J_0^2(a\mu)a\mu}{(\alpha_m^2 - a^2\mu^2)(\alpha_n^2 - a^2\mu^2)\sqrt{k^2 - \mu^2}} d\mu, \tag{15}$$

$$I_I(k,m,n) = -ka\int_k^{\infty} \frac{J_0^2(a\mu)a\mu}{(\alpha_m^2 - a^2\mu^2)(\alpha_n^2 - a^2\mu^2)\sqrt{\mu^2 - k^2}} d\mu. \tag{16}$$

It can be seen that the numerators and denominators of these integrals are simultaneously zero when $\alpha_m = a\mu$ or $\alpha_n = a\mu$, so these are indeterminate points. Using Taylor's series, it can be shown that the functions are actually continuous. Hence, the integrals can be solved numerically so long as these indeterminate points are avoided. Also, the weak singularity at $\mu = k$ can be removed by means of suitable substitutions, as shown in the following sections. However, the integrands are strongly oscillatory and the integral I_I has an infinite limit. Therefore, it is more efficient to solve these integrals analytically to yield fast converging expansions.

B. Solution of the finite integral

After substituting $\mu = k\sqrt{1-t^2}$, Eq. (15) for the finite integral becomes

$$I_F(k,m,n) = \int_0^1 \frac{k^2 a^2 J_0^2(ka\sqrt{1-t^2})}{(\alpha_m^2 - k^2a^2(1-t^2))(\alpha_n^2 - k^2a^2(1-t^2))} dt. \tag{17}$$

The Bessel functions can then be expanded using the following Lommel expansion:[6]

$$J_0(ka\sqrt{1-t^2}) = \sum_{p=0}^{\infty} \frac{J_p(ka)}{p!}\left(\frac{ka}{2}\right)^p t^{2p}, \tag{18}$$

so that the expanded integral can be written

$$I_F(k,m,n) = k^2a^2 \sum_{p=0}^{\infty}\sum_{q=0}^{\infty} \frac{J_p(ka)J_q(ka)}{p!\,q!}\left(\frac{ka}{2}\right)^{p+q} \times \int_0^1 \frac{t^{2p+2q}}{(\alpha_m^2 - k^2a^2(1-t^2))(\alpha_n^2 - k^2a^2(1-t^2))} dt. \tag{19}$$

After solving the integral,[3] and truncating the infinite expansion limits to P and Q, the final expression can be written

$$I_F(k,m,n)|_{m\neq n} = k^2a^2 \sum_{p=0}^{P}\sum_{q=0}^{Q} \frac{J_p(ka)J_q(ka)}{p!\,q!\,(2p+2q+1)(\alpha_m^2 - \alpha_n^2)} \times \left(\frac{ka}{2}\right)^{p+q} \left\{ \frac{1}{k^2a^2 - \alpha_m^2} {}_2F_1\left(1, u-1; u; \frac{k^2a^2}{k^2a^2 - \alpha_m^2}\right) - \frac{1}{k^2a^2 - \alpha_n^2} {}_2F_1\left(1, u-1; u; \frac{k^2a^2}{k^2a^2 - \alpha_n^2}\right)\right\}, \tag{20}$$

where $u = p+q+3/2$ and which is valid for $m \neq n$. It can be seen that if $m=n$, then $\alpha_m^2 - \alpha_n^2 = 0$, which leads to a singular expression. In the case of the shell, this problem did not arise due to the presence of damping resistance in the boundary conditions, which gave rise to complex eigenvalues so that the difference between the squares of two complex conjugate eigenvalues was non-zero. Here, for $m=n$ the following alternative expression has to be used:

$$I_F(k,m)|_{m=n} = k^2a^2 \sum_{p=0}^{P}\sum_{q=0}^{Q} \frac{J_p(ka)J_q(ka)}{p!\,q!\,(2p+2q+1)(k^2a^2 - \alpha_m^2)^2} \times \left(\frac{ka}{2}\right)^{p+q} {}_2F_1\left(2, u-1; u; \frac{k^2a^2}{k^2a^2 - \alpha_m^2}\right). \tag{21}$$

C. Solution of the infinite integral

After substituting $\mu = k\sqrt{t^2+1}$, Eq. (16) for the finite integral becomes

$$I_I(k,m,n) = -\int_0^\infty \frac{k^2a^2J_0^2(ka\sqrt{t^2+1})}{(\alpha_m^2 - k^2a^2(t^2+1))(\alpha_n^2 - k^2a^2(t^2+1))}dt. \tag{22}$$

The Bessel functions can then be expanded using Gegenbauer's summation theorem[5] as follows:

$$J_0(ka\sqrt{t^2+1}) = 2\sum_{p=0}^{\infty} \frac{(-1)^p}{1+\delta_{p0}} J_{2p}(ka)J_{2p}(kat), \tag{23}$$

so that the expanded integral can be written

$$I_I(k,m,n) = -4k^2a^2 \sum_{p=0}^{\infty}\sum_{q=0}^{\infty} \frac{(-1)^{p+q}J_{2p}(ka)J_{2q}(ka)}{(1+\delta_{p0})(1+\delta_{q0})} \times \int_0^\infty \frac{J_{2p}(kat)J_{2q}(kat)}{(\alpha_m^2 - k^2a^2(t^2+1))(\alpha_n^2 - k^2a^2(t^2+1))}dt. \tag{24}$$

After solving the integral,[3] and truncating the infinite expansion limits to P and Q, the final expression can be written

$$I_I(k,m,n)|_{m\neq n} = -\frac{ka}{\pi}\sum_{p=0}^{P}\sum_{q=0}^{Q} \frac{J_{2p}(ka)J_{2q}(ka)}{(1+\delta_{p0})(1+\delta_{q0})(v-2)_2(u-2)_2(\alpha_m^2-\alpha_n^2)} \times \left\{ {}_3F_4\left(1,1,\frac{3}{2};3-u,u,3-v,v;k^2a^2-\alpha_m^2\right) - {}_3F_4\left(1,1,\frac{3}{2};3-u,u,3-v,v;k^2a^2-\alpha_n^2\right)\right\}, \tag{25}$$

where $u=p+q+3/2$, $v=p-q+3/2$ and which is valid for $m\neq n$. Again, in order to avoid singularities, for $m=n$ the following alternative expression is provided:

$$I_I(k,m)|_{m=n} = \frac{3ka}{2\pi}\sum_{p=0}^{P}\sum_{q=0}^{Q} \frac{J_{2p}(ka)J_{2q}(ka)}{(1+\delta_{p0})(1+\delta_{q0})(u-3)_4(v-3)_4} \times {}_3F_4\left(2,2,\frac{5}{2};4-u,u+1,4-v,v+1;k^2a^2-\alpha_m^2\right). \tag{26}$$

It should be noted that in the case of the shell,[2] the solution to the infinite integral also contained Bessel functions of the second kind, in addition to the hypergeometric functions, due to the eigenvalues being complex. Here they are real, so those Bessel functions would not be valid and have been removed in order to obtain the correct result.

VII. FAR FIELD PRESSURE RESPONSE

The far field pressure is derived by inserting the following far-field Green's function in spherical-cylindrical coordinates

$$g(r,\theta,\phi|w_0,\phi_0,z_0) = \frac{1}{4\pi r}e^{-ik(r-w_0\sin\theta\cos(\phi-\phi_0)-z_0\cos\theta)} \tag{27}$$

in Eq. (3) and integrating over the surface of the membrane to obtain

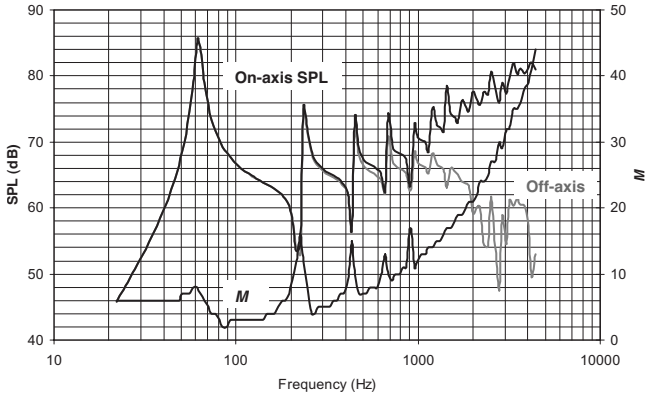

FIG. 2. On-axis and 45° off-axis pressure responses and summation limit M using the spheroidal trial function of Eq. (1), where $a=125$ mm, $h=12$ μm, $T=100$ N/m, $\rho_D=1667$ kg/m^3, $p_I=1$ Pa, and $r=1$ m.

$$\tilde{p}(r,\theta) = -\frac{ia}{4r}\tilde{p}_I e^{-ikr}D(\theta), \tag{28}$$

where r is the distance from the origin to the observation point and θ is the angle subtended to the axis of symmetry. The directivity function $D(\theta)$ is given by

$$D(\theta) = 2ka\sum_{m=1}^{M} \frac{\alpha_m J_1(\alpha_m)J_0(ka\sin\theta)}{\alpha_m^2 - (ka\sin\theta)^2}\tau_m. \tag{29}$$

For $\theta=0$ (i.e., on axis), this simplifies to

$$D(0) = 2ka\sum_{m=1}^{M} \frac{J_1(\alpha_m)}{\alpha_m}\tau_m. \tag{30}$$

The on-axis pressure response without damping is shown in Fig. 3 where the sound pressure level (SPL) is given by: $SPL=20\log_{10}|\tilde{p}(r,0)/(20\times10^{-6})|$. Figure 2 shows the response calculated using the surface-velocity trial function given in Eq. (1) and the far-field expression given in the previous paper.[1] The summation limit M is shown for each of the 114 points plotted. The summation limit was determined using a convergence criterion of 0.002 dB maximum difference between the SPL computed with M and $(M+1)$ terms. The remaining summation limits P and Q were set to $P=Q=2M$.

VIII. DISCUSSION OF THE RESULTS

The on-axis pressure responses shown in Figs. 2 and 3 are fairly typical of clamped membranes and plates in general. At the eigenfrequencies the membrane's displacement becomes very large. When most of the membrane's surface is moving in the same direction, large peaks are produced. Also, there are frequencies at which the displacement is still large, but different regions of the membrane are moving in opposite directions so as to cancel each other out: Instead of radiating sound, air is just moved back and forth between the areas of the surface that are moving in opposite phase. An excellent illustration of this has been provided by Streng.[7] The damping effect of the increasingly resistive radiation impedance at high frequencies is fairly evident. The direct nature of calculation method shows considerable detail in this region, enabled by the elimination of collocation or least

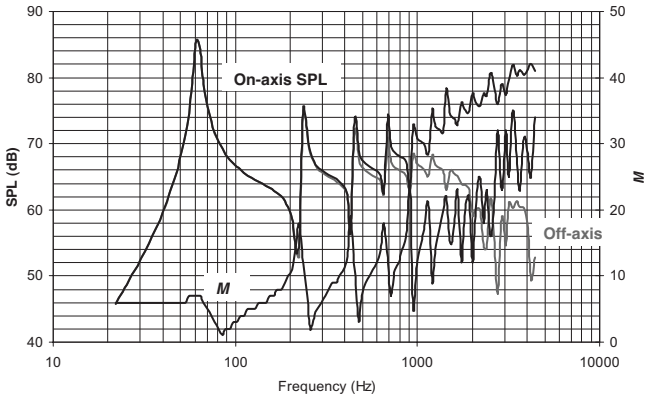

FIG. 3. On-axis and 45° off-axis pressure responses and summation limit M using the eigenfunction-expansion trial function of Eq. (2) with same parameters as Fig. 2.

squares methods. The actual differences between the pressures in Figs. 2 and 3 are fairly small. On axis, the maximum difference is 0.03 dB, rising to 0.1 dB at 45° off axis. As expected, the off axis response rolls off early due to high-frequency beaming, but still shows significant modal variations.

Also shown in these figures are the numbers of terms in the summations required to meet the convergence criterion of less than 0.002 dB difference in SPL when one extra term is added to the summation. Not surprisingly, it can be seen that generally more terms are required at higher frequencies due to the increasing complexity in the displaced membrane shape. Also, more terms are required at the eigenfrequencies because the driving force and acoustic pressure are distributed in such a way that excites not just that particular eigenfrequency, but a complex mixture of higher order modes too. Interestingly, fewer terms are required in the case of the eigenfunction method in between the eigenfrequencies, so here it must provide a more natural fit to the displaced shape. However, at the eigenfrequencies, the summation limit tends to be slightly greater than with the spheroidal method.

Regarding the speed of the calculations, this would of course vary considerably depending on whether a compiled or non-compiled program is used, numerical algorithms, type of hardware and other factors too. Suffice to say that the spheroidal method was found to be about ten times faster. This is mainly due to the fact that the hyperbolic functions in Eqs. (21) and (26) are functions of both p and q in the double summations, whereas in the case of the spheroidal method[1] the hypergeometric function is a function of q only.

IX. CONCLUSIONS

An alternative method has been presented for calculating the radiation characteristics of a membrane using a trial function based upon an eigenfunction expansion. This method, like the previous one which used a spheroidal trial function, does not require numerical integration.

Since the two methods give SPL values within 0.03 dB of each other on axis, it is not possible to state that one is necessarily more accurate than the other, but the fact that the two results are so consistent means that neither is likely to be wildly inaccurate.

The simpler formulas provided by the spheroidal series make it easier to derive expressions for other radiation characteristics such as the near field pressure and radiation impedance. Unfortunately, it appears to be restricted to cases where the surface velocity/deflection is either zero[1] or infinity[8] at the rim, such as circular membranes,[1] sound holes,[8] and clamped or simply supported plates and shells. Otherwise, for a finite rim velocity, the eigenfunction expansion has to be used. Examples of the latter are circular plates or shells[2] with non-zero rim velocity as in dynamic loudspeakers, earpieces and microphones, where the contribution of the surround is ignored (but its stiffness can still be included in the boundary conditions[2]). The rim velocity boundary condition affects the modal structure which, in turn, affects the computed sound pressure. Although the eigenfunction method is slower and therefore less attractive for the current problem, it has been verified and can therefore be applied with confidence to other uses where the spheroidal method is unsuitable.

Calculations of modes in circumferentially nonuniform lined ducts

WenPing Bi[a)]
Laboratoire d'Acoustique de l'Université du Maine, UMR CNRS 6613, Faculté des sciences, 72085 Le Mans, France

(Received 28 June 2007; revised 15 January 2008; accepted 24 February 2008)

This paper proposes a computationally efficient method of determining eigenfunctions and eigenvalues of acoustic modes propagating in circular lined ducts with zero or uniform flow. Linings with circumferentially nonuniform impedance, as found in nacelle acoustics, are the focus. The method of solution adapts in two important respects—the presence of flow and the imposition of impedance boundary conditions—the series expansion method first proposed by Pagneux *et al.* [J. Acoust. Soc. Am. **110**, 1307–1314 (2001)] to calculate the eigenvalues of Lamb modes. The inclusion of flow, and a corresponding different method of solution leading to an improved convergence of eigenvalues ($O(N^{-5})$, N is the truncation of radial basis of expansion), is the important new feature as compared to the previous adaptation by Bi *et al.* [J. Acoust. Soc. Am. **122**, 280–291 (2007)]. As a result, it becomes possible to safely determine and in a simple manner the eigenvalues and eigenfunctions of circumferentially nonuniform lined ducts in the presence of uniform flow, up to relatively high frequencies (e.g., $30<kR<80$). All required eigenvalues are calculated at a time and no initial values guesses are needed. Results are presented and the method is discussed. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2897105]

I. INTRODUCTION

Determining the modal solutions is a very useful step in developing an understanding of sound propagation and attenuation in lined ducts with or without flow. The imaginary part of the axial wave number determines the rate of attenuation. The maximum attenuation is found for an impedance leading to the coalescence of two or more modes.[1] However, the determination of all different modes is generally difficult. As quoted in Astley *et al.*,[2] "The evaluation of the eigenvectors even for ducts of separable geometry, is a nontrivial exercise, particularly when flow is present. Surface modes exist for particular ranges of wall impedance, and the development of robust methods which are able to resolve all of the modes all of the time is not a simple matter." When the lining impedance is circumferentially nonuniform, especially when it is piecewise constant or includes small rigid splices, and when the frequency is relatively high, say the dimensionless frequency $30<K<80$, which are typical cases of interest in the lined intakes of an aeroengine, the calculations of modes are still not well resolved.

Calculations of modes in lined ducts (with uniform mean flow given by Mach number Ma_0) mean solving the following Laplacian eigenvalue problem:

$$\Delta_\perp \phi_i = -\gamma_i^2 \phi_i, \tag{1}$$

with the wall boundary condition[3]

$$\frac{\partial \phi_i}{\partial r} = Y(\theta)\left(1 - \mathrm{Ma}_0 \frac{K_{z,i}}{K}\right)^2 \phi_i, \quad \text{at } r = 1, \tag{2}$$

where

$$\Delta_\perp = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2}{\partial \theta^2}, \tag{3}$$

$K=2\pi fR/c$ refers to the dimensionless frequency, f is frequency, R is radius, c is sound velocity in air, γ_i and ϕ_i refer to the transverse wave numbers and eigenfunctions respectively, $\gamma_i^2=(K-\mathrm{Ma}_0K_{z,i})^2-K_{z,i}^2$, $K_{z,i}$ are the axial wave numbers, $Y(\theta)=-jK\beta(\theta)$, and $\beta(\theta)$ is the liner admittance which can vary arbitrarily around the duct wall.

The equations are simple, but not evident to solve without resorting to purely numerical techniques. When the admittance β is uniform along θ, the dispersion relation equation can be written explicitly. Root finding methods, e.g., Newton–Raphson iteration, are generally used to solve it, after supposing some initial roots. In general, initial roots are unknown. Thus, in practice one often attributes a factor to the admittance of the lining, which is then increased step by step, from zero value (rigid duct with known solutions) to unit value (lining duct), using the solution of the preceding step as the initial solution. Another method is to start the computation at low frequencies where the admittance generally tends to zero, and to track the solutions when the frequency is increased step by step. Eversman and Cook[4] changed the eigenvalue equation into a differential one which can be integrated by using the Runge–Kutta algorithm. Montetagaud *et al.*[5] used this method with a more precise step. Rienstra[6] identified the modes in ducts in two categories: The duct modes resulting from the finiteness of

[a)]Electronic mail: wenping.bi@univ-lemans.fr

the duct geometry, and the surface waves that exist only near the wall surface in a way essentially independent of the rest of the duct. He was interested in the high frequency regime, which corresponds to typical cases in the turbofan engine duct applications. He gave the areas in the complex impedance Z plane in which the surface waves exist. He proposed a routine in the complex Z plane from $Z=\infty$ to the sought value to trace the eigenvalue as a function of Z. He pointed out that when the sought Z value is in the areas where the surface waves will exist we have to make sure to pick up these eigenvalues.

Finite Element Method (FEM) or Galerkin method are also proposed to solve the eigenvalue problem. The first instances of FEM used to calculate flow duct modes were devised by Astley and Eversman[7,8] for circumferentially uniform lined ducts. Other examples for circumferentially nonuniform lined ducts can be found in Refs. 2, 9, and 10. The eigenfunctions are expanded in terms of a basis which is independent of the eigenvalues. The Helmholtz equation (1) with boundary condition (2) is projected over this basis and then diagonalized. Other methods, e.g., Refs. 11–16, used to solve the eigenvalue problem in lined ducts are reviewed in detail in Ref. 17.

Recently, a multimodal expansion method was developed by Pagneux and Maurel[18] to calculate the eigenvalue spectrum of Lamb waves. They expanded the eigenfunctions of Lamb waves over a complete set of orthogonal functions. Application of this expansion converts the eigenproblem of Laplace operator and boundary conditions to a generalized eigenvalue problem of a matrix. There is widely available software for solving this matrix eigenvalue problem. All the required eigenvalues are calculated at a time and no initial values guesses are needed.

We extend in the present paper Pagneux's method to the problem of the determination of modes with zero or uniform flow and for ducts lined with circumferentially nonuniform lining. This work is motivated by the applications in the lined intake of an aeroengine in which the dimensionless frequency K may be up to 80, hundreds of modes are needed to calculate, the lining impedance may be circumferentially nonuniform, particularly, it may be in segments, leading to mathematically discontinuous boundary conditions.

In order to valuably apply the method it is necessary to address, in a convenient manner, two problems posed by the nature of the boundary conditions, namely, their "impedance" nature and the presence in them of the squared axial wave number. The first problem was addressed in a previous paper.[17] Impedance boundary conditions are difficult to fulfill by using, as is usual, the complete and orthogonal set of rigid duct eigenfunctions, resulting in a "slow" convergence of the method. A simple way to circumvent this problem consists of subtracting to the field we want to determine, a part suitably chosen to carry the information of the impedance boundary. Thanks to this subtraction, the remaining field to be developed on the usual rigid duct modes now fulfill the hard-wall boundary conditions, leading to an improved convergence.

The second problem, the inclusion of uniform flow, is specifically addressed in the present paper. This inclusion imposes modifying in suitable manner the mathematical treatment, in such a way that the benefits of the improved convergence will not be lost in presence of flow.

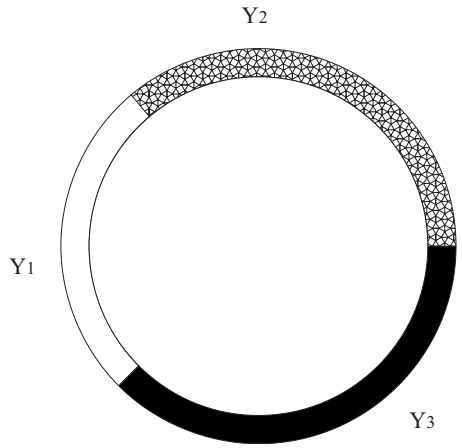

FIG. 1. A typical configuration of circumferentially nonuniform impedance boundary considered in this paper. Y_1, Y_2, and Y_3 are three segments of admittances.

The assumption of uniform flow, although being of course an important simplification, may provide useful insights on the main effects of flow. In practical applications the flow has a profile or may be more complicate. Including the shear flow in the present method, which will produce a continuous spectrum of hydrodynamic modes, is a very challenging work to be addressed in the future. At present time, precise numerical calculations of sound propagation in nonuniform lined ducts with true flow will take weeks or maybe more, even using huge computers. Those evaluations are only possible for some carefully chosen cases. The present method with the assumption of uniform flow may provide important information for those selections.

The paper is organized as follows. In Sec. II, the derivation of equations is presented for nonuniform boundary conditions. A validation of the method is presented in Sec. III. The convergence rates of eigenvalues and eigenfunctions are examined in Sec. IV. Then, in Sec V, some numerical examples are shown to illustrate the robustness of the method. In Sec. VI, we discuss two problem. In the first part, we show another important advantage of the method proposed in this paper. In the second part, we discuss a more general problem: The proper form of boundary conditions when the impedances are azimuthal discontinuous. Finally, conclusions are given in Sec. VII.

II. DERIVATION OF THE EQUATIONS

We consider a cylindrical lined duct of uniform cross section. The lining is assumed uniform along the duct axis z; at variance, any nonuniform lining pattern can be considered with respect to the azimuthal angle θ. A typical configuration is shown in Fig. 1. We wish to determine the possible modal solutions in this translational invariant lining duct in presence of a uniform flow. The sound propagation in air is assumed to be linear and lossless. Harmonic sound waves with a time factor $e^{j\omega t}$ are assumed.

The wanted eigenfunctions $\phi(r,\theta)$ may always be expanded in terms of the orthogonal and complete set of eigenfunctions $\Psi_{mn}=(1/\sqrt{\pi\Lambda_{mn}})(J_m(\alpha_{mn}r)/J_m(\alpha_{mn}))e^{-jm\theta}$ of the rigid duct, i.e.,

$$\phi(r,\theta)=\sum_{m=-\infty,n=0}^{\infty}\Phi_{mn}\Psi_{mn}(r,\theta), \tag{4}$$

where Λ_{mn} refer to the normalization coefficients, J_m is the m order bessel functions, α_{mn} is the solution of $\partial_r J_m(\alpha r)=0$ at $r=1$, m and n azimuthal and radial indices (the sum over index m will be suppressed in the case of circumferentially uniform impedance boundary condition). However, by definition these functions verify the boundary conditions $\partial_r\Psi_{mn}(r,\theta)|_{r=1}=0$. Thus, in order that ϕ may verify the wanted impedance boundary conditions (2), expansion (4) cannot be substituted directly in boundary condition (2) and derived term by term everywhere with respect to r. This means that the above expansion converges sufficiently slowly (with respect to index n) that the sum and derivative symbols do not commute. This suggests removing an arbitrary function $X(r,\theta)$, having nonzero derivative at $r=1$, before projecting as before over the Ψ_{mn}

$$\phi(r,\theta)-X(r,\theta)=\sum_{m=-\infty,n=0}^{\infty}\Phi_{mn}\Psi_{mn}(r,\theta). \tag{5}$$

This function will be chosen so as $\partial_r(\phi-X)|_{r=1}=0$, then ensuring that the expansion may be derived term by term, signature of an improved convergence [which will be of the type $O(n^{-4})$]. Then writing function $X(r,\theta)$ in the form (circumferentially nonuniform impedance boundary conditions)

$$X(r,\theta)=\sum_{m=-\infty}^{\infty}A_m\chi_m(r)e^{-jm\theta}, \tag{6}$$

with

$$\left.\frac{d\chi_m(r)}{dr}\right|_{r=1}=1, \tag{7}$$

it will be possible to arrange a choice of the A_m satisfying the condition $\partial_r(\phi-X)|_{r=1}=0$. In fact, as the left-hand side of Eq. (2) is determined by the $X(r,\theta)$ term only, this term need not appear in the right-hand side and our calculations will be simpler if we require additionally

$$\chi_m(r)|_{r=1}=0. \tag{8}$$

Notice that this is different from Ref. 17 where this condition is necessary.

A convenient choice for the $\chi_m(r)$ is then the following:

$$\chi_m(r)=B_m J_m(\beta_{m,0}r), \tag{9}$$

where $\beta_{m,0}$ is the first root of

$$J_m(\beta_m)=0, \tag{10}$$

and

$$B_m=\frac{-1}{\beta_{m,0}J_{m+1}(\beta_{m,0})}. \tag{11}$$

In Ref. 17, we consider a problem of propagation in the case of zero flow, we proceed by directly exploiting boundary condition (2). Substituting Eq. (5) in condition (2) and using conditions (7) and (8) and $\partial_r\Psi_{mn}(r,\theta)|_{r=1}=0$, yield the A_m in terms of the expansion coefficients Φ_{mn} [see Eqs. (17) and (27) in Ref. 17]. This leads to an expansion of eigenfunctions as [Eqs. (22) and (28) in Ref. 17]

$$\phi(r,\theta)=\mathbf{\Psi}^T\mathsf{M}\mathbf{\Phi}, \tag{12}$$

and a generalized eigenvalue problem of a matrix A_0 [Eqs. (24) and (30) in Ref. 17],

$$K_z^2\mathsf{M}\mathbf{\Phi}=\mathsf{A}_0\mathbf{\Phi}, \tag{13}$$

where matrices M and A_0 (A in Ref. 17) can be found in Ref. 17 by Eqs. (23), (25), (29), and (31). $\mathbf{\Phi}$ and $\mathbf{\Psi}$ are column vectors of dimension N_t, their elements are Φ_{mn} and Ψ_{mn}. $N_t=M\times N$, M and N are the truncations of indices m and n.

On the other hand, when the uniform flow is included, a multiplicative factor $(1-\mathrm{Ma}_0K_{z,i}/K)^2$ appears in the corresponding relations, showing that the A_m are now polynomial expressions of order two on the axial wave number $K_{z,i}$. Thus, if we were to proceed like in Ref. 17 [directly expressing the A_m from condition (2), substituting Eqs. (5) and (6) into Eq. (1) and projecting the latter over Ψ_{mn}] we would obtain a system of algebraic equations of order four with respect to $K_{z,i}$ (instead of order 2). This would require much computer memory to solve and the benefits of the introduction of the $X(r,\theta)$ term for an improved convergence would be lost.

Thus, in contrast to Ref. 17, we will not express A_m from the outset of the calculation. We instead follow the idea of Attanassoulis and Belibassakis[19] which keeps A_m as a set of unknown variables. Additional M equations are needed to calculate A_m, where M is the truncation number of index m. These will be the M equations obtained by projecting both sides of Eq. (1) over the (mutually orthogonal) $\chi_m(r)e^{-jm\theta}$. In the following, we consider the general case of uniform flow and nonuniform admittance $Y(\theta)$. The case of zero flow and/or uniform admittance are straightforward simplifications.

Let us project $\phi(r,\theta)$ over the basis Ψ_{mn} and the set of functions $\chi_m e^{-jm\theta}$. Following the matricial terminology, we yield

$$\int\phi(r,\theta)\mathbf{\Psi}^*dS=\mathbf{\Phi}+\mathbf{\Xi}\mathbf{A}, \tag{14}$$

$$\int\phi(r,\theta)\chi^*dS=\mathbf{\Xi}^T\mathbf{\Phi}+2\pi\mathbf{\Pi}\mathbf{A}, \tag{15}$$

where $\mathbf{\Xi}$ is a block diagonal matrix of dimension $N_t\times M$. In each block m of matrix $\mathbf{\Xi}$, it is a column vector of dimension N, its elements are $2\sqrt{\pi}/(\sqrt{\Lambda_{mn}}(\alpha_{mn}^2-\beta_{m,0}^2))$, with $n=1,2,\ldots,N$. Π is a diagonal matrix, $\|\chi_m\|^2=1/(2\beta_{m,0}^2)$ are in its main diagonal. $\mathbf{A}$ and χ are column vectors of dimension M, their elements are A_m and $\chi_m e^{-jm\theta}$. The superscript T and asterisk indicate the transpose and complex conjugate, respectively. The detailed derivation of Eqs. (14) and (15) are

shown in the Appendix. Equations (14) and (15) are combined to yield

$$\int \phi(r,\theta)\mathbf{\Psi}_{\mathbf{A}}^{*}dS = \mathsf{M}_1\mathbf{\Phi}_{\mathbf{A}}, \tag{16}$$

where

$$\mathbf{\Phi}_{\mathbf{A}} = \begin{bmatrix} \mathbf{\Phi} \\ \mathbf{A} \end{bmatrix}, \quad \mathbf{\Psi}_{\mathbf{A}} = \begin{bmatrix} \mathbf{\Psi} \\ \chi \end{bmatrix}, \tag{17}$$

M_1 is a $(N_t+M)\times(N_t+M)$ matrix, it is expressed as

$$\mathsf{M}_1 = \begin{bmatrix} \mathsf{I} & \Xi \\ \Xi^T & 2\pi\Pi \end{bmatrix}, \tag{18}$$

where I refers to identity matrix $(N_t\times N_t)$.

Using Eq. (16), we project Eq. (1), to yield (see the Appendix)

$$(\mathsf{A}_1K_{z,i}^2 + \mathsf{A}_2K_{z,i} + \mathsf{A}_3)\mathbf{\Phi}_{\mathbf{A}} = 0, \tag{19}$$

where matrix A_1, A_2, and A_3 are

$$\mathsf{A}_1 = \begin{bmatrix} \mathrm{Ma}_0^2\mathsf{I} + \dfrac{\mathrm{Ma}_0^2}{K^2}\mathsf{C} - \mathsf{I} & (\mathrm{Ma}_0^2-1)\Xi \\ (\mathrm{Ma}_0^2-1)\Xi^T & 2\pi(\mathrm{Ma}_0^2-1)\Pi \end{bmatrix},$$

$$\mathsf{A}_2 = 2K\mathrm{Ma}_0\begin{bmatrix} \mathsf{I} + \dfrac{1}{K^2}\mathsf{C} & \Xi \\ \Xi^T & 2\pi\Pi \end{bmatrix},$$

$$\mathsf{A}_3 = \begin{bmatrix} K^2\mathsf{I} - \mathsf{L}_1 + \mathsf{C} & (K^2\mathsf{I} - \mathsf{L}_1)\Xi \\ (K^2\mathsf{I}_2 - \mathsf{L}_2)\Xi^T - 2\sqrt{\pi}\Lambda & 2\pi K^2\Pi - \pi\mathsf{I}_2 \end{bmatrix}, \tag{20}$$

where matrices L_1 and L_2 are diagonal matrices, α_{mn}^2 and $\beta_{m,0}^2$ are in their main diagonal elements, respectively. Matrix Λ is a block diagonal matrix of dimension $M\times N_t$. Each block m of the matrix Λ is a row vector of dimension N, its elements are $1/\sqrt{\Lambda_{mn}}$, with $n=1,2,\ldots,N$. I_2 is an identity matrix of dimensions $M\times M$. Matrix C is

$$\mathsf{C} = \int_0^{2\pi} Y(\theta)\mathbf{\Psi}^*(1,\theta)\mathbf{\Psi}^T(1,\theta)d\theta. \tag{21}$$

Equation (19) is a nonlinear eigenvalue problem with respect to K_z of dimension $(N_t+M)\times(N_t+M)$, it can be recasted as a linear eigenvalue problem with respect to K_z of dimension $2(N_t+M)\times 2(N_t+M)$

$$K_z\mathsf{A}\mathbf{\Phi}_{\mathbf{B}} = \mathsf{B}\mathbf{\Phi}_{\mathbf{B}}, \tag{22}$$

where

$$\mathsf{A} = \begin{bmatrix} \mathsf{A}_1 & 0 \\ 0 & \mathsf{I} \end{bmatrix}, \quad \mathsf{B} = \begin{bmatrix} -\mathrm{j}\mathsf{A}_2 & \mathsf{A}_3 \\ -\mathsf{I} & 0 \end{bmatrix}, \quad \mathbf{\Phi}_{\mathbf{B}} = \begin{bmatrix} \mathbf{\Phi}_{\mathbf{C}} \\ \mathbf{\Phi}_{\mathbf{A}} \end{bmatrix}, \tag{23}$$

where $\mathbf{\Phi}_{\mathbf{C}}$ is a column vector which is dependent on $\mathbf{\Phi}_{\mathbf{A}}$.

Equation (22) is a generalized eigenvalue problem with generalized eigenvalue K_z and generalized eigenvectors $\mathbf{\Phi}_{\mathbf{B}}$, it can be easily solved by any packages of eigenvalue solver.

It is evident that in the zero flow case, the generalized eigenvalue problem Eq. (19) is

TABLE I. Eigenvalues calculated by method in this paper and FEM.

$$K_z^2\mathsf{A}_1\mathbf{\Phi}_{\mathbf{A}} = \mathsf{A}_3\mathbf{\Phi}_{\mathbf{A}}, \quad \mathrm{Ma}_0 = 0. \tag{24}$$

It is noted that because the boundary condition is circumferentially nonuniform, rigid modes are coupled between azimuthal orders. The indices m and n of the above vectors and matrices are $-\infty < m < \infty$ and $0 \le n < \infty$.

III. VALIDATION OF THE METHOD

To validate the present method, we compare the results with those of FEM in partial differential equation (PDE) Toolbox of MATLAB. The PDE Toolbox defines a two-dimensional eigenvalue problem with local boundary conditions, and provides the solutions using a FEM. For simplicity, we chose to calculate the eigenvalues $K_{z,i}$ of circumferentially uniform lined ducts. The validation of circumferentially nonuniform lined ducts is straightforward. With dimensionless frequency $K=6.8$, lining impedance $Z/\rho c = 1.5-1.3132j$, the computed eigenvalues are shown in Table I.

It appears that the two results agree up to three significant digits for both real and imaginary parts.

IV. CONVERGENCE RATES

In this section, we numerically show the convergence rates of the method. The convergence rate of eigenfunctions means, in this paper, the coefficients $|\Phi_{mn}|$ of expansion (5) decrease as indices m and n increase. In the numerical analysis of convergence, the truncations of M and N, corresponding to the indices of m and n, respectively, are chosen as large as possible in order to obtain a stable comportment of $|\Phi_{mn}|$. The rate of radial convergence is $O(n^{-4})$ when m is fixed and the rate of circumferential convergence is $O(m^{-3})$ when n is fixed. They are same as in Ref. 17. More details for the convergence rates of eigenfunctions can be found in Ref. 17.

For the eigenvalues, the convergence rate means the relative errors $|K_z - K_{z,\mathrm{exa}}|/|K_{z,\mathrm{exa}}|$ versus the truncation $N(M)$ [not the indices $n(m)$]. It is shown in Figs. 2 and 3 for the azimuthally uniform and nonuniform boundary conditions, respectively, where the $K_{z,\mathrm{exa}}$ refers to the numerical exact values calculated by the root finding method.[11] As a result of the new treatment in this paper, the convergence rate of eigenvalues is improved and becomes $O(N^{-5})$ for azimuthal

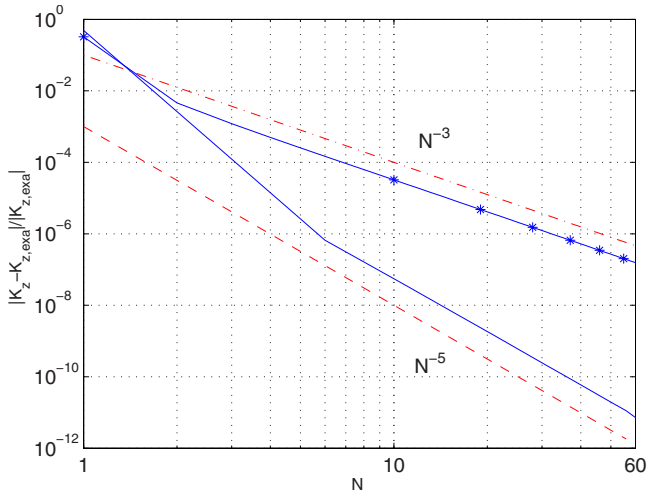

FIG. 2. (Color online) The relative errors of eigenvalues $|K_z-K_{z,\mathrm{exa}}|/|K_{z,\mathrm{exa}}|$ vs truncation N, azimuthally uniform boundary condition. $K=6.8$ and $Z/\rho c=1.5-1.3132j$. Solid line with star, method of Ref. 17 or solutions of Eq. (13), $K_{z,\mathrm{exa}}=4.855\,461\,748\,963\,631-0.468\,727\,712\,260\,302j$ no flow; solid line, method proposed in this paper or solutions of Eq. (22), $K_{z,\mathrm{exa}}=4.506\,069\,937\,543\,199-0.321\,062\,590\,157\,034j$, uniform flow, $\mathrm{Ma}_0=0.5$.

uniform boundary conditions. This is to be compared to the convergence rate of the treatment in Ref. 17 which is $O(N^{-3})$ and also shown in Fig. 2.

In absence of a direct mathematical substantiation of this difference, it may nevertheless be shown that the treatment in this paper will achieve a higher rate of convergence of eigenvalues than Ref. 17 does. For the sake of clarity, we assume uniform lining without flow. The eigenvalue equation obtained by the method proposed in Ref. 17 is in the form of Eq. (13). It can be rewritten as [see Eqs. (24) and (25) in Ref. 17]

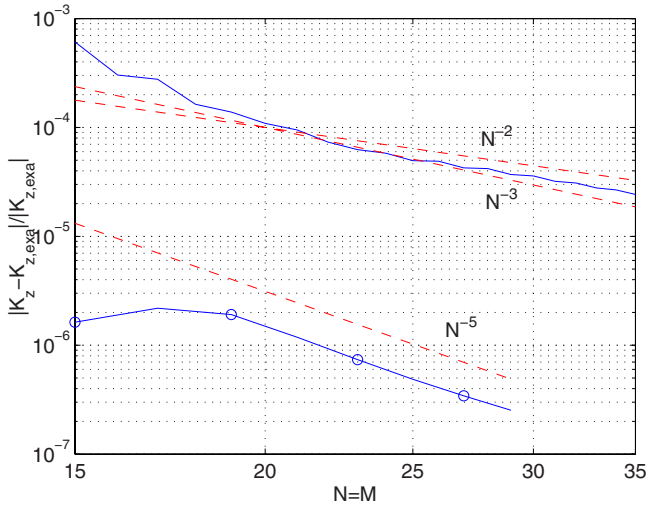

FIG. 3. (Color online) The relative errors of eigenvalues $|K_z-K_{z,\mathrm{exa}}|/|K_{z,\mathrm{exa}}|$ vs truncation $N=M$, azimuthally nonuniform boundary condition. $K=31.26$, two equal sized impedance $Z_1/\rho c=2-j$ and $Z_2/\rho c=2-0.5j$ distributed oppositely along the circumference of duct wall. Solid line, method of Ref. 17 or solutions of Eq. (13), $K_{z,\mathrm{exa}}=19.377\,398\,211\,660\,669-1.134\,878\,671\,886\,926j$, no flow; solid line with circle, method proposed in this paper or solutions of Eq. (22), $K_{z,\mathrm{exa}}=11.949\,004\,812\,788\,372-0.445\,168\,142\,112\,382j$, uniform flow, $\mathrm{Ma}_0=0.5$.

$$K_z^2\mathsf{M}\boldsymbol{\Phi}=(K^2\mathsf{I}-\mathsf{L}_1)\mathsf{M}\boldsymbol{\Phi}+\mathsf{C}\boldsymbol{\Phi}, \tag{25}$$

where C, as shown in Eq. (21), is a matrix of dimension $N\times N$, it depends only on m. The coefficient $\boldsymbol{\Phi}$ converges as $O(n^{-4})$, with m fixed as shown in Fig. 2 in Ref. 17. So the last term in the right-hand side converges as $O(n^{-4})$ with fixed m. But the other terms include $\mathsf{M}\boldsymbol{\Phi}$, the expansion coefficients of rigid mode basis $\boldsymbol{\Psi}$ as shown in Eq. (12). It converges as $O(n^{-2})$ with m fixed as shown in Eq. (42) in Ref. 17.

At variance, the eigenvalue equation proposed in this paper in zero flow case is shown in Eq. (24). It can be rewritten as

$$K_z^2\begin{bmatrix}\mathsf{I} & \boldsymbol{\Xi}\\ \boldsymbol{\Xi}^T & 2\pi\Pi\end{bmatrix}\begin{bmatrix}\boldsymbol{\Phi}\\ \mathbf{A}\end{bmatrix}=\begin{bmatrix}K^2\mathsf{I}-\mathsf{L}_1+\mathsf{C} & (K^2\mathsf{I}-\mathsf{L}_1)\boldsymbol{\Xi}\\ (K^2\mathsf{I}_2-\mathsf{L}_2)\boldsymbol{\Xi}^T-2\sqrt{\pi}\Lambda & 2\pi K^2\Pi-\pi\mathsf{I}_2\end{bmatrix}\begin{bmatrix}\boldsymbol{\Phi}\\ \mathbf{A}\end{bmatrix}. \tag{26}$$

In the case of uniform lining, as shown in the expansions of Eqs. (5) and (6), only one supplement term is needed to improve the convergence rate for a fixed azimuthal index m. The column vector $\mathbf{A}$ reduces to a scalar A_{m_0}. Matrices Π and I_2 also reduce to scalars; matrices I, C, and L_1 reduce to dimensions of $N\times N$; matrix $\boldsymbol{\Xi}$ reduces to a column vector of dimension $N\times 1$; matrix Λ reduces to a row vector of dimension $1\times N$. Details of the derivation are shown in the Appendix. In conclusion, in the case of uniform lining without flow, Eq. (26) is a system of $N+1$ equations. For the analysis of the properties of convergence, we can consider only the first N equations. It is rewritten as

$$K_z^2\mathsf{I}\boldsymbol{\Phi}=(K^2\mathsf{I}-\mathsf{L}_1)\boldsymbol{\Phi}+\mathsf{C}\boldsymbol{\Phi}+(K^2\mathsf{I}-\mathsf{L}_1-K_z^2)\boldsymbol{\Xi}A_{m_0}. \tag{27}$$

Consider first the last term in the right-hand side. The convergence behavior of this term depends only on $\boldsymbol{\Xi}$ and L_1 when n tends to infinity for fixed $m=m_0$. The elements of vector $\boldsymbol{\Xi}$ are (see Appendix, Eq. (A1))

$$\Xi_{m_0,n}=\frac{1}{\alpha_{m_0,n}^2-\beta_{m_0,0}^2}\frac{2\sqrt{\pi}}{\sqrt{\Lambda_{m0},n}}, \tag{28}$$

for fixed $m=m_0$ and behave like $1/\alpha_{m_0,n}^2$ in the limit $n\to\infty$ [see Ref. 17, Eq. (14)]. As we have indicated earlier, the elements of diagonal matrix L_1 are $\alpha_{m_0,n}^2$ on its main diagonal. So the term $(K^2\mathsf{I}-\mathsf{L}_1-K_z^2)\boldsymbol{\Xi}A_{m_0}$ tends to a constant c_0 when n tends to infinity for fixed m. Now Eq. (27) can be reduced as

$$K_z^2\mathsf{I}\boldsymbol{\Phi}=(K^2\mathsf{I}-\mathsf{L}_1)\boldsymbol{\Phi}+\mathsf{C}\boldsymbol{\Phi}+c_0,\quad n\to\infty. \tag{29}$$

The coefficient $\boldsymbol{\Phi}$ converges as $O(n^{-4})$, with m fixed, as shown in Fig. 2 of Ref. 17. Thus we should expect that Eq. (29) results in a faster rate of convergence of eigenvalues than Eq. (25) does.

For azimuthal discontinuous boundary conditions, the above convergence rates are approximately kept as shown in Fig. 3. The convergence rate is $O(N^{-5})$ with truncations $M=N$ for the treatment in this paper. The convergence rate of

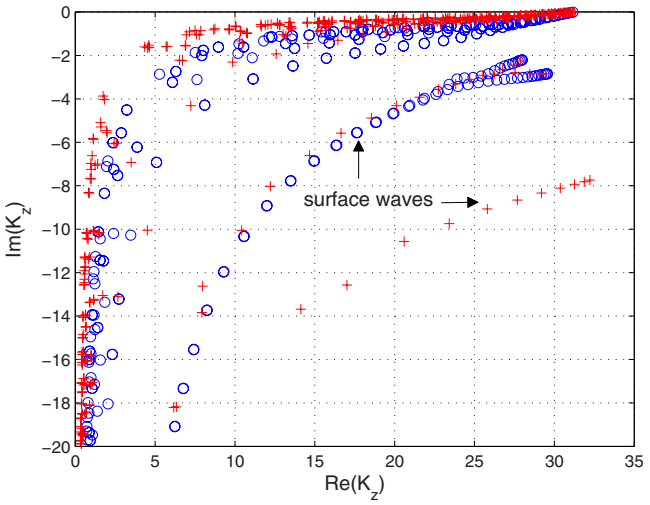

FIG. 4. (Color online) Axial wave numbers. $K=31.26$, ○: two equal sized impedance $Z_1/\rho c=2-j$ and $Z_2/\rho c=2-0.5j$ distributed oppositely along the circumference of duct wall; +: three equal sized impedance $Z_1/\rho c=2-j$, $Z_2/\rho c=2-0.5j$, and $Z_3/\rho c=1-j$ distributed uniformly along the circumference of duct wall, no flow, $N=20$, $M=35$.

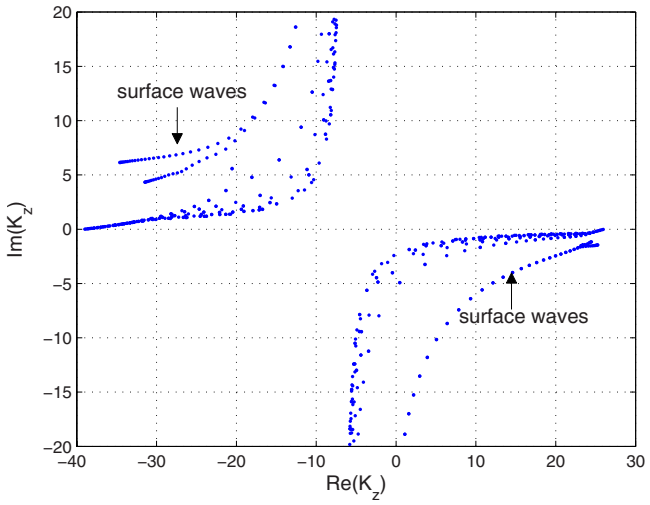

FIG. 5. (Color online) Axial wave numbers. $K=31.26$, two equal sized impedance $Z_1/\rho c=2-j$ and $Z_2/\rho c=2-0.5j$ distributed oppositely along the circumference of duct wall, uniform flow with Mach number $\mathrm{Ma}_0=0.2$, $N=25$, $M=35$.

the treatment in Ref. 17, i.e., Eq. (13), is between $O(N^{-2})$ and $O(N^{-3})$ with truncations $M=N$.

V. EXAMPLES

The present method with zero or uniform flow is especially adapted to calculate the modes in lined ducts with arbitrary nonuniform boundary conditions. In this section, we focus on the discontinuous boundary conditions which are the typical cases in the lined intakes of an aeroengine.

The first example, two and three equal sized impedance, is without flow. The dimensionless frequency is $K=31.26$. Two calculations are shown in Fig. 4, corresponding to Case 1 (symbol ○ in Fig. 4): two equal sized impedance $Z_1/\rho c=2-j$ and $Z_2/\rho c=2-0.5j$; and Case 2 (symbol + in Fig. 4): three equal sized impedance $Z_1/\rho c=2-j$, $Z_2/\rho c=2-0.5j$, and $Z_3/\rho c=1-j$. The surface waves, as indicated in Fig. 4, can be identified by the variations of eigenfunctions along r (not shown in the paper). It is well known that[6,20] when the impedance boundary condition is azimuthally uniform, there may exist two branches of surface waves propagating in opposite directions. When the lining impedance is azimuthally discontinuous, e.g., two segments of impedance as in the case 1, we find in Fig. 4, as we expect, that there exist four branches of surface waves (only the two branches having negative imaginary parts appear). One of the two branches shown in Fig. 4 corresponds to impedance $Z/\rho c=2-j$, but is modified by the presence of impedance $Z/\rho c=2-0.5j$; the other branch corresponds to impedance $Z/\rho c=2-0.5j$, but is modified by the presence of impedance $Z/\rho c=2-j$. As we expect, when the number of the lining segments increases to three as in the case 2, two other branches of surface waves appear (only one can be seen in Fig. 4) corresponding to the impedance $Z/\rho c=1-j$, which are of course modified by the presence of other impedance. It is worthy to note that when the impedance boundary condition is azimuthally uniform, distinct surface waves will appear for every azimuthal mode order m; but when the impedance boundary condition is nonuniform the different surface waves will be made of a complicate mixture of coupled components having different m values.

The second example (Fig. 5) is for a circumferentially nonuniform boundary condition with uniform flow. The nonuniform boundary is the same as Case 1 in the first example: two equal sized impedance $Z_1/\rho c=2-j$ and $Z_2/\rho c=2-0.5j$ distributed oppositely along the circumference of duct wall. The dimensionless frequency is $K=31.26$, the Mach number is $\mathrm{Ma}_0=0.2$. It is shown that the uniform flow makes the downstream split modes (with negative imaginary parts) to be closer and the upstream split modes (with positive imaginary parts) to be more separate.

Finally, we show in Fig. 6 the eigenfunctions modified by the presence of rigid splices, such as the ones generally found in the lined intakes of an aeroengine. The dimensionless frequency is $K=31.26$, the lining impedance is $Z/\rho c=2-j$. The centers of the two splices, with angle 0.3 rad, are at 0 and π.

VI. DISCUSSION

In this section, we first discuss another important advantage of the method proposed in this paper. We then turn to discuss a more general problem: Which form of the boundary conditions is more proper to use when the impedance boundary is circumferentially discontinuous?

The method proposed in this paper belongs to the general class of spectral or pseudospectral (collocation) methods but has one interesting feature we wish to stress. Those methods can calculate all needed eigenvalues one time without guessing the initial values. But as pointed out by Boyd,[21] in solving a linear eigenvalue problem by one conventional spectral method using $N+1$ terms in the truncated spectral series, the lowest $N/2$ eigenvalues are usually accurate to within a few percent while the larger $N/2$ eigenvalues differ from those of the differential equation by such large amounts

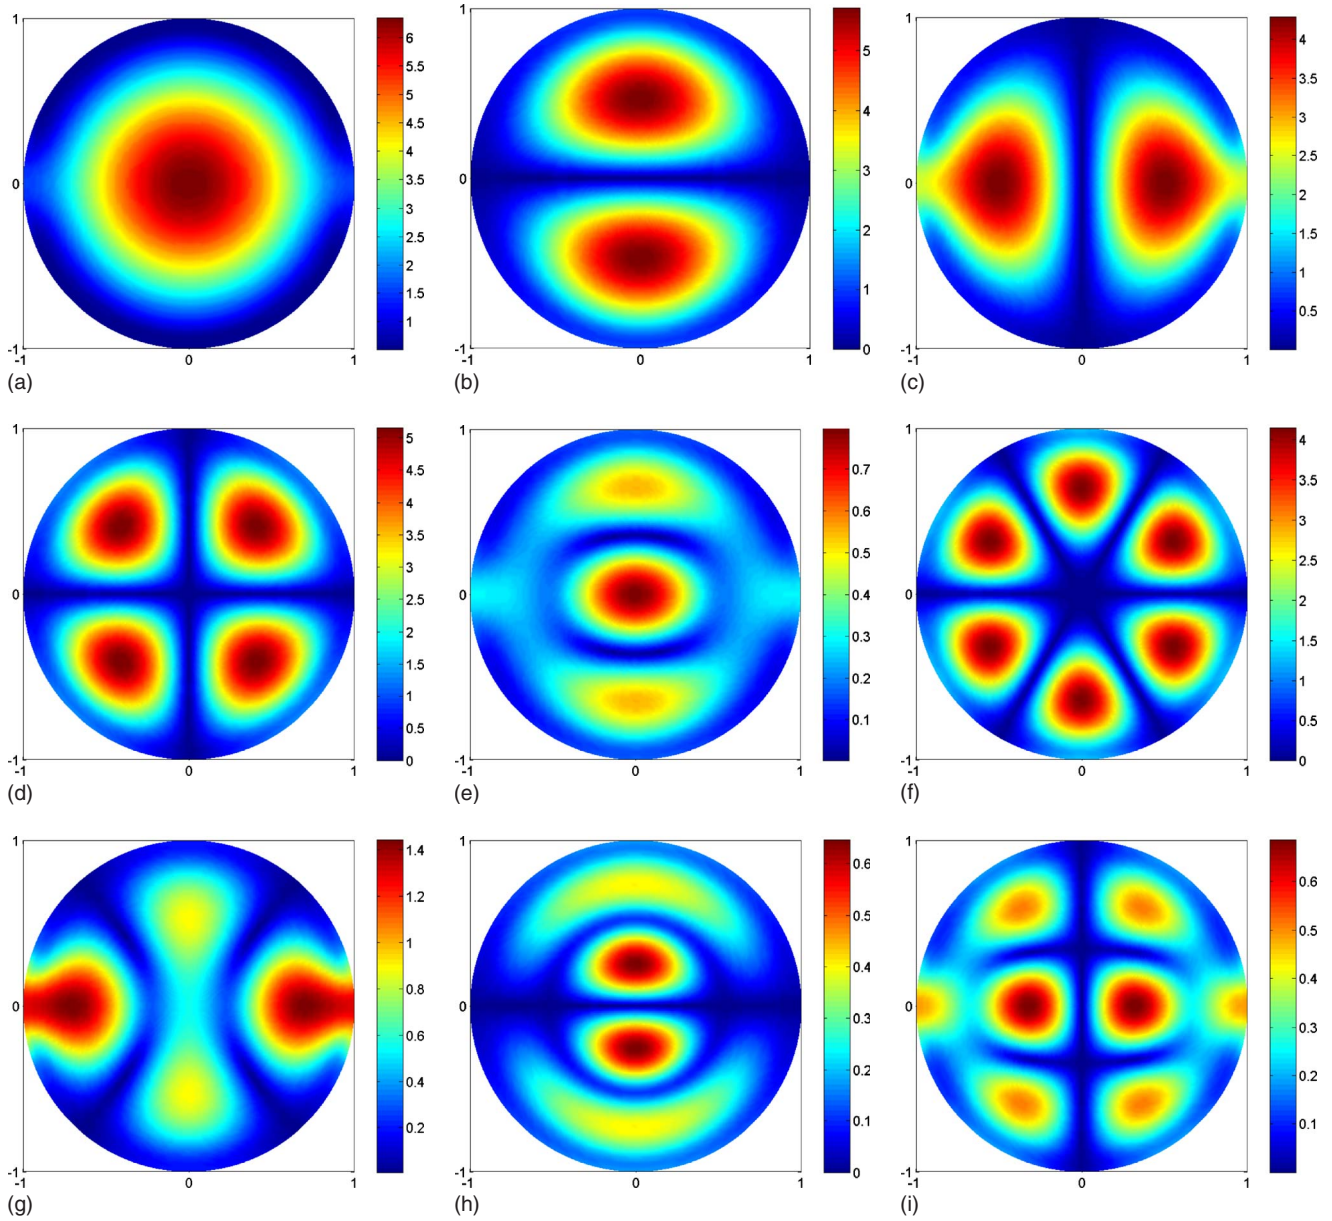

FIG. 6. (Color online) The first nine eigenfunctions (not normalized), according to the ascending order of the imaginary parts of the axial wave numbers, modified by the presence of rigid splices, (a), $K_{z,1}=31.16-0.01j$, (b), $K_{z,2}=31.01-0.03j$, (c), $K_{z,3}=31.02-0.05j$, (d), $K_{z,4}=30.81-0.06j$, (e), $K_{z,5}=30.75-0.07j$, (f), $K_{z,6}=30.56-0.09j$, (g), $K_{z,7}=30.85-0.09j$, (h), $K_{z,8}=30.40-0.11j$, and (i), $K_{z,9}=30.48-0.12j$. The dimensionless frequency is $K=31.26$, the lining impedance is $Z/\rho c=2-j$. The centers of the two splices, with angle 0.3 rad, are at 0 and π, no flow.

as to be useless. Boyd further proposed a strategy to verify the eigenvalues being well resolved. The strategy is to plot the logarithm of the reciprocal of the difference between corresponding eigenvalues as calculated at different truncation N, or named as the reciprocal eigenvalue drift ratios $1/(K_z(N_1)-K_z(N_2))$, where $K_z(N_1)$ and $K_z(N_2)$ refer to the nth eigenvalue calculated with different truncations N_1 and N_2, respectively. If the reciprocal eigenvalue drift ratios are very small for some eigenvalues, it means that those eigenvalues are not accurate. We plot the reciprocal eigenvalue drift ratios $1/(K_z(N_1)-K_z(N_2))$ in Fig. 7. It is an interesting feature of our method that all the 500 eigenvalues calculated using truncation $N_1=500$ are well resolved. This is explained by our addition of the $X(r,\theta)$ terms in Eq. (5), which are chosen so as to ensure that $\partial_r(\Sigma_{mn}\Phi_{mn}\Psi_{mn})|_{r=1}=0$, i.e., the basis Ψ_{mn} is used to represent a field verifying hard walled boundary conditions.

At the end of the paper, we hope to discuss a more general problem: When the impedance boundary is circumferentially discontinuous, which often occurs in the lined intake of an aeroengine where the lining impedance are in segments or with small rigid splices, which form of the boundary conditions is more proper to use to achieve a reasonable convergence rate? To answer this question, we do not restrict only the method proposed in the present paper. At variance, we use the root finding method, e.g., as in Refs. 11–14, to study this problem. In general, we may chose between the two forms (for simplicity, the case of without flow is considered only)

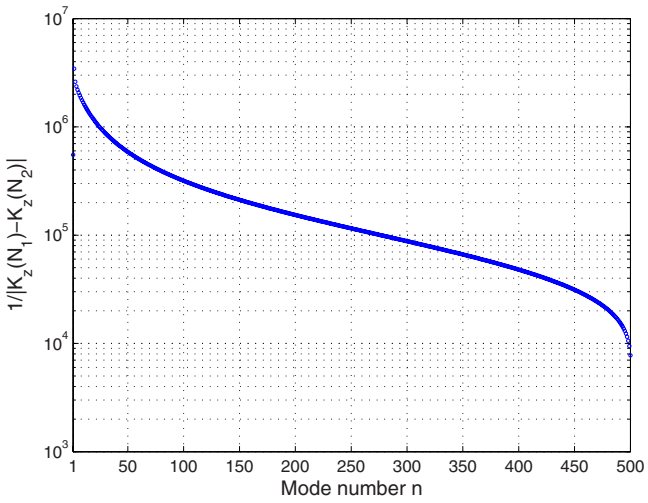

FIG. 7. (Color online) The reciprocal eigenvalue drift ratios $1/(K_z(N_1) - K_z(N_2))$ vs mode number n, $K_z(N_1)$ and $K_z(N_2)$ refers to the nth eigenvalue calculated with truncation $N_1=500$ and $N_2=1000$, respectively. $K=31.26$, circumferentially uniform impedance boundary condition, $Z/\rho c=2-j$, $m=26$.

$$\frac{\partial \phi_i}{\partial r} = Y(\theta)\phi_i, \quad r=1, \tag{30}$$

$$Z(\theta)\frac{\partial \phi_i}{\partial r} = \phi_i, \quad r=1. \tag{31}$$

Physically, the previous two forms are equivalent, but mathematically, they lead to significantly different convergence rates. This is shown in Fig. 8 by the relative error defined as $|(K_z - K_{z,\text{exa}})|/|K_{z,\text{exa}}|$ versus truncation M, where $K_{z,\text{exa}}$ refers to the numerically exact value. The eigenvalues K_z and $K_{z,\text{exa}}$ are calculated by a root finding method as Fuller's.[11] The convergence rate of form (30), in solid line with cross marks, is $O(M^{-3})$. It is considerably better than the convergence rate

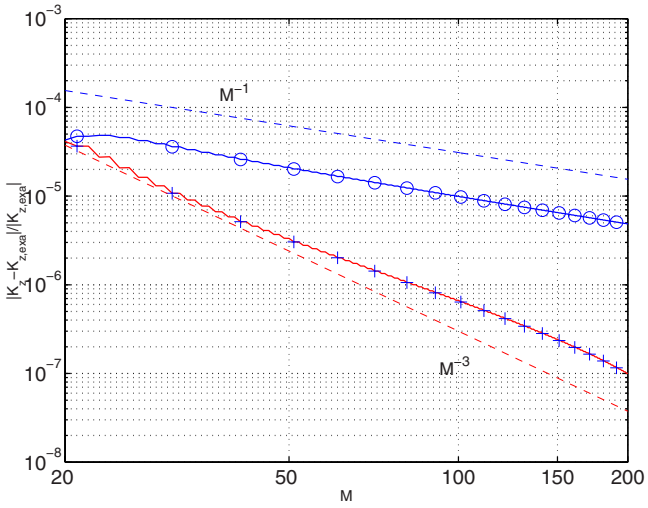

FIG. 8. (Color online) Convergence rates of different forms of boundary conditions by a root finding method as Fuller's (Ref. 11). Solid line with crosses corresponds to Eq. (30), solid line with circles corresponds to Eq. (31). The reference curves $O(M^{-1})$ and $O(M^{-3})$ are also plotted on the figure.

$O(M^{-1})$ of form (31) in solid line with circle marks. This result is a little puzzling. Elements for a clear understanding of it were given by Li[22]. He pointed out that in Eq. (31), the two functions $Z(\theta)$ and $\partial_r \phi_i(r,\theta)$ both have discontinuities, and their discontinuities are concurrent complementary (to assure $\phi_i(r,\theta)$ being continuous). In this case, the Fourier expansions of the left-hand side of Eq. (31) does not converge to the right-hand side which is continuous at those discontinuities.

The proper form of boundary condition (30) is used in this paper. The effects of circumferentially nonuniform impedance are expressed in the coupling matrix (21). It is obtained from the projection of $\nabla_\perp^2 \phi$ in the Appendix by using boundary condition (2). As we have shown earlier, the eigenvalues converge as $O(N^{-5})$ as the truncations $N=M$. This is because of the particular form we use of boundary condition (2) [reduced to condition (30) in the case of zero flow]. In fact, we are forced to set it in the given form.

VII. CONCLUSIONS

The series expansion method proposed in Ref. 18 to calculate Lamb modes has been extended to calculate the modes in nonuniformly lined ducts with zero and uniform flow, which is of important concern in nacelle acoustics applications. This results in a powerful method, capable to treat many demanding configurations (including nonuniform lining along the azimuthal direction, high-frequencies and presence of uniform flow) found in these applications.

The radial convergence rate of the eigenvalues is $O(N^{-5})$ for circumferentially uniform boundary conditions. For circumferentially discontinuous boundary conditions, the convergence rate of the eigenvalues is $O(N^{-5})$, when we chose equal truncations $N=M$ for the radial and azimuthal modes indices.

This method is an alternative to the usual root finding technique and FEM. It is easy to implement. For a given frequency, Mach number and lined impedance distribution, it is simple to evaluate the matrices A_1, A_2, and A_3 in Eq. (20), to put them in Eqs. (22) and (23), and then to use any eigenvalue solver package to obtain the eigenvalues and eigenfunctions. All modes are calculated at a time, with surface waves also well resolved.

Extension of the attractive features of the present method to account for nonuniform geometries and/or nonuniform flow would be worthwhile undertaking in view of providing a more generally applicable alternative to the FEM.

APPENDIX: PROJECTIONS OF Φ AND $\nabla_\perp^2\Phi$

In this appendix, we will show the derivation of the projections of ϕ and $\nabla_\perp^2\phi$ for a circumferentially nonuniform boundary condition. When the boundary condition is circumferentially uniform, the derivation in this appendix can be easily simplified. Using Eqs. (5), (9), and (11), the projection of ϕ over the basis $\mathbf{\Psi}^*$ for circumferentially nonuniform boundary condition is

$$\begin{aligned}\int \phi(r,\theta)\Psi_{mn}^* dS &= \int \left(\sum_{m'n'} \Phi_{m'n'}\Psi_{m'm'} + \sum_{m'} A_{m'}\chi_{m'}e^{-jm'\theta}\right)\Psi_{mn}^* dS \\ &= \Phi_{mn} + \frac{1}{\sqrt{\pi\Lambda_{mn}}}\frac{1}{J_m(\alpha_{mn})}\int_0^{2\pi}\sum_{m'} A_{m'}e^{-j(m'-m)\theta}d\theta\int_0^1 \chi_{m'}J_m(\alpha_{mn}r)rdr \\ &= \Phi_{mn} + \frac{1}{\sqrt{\pi\Lambda_{mn}}}\frac{1}{J_m(\alpha_{mn})}2\pi A_m B_m\int_0^1 J_m(\beta_{m,0}r)J_m(\alpha_{mn}r)rdr = \Phi_{mn} + \frac{1}{\alpha_{mn}^2-\beta_{m,0}^2}\frac{2\sqrt{\pi}}{\sqrt{\Lambda_{mn}}}A_m, \end{aligned} \tag{A1}$$

where we have used the relation[23]

$$\int_0^x tJ_\mu(at)J_\mu(bt)dt = \frac{x}{a^2-b^2}\left[J_\mu(ax)\frac{dJ_\mu(bx)}{dx} - J_\mu(bx)\frac{dJ_\mu(ax)}{dx}\right].$$

Following the matricial terminology, Eq. (A1) is written as

$$\int \phi(r,\theta)\mathbf{\Psi}^* dS = \mathbf{\Phi} + \Xi\mathbf{A}. \tag{A2}$$

For circumferentially nonuniform boundary conditions, Ξ is a block diagonal matrix of dimension $N_t\times M$, where N_t indicates $M\times N$, and M and N indicate the circumferential and radial mode truncation. In each block m of matrix Ξ, it is a column vector of dimension N, its elements are $2\sqrt{\pi}/(\sqrt{\Lambda_{mn}}(\alpha_{mn}^2-\beta_{m,0}^2))$, with $n=1,2,\ldots,N$. When the impedance boundary conditions are circumferentially uniform, Ξ reduces to column vector of dimension N for a fixed m_0. Its elements are $2\sqrt{\pi}/(\sqrt{\Lambda_{m_0n}}(\alpha_{m_0n}^2-\beta_{m_0,0}^2))$with $n=1,2,\ldots,N$. $\mathbf{A}$ is a column vector of dimension M. Its elements are A_m, each A_m corresponds to one circumferential index m. When the impedance boundary condition is circumferentially uniform, $\mathbf{A}$ reduces to scalar A_{m_0}, which means that only one term is needed to add in expansion (5). $\mathbf{\Phi}$ and $\mathbf{\Psi}$ are column vectors of dimension N_t, their elements are Φ_{mn} and Ψ_{mn}, respectively.

Similar to Eq. (A1), it is easy to obtain

$$\begin{aligned}&\int \phi(r,\theta)(\chi_m e^{-jm\theta})^* dS \\ &= \int \left(\sum_{m'n'} \Phi_{m'n'}\Psi_{m'n'} + \sum_{m'} A_{m'}\chi_{m'}e^{-jm'\theta}\right)(\chi_m e^{-jm\theta})^* dS \\ &= \sum_{n'} \Phi_{mn'}\frac{1}{\alpha_{mn'}^2-\beta_{m,0}^2}\frac{2\sqrt{\pi}}{\sqrt{\Lambda_{mn'}}} + 2\pi\|\chi_m\|^2 A_m, \end{aligned} \tag{A3}$$

where $\|\chi_m\|^2$ is

$$\|\chi_m\|^2 = \int_0^1 \chi_m^2 rdr = \frac{1}{2\beta_{m,0}^2}, \tag{A4}$$

where we have used Eqs. (9) and (11). Following the matrical terminology, Eq. (A3) is written as

$$\int \phi(r,\theta)\chi^* dS = \Xi^T\mathbf{\Phi} + 2\pi\Pi\mathbf{A}. \tag{A5}$$

Vector χ is a column vector of dimension M, its elements are $\chi_m\exp(-jm\theta)$. When the impedance boundary condition is curcumferentially uniform, χ reduces to be a scalar $\chi_{m_0}\exp(-jm_0\theta)$. Π is a diagonal matrix, $\|\chi_m\|^2$ are in its main diagonal. When the impedance boundary condition is curcumferentially uniform, it reduces to a scalar $\|\chi_{m_0}\|^2$.

Using Eqs. (14) [or Eq. (A2)] and (15) [or Eq. (A5)], we project $\nabla_\perp^2\phi$ to yield

$$\begin{aligned}\int \nabla_\perp^2\phi\mathbf{\Psi}^* dS &= \int \phi\nabla_\perp^2\mathbf{\Psi}^* dS + \oint\left(\mathbf{\Psi}^*\frac{\partial\phi}{\partial r} - \phi\frac{\partial\mathbf{\Psi}^*}{\partial r}\right)dC \\ &= \int \phi(-\mathsf{L}_1)\mathbf{\Psi}^* dS + \oint \mathbf{\Psi}^*(1,\theta) \\ &\quad\times Y(\theta)\left(1-\mathrm{Ma}_0\frac{K_{z,i}}{K}\right)^2\phi dC = -\mathsf{L}_1(\mathbf{\Phi}+\Xi\mathbf{A}) \\ &\quad + \left(1-\mathrm{Ma}_0\frac{K_{z,i}}{K}\right)^2\mathsf{C}\mathbf{\Phi}, \end{aligned} \tag{A6}$$

$$\begin{aligned}\int \nabla_\perp^2\phi\chi^* dS &= \int \phi\nabla_\perp^2\chi^* dS + \oint\left(\chi^*\frac{\partial\phi}{\partial r} - \phi\frac{\partial\chi^*}{\partial r}\right)dC \\ &= \int \phi(-\mathsf{L}_2)\chi^* dS - \oint \phi\frac{\partial\chi^*}{\partial r}dC \\ &= -\mathsf{L}_2(\Xi^T\mathbf{\Phi} + 2\pi\Pi\mathbf{A}) - 2\sqrt{\pi}\Lambda\mathbf{\Phi}, \end{aligned} \tag{A7}$$

where we have used Eqs. (9) and (11). Matrix L_1 is a diagonal matrix, $\alpha_{m,n}^2$ are in its main diagonal elements. Matrix C is

$$\mathsf{C} = \int_0^{2\pi} Y(\theta)\boldsymbol{\Psi}^*(1,\theta)\boldsymbol{\Psi}^T(1,\theta)d\theta. \quad \text{(A8)}$$

Matrix L_2 is a diagonal matrix, $\beta_{m,0}^2$ are in its main diagonal. Matrix Λ is a block diagonal matrix of dimension $M \times N_t$. In each block m of matrix Λ, it is a row vector of dimension N, its elements are $1/\sqrt{\Lambda_{mn}}$, with $n=1,2,\ldots,N$.

On the steering of sound energy through a supercritical plate by a near-field transducer array

Brian E. Anderson,[a] W. Jack Hughes, and Stephen A. Hambric
Applied Research Laboratory, The Pennsylvania State University, P.O. Box 30, State College, Pennsylvania 16804, USA

(Received 19 October 2007; revised 13 December 2007; accepted 7 February 2008)

The ability to direct sound energy through the flexural vibrations of a submerged plate at various angles of incidence using a near-field transducer array is investigated. An alumina bar is placed in front of a one-dimensional, eight-element transducer array, between the array and the water. Operating in a receive mode, data were taken as a function of angle of incidence and compared to data taken without the presence of the alumina bar. The array was also operated in transmit mode and results were compared to corresponding receive mode data, showing that reciprocity holds. Results show that in fact sound energy can be steered through a plate, and that the measurement method used provides a convenient method of measuring the angular dependence of transmission through a plate, including measurements at frequencies above the plate's critical frequency. Experimental results of sound transmission versus angle of incidence of finite sized plates agree qualitatively with theoretical results from an analysis of the transmission through an unbounded flexible partition. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2890738]

I. INTRODUCTION

Arrays of transducer elements are often used to channel sound radiation into specific directivity patterns to image objects at specific angles. In some applications it is desirable to send sound through a plate or wall to allow imaging of objects on the other side, especially when it is not feasible to physically inspect the other side of the plate or wall. One potential application would be to place an array on the inner surface of the hull of a ship or submarine. There have been various studies on the effects of steering an array through acoustic windows, including modeling and testing,[1–7] but the main goal of those studies is to design an acoustically transparent barrier between the array electronics and the water. This paper investigates the steering of sound energy through a plate with an array mounted to the plate and proposes a method to measure the angular dependence of sound transmission through a plate.

The critical or coincidence frequency for sound transmission is the frequency at which the speed of sound in the acoustic fluid matches that of the speed of bending waves in a plate, resulting in nearly perfect transmission of sound at grazing incidence. As frequency is increased, the angle at which the coincidence effect occurs (high degree of sound transmission) shifts progressively away from grazing incidence and closer to normal incidence. The angular shifting of the coincidence effect occurs due to the dispersive nature of bending waves in plates. The theory of the coincidence effect and its frequency dependence is generally credited to Cremer.[8] Cremer's work in 1942 has influenced many other researchers in this field. Experimental verification of the coincidence effect was conducted in 1956 by Lamb,[9] and then also in 1957 by Eichler and Lambert.[10] Numerous studies have been conducted on the transmission of sound through partitions, but generally these studies are either done for subcritical plates or they measure the diffuse field transmission characteristics (an average over all angles of incidence, generally by using a reverberation chamber).

It was not until Davies and Gibbs' work in 1981 that a practical technique for measuring the angular dependence of sound transmission through a partition was proposed.[11] Davies and Gibbs used a method similar to that proposed by Louden[12] where an impulsive source sends sound through the partition under test at selected angles. The direct arrival of energy through a partition was compared to the direct arrival of energy received without the partition present, thus allowing the sound transmission to be characterized. They utilized various averaging schemes to improve upon their results. Unfortunately, their technique was contaminated by spherically incident wave fronts which excited bending waves in the partition which produced arrivals of energy shortly after the direct arrival (which was later termed the precursor phenomenon). Balilah and Gibbs further refined the technique proposed by Davies and Gibbs by making the technique more portable and by suggesting ways to reduce the effect of the precursor phenomenon.[13] Unfortunately these techniques require a large area of the material under test (partition) to avoid the arrival of the flanking transmission around the partition, thus smaller samples of material cannot be tested.

This paper proposes a technique in which a pulsed wave field is incident upon a plate which has an array of transducers mounted on the back side of the plate. The incident signal is emitted by a transmitter which is located in the far-field of the array. The measurement is repeated for many angles in the forward 180°. The signals detected by the array of transducers can be digitally steered in postprocessing to provide a

[a]Present address: Los Alamos National Laboratory, Geophysics Group, MS D443, Los Alamos, NM 87545. Electronic mail: bea@lanl.gov.

high degree of directivity in the direction of the incident wave energy. Thus the problem of incident spherical waves is avoided. The wave field detected from the same array without a plate is also measured. A comparison of the detected signals with and without the plate yields the transmission as a function of angle of incidence.

In this paper a comparison of theoretical analysis to experimental results is given for the angular dependence of sound transmission through a plate. The theoretical analysis utilizes an expression derived from unbounded/infinite plate theory (finite thickness). Experimental results were obtained with a finite sized plate. A more complete discussion of the theory, modeling, and experiments conducted in this study are given in the dissertation by Anderson.[14]

II. TRANSMISSION THROUGH UNBOUNDED FLEXIBLE PARTITIONS

This section will provide a brief presentation of the theory of sound transmission through an unbounded flexible partition vibrating in flexure (infinite-sized, thin-plate theory). A complete theoretical analysis of this theory is given by Fahy (Ref. 15, pp. 277–295). Theory for unbounded flexible partitions can also be used as an approximation for modeling the angular dependence of sound transmission for finite sized plates.

The specific acoustic impedance, $\tilde{z}_{SP}$, for an unbounded flexible plate partition is given by

$$\tilde{z}_{SP} = \frac{1}{\omega} D \eta \kappa^4 - j \frac{1}{\omega} (D\kappa^4 - m\omega^2), \tag{1}$$

where ω is the angular frequency, D is the bending stiffness of the plate, η is the damping loss factor in the plate, κ is the structural wave number in the plate, j is the imaginary number $\sqrt{-1}$, and m is the mass per unit area of the plate. The structural wave number in the plate depends on the wave speed of the type of wave excited. Two types of waves will be considered here, driven waves excited by an incident wave field, and bending waves which have dispersive wave speeds which increase as a function of $\sqrt{\omega}$ for low frequencies (at larger frequencies the bending wave speed asymptotically approaches the shear wave speed).

The general transmission coefficient, τ, for sound transmission through an unbounded flexible partition is given in Fahy's Eq. (5.36) (with some additional substitutions) as

$$\tau = \left| \frac{2\rho_2 c_2 \sec\theta_2}{\frac{1}{\omega} D \eta \kappa^4 - j \frac{1}{\omega} (D\kappa^4 - m\omega^2) + \rho_1 c_1 \sec\theta_1 + \rho_2 c_2 \sec\theta_2} \right|^2 \frac{\rho_1 c_1}{\rho_2 c_2} \left[\frac{1 - \left(\frac{c_2}{c_1} \sin\theta_1 \right)^2}{1 - \sin^2\theta_1} \right]^{1/2}, \tag{2}$$

where θ is an angle measured from normal incidence, ρ is the density, c is the acoustic speed of sound, and the subscripts 1 and 2 correspond to material properties of the incident and transmitted acoustic fluids (or the corresponding angle on either side of the partition). The term in the square brackets of Eq. (2) governs refraction of a wave from one fluid to the other, and if the fluid on both sides is the same then the refraction term and the impedance ratio term vanish and Eq. (2) becomes

$$\tau = \frac{(2\rho c \sec\theta)^2}{\left[2\rho c \sec\theta + \frac{1}{\omega} D \eta k^4 \sin^4\theta \right]^2 + \left[m\omega - \frac{1}{\omega} D k^4 \sin^4\theta \right]^2}, \tag{3}$$

where k is the acoustic wave number ($k \sin\theta = \kappa$). The second term in the denominator of Eq. (3) is governed by the damping in the plate, while the third and fourth terms are governed by the mass and stiffness in the plate, respectively. The standard equation for normal incidence mass law transmission results when Eq. (3) is evaluated at 0°, or when the bending stiffness term of Eq. (3) is very small compared to the mass term (η is generally much less than one).

The critical frequency, f_C, is defined as the frequency at which the acoustic sound speed in water equals the bending wave speed in the plate. The bending wave speed in a thin plate (thin plate theory ignores effects due to shear deformation and rotary inertia) is dispersive and increases with frequency,

$$c_B = \left(\omega^2 \frac{D}{m} \right)^{1/4}. \tag{4}$$

At the critical frequency transmission through a plate at grazing incidence is very high. Above the critical frequency, as the frequency is increased, the angle of high transmission (called the coincidence angle, θ_{CO}, which occurs when the imaginary part of the plate's impedance goes to zero) shifts toward normal incidence

$$\sin^2\theta_{CO} = \frac{c^2}{c_B^2} = \frac{c^2}{\omega} \sqrt{\frac{m}{D}}. \tag{5}$$

Thus, the coincidence angle is proportional to the arcsine of the inverse square root of frequency. The critical frequency may be solved for by evaluating Eq. (5) at grazing incidence ($\theta_{CO} = 90°$)

$$f_C = \frac{c^2}{2\pi}\left(\frac{m}{D}\right)^{1/2}. \tag{6}$$

The transmission coefficient at the coincidence angle is

$$\tau(\theta_{CO}) = \left(1 + \frac{\eta m\omega}{2\rho c}\sqrt{1 - \frac{c^2}{\omega}\sqrt{\frac{m}{D}}}\right)^{-2}. \tag{7}$$

A steered array of transmitting transducers effectively approximates a traveling wave in the plane of the array. The speed of this traveling wave must exceed the speed of sound in the fluid medium if the radiation is to be between grazing and normal incidence. This principle is called trace wave number matching (Ref. 15, pp. 175–177). In order to radiate sound at a given forward angle, θ_0, one must set up a traveling wave on a steered array such that

$$c_0 = \frac{c}{\sin\theta_0} = \frac{d}{\tau_0}, \tag{8}$$

where c_0 is the speed of the traveling wave, d is the center-to-center distance between consecutive transducers in the array, and τ_0 is the electronic time delay necessary to progressively implement across the array between consecutive transducers. Thus if one scans the surface of an array and measures the effective traveling wave sound speed, one can then determine at what angle the array is radiating.

III. EXPERIMENT SETUP

A. Array setup

Two different one-dimensional eight element arrays were mounted onto the polyurethane acoustic window of an array module. The transducers used are of a typical Tonpilz design with a nominal resonance frequency of 25 kHz. One array was placed directly on the acoustic window, while the other array was bonded onto an alumina bar with a 1.6-mm-thick layer of polyurethane between the array elements and the alumina bar. The alumina bar is a high purity 99.8% aluminum oxide ceramic (AmAlOx 68 alumina) and is 1.02 cm thick, 3.05 cm wide, and 24.4 cm in length. Plastic shims were placed between neighboring transducers to maintain a consistent spacing between all transducers. Figure 1(a) shows a photograph of a close up of the array bonded to the alumina bar. Figure 1(b) shows a photograph of the two arrays placed side by side on the window of the array module.

B. Scanning laser measurements

To confirm that the appropriate traveling flexural waves are generated in the plate driven by the array of transducers, a set of measurements was conducted using a PolyTec scanning laser vibrometer. The vibration of the plate induced by the array was imaged with the scanning laser. Reflective tape was placed on the acoustic window (assumed to be acoustically transparent) to provide high reflectivity of the laser signal and to provide an accurate measure of the plate vibration. A 7 by 43 point scan grid was used with a spacing of 6 mm between scan points. The measurements were conducted with the array module submerged in a small water tank with an optically transparent wall to allow the laser to scan the submerged surface while being physically located outside the water. Figure 2(b) shows a photograph of the scanning laser measurement setup. The array was operated in transmit mode at various frequencies and steer angles. Care was taken to eliminate the possibility of obstruction of the desired data from a reflected wave off the tank walls by applying an appropriate time window and transmit repetition rate.

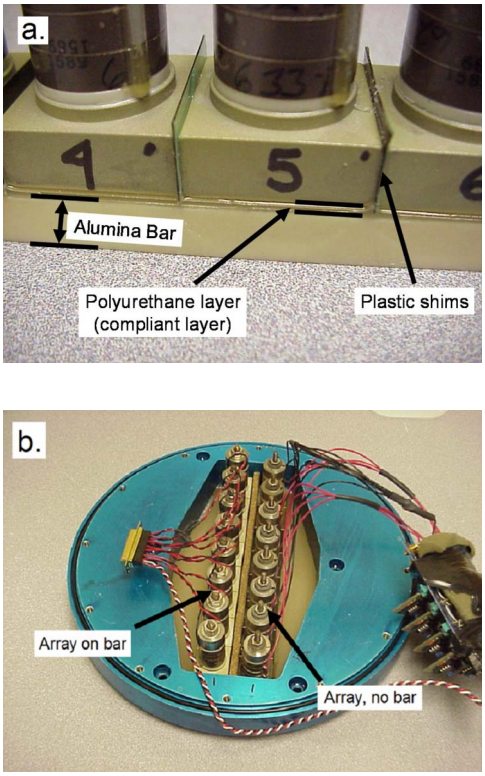

FIG. 1. (Color online) (a) Close up photograph of the alumina bar with an eight element line array mounted on it. (b) Photograph of the two eight element line arrays used in the water tank measurements.

C. Water tank measurements

The water tank facility at Penn State measures 5.3 $\times 5.5 \times 7.9$ m in size. The water tank is kept at a constant temperature and is lined with acoustical absorbing material. A calibrated transmitter or a calibrated receiver can be placed at one end of the tank to transmit/receive sound toward/from a transducer array under test at the other end of the tank. A computer controlled turntable can rotate the Array Under Test (AUT) with fractional degree increments. When the AUT is in a receive mode, up to 64 channels of complex data may be simultaneously acquired by a vector signal analyzer. The advantage of receive mode measurements is that in the postprocessing phase, the array can be arbitrarily steered to any angle by applying appropriate digital delays. In transmit mode each channel of the AUT must be amplified separately and set beforehand with fixed digital delays. Figure 2(a) shows a photograph of the array module just before being lowered into the water tank.

The array module was lowered into the water and connected up to the turntable. In one set of measurements the array mounted on the alumina bar was operated in a transmit

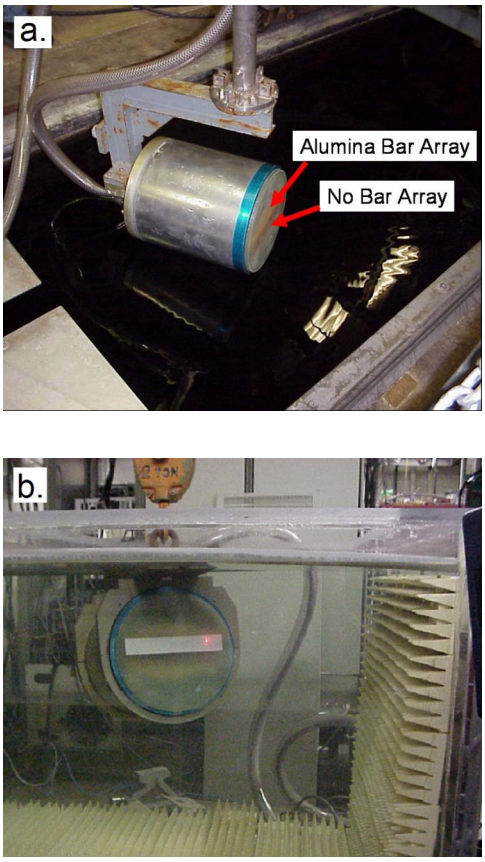

FIG. 2. (Color online) (a) Photograph of the array module before being lowered into the water tank. (b) Photograph of the array module in the small water tank while performing a scanning laser measurement.

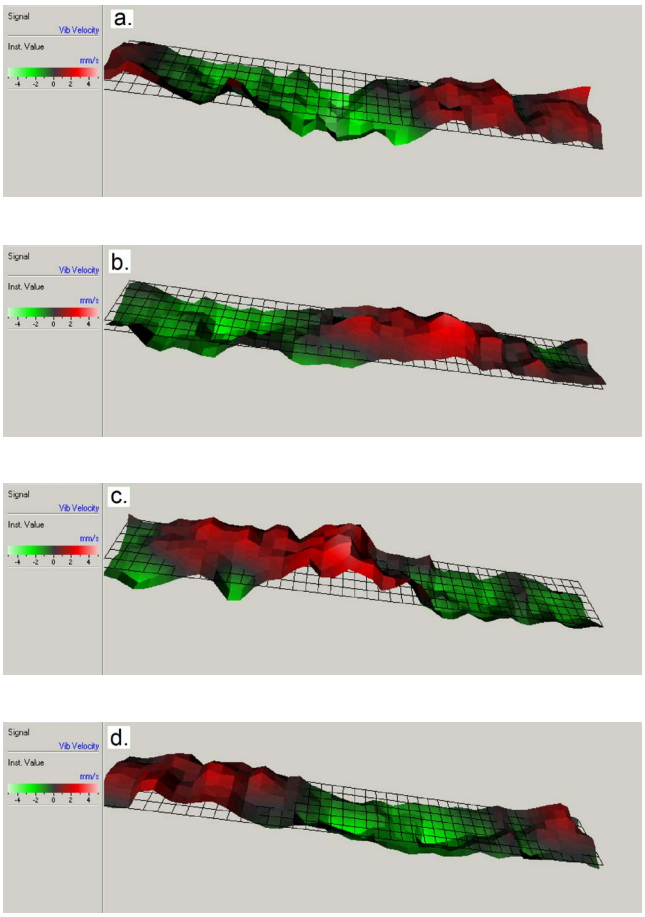

FIG. 3. (Color online) Velocity data from scanning laser data at 25 kHz and 15°. Each subplot represents progressive phase snapshots [(a) 0°, (b) 80°, (c) 180°, and (d) 280°] of the traveling wave progressing from right to left.

mode at various frequencies and also at various steer angles by applying appropriate digital delays. In another set of measurements the array mounted on the bar and the array without a bar were each operated in a receive mode at various frequencies while recording complex data on each receiver channel.

IV. RESULTS

A. Scanning laser measurements

The scanning laser results for a steer angle of 15° at a frequency of 25 kHz may be found in Fig. 3. The results are given at four different phase snapshots [(a) 0°, (b) 80°, (c) 180°, and (d) 280°] to illustrate the propagation of the traveling wave from right to left from Figs. 3(a)–3(d). According to Eq. (8), the speed of the steered array traveling wave, c_S, should approximately equal 1500 m/s/sin(15°)=5800 m/s. In Fig. 3(a), the peak on the right-hand side travels about 29 scan points (6 mm between points, therefore 174 mm) to its location in Fig. 3(d) in 280° of the phase cycle. That means that for a full 360° cycle, the wave travels 224 mm. The time duration, or period, of a cycle corresponds to the inverse of the frequency. Thus the duration of a period at 25 kHz is 40 μs. The traveling wave speed then is 224 mm/40 μs =5600 m/s. This value represents a fairly rough estimation, but it is within 3.5% of the 5800 m/s expected sound speed. Thus the scanning laser results show that the dominant traveling flexural wave on the radiating surface of the bar corresponds to the intended traveling wave setup by the transducer array.

B. Water tank measurements

Figure 4 displays sample plots comparing directivity patterns, normalized to their respective main lobe peak levels, from the transmit measurements and the receive measurements with the alumina bar array. The near perfect agreement of transmit and receive directivity patterns demonstrates that the array mounted on the alumina bar is a reciprocal system (Ref. 16, p. 378). The measurements of patterns from the array operated in a receive mode show that the data taken at large angles (approximately $>\pm 60°$) is corrupted by the noise floor of the system.

With array measurements in receive mode, the data may be processed to compute directivity patterns steered to any forward angular direction desired. Thus a 180° directivity pattern may be generated for each of the available 180° of steer angles. One convenient method of displaying these data is to create an amplitude map surface plot of receive angle versus steer angle, such that a vertical line (from −90° to +90°) at a fixed steer angle corresponds to the directivity pattern at that steer angle. Figure 5 displays sample surface plot maps of amplitude versus receive angle versus steer

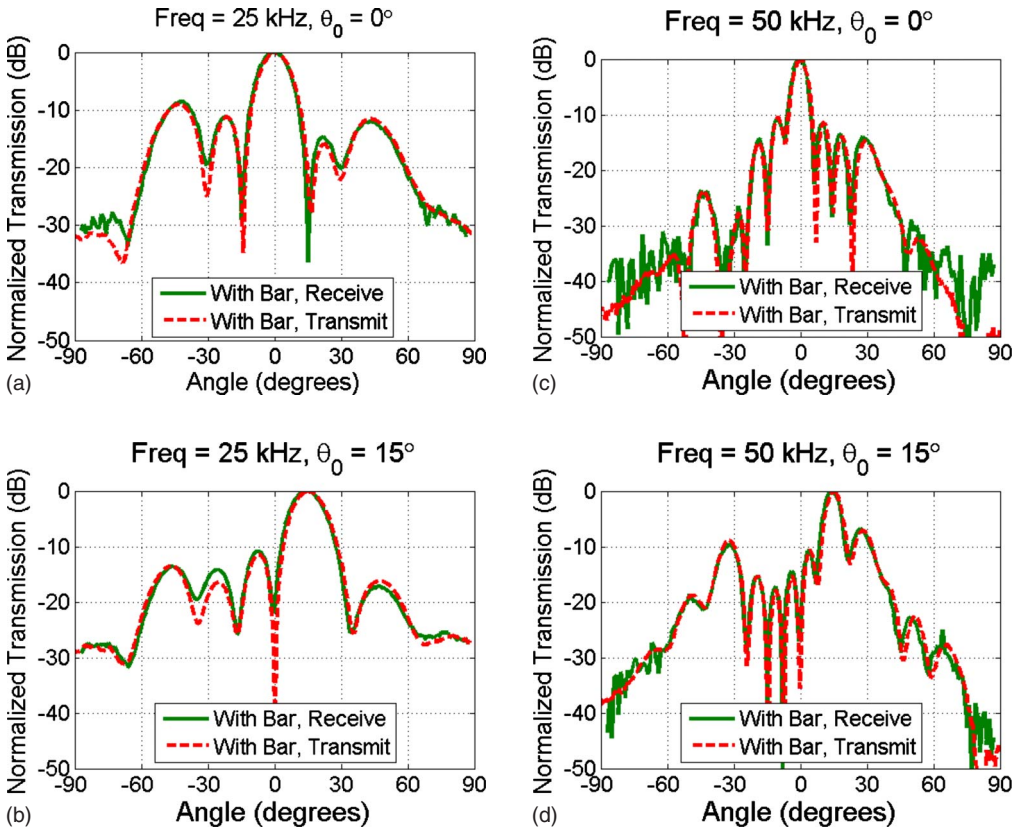

FIG. 4. (Color online) Directivity pattern plots of amplitude vs receive angle for the array mounted on the alumina bar operated in a transmit mode and in a receive mode at the frequencies and steer angles displayed in the titles of each subplot.

angle, with each vertical line of data normalized to its respective main lobe level, at 25 kHz (left subplots) and 50 kHz (right subplots) and for the array without the bar (upper subplots) and the array with the alumina bar (lower subplots). The dominant ridge in each subplot running from the lower left to the upper right corresponds to the main lobe at each steer angle. The presence of this ridge in the surface plots from the data taken from the array mounted on the bar demonstrates that the array can in fact steer sound energy through the alumina bar at the desired steer angle without refraction. Thus it is accurate to assume that the refraction term in square brackets in Eq. (2) may be discarded. Note that the width of the main lobe ridge in data taken from each of the two arrays is approximately the same, meaning that the presence of the alumina bar does not widen the main lobe. Thus the dispersive nature of bending waves in the bar does not alter the driven wave speed, since widening of a lobe would correspond to dispersion of wave speeds. The absence of refraction and dispersion, in the transmission of the driven wave through a plate, are important practical considerations when evaluating the feasibility of using an array to image objects behind a plate.

Note the horizontal ridges which occur in Figs. 5(b) and 5(d) located at receive angles of $\pm 45°$ and at $\pm 30°$, respectively. These horizontal ridges are located at the respective coincidence angles for each frequency [from Eq. (5), $\theta_{CO}(25\ \text{kHz}) = 45°$ and $\theta_{CO}(50\ \text{kHz}) = 30°$ for the alumina bar used]. The coincidence angle is the angle at which bending waves radiate most efficiently.

Another way to analyze the effect of the presence of the alumina bar is to compare the level of the main lobe at each steer angle from the data taken from each array configuration (with and without the alumina bar). The only difference between these two sets of steering data is due to the alumina bar, thus it provides a convenient method of measuring the sound transmission through the alumina bar as a function of angle. The theoretical expression for sound transmission through an undamped ($\eta = 0$) plate or bar given in Eq. (3) was evaluated at various frequencies using material property values which correspond to measured values for the alumina bar density ($\rho = 3956\ \text{kg/m}^3$), Young's modulus ($E = 391$ GPa), and bar thickness ($h = 1.02$ cm). [Thus the critical frequency for the alumina bar is $f_C = 12.0$ kHz, assuming the Poisson ratio specified by the manufacturer ($\sigma = 0.22$)].

Figure 6 shows a comparison of the theoretical and measured sound transmission through an alumina bar. Both plots are normalized to the normal incidence mass law sound transmission levels (measured plots were adjusted such that the small increase at normal incidence was ignored). The theoretical expressions were not evaluated at angles greater than $\pm 65°$ since the theoretical expression does not generally give accurate results at large angles, as noted by Fahy (Ref. 15, pp. 292–294). Also, measurements at large angles are corrupted by the measurement noise floor as noted in the reciprocity comparison discussion. Although the analytic approach is approximate (based on thin infinite plate theory), the simulated general behavior matches that observed in the

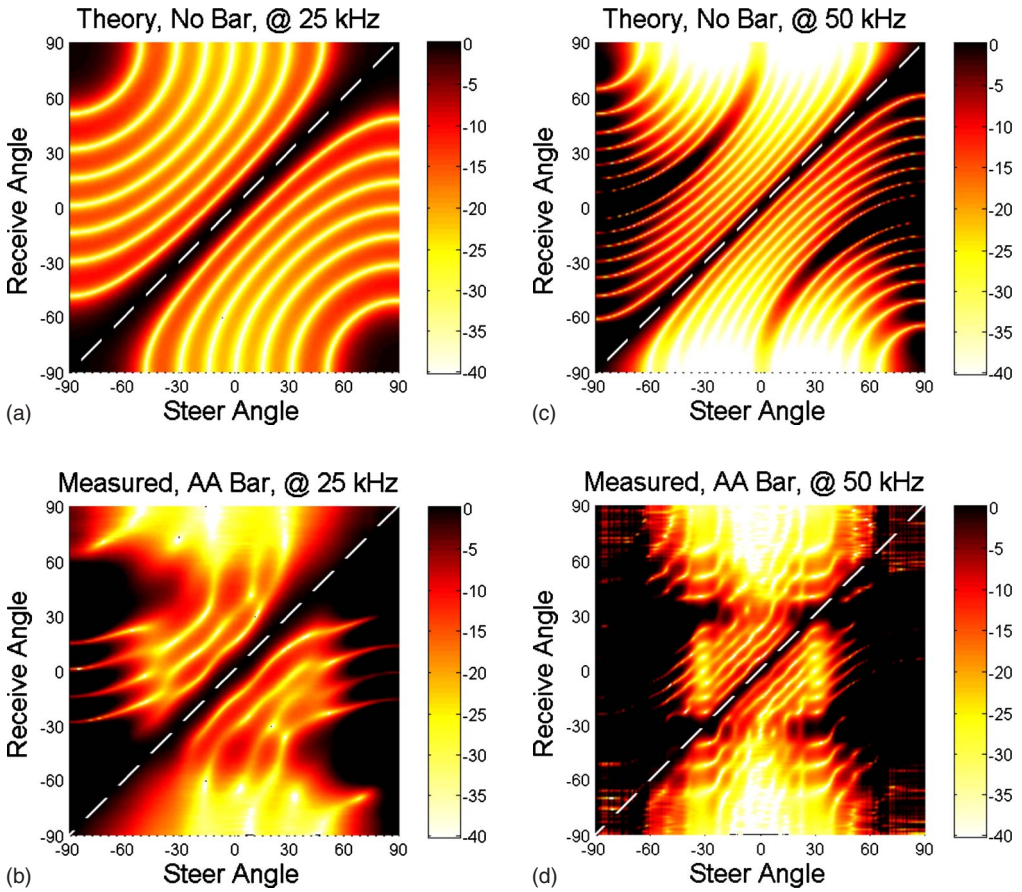

FIG. 5. (Color online) Surface plots of directivity amplitude vs steer angle and receive angle. The upper subplots are from data without the alumina bar, while the bottom subplots are from data with the alumina bar. The subplots on the left are for 25 kHz while the subplots on the right are for 50 kHz.

measurements. This means that the approximate analytic theory may be used for qualitative studies of other plate and array configurations. The discrepancies in levels at coincidence angles and at normal incidence are due to the approximate nature of the analytics used here (infinite, rather than finite plate; thin plate theory, rather than thick; approximate treatment of damping).

V. CONCLUSION

Results have shown that indeed a phased array of transducers can induce a traveling flexural wave on a rectangular bar which then radiates sound into the same direction as the phased array would radiate without a bar. Results also show that placing a bar in the near-field of the array allows measurement of transmission versus angle. The measured transmission versus angle for a finite sized plate does agree qualitatively with the theoretical transmission versus angle for an unbounded thin plate of the same thickness and material properties. It should be noted that the frequencies used in this study were above the plate's critical frequency. Below the critical frequency, one would not encounter the coincidence effects in the array's radiation pattern, since bending waves would not radiate efficiently even though they would be excited.

The ability to steer sound energy through a plate allows one to image objects on the other side of the plate when it is otherwise impossible to physically access that side of the plate. Sound transmission through a partition or plate is the highest at the coincidence angle, thus applications could be developed to exploit the ability to transmit and receive sound with a high degree of transmission at this angle. Conceivably, an array may be placed on the wall of a submarine hull or boat to image objects in the water.

A novel technique which allows measurement of the transmission coefficient as a function of angle has been presented in this paper. This technique is similar in nature to the techniques proposed by Louden,[12] Davies and Gibbs,[11] and Balilah and Gibbs[13] in that sound is sent through a plate at various angles, thus allowing measurement of the angular dependent transmission coefficient. However, the advantage of the proposed technique is that it exploits the high directivity of an array to avoid the flanking transmission and precursor waves encountered in the research done by Davies and Gibbs and Balilah and Gibbs which were due to using spherical wave sources. In addition, while the techniques proposed by the above-mentioned researchers essentially require relatively large partition samples, the proposed technique measures relatively small plate samples.

The results presented here were for one-dimensional measurements of the angular dependent transmission coefficient using a line array and a bar under test. The investigation has been extended to two dimensions by the authors, using a two-dimensional array of transducers.[14] The measurements yielded results consistent with the results found in

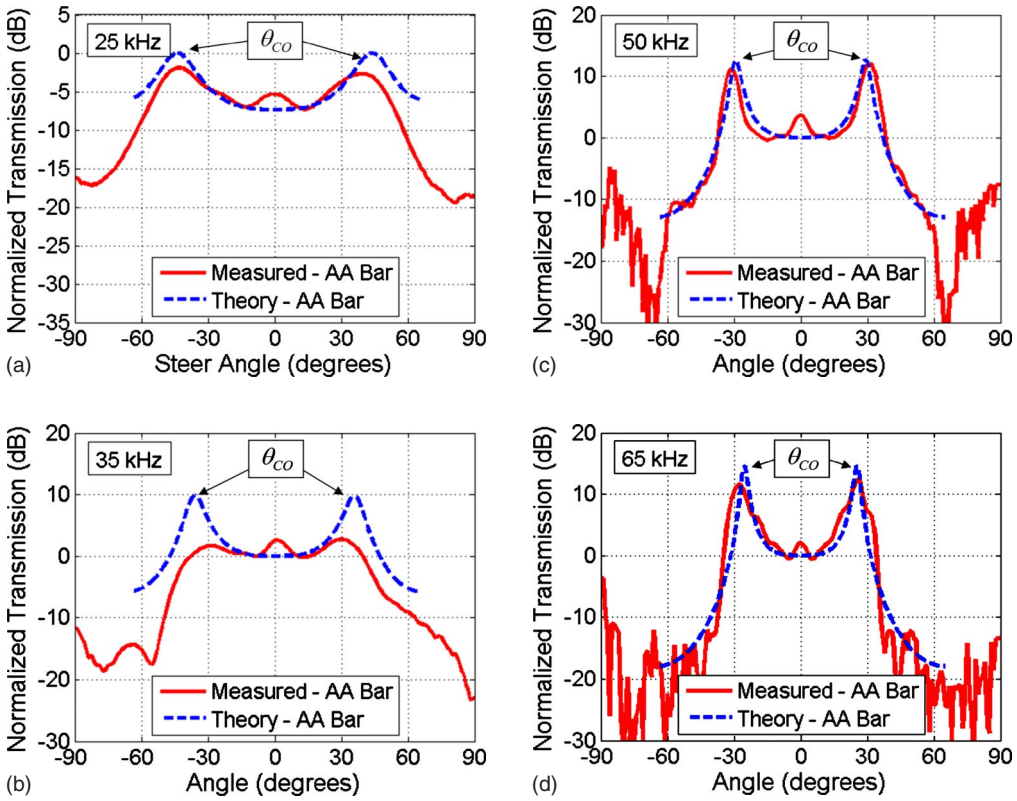

FIG. 6. (Color online) Plots of transmission through the alumina (AA) bar vs incidence angle for the frequencies indicated in the upper left of each subplot.

the material presented in this paper, and may be presented in a future paper. Finally, the analytic approach presented here (based on infinite thin plate theory) is approximate. Future analytic work in this area should focus on thick plate effects, and on finite dimensions, perhaps using numerical methods.

(Received 5 April 2007; revised 8 January 2008; accepted 9 January 2008)

Modern array systems allow for excitation of separate elements using arbitrary wave forms. This is utilized in pulse compression and coded excitation techniques to improve the imaging performance. Such techniques are however somewhat inflexible since they use predefined excitation schemes. This paper presents a more flexible method for optimizing the input signals to an ultrasonic array in such a way that the scattering strengths at arbitrarily chosen control points in the insonified object can be estimated with as small an error as possible, measured with a mean squared error criteria. The statistically motivated method is based on a linear model of the array imaging system and the method takes into account both prior information regarding the scattering strengths and measurement errors. The input signals are found by using genetic optimization and are constrained to have finite duration and bounds on the maximum amplitudes. Different constellations of control points, and different signal-to-noise ratios, yield different excitation schemes. The design approach finds multiple selective focal laws when choosing relatively well separated control points and when the control points are closely spaced, the resulting excitations result in more diffuse fields. Because of the flexibility in choosing the control points, the design method will be useful when developing transmission schemes aiming at fast imaging of large image areas using few transmissions.

I. INTRODUCTION

Traditionally, acoustic array data have been processed by means of spatial filtering, or beamforming, to obtain an image of the scattering objects.[1–3] Beamforming using the classical time-domain delay-and-sum method is analogous to the operation of an acoustical lens and it can be performed efficiently using delay-line operations in real time or using postprocessing as in synthetic aperture systems.[4–7] Delay-and-sum beamforming, which is essentially based on a geometrical optics approach,[8] is computationally attractive due to its simplicity but it has several inherent drawbacks. One such drawback is that the resolution of traditional delay-and-sum beamforming methods is determined by the product of the transmitted and received beam patterns. These beam patterns are determined by the position-dependent point spread functions (PSFs) associated with the array system. These are determined by the aperture size, element size, and transmit pulse; hence resolution is directly related to the physical size of the array.[8] Classical beamforming can, therefore, not achieve higher resolution than the so-called diffraction limit.

Researches have developed various methods to improve resolution in ultrasonic array imaging using, for example, time-dependent (dynamic) receive focusing[9] or to select a transmit aperture so that the PSFs are as position invariant as possible over the region of interest (ROI).[10,11] Such approaches can, however, never circumvent the fundamental limitations of delay-and-sum methods.

Due to the inherent limitations of classical beamforming there has been an increasing interest in model-based array imaging methods. The idea with these methods is to set up a model for the imaging system that takes both electrical and acoustical (diffraction) effects into account[12,13] with the aim to compensate for both these effects. If this is successful then one can relax some of the restrictions normally imposed on array designs, that is, (i) undersampled arrays can be used since artifacts due to grating lobes can be compensated for, and (ii) long transmit sequences can be used which implies more transmitted acoustic energy, and as a consequence, the reconstructions become less noisy. Another potential benefit is that by using this methodology rather large areas can be reconstructed using a single, or at least very few transmissions, which is of interest in applications where a high frame rate is required.

The model-based methods can roughly be divided into two groups. In the first one the imaging problem is seen as an inverse problem where the goal is to remove effects of the so-called *propagation operator*. Since this type of problem is known to be "ill-posed," regularization is generally required in order to obtain numerically stable and noise resistant reconstructions.[14,15]

[a)]Electronic mail: fredrik.lingvall@ifi.uio.no
[b)]Electronic mail: tomas.olofsson@signal.uu.se

In the second group the imaging problem is seen as an inference problem[16,17] where the objective is to estimate the scattering strengths based on the information that is available. Such information is typically the PSFs associated with the array system (the propagation operator) and some assumptions regarding the scattering strengths.[18,19]

The main objective of this paper is the design of suitable transmit sequences to improve imaging performance. Input signal design for ultrasonic imaging has been studied extensively over the last two to three decades. Proposed approaches in ultrasonic imaging include, for example, coded-excitation methods and time-reversal-based methods.

Coded-excitation methods have become more popular in ultrasonic array imaging research in the last decade. In these methods a longer signal such as frequency modulated chirps or binary sequences, like Golay codes, are used instead of short pulses.[20–22] The temporal resolution is then restored on receive by pulse compression matched filtering. The benefit of these methods is an increased signal-to-noise ratio (SNR) in the beamformed images but they are still diffraction limited and the resolution is independent of the SNR (a high SNR will not improve resolution). The latter drawback can be alleviated by using spectral inversion[23] but these types of coded-excitation methods still have many of the deficiencies of conventional beamforming.

In time-reversal imaging, a pulse is first transmitted and after receiving the response, the acquired signals are reversed in time and then retransmitted.[24] The resulting field is then refocused to the strong scatterers even when the propagation medium is inhomogeneous. However, this approach has several drawbacks. First, a strong scatterer is needed to achieve focusing, and second, one may be interested in focusing at other points as well. Furthermore, the time-reversal operation is equivalent to the operation of a matched filter,[24] and although the matched filter approach is known to be robust[14,25] and has the property to optimize the SNR at the focal point, there are no restrictions on the estimation errors for points around the focal point resulting in a resolution similar to conventional array imaging.[14]

To alleviate these problems model-based inverse imaging can be included in the input signal design. A simple approach, suggested for transmit pulse design in nondestructive testing, is to use a weighted inverse of the double-path impulse response as an input signal for one-dimensional A-scan data.[26] In more advanced multidimensional imaging, a "stabilized" inverse of the propagation operator has been suggested for designing input signals so that a precise control over the intensity level at a predefined set of control points can be obtained.[14,27,28] This technique has also been used to improve the performance of coded-excitation methods.[29]

The input signal design approach taken in this paper is based on the second type of model-based imaging methods described earlier. Instead of specifying a desired response at some chosen control points, or specifying a coded excitation, the input signals are obtained by minimizing the *expected squared estimation error* for the optimal linear estimator[13,18,19] at a chosen set of control points.

The optimal linear estimator was chosen here since it allows for the estimation error to be expressed in a closed form which makes optimization of its performance feasible. Furthermore, the optimal linear estimator has the desirable properties to be able to compensate for both diffraction effects due to finite size of the array elements[30] as well as grating lobes or any other broad beam pattern.[13] The performance of the linear estimator is mostly determined by the SNR at the particular ROI. That is, if the signal energy at a region is sufficient then the optimal linear estimator can compensate for diffraction effects, arbitrary beam patterns, electrical characteristics of the transducer array, and very high resolution images can be obtained which are not diffraction limited.

Statistically motivated input signals have been used before in ultrasonic array imaging where temporal (one-dimensional) input signal optimization for the Wiener filter was considered.[31] It was shown that if an energy constraint was used, then the power spectrum of the input signal can be found leaving the phase of the signal arbitrary. It was also shown that genetic algorithms can be used to find binary input signals resulting in a low mean squared error (MSE) for the Wiener filter, which resulted in a superior range resolution, lower range sidelobes, and higher SNR compared to traditional pulse compression methods. However, the one-dimensional approach does not take into account the effects of the nonstationary PSFs, which is suboptimal since then not all of the diversity inherent in the array imaging problem is considered. In this paper a model is used that does take into account nonstationary PSFs and the constraints on the finite length input signals are only on the bounds of their maximum amplitude vales.

This paper is organized as follows: In Sec. II the linear model based on the impulse response method is introduced and in Sec. III the optimal linear estimator is presented. Section IV presents a performance criterion and suggests an optimization strategy. Some simulation examples are then shown in Sec. V, and finally in Sec. VI a discussion is given.

II. A DISCRETE LINEAR MODEL OF THE IMAGING SYSTEM

Here we will introduce the linear model, based on the impulse response concept,[32,33] that later will be used in the reconstruction algorithm (i.e., in the estimator presented in Sec. III). The objective is to model the double-path (pulse-echo) B-scan response given an array layout and a set of input signals, one separate input signal for each transmit element. To accomplish this we first describe the A-scan signal acquired at one receive element resulting from a scatterer at a single observation point, $\mathbf{r}=(x,y,z)$. This model is then extended to B-scan data for an arbitrary number of observation points.

Consider an array with K transmit elements and L receive elements and contributions from a scatterer at $\mathbf{r}$ with a scattering strength $o(\mathbf{r})$. The received A-scan signal from the lth receive element, $y_l(\mathbf{r},t)$ can be expressed as[19]

$$y_l(\mathbf{r},t) = \left(\sum_{k=0}^{K-1} h_k^{\text{f-SIR}}(\mathbf{r},t) * h_k^{\text{ef}}(t) * u_k(t) \right) \times o(\mathbf{r}) * h_l^{\text{b-SIR}}(\mathbf{r},t) * h_l^{\text{eb}}(t) + e_l(t), \quad (1)$$

where an asterisk (∗) denotes temporal convolution. The sum inside the parentheses in Eq. (1) represents the transmit process where $h_k^{\text{f-SIR}}(\mathbf{r},t)$ is the forward spatial impulse response (SIR) for the kth transmit element, $h_k^{\text{ef}}(t)$ is the forward electrical impulse response, and $u_k(t)$ is the kth input signal. The receive process is described by the backward SIR, $h_l^{\text{b-SIR}}(\mathbf{r},t)$, for the lth receive element and the corresponding backward electrical impulse response is denoted $h_l^{\text{eb}}(t)$. Finally, $e_l(t)$ represents the combination of measurement noise and any other model error for the lth receive element. The response for all observation points is obtained by superimposing the responses for all points in the ROI. For the discrete case, this summation can be written as a matrix-vector multiplication as follows:[19,30,34]

$$\mathbf{y} = \begin{bmatrix} \mathbf{y}_0 \\ \mathbf{y}_1 \\ \vdots \\ \mathbf{y}_{L-1} \end{bmatrix} = \mathbf{P}\mathbf{o} + \begin{bmatrix} \mathbf{e}_0 \\ \mathbf{e}_1 \\ \vdots \\ \mathbf{e}_{L-1} \end{bmatrix} = \mathbf{P}\mathbf{o} + \mathbf{e}. \quad (2)$$

The column vector $\mathbf{y}$ is the vectorized B-scan data and $\mathbf{o}$ is the vectorized image of scattering strengths; the L column vectors $\mathbf{y}_l$ in Eq. (2) represent the discrete-time A-scans for each receive element. The *propagation matrix*, $\mathbf{P}$, in Eq. (2) describes both the transmission and the reception process for an arbitrary excited array. Note that $\mathbf{P}$ is a function of the K arbitrary discrete input signals $\mathbf{u}_k$.

III. THE OPTIMAL LINEAR ESTIMATOR

The optimal linear estimator—also known as the linear minimum mean squared error estimator, the maximum *a posteriori* estimator under Gaussian assumptions, or the Wiener filter—is briefly introduced in this section. The estimator can be found by assuming a linear estimator, $\hat{\mathbf{o}} = \mathbf{K}_{\text{OPT}}\mathbf{y}$, and then minimize the mean squared error criteria given by[13,18]

$$\mathbf{K}_{\text{OPT}} = \arg\min_{\mathbf{K}} \mathrm{E}\{\|\mathbf{o} - \mathbf{K}\mathbf{y}\|^2\} = \mathbf{C}_o\mathbf{P}^T(\mathbf{P}\mathbf{C}_o\mathbf{P}^T + \mathbf{C}_e)^{-1}. \quad (3a)$$

where $\mathrm{E}\{\cdot\}$ is the expectation operator. The estimator (3a) can be rewritten in the equivalent form

$$\mathbf{K}_{\text{OPT}} = (\mathbf{P}^T\mathbf{C}_e^{-1}\mathbf{P} + \mathbf{C}_o^{-1})^{-1}\mathbf{P}^T\mathbf{C}_e^{-1}. \quad (3b)$$

The latter form (3b) can also be obtained by assuming a Gaussian distributed $\mathbf{o}$ and $\mathbf{e}$ and then choose the estimate $\hat{\mathbf{o}}$ where the *a posteriori* distribution has its maximum. Also, here we have assumed that $\mathbf{o}$ and $\mathbf{e}$ are mutually independent with covariance matrices $\mathbf{C}_o = E\{\mathbf{o}\mathbf{o}^T\}$ and $\mathbf{C}_e = E\{\mathbf{e}\mathbf{e}^T\}$, respectively.

Note that the performance of the estimator (3) is largely dependent on how the transmitted wave field is distributed in space. The most commonly used method to control the distribution of the wave field is by focusing, that is, a short pulse is transmitted on all array elements and appropriate delays are applied so that the field generated by the corresponding elements arrive at the focal point at the same time instant. The drawback of classical focusing is that only a small region will become insonified for each transmission. As mentioned earlier, modern array systems have the capability to transmit arbitrary wave forms and this feature can be utilized to design suitable input signals so the reconstruction performance for the estimator (3) is maximized. In order to accomplish this task we need a method to evaluate the performance, which is the topic of Sec. IV.

IV. THE PERFORMANCE CRITERION

In this section a performance measure and a criterion to optimize the performance is introduced. The performance measure is based on the reconstruction error, $\boldsymbol{\epsilon} = \hat{\mathbf{o}} - \mathbf{o}$, for the optimal linear estimator (3). First note that the covariance matrix for $\boldsymbol{\epsilon}$ can be expressed in a closed form which is given by[35]

$$\mathbf{C}_\epsilon = \mathbf{C}_o - \mathbf{C}_o\mathbf{P}^T(\mathbf{P}\mathbf{C}_o\mathbf{P}^T + \mathbf{C}_e)^{-1}\mathbf{P}\mathbf{C}_o = (\mathbf{C}_o^{-1} + \mathbf{P}^T\mathbf{C}_e^{-1}\mathbf{P})^{-1}. \quad (4)$$

Second, if we assume that there are no correlations between the scatterers and that the noise is white then $\mathbf{C}_o = \sigma_o^2\mathbf{I}$, $\mathbf{C}_e = \sigma_o^2\mathbf{I}$, and $\mathbf{C}_\epsilon$ reduces to

$$\mathbf{C}_\epsilon = \sigma_o^2\mathbf{I} - \sigma_o^2\mathbf{P}^T(\sigma_o^2\mathbf{P}\mathbf{P}^T + \sigma_e^2\mathbf{I})^{-1}\mathbf{P}\sigma_o^2 = (\mathbf{I}/\sigma_o^2 + \mathbf{P}^T\mathbf{P}/\sigma_e^2)^{-1}. \quad (5)$$

Since each diagonal element in $\mathbf{C}_\epsilon$ is the expected squared estimation error of the corresponding element in $\mathbf{o}$ (the expected error at the corresponding observation point) it can be used to evaluate and visualize performance. In particular, one can rearrange the diagonal elements of the $MN \times MN$ matrix $\mathbf{C}_\epsilon$ to form an $M \times N$ image, and then, one can directly see at which regions the error is small and where it is large.

To illustrate this technique we have simulated a 3.5 MHz, 16 element array with a pitch of 1 mm using the DREAM Toolbox.[36] The array was focused using traditional focusing at $z = 50$ mm. Two different SNRs were used, one high SNR and one low SNR, respectively, but the input signals were the same for both SNRs. The resulting error images are shown in Fig. 1 where a dark area indicates a region with low error and a white (bright) area indicates a region with a large error. The error image for the high SNR is shown in Fig. 1(a), and one can observe that the error is small in regions close to the center axis under the array, that is, in regions where the amplitude of the wave field is high. One can also observe that the region with a low error is considerably smaller for the low SNR error image, shown in Fig. 1(b), compared to the high SNR error image.

Note also that it is not required that the field is "focused" in the sense that it is closed to the focal point to obtain good reconstruction results since the expected error in Fig. 1(a) is small also at many points far from focal point. The error does, however, depend on the SNR and for low SNR, the error is only small for points close to the focal point.

From the example shown in Fig. 1 it is clear that if we want a small error over a larger region (from a single trans-

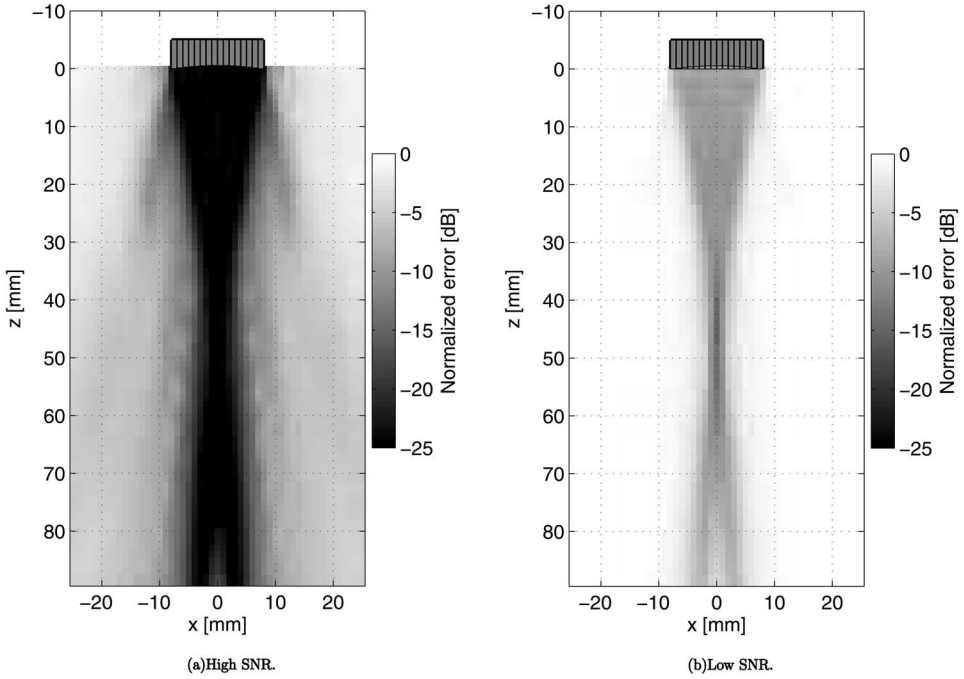

FIG. 1. Two examples of error images, normalized with respect to σ_o^2, for a 16 element array conventionally focused at $z=50$ mm. The error images are formed by rearranging the diagonal elements of the error matrix $\mathbf{C}_\epsilon$ [see Eq. (5)] for the optimal linear estimator (3) as an $M\times N$ image.

mission) then it is not sufficient to use traditional focusing and the objective here is then to minimize the error, for an arbitrarily chosen set of observation points, by means of finding suitable input signals for that task. To accomplish this first note that if the eigenvalues of the product $\mathbf{P}^T\mathbf{P}/\sigma_e^2$ are significantly larger than $1/\sigma_e^2$ then the expected error in Eq. (5) will become small. Moreover, since the elements in $\mathbf{P}$ are formed by convolutions with the input signals [cf., Eq. (1)], a small error can be achieved by simply increasing the amplitudes of the input signals. This will, however, force the input signals to infinity if there were no constraints on them.[31] For a practical system the input signals are limited and here we assume that we have an array system which have separate transmit and receive buffers for all channels; and these buffers have a limited size and the discrete representation of the signals limits the amplitudes to a predefined interval.

Let us denote the input signal's lengths L_u and let the amplitudes be restricted to the interval $(-u_{\max}\leqslant u_i\leqslant u_{\max})$. The criterion we have chosen to optimize is the MSE, $\Sigma_i E\{(\hat{o}_i-o_i)^2\}$, which is the sum over the diagonal elements (the trace) in $\mathbf{C}_\epsilon$

$$\hat{\mathbf{u}} = \arg\min_{\mathbf{u}} \mathrm{tr}\{\mathbf{C}_\epsilon\}$$
$$\text{subject to} \quad |u_i| \leqslant u_{\max}\forall_i, \tag{6}$$

where $\mathrm{tr}\{\cdot\}$ is the trace operator and $i=0,\ldots,L_u-1$. Note that the criterion (6) is nonlinear and we may have many local minima. Here we have used genetic optimization to find good input signal candidates.

It should be emphasized that this optimization approach to input signal design is very general in the sense that it is possible to find input signals for any array configuration provided the impulse responses for the model (2) can be obtained. Hence, both two- and three-dimensional imaging can be treated using, for example, one-dimensional linear arrays or two-dimensional arrays, which may or may not be undersampled.

In the remaining part of this paper a number of examples will be presented, from various setups, that show some properties and consequences of this input signal optimization approach.

V. SIMULATION EXAMPLES

Here we will present simulation examples for various single transducer and array imaging setups. The wave field simulations have been performed using the DREAM TOOLBOX,[36] which is a software package based on the *discrete representation* (DR) computational concept.[37]

A. The one-dimensional case: One transducer and a single observation point

Before we study the full multidimensional array case let us consider a single observation point and a single transducer operating in pulse-echo mode [see the illustration in Fig. 2(a)]. In such case the continuous-time model reduces to

$$\begin{aligned} y(t) &= h^{\text{f-SIR}}(t) * h^{\text{ef}}(t) * u(t)o \\ &\quad * h^{\text{b-SIR}}(t) * h^{\text{eb}}(t) + e(t) \\ &= h(t) * u(t)o + e(t), \end{aligned} \tag{7}$$

where $h(t)$ is the double-path impulse response for the single observation point where the dependence of $\mathbf{r}$ has been dropped in the notation here since we only have one observation point. In order to discretize Eq. (7) one can note that a discrete-time convolution of the signals $h(t)$ and $u(t)$, represented by the vectors $\mathbf{h}$ and $\mathbf{u}$, respectively, can be expressed as a matrix-vector multiplication of a Toeplitz matrix,[38] $\mathbf{H}$, consisting of delayed versions of $\mathbf{h}$ in its col-

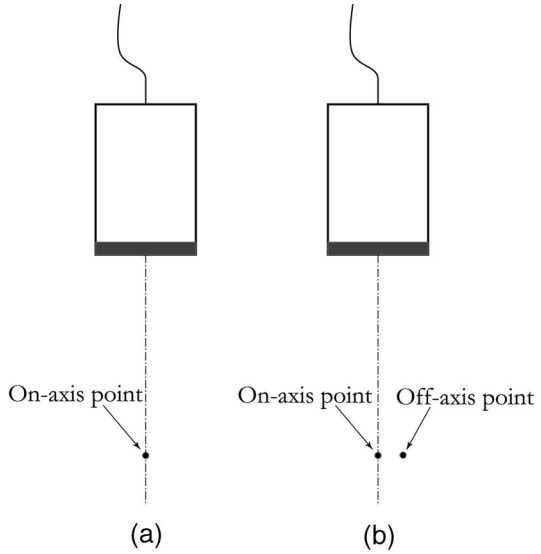

FIG. 2. Illustration of a single (circular) transducer with two configurations of observation points. (a) One on-axis observation point. (b) Two observation points, one located on-axis and one off-axis.

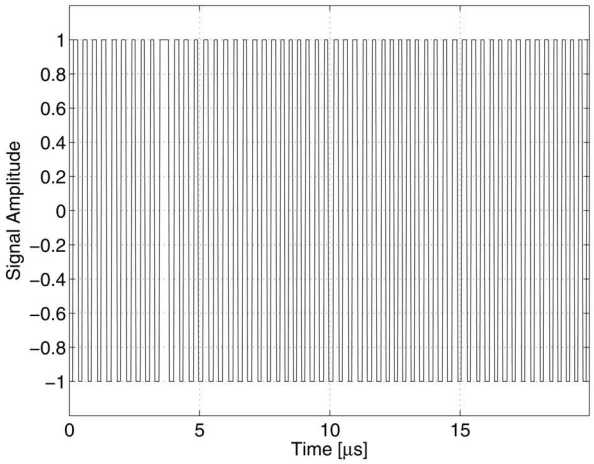
umns, and the vector $\mathbf{u}$. Hence, the discrete-time equivalent of Eq. (7) can be expressed as

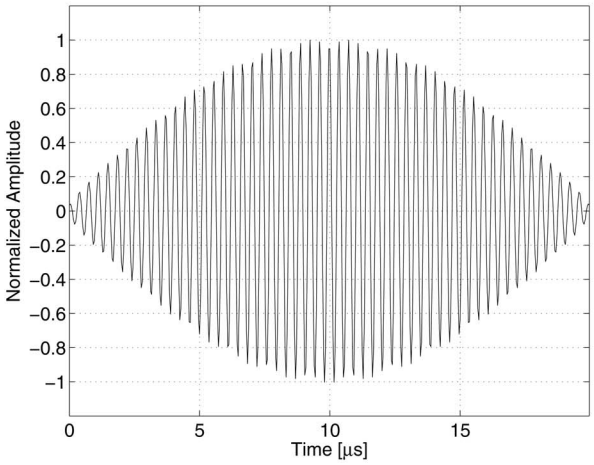
$$\mathbf{y} = \mathbf{H}\mathbf{u}o + \mathbf{e}. \tag{8}$$

Thus, for this simple case the output signal only depends on the convolution of the input signal $\mathbf{u}$ and the impulse response $\mathbf{h}$ scaled with the (unknown) scattering amplitude o.



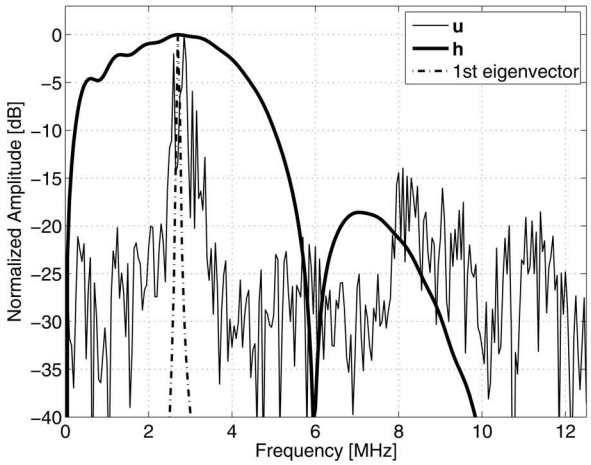
The expected error, found by using Eq. (8) in Eq. (5), then reduces to the scalar

$$\sigma_\epsilon^2 = (1/\sigma_o^2 + \mathbf{u}^T\mathbf{H}^T\mathbf{H}\mathbf{u}/\sigma_e^2)^{-1} = \frac{\sigma_e^2}{(\sigma_e^2/\sigma_o^2) + \mathbf{u}^T\mathbf{H}^T\mathbf{H}\mathbf{u}}. \tag{9}$$



In this simple case we can immediately notice that it is sufficient to maximize the scalar $\mathbf{u}^T\mathbf{H}^T\mathbf{H}\mathbf{u}$ in order to minimize the error. That is, in this case the optimized input signals will not depend on the SNR.

An idea that may be tempting is to let $\mathbf{u}$ be the eigenvector corresponding to the largest eigenvalue of the matrix $\mathbf{H}^T\mathbf{H}$, since then, we will drive the system where it is most sensitive. This approach is, however, not optimal in the sense of the criterion (6); choosing the eigenvector as the input signal corresponds to a criterion where the restriction is on the energy, $\mathbf{u}^T\mathbf{u}$, of the input signals and not bounds of their max amplitudes. In order to use such eigenvectors as input signals they need to be scaled to fit within the amplitude bounds, which will result in a larger error compared to using signals specifically optimized to fit within these bounds.



To illustrate this let us study a (broadband) 3.5 MHz circular transducer with a diameter of 10 mm and a single observation point at $(0,0,50)$ mm. An input vector with a length of L_u=500 samples was optimized for this scenario where the max amplitude, $u_{\max}$, was set to 1. The optimized input signal is shown in Fig. 3(a) and the eigenvector corresponding to the largest eigenvalue of $\mathbf{H}^T\mathbf{H}$ is shown in Fig. 3(b). Furthermore, in Fig. 3(c), the spectra for $\mathbf{u}$ (thin solid line), the eigenvector of $\mathbf{H}^T\mathbf{H}$ (dash-dotted), and the double-path impulse response, $\mathbf{h}$ (thick solid line) are also shown.

(a)Optimized input signal $\mathbf{u}$.

(b)Eigenvector corresponding to the largest eigenvalue, $\lambda_{\max}$, of $\mathbf{H}^T\mathbf{H}$.

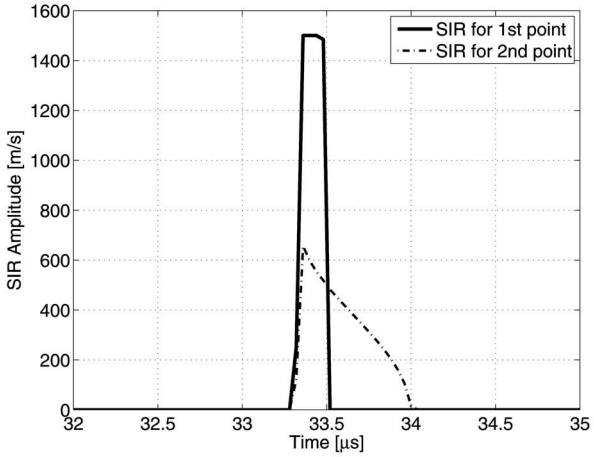
(c)Thin line: amplitude spectrum of the input signal $\mathbf{u}$, thick line: amplitude spectrum of the impulse response $\mathbf{h}$, dash-dotted thick line: spectrum of the Eigenvector corresponding to the largest eigenvalue of $\mathbf{H}^T\mathbf{H}$.

FIG. 3. Simulation example of an optimized input signal for a 10 mm (in diameter), 3.5 MHz circular transducer and an observation point at $(0,0,50)$ mm.

By comparing the spectrum of the input signal to the spectrum of the double-path impulse response one can observe

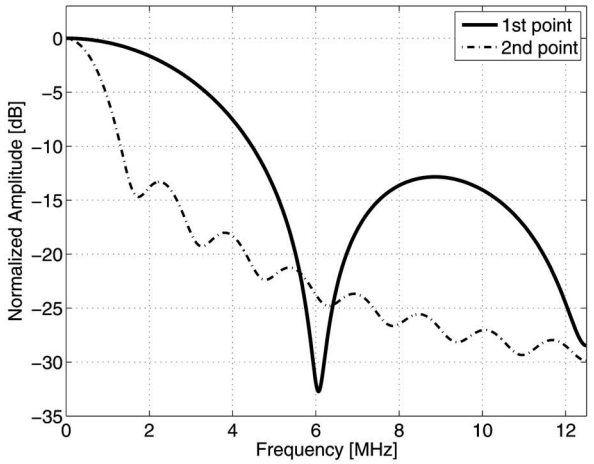
that the peak of the input signal's spectrum coincides withthe peak of the impulse response's spectrum. Thus, the optimized input signal drives the system where it has the most sensitivity. This is also true for the eigenvector signal since its spectrum also peaks at the peak of the impulse response's spectrum. However, using the optimized signal will result in a smaller reconstruction error since the total energy in the optimized signal is always higher than for the eigenvector approach; for the example presented in Fig. 3 the error when using the eigenvector signal was 4.7 dB larger compared to using the optimized signal.

This is generally valid for all optimized signals presented in this paper. The optimal values of the input signals will always occur at corner points of the constraints in Eq. (6); that is, the value of the optimized signal will either be $-u_{\max}$ or $u_{\max}$. The discrete nature of the optimized signal is rather natural since the highest acoustic output will be attained when the input signal is maximal, e.g., since the system is linear a lowering of the input amplitude can never increase the total output energy. The form of the output signal is also attractive from a hardware design point-of-view since a binary output buffer can be used (e.g., $-u_{\max}$ can be represented with a "0" and $u_{\max}$ with a "1," and digital-to-analog converters are not needed).



The optimized signal type, shown in Fig. 3, is known in the automatic control community as "bang-bang" signals. It has also been known from the 1960s in optimal experimental design that the bang-bang type of input signals are optimal in parameter estimation of linear dynamic systems when the constraints are of max/min type.[39,40]

B. One transducer and two observation points



In the simple one-dimensional example presented in Sec. V A the optimized input signal did not depend on the SNR. This is, however, not true for more complex systems. To illustrate this let us consider two observation points and a single transducer [see the illustration in Fig. 2(b)]. Similar to the one-dimensional case, a discrete model can be obtained by expressing convolutions as matrix-vector multiplications. However, when we have two observation points the total A-scan response, $\mathbf{y}$, will now be a sum of two A-scan responses, one from each of the corresponding observation points. The total A-scan response can therefore be expressed as

$$\begin{aligned}\mathbf{y} &= \mathbf{H}_1\mathbf{u}o_1 + \mathbf{H}_2\mathbf{u}o_2 + \mathbf{e} \\ &= \mathbf{p}_1 o_1 + \mathbf{p}_2 o_2 + \mathbf{e} \\ &= (\mathbf{p}_1\mathbf{p}_2)\begin{pmatrix} o_1 \\ o_2 \end{pmatrix} + \mathbf{e}, \end{aligned} \tag{10}$$

where $\mathbf{H}_1$ and $\mathbf{H}_2$ are the Toeplitz matrices derived from the double-path impulse responses for the two observation points: 1 (on-axis) and, 2 (off-axis), $\mathbf{p}_1$ and $\mathbf{p}_2$ are the corresponding double-path (A-scan) responses (for unit area scatterers), and the two scalars o_1 and o_2 are the scattering strengths at observation point 1 and 2, respectively. The 2×2 error matrix, $\mathbf{C}_\epsilon$, for the linear estimator, based on Eq. (10), then becomes

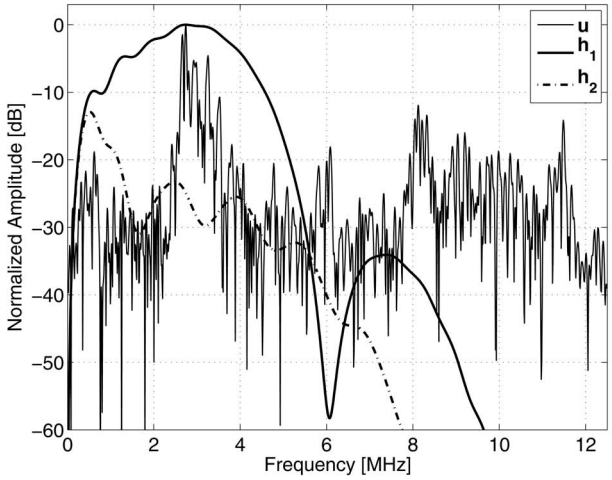
(a) Spatial impulse responses (SIRs) for observation point 1 and 2.

(b) Normalized frequency responses of the SIRs for observation point 1 and 2.

FIG. 4. Spatial impulse responses and their corresponding frequency responses for a ∅10 mm circular transducer. Thick solid line: SIR corresponding to observation point 1 at (0,0,50) mm. Dash-dotted line: SIR corresponding to observation point 2 at (5,0,50) mm. (a) SIRs for observation points 1 and 2. (b) Normalized frequency responses of the SIRs for observation points 1 and 2.

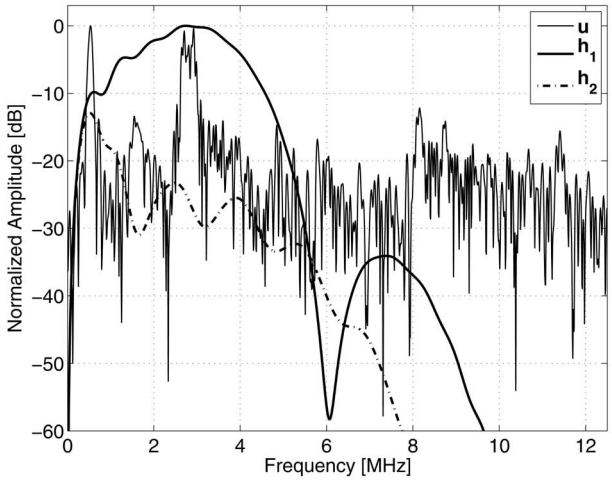
$$\begin{aligned}\mathbf{C}_\epsilon &= \sigma_e^2 \begin{pmatrix} \mathbf{u}^T\mathbf{H}_1^T\mathbf{H}_1\mathbf{u} + \dfrac{\sigma_e^2}{\sigma_o^2} & \mathbf{u}^T\mathbf{H}_1^T\mathbf{H}_2\mathbf{u} \\ \mathbf{u}^T\mathbf{H}_2^T\mathbf{H}_1\mathbf{u} & \mathbf{u}^T\mathbf{H}_2^T\mathbf{H}_2\mathbf{u} + \dfrac{\sigma_e^2}{\sigma_o^2} \end{pmatrix}^{-1} \\ &= \sigma_e^2 \begin{pmatrix} \mathbf{p}_1^T\mathbf{p}_1 + \dfrac{\sigma_e^2}{\sigma_o^2} & \mathbf{p}_1^T\mathbf{p}_2 \\ \mathbf{p}_2^T\mathbf{p}_1 & \mathbf{p}_2^T\mathbf{p}_2 + \dfrac{\sigma_e^2}{\sigma_o^2} \end{pmatrix}^{-1}. \end{aligned} \tag{11}$$

Let us again consider a 10 mm circular transducer but now with two observation points at (0,0,50) mm and (5,0,50) mm, respectively. The corresponding SIRs and their frequency responses[33,41] are shown in Fig. 4. The SIR from the off-axis point (5,0,50) has a significantly lower cut-off frequency than the SIR for the on-axis point



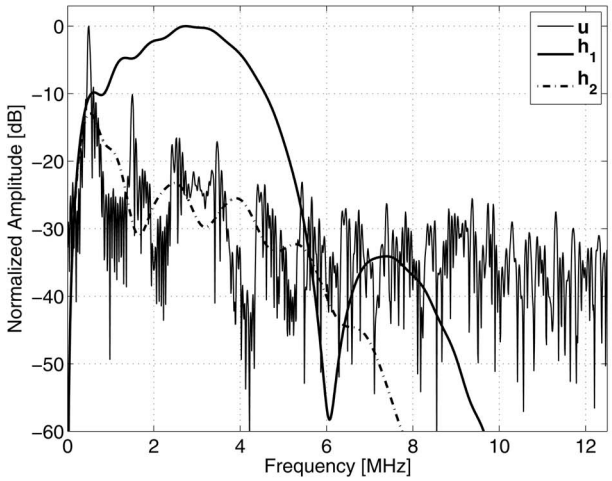
$(0,0,50)$, which corresponds to the fact that the beam width is frequency dependent. Thus, the transducer size effects, or the diffraction effects, result in a system that has a spatially varying frequency dependent sensitivity. In this particular example, the system is more sensitive at the on-axis point $(0,0,50)$ than at the off-axis point $(5,0,50)$.

Let us now study the elements $(\mathbf{C}_\epsilon)_{1,1}$ and $(\mathbf{C}_\epsilon)_{2,2}$ of the error matrix in Eq. (11). In order for the input signal to have a significant impact on the error, both the factors $\mathbf{p}_1^T\mathbf{p}_1$ and $\mathbf{p}_2^T\mathbf{p}_2$ cannot be much less in magnitude than σ_e^2/σ_o^2. If this would be the case then the acquired data basically do not give us any new information. If only one of the factors is small in comparison to σ_e^2/σ_o^2 then we will be "blind" at the corresponding observation point but not the other.



To illustrate the dependence of the SNR, simulations with three different SNRs are presented in Fig. 5. The thick solid lines indicate the double-path frequency responses corresponding to the on-axis point, $(0,0,50)$, the dash-dotted lines indicate the double-path frequency responses for the off-axis point, $(5,0,50)$, and the thin lines indicate the frequency responses for the optimized input signals.

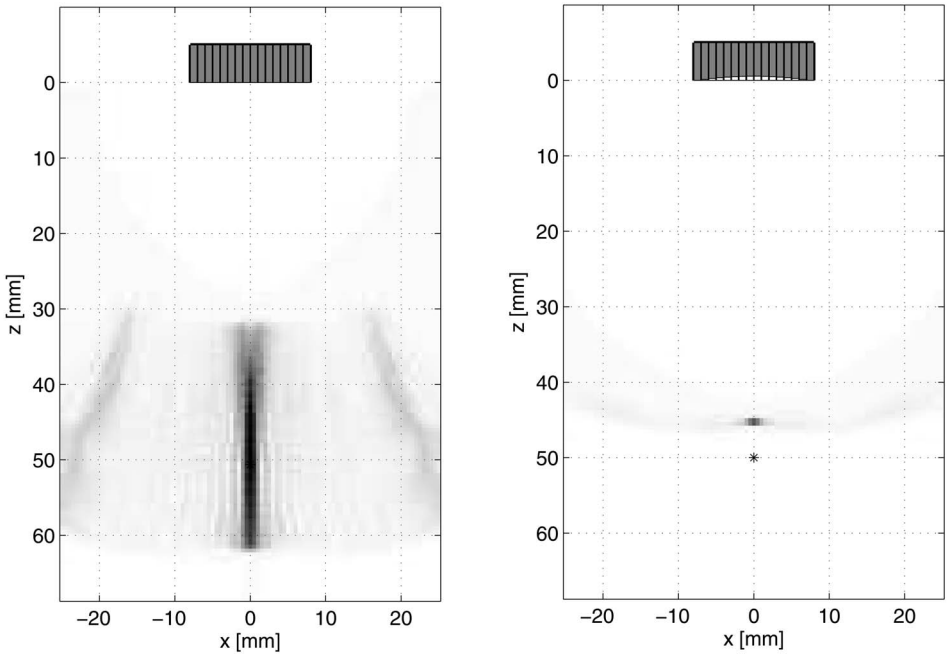
In Fig. 5(a) the SNR was very low and only the error for the on-axis point could be affected by the input signal. This can be seen in the spectra in Fig. 5(a) where most of the input signal's energy is transmitted where the frequency response for the on-axis point has its peak. If the SNR is increased then also the off-axis point will contribute in the optimization and, as shown in Fig. 5(b), the spectra of the input signal now have significant contributions where the spectra for both the on-axis and off-axis points have their corresponding peaks. If we now increase the SNR even further, as shown in Fig. 5(c), then the input signal's spectra will be concentrated at the peak of the off-axis point's spectra. This phenomenon can be explained by the fact that the on-axis and off-axis spectra overlap and if the SNR is high enough then (1) it is possible to estimate scattering from both points using a signal with an "overlapping" spectra, and (2) the off-axis point will contribute most to the error so it makes sense to minimize that error contribution (the error contribution from the on-axis point is already small).



The conclusion from this example is that the distribution of the transmitted acoustic field will depend on the SNR and if the SNR is low then points close to the center axis under the transducer will be favored before points far from the center axis. Note that in the simple example presented here we could only control the error merely by sending the energy in suitable frequency bands. If we increase the number of transducers we have a greater possibility to improve the performance since then we have the possibility to adapt the beam pattern both in time and space which is the topic of the following.

(a)Low SNR ($\sigma_e^2 = 10^5$).

(b)Medium SNR ($\sigma_e^2 = 10^3$).



(c)High SNR ($\sigma_e^2 = 10^{-5}$).

FIG. 5. Simulation examples the frequency responses for optimized input signals for three different SNRs. The simulations were performed for a 10 mm (in diameter), 3.5 MHz circular transducer and two observation points at $(0,0,50)$ mm and $(5,0,50)$ mm, respectively. Thin solid line: Input signals. Thick solid line: Response for $\mathbf{h}_1$ corresponding to point $(0,0,50)$. Dash-dotted thick line: Response for $\mathbf{h}_2$ corresponding to point $(5,0,50)$.

C. Linear array examples

In this section we will present input signal design examples using a linear array. In the examples presented here the SNR can be considered as relatively high. A high SNR was chosen in order to show how the beam pattern can be adapted also for off-axis points; a very low SNR would oth-

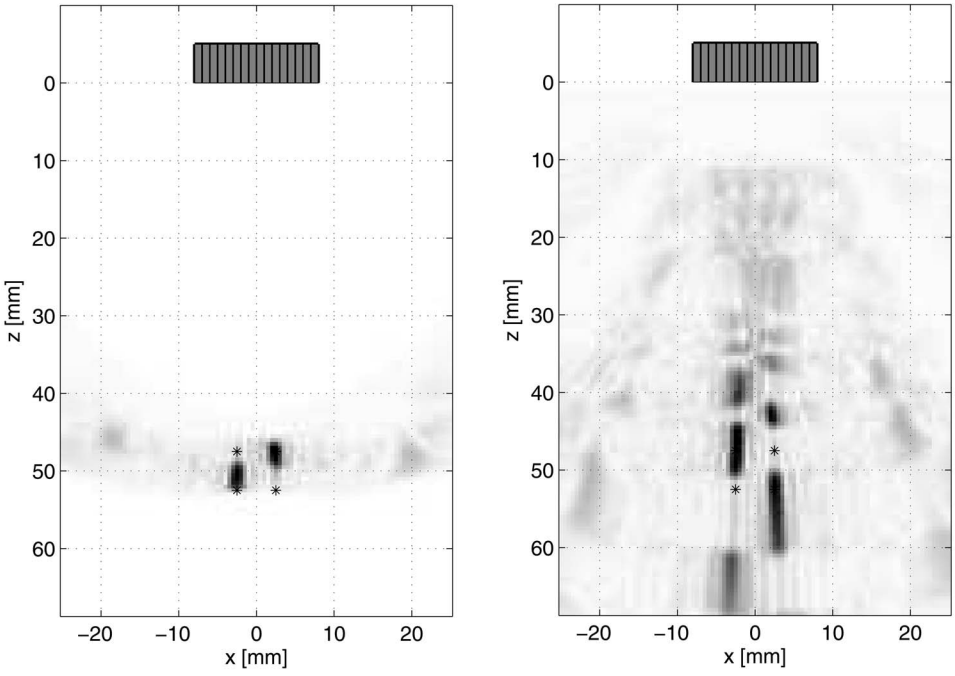
(a)Wavefield snapshot at $t = 41.9\mu s$.

(b)Wavefield snapshot at $t = 31.1\mu s$ for a traditionally focused array.

FIG. 6. An example of a wave field resulting from using input signals optimized for a single control point. A 16 element array (with 0.9-mm-wide elements and a pitch of 1 mm) with 500-sample-long input signals optimized for a single point at (0,0,50.6) mm.

erwise, as was discussed in Sec. V B, force most of the energy to be transmitted directly under the aperture of the array.

Before we present the array examples it should be noted that our possibility to control the beam pattern and, therefore also the reconstruction error, depends very much on the experimental constraints. Longer input signals, higher amplitudes, and broadband transducers will give us more diversity and a higher degree of control of the acoustic field than using short signals, low signal amplitudes, and narrow band transducers.



Also, let us define the set of observation points that we use in the optimization process as *control points* and reserve the name *observation points* for the points that are used in the reconstruction process. We make this distinction since one can optimize the input signals for one set of points and use a different set, typically more dense, in the actual reconstruction process.

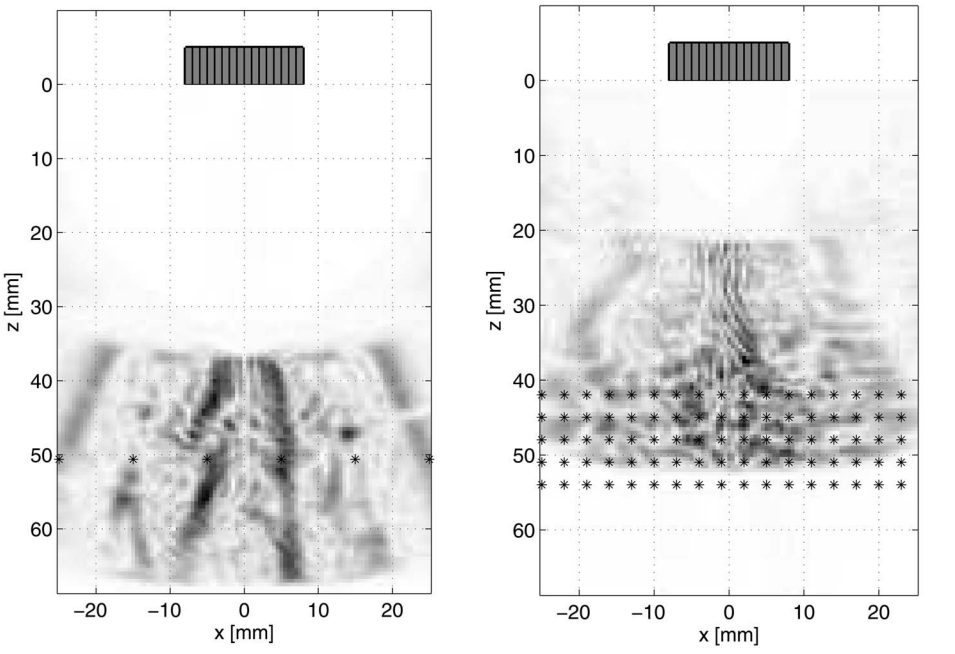
Example 1 (The significance of input signal length). The input signal length has a direct effect on the reconstruction performance. With a longer signal one can transmit energy over a longer period of time, which results in a significantly lower estimation error compared to using very short pulses. To illustrate how input signal optimization, using a relatively long signal, influences the beam pattern a simulation for a 16 element array with 0.9 mm wide elements and a pitch of 1 mm is presented in Fig. 6. The array elements have center frequency of 3.5 MHz, corresponding to a wavelength of $\lambda \approx 0.4$ mm in water, and the length of the input signals, L_u was 500 samples (20 μs). Figure 6(a) shows a simulated wave field snapshot at $t=41.9$ μs and, for comparison, a snapshot at $t=33.5$ μs using traditional focusing is shown in Fig. 6(b). The optimization results in a transmitted wave field which has a time varying focus region and the single control point (0,0,50) is therefore insonified over a considerably longer time compared to using traditional focusing.

Example 2 (Time-space coding). Array imaging using long input signals offers a high degree of diversity and a possibility to control the wave field both in time and space. If the signals are long enough and the number of array elements is sufficient one can insonify very large ROIs. To illustrate how the time and space properties of the wave field are influenced by the optimization process let us consider the same array as used in Example 1 but now we have four control point instead of one. The control points were located at (−2.5,0,47.54), (2.5,0,47.5), (−2.5,0,52.5), and (−2.5, 0,52.5) mm, respectively. The simulation results are shown in Fig. 7, where the wave field resulting from optimization for four relatively closely spaced control points using two different signal lengths are displayed. Figure 7(a) shows a wave field snapshot for an input signal length of 100 samples and Fig. 7(b) shows the corresponding snapshot for a length of 1000 samples.

From Fig. 7(a) one can observe that the energy for control points at the same depth is, at each time instant, low for one control point and high for the other, which makes it easier for the estimator to discriminate from which direction the scattering originates. This phenomenon is seen in the wave fields from both signal lengths. The only difference is that the long signal allows for more of these "pulses" than the short signal resulting in a lower estimation error.

Example 3 (Distribution of energy). In order to reduce the number of transmissions it is desirable to be able to insonify large ROIs from a single transmission. Here this can be achieved by simply distributing the control points over a larger-than-normal area. The input signal optimization process will then try to find input signals, and the corresponding wave fields, so that all control points are sufficiently insoni-

(a)Input signal length $L_u = 100$ samples (snapshot at 35.6μs).



(b)Input signal length $L_u = 1000$ samples (snapshot at 47.9μs).

FIG. 7. Wave field snapshots for input signals optimized for four control points at: $(-2.5,0,47.5)$, $(x=2.5,0,47.5)$, $(-2.5,0,52.5)$, and $(-2.5,0,52.5)$ mm using the same array as in Fig. 6.

fied. It should, however, be noted that the error will most likely not be the same for all control points since, as mentioned in Sec. V B, the array system has a different sensitivity at different control points. The sensitivity is highest directly under the array aperture so a large aperture (with many elements) will perform better than a small one.

To illustrate how input signal optimization can generate laterally broad wave fields two examples are presented in Fig. 8 where the control points are distributed over a large region. Figure 8(a) shows an example with six horizontally located control points and one can observe that a multibeam field is obtained where most of the energy is concentrated around the control points. The example shown in Fig. 8(b) has a relatively large number of control points. Here, a more diffuse field is obtained insonifying the total region of control points.

The conclusion from the examples presented in this section is that the statistically motivated input signal design method proposed here is very flexible in the sense the input signals can be designed for any particular set of control points. The found signals will also result in the lowest possible estimation error for the optimal linear estimator (2) at

(a)Six control points horizontally aligned at $z = 50.6$ mm.

(b)85 control points uniformally located at $-25 < x < 25$, $42 < z < 52$ mm.

FIG. 8. Wave field snapshots at $t=45.5$ μs and $t=35.5$ μs, respectively, for $L_u=500$-sample-long optimized input signals.

the chosen control points for the array system at hand. Also, note that we have chosen to present the proposed method using a linear array and two-dimensional imaging only to facilitate the presentation, but the method can equally well be applied to two-dimensional arrays and/or three-dimensional imaging.

VI. DISCUSSION AND CONCLUSIONS

This paper treats the particular problem of input signal design for ultrasonic array imaging. This problem can be seen as a part of the general framework of optimal experimental design. Here the goal is to design the experiment in such a way that it is as informative as possible regarding the quantity that we want to study. In this case the quantity is the scattering strengths in some ROI and the objective is thus to design the experiment such that we get as much information as possible of the scattering using as much as possible of the capabilities of our measurement system.

When designing the experiment several decisions have to be made that will influence the outcome of the experiment. Typically the design of the experiment must account for several factors such as (from Goodwin[42]):

(1) "the goal of the experiment and the intended application of the results,"
(2) "the class of models to be used,"
(3) "the identification methods and the criterion of best fit,"
(4) "the extent of prior knowledge about the system," and
(5) "the constraints for the operation of the system, both to maintain safe operation and to ensure the system is not forced into an operation regime where the model becomes invalid."

Clearly our goal is to obtain the best image possible but we must first acknowledge the above-mentioned factors and specify the conditions and restrictions of our experiment. For example, if we acquire many signals over a long period of time we will improve the SNR in our estimates but then we cannot perform real-time imaging. Here we have focused on how to optimally design the experiment for so-called single-snapshot processing. If we would have time for more transmissions, mechanical scanning, etc., then the design may have been different.

Also, even though the model used here takes into account many of the properties not considered in traditional beamforming we have restricted the model to be linear. A more advanced model that, for example, has a quadratic term could also be considered. Such a model can better describe (first order) multiple scattering but it would also require a more complex estimator and therefore a more difficult design problem.

The choice of identification method and criterion used here is based on the capabilities of modern ultrasonic array systems and current research in high resolution imaging methods. Since many modern array systems have the capability to transmit arbitrary wave forms and high resolution algorithms can compensate for those wave forms[19] a less restrictive design than normally used can be allowed.

The constraints chosen here were only on the max/min amplitudes and the length of the input signals. These constraints were only due to the practical limitations of the hardware and we have aimed to make no further implicit or explicit restrictions that could degrade the performance. A typical example that results in reduced performance is aperture weighting, which is commonly used in sensor array processing; aperture weighting, or apodization, is a common technique in ultrasonic array imaging to suppress sidelobes. This is, however, clearly suboptimal since by apodizing the aperture less energy is transmitted and/or received, which essentially throws away valuable information.[43]

With these design decisions and restrictions in mind a method for input signal design in ultrasonic array imaging has been proposed in this paper. The method is capable of optimizing the input signals in such way that the scattering strengths at arbitrarily chosen control points can be estimated with as low an error as possible. The input signals, which take the form of binary bang-bang signals, are found by minimizing the expected error for the optimal linear estimator which is based on a linear model of the array system.

It is found that the optimized input signals depend on the SNR and to achieve good reconstruction results the acoustic field at a control point must be high enough relative to the noise. There is, however, no direct relation between the beamwidth of the field at that point since the used estimator has the capability to compensate for the beam patterns. Furthermore, the method automatically utilizes time–space coding possibilities inherent in ultrasonic array systems allowing multiple beams from a single transmission. This enables very fast imaging systems where the scattering amplitudes in large region of interests can be estimated using very few transmissions which is important in many applications such as in, for example, medical imaging where motion artifacts can be a problem if the frame rate is too low.[44]

Using microphone arrays for estimating source locations and strengths has become common practice in aeroacoustic applications. The classical delay-and-sum approach suffers from low resolution and high sidelobes and the resulting beamforming maps are difficult to interpret. The deconvolution approach for the mapping of acoustic sources (DAMAS) deconvolution algorithm recovers the actual source levels from the contaminated delay-and-sum results by defining an inverse problem that can be represented as a linear system of equations. In this paper, the deconvolution problem is carried onto the sparse signal representation area and a sparsity constrained deconvolution approach (SC-DAMAS) is presented for solving the DAMAS inverse problem. A sparsity preserving covariance matrix fitting approach (CMF) is also presented to overcome the drawbacks of the DAMAS inverse problem. The proposed algorithms are convex optimization problems. Our simulations show that CMF and SC-DAMAS outperform DAMAS and as the noise in the measurements increases, CMF works better than both DAMAS and SC-DAMAS. It is observed that the proposed algorithms converge faster than DAMAS. A modification to SC-DAMAS is also provided which makes it significantly faster than DAMAS and CMF. For the correlated source case, the CMF-C algorithm is proposed and compared with DAMAS-C. Improvements in performance are obtained similar to the uncorrelated case.

I. INTRODUCTION

Microphone arrays have become an important element of aeroacoustic testing in recent years. These arrays can be electronically steered into desired regions in space to create an image of acoustic sources at a given frequency. This image consists of the sound pressure levels of each location in the region of interest.[1,2] Perhaps, the most commonly used beamforming algorithm in practice is the delay-and-sum beamformer,[1,3] which basically sums the delayed and weighted versions of each microphone signal so that the actual source signals are reinforced and the unwanted noise signals tend to cancel.

A well-known issue with the classical delay-and-sum approach is that the beamforming maps are usually contaminated by large sidelobes. Sidelobes can cause both the *smearing* and *leakage* of the sources.[4] Consider a scenario with two closely spaced sources so that the response of the array to the first source does not wither away before the response to the second source starts. This will result in the smoothing, or smearing, of the spectrum in the sense that the two peaks will be merged into a single broad peak. Looking from a different perspective, a strong source can yield power at other locations, where no source is present, through the convolution with the sidelobes. This latter form of degradation is called leakage. Therefore, it is usually difficult to identify the true source locations and strengths through the beamforming map obtained via the delay-and-sum method. Another problem with this method is that the beamwidth tends to increase with decreasing frequency.

Various other microphone array processing methods have been developed in order to mitigate the drawbacks of the delay-and-sum beamformer. Weighting schemes that maintain a constant beamwidth over a frequency range for the delay-and-sum beamformer have been discussed in the literature.[5,6] Also, several robust adaptive beamforming techniques have been proposed as alternatives to the delay-and-sum method.[7–9] The latter two of these techniques[8,9] are parametric approaches that require the number of sources to be known. Capon type beamformers cannot provide a sparse representation of the imaging scene and fail to work for coherent sources.[7]

In order to remedy the sidelobe problem of the delay-and-sum method, a postprocessing technique called the deconvolution approach for the mapping of acoustic sources (DAMAS) was developed.[10,11] This approach is considered a breakthrough in the area of aeroacoustic noise measurement

and has been used widely in practice. DAMAS solves an inverse problem using the known steering vectors to decouple the actual source powers from the array characteristics based on the incoherence assumption of the noise sources. This inverse model can be written in a linear matrix equation form which, due to the structure of the matrices, cannot be solved easily. DAMAS uses an iterative scheme for solving this inverse problem. Many other algorithms related to DAMAS have been proposed in the literature.[12] LORE[13] is a deconvolution method that uses a two stage process to solve the inverse problem. In the first step a method similar to DAMAS is used to reduce the problem dimensions and in the second step an optimization scheme is used to solve the reduced inverse problem. DAMAS2 and DAMAS3[14] offer alternatives and extensions to DAMAS by using FFT and assuming that the point spread function is shift-invariant. DAMAS-C[15] extends DAMAS to the coherent sources case. Although requiring high computational resources, this approach is the first deconvolution algorithm considering correlated sources. DAMAS has also been applied to the three-dimensional source localization problem.[16]

In this paper, we introduce new approaches for solving the inverse problem for deconvolution via exploiting sparse signal representations. The sparse signal representation is extensively studied in many areas including statistics and signal processing for the recovery of signals consisting of only few nonzero elements with a known linear relation to the measured data. The sparse signal representation problem mainly aims to find the sparsest $\mathbf{x}$ such that $\mathbf{y}=\mathbf{A}\mathbf{x}$ is satisfied. Stated more formally, the objective is to minimize $\|\mathbf{x}\|_0$ such that $\mathbf{y}=\mathbf{A}\mathbf{x}$ where $\mathbf{A}$ is known and $\mathbf{y}$ is measured. The problem in its original form is a combinatorial problem and has an exponential complexity making it impractical.[17] Fortunately, when $\mathbf{x}$ is sufficiently sparse,[17] $\|\mathbf{x}\|_0$ can be replaced by $\|\mathbf{x}\|_1$ which leads to a convex optimization problem that can be solved much more easily using LASSO[18] or BP.[19] There are many works in the literature elaborating on this relaxation from the ℓ_0 norm to the ℓ_1 norm both in the noiseless and noisy case.[17,20–22] In a nutshell, when $\mathbf{x}$ contains a small number of nonzero elements with respect to its size, the solutions with the ℓ_0 and ℓ_1 norms coincide under some mild conditions. Alternatively, FOCUSS[23] can be used to iteratively solve the sparse problem. This method requires proper initialization of $\mathbf{x}$. Nevertheless, FOCUSS algorithms have been successfully applied to brain (EEG) signals and far field source localization problems. A Bayesian approach can also be used to estimate $\mathbf{x}$ using various prior probability distributions to enforce sparsity. Although these approaches do not require a user parameter,[24–26] they still need some kind of initialization. Note that LASSO can also be thought of as a Bayesian approach assuming a Gaussian likelihood for $\mathbf{y}$ and a Laplacian prior for $\mathbf{x}$ which is known to enforce sparsity. Another algorithm, the ℓ_1-SVD algorithm,[27] is proposed for estimating source locations in a manner similar to BP but for the multiple snapshot and complex case. The algorithm requires an initial estimate for the number of sources. Although this estimate does not have to be exact, a small error is required for good performance. Also, the algorithm has a user parameter whose selection is not trivial. Note that this method is designed to work with the time signals. In aeroacoustic applications, however, huge amounts of time data are collected and it is preferred to work with the covariance matrix since it requires much less storage space and is more convenient to deal with. Finally, Fuchs[28] also discusses methods for the recovery of source locations for the far-field linear array case by appending a noise basis vector to the steering matrix and using deconvolution together with sparsity. It is interesting to note that these approaches in the signal processing literature are similar to DAMAS. Fuchs also provides an extension to his method by using a uniform circular array and a sparse algorithm similar to BP.[29] In this method, the user parameter is selected to be a constant, which can introduce errors.

The remainder of this paper is organized as follows. In Sec. II we parametrize the aeroacoustic source localization problem. After reviewing DAMAS in Sec. III, we describe the sparsity constrained DAMAS algorithm (SC-DAMAS), which is an application of LASSO to the specific inverse problem of DAMAS, in Sec. IV. In contrast to selecting a constant,[29] the user parameter of the algorithm is selected by an adaptive and simple method which uses the eigenvalues of the sample covariance matrix. We also discuss a way to significantly speed up SC-DAMAS. Next in Sec. V, we propose another algorithm called the covariance matrix fitting (CMF) which also exploits sparsity for deconvolution but in a different way than the DAMAS formulation. Both of the algorithms are formulated as convex optimization problems and only use the sample covariance matrix. These algorithms are guaranteed to converge to the globally optimal solution and they take less computation time than DAMAS. The CMF algorithm is more robust to noise than both DAMAS and SC-DAMAS. In Sec. VI, we extend our analysis to deal with correlated sources. We propose CMF-C, which is an extension of CMF to the correlated signals case, and compare it with DAMAS-C. The performance of the algorithms is evaluated using synthetic data for various scenarios in Sec. VIII. The simulation results show that the proposed algorithms can be directly employed in aeroacoustic applications due to their simplicity and good performance. Finally, we conclude the paper in Sec. VIII.

II. PROBLEM FORMULATION

Consider the wave field generated by K near-field wideband sources located at $\mathbf{x}$ where $\mathbf{x}\triangleq[\mathbf{x}_1,\mathbf{x}_2,\ldots,\mathbf{x}_K]$ and $\mathbf{x}_k$ is the three-dimensional location of signal k, $k=1,\ldots,K$. At the pre-processing stage, the time data of each microphone is divided into I segments where each segment consists of L time samples. Each segment of data is then converted into L narrow frequency bins by the L-point discrete Fourier transform (or FFT). In this case, the $M\times 1$ array output vector of an M element microphone array in the presence of additive noise can be represented as,[4,30]

$$\mathbf{y}_i(\omega_l)=\mathbf{A}(\mathbf{x},\omega_l)\mathbf{s}_i(\omega_l)+\mathbf{e}_i(\omega_l),\quad i=1,\ldots,I, \tag{1}$$

for $l=1,\ldots,L$, where $\mathbf{A}$ is the $M\times K$ steering matrix defined as $\mathbf{A}(\mathbf{x},\omega_l)\triangleq[\mathbf{a}(\mathbf{x}_1,\omega_l),\mathbf{a}(\mathbf{x}_2,\omega_l),\ldots,\mathbf{a}(\mathbf{x}_K,\omega_l)]$ and the signal wave forms of the sources are given by

$\mathbf{s}_i(\omega_l) \triangleq [s_{i,1}(\omega_l), s_{i,2}(\omega_l), \ldots, s_{i,K}(\omega_l)]^T$, $i=1,\ldots,I$. The elements of $\mathbf{e}_i(\omega_l)$ and $\mathbf{s}_i(\omega_l)$ are assumed to be independent zero mean random variables for $i=1,\ldots,I$.

The steering vector for source k is

$$\mathbf{a}(\mathbf{x}_k,\omega_l) = \frac{1}{C(k,l)} \begin{bmatrix} \frac{1}{x_{1,k}} e^{-j\omega_l x_{1,k}/c_0} \\ \vdots \\ \frac{1}{x_{M,k}} e^{-j\omega_l x_{M,k}/c_0} \end{bmatrix} = \frac{\bar{\mathbf{a}}(\mathbf{x}_k,\omega_l)}{C(k,l)}, \tag{2}$$

where $x_{m,k}$ is the distance between the mth microphone and the kth source and $C(k,l)=\|\bar{\mathbf{a}}(\mathbf{x}_k,\omega_l)\|_2$, i.e., $C(k,l)$ is a constant used to normalize the columns of $\mathbf{A}(\mathbf{x}_k,\omega_l)$. Note that this does not restrict the following analysis in any way.

The sample covariance matrix, or the cross spectral matrix, for a given ω_l, $l=1,\ldots,L$, is calculated as

$$\hat{\mathbf{R}}(\omega_l) = \frac{1}{I}\sum_{i=1}^{I} \mathbf{y}_i(\omega_l)\mathbf{y}_i^H(\omega_l). \tag{3}$$

The problem is to estimate the power levels of the sources $\tilde{x}_k(\mathbf{x}_k,\omega_l)=(1/I)\Sigma_{i=1}^{I}|s_{i,k}(\omega_l)|^2$, for $l=1,\ldots,L$, $k=1,\ldots,K$, and their locations $\mathbf{x}$ from the observed data $\mathbf{y}_i(\omega_l)$, $l=1,\ldots,L$, $i=1,\ldots,I$.

The delay-and-sum beamformer output power at a given location $\mathbf{x}'$ and angular frequency ω_l, $l=1,\ldots,L$, is computed as

$$\tilde{y}(\mathbf{x}',\omega_l) = \frac{1}{M^2}\tilde{\mathbf{a}}^H(\mathbf{x}',\omega_l)\hat{\mathbf{R}}(\omega_l)\tilde{\mathbf{a}}(\mathbf{x}',\omega_l), \tag{4}$$

where,

$$\tilde{\mathbf{a}}(\mathbf{x}_k,\omega_l) = C(k,l)\begin{bmatrix} x_{1,k}e^{-j\omega_l x_{1,k}/c_0} \\ \vdots \\ x_{M,k}e^{-j\omega_l x_{M,k}/c_0} \end{bmatrix}. \tag{5}$$

In aeroacoustic noise measurement applications, the power levels are usually calculated separately for each frequency bin l, $l=1,\ldots,L$, and hence in the sequel ω_l will be dropped from the notation for simplicity.

III. REVIEW OF DAMAS

In this section, the inverse equation solved in DAMAS will be obtained from a slightly different perspective than the derivation in the original paper.[11] DAMAS uses the delay-and-sum beamformer results to obtain the deconvolved source strengths. Hence, substituting Eqs. (1) and (3) in Eq. (4) and dropping the $\mathbf{x}'$ term from $\tilde{\mathbf{a}}$, for notational simplicity, we obtain

$$\begin{aligned}\tilde{y} &= \frac{1}{M^2}\tilde{\mathbf{a}}^H\left[\mathbf{A}(\mathbf{x})\left(\frac{1}{I}\sum_{i=1}^{I}\mathbf{s}_i\mathbf{s}_i^H\right)\mathbf{A}^H(\mathbf{x}) + \sigma^2\mathbf{I}\right]\tilde{\mathbf{a}} \\ &= \frac{1}{M^2}\tilde{\mathbf{a}}^H\left[\frac{1}{I}\sum_{i=1}^{I}[\mathbf{a}(\mathbf{x}_1)s_{i,1} + \cdots + \mathbf{a}(\mathbf{x}_K)s_{i,K}][\mathbf{a}(\mathbf{x}_1)s_{i,1} \right. \\ &\quad \left. + \cdots + \mathbf{a}(\mathbf{x}_K)s_{i,K}]^H + \sigma^2\mathbf{I}\right]\tilde{\mathbf{a}}. \end{aligned} \tag{6}$$

The cross terms in Eq. (6) are assumed to be negligible which is a resonable assumption when $I \gg 1$. In DAMAS, this expression is approximated by also neglecting the noise term to obtain

$$\begin{aligned}\tilde{y}(\mathbf{x}') &= \frac{1}{M^2}\tilde{\mathbf{a}}^H(\mathbf{x}')\left[\sum_{k=1}^{K}\frac{1}{I}\sum_{i=1}^{I}|s_{i,k}|^2\mathbf{a}(\mathbf{x}_k)\mathbf{a}^H(\mathbf{x}_k)\right]\tilde{\mathbf{a}}(\mathbf{x}') \\ &= \sum_{k=1}^{K}\tilde{A}_k(\mathbf{x}')\tilde{x}(\mathbf{x}_k), \end{aligned} \tag{7}$$

where $\tilde{x}(\mathbf{x}_k) \triangleq (1/I)\Sigma_{i=1}^{I}|s_{i,k}|^2$ and

$$\tilde{A}_k(\mathbf{x}') = \frac{1}{M^2}|\tilde{\mathbf{a}}^H(\mathbf{x}')\mathbf{a}(\mathbf{x}_k)|^2, \quad k=1,\ldots,K. \tag{8}$$

Usually, the number of sources, K, is unknown and is replaced by N, which is the number of scanning points in the region. Also, $\mathbf{x}$ and $\mathbf{x}'$ are scanned over the same set of grid points for simplicity assuming that a certain minimum desired resolution is satisfied. If the power at each scanning point is stacked up to form a power vector $\tilde{\mathbf{y}}$, we arrive at

$$\begin{bmatrix} \tilde{y}(\mathbf{x}_1) \\ \tilde{y}(\mathbf{x}_2) \\ \vdots \\ \tilde{y}(\mathbf{x}_N) \end{bmatrix} = \begin{bmatrix} \tilde{A}_1(\mathbf{x}_1) & \tilde{A}_2(\mathbf{x}_1) & \cdots & \tilde{A}_N(\mathbf{x}_1) \\ \tilde{A}_1(\mathbf{x}_2) & \tilde{A}_2(\mathbf{x}_2) & \cdots & \tilde{A}_N(\mathbf{x}_2) \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{A}_1(\mathbf{x}_N) & \tilde{A}_2(\mathbf{x}_N) & \cdots & \tilde{A}_N(\mathbf{x}_N) \end{bmatrix} \begin{bmatrix} \tilde{x}(\mathbf{x}_1) \\ \tilde{x}(\mathbf{x}_2) \\ \vdots \\ \tilde{x}(\mathbf{x}_N) \end{bmatrix}, \tag{9}$$

or $\tilde{\mathbf{y}}=\tilde{\mathbf{A}}\tilde{\mathbf{x}}$, each term of which can be expressed as

$$\tilde{y}_n = \tilde{A}_{n,1}\tilde{x}_1 + \tilde{A}_{n,2}\tilde{x}_2 + \cdots + \tilde{A}_{n,N}\tilde{x}_N, \tag{10}$$

where $n=1,\ldots,N$. The solution for $\tilde{\mathbf{x}}$ can be obtained by using the Gauss–Seidel method and noting that $\tilde{A}_{nn}=1$, from the definition of $\tilde{\mathbf{A}}$, as follows:

$$\tilde{x}_n^{(k)} = \max\left(0, \tilde{y}_n - \left[\sum_{j=1}^{n-1}\tilde{A}_{nj}\tilde{x}_j^{(k)} + \sum_{j=n+1}^{N}\tilde{A}_{nj}\tilde{x}_j^{(k-1)}\right]\right), \tag{11}$$

where k is the current iteration number limited above by a user defined maximum number of iterations, $\tilde{\mathbf{x}}^{(0)}=\mathbf{0}$ and the positivity of every element of $\tilde{\mathbf{x}}$ is enforced since $\tilde{\mathbf{x}}$ represents power.

The major drawbacks of this algorithm may be summarized as follows. First of all, neglecting the noise term in Eq. (7) introduces a modeling error since, in almost all practical cases, some kind of noise will contaminate the data. Second, the algorithm requires many iterations, on the order of thousands, to give reasonable results, which can become very time consuming depending on the resolution, i.e., the length of $\tilde{\mathbf{x}}$. Also, the delay-and-sum beamformer has to be implemented before using DAMAS which also means more processing time and effort. Finally, the Gauss–Seidel method is not guaranteed to converge unless $\tilde{\mathbf{A}}$ is diagonally dominant, i.e., for each row, the absolute value of the diagonal term is greater than the sum of absolute values of other terms which is usually not true.[12] Despite these drawbacks, the algorithm has been successfully employed in many practical applications.

Diagonal removal (DR). The first of the above-mentioned drawbacks can be overcome by the use of diagonal removal which eliminates the noise occurring in the diagonal of $\hat{\mathbf{R}}$ by removing the diagonal elements, i.e., making them zero.[2,10,11] In this case, the delay-and-sum output is calculated as

$$\tilde{y}^{\mathrm{DR}}(\mathbf{x}') = \frac{1}{M^2 - M}\tilde{\mathbf{a}}^H(\mathbf{x}')\tilde{\mathbf{R}}\tilde{\mathbf{a}}(\mathbf{x}'), \tag{12}$$

where $\tilde{\mathbf{R}}$ is obtained by removing the diagonal elements of $\hat{\mathbf{R}}$. Then, $\tilde{\mathbf{y}}^{\mathrm{DR}} = \tilde{\mathbf{A}}^{\mathrm{DR}}\tilde{\mathbf{x}}$, where

$$\tilde{A}_k^{\mathrm{DR}}(\mathbf{x}') = \frac{1}{M^2 - M}\tilde{\mathbf{a}}^H(\mathbf{x}')[\mathbf{a}(\mathbf{x}_k)\mathbf{a}^H(\mathbf{x}_k)]_{\mathrm{diag.}=0}\tilde{\mathbf{a}}^H(\mathbf{x}'), \tag{13}$$

for $k = 1, \ldots, K$.

In the rest of the paper, DAMAS is applied with diagonal removal in all cases. Otherwise, the performance becomes worse as σ^2 increases. Consequently, we will denote $\tilde{\mathbf{y}}^{\mathrm{DR}}$ and $\tilde{\mathbf{A}}^{\mathrm{DR}}$ as $\tilde{\mathbf{y}}$ and $\tilde{\mathbf{A}}$, respectively, in order to simplify the notation.

IV. SPARSITY CONSTRAINED DAMAS (SC-DAMAS)

A. Sparsity constrained formulation

Assume that a measured vector $\tilde{\mathbf{y}}$ exists which is known to satisfy the linear relation $\tilde{\mathbf{y}} = \tilde{\mathbf{A}}\tilde{\mathbf{x}}$ where $\tilde{\mathbf{A}}$ is known and $\tilde{\mathbf{x}}$ is an unknown quantity that is to be estimated, see Eq. (9). In its simplest form, sparse modeling can be stated as follows:

$$\text{minimize } \|\tilde{\mathbf{x}}\|_0 \text{ subject to } \tilde{\mathbf{y}} = \tilde{\mathbf{A}}\tilde{\mathbf{x}}. \tag{14}$$

Usually, this problem is a combinatorial problem which becomes intractable quickly as the dimension of $\tilde{\mathbf{x}}$ increases.[17] If the solution is sufficiently sparse, the ℓ_0 norm can be replaced with the ℓ_1 norm to make the problem convex.[17] The important point in Eq. (14) is that the matrix $\tilde{\mathbf{A}}$ is usually ill conditioned and not invertible. Otherwise, the solution could be obtained by taking the inverse, had $\tilde{\mathbf{A}}$ been a square matrix, or by the least-squares method otherwise.

Following the above-presented discussion, the problem in Eq. (9) is directly applicable in the sparse signal representation context by observing that $\tilde{\mathbf{x}}$ is sparse due to replacing K by N in Eq. (9) and noting that $N \gg K$. In other words, since $\tilde{\mathbf{A}}$ contains all the scanning points and only a small portion of the region is expected to possess strong sources, $\tilde{\mathbf{x}}$ will contain few nonzero elements with respect to its size. Thus, we can immediately think of applying a slightly modified version of LASSO[18] to this problem,

$$\begin{aligned} &\text{minimize} \quad \|\tilde{\mathbf{y}} - \tilde{\mathbf{A}}\tilde{\mathbf{x}}\|_2^2, \\ &\text{subject to} \quad \|\tilde{\mathbf{x}}\|_1 \leqslant \lambda, \quad \tilde{x}_n \geqslant 0, \quad n = 1, \ldots, N, \end{aligned} \tag{15}$$

where the modification is to enforce every element of $\tilde{\mathbf{x}}$ to be positive. Here, the user parameter λ is unknown and has to be empirically tuned or estimated from the observation vector $\tilde{\mathbf{y}}$ and $\tilde{\mathbf{A}}$. The following section describes a simple method for choosing the parameter λ automatically. Also, it is empirically observed that the method in Eq. (15) is not very sensitive to the selection of λ. In fact, if we let $\lambda \to \infty$, the formulation will reduce to a non-negative least-squares problem. However, using prior knowledge about the sparsity of $\tilde{\mathbf{x}}$ will improve the estimate in most cases. The problem in Eq. (15) is a quadratic convex optimization problem which can be solved efficiently via readily available interior point methods[31,32] to find the globally optimal solution for $\tilde{\mathbf{x}}$. *Self-Dual Minimization*[31] is an extensively used software package in the signal processing community for solving optimization problems over symmetric cones including linear, quadratic, second-order conic and semidefinite programs. The detailed discussion of advanced optimization methods is beyond the scope of this paper and the interested reader is referred to a text on convex optimization.[33]

B. Estimating the user parameter

In the formulation Eq. (15), λ constrains the ℓ_1 norm of $\tilde{\mathbf{x}}$, which represents the total power of the signals. Since this value is unknown, a way of determining λ has to be found for practicality. Let

$$\mathbf{R} = E\{\mathbf{y}_i\mathbf{y}_i^H\} = \mathbf{A}\mathbf{D}\mathbf{A}^H + \sigma^2\mathbf{I}, \tag{16}$$

where $\mathbf{D} = E\{\mathbf{s}_i\mathbf{s}_i^H\}$, which is a diagonal matrix for uncorrelated sources, is given by

$$\mathbf{D} = \begin{bmatrix} d_1 & 0 & \cdots & 0 \\ 0 & d_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & d_K \end{bmatrix}, \tag{17}$$

where d_k, $k = 1, \ldots, K$ is the power of the kth source. The eigendecomposition of $\mathbf{A}\mathbf{D}\mathbf{A}^H$ can be written as $\mathbf{A}\mathbf{D}\mathbf{A}^H = \mathbf{U}\Lambda\mathbf{U}^H$, where the columns of the unitary matrix $\mathbf{U}$ denote the eigenvectors of $\mathbf{A}\mathbf{D}\mathbf{A}^H$ and the diagonal elements of the diagonal matrix Λ are the corresponding eigenvalues, denoted as $\lambda_1 \geqslant \lambda_2 \geqslant \cdots \geqslant \lambda_K \geqslant 0 = \cdots = 0$. Λ is an $M \times M$ matrix where $M \gg K$. Then, $\mathbf{R}$ can be written as

$$\mathbf{R} = \mathbf{U}(\Lambda + \sigma^2\mathbf{I})\mathbf{U}^H \triangleq \mathbf{U}\Gamma\mathbf{U}^H, \tag{18}$$

where the diagonal elements of the diagonal matrix Γ are $\gamma_1 \geqslant \gamma_2 \geqslant \cdots \geqslant \gamma_K \geqslant \sigma^2 = \cdots = \sigma^2$. Note that

$$\begin{aligned} \mathrm{Tr}(\Lambda) &= \mathrm{Tr}(\mathbf{U}\Lambda\mathbf{U}^H) = \mathrm{Tr}(\mathbf{A}\mathbf{D}\mathbf{A}^H) = \mathrm{Tr}(\mathbf{D}\mathbf{A}^H\mathbf{A}) = \mathrm{Tr}(\mathbf{D}) \\ &= \sum_{k=1}^{K} d_k, \end{aligned} \tag{19}$$

which is the total power of the sources. Here, we have used the fact that the columns in $\mathbf{A}$ have unit norm and $\mathbf{D}$ is diagonal.

In practice, we only have the estimated covariance matrix given in Eq. (3) instead of the true covariance matrix $\mathbf{R}$. Let $\hat{\mathbf{R}} = \hat{\mathbf{U}}\hat{\Gamma}\hat{\mathbf{U}}^H$ denote the eigendecomposition of $\hat{\mathbf{R}}$ with the eigenvalues of $\hat{\mathbf{R}}$, i.e., the diagonal elements of $\hat{\Gamma}$, arranged in nonincreasing order. Then, we can determine the user parameter λ in Eq. (15) as

$$\lambda = \mathrm{Tr}(\hat{\boldsymbol{\Gamma}} - \hat{\gamma}_M \mathbf{I}), \tag{20}$$

where $\hat{\gamma}_M$ is the smallest diagonal element of $\hat{\boldsymbol{\Gamma}}$. We refer to the approach of solving Eq. (15) using the λ determined in Eq. (20) as the sparsity constrained DAMAS (SC-DAMAS). We will show using numerical examples that SC-DAMAS is computationally more efficient than DAMAS. Note that, SC-DAMAS also uses the diagonal removal approach described for DAMAS.

C. A more efficient implementation of SC-DAMAS

The delay-and-sum estimate $\tilde{\mathbf{y}}$ usually contains redundant information due to its wide beamwidth. Therefore, it is not always necessary to beamform at all N locations in the region when using SC-DAMAS. Beamforming at fewer points reduces the size of $\tilde{\mathbf{y}}$ and increases the speed of SC-DAMAS. In this case, Eq. (9) becomes

$$\begin{bmatrix} \tilde{y}(\mathbf{x}_1) \\ \tilde{y}(\mathbf{x}_2) \\ \vdots \\ \tilde{y}(\mathbf{x}_{N_0}) \end{bmatrix} = \begin{bmatrix} \tilde{A}_1(\mathbf{x}_1) & \tilde{A}_2(\mathbf{x}_1) & \cdots & \tilde{A}_N(\mathbf{x}_1) \\ \tilde{A}_1(\mathbf{x}_2) & \tilde{A}_2(\mathbf{x}_2) & \cdots & \tilde{A}_N(\mathbf{x}_2) \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{A}_1(\mathbf{x}_{N_0}) & \tilde{A}_2(\mathbf{x}_{N_0}) & \cdots & \tilde{A}_N(\mathbf{x}_{N_0}) \end{bmatrix} \begin{bmatrix} \tilde{x}(\mathbf{x}_1) \\ \tilde{x}(\mathbf{x}_2) \\ \vdots \\ \tilde{x}(\mathbf{x}_N) \end{bmatrix}, \tag{21}$$

where $N_0 < N$. Note that $\tilde{\mathbf{A}}$ has become a fat matrix, i.e., the number of its rows is smaller than the number of its columns. It will be shown in Sec. VII that this approach can save a significant amount of computation time without degrading the performance. A similar approach cannot be used with DAMAS since DAMAS requires N equations to solve for the N unknowns in $\tilde{\mathbf{x}}$. Formulating the same problem as a sparse problem alleviates the need for N equations.

V. COVARIANCE MATRIX FITTING

Instead of using the sample covariance matrix to obtain delay-and-sum estimates and then trying to deconvolve the results, we introduce a method for estimating source locations and strengths based directly on the sample covariance matrix in Eq. (3) and the steering vector in Eq. (2). Specifically, the covariance matrix fitting approach determines σ_0^2 and $\{d_n\}_{n=1}^N$ via

$$\begin{aligned} &\text{minimize}_{\{d_n\}_{n=1}^N, \sigma^2} \quad \|\hat{\mathbf{R}} - \mathbf{A}\mathbf{D}\mathbf{A}^H - \sigma^2 \mathbf{I}\|_F^2, \\ &\text{subject to} \quad d_n \geqslant 0, \quad n = 1, \ldots, N, \quad \sum_{n=1}^{N} d_n \leqslant \lambda, \\ &\qquad\qquad \sigma^2 \geqslant 0, \end{aligned} \tag{22}$$

which is a quadratic convex optimization problem where λ is defined in Eq. (20), d_n is the noise power level for grid n, $n = 1, \ldots, N$, and $\mathbf{D}$ is an $N \times N$ diagonal matrix with $\{d_n\}_{n=1}^N$ as its diagonals, see Eq. (17). Also recall that $\mathbf{A} = [\mathbf{a}(\mathbf{x}_1), \mathbf{a}(\mathbf{x}_2), \ldots, \mathbf{a}(\mathbf{x}_N)]$. The idea behind this method is quite intuitive in the sense that it basically tries to fit the unknown signal powers and the noise power to the model in Eq. (16) such that the solution is sparse. In contrast to deleting the diagonals of $\hat{\mathbf{R}}$, this method tries to extract the noise and use the signal components in the diagonal. Moreover, this formulation does not require the implementation of the delay-and-sum beamformer as an initial step and it converges quickly thanks to the convex formulation. Similar to SC-DAMAS, this algorithm also turns out to be quite insensitive to λ.

VI. CORRELATED SOURCES

DAMAS, SC-DAMAS, and CMF algorithms all assume that the noise sources are uncorrelated so that the cross terms in Eq. (6) can be neglected. However, if the sources are correlated, this assumption no longer holds and the algorithms have to be modified to deal with this case. After briefly reviewing DAMAS-C[15] for completeness, we will introduce the extension of the CMF approach to the correlated case.

A. DAMAS-C

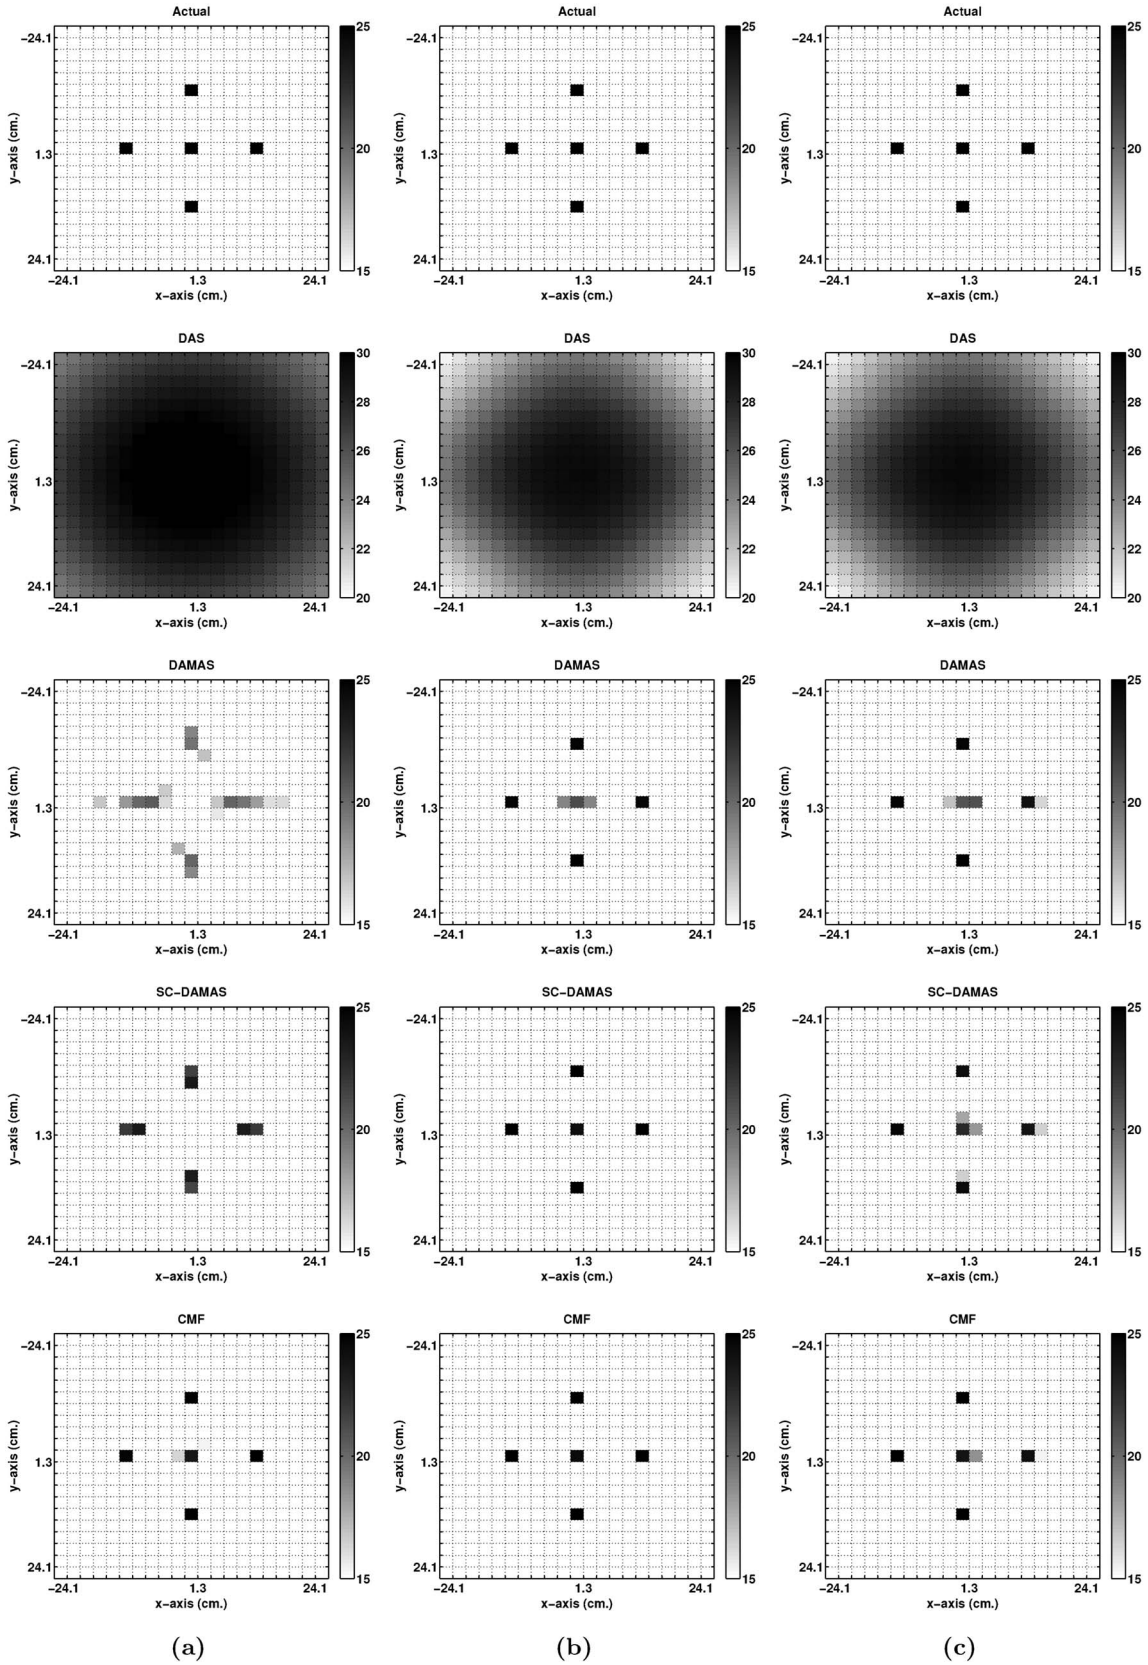
DAMAS-C extends DAMAS to deal with correlated signals.[15] Similar to DAMAS, this algorithm uses Eq. (6) but without ignoring the cross terms. In this case, we end up with $N(N+1)/2$ unknowns and thus have to evaluate the delay-and-sum beamformer at more points. For this purpose, the cross-beamformer output is[15]

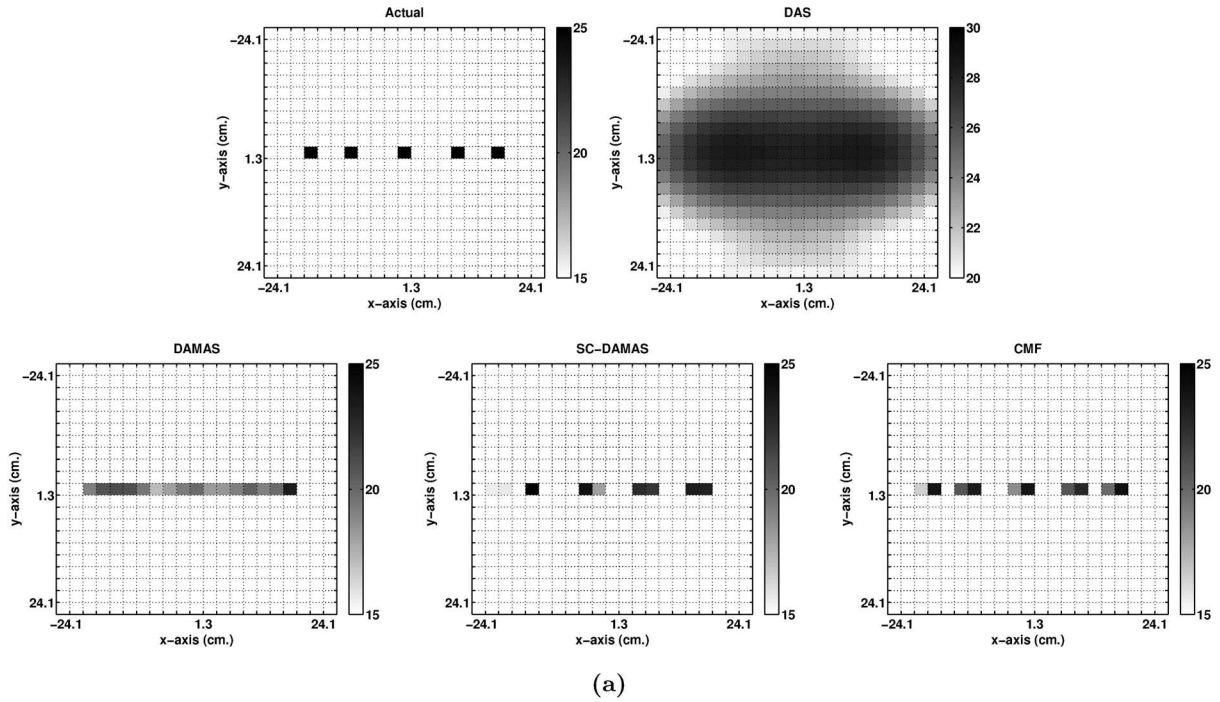
$$\acute{y}(\mathbf{x}', \mathbf{x}'') = \frac{1}{M^2} \tilde{\mathbf{a}}^H(\mathbf{x}') \hat{\mathbf{R}} \tilde{\mathbf{a}}(\mathbf{x}''), \tag{23}$$

which is similar to Eq. (4). Then, the inverse problem can be defined as in the following:

$$\begin{bmatrix} \acute{y}(\mathbf{x}_1, \mathbf{x}_1) \\ \acute{y}(\mathbf{x}_1, \mathbf{x}_2) \\ \vdots \\ \acute{y}(\mathbf{x}_1, \mathbf{x}_N) \\ \acute{y}(\mathbf{x}_2, \mathbf{x}_1) \\ \vdots \\ \acute{y}(\mathbf{x}_N, \mathbf{x}_N) \end{bmatrix} = \begin{bmatrix} \acute{A}_{1,1}(\mathbf{x}_1, \mathbf{x}_1) & \cdots & \acute{A}_{1,N}(\mathbf{x}_1, \mathbf{x}_1) & \cdots & \acute{A}_{N,N}(\mathbf{x}_1, \mathbf{x}_1) \\ \acute{A}_{1,1}(\mathbf{x}_1, \mathbf{x}_2) & \cdots & \acute{A}_{1,N}(\mathbf{x}_1, \mathbf{x}_2) & \cdots & \acute{A}_{N,N}(\mathbf{x}_1, \mathbf{x}_2) \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ \acute{A}_{1,1}(\mathbf{x}_N, \mathbf{x}_N) & \cdots & \acute{A}_{1,N}(\mathbf{x}_N, \mathbf{x}_N) & \cdots & \acute{A}_{N,N}(\mathbf{x}_N, \mathbf{x}_N) \end{bmatrix} \begin{bmatrix} \acute{x}(\mathbf{x}_1, \mathbf{x}_1) \\ \acute{x}(\mathbf{x}_1, \mathbf{x}_2) \\ \vdots \\ \acute{x}(\mathbf{x}_1, \mathbf{x}_N) \\ \acute{x}(\mathbf{x}_2, \mathbf{x}_1) \\ \vdots \\ \acute{x}(\mathbf{x}_N, \mathbf{x}_N) \end{bmatrix}, \tag{24}$$

or





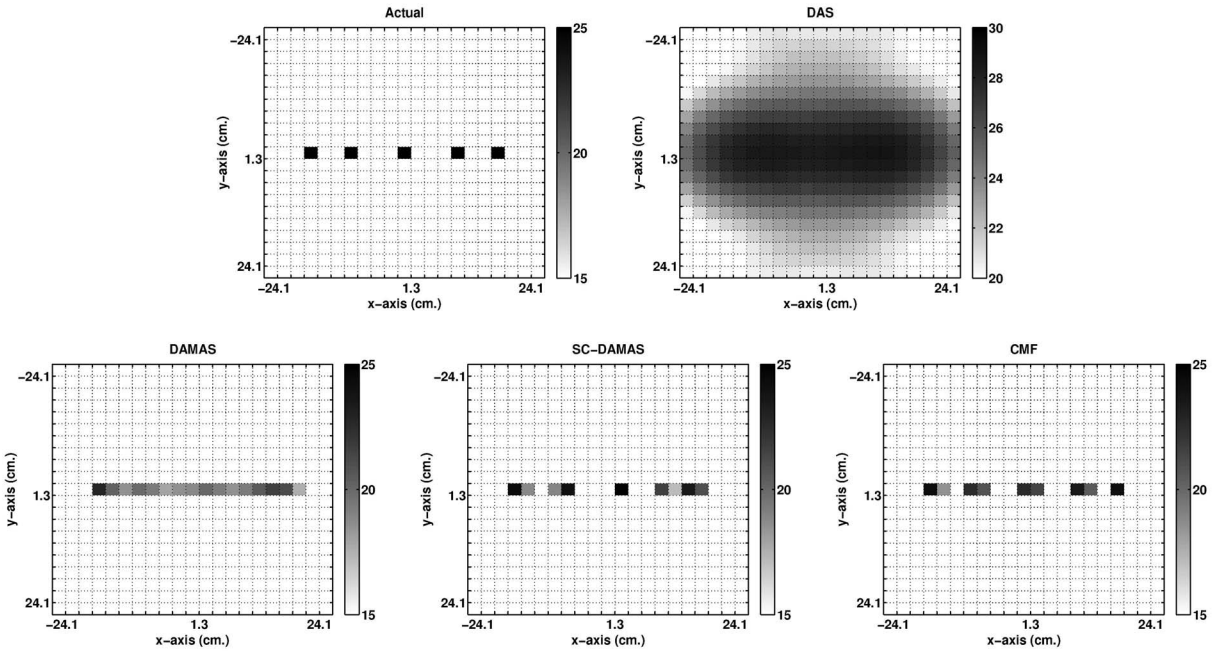


FIG. 1. The beamforming maps of the actual sources, DAS, DAMAS, SC-DAMAS, and CMF with three different settings as follows: $I=10\,000$, (a) $f=10$ kHz and $\sigma^2=0$, $f=15$ kHz: (b) $\sigma^2=0$, (c) $\sigma^2=100$. The 2D plots represent the beamforming area and the power levels are in decibels.

$$\acute{\mathbf{y}} = \acute{\mathbf{A}}\acute{\mathbf{x}}, \tag{25}$$

where $\acute{A}_{k,l}(\mathbf{x}',\mathbf{x}'')=(1/M^2)\tilde{\mathbf{a}}^H(\mathbf{x}')\mathbf{a}(\mathbf{x}_k)\mathbf{a}^H(\mathbf{x}_l)\tilde{\mathbf{a}}(\mathbf{x}'')$, $k,l=1,\ldots,K$. Although the derivation is straightforward, this equation is cumbersome. Note that the sizes of $\acute{\mathbf{y}}$, $\acute{\mathbf{A}}$, and $\acute{\mathbf{x}}$ are squares of the sizes of their uncorrelated counterparts $\tilde{\mathbf{y}}$, $\tilde{\mathbf{A}}$, and $\tilde{\mathbf{x}}$. This equation is solved for $\acute{\mathbf{x}}$ with a very similar

(a)

(b)

FIG. 2. The beamforming maps of the actual sources, DAS, DAMAS, SC-DAMAS, and CMF with two different settings as follows: $f=20$ kHz, $I=500$ and (a) $\sigma^2=0$, (b) $\sigma^2=5$. The 2D plots represent the beamforming area and the power levels are in decibels.

algorithm to DAMAS. Again, positivity is enforced as in Eq. (11). Yet, now there may be complex terms arising from the cross products and a suitable constraint has to be found for these terms too. The correlations are assumed to be in phase and real in DAMAS-C.[15] With this assumption, the positivity is enforced on every element of $\acute{\mathbf{x}}$, see Eq. (11), as the iterations proceed. As a final note, diagonal removal is also applied with DAMAS-C in our simulations.

B. CMF-C

The extension of CMF to the correlated case is as follows:

$$\text{minimize}_{\mathbf{D},\sigma^2} \quad \|\hat{\mathbf{R}} - \mathbf{A}\mathbf{D}\mathbf{A}^H - \sigma^2\mathbf{I}\|_F^2,$$

$$\text{subject to} \quad \mathbf{D} \geqslant 0, \quad \text{tr}(\mathbf{D}) \leqslant \lambda, \quad \sigma^2 \geqslant 0, \tag{26}$$

which looks simpler than the DAMAS-C formulation. Note that $\mathbf{D}$ is no longer a diagonal matrix and when the sources are uncorrelated, Eq. (26) reduces to the CMF formulation, Eq. (22). CMF-C is a semidefinite quadratic program and can also work with complex correlations between source signals in contrast to DAMAS-C. λ is determined as in Eq. (20).

Both CMF-C and DAMAS-C require extreme computation times as the number of grid points increases since the

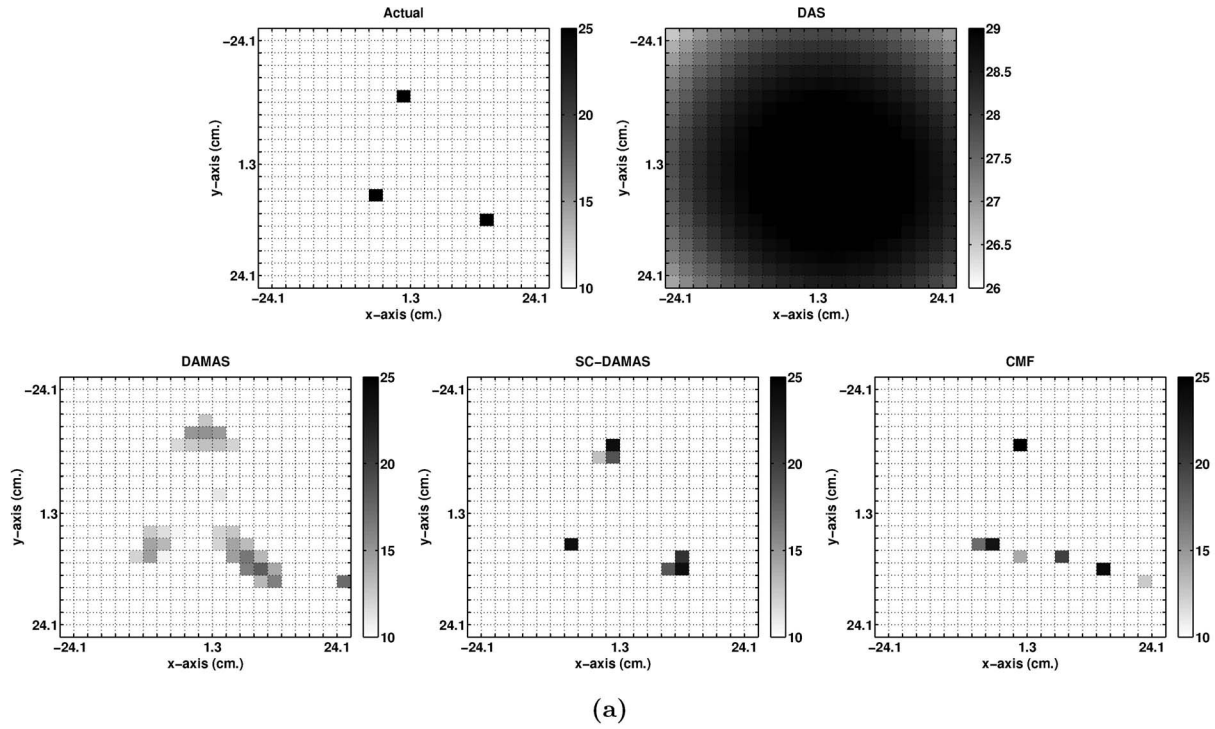

FIG. 3. The beamforming maps of the actual sources, DAS, DAMAS, SC-DAMAS, and CMF with two different settings as follows: $f=5$ kHz, $I=500$ and (a) $\sigma^2=0$, (b) $\sigma^2=4$. The 2D plots represent the beamforming area and the power levels are in decibels.

number of unknowns in both is approximately N^2. Nevertheless, a parallel implementation can make these algorithms usable in practice.[15] We will evaluate these algorithms only for a small grid size in Sec. VII. Note that a similar approach to SC-DAMAS can be used to solve the DAMAS-C problem given in Eq. (25) but this issue is not further explored here since our experience is that even in the uncorrelated case CMF usually results in better performance than SC-DAMAS. In results not shown here, it was observed that this is true in the correlated case, too.

VII. NUMERICAL EXAMPLES

In this section, we evaluate the performances of DAMAS, SC-DAMAS, and CMF for the SADA array.[1,34] SADA is a two-dimensional (2D) array consisting of 33 microphones and has a maximum diagonal aperture size of 19.71 cm. A microphone is located at the center and the others are arranged in four circles of eight microphones each where the diameter of each circle is twice the diameter of the circle it encloses. We assume that the SADA is at a distance

TABLE I. Characteristics of the acoustic imaging algorithms.

	DAS	DAMAS	SC-DAMAS	CMF
Resolution	Low	Medium	High	High
Sensitivity to noise	Low	Medium	Medium	Low
Computation Time	Low	High	Medium	Medium
Max. number of variables	High	Medium	Low	Low

of 1.52 m from the region of interest similar to the DAMAS paper.[10,11] The span for the x axes and y axes is from −25.4 to 25.4 cm and the resolution in both directions is 2.54 cm. We simulate the received signal at each microphone according to Eq. (1). The noise components $\mathbf{e}_i(\omega_l)$ in Eq. (1) are assumed to be uncorrelated with the source signals and distributed as circularly symmetric i.i.d. complex Gaussian random variables with mean zero and variance σ^2. The signal wave forms are also distributed as circularly symmetric i.i.d. complex Gaussian random variables with mean zero and a certain power level which is assumed to be 25 dB. This value is chosen without loss of generality since σ^2 will be varied throughout the experiments.

There are three parameters which affect the performances of the algorithms directly: number of snapshots I, noise variance σ^2, and frequency of interest $f=\omega/(2\pi)$. The incoherence assumption breaks down as the number of snapshots decreases since the cross terms in Eq. (6) are no longer negligible and also the additional noise term in Eq. (6) is no longer $\sigma^2\boldsymbol{I}$. Noise affects all the algorithms negatively as in all applications. Finally, the frequency determines the resolution of the algorithms since as the frequency increases, the difference in the steering vectors for nearby sources increases and hence it is easier for the algorithms to discriminate them. We will first evaluate DAMAS, SC-DAMAS, and CMF for uncorrelated sources and then evaluate DAMAS-C and CMF-C for correlated sources.

We start our simulations with a relatively easy scenario where the number of snapshots is large, $I=10\,000$, and $\sigma^2=0$ in which case the assumptions of the algorithms are almost correct. The resulting beamforming maps are shown in Figs. 1(a) and 1(b), where the horizontal axis and the vertical axis represent the 2D scanning plane and the power levels are represented in a gray color scale over a span of 10 dB. As expected, the delay-and-sum algorithm merges the peaks as if there were a single source. CMF works quite well and SC-DAMAS and DAMAS show good performance when the frequency is high. Next, the noise variance σ^2 is increased to 100. As shown in Fig. 1(c), CMF is more robust to noise than DAMAS and SC-DAMAS. Note that for all the examples in this section, DAMAS has been run for 10 000 iterations after which no significant improvement was observed.

TABLE III. Speeding up of SC-DAMAS for the example of Fig. 1(b). Timing values are in seconds.

N_0	441	196	121	81	36
Time	24.0	12.7	4.2	2.8	1.3

Next, we decrease the number of snapshots to 500 and increase the frequency to 20 kHz to resolve a more complicated source distribution. The results are shown in Fig. 2 for $\sigma^2=0$ and 5. The location estimates of SC-DAMAS for some of the sources are inaccurate and DAMAS is not able to discriminate the sources. CMF, however, is able to recover the sources reasonably well in both cases. If the frequency is decreased to $f=5$ kHz, DAMAS performance degrades significantly as also observed in other studies.[16] Figure 3 shows the imaging maps for $\sigma^2=0$ and 4 with $I=500$. DAMAS is not able to recover the source location for $f=5$ kHz even after 50 000 iterations. We again observe offsets in the location estimates of SC-DAMAS and when the noise is increased, the results become worse. This is due to the fact that SC-DAMAS is solving the same DAMAS inverse problem. In Fig. 3(a), the highest outlier for CMF is 5 dB below the actual signal levels and in Fig. 3(b), CMF provides the best performance. This performance gain can be attributed to the different formulation of CMF than DAMAS and SC-DAMAS. Recall that CMF does not rely on the delay-and-sum beamformer estimates and does not delete the diagonals. Note that the source distribtution considered for the last case is simpler than the other two since the frequency is low.

A qualitative assessment of the algorithms is given in Table I. The computational complexity of DAMAS was higher than that of SC-DAMAS and CMF in our simulations. Note that the public domain solver[31] we use for finding the optimal solutions to the SC-DAMAS and CMF problems works up to $N=1000$ grid points when the signals are complex valued. However, a commercial software designed for this purpose can go up to many more variables and hence the formulations are applicable to higher resolutions if desired. Table II shows the computation times of each algorithm for the examples considered in this section. We observe that SC-DAMAS is the fastest and CMF takes almost thrice the time of SC-DAMAS. DAMAS takes almost twice the time of CMF and eight times the time of SC-DAMAS. Furthermore, as mentioned in Sec. IV, the sparse formulation of SC-DAMAS allows us to reduce the size of $\tilde{\mathbf{y}}$ in Eq. (9) which provides more improvements in speed. In Table III, we noted the computation time of SC-DAMAS for different values of N_0 for the example considered in Fig. 1(b). The performance of SC-DAMAS undergoes only a minor degradation when

TABLE II. Computation times for DAMAS, SC-DAMAS, and CMF in seconds on personal computer, 2.0 GHz dual core processor, 2 Gbytes of RAM.

CMF	66	65	71	69	65	75	73

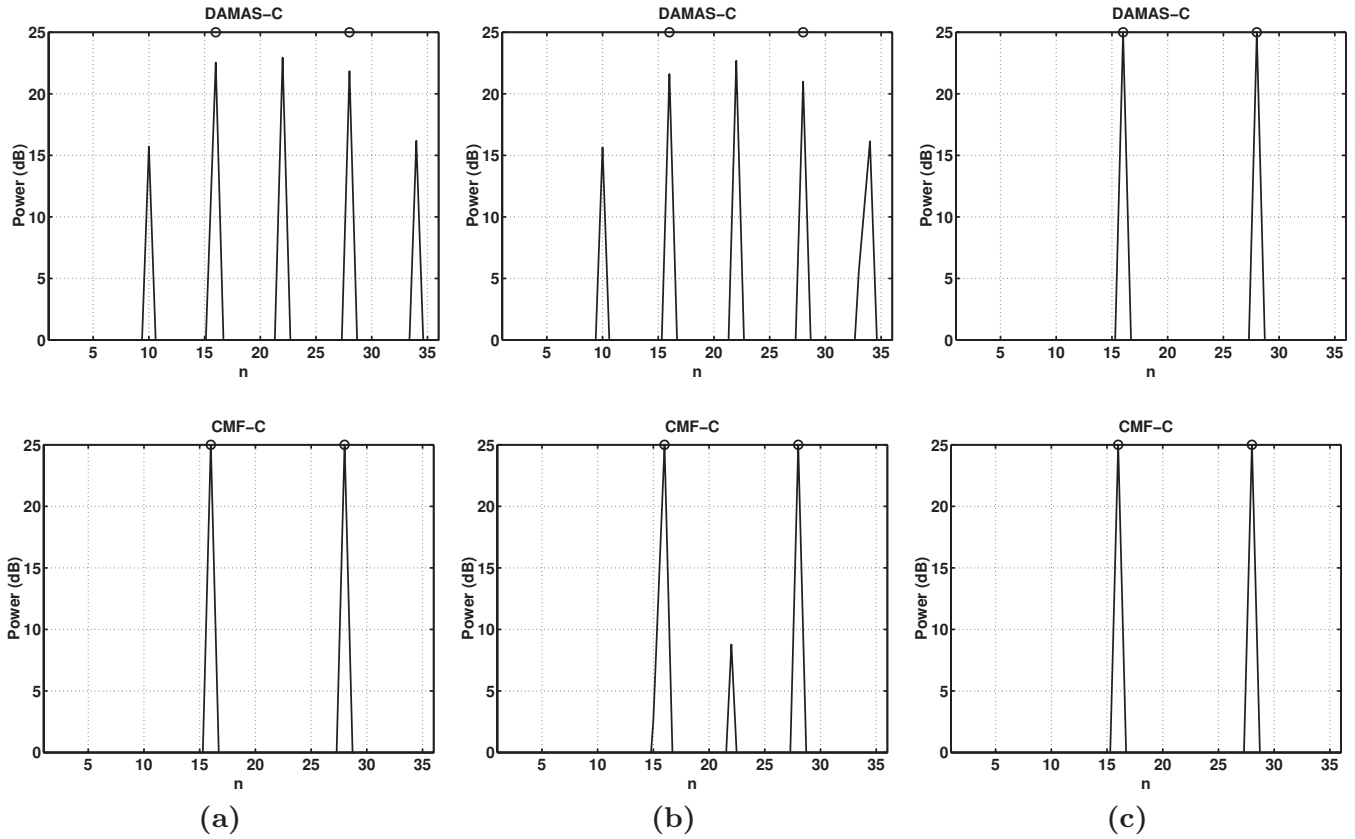

FIG. 4. The power estimates with DAMAS-C and CMF-C with three different settings as follows: $I=500$, (a) $f=10$ kHz and $\sigma^2=0$, (b) $f=10$ kHz and $\sigma^2=2$, (c) $f=20$ kHz and $\sigma^2=0$. DAMAS-C was run for 10 000 iterations. The y axis represents the power values in decibels and the x axis represents the index corresponding to the 2D grid point. The true source locations and powers are marked with circles.

$N_0 \geqslant 36$. Below that, the algorithm does not provide accurate results. The savings are huge and the problem can be solved in almost 1 s when $N_0=36$, which should be compared with 167 s for DAMAS and 62 s for CMF keeping in mind that CMF provides better results than SC-DAMAS and SC-DAMAS provides better results than DAMAS. In any case, SC-DAMAS offers a fast way of solving Eq. (9).

Finally, the performances of DAMAS-C and CMF-C are evaluated when there are two coherent acoustic signals in the scanning region. We assume a simple scenario which consists of 36 grid points between −12.7 and 12.7 cm with 5.08 cm increments in both x and y directions. Thus, the number of unknowns is 666 for each algorithm. The results are shown in Fig. 4. In these plots, rather than showing the 2D images, we plot the one-dimensional versions where the horizontal axis corresponds to the grid number n, where $n=1,\ldots,N$, and the vertical axis is the power levels in decibels since this way the power estimates are seen more clearly for this case. The actual noise locations and strengths are indicated with circles in the plots. We observe that DAMAS-C does not provide accurate estimates for the lower frequency scenario. But when the frequency increases, it can discriminate the sources. Note that results not shown here showed that DAMAS and CMF, which were designed for uncorrelated sources, cannot separate the two coherent sources, as expected. CMF-C can correctly identify the two sources even when $\sigma^2 \neq 0$ as shown in Fig. 4(b). The outlier occurring in this case is almost 16 dB below the correct estimates and is reasonable when compared to DAMAS performance. DAMAS-C and CMF-C take much more time than DAMAS and CMF due to the larger number of unknowns in the coherent case. As mentioned before, it is also possible to extend SC-DAMAS to the correlated case to achieve computational savings by sacrificing some accuracy as compared to CMF-C.

VIII. CONCLUSIONS

In this paper, a sparsity constrained deconvolution algorithm (SC-DAMAS) and a sparsity constrained covariance matrix fitting algorithm (CMF) were presented for the recovery of acoustic source locations and strengths. The former algorithm is an extension of DAMAS and tries to solve the same basic equation by exploiting sparsity. Similar to DAMAS, SC-DAMAS employs diagonal removal to mitigate the effects of noise, whereas the CMF algorithm eliminates noise without deleting the diagonals of the covariance matrix completely. Also, DAMAS and SC-DAMAS algorithms require the implementation of the delay-and-sum method and depend on the performance of this method. On the other hand, CMF is independent of the delay-and-sum algorithm. DAMAS, SC-DAMAS, and CMF were evaluated using synthetic data and the CMF approach showed the best performance both in terms of accuracy and robustness to noise. An alternative implementation of SC-DAMAS was provided which offers a very fast algorithm as compared to

DAMAS and CMF. Keeping in mind the better performance of SC-DAMAS than DAMAS, this could be a very practical deconvolution algorithm for aeroacoustic applications. DAMAS is observed to provide relatively worse performance as the frequency decreases. The number of snapshots affects all the algorithms significantly. Usually, large amounts of data are collected in aeroacoustic applications and the values used in the simulations are not far from being practical. An extension of CMF, CMF-C, was also proposed to deal with correlated sources and it was shown to provide better performance than DAMAS-C. The next step is to evaluate the algorithms on real data.

LIST OF SYMBOLS

$\mathbf{a}(\mathbf{x}')$ = steering vector for location $\mathbf{x}'$
$\mathbf{A}(\mathbf{x}')$ = steering matrix
$\widetilde{\mathbf{A}}$ = matrix used in the inverse problem
$\widetilde{A}_{i,j}$ = (i,j)th element of $\widetilde{\mathbf{A}}$
BP = Basis pursuit
CMF = Covariance matrix fitting
CMF-C = extension of CMF to the correlated case
c_0 = sound propagation velocity in air, taken as 343 m/s
DAS = delay-and-sum beamformer
DAMAS = deconvolution approach for the mapping of acoustic sources
DAMAS-C = extension of DAMAS to the correlated case
DR = diagonal removal
$E\{.\}$ = expectation operation
$\mathbf{e}$ = noise
f = focusing frequency
FFT = fast Fourier transform
FOCUSS = focal underdetermined system solution
i.i.d. = independent identically distributed
I = number of snapshots
K = number of sources
L = number of frequency bins
LASSO = least absolute shrinkage and selection operator
LORE = localization and optimization of array results
M = number of microphones in the array
N = number of scanning points in the region
$\mathbf{R}$ = theoretical covariance matrix
$\hat{\mathbf{R}}$ = sample covariance matrix (cross spectral matrix)
SADA = small aperture directional array
SC-DAMAS = sparsity constrained DAMAS
SVD = singular Value Decomposition
$\mathbf{s}_k$ = signal wave form of source k
$\mathrm{Tr}(\cdot)$ = trace of the matrix argument
$\mathbf{x}_k$ = 3D location of source k
$\mathbf{x}$ = vector of all source locations
$\mathbf{x}', \mathbf{x}''$ = arbitrary 3D locations in space
$x_{m,k}$ = distance between the mth microphone and the kth source
$\widetilde{\mathbf{x}}$ = vector of $\{\widetilde{x}(\mathbf{x}_n)\}_{n=1}^{N}$
$\widetilde{x}_i$ = ith element of $\widetilde{\mathbf{x}}$
$\widetilde{x}(\mathbf{x}')$ = the actual source power level at $\mathbf{x}'$
$\mathbf{y}_i$ = measurement vector at snapshot i
λ = user parameter for SC-DAMAS and CMF
σ^2 = noise variance
ω = angular frequency
$\|\cdot\|_0$ = ℓ_0 norm: the number of nonzero elements
$\|\cdot\|_1$ = ℓ_1 norm: the absolute sum of the elements
$\|\cdot\|_2$ = ℓ_2 norm
$\|\cdot\|_{\mathrm{F}}$ = Frobenius norm
$(\cdot)^T$ = transpose of the argument
$(\cdot)^H$ = conjugate transpose of the argument
$(\cdot) \succcurlyeq 0$ = the matrix argument is positive semi-definite
$[\cdot]_{\mathrm{diag.}=0}$ = diagonal of the matrix argument is zero

Model-based detection of synthetic bat echolocation calls using an energy threshold detector for initialization

Mark D. Skowronski[a] and M. Brock Fenton[b]
Department of Biology, University of Western Ontario, London, Ontario N6A 5B7, Canada

(Received 4 July 2007; revised 21 January 2008; accepted 14 February 2008)

Detection of echolocation calls is fundamental to quantitative analysis of bat acoustic signals. Automated methods of detection reduce the subjectivity of hand labeling of calls and speed up the detection process in an accurate and repeatable manner. A model-based detector was initialized using a baseline energy threshold detector, removing the need for hand labels to train the model, and shown to be superior to the baseline detector using synthetic calls in two experiments: (1) an artificial environment and (2) a field playback setting. Synthetic calls using a piecewise exponential frequency modulation function from five hypothetical species were employed to control the signal-to-noise ratio (SNR) in each experiment and to provide an absolute ground truth to judge detector performance. The model-based detector outperformed the baseline detector by 2.5 dB SNR in the artificial environment and 1.5 dB SNR in the field playback setting. Atmospheric absorption was measured for the synthetic calls, and 1.5 dB increased the effective detection radius by between 1 and 7 m depending on species. The results demonstrate that hand labels are not necessary for training detection models and that model-based detectors significantly increase the range of detection for a recording system. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2896752]

I. INTRODUCTION

Echolocation plays an important role in the lives of bats in the suborder Microchiroptera.[1,2] Bats use echolocation for orientation and prey detection. Echolocation calls also serve as part of bats' repertoire of social calls used to convey information among individual bats.[3,4] Biologists interested in surveying an area for bats often use acoustical methods to augment traditional capture-based research methods.[5,6] Acoustic monitoring can provide details about the species and relative abundances of bats in an area as well as an indication of where and when they forage. Acoustic sampling allows us to monitor bats that are difficult to catch and in situations that are difficult to cover with nets (e.g., over open water, in dense foliage, high above the ground).[7]

Historically, analysis of acoustical data from echolocating bats involved hand labeling the end points of calls by an expert using oscillograms, sonograms, and spectrograms to view data.[5,8,9] Values for global call features, such as duration, frequency of most energy, and bandwidth, were determined from various representations of the data either by hand or using automated algorithms. Recent advances in commercial acoustic recording equipment (e.g., Pettersson Elektronik AB, Uppsala, Sweden; Avisoft Bioacoustics, Berlin, Germany) allow observers to collect large amounts of call data, which poses practical problems for analysis by hand. First, hand labeling is a slow process: A minute of typical field recording data may take 60 min to rigorously detect all calls in the data, and field seasons may generate hundreds of hours of data to analyze. Second, hand labeling is subjective, and it can be difficult to obtain any absolute ground truth about the presence of calls in a recording. This means that the hand-labeling expert must decide which parts of the recorded data are calls and which parts are noise. Subjectivity is most pronounced for weak calls that may or may not be useful, based on the hand-labeling expert's opinion, because global call feature estimate error (e.g., for call duration, bandwidth, maximum frequency) is larger when less of the call is above the background noise level of the recording. Together, subjectivity and voluminous data challenge the repeatability of hand labeling.

Automated techniques have been used to address the issues of hand labeling bat calls. Conventional techniques for automated bat call detection use signal energy, either broadband or narrow band.[6,9] Skowronski and Harris (2006) showed that conventional automated bat call detection was inferior to model-based detection, inspired by the extensive research of acoustical analysis of human speech.[10] However, detection models require labeled data for training, and this can be generated in two ways: (1) hand labels or (2) another detector. The initializing detector can be any method that marks call end points.

The purpose of the current work was to investigate the effectiveness of initializing a model-based detector of bat calls with a conventional energy threshold detector. To provide an absolute ground truth of calls to detect, we used synthetic echolocation search-phase calls in the detection experiments. The merits and drawbacks of using synthetic calls are discussed in the following and then the results from two detection experiments: (1) an artificial noise environment and (2) an outdoor playback environment.

II. METHODS

Using synthetic calls in detection experiments allowed us to work with signals whose time and location were

[a]Electronic mail: mskowro2@uwo.ca
[b]Electronic mail: bfenton@uwo.ca

known, providing an absolute ground truth not available with real bat recordings. Subjective hand labeling is a limitation of conventional bat call detection experiments which has traditionally provided the ground truth for such experiments. Second, we had precise control over the signal-to-noise ratio (SNR) of each call in the artificial environment experiment, allowing us to vary the difficulty of the detection problem by varying the SNR. This advantage was sacrificed somewhat for the playback experiment to operate with more realistic noise and to better account for propagation effects (e.g., colored noise, echoes, atmospheric absorption). Third, we had practically an unlimited number of calls to use in our experiments, allowing us flexibility in our experiment design and scope. Call synthesis and the autodetection experiments were conducted using MATLAB 7.4 (The Mathworks, Natick, MA).

Using synthetic calls in detection experiments has limitations. The parametric functions that we used only approximate the frequency modulation curves (i.e., instantaneous frequencies) of real bat calls and cannot account for curves that are not monotonic or that have points of inflection (i.e., concavity sign change). The amplitude modulation of the synthetic calls that we used is simplistic and does not reflect, among other characteristics, the fact that real calls are emitted from moving bats and exhibit Doppler effects and intricate amplitude modulations due to interference. Furthermore, the synthetic calls do not contain harmonics or calls that overlap in time, and the calls used in the artificial environment experiment do not contain echoes, all of which are found in real echolocation recordings. Nevertheless, synthetic bat calls allowed us to perform rigorous detection experiments with an absolute ground truth and to compare the relative performance of various automated detector algorithms.

A. Synthetic calls

Synthetic bat calls consisting of a frequency-modulated sinusoid were constructed using a piecewise exponential curve. The exponential function was chosen as a basis for the synthetic calls based on the results from Parsons and Jones, who showed that the exponential curve was one of the most accurate functions of frequency modulation for species classification of bats.[11] The following is a normalized expression for the exponential frequency modulation (FM) curve, spanning unity time and frequency:

$$g(t) = \frac{e^{at} - 1}{e^{a} - 1}, \tag{1}$$

where $g(t)$ is normalized frequency over time $t \in [0,1]$ and $a \geqslant 0$ is the single model parameter that controls the curvature of the function. As $a \to 0$, the function becomes a linear curve, while the function approaches a right angle as a increases. The function is scaled such that $g(0)=0$ and $g(1)=1$.

To control the location of the point on the FM curve farthest from the diagonal line between the beginning and end of the curve, the *turning point*, we concatenated two exponential curves together (Fig. 1). The turning point has two degrees of freedom, $[t_0, g_0]$, and can be placed anywhere

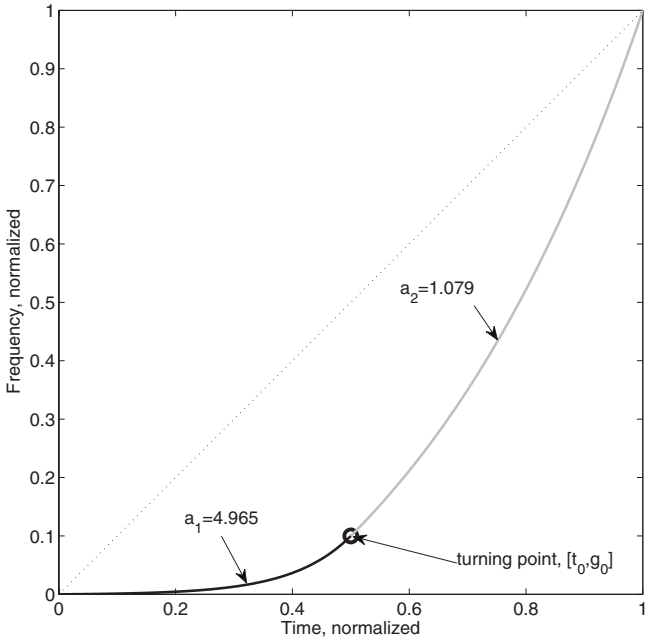

FIG. 1. Normalized piecewise exponential frequency modulation curve. The two exponential functions, shown with separate parameters a_1 and a_2 from Eq. (2), are joined at the turning point $[t_0, g_0]$. The diagonal line represents a linear modulation curve for comparison.

in the triangle space below the diagonal in Fig. 1 (since $a \geqslant 0$) to create a family of normalized monotonic curves. If the turning point is placed close to the diagonal, the FM curve is nearly linear, and long constant-frequency or steep frequency-modulated parts can be created by placing the turning point close to the horizontal or vertical legs of the lower triangle space, respectively.

The values for a for the two pieces of the FM curve are solved by the constraints that the pieces must pass through $[t_0, g_0]$ and have unity slope at $[t_0, g_0]$. Let $g_1(t)$ and $g_2(t)$ be the first and second pieces of the FM curve, respectively. Then

$$g_1(t) = g_0 \frac{e^{a_1 t/t_0} - 1}{e^{a_1} - 1}, \quad t \in [0, t_0],$$

$$g_2(t) = g_0 + (1 - g_0) \frac{e^{a_2 (t - t_0)/(1 - t_0)} - 1}{e^{a_2} - 1}, \quad t \in [t_0, 1], \tag{2}$$

where the extra shifting and scaling terms added to Eq. (1) ensure that $g_1(0)=0$, $g_1(t_0)=g_2(t_0)=g_0$, and $g_2(1)=1$. To solve for a_1 and a_2 in Eq. (2), the derivatives of g_1 and g_2 are equated to unity at $t=t_0$ which simplifies to

$$e^{a_1}(t_0 - g_0 a_1) - t_0 = 0,$$

$$(1 - t_0)(e^{a_2} - 1) - a_2(1 - g_0) = 0. \tag{3}$$

The expressions in Eq. (3) can be solved independently using empirical one-dimensional line search techniques (ignoring the trivial solutions $a_1=0$ and $a_2=0$).

The normalized frequency curve $g(t)$, the concatenation of $g_1(t)$ and $g_2(t)$, is upward-sweeping and concave up, which we refer to as call type I. Other types of calls can be constructed by flipping the time and/or frequency axes of

$g(t)$. A downward-sweeping and concave-up call is call type II with normalized frequency $\tilde{g}(t)=g(1-t)$. A type III call is downward sweeping and concave down with normalized frequency $\tilde{g}(t)=1-g(t)$, and a type IV call is upward sweeping and concave down with normalized frequency $\tilde{g}(t)=1-g(1-t)$.

To create a synthetic call, the process begins by selecting call parameters: starting frequency F_{start}, ending frequency F_{end}, duration T, turning point $[t_0, g_0]$, and sampling rate f_s. The starting and ending frequencies along with the turning point dictate the call type (I–IV, described earlier). To simplify the line searches used to solve Eq. (3), the turning point of the desired call type is translated to lie in the lower triangle space of a type I call shown in Fig. 1. For example, a downward-sweeping call with a turning point of [0.2, 0.1] (type II call) would be translated to [0.8, 0.1] before solving Eq. (3), while a downward-sweeping call with a turning point of [0.6, 0.7] (type III call) would be translated to [0.6, 0.3]. Once the parameters a_1 and a_2 are determined, the normalized FM curve of the desired call type $\tilde{g}(t)$ is shifted and scaled to fit between F_{start} and F_{end} for a call of duration T:

$$F(t) = F_{\min} + B\tilde{g}(t/T), \quad t \in [0,T], \tag{4}$$

where $F(t)$ is the instantaneous frequency of the synthetic call, $F_{\min}=\min(F_{\text{start}}, F_{\text{end}})$, and $B=|F_{\text{end}}-F_{\text{start}}|$ is the bandwidth of the call. The instantaneous frequency in Eq. (4) is integrated to form the instantaneous phase

$$\phi(t) = \int_0^t F(\tau)d\tau, \quad t \in [0,T], \tag{5}$$

which is used to form the synthetic call in the time domain

$$x(t) = A(t)\sin(2\pi\phi(t)), \quad t \in [0,T], \tag{6}$$

where $A(t)$ is an amplitude modulation function. For the current experiments, $A(t)$ was a Hamming window of length T. A discrete-time version of $x(t)$ is created using the desired sampling rate f_s.

B. Detection experiments

We performed two detection experiments using synthetic calls. The first was an artificial environment experiment in which the synthetic calls were embedded in additive white noise, while the second was a playback experiment in which the synthetic calls were broadcast in an outdoor environment using a high-frequency speaker and recorded using a microphone system.

In both experiments, we created calls from five hypothetical species. The parameters for each species were selected such that the calls had durations, bandwidths, and shapes typical of real species (compared with Vespertilionids[12] and neotropical species)[13] and that together the five species covered a wide range of frequency (Fig. 2; Table I). For each call, a set of parameters was selected from a uniform random distribution according to the value ranges listed in Table I.

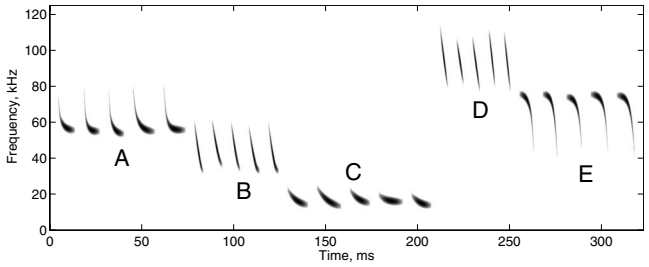

FIG. 2. Spectrogram of example calls for five hypothetical species, labeled A–E. See Table I for call parameters.

1. Artificial environment

In the first experiment, calls from each species were synthesized according to the parameter distributions listed in Table I and embedded in additive white Gaussian noise with zero mean and unity variance. To better mimic the analysis of real calls (e.g., the utility of spectral mean subtraction),[10,14] all calls were embedded into 16 bit files at a sampling rate of 250 kHz with 100 ms spacing between the beginning of adjacent calls. The files were uncompressed and encoded using pulse-code modulation. The SNR of each call was controlled by scaling the amplitude of the call to produce the desired signal power and SNR (i.e., noise power was constant for all calls). One file was created for each of the 12 SNRs tested (−13 to −3 dB in 1 dB increments and 0 dB), and each file contained 200 calls from each of the five species. A second file at 0 dB SNR with 200 calls from each species was created to train the model-based detector.

The primary advantage of using synthetic calls was that they provided an absolute ground truth for the detection experiments. While the calls of the five species used in the experiments were not designed to approximate calls from any real bat species, they contained the essence of real bat calls: frequency- and amplitude-modulated tones of relevant shape, bandwidth, and duration. Other characteristics typically found in real recordings of echolocating bats—echoes, harmonics, closely spaced or overlapping calls, feeding buzzes, insect noise, atmospheric absorption, source and microphone directionality—would add to the realism of the synthetic recording environment but were beyond the scope of the current study.

2. Playback recordings

In the second experiment, we created a file of synthetic calls for playback in an outdoor environment. The file was played through a ScanSpeak ultrasound speaker from Avisoft

TABLE I. Call parameters for five hypothetical species. Parameters selected from uniform distribution over listed range of values. See Fig. 2 for example call spectrograms.

Species	F_{start} (kHz)	F_{end} (kHz)	Duration (ms)	t_0	g_0
A	75–85	52.5–57.5	8–12	0.15–0.25	0.15–0.25
B	56–64	32.5–37.5	4–6	0.55–0.65	0.15–0.25
C	19.5–24.5	13.5–16.5	9–14	0.35–0.45	0.25–0.35
D	105–115	76.5–83.5	3–4	0.15–0.25	0.75–0.85
E	74–76	39–49	7–10	0.65–0.75	0.75–0.85

and recorded with an Avisoft UltraSoundGate 116 single-channel recorder using a CM16 condenser microphone capsule and CMPA preamplifier unit, both from Avisoft. The speaker and microphone were facing each other and aligned on axis (providing the flattest frequency response of both), and recordings were made in a flat grassy field. The speaker and microphone were spaced 4 m apart and mounted 1.76 m above the ground on tripods.

The file consisted of 200 calls of each of the five species embedded in additive white noise at SNRs from 11 to 50 dB in 1 dB increments (40 000 calls total). We used a range of embedded SNRs to accurately control the range of *recorded* SNRs of each species, which allowed us to compared the detectors in the same way as in the artificial environment experiment. The speaker and microphone gains were set well within their linear ranges such that calls with the highest embedded SNR were easily detected and calls with the lowest embedded SNR were not detectable better than random chance. The broadcast and recorded files were time-aligned using cross correlation.

3. Feature extraction and detectors

For both experiments, frame-based features were extracted from each file using 0.5 ms Blackman windows at 4000 frames/s (125 samples/frame at 250 kHz sampling rate and 50% overlap between adjacent frames). The spectrum of each frame was estimated using a 512-point zero-padded fast Fourier transform, and spectral mean subtraction was applied to each 2 s group of frames. The maximum energy of each frame, E (in dB), and the frequency of maximum energy, FME (in Hz), were determined. First-order temporal derivatives (Δ coefficients) of E and FME were estimated by linear regression using ± 3 frames around each frame, and second-order derivatives ($\Delta\Delta$ coefficients) were estimated by linear regression of the Δ coefficients.[10,15] The log-compressed mean-squared errors from the linear regression of E and FME were also included, called *smoothness* features. Peak energy and FME vary smoothly between frames of a call but coarsely between frames of background noise, making smoothness features useful for discriminating between calls and background noise. In summary, the following eight features were determined for each frame: E, FME, ΔE, ΔFME, $\Delta\Delta E$, $\Delta\Delta$FME, and smoothness of E and FME.

Three detectors were used in the experiments: (1) a baseline spectral peak detector, (2) a model-based detector trained with absolute ground truth endpoints, M_{abs}, and (3) a model-based detector trained with end points obtained from the baseline energy threshold detector, M_E. For the baseline detector, the variable E used by the model-based detector was compared to an energy threshold (described in the following). The model-based detectors used a Gaussian mixture model (GMM) to model both the frame-based call features and the background noise features,[10] and the output was the difference in log-likelihoods between the call and background GMMs. A threshold of 20 dB above the noise floor was used by the energy threshold detector to initialize M_E. Compared to M_{abs}, M_E should degrade in performance due to imperfect initial end point estimates provided by the baseline detector.

C. Detector evaluation

All detectors operated on a single measure for each analysis frame: peak energy E for the baseline detector, and log-likelihood difference for the model-based detectors. We evaluated the detectors by sweeping a detection threshold and generating a receiver operator characteristic (ROC) curve for each detector. For each detection threshold, all consecutive frames with a detector measure above the threshold were grouped together. The peak frame of each group was labeled a detected call peak. If the detected call peak was within 10 ms of the ground-truth end points of a call, a *hit* was recorded; otherwise, the detected call was recorded as a *false positive*. If no detected calls hit a ground-truth call, a *miss* was recorded for that call. The detection threshold controlled the tradeoff between hit rate (HR) and false positive rate (FPR):

$$\text{HR} = \frac{\text{hits}}{\text{hits} + \text{misses}},$$

$$\text{FPR} = \frac{\text{false positives}}{\text{hits} + \text{false positives}}, \tag{7}$$

where a higher detection threshold produced fewer false positives but more misses. Note that hits plus misses is the number of ground-truth calls and hits plus false positives is the number of detected calls. For the case of no detected calls (i.e., no hits and no false positives), FPR was set to 0 by convention.

A perfect detector has HR=1 and FPR=0. As a high detection threshold was lowered, fewer misses and more false positives were recorded, which produced a higher HR but higher FPR as well. Eventually, the detection threshold was so low that the HR and FPR were close to unity. Below this threshold level, HR and FPR decreased because separate calls merged into a single, large group and counted as a single detected call. When the threshold was below the minimum detector measure in a file, the entire file was detected as a single call. In the results to follow, we stopped decreasing the detection threshold when HR and FPR stopped increasing toward unity.

III. RESULTS AND DISCUSSION

A. Artificial environment

We embedded calls in files at SNRs of -13 to -3 dB, in 1 dB increments, and 0 dB. Figure 3 shows example spectrograms of a call from species A at various SNRs. All three detectors, the spectral peak baseline, M_{abs}, and M_E, were used to detect calls in each file. Figure 4 shows the ROC curves for the three detectors at -9 dB SNR. The model-based detectors outperformed the baseline detector, and M_E performed slightly better than the ground-truth-trained detector M_{abs} (Fig. 4). Results for all SNRs are shown in Fig. 5, which plots SNR versus the point on each ROC curve where HR=1−FPR (the cross-diagonal intersection in Fig. 4).

The results in Fig. 5 show that M_E outperformed the baseline detector by approximately 2.5 dB, meaning that M_E detected calls fainter by 2.5 dB compared to the baseline

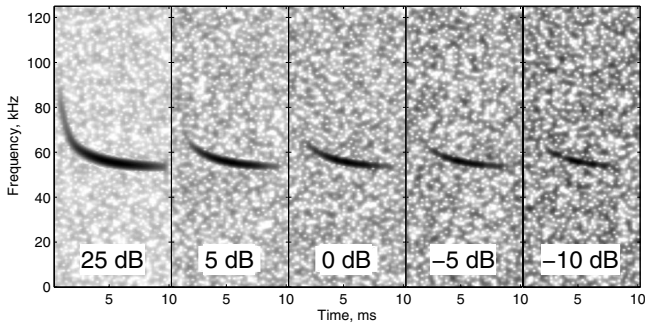

FIG. 3. Example noisy spectrograms. A synthetic call from species A was embedded in white noise at various SNRs, listed at the bottom of each pane. Less of the call is visible above the background noise for lower SNRs. All spectrograms were created using 250-point Blackman windows (1 ms) with 80% overlap, zero padded to 2048 points. The color map for each pane was scaled for maximum contrast.

detector for a given level of detector performance. In terms of "effective" detection range of a physical recording system, 2.5 dB translates into approximately 1.9 m increased detection radius of a recording system (1.32 dB/m atmospheric absorption at 40 kHz, 20 °C, and 50% relative humidity).[16] To better estimate the difference in effective detection range, we estimated the atmospheric absorption coefficient for calls from each species (described in the following).

The detector model M_E also slightly outperformed M_{abs}, even though M_{abs} was trained with absolute ground truth end points while M_E was trained using end points from the baseline detector which may be imperfect. Since M_{abs} and M_E were trained with calls at 0 dB SNR, the ends of each call were below the noise level because of the Hamming window amplitude modulation function $A(t)$ from Eq. (6) applied to

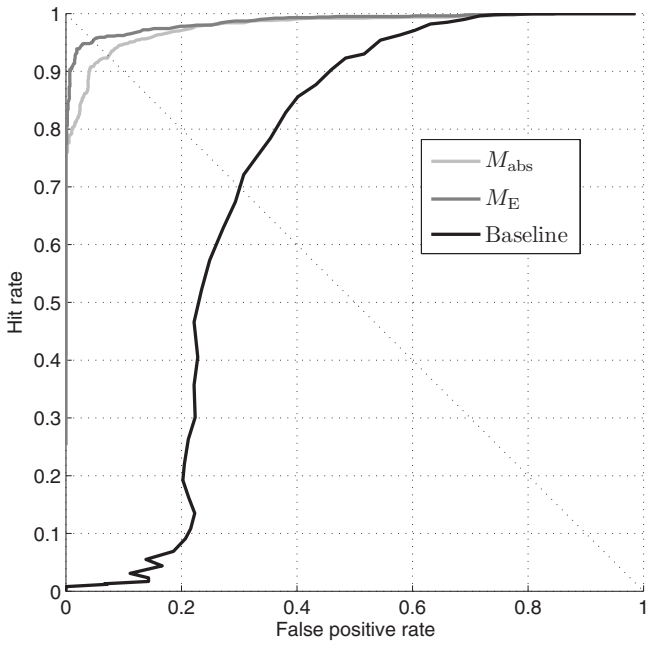

FIG. 4. Receiver operator characteristic curves for artificial environment detection experiment at −9 dB SNR. The cross diagonal line intersects each curve at the point where HR=1−FPR. The detectors are: ground-truth-trained model-based detector M_{abs}, the model-based detector initialized with the baseline detector M_E, and a spectral peak energy baseline detector.

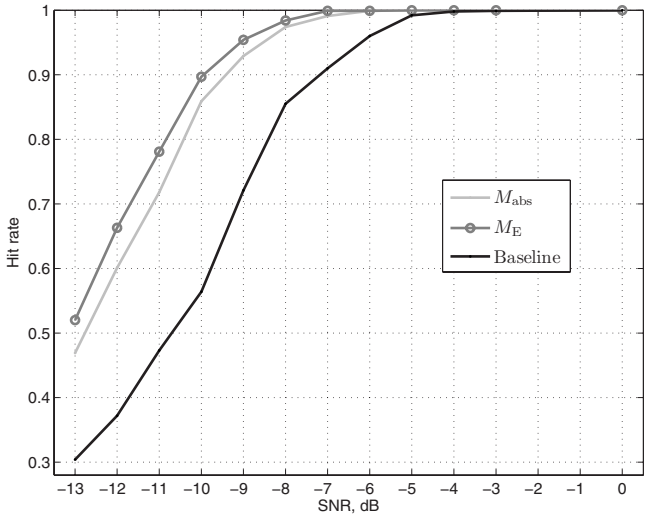

FIG. 5. HR vs SNR for artificial environment detection experiment. HR for each detector is for the point on each detector's ROC curve where HR=1−FPR.

each call. For M_E, the end points of each training call were set as two standard deviations above the noise peak distribution which effectively trimmed off the noise-corrupted ends of training calls. Since the training calls for M_{abs} contained some noisy frames, the call and background models for M_{abs} were more similar than those for M_E, resulting in less discriminability between the call and background models for M_{abs} and subsequently less detection power compared to M_E.

B. Playback recordings

Recordings were made outdoors in an open field at 31 °C and 52% relative humidity, measured using a Kestrel 4000 Pocket Weather Tracker (Nielsen-Kellerman Company, Boothwyn, PA). Since atmospheric absorption and off-axis misalignment between the speaker and microphone affected the recorded SNR of calls from each species differently, we analyzed the detectors for each species separately. Figure 6 shows embedded SNR versus HR where HR=1−FPR for species A through E. The plots in Fig. 6 are to the same scale, although the axis showing embedded SNR is shifted for each species depending on the propagation losses for each species' calls. For example, species D has the highest-frequency calls, which are most attenuated by the atmosphere, and required a higher embedded SNR to be detected at 4 m for a given level of detector performance compared to calls from the other species.

For all species except species D, the model-based detectors outperformed the baseline detector by 1–1.5 dB with little difference between the results for M_{abs} and M_E. The baseline and model-based detectors performed about the same for species D, whose calls were the highest in frequency and shortest in duration. The "jagged" look of the curves in Fig. 6 compared to similar curves from the artificial environment experiment in Fig. 5 is due to two sources: (1) the noise characteristics of the recordings made in the playback experiment and (2) the larger variance in recorded SNR due to atmospheric absorption and off-axis misalignment be-

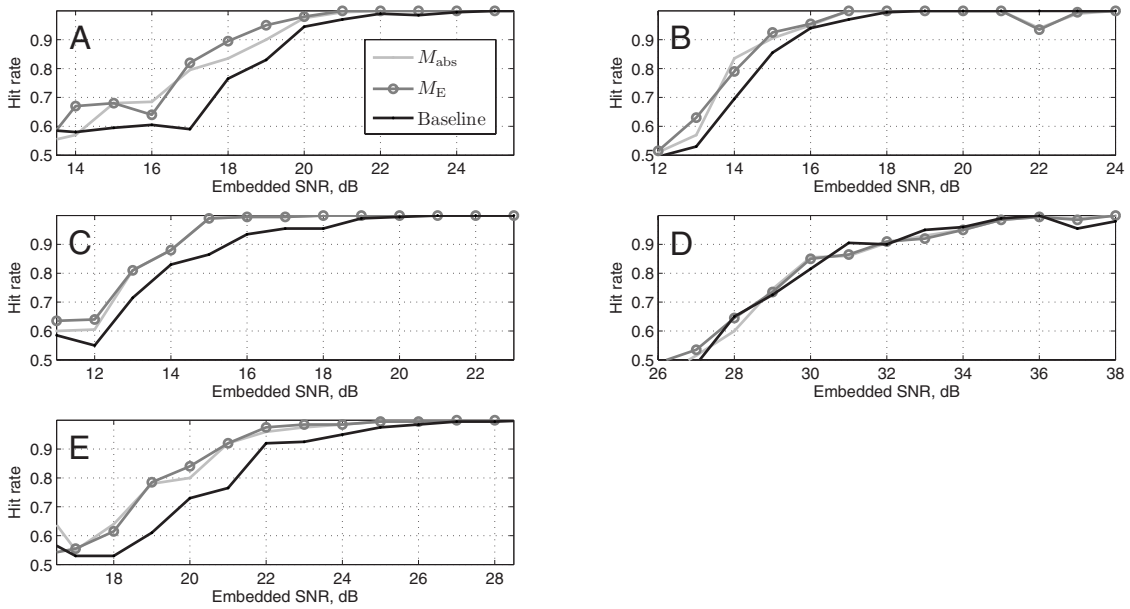

FIG. 6. HR vs embedded SNR for playback experiment. HR for each detector is for the point on each detector's ROC curve where HR = 1 − FPR. Species label, A–E, in upper left corner of each plot.

tween the speaker and microphone. The noise in the recorded files was not white and stationary like the noise in the artificial environment experiment and contained bursts of noise which increased FPR for the detectors.

To illustrate the relationship between SNR and effective detection radius, we estimated the atmospheric absorption coefficient for each species' calls. Using the same equipment and recording environment as the playback detection experiment, we played 200 calls from each species at 50 dB embedded SNR with a distance between the speaker and microphone of 1–12 m in 1 m increments. Recordings were made in an open field at 25 °C and 29% relative humidity. We extracted frame-based features from all recordings and found the spectral peak of each call using ground truth end points. To estimate the atmospheric absorption of each species' calls, we fit the spectral peak data to the following model:

$$\mathrm{E}(r) = -20\log_{10}(r) - \alpha r + \beta, \tag{8}$$

where $E(r)$, in decibels, is the spectral peak of a call at distance r, in meters, from the acoustic source. The log term accounts for spherical spreading loss, and α, in decibels per meter, is the atmospheric absorption coefficient. The term β is a gain term and accounts for the speaker and microphone gains. We used a least-squares curve fit function in MATLAB to find the model parameters in Eq. (8) for each species.

TABLE II. Curve fit parameters and coefficients of determination for models shown in Fig. 7.

Species	α (dB/m)	β (dB)	R^2
A	1.40	61.3	0.97
B	1.25	64.4	0.98
C	0.17	51.3	0.96
D	2.14	56.0	0.94
E	1.88	63.2	0.98

Figure 7 shows the mean ± standard deviation for each species at each distance along with the curve fit for each species, and Table II shows the curve fit parameters and coefficient of determination, R^2, for each model.

Table II shows that the atmospheric absorption term α ranged from 0.17 dB/m for the low-frequency species C to 2.14 dB/m for the high-frequency species D, and α for the other species fell in between in accordance with their frequency ranges. The term α for species D is probably underestimated since spectral peaks for $r \geq 10$ m were saturated by noise, as seen in Fig. 7. Comparing α in Table II to the SNR differences between the baseline and model-based detectors in Fig. 6, model-based detectors increased the effective detection range by the following: species A, 1.1 m; species B,

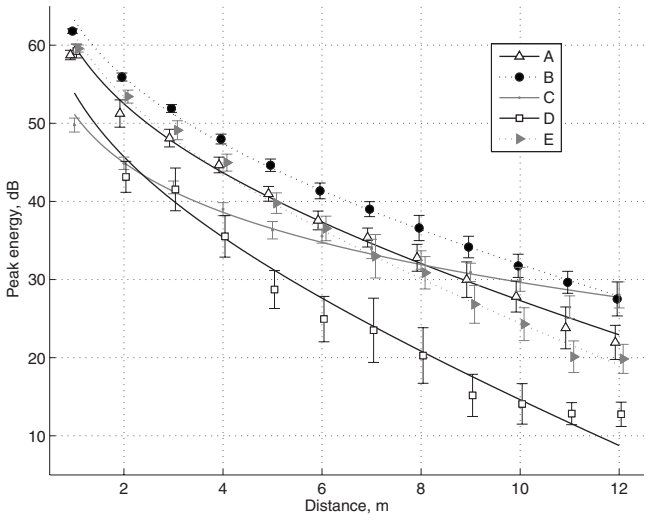

FIG. 7. Peak energy vs distance between speaker and microphone for each species in playback experiment. Symbols are mean ± standard deviation of 200 calls of each species, and lines are nonlinear regression expressions [Eq. (8)]. See Table II for model coefficients.

1.0 m; species C, 7 m; species D, 0 m; species E, 0.80 m. If a recording system has an effective detection range of 10 m using a spectral peak detector and an energy threshold that produces a hit rate of 0.75, then the same recording system would have an effective detection range of approximately 11 m for the majority of the species tested using a model-based detector with the same hit rate. Since detection volume is proportional to the cube of detection range (i.e., detection radius), this represents a 33% increase in effective detection volume.

Acoustic monitoring of bat activity has become a routine approach used by many bat biologists and others. Extending the volume of airspace sampled by acoustic monitoring has important repercussions, whether the monitoring is for an ecological and behavioral study, or associated with an assessment of bat activity tied to development such as a wind farm. Increasing the ability to detect and accurately assess the echolocation calls of bats is one part of the problem, the other is quickly and efficiently screening recordings to identify bat calls and extract information about them. Our model-based detection system both extends the volume of airspace sampled and makes it possible to quickly review and assess recordings of bat calls.

Real recordings of echolocating bats have several characteristics not included in the current experiments that greatly affect detector accuracy. For the baseline energy-based detector, *any* energy above the detection threshold produces a detected call, which tend to be false positives and can be quite numerous (e.g., recordings made near a pond full of croaking frogs). Such noises many times fall below the frequency range of interest and can be attenuated with appropriate filtering, but many insects produce acoustic noise in frequency bands that overlap with the frequency ranges of bat calls. Echoes also fall in the same frequency range as bat calls and can be detected as false positives with the baseline detector if they are intense enough. Echoes may last much longer than their original calls, potentially producing several false positives for each hit if the echo fluctuates above and below the detection threshold. This can be controlled by introducing a minimum time between detected calls, but such a solution tends to increase the number of misses because either calls from the same bat are closely spaced (e.g., feed buzz) or calls from separate bats with overlapping passes of calls are closely spaced or overlap in time.

Model-based detectors are less susceptible to real-world noise sources than the baseline detector because the model-based detector relies on more than just energy to determine if an analysis frame contains a bat call. However, other characteristics of real recordings of echolocating bats can hinder the performance of model-based detectors. The most significant is the so-called "test/train" mismatch phenomenon in the application of any statistical model. That is, the recorded (test) data are significantly different from the data used to train the models. The models could be trained on different species or with data recorded with different equipment (and associated equipment noise characteristics) or in environments with different acoustic noise characteristics (e.g., different insect populations). The training set may not contain any feeding buzzes or may not contain the full repertoire of search-phase calls of a species of interest (e.g., the high variability of calls from *Molossus* species)[17] or may contain calls with echoes of intensity different from that of test data. Closely spaced or overlapping calls would register as a single detected call as they would for the baseline detector. Therefore, the training data must be sufficiently broad for the model-based detectors to generalize well to novel recordings.

Characteristics of real calls not accounted for in the current experiments may also impact detector performance. Peak energy may jump between harmonics of a call (e.g., between the fundamental and second harmonics of calls from *Eptesicus fuscus*), causing a discontinuity in FME and erroneous slope and smoothness estimates. The model-based detectors may end a call at the discontinuity instead of the true end point, affecting global call feature measurements. Furthermore, calls may contain a notched amplitude modulation function that attenuates part of a call harmonic below the noise level at certain narrow frequency bands (e.g., calls from *Idionycteris phyllotis*),[18] which may produce multiple hits for the same call. A limitation of the model-based methods of detection is that likelihood is measured *locally* (within the neighborhood of a few frames), and global characteristics of calls are not utilized to make detection decisions. One method currently under study to address this limitation is the links detector which uses local and global call features to detect calls and call harmonics while rejecting echoes and noncall noises in a unified model-based framework.[19]

IV. CONCLUSIONS

We showed that a model-based bat call detector, trained with calls labeled by a baseline threshold energy detector, outperformed the baseline detector in terms of SNR of a call for a given level of detector performance. Skowronski and Harris (2006) showed that model-based detectors, trained with hand labels, were superior to energy-based detectors, and the current results extend those findings to show that models can be trained using labels from a simple detector instead of hand labels, resulting in a fully automated model-based detection algorithm.

We used synthetic echolocation calls, constructed with a piecewise exponential frequency modulation function, in the detection experiments to provide an absolute ground truth for call location and to accurately control the SNR of calls. We created random distributions of call parameters for five hypothetical species, which spanned a wide frequency range and were designed to approximate real echolocation calls. Using synthetic calls provided for us an unlimited number of labeled calls to use in our experiments, giving us flexibility in our experiment design and scope. In both experiments, a total of 65 000 synthetic calls were constructed. The piecewise exponential model can be extended to form more complex calls. For example, the "Z"-shaped calls of *Pteronotus davyi*[20] can be synthesized by concatenating a type III call with a type II call. The basic model in Eq. (1) can be extended to more than two pieces if extra constraints are included, or the model can be modified to included pure-tone

segments to better approximate the constant-frequency tails of calls from some species.

In the artificial environment experiment, the results in Fig. 5 show that, at a level of detector performance of 80% hit rate and 20% false positive rate, the baseline algorithm detected calls down to −8.4 dB SNR while the model-based detector M_E detected calls down to −11.9 dB SNR. Fainter calls by 2.5 dB were detected by the model-based detector, which translates into an increase in effective detection range of a physical acoustical recording system. The increase in performance of the model-based detector was due to the increase in information used by the model. Whereas the baseline detector only considered spectral peak energy, the model detector used spectral peak energy and spectral peak frequency as well as local shape information (i.e., slope, concavity, and smoothness).

The playback experiment was designed to repeat the artificial environment experiment using realistic noise sources and accounting for acoustic propagation effects. The results showed that model-based detection outperformed the baseline detector by 1–1.5 dB SNR, except for species D whose calls were equally detected by all algorithms. Our estimates for atmospheric absorption of calls from each species showed that 1–1.5 dB SNR difference translates into approximately 1 m increased effective detection range, except for the low-frequency species C whose calls could be detected 7 m farther away using the model-based detector. Adding 1 m of range to a recording system whose effective detection range is 10 m increases the effective detection volume by 33%. This result shows that calls can be detected in a significantly larger volume of space at a fixed level of detector performance (i.e., fixed hit rate) when using model-based detectors compared to the conventional energy threshold detector.

(Received 17 September 2007; revised 3 March 2008; accepted 4 March 2008)

An efficient method for measuring stimulus-frequency otoacoustic emissions (SFOAEs) was developed incorporating (1) stimulus with swept frequency or level and (2) the digital heterodyne analysis. SFOAEs were measured for 550–1450 Hz and stimulus levels of 32–62 dB sound pressure level in eight normal human adults. The mean level, number of peaks, frequency spacing between peaks, phase change, and energy-weighted group delays of SFOAEs were determined. Salient features of the human SFOAEs were stimulated with an active cochlear model containing spatially low-pass filtered irregularity in the impedance. An objective fitting procedure yielded an optimal set of model parameters where, with decreasing stimulus level, the amount of cochlear amplification and the base amplitude of the irregularity increased while the spatial low-pass cutoff and the slope of the spatial low-pass filter decreased. The characteristics of the human cochlea were inferred with the model. In the model, an SFOAE consisted of a long-delay component originating from irregularity in a traveling-wave peak region and a short-delay component originating from irregularity in regions remote from the peak. The results of this study should be useful both for understanding cochlear function and for developing a clinical method of assessing cochlear status. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2902184]

I. INTRODUCTION

Otoacoustic emissions (OAEs) are sounds generated by the inner ear (Kemp, 1978). As OAEs are related to movements of the cochlear partition, major goals of investigations of OAEs include: (1) to infer noninvasively basic characteristics of cochlear biomechanics of humans and animals in normal and pathological conditions (e.g., Kemp, 1978; Kim, 1980; Kim *et al.*, 1980; Zurek *et al.*, 1982; Kemp, 1986; Matthews and Molnar, 1986; Zwicker, 1986; Shera *et al.*, 2002; Goodman *et al.*, 2003; Siegel *et al.*, 2005) and (2) to assess the functional status of the cochlea noninvasively (e.g., Kemp *et al.*, 1990; Lonsbury-Martin and Martin, 1990; Probst *et al.*, 1991; Shera, 2004).

The present study is intended to contribute to these goals by: (1) introducing a new efficient method of measuring OAEs and providing human OAEs obtained with the method, and (2) interpreting experimentally observed OAEs in terms of an active cochlear model. Our study investigated stimulus-frequency OAEs (SFOAEs). A presumed advantage of SFOAE over distortion product OAEs (DPOAEs) is that the information conveyed by SFOAEs may be simpler than that by DPOAEs because SFOAEs involve only one frequency whereas DPOAEs involve multiple frequencies. Most likely, though, further studies of all types of OAEs will continue to be helpful in advancing our knowledge of cochlear biomechanics and in developments of methods for assessing the cochlear functional status.

In conventional methods of SFOAE measurement (e.g., Brass and Kemp, 1993; Shera and Guinan, 1999, 2003), the SFOAE is measured for one frequency at a time. It is thus necessary to make separate measurements at a large number of frequencies if one wishes to determine high-resolution fine structures of SFOAE level and phase versus frequency.

We have developed a new efficient method for measurement of SFOAEs whereby high-resolution fine structures of SFOAE versus frequency can be obtained more rapidly. The new method employs a stimulus where frequency is continuously swept and the response waveform is analyzed using the digital heterodyne analysis. Analogously, the present method can also obtain input-output functions of SFOAE where the

[a)]Author to whom correspondence should be addressed. Electronic mail: kim@neuron.uchc.edu.

stimulus level is continuously swept. The digital heterodyne analysis method was previously used for measurement of a time-dependent change (i.e., adaptation) of a DPOAE (Kim *et al.*, 2001) or an SFOAE (Guinan *et al.*, 2003) of a particular frequency. The latter studies involved using constant stimulus frequencies as opposed to time-varying stimulus frequencies used in the present study.

An important characteristic of SFOAEs is their fine structures in the frequency domain. Level of SFOAEs versus frequency exhibit a complex quasi-periodic pattern of peaks and troughs, while the phase of SFOAEs versus frequency also exhibits a complex pattern of many cycles of phase change indicating a frequency-dependent group delay (Kemp and Chum, 1980; Zweig and Shera, 1995; Shera and Guinan, 1999, 2003). The fine structures of SFOAEs have been interpreted to be a result of reflections of cochlear traveling waves arising from spatially distributed irregularities (or roughness) in cochlear-partition impedance (Shera and Zweig, 1991; Zweig and Shera, 1995; Talmadge *et al.*, 1998, 2000).

As an *in vivo* measurement of cochlear-partition motion is not feasible in humans, OAEs provide a useful basis for making indirect inferences for human cochlear mechanical responses. Along this line, one of the goals of the present study was to use features of human SFOAEs as a basis for specifying parameters of an active cochlear model and to make inferences about the human cochlear biomechanics. A cochlear model developed in the present study was able to reproduce salient features of the human SFOAE fine structures. Model parameters important for SFOAE simulation were the amount of cochlear amplification and the spatial-frequency contents of the partition-impedance irregularity. The correspondence between the human SFOAEs and the model results allowed us to infer characteristics of human cochlear-partition motion regarding the amount of amplification, sharpness of tuning and phase properties at various stimulus levels.

II. METHODS FOR MEASUREMENTS OF HUMAN SFOAES

The present SFOAE measurements were conducted at the University of Connecticut Health Center while Y.-S. Choi was visiting there.

A. Subjects

SFOAEs were obtained from eight ears of eight human subjects, five men and three women, aged 24–40 years. In a ninth (male, 32 years old) subject, SFOAE data were collected by the conventional method in addition to the current novel method for comparison. All of the subjects had normal hearing as documented by their audiometric thresholds being 20 dB hearing level (HL *re* American National Standards Institute S3.21, 1978) or better at octave frequencies in the range from 0.25 to 8 kHz. They also had normal patterns of tympanogram. For each subject, there were one or more recording sessions with each session typically taking 30–45 min. One session consisted of about 20 subsessions with each taking approximately 1.5 min. After groups of a few subsessions, the subjects had short breaks (~1 min each) to allow body movements for a comfortable posture, to relieve discomfort of the probe and ear mold (see below) being in the ear canal, and to remove any potential long-term adaptation.

During the recording sessions, the subjects remained awake sitting quietly on a chair in a double-walled acoustic chamber (Industrial Acoustics Co.). The present study was approved by the Institutional Review Board for Human Subjects of University of Connecticut Health Center.

B. Equipment

Stimuli were synthesized, stimulus presentation was controlled, and acoustic waveforms were recorded using a Windows-PC which contained a sound card (Card Deluxe, Digital Audio Labs) with 24 bit analog-to-digital and digital-to-analog converters operating at a sampling rate of 22 kHz. We used a program called SYSRES (Neely and Stevenson, 2002) to present the custom-synthesized stimulus and collect the acoustic waveforms.

The acoustic system included one microphone and two earphones (ER-10C, Etymotic Research) designed for ear-canal insertion. Individualized ear molds were made for the human subjects with silicon-based impression material. During the recording period, the ear mold was inserted into a subject's ear canal, and the tube of the ER-10C acoustic probe was inserted into the hole running through the ear mold. This arrangement, having a tight coupling between the acoustic probe and the ear canal, was intended to provide a higher signal-to-noise ratio and a more controlled positioning of the probe than a conventional arrangement where the probe was inserted in the ear canal with a foam tip.

C. Suppression method to extract SFOAEs

The measurement of SFOAEs requires separation of the recorded acoustic signal into the "stimulus" and emission components. The stimulus component represents both a signal generated by an earphone and passive acoustic properties of the earphone coupler and the passive acoustic input impedance looking into the ear canal. The emission component represents a signal generated by the ear. One method of such separation is based on the fact that an SFOAE is suppressed when a suppressor tone is added at a frequency near the probe tone (e.g., Kemp and Souter, 1988; Brass and Kemp, 1993; Shera and Guinan, 1999). In this method, the stimulus component is obtained from a condition where both a probe tone and a suppressor tone are applied as the stimulus. An SFOAE is then obtained by vector subtraction of the stimulus component from the signal containing both the stimulus and SFOAE. The present study used this method.

D. Frequency-sweeping method: Stimulus generation

The stimulus frequency was continuously swept from 500 to 1500 Hz in order to obtain high-resolution fine structures of SFOAEs. We applied a stimulus signal and recorded pressure response of the ear canal. At each measurement, the acoustic stimulus was repeated 32 times. As the duration of the stimulus was approximately 3 s, it took about 1.5 min for

TABLE I. Midway stimulus level in dB SPL and the range of levels obtained at the input attenuation level of −50 dB *re* maximum voltage into the earphone for each subject. The last column shows the corresponding information pooled for all subjects.

Subject ID No.	1	2	3	4	5	6	7	8	all
Mid-level (dB SPL)	49	39	39	37	42	40	37	39	42
Range (±dB)	2	3	7	4	3	8	4	3	10

a measurement covering 500–1500 Hz at one stimulus level. The stimulus had two channels delivered through two channels of the soundcard which were connected to two earphones of the ER-10C probe. One channel of the stimulus produced a probe tone whereas the other channel produced a suppressor tone. Each channel had two equal-length (32768 samples/(22000 samples/s=1.489 s) intervals. The two intervals of the probe channel were identical whereas the first interval of the suppressor channel was silence.

The probe and suppressor signals, $p(t)$ and $s(t)$, were:

$$p(t) = A_p \cdot \sin\left[2\pi \cdot \left\{500 \times \frac{f_{\text{sam}}}{31448} \times (t-0.03)^2 + 500 \times (t-0.03)\right\}\right], \quad (1)$$

$$s(t) = A_s \cdot \sin\left[2\pi \cdot \left\{500 \times \frac{f_{\text{sam}}}{31448} \times (t-0.03)^2 + 650 \times (t-0.03)\right\}\right]. \quad (2)$$

A_p and A_s represent amplitudes of the probe and suppressor tones, respectively, f_{sam} the sample rate in Hz. The unit of time, t, was seconds (s). The above equations included 0.03 s silent portions that were intended to avoid transients. The probe frequency was swept linearly from 500 to 1500 Hz. The suppressor frequency was also swept linearly such that it was 150 Hz above the probe frequency. For both $p(t)$ and $s(t)$, we used 30 ms rise/fall times with half Blackman windows. After subtracting the silent and rise/fall portions, the above signal waveform was stable for 1.37 s.

We converted the voltage amplitude of a stimulus tone to the earphone, A_p or A_s, relative to the maximum voltage as attenuation of the tone in dB. A constant attenuation corresponded to a variable sound pressure level (SPL) as a result of a frequency dependence of the earphone and the acoustic load impedance of the ear canal. In the present study, −50 dB attenuation, for example, corresponded to 37 ± 4 dB SPL (*re* 20 μPa) for 500–1500 Hz in one subject (No. 7). Further details on this topic are described in Sec. III A, Table I.

For each measurement, the probe stimulus was applied at a constant attenuation with the probe frequency swept from 500 to 1500 Hz. The attenuation level of the probe tone varied from −70 dB to −25 dB in 5 dB steps. In the present report, only the results with attenuation of −60 dB to −30 dB in 10 dB steps were systematically analyzed across all subjects. The suppressor level was 20–40 dB above that of the probe level; i.e., the suppressor level was −20, −15, −10, and −5 dB *re* max when the probe level was −60, −50, −40, and −30 dB *re* max, respectively. When the probe level was higher, we had to use smaller difference between the suppressor level and the probe level in order to keep the absolute level of the suppressor.

E. Digital heterodyne analysis of SFOAEs

We used the digital heterodyne method to determine SFOAE level and phase as a function of frequency which, in turn, are functions of time in the present study. The digital heterodyne method, a Fourier-transform application, was developed by Stephen T. Neely (Boys Town National Research Hospital, Omaha, NE, personal communication), and previously used to measure an OAE at a particular frequency as a function of time for a fixed stimulus (Kim *et al.*, 2001; Guinan *et al.*, 2003).

In the context of the present study, we took a discrete Fourier transform of the 1.43-s-long original response waveform sampled at 22 kHz. A band of positive frequencies (1000 spectral components) around an SFOAE analysis frequency was then selected in the frequency domain and shifted down ("heterodyned") such that the SFOAE frequency was set to be the zero frequency. Next, a Blackman low-pass filter was applied to the shifted spectrum.

The optimal bandwidth ("BW") of the heterodyne low-pass filter is proportional to square root of the frequency sweep rate. This is because opposing constraints on the BW are imposed in the frequency- and time-domain parts of the heterodyne analysis. An unduly wide BW of the low-pass filter will allow energy at a frequency remote from an analysis frequency to be included in the frequency-domain part of the heterodyne analysis whereas an unduly narrow BW of the filter (which has a long integration time), together with a frequency-swept stimulus, will allow energy at a frequency remote from the analysis frequency to be included in the time-domain part of the heterodyne analysis. We empirically found, for a Blackman low-pass filter used in this study, the optimal value of BW (defined as the bandwidth at a relative amplitude of 0.7):

$$\text{BW} = 0.345^*(\text{sr})^{0.5}, \quad (3)$$

where sr corresponded to sweep rate in Hz/s. [Note: the unit of $(\text{Hz/s})^{0.5}$ is Hz.] By substituting sr=699.3 Hz/s (1000 Hz/1.43 s) into Eq. (3), we obtained BW=9.1 Hz.

We then took an inverse discrete Fourier transform of the shifted and low-passed, yielding a complex-valued time-domain signal. The latter consisted of 1000 time points representing the magnitude and phase of the SFOAE of a particular analysis frequency as a function of time over 1.43 s with each time point representing 1.43 ms.

Originally, the heterodyne method was used to extract one specific frequency component as a function of time for a

fixed stimulus. A novel aspect of the present method is that a time dependence of the heterodyne analysis output is made to be equivalent to a frequency dependence by combining a frequency-swept stimulus with the heterodyne analysis.

To extract an SFOAE at a particular analysis frequency, the total 1.43 s recorded signal was first multiplied with a 227 ms Blackman window (spanning a frequency range of ± 79 Hz) centered at the point when the probe-tone frequency was equal to the analysis frequency to suppress the suppressor-tone signal; the suppressor frequency was 150 Hz higher than the probe frequency. The magnitude of the heterodyne-analysis output for a particular analysis frequency showed a peak near a time when the stimulus frequency was equal to the analysis frequency. A peak occurred slightly later (at a time to be called "$t_$peak") than the time when the stimulus frequency was equal to the analysis frequency ("$t_$stimulus"). The average delay between $t_$peak and $t_$stimulus among all of the present data was 3.1 ms. This delay represents a combination of a round-trip delay of the SFOAE signal and a delay of the measurement system.

Each original acoustic waveform was shifted by 3.1 ms to compensate for the delay described above. Then the heterodyne analysis was applied to the shifted waveform, and the magnitude, $m(f)$, and phase, $\theta(f)$, of an SFOAE for a particular analysis frequency, f, was determined by taking the magnitude and phase of the heterodyne-analysis output at the time when the stimulus frequency was equal to the analysis frequency. We converted the SFOAE magnitude, m in μPa, into an SFOAE level in dB SPL *re* 20 μPa by using

$$\text{SFOAE level} = 20 \cdot \log_{10}(m/20\ \mu\text{Pa}). \tag{4}$$

We repeated the above heterodyne analysis for a particular response waveform with a large number of analysis frequencies ranging from 550 to 1450 Hz in small steps. Because the analysis could be performed after the data were collected, the analysis time did not increase the recording time. The frequencies of 500–550 and 1450–1500 Hz were excluded to avoid transients. The minimum frequency separation where the contribution to an analysis frequency was less than 0.7 relative to the contribution by the analysis frequency itself was given by the bandwidth of the low-pass filter, ± 9.1 Hz. Thus, for the present SFOAE measure at each analysis frequency, the signal component at a frequency 9.1 Hz away from the analysis frequency had a relative contribution of 0.7. In describing our results, we chose to display the SFOAE measures versus frequency with a 5 Hz spacing rather than a 9.1 Hz spacing to improve visualization.

F. Noise floor computation

Noise floor was computed in separate steps from the normal SFOAE analysis. As stated above, the heterodyne output corresponds to the level and phase of a particular analysis frequency versus time; the full time range of measured waveform (0–1.43 s) in the present study was mapped to a probe-stimulus-frequency range of 500–1500 Hz. Such a heterodyne output typically exhibited high levels near the points where the probe frequency or suppressor frequency (150 Hz above the probe frequency) was equal to the analysis frequency. The level near the point of suppressor frequency was attenuated by applying a 227 ms Blackman window (spanning a frequency range of ± 79 Hz) centered at the probe frequency, as stated above. In a wide region of the full range of time/frequency in the heterodyne analysis output, neither the probe frequency nor the suppressor frequency was near the analysis frequency. In such a "remote region," consequently, the level of the heterodyne analysis output was quite low.

We defined a remote region to be a region spanning probe frequencies over a 400 Hz range. For this purpose, we treated the full probe frequency range of 550–1450 Hz as a circular range. For a particular analysis frequency, a probe frequency in the remote region was at least 150 Hz higher than, and at least 350 Hz lower than, the analysis frequency. For example, if the analysis frequency was 1000 Hz, the remote region consisted of two subregions of probe frequencies: (1) 550–650 Hz, and (2) 1150–1450 Hz.

For a particular analysis frequency, the 400-Hz-wide remote probe-frequency region consisted of 80 sample points separated by 5 Hz steps. For each of the 80 remote probe-frequency points, we multiplied the original response waveform with a 227 ms Blackman window centered at the "remote point" under consideration and then performed the heterodyne analysis yielding one remote level. We repeated the process 80 times for the 80 remote points and defined the average of the 80 remote levels to be the noise floor level for one analysis frequency under consideration. This process was repeated for each of all analysis frequencies.

G. Quantification of response features of SFOAE fine structures

SFOAEs exhibited fine structures, i.e., multiple peaks and troughs of level and many cycles of phase change over a frequency range of 550–1450 Hz. Based on such data in each subject, we quantified the following response features: (1) mean level (ML) of SFOAE in dB SPL; (2) number of peaks (NP); (3) frequency spacing (Δf) between SFOAE peaks in Hz; (4) number of cycles (NC) of SFOAE phase change; (5) energy-weighted group delay (EGD) in ms; and (6) standard deviation of EGD (σ_{EGD}) in ms.

Regarding NP, we required that an acceptable peak should be surrounded troughs each with a minimum 2 dB depth; the latter was measured between a relevant local minimum and the straight line connecting two neighboring peak candidates (local maxima). To determine energy-weighted group delays (EGDs), we first unwrapped SFOAE phase versus frequency where the neighboring phase values were constrained to be within one half cycle. The EGD was obtained by differentiating the unwrapped SFOAE phase, θ, with respect to frequency, f, with an energy weighting as follows:

$$\text{EGD}(f_c) = \frac{-\sum_{\text{f}} A^2(f) \cdot \frac{d\theta}{df}}{\sum_{\text{f}} A^2(f)}; \tag{5}$$

where, $A(f)$ and f_c represent the SFOAE amplitude at frequency f and the center of the processed frequency range,

respectively. The value of $d\theta/(df)$ was obtained by dividing the difference between the two neighboring phase values by the 5 Hz frequency difference. We used 25-Hz-wide ranges centered at various frequencies for information about how a narrowband EGD changes as a function of the center frequency, and a 900-Hz-wide range for information about the overall EGD processed for the whole 550–1450 Hz range. This definition of EGD was adapted from Goldstein *et al.* (1971) who indicated that EGD of a band-limited filter corresponds to the center of gravity of the impulse response of the filter. The advantage of EGD over the un-weighted group delay (GD) is that the former incorporates the fact that GD associated with a large amplitude is more meaningful than one associated with a small amplitude. We also determined normalized energy-weighted group delays (NEGDs) in units of cycles as follows:

$$\mathrm{NEGD}(f_c) = \mathrm{EGD} \times f_c. \tag{6}$$

The measure σ_{EGD} describes the variability of 25-Hz-wide EGDs over the 550–1450 Hz range in each subject.

H. Level-sweeping method

The level-sweeping method allowed us to measure the SFOAE input-output functions at specific frequencies. The frequency-swept data obtained at −40 dB *re* maximum were used to choose several peak and trough frequencies. Measurements were made at selected probe frequencies with swept stimulus levels. After the measurement, the probe (f_1) component was obtained using the heterodyne analysis method as above. The input-output functions of the SFOAE level and phase at a specific probe frequency were constructed by pairing the output level and phase with the corresponding input level.

At each measurement, the acoustic stimulus was repeated eight times. The duration of the stimulus was approximately 12 s hence each measurement required about 1.5 min. The stimulus had two channels with each having two intervals (as above). The probe frequency was fixed but level was varied, and the suppressor frequency was fixed at 150 Hz above the probe frequency and the level was varied. During the level sweep, the amplitudes of the waveforms were exponentially increased or decreased. These exponential changes of amplitudes over time correspond to linear sweeps of the stimulus levels in dB SPL versus time.

To construct the SFOAE input-output function, the heterodyne analysis was applied to extract the probe frequency component. Finally, the SFOAEs were extracted by taking the vector difference between the two intervals (as above). Generally, the probe level ranged from 10 to 70 dB SPL with the suppressor level ranging from 50 to 90 dB SPL; the suppressor level was 20–40 dB above the probe level. In cases where the maximum ear canal pressure of the suppressor channel was less than 90 dB SPL, the ranges of the probe and suppressor levels were adjusted. The present method of obtaining input-output functions with a continuously swept stimulus level is similar to that described by Neely *et al.* (2003).

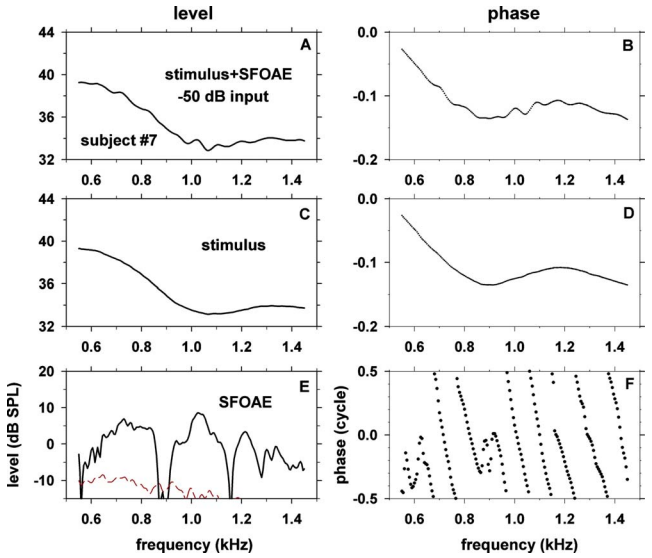

FIG. 1. (Color online) Procedure for obtaining SFOAE level and phase using frequency-swept stimuli illustrated with results obtained with a stimulus level of −50 dB *re* maximum voltage in one subject, No. 7. The left and right columns show signal level (in dB SPL) and phase (in cycles), respectively. In the top row (panels A and B), the signal (in the first interval) was a mixture of stimulus and SFOAE. In the second row (panels C and D), the signal (in the second interval) was stimulus with little SFOAE present as SFOAE was suppressed by the suppressor tone. The vector difference between the signals in the top two rows, shown in the third row (panels E and F), corresponds to SFOAE. Negative phase values were defined to be a phase lag. In panel E, dashed line represents noise floor.

III. RESULTS OF HUMAN SFOAES

A. Frequency-sweeping experiment

The procedure for obtaining SFOAE level and phase versus frequency is illustrated with an example obtained in one subject (No. 7) with a probe stimulus level of −50 dB *re* maximum voltage into the earphone (Fig. 1). As described in Methods, the stimulus consisted of two intervals where the first interval contained only the probe frequency component and the second interval contained both the probe and the suppressor frequency components. We obtained SFOAE level and phase versus frequency (Fig. 1, bottom row) by taking vector differences between the heterodyne outputs derived from the first interval (corresponding to SFOAEs plus probe stimuli, Fig. 1, top row) and those derived from the second interval (corresponding to probe stimuli, Fig. 1, middle row). The signals in the middle and bottom rows of Fig. 1 display a slowly varying pattern superimposed on a rapidly varying pattern. The slowly varying stimulus (middle row) represents the frequency-dependent properties of the stimulus-generating system and the input impedance looking into the ear. The dashed line in panel E shows the noise floor computed as described in Methods

The data of Fig. 1 are consistent with the concept that the stimulus+SFOAE fine structure has a frequency spacing the reciprocal of which corresponds to a round-trip delay (Zweig and Shera, 1995). The frequency spacing between peaks of the stimulus+SFOAE around 1 kHz [Fig. 1(A)] is 81 Hz. The reciprocal of 81 Hz is 12.3 ms. This value is close to the group delay of SFOAEs around 1 kHz, 11.1 ms [see below, Fig. 2(I)].

TABLE II. Comparison of SFOAEs obtained with the conventional analysis method against those obtained with the heterodyne analysis method. The two types of analysis methods were applied to a common set of data records obtained with conventional stimuli where the stimulus frequency was kept constant (at one of three values) over a 1.43 s stimulus period. The stimulus levels were 57, 54, and 52 dB SPL for 800, 1000, and 1100 Hz, respectively. Each entry is level (in dB SPL) and phase (in cycle) of SFOAE for a particular frequency. Results from one ear of Subject No. 9.

	800 Hz	1000 Hz	1100 Hz
Heterodyne	24.8 dB; 0.511 cyc.	23.6 dB; 0.480 cyc.	22.3 dB; 0.038 cyc.
Conventional	24.5 dB; 0.524 cyc.	23.3 dB; 0.482 cyc.	22.2 dB; 0.035 cyc.

As seen in panel C of Fig. 1, ear-canal sound pressure level varied as a function of frequency when the stimulus level was kept at a constant attenuation of voltage into the earphone. In this subject, −50 dB *re* maximum voltage corresponded to 37 ± 4 dB SPL *re* 20 μPa. The range of dB SPL values in various subjects at −50 dB *re* maximum voltage are described in Table I.

To verify that the current method generates results consistent with those of the conventional method (using a fixed-frequency stimulus), we analyzed a common dataset obtained with a constant stimulus frequency using two analysis methods: (1) a simple conventional Fourier transform, and (2) the heterodyne analysis. The results of one subject (No. 9) for three stimulus frequencies are summarized in Table II. The differences between the results obtained by the two analysis methods were within 0.3 dB in level and 0.013 cycle in phase. These data demonstrate that the results obtained with the current heterodyne analysis method are consistent with those obtained with the conventional method.

The results obtained with stimulus level from 27 to 57 dB SPL in subject No. 7 are shown in Fig. 2. The three columns represent SFOAE level, phase and 25-Hz-wide EGDs, respectively. The effective frequency resolution of the present data is 9.1 Hz as stated in Methods, and the data are plotted with 5 Hz steps. Prominent features of the data are: (1) SFOAE level versus frequency exhibits many quasi-periodic peaks and troughs; (2) when SFOAE phase is unwrapped, the phase versus frequency tends to be almost a straight line with a steep slope but there are conspicuous irregularities in the slope; (3) the 25-Hz-wide EGD varies irregularly as a function of frequency; and (4) all of the SFOAE fine-structure features change noticeably with stimulus level. The quasi-periodic peaks/troughs in SFOAE level versus frequency (Fig. 2, left column) should not be equated to quasi-periodic peaks/troughs seen in a mixture of SFOAE and stimulus [Fig. 1(A)]. An SFOAE itself (after removing the stimulus) still exhibits a quasi-periodicity. The mean level (ML) of SFOAE changed from −7.2 dB SPL at stimulus level of 27 dB SPL to 11.6 dB SPL at stimulus level of 57 dB SPL. The number of peaks (NP) of SFOAE in the 550–1450 Hz range decreased from 21 peaks at 27 dB SPL to six peaks at 57 dB SPL. The frequency spacing between peaks, Δf, increased from 42 to 121 Hz and the number of cycles of phase change (NC) decreased from 8.0 to 6.0 cycles over the same range of stimulus levels.

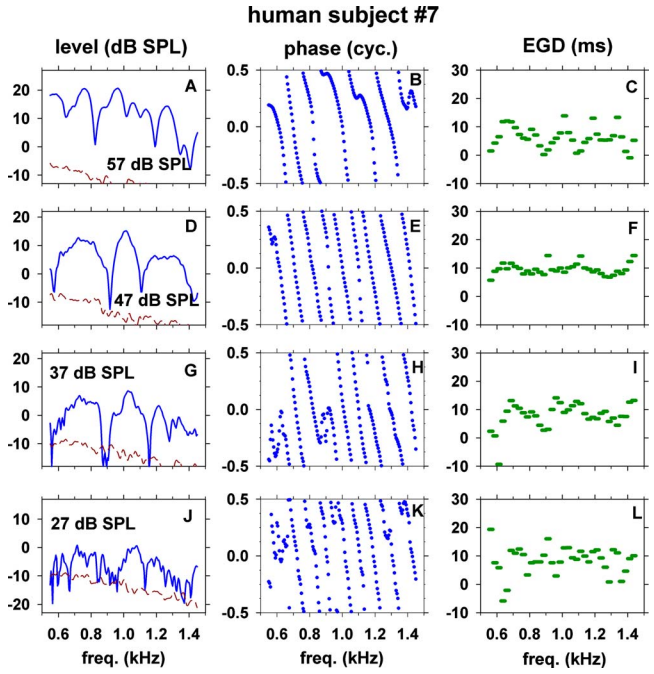

FIG. 2. (Color online) Level, phase, and 25-Hz-wide energy-weighted group delay (EGD) of SFOAE in one subject (No. 7) versus frequency at several stimulus levels (27–57 dB SPL). Dashed lines in the left panels show noise floor.

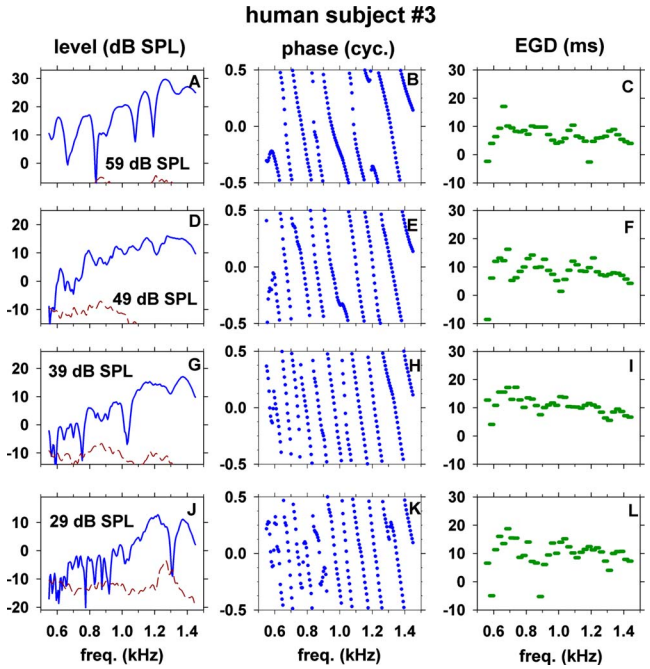

FIG. 3. (Color online) Level, phase, and 25-Hz-wide EGD of SFOAE in another subject (No. 3) versus frequency at several stimulus levels (29–59 dB SPL).

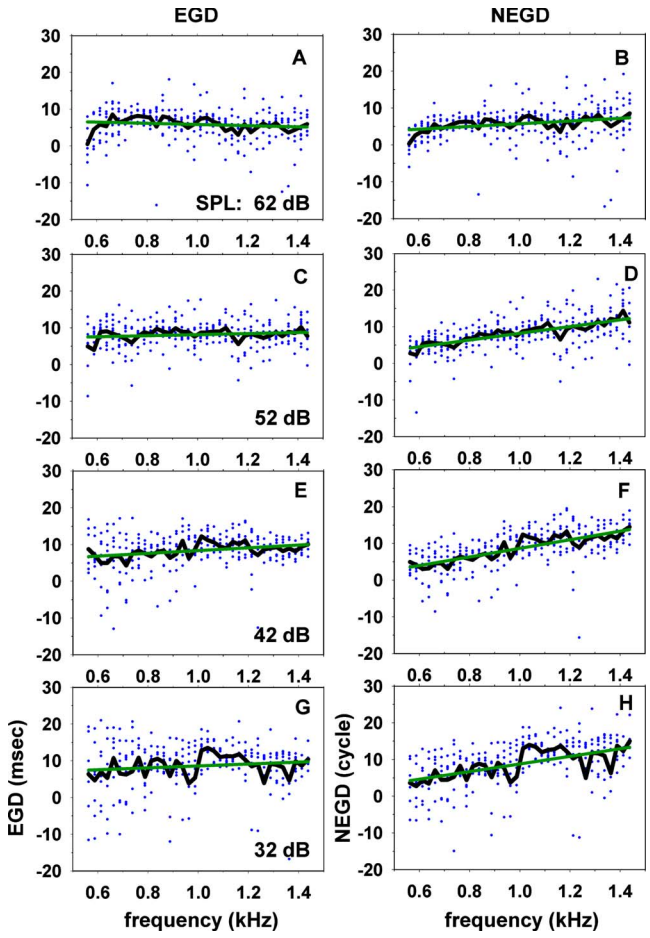

FIG. 4. (Color online) Energy-weighted group delays (EGDs) and normalized EGDs (NEGDs) of all subjects at several stimulus levels (32–62 dB SPL). Individual dots represent 25-Hz-wide EGDs or NEGDs of all subjects. At every 25 Hz band, individual EGDs or NEGDs were averaged and shown as a jagged line in each panel. A straight line is a linear regression line for the average values for various frequencies.

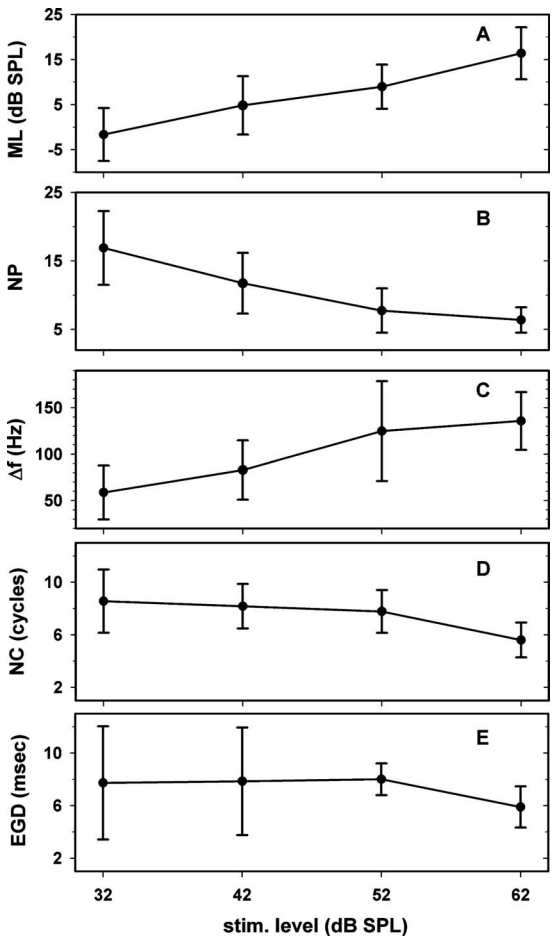

FIG. 5. Means ± standard deviations of five response features of SFOAEs among eight human subjects versus stimulus level: mean level (ML) of SFOAE, number of peaks (NP), frequency spacing (Δf), number of cycles of phase change (NC), and energy-weighted group delays (EGDs) in ms.

Results from another subject (No. 3) are shown in Fig. 3 for stimulus levels of 29–59 dB SPL to illustrate an intersubject variability. Although there are quantitative differences between the two subjects, the results from the two subjects are qualitatively similar; e.g., (1) there are many peaks/troughs of SFOAE level, (2) there are many cycles of phase change, (3) the 25-Hz-wide EGD varies irregularly as a function of frequency; and (4) NP, Δf, and NC change with stimulus level. ML changed from −0.5 dB SPL at stimulus level of 29 dB SPL to 17.5 dB SPL at stimulus level of 59 dB SPL. NP decreased from 16 to 7 peaks, Δf increased from 54 to 133 Hz and NC decreased from 9.2 to 6.6 cycles over the range of 29–59 dB SPL stimulus level.

Major troughs of SFOAE level tended to have concomitant rapid changes in phase slope and EGD. For example, there were major troughs at ~820, 1190, and 1410 Hz in Fig. 2(A) (57 dB SPL) and at ~910 and 1110 Hz in Fig. 2(D) (47 dB SPL). At such frequencies, the phase slopes abruptly changed [Figs. 2(B) and 2(E)] and the EGD values deviated from the neighboring values [Figs. 2(C) and 2(F)]. The phase slope became either steeper, shallower, or inverted with the EGD becoming longer, shorter, or negative. Analogous examples of concomitant microstructures of level, phase, and EGD of SFOAEs were also observed in another subject, e.g., troughs at ~1080 and 1200 Hz [Fig. 3(A)] were associated with rapid or irregular changes of phase slope [Fig. 3(B)] and EGD [Fig. 3(C)].

The 25-Hz-wide EGDs and normalized EGDs (NEGDs) of all eight subjects are plotted versus frequency as scattered dots in Fig. 4. The jagged and straight lines represent the average values and linear regression lines of the average values, respectively. There was a large variability in EGD and NEGD across subjects and across frequency. However, the linear regressions showed that EGDs tended to be almost constant and NEGDs tended to increase with increasing frequency across the 550–1450 Hz range. The value of EGD tended to decrease with increasing stimulus level. For example, EGD near 1 kHz tended to be ~9 ms at 32 dB SPL and ~6 ms at 62 dB SPL; the corresponding values of NEGD were 9 at 32 dB SPL and 6 at 62 dB SPL.

We determined ML, NP, Δf, NC and EGD for all subjects. Means and standard deviations of each of these measures across the subjects are shown at four stimulus levels in Fig. 5. For this figure, EGDs were calculated over the full 900-Hz-wide range NP, NC, and EGD decreased whereas ML and Δf increased with increasing stimulus level.

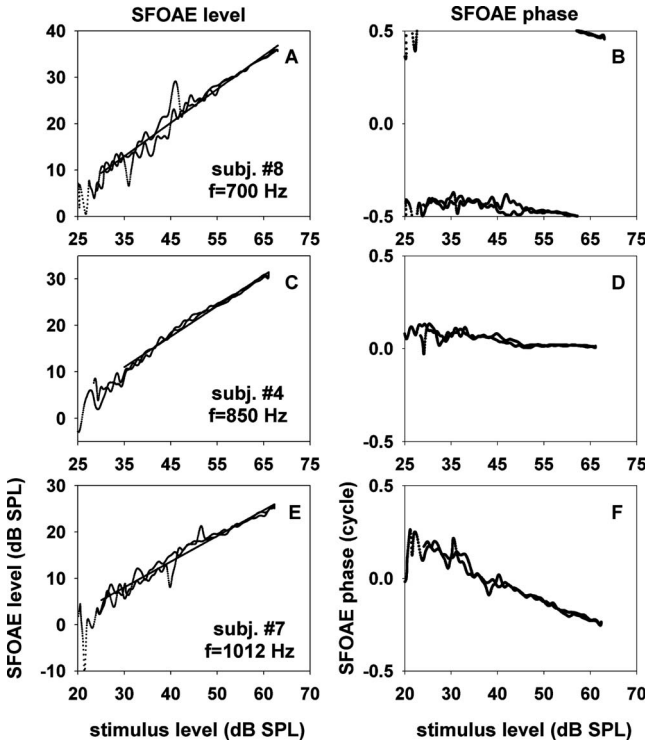

FIG. 6. SFOAE level and phase versus stimulus level for "peak stimulus frequencies." The latter were defined to be stimulus frequencies corresponding to peaks of SFOAE level versus frequency at 52 dB SPL. The three rows correspond to data from three different subjects; the subject identification numbers and the selected stimulus frequencies are shown in the insets. The input-output functions of SFOAE level were fitted with straight lines. The slopes of the fitting lines were 0.72, 0.66, and 0.55 dB/dB for panels A, C, and E, respectively.

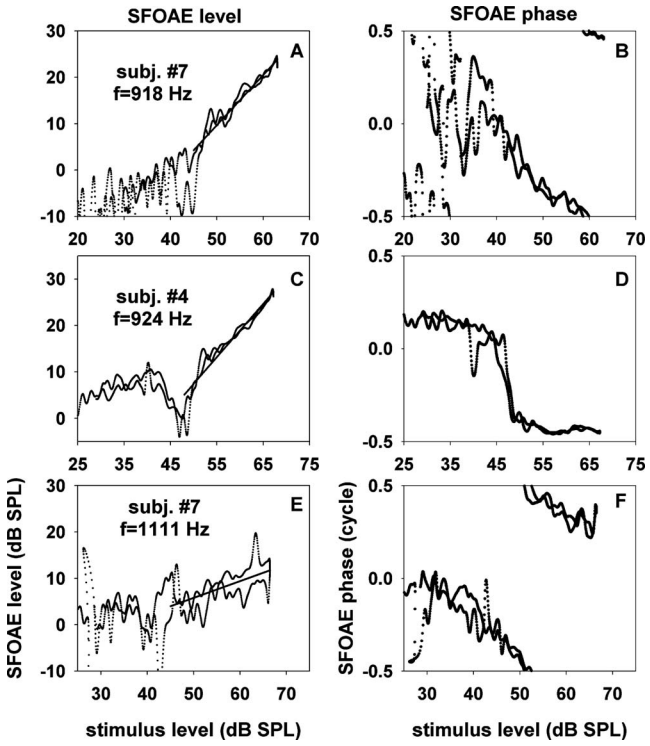

FIG. 7. SFOAE level and phase versus stimulus level for "trough stimulus frequencies." The latter were defined to be stimulus frequencies corresponding to troughs of SFOAE level versus frequency at 52 dB SPL. The three rows correspond to data from three different cases; the subject identification numbers and the selected stimulus frequencies are shown in the insets. The portions of the input-output functions of SFOAE level, where slopes could be ascertained, were fitted with straight lines. The slopes of the fitting lines were 1.08, 1.15, and 0.36 dB/dB for panels A, C, and E, respectively.

B. Level-sweeping experiment

We determined dependence of SFOAE level and phase upon stimulus level by using the stimulus level-sweeping method described in Sec. II H. For these measurements, we selected the probe frequency corresponding to a peak or a trough (in a graph like Figs. 2 and 3). Results obtained with a peak frequency in three subjects are shown in Fig. 6. The input-output functions in log-log plots were approximately straight lines. The data of Fig. 6 were fit with slopes ranging from 0.55 to 0.72 dB/dB. The phase of SFOAE remained nearly independent of stimulus level or became lagging as the stimulus level increased. The amount of phase change was small (<0.14 cycle) in two (panels B and D) of the three cases and larger (0.47 cycle) in the third case (panel F). Slope and phase change obtained with a peak frequency in each subject are described in Table III. The input-output slope ranged 0.52–0.72 whereas the amount of phase change ranged −0.13 to −0.47; a negative phase change corresponds to a phase lag.

Analogously, we determined dependence of SFOAE level and phase upon stimulus level for trough frequencies as shown in Fig. 7. These data illustrate that SFOAE versus stimulus level can be complex and variable if the probe frequency falls in a trough of SFOAE level versus frequency. The example of panel C is a clear illustration of a nonmonotonic input-output level function together with a rapid phase change of about a half cycle around the level notch. The present level-sweep method is particularly useful in characterizing such complex input-output functions because a high resolution of stimulus level is necessary to determine the nonmonotonic nature of emission level and a rapid phase change restricted to a small region of stimulus level.

In the left panels of Fig. 7, partial regions were selected where slopes could be measured. These slopes are summarized in Table IV. Two entries for a particular subject correspond to results obtained with two trough frequencies. The input-output slopes for trough frequencies ranged from 0.36 to 1.83. The range of slopes for trough frequencies was wider

TABLE III. Slopes of input-output functions of SFOAE level and changes of SFOAE phase with stimulus level at frequencies corresponding to SFOAE-level peaks.

Subject ID No.	2	3	4	5	7	8
Slope (dB/dB)	0.52	0.66	0.66	0.55	0.55	0.72
Δ phase (cycle)	−0.25	−0.26	−0.13	−0.47	−0.45	−0.14
Frequency (Hz)	820	961	850	1075	1012	700

TABLE IV. Slopes of input-output functions of SFOAE level at frequencies corresponding to SFOAE-level troughs in regions where slopes could be defined. Multiple entries within a subject represent multiple trough frequencies. There was no correlation between slope and frequency.

Subject ID No.	2	3	4	5	6	7	8
Slope (dB/dB)	0.50	0.37	0.87	0.61	0.48	0.36	0.75
Frequency (Hz)	1320	896	1121	1420	1200	1111	1450
Slope (dB/dB)	NA	1.83	1.53	0.75	0.75	1.08	0.78
Frequency (Hz)	NA	1014	1193	1295	1396	918	770

than that for peak frequencies. Measurements of phase changes in this case were omitted because the starting or ending points of the phases were not clear in most cases.

The facts that SFOAE level can change nonmonotonically with stimulus level and that the peak frequencies shift with stimulus level are illustrated with results from one subject in Fig. 8. It describes SFOAE level over a small range of frequencies (1000–1250 Hz) around a peak and the neighboring troughs for various stimulus levels. At 1160 Hz, SFOAE level was a nonmonotonic function of stimulus level similar to Fig. 7(C). The peak of SFOAE level was centered at 1140 Hz at stimulus level of 22 dB SPL but it gradually shifted toward lower frequencies with increasing stimulus level. The peak frequency decreased to 1065 Hz at 62 dB SPL.

IV. MODEL DEFINITION AND METHODS

A. Basic concept

The present model is intended to represent the human cochlea with a length of 35 mm. To simulate SFOAEs one needs to calculate the forward and backward waves in the cochlea by solving the wave equation. We adopted the one-dimensional transmission line model of the cochlea as described by Zweig *et al.* (1976). The nonuniform transmission line model incorporates a second-order differential equation for the wave propagation and reflection as

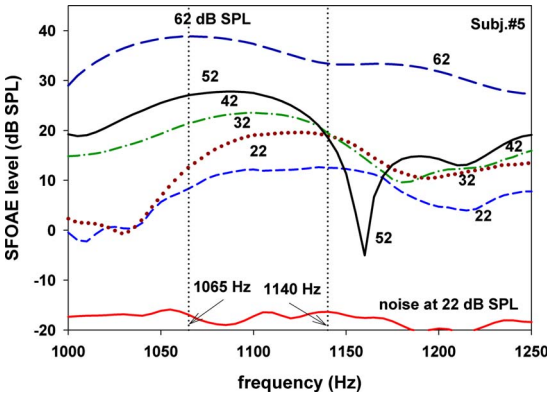

FIG. 8. (Color online) An example illustrating that a peak of SFOAE level shifted as a function of stimulus level. As the stimulus level increased, the position of the peak shifted to a lower frequency. The data also illustrate the fact that SFOAE level for a frequency near a trough (1160 Hz) can be a nonmonotonic function of stimulus level. The lowest curve shows noise floor at 22 dB SPL.

$$\frac{d^2P}{dx^2} - \frac{d\ln Z_s}{dx}\frac{dP}{dx} - Y_b Z_s P = 0, \tag{7}$$

where P is pressure difference between scalae, Z_s scala impedance per centimeter, Y_b cochlear-partition admittance per unit length, and x distance from the stapes. The cochlear-partition admittance and scala impedance were selected to maintain an approximate shift invariance. In other words, the excitation pattern shifts with frequency along the cochlea without much changing its shape. The model was made *active* by having Y_b include a region of negative damping (Neely and Kim, 1983, 1986, 2008).

$$Y_b(s) = \frac{7.186 \times 10^{-2} \exp(-1.51x)}{Z_b(s)}, \tag{8}$$

$$Z_b(s) = Z_1(s) + g \times \frac{1.666 \times Z_2(s) \cdot Z_3(s)}{Z_2(s) + Z_3(s)}, \tag{9}$$

where

$$Z_1 = sM_1 + R_1 + K_1/s, \tag{10}$$

$$Z_2 = sM_2 + R_2 + K_2/s, \tag{11}$$

$$Z_3 = R_3. \tag{12}$$

$$K_1 = 1.291 \times 10^8 \exp(-3.01x),$$
$$R_1 = 1.797 \times 10^2 \exp(-1.51x), \quad M_1 = 0.002. \tag{13}$$

$$K_2 = 6.455 \times 10^1 \exp(-3.01x),$$
$$R_2 = 3.595 \times 10^{-1} \exp(-1.51x), \quad M_2 = 6.0 \times 10^{-9}. \tag{14}$$

$$R_3 = -3.593 \times 10^{-1} \exp(-1.51x). \tag{15}$$

In these equations $s = i2\pi f$ is the Laplace-transform variable, while K, R and M represent the stiffness, damping and mass, respectively. Z_1 represents the cochlear-partition impedance when the cochlea is in a passive mode, and Z_2 and Z_3 create a frequency-dependent negative-damping region. Negative damping provided cochlear amplification and a proper shape of the cochlear excitation pattern (Neely and Kim, 1983, 1986, 2008). The parameter g in Eq. (9) determined the magnitude of negative damping and the amount of cochlear amplification. When g was zero, the cochlea was in a passive mode and exhibited no amplification. The model

was piecewise linear and represented the cochlear nonlinear behavior by increasing g (producing greater amplification) with decreasing stimulus level.

The scala impedance Z_s was chosen to have a decreasing cross-sectional area to compensate for the decreasing stiffness in the cochlear-partition impedance as

$$Z_s(s) = \rho s/A_s, \tag{16}$$

$$A_s = 3.592 \times 10^{-3} \exp(-1.51x). \tag{17}$$

In this equation, $\rho=1$ represents the fluid density. These parameter values were selected to keep the characteristic impedance of the transmission line $Z_c=\sqrt{Z_s/Y_b}$ as uniform as possible to minimize reflections.

The pressure difference P has both the forward (P_f) and backward (P_r) wave components, which may be decomposed as

$$P_f = \frac{1}{2}(P - P'/\beta), \tag{18}$$

$$P_r = \frac{1}{2}(P + P'/\beta). \tag{19}$$

where $P' \equiv dP/dx$ is the x derivative (or gradient) of P, and $\beta=\sqrt{Z_sY_b}$ is the propagation function. This decomposition formula was originally derived for a uniform transmission line (e.g., Durney and Johnson, 1969), and is exact only when the characteristic impedance is constant along the cochlea. We need to decompose the forward and backward waves only at the two ends of the cochlea, i.e., the stapes and helicotrema, for calculation of the reflectance (see below) and boundary conditions. The characteristic impedance is almost constant in these regions. Therefore, Eqs. (18) and (19) are applicable to the present model.

Cochlear reflectance, $\Re$, is defined as the ratio of the reverse-wave pressure to the forward-wave pressure wave at the stapes as

$$\Re = P_r/P_f. \tag{20}$$

If we assume that the effect of the middle ear is an amplitude scaling (see Sec. IV B below), then SFOAE can be modeled as the product of the cochlear reflectance, the round-trip middle ear gain, and the incident pressure at the eardrum (i.e., the stimulus) as

$$P_{\mathrm{SFOAE}} = \Re \cdot G_m \cdot P_S, \tag{21}$$

where P_{SFOAE}, G_m and P_S denote the pressure of SFOAE, round-trip middle ear gain, and the pressure of stimulus in the ear canal, respectively

We first solved the transmission line equation (7) numerically for pressure P along the length of the cochlea. The cochlear length $L=35$ mm was represented by $N=3501$ points (including both end points), and the differential equation was converted into difference equations by the finite-difference method. Since we are interested in the reflection coefficient only, the boundary condition at the stapes side was set as $P=1$. At the helicotrema there should be no backward wave, which results in $P=-P'/\beta$ as the helicotrema boundary condition. The resulting matrix equation was solved numerically for the pressure P, and the forward and backward pressures were calculated at the stapes.

B. Round-trip middle ear gain

Puria (2003) measured forward and reverse middle-ear pressure gain. These pressure gains varied slowly with frequency compared with SFOAE fine structures. In the current study, we are interested in the frequency range from 550 to 1450 Hz. In that range, the round-trip amplitude gain varied slowly between about −6 and −27 dB, and the phase changed between about 0.25 cycle and −0.4 cycle. From the data of Puria (2003), we determined that the average middle-ear round-trip amplitude gain over 500–1500 Hz was −17 dB. The phase part of the middle-ear round-trip function was negligible compared to the total phase change observed in SFOAE (i.e., NC). Therefore, we approximated the middle-ear round-trip function, G_m, with −17 dB and ignored the phase change.

C. Cochlear irregularity

Previous theoretical studies suggest that SFOAEs are generated by distributed irregularity in the cochlear-partition impedance (Zweig and Shera, 1995). It is not known which component of the impedance (i.e., stiffness, damping or mass) is most important for generation of SFOAE. Although we found that fine structures of the model cochlear reflectance could be generated with irregularity in only one of the three impedance components, irregularity in the overall impedance produced the widest range of model behavior. Therefore, we chose to apply irregularity to the overall impedance of the cochlear partition.

Irregularity in the cochlear-partition impedance was introduced by using:

$$\hat{Z}_1(x) = Z_1(x)[1 + I_r(x)], \tag{22}$$

$$I_r(x) = \alpha \cdot u_1(x)\exp[i \cdot 2\pi \cdot u_2(x)], \tag{23}$$

where $\hat{Z}_1(x)$, and $Z_1(x)$ are rough and smooth impedances, respectively, of the cochlear partition as functions of x. The relative irregularity, $I_r(x)$, is a complex quantity having a random magnitude between 0 and α ($\alpha<1$) and a random phase between 0 and 1 cycle; $u_1(x)$ and $u_2(x)$ are uniformly distributed random numbers ranging from 0 to 1. In the initial form of the model, the irregularities at different positions along the cochlea were independent of each other.

We modified the above concept of independently distributed irregularity along the cochlear distance by introducing a novel hypothesis that the spatial-frequency content of the distributed irregularity of the cochlear-partition impedance is low-pass filtered by the cochlear-amplifier mechanism and that both the amount of cochlear amplification and the spatial filter cutoff frequency change monotonically with stimulus level. Thus, $\hat{Z}_1$ was represented as:

$$\hat{Z}_1 = Z_1[1 + \hat{I}_r(x)], \tag{24}$$

$$\hat{I}_r(x) = F^{-1}[F\{I_r(x)\} \cdot L(f_s)], \tag{25}$$

$$L(f_s) = \left(1 + \left|\frac{f_s}{f_{s_0}}\right|^n\right)^{-1}, \tag{26}$$

where, $F\{\cdot\}$, $F^{-1}\{\cdot\}$, f_s, f_{s_0}, and n represent spatial Fourier transform, inverse spatial Fourier transform, spatial frequency, spatial low-pass filter cutoff frequency, and the order of the filter, respectively. The spatially filtered irregularity $\hat{I}_r(x)$ can be also expressed as

$$\hat{I}_r(x) = \alpha \cdot u_3(x)\exp[i \cdot 2\pi \cdot u_4(x)], \tag{27}$$

where $u_3(x)$ and $u_4(x)$ are random numbers which have low-pass filtered spatial profiles.

D. Fit-error function

To quantify the difference between human SFOAE data (target) and the model results, we defined a fit-error function as:

$$E_{\text{fit}}(52 \text{ dB SPL}) = 0.2 \times E_{\text{NP}} + 0.2 \times E_{\text{NC}} + 0.2 \times E_{\text{EGD}} + 0.2 \times E_{\sigma\text{EGD}} \tag{28}$$

$$E_{\text{fit}}(\text{other}) = 0.2 \times E_{\text{ML}} + 0.2 \times E_{\text{NP}} + 0.2 \times E_{\text{NC}} + 0.2 \times E_{\text{EGD}} + 0.2 \times E_{\sigma\text{EGD}} \tag{29}$$

$$E_X = 1 - \exp[-10 \times \{(V_X - T_X)/T_X\}^2] \tag{30}$$

$$E_{\text{ML}} = 1 - \exp[-0.01 \times (V_{\text{ML}} - T_{\text{ML}})^2], \tag{31}$$

where E_X is either E_{NP}, E_{NC}, E_{EGD} or $E_{\sigma\text{EGD}}$, and V_X is either V_{NP}, V_{NC}, V_{EGD} or $V_{\sigma\text{EGD}}$, which represent the model values of NP, NC, EGD and STD of 25-Hz-wide EGDs, respectively; T_X represents the corresponding target value, e.g., T_{NP} corresponds to the target NP. V_{ML} is the model value of ML and T_{ML} is the target ML. The target ML at stimulus levels other than 52 dB SPL was calculated from the model ML value at 52 dB SPL with a 0.58 dB/dB slope. The 0.58 dB/dB slope corresponds to the slope of the human SFOAE ML versus stimulus level. When the model reflectance was greater than 0 dB at any frequency, the model result was rejected (the fit-error function was assigned a value of infinity).

V. MODEL RESULTS

A. Frequency-distance map of the cochlea

The frequency-distance map of the model is compared with the Greenwood (1990) function of the human cochlear map (Fig. 9). The two maps are in close agreement except for a region near the apical end. This study is focused on the frequency range of 550–1450 Hz where the two maps were in agreement. This agreement supports the model as a representation of the human cochlea.

B. Model SFOAE fine structures

We adjusted model parameters attempting to reproduce mean values of response features (ML, NP, NC, EGD, and σ_{EGD}) of eight subjects in the frequency range 550–1450 Hz. The above measures, except for σ_{EGD}, were plotted in Fig. 5. We generated 11 versions of the impedance irregularity spatial profiles using 11 random seeds. We obtained the mean values of the model response features among the 11 random-seed cases for each of the four stimulus levels. The four model parameters (g, α, f_{s_0}, and n) were adjusted to find a best fit for the human SFOAE data for four stimulus levels as follows. Initially we adjusted g from 0.70 to 1.00 in steps of 0.05, α from 0.02 to 0.78 in steps of 0.04, f_{s_0} from 0.50 to 1.50 cycles/mm in steps of 0.1 cycles/mm, and n from 5 to 60 in steps of 5.

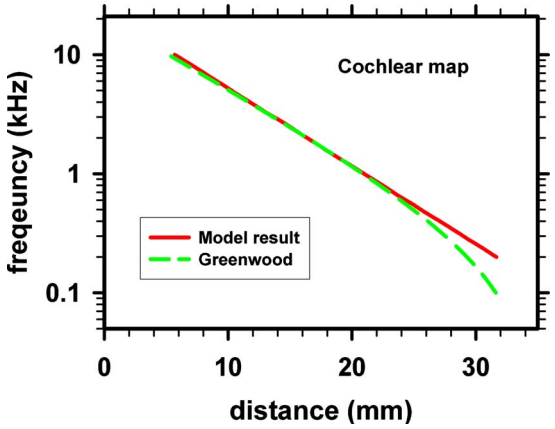

FIG. 9. (Color online) Cochlear frequency-distance map of the model (at 32 dB SPL) compared with the Greenwood (1990) function for the human cochlea.

During this adjustment, we first simulated the 52 dB SPL data. We treated the 52 dB data as the reference (or anchor) among the four stimulus levels. The fit-error function for 52 dB data, Eq. (28), included error components associated with four response features (NP, NC, EGD and σ_{EGD}) but excluded an error component associated with ML. We chose this approach because the model exhibited a difficulty of fitting all features including ML. Once we obtained the optimal model parameters for a best fit of the 52 dB data based on Eq. (28), we then attempted to simulate the optimal model behavior for other stimulus levels using all features including ML, i.e., using Eq. (29). This approach was intended to reproduce an optimal slope of SFOAE-level versus stimulus level. Accordingly, we derived target values of ML for 32, 42 and 62 dB SPL by combining the model ML at 52 dB and a slope of 0.58 dB/dB. The latter slope was obtained as the slope of a linear regression line fit for the human data of ML versus stimulus level [Fig. 5(A)].

During the search for optimal model parameters (g, α, f_{s_0}, and n), we imposed the constraint that each of the model parameters should vary monotonically and smoothly with stimulus level. A smooth change meant that the slope of each parameter versus stimulus level should also vary monotonically with stimulus level

We defined the total fit error to be the sum of four fit errors for the four stimulus levels. After finding the initial candidate optimal parameter set that minimized the total fit error based on the coarse steps of the parameter values, we performed a further search with fine steps of each parameter

TABLE V. Means ($\bar{m}$) and standard deviations (σ) of six response features of model SFOAE results obtained with 11 random seeds of the cochlear-partition irregularity under the condition of the optimal values of the model parameters. The response features were: mean level (ML) of SFOAE in dB SPL; number of peaks (NP); frequency spacing (Δf) between SFOAE peaks in Hz; number of cycles (NC) of SFOAE phase change; energy-weighted group delay (EGD) in ms; and standard deviation of EGD (σ_{EGD}) in ms.

Stimulus level (dB SPL)		Model result					
		ML	NP	Δf	NC	EGD	σ_{EGD}
32	$\bar{m}$	−13.9	15.0	56.6	7.2	9.0	6.8
	σ	1.5	1.2	4.3	2.3	2.7	1.8
42	$\bar{m}$	7.0	11.1	77.8	7.7	8.1	5.4
	σ	1.1	1.4	12.2	1.3	1.0	1.3
52	$\bar{m}$	1.5	7.1	111.7	7.1	7.9	3.8
	σ	1.6	1.0	24.8	0.8	1.5	0.7
62	$\bar{m}$	4.0	5.5	151.8	5.3	6.1	3.8
	σ	1.7	0.9	20.2	1.3	1.1	0.8

around the initial candidate optimal parameter values. The fine step size was 0.01 for g, 0.02 for α, 0.5 cycles/mm for f_{s_0}, and 1 for n. The set of model parameters that yielded the smallest average total fit error across the 11 random-seed cases representing the response features ML, NP, NC, EGD and σ_{EGD}, was chosen as *the optimal parameter set*. The model response features obtained with the optimal parameter set are summarized in Table V, and the optimal parameters of the model and the fit errors are shown in Table VI.

Figures 10 and 11 show simulated SFOAE level, phase, and 25-Hz-wide EGD versus frequency obtained with the optimal parameter set of the model and with two particular random seeds Nos. 6 and 1, respectively. The model exhibited SFOAE characteristics similar to those of the human SFOAEs shown in Figs. 2 and 3. Thus, the model successfully reproduced salient features of the human SFOAEs at stimulus levels of 32–62 dB SPL.

Analogous to the human SFOAEs, major troughs of SFOAE level of the model also tended to have concomitant rapid changes in phase slope and EGD values. For example, the SFOAE level in Fig. 10(G) exhibited major troughs at ~720 and 980 Hz. Around these frequencies, there were concomitant rapid changes in the phase slopes [Fig. 10(H)] and EGDs [Fig. 10(I)]. Analogous examples of troughs [Fig. 11(A)] and rapid changes of phase slopes [Fig. 11(B)] and EGDs [Fig. 11(C)] are also visible around 810 and 1210 Hz in results obtained with a different random seed.

The confidence intervals of model parameters were determined as follows. Within the confidence interval of a parameter, the fit error did not exceed twice the optimal fit error among the 11 random-seed cases. That is, the model generated sufficiently similar features of SFOAEs when the model parameters were within the confidence intervals. The confidence intervals are shown in Table VII. For example, for 52 dB SPL, optimal fit-error E_{fit} was 0.040 among 11 cases (Table VI). If we vary g in a range of 0.87–0.91 while fixing the other three parameters, then the fit error remained smaller than $2\times E_{\mathrm{fit}}$, i.e., 0.080. In some cases, fit-error values were

TABLE VI. Optimal values of the model parameters that produced minimal fit-errors (E_{fit}). E_{fit}, dimensionless, is defined in Eqs. (28) and (29). The model parameters were g (dimensionless amplification parameter), α (dimensionless scale factor for the cochlear-partition impedance irregularity), f_{s_0} (cutoff frequency, in cycles/mm, of a low-pass spatial-frequency filter acting on the irregularity), and n (dimensionless parameter for the slope of the low-pass spatial-frequency filter).

Stimulus level (dB SPL)	g	α	f_{s_0}	n	E_{fit}
32	0.93	0.42	0.85	9	0.13
42	0.91	0.22	1.20	13	0.073
52	0.88	0.10	1.40	24	0.040
62	0.73	0.08	1.40	50	0.053

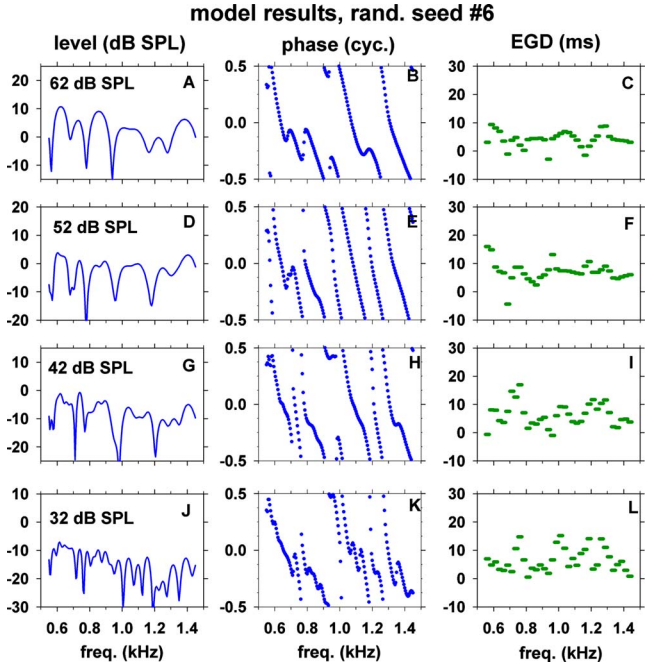

FIG. 10. (Color online) SFOAE fine structures of the model obtained with random seed No. 6 for the cochlear-partition impedance irregularity. The three columns correspond to the model SFOAE level, phase and energy-weighted group delay (EGD) versus frequency. The four rows correspond to four stimulus levels indicated in the insets. The model parameters were set to the optimal values described in Table VI.

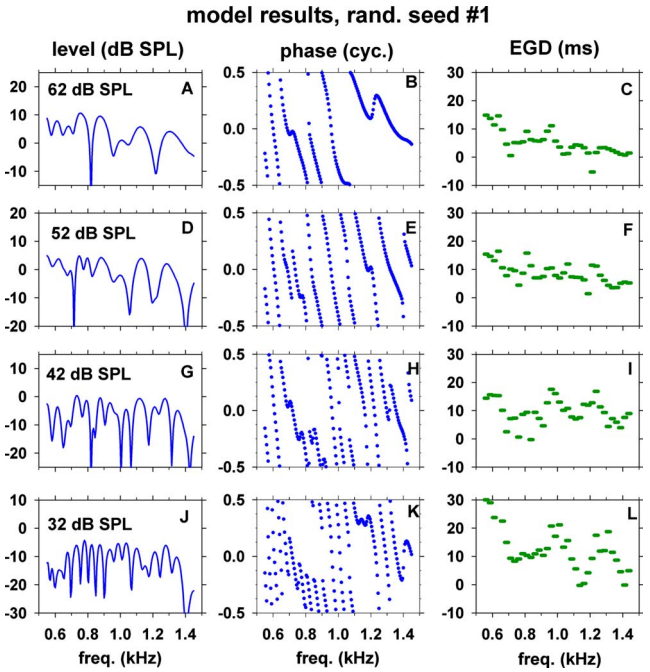

FIG. 11. (Color online) SFOAE fine structures of the model. All conditions of the model were the same as those of Fig. 10 except for the use of random seed No. 1 for the cochlear-partition impedance irregularity.

quite sensitive to the parameter change so that we introduced very small value ε which is smaller than 0.025 for f_{s_0} and 0.5 for n to represent the confidence interval. However, n value for 62 dB SPL in Table VII could be increased indefinitely because there was little effect on the low-pass filter when $n > 16$. Generally, the confidence intervals of the four model parameters shown in Table VII were narrow. That is, the model parameters for different stimulus levels were distinct with little overlaps. This indicates that the model parameters were well constrained by the human SFOAE features.

Changes of the model response features as results of changes in the model parameters are described in Table VIII using the 52 dB SPL stimulus condition as an example. Table VIII includes the optimal parameter set ($g=0.88$, $\alpha=0.10$, $f_{s_0}=1.40$ cycles/mm and $n=24$) together with other points of the parameter space corresponding to the extremes of the confidence interval of each parameter. Values of the model response features for the above conditions are shown. Within the confidence intervals, the relative magnitudes of changes in ML, NP, Δf, NC, EGD and $Q_{3\ \mathrm{dB}}$ were less than 2.2 dB, 8.5%, 9.7%, 8.5%, 11.4% and 4.2%, respectively Within the intervals, increases of g, α, or f_{s_0} led to increases of ML, NP, NC and EGD. A decrease of n led to a similar effect. Regarding $Q_{3\ \mathrm{dB}}$, only g among the four parameters affected $Q_{3\ \mathrm{dB}}$ such that an increase of g led to an increase of $Q_{3\ \mathrm{dB}}$.

C. Spatial profiles of irregularity

Spatial profiles of the amplitude (left column) and phase (right column) of the impedance irregularity under the condition of the optimal model parameters are described in Fig. 12. At 32 dB SPL, where the spatial low-pass cutoff frequency was the lowest, the spatial profile of amplitude and phase of the irregularity varied most slowly over cochlear distance among the four cases corresponding to four stimulus levels. With increasing stimulus level, the spatial low-pass cutoff gradually increased leading to increasingly more rapid changes of irregularity over distance.

D. Estimated human cochlear excitation patterns and transfer functions

Using the optimal model parameters described above, we determined cochlear excitation patterns and transfer functions of the model cochlear partition. The excitation patterns for 1 kHz stimulus frequency, corresponding to the ratio of cochlear-partition velocity to stapes velocity as a function of cochlear distance for a fixed frequency, are shown in Fig. 13, panels A and B. With decreasing stimulus level, the excitation pattern became sharper and the traveling-wave peak became higher moving slightly apically. The total phase lag of the excitation pattern was more than 15 cycles over the full cochlear distance. At the highest stimulus level, the phase-versus-distance slope became shallower.

The cochlear-partition transfer functions, corresponding to the ratio of cochlear-partition velocity to stapes velocity as a function of stimulus frequency for a fixed cochlear distance (i.e., the 1 kHz place), are shown in Fig. 13, panels C and D. The shapes of the partition responses versus distance (panel C) were quite similar to the partition responses versus stimulus frequency (panel A).

The sharpness of the partition transfer functions were quantified in terms of three types of quality factors and peak-to-shoulder ratio (PSR), also known as the tip-to-tail ratio.

TABLE VII. Confidence intervals of the model parameters g, α, f_{s_0}, and n. The confidence interval of each parameter was defined as one where the average fit error among the 11 random seed cases remained smaller than twice the optimal fit error. The confidence interval was determined by varying only one parameter at a time with the other parameters fixed at the optimal value (described in Table VI). The units of f_{s_0} are cycles/mm and the other three parameters are dimensionless. The symbol, ε, is intended to indicate a small quantity; it was less than the following values: 0.025 for f_{s_0}, and 0.5 for n.

	Stimulus level (dB SPL)			
Parameters	32	42	52	62
g	0.91–0.94	0.90–0.92	0.87–0.91	0.67–0.81
α	0.16–0.64	0.18–0.26	0.08–0.12	0.06–0.16
f_{s_0}	$(0.85-\varepsilon)$–$(0.85+\varepsilon)$	$(1.20-\varepsilon)$–$(1.20+\varepsilon)$	1.40–1.45	$(1.40-\varepsilon)$–$(1.40+\varepsilon)$
n	$(9-\varepsilon)$–$(9+\varepsilon)$	$(13\sim\varepsilon)$–$(13+\varepsilon)$	20–28	16–∞

TABLE VIII. Changes in model response features as results of changes in each model parameter at 52 dB SPL stimulus level. The range of each parameter was the confidence interval of the parameter described in Table VII. See the caption of Table VI for definitions of the model parameters.

		Model response features						
Parameter		ML (dB SPL)	NP	Δf (Hz)	NC (cyc.)	EGD (ms)	σ_{EGD} (ms)	$Q_{3\ dB}$
Optimal parameters		−1.5	7.1	111.7	7.1	7.9	3.8	7.1
g	0.87	−1.8	6.9	115.5	7.0	7.7	3.8	7.0

Quality factors $Q_{3\ dB}$ and $Q_{10\ dB}$ correspond to the center frequency divided by the width of transfer function measured 3 and 10 dB below the peak, respectively. Q_{ERB} correspond to an analogous measure where the width of an equivalent rectangular bandwidth is used. For PSR, the shoulder corresponds to the part of the transfer function at a frequency below the peak where the curves of different stimulus levels converge. The values of these parameters for the model partition transfer functions are indicated in Table IX. $Q_{3\ dB}$ and Q_{ERB} ranged 5.5–8.0, $Q_{10\ dB}$ 3.2–4.3, and PSR 38–60 dB.

E. Decomposition of model SFOAE into long- and short-delay components

To determine the cochlear locations where SFOAEs are generated in the model, we examined the model behavior with the impedance irregularity confined either in a region around the traveling-wave peak or in regions remote from the peak. The traveling-wave peak region was associated with steeper phase-versus-distance slope [Figs. 13(B) and 14(B)]. In terms of wavelength (λ), i.e., the cochlear distance spanned by one cycle of phase change, the peak region has shorter λ than the remote regions [Fig. 14(C)]. We defined the peak region to be a cochlear region with $\lambda < 2.5$ mm, and the remote regions to be the remaining cochlear regions.

Besides the normal impedance irregularity distributed throughout the full cochlear length, we also prepared two other types of impedance irregularity profile: (1) irregularity restricted to the peak region with $\lambda < 2.5$ mm, and (2) irregularity restricted to the remote regions with $\lambda > 2.5$ mm.

The model SFOAEs obtained with three types of irregu-

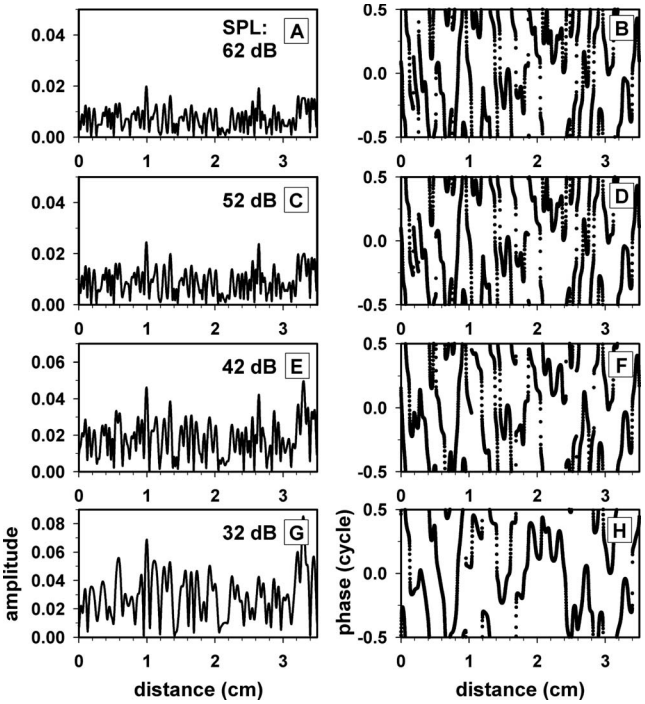

FIG. 12. Spatial profiles of amplitude (left column) and phase (right column) of the model cochlear-partition impedance irregularity. The four rows correspond to four stimulus levels. The model parameters were set to the optimal values described in Table VI.

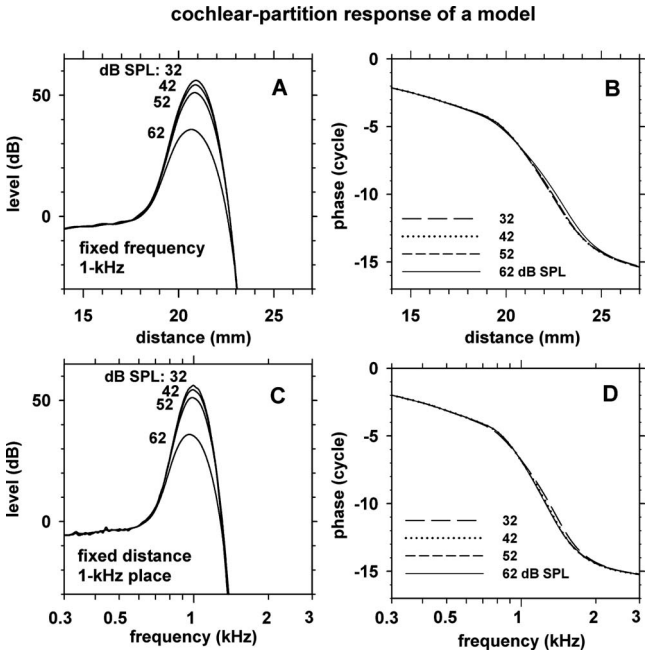

FIG. 13. Cochlear-partition response level and phase versus cochlear distance for 1 kHz stimulus frequency (panels A and B) and versus stimulus frequency for the 1 kHz cochlear place (panels C and D). Four curves in each panel correspond to four stimulus levels (32–62 dB SPL) indicated in the insets. The cochlear-partition response was relative to the stapes input. The model parameters were set to the optimal values described in Table VI.

TABLE IX. Response characteristics of the model cochlear-partition transfer functions at the 1 kHz place at stimulus levels of 32–62 dB SPL (described in Fig. 13). Means and standard deviations (STDs) were calculated for 11 random-seed cases. The results were obtained with the optimal model parameters described in Table VI. $Q_{3\ dB}$ and $Q_{10\ dB}$ are "quality factors" measured at 3 and 10 dB points relative to the peak; Q_{ERB} is a quality factor measured using the equivalent rectangular bandwidth (ERB). The quality factors are dimensionless. PSR stands for peak-to-shoulder ratio, also known as tip-to-tail ratio.

	Stimulus Level (dB SPL)							
	32		42		52		62	
	Mean	STD	Mean	STD	Mean	STD	Mean	STD
$Q_{3\ dB}$	8.0	0.53	7.6	0.30	7.1	0.19	5.8	0.07
Q_{ERB}	7.6	0.58	7.1	0.24	6.6	0.12	5.5	0.06
$Q_{10\ dB}$	4.3	0.24	4.1	0.12	3.9	0.05	3.2	0.02
PSR (dB)	60	1.6	57	0.8	54	0.3	38	0.2

larity profiles at 32 dB SPL are shown in Fig. 15. The three rows correspond to the three types of irregularity profiles: fully present (top), restricted to the peak region (middle), or to the remote regions (bottom). As the spatially restricted irregularity profiles were specifically associated with the 1 kHz traveling-wave peak, the model results of Fig. 15 are shown only for a narrow range of frequencies, 950–1050 Hz, around 1 kHz. The phase slope of the model SFOAE generated by the irregularity in the peak region [Fig. 15(D)] was steep with an EGD of 20.8 ms. The ratio of 20.8 ms to EGD of the 1 kHz place of the cochlea at 32 dB SPL (12.6 ms) is 1.7. This is slightly smaller than 2, expected from a situation where the signal propagates to the traveling-wave peak and back to the ear canal. In contrast, the phase slope of SFOAE generated by the remote regions [Fig. 15(F)] was shallow with an EGD of 4.1 ms, which is much shorter than the EGD of the 1 kHz cochlear place (12.6 ms.).

The results described in Fig. 15 demonstrate that, in the model, (1) the SFOAE consists of a long-delay component generated by irregularity in the traveling-wave peak region and a short-delay component generated by irregularity in the remote regions, (2) the levels of the long- and short-delay components are comparable to each other and they both change slowly with frequency, and (3) the rapidly changing fine structure of SFOAE of the model is a result of quasi-periodic vector cancellations between the long- and short-delay components.

VI. DISCUSSION

A. Main results

The main results of the present study are: (1) introduction of a novel method of efficiently measuring SFOAE level and phase as functions of frequency by a combined use of frequency-swept stimuli and the digital heterodyne analysis; (2) measurement of high-resolution data of SFOAE level, phase, and EGD versus frequency in normally hearing human adult subjects; (3) reproduction of salient features of the human SFOAEs in an active cochlear model; (4) inferences about characteristics of human cochlear-partition motion, and (5) demonstration that, in the model, an SFOAE consists of a long-delay component generated by irregularity in the traveling-wave peak region and a short-delay component generated by irregularity in cochlear regions remote from the peak.

B. Novelty and advantages of the present method of SFOAE measurement

The novelty of the present method lies in an unprecedented efficiency of measuring high-resolution SFOAEs by a combined use of *continuously* sweeping the stimulus frequency and the digital heterodyne analysis. The frequency resolution of the present method depends on the square root of the frequency sweep rate as stated in Methods, Eq. (3). Accordingly, a twofold higher frequency resolution can be

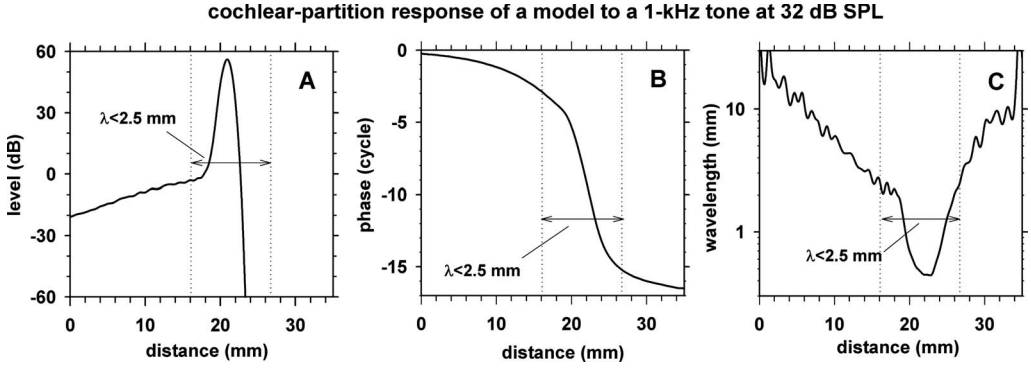

FIG. 14. Cochlear-partition response to a 1 kHz 32 dB SPL stimulus in terms of level (A), phase (B) and wavelength (C) as functions of cochlear distance. The cochlear-partition response was relative to the stapes input. The model parameters were set to the optimal values described in Table VI.

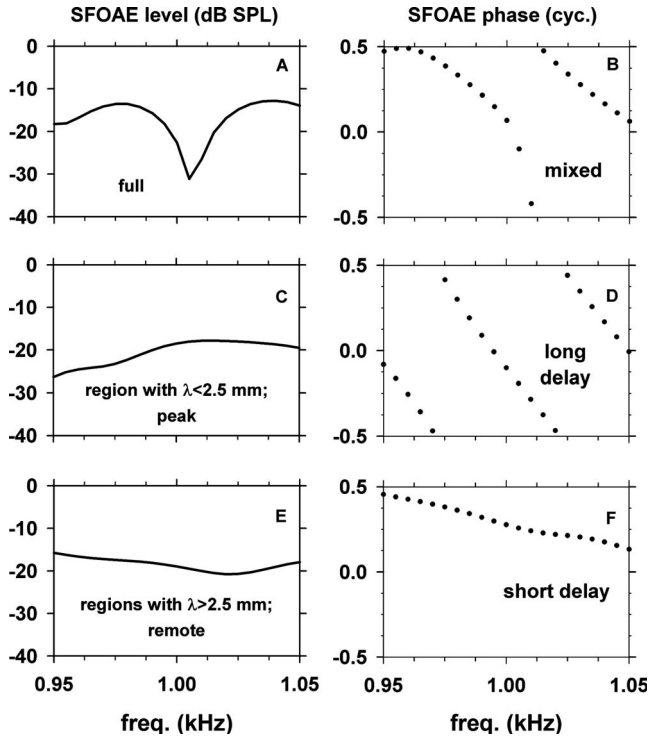

FIG. 15. Level and phase of the model SFOAE at 32 dB SPL versus frequency over a narrow range of frequencies (950–1050 Hz) obtained with three types of spatial profiles of the cochlear-partition impedance irregularity: fully present (*top*), restricted in a region around the traveling-wave peak with $\lambda < 2.5$ mm (*middle*) and in regions remote from the peak with $\lambda > 2.5$ mm (*bottom*).

achieved by decreasing the sweep rate four times. Equivalently, a fourfold faster sweep rate can be achieved if one is willing to decrease frequency resolution by a factor of 2.

In the conventional methods of SFOAE measurement (Shera and Guinan, 1999; Shera and Guinan, 2003; Goodman *et al.*, 2003; Schairer *et al.*, 2006), SFOAE fine structures are measured with many probe frequencies, one frequency at a time. Consequently, the conventional method has a greater overhead, i.e., rise and fall gating times and the times involved for saving the data on a storage device for each individual frequency rendering it inefficient.

An efficient recording method facilitates data collection with less variability and a higher signal-to-noise ratio for a given recording time. Data obtained over long recording times are more susceptible to artifacts arising from unavoidable random movements of the subjects making the data more variable.

C. Future applications of swept stimuli and heterodyne analysis

The present method can be used to obtain SFOAEs over a wider range of frequencies, e.g., 500–8000 Hz (Hill *et al.*, 2008). In such a study, an exponential frequency sweep is more desirable than a linear frequency sweep. A simple variation of the present method will allow one to measure DPOAEs as a continuous function of either primary frequencies (Long *et al.*, 2008) or primary levels. For example, one may sweep f_1, f_2 or f_2/f_1 over a period of time. The heterodyne analysis will then yield DPOAE level and phase (e.g., at $2f_1-f_2$) for various f_2, for example, by extracting DPOAE level and phase at various time points. A similar concept of measuring input-output functions of DPOAE level was introduced by Neely *et al.* (2003).

D. Why is SFOAE group delay far shorter than expected?

Prevailing concepts about SFOAEs are that: (1) SFOAEs are generated predominantly in a cochlear region around the traveling-wave peak, and (2) the SFOAE group delay at a frequency are approximately twice the group delay of the cochlear partition at the traveling-wave peak (Zweig and Shera, 1995). Siegel *et al.* (2005) observed that the group delays of SFOAEs in chinchillas were similar to (for frequencies >4 kHz), or shorter than (for frequencies <4 kHz) the group delays of the cochlear partition at the characteristic frequencies (the partition group delays were estimated from responses of cochlear nerve fibers in chinchillas). This observation is *inconsistent* with the prevailing concept indicated above. Siegel *et al.* highlighted this discrepancy as an important issue for the hearing-science field.

Shera *et al.* (2006) suggested that one approach to resolve the discrepancy between the Zweig–Shera model prediction and the Siegel *et al.* observation is to hypothesize that the total SFOAE is a mixture of a reflection-source emission component with a long delay and a nonlinear-distortion-source emission component with a short delay. (A similar suggestion was made by Goodman *et al.*, 2003) After Shera *et al.* separated ("un-mixed") the total SFOAE into short- and long-delay components, they found that the group delays of the long-delay component of SFOAE were closer to the predicted group delays. However, the group delays of the long-delay SFOAE component were still shorter than the predicted group delays for all frequencies with the differences being greater for frequencies <4 kHz. Furthermore, it remains unknown whether the short-delay component of SFOAE indeed represents a distortion-source emission or some other type of reflection-source emission.

The results of the present cochlear model (Fig. 15) provide a novel hypothesis that the short- and long-delay components of SFOAE are both reflection-source emissions but arise from different regions of the cochlea. In the model, the short-delay SFOAE component arises from irregularity located in cochlear regions remote from the traveling-wave peak whereas the long-delay component arises from irregularity in the peak region. Because the model is piecewise linear, there is no nonlinear-distortion-source emission in the model. Future experiments should verify the validity of this hypothesis.

E. Comparison with the coherent reflection model

The coherent reflection model of SFOAE [Zweig and Shera, 1995, Eq. (23), page 2023] states that reflected wavelets of a forward cochlear traveling wave combine in phase (i.e., creates coherent reflection) when $2^*\Delta x = \lambda$, or $\Delta x = \lambda/2$, where λ is the wavelength and Δx is distance between cochlear mechanical irregularities. An equivalent statement

is that reflected wavelets create coherent reflection when the spatial-frequency (f_s) content of the irregularity profile is large at $f_s=2/\lambda$.

In our model, λ at the peak of the traveling-wave envelope is ~0.5 mm for a 1 kHz sinusoidal stimulus at 32 dB SPL [Fig. 14(C)]. Thus, in order to produce coherent reflection at the traveling-wave peak, the spatial-frequency content of the irregularity profile has to be large at $f_s=2/\lambda=2/0.5=4$ cycles/mm.

A region of the cochlear model that includes the traveling-wave peak and nearby regions has shorter wavelengths [$\lambda=0.45-2.5$ mm, Fig. 14(C)] than the basal region further away from the peak [$\lambda=2.5-25$ mm, Fig. 14(C)]. In the peak region with $\lambda=0.45-2.5$ mm, generation of coherent reflection requires that the spatial-frequency content of the irregularity profile has to be large at $f_s=2/\lambda=0.8-4$ cycles/mm.

In contrast, the irregularity profiles in the model were filtered with a steep *low*-pass spatial-frequency filter with a cutoff frequency of 0.85 cycles/mm at 32 dB SPL; this parameter was obtained as a result of an objective fitting procedure. Therefore, the spatial-frequency content of the model irregularity profile was quite small at the 0.8–4 cycles/mm required for generation of coherent reflection in the short-λ peak region. Consequently, the SFOAE originating from the peak region of the model was much lower than expected from the coherent-reflection model which assumes that the spatial-frequency content of the irregularity profile is large at $f_s=2/\lambda$.

Because λ is much longer (2.5–25 mm) in the basal region, the spatial frequency for large irregularity required by coherent reflection is much lower ($f_s=2/\lambda=0.08-0.8$ cycles/mm) in the basal region than in the peak region. The low-pass spatial-frequency filter with a cutoff frequency of 0.85 cycles/mm preserves amplitudes of irregularity at the above required spatial frequencies. Therefore, the irregularity profile in the long-λ basal region of the model was in a more favorable condition for generation of coherent reflection than the irregularity profile in the short-λ peak region.

The above considerations provide an explanation of a surprising behavior of the present cochlear model. That is, in the model, the levels of the short- and long-delay SFOAE components originating from the remote and peak regions, respectively, are comparable to each other, thus creating rapidly changing peaks and troughs of SFOAE level versus frequency.

F. Comparison with previous studies

Changes in SFOAE fine structures with stimulus levels were reported by Goodman *et al.* (2003). Stimulus-level-dependent changes of frequency spacing, observed in the Goodman *et al.* study and the present study, represent a nonlinear behavior. This behavior was simulated by the present model with stimulus-level-dependent changes of the model parameters (g, α, f_{s_0}, and n).

Our observation of an increase of normalized group delay with frequency over 500–1500 Hz is consistent with previous studies (Shera and Guinan, 2003; Schairer *et al.*, 2006). The present observation of a decreasing group delay of SFOAE with increasing stimulus level (Figs. 4 and 5) is consistent with Schairer *et al.*, (2006). Mechanical responses of a basal part of the chinchilla cochlea also exhibited an analogous decrease of group delay with increasing stimulus level (Ruggero *et al.*, 1997).

G. Model assumptions

Although the model results successfully reproduced the six features of the human SFOAE fine structures (e.g., Fig. 5 and Table V), some differences between the model results and the human data were noticeable. One such example is the SFOAE phase versus frequency pattern. The human phase-frequency pattern (Figs. 2 and 3) tended to be more evenly spread out across the 550–1450 Hz range than the model counterpart (Figs. 10 and 11). It is not clear what changes in the model can improve in this regard.

There were other shortcomings of the model. We used a piecewise-linear frequency-domain model of the cochlea. Development of a nonlinear time-domain version of the model will be a desirable future goal. We used a one-dimensional cochlear model even though a cochlear model should ultimately be three dimensional. We believe, however, that important insights were gained by using a simplified one-dimensional model. Exploration of the parameter space of the model was facilitated by the simplified form of the model.

In addition, the boundary condition at the stapes did not include properties of the middle ear. A lossy-impedance boundary condition provided by the middle ear at the stapes should better represent reflection of the backward wave at the stapes (e.g., Shera and Zweig, 1991; Zweig and Shera, 1995; Talmadge *et al.*, 1998, 2000). Since the round-trip reflectance, i.e., the multiplication of reflectance from the cochlear-partition irregularities and the reflectance from the stapes, is small, the effects of multiple reflections may be small for the cases presented in this paper.

H. Is spatial profile of irregularity controlled by the cochlear amplifier?

In the model, the model parameters (g, α, f_{s_0}, and n), co-varied with stimulus level (Table VI). Specifically, as the stimulus level decreased, the model became more active (amplification increased), the base amplitude of the irregularity increased, and the spatial low-pass filter exhibited a lower cutoff and a steeper filter slope. These hypothesized relationships among the model parameters and stimulus level were found as a result of the objective fitting procedure searching for the optimal model parameters that best reproduced the human SFOAE fine structures at various stimulus levels.

A possible implication of the present hypothesis is that the spatial frequency content of the cochlear-partition impedance irregularity profile is controlled by the cochlear amplifier mechanism. When the model becomes more active at a lower stimulus level, the hypothesis implies that the active

mechanism exerts a more prominent longitudinal coupling of the organ of Corti whereby the partition impedance changes more slowly along the cochlear distance.

I. Inferences about the human cochlea

The present human SFOAE data together with an active cochlear model allowed us to make inferences about characteristics of the human cochlear-partition responses. The detailed and reliable measurements of SFOAE fine structures proved valuable in guiding the process of adjusting parameters of an active cochlear model. The optimal model parameters were well constrained by the six features of the SFOAE fine structures (Table V) with narrow confidence intervals (Tables VII and VIII). The present model suggests that: (1) the human cochlear-partition response at the 1 kHz place at 32 dB SPL has a sharp tuning ($Q_{3\ \mathrm{dB}}$ of 8.0) and a large amplification (peak-to-shoulder ratio of 60 dB), and (2) the tuning becomes broader and the amplification smaller as the stimulus level increased to 62 dB SPL.

Psychophysically observed Q_{ERB} of the human cochlear tuning at 1 kHz at a low stimulus level have been reported to be 7.5 (Glassberg and Moore, 1990), 12.7 (Shera *et al.*, 2002), and 11 (Oxenham and Shera, 2003). The present cochlear-model prediction of $Q_{\mathrm{ERB}}=7.6$ at 32 dB SPL is close to the value of Glassberg and Moore.

To compare the frequency-tuning characteristics of the present model with those of animal cochlear nerve fibers, we used the facts that the human 1 kHz cochlear place is located 60% from the stapes (Figs. 9 and 13) and that a 60% position corresponds to 2.8 kHz in cat (Liberman, 1982), 2 kHz in guinea pig (Wilson and Johnstone, 1975) and 1 kHz in chinchilla (Eldredge *et al.*, 1981). Because the tuning sharpness of a cochlear nerve fiber changes with the fiber's characteristic frequency (CF), it is appropriate to use a common relative cochlear position (60% from the stapes in this case) in a comparison of tuning sharpness across species. In cat, threshold tuning curves of cochlear nerve fibers with CF $=2.8$ kHz show an average $Q_{10\ \mathrm{dB}}=4.5$ (Liberman, 1990). In guinea pig, cochlear nerve fibers and medial olivocochlear nerve fibers with CF≈ 2 kHz show $Q_{10\ \mathrm{dB}}\approx 2.3\sim 4$ (Pickles, 1984; Brown *et al.*, 1998). In chinchilla, cochlear nerve fibers with CF≈ 1 kHz show $Q_{10\ \mathrm{dB}}\approx 1.7$ (Temchin *et al.*, 2005). Thus, the cochlear places at 60% from the stapes in these species exhibit a diverse range of $Q_{10\ \mathrm{dB}}$. The present human model prediction of $Q_{10\ \mathrm{dB}}=4.3$ at 32 dB SPL is similar to the $Q_{10\ \mathrm{dB}}$ value of cat (Liberman, 1990).

The present model predictions about the human cochlea are consistent with cochlear-partition responses of animals regarding the shapes of the amplitude and phase parts of the transfer function and stimulus-level-dependent changes in several response measures: (1) broadening of frequency tuning with increasing stimulus level, and (2) decrease of peak-to-shoulder ratio with increasing stimulus level (Rhode, 1971, 2007; Sellick *et al.*, 1982; Ruggero *et al.*, 1997 Robles and Ruggero, 2001; Ren *et al.*, 2006). Peak-to-shoulder ratio is related to the cochlear-amplifier gain. Cochlear amplifier gain, defined in various ways, has been observed in animals to be in a range of 40–80 dB (Ruggero *et al.*, 1997; Rhode, 2007). Peak-to-shoulder ratio of basal points of the chinchilla cochlear partition (CF$=5\sim 10$ kHz) were observed to be 33–50 dB at low stimulus levels (Ruggero *et al.*, 1997; Rhode, 2007). The present prediction of peak-to-shoulder ratio of the human cochlea, 60 dB at a stimulus level of 32 dB SPL, is slightly higher than those observed in the chinchilla cochlear partition.

ACKNOWLEDGMENTS

This study was supported in part by USA NIH-NIDCD Grant Nos. R01DC00360 (PI, D.O.K.) and R01DC08318 (PI, S.T.N.). The experiments were conducted while Y.-S.C. was visiting the University of Connecticut Health Center supported by Brain Korea 21 Project, the School of Information Technology, KAIST, in 2002–2003. Y.-S.C. and S.-Y.L. have been supported partly by the Brain Neuroinformatics Research Program sponsored by Korean MOST and MOCIE from 2001. We thank Dr. Gerhard Hill for assistance in making measurements using the conventional method, Dr. S. Puria for providing numerical middle-ear data, Dr. M. Ruggero and Dr. A. Temchin for providing numerical cochlear-partition data. We also thank Dr. J. Siegel, Dr. C. Shera, and Dr. M. Ruggero for helpful discussions on topics of this study.

Pitch strength decreases as F0 and harmonic resolution increase in complex tones composed exclusively of high harmonics[a)]

D. Timothy Ives[b)] and Roy D. Patterson
Centre for the Neural Basis of Hearing, Department of Physiology, Development and Neuroscience, University of Cambridge, Downing Street, Cambridge, CB2 3EG, United Kingdom

(Received 15 January 2007; revised 4 February 2008; accepted 7 February 2008)

A melodic pitch experiment was performed to demonstrate the importance of time-interval resolution for pitch strength. The experiments show that notes with a low fundamental (75 Hz) and relatively few resolved harmonics support better performance than comparable notes with a higher fundamental (300 Hz) and more resolved harmonics. Two four note melodies were presented to listeners and one note in the second melody was changed by one or two semitones. Listeners were required to identify the note that changed. There were three orthogonal stimulus dimensions: F0 (75 and 300 Hz); lowest frequency component (3, 7, 11, or 15); and number of harmonics (4 or 8). Performance decreased as the frequency of the lowest component increased for both F0's, but performance was better for the *lower* F0. The spectral and temporal information in the stimuli were compared using a time-domain model of auditory perception. It is argued that the distribution of time intervals in the auditory nerve can explain the *decrease* in performance as F0, and spectral resolution *increase*. Excitation patterns based on the same time-interval information do not contain sufficient resolution to explain listener's performance on the melody task.

I. INTRODUCTION

A series of experiments with filtered click trains and harmonic complexes has shown that pitch strength decreases as the lowest harmonic of a complex increases. The phenomenon has been demonstrated for the lowest harmonics using magnitude estimation (Fastl and Stoll, 1979; Fruhmann and Kluiber, 2005), and for higher harmonics using a variety of pitch discrimination tasks [e.g., Ritsma and Hoekstra, 1974; Cullen and Long, 1986; Houtsma and Smurzynski, 1990; see Krumbholz *et al.* (2000) for a review]. This paper reports an experiment that makes use of this phenomenon to demonstrate the importance of time-interval resolution for pitch strength. A harmonic complex with eight, adjacent components was used to measure performance on a melodic pitch task (Patterson *et al.*, 1983; Pressnitzer and Patterson, 2001), as a function of the frequency of the lowest harmonic in the complex. The important variable was the fundamental (F0) of the complex which was either low (75 Hz) or high (300 Hz), and the main empirical question was which fundamental supports better performance on the melodic pitch task?

In time-domain models of peripheral processing, the reduction in pitch strength with increasing harmonic number is associated with the loss of phase locking at high frequencies (e.g., Patterson *et al.*, 2000; Krumbholz *et al.*, 2000; Pressnitzer *et al.*, 2001). As a result, time-domain models predict that performance based on complexes limited to high harmonics will be worse for the *higher* fundamental (300 Hz); the higher harmonics occur above 3000 Hz for the 300 Hz fundamental, where the internal representation of the time interval information is smeared by the loss of phase locking.

In spectral models of pitch perception, the reduction in pitch strength with increasing harmonic number is associated with the loss of harmonic resolution at high harmonic numbers. This occurs because the frequency spacing between components of a harmonic complex is fixed, whereas the bandwidth of the auditory filter increases with filter center frequency. Thus, for all fundamentals, harmonic resolution (harmonic-spacing/center-frequency) decreases as harmonic number increases. It is also the case that the frequency resolution of the auditory filter improves somewhat with filter center frequency, where filter resolution is defined as the ratio of the center frequency (f_c) to the bandwidth (bw); it is referred to as the quality (Q) of the filter ($Q=f_c/\mathrm{bw}$). As a result, spectral models, which ignore the effects of phase locking, predict that performance will be worse for the *lower* fundamental with the lower value of Q.

The results of the experiment show that performance on the melodic pitch task is worse for the higher fundamental in support of the view that it is time-interval resolution rather than harmonic resolution that imposes the limit on pitch strength for these harmonic complexes.

[a)]Portions of this work were presented in "Why pitch strength decreases with increasing harmonic number in complex tones" at the 153rd Meeting of the Acoustical Society of America, Salt Lake City, 2007.

A. Spectral and temporal summaries of the pitch information in complex sounds

The logic of the experiment will be illustrated using a time-domain model of auditory processing, since such models make it possible to compare the spectral and temporal information that is assumed to exist in the auditory system at the level of the auditory nerve. There are a number of different time-domain models which are typically referred to by the representation of sound that they produce, for example, the "correlogram" (Slaney and Lyon, 1990), the "autocorrelogram" (Meddis and Hewitt, 1991), and the "auditory image" (Patterson *et al.*, 1992, 1995). The example is based on the auditory image model (AIM) and the specific implementation is that described in Bleeck *et al.* (2004). The first three stages of AIM are typical of most time-domain models of auditory processing. A bandpass filter simulates the operation of the outer and middle ears, and then an auditory filterbank simulates the spectral analysis performed in the cochlea by the basilar partition. The shape of the auditory filter is typically derived from simultaneous noise-masking experiments, rather than pitch experiments. In this case, it is the gammatone auditory filterbank of Patterson *et al.* (1995). The simulated membrane motion is converted into a simulation of the phase-locked, neural activity pattern (NAP) that flows from the cochlea in response to the sound; the simulated NAP represents the probability of neural firing, it is produced by compressing, half-wave rectifying and low-pass filtering the membrane motion, separately in each filter channel. The NAPs produced by AIM are very similar to those produced by correlogram and autocorrelogram models of pitch perception (e.g., Slaney and Lyon, 1990; Meddis and Hewitt, 1991; Yost *et al.*, 1996).

The NAPs produced in response to two complex sounds composed of harmonics 3–10 of a 300 Hz fundamental and a 75 Hz fundamental are shown in Figs. 1(a) and 1(b), respectively. The dimensions of the NAP are time (the abscissa) and auditory-filter center frequency on a quasilogarithmic axis (the ordinate). Figure 1 covers the frequency range from 50 to 12 000 Hz. The time range encompasses three periods of the corresponding fundamental; so for the 300 Hz F0 the range is 10 ms, and for the 75 Hz F0 the range is 40 ms. The vertical and horizontal side panels to the right and below each figure show the average of the activity in the NAP across one of the dimensions. The average over time is shown in the vertical (or spectral) profile; the average over frequency is shown in the horizontal (or temporal) profile. The spectral profiles are often referred to as excitation patterns (e.g., Glasberg and Moore, 1990), and they show that there are more resolved harmonics in the NAP of the sound with the higher F0 (300 Hz) [Fig. 1(a)] than for the lower F0 (75 Hz) [Fig. 1(b)]. This suggests that using the spectral profiles to predict pitch strength would lead to a higher value of pitch strength for the higher F0. The spectral summaries derived from other time-domain models and the spectral summaries used in spectral models of auditory processing would all lead to the same, qualitative, prediction. With regard to temporal information, the NAPs reveal faint ridges in the activity, which occur every 3.3 ms for the 300 Hz NAP and every 13.3 ms for the 75 Hz NAP. However, it is difficult to see the strength of the temporal regularity in the NAP because the propagation delay in the cochlea means that the temporal pattern in the lower channels is progressively shifted in time. Similarly, the temporal profiles provide only a poor representation of the temporal regularity in these sounds. This is a general limitation of time-frequency representations of the information in the auditory nerve.

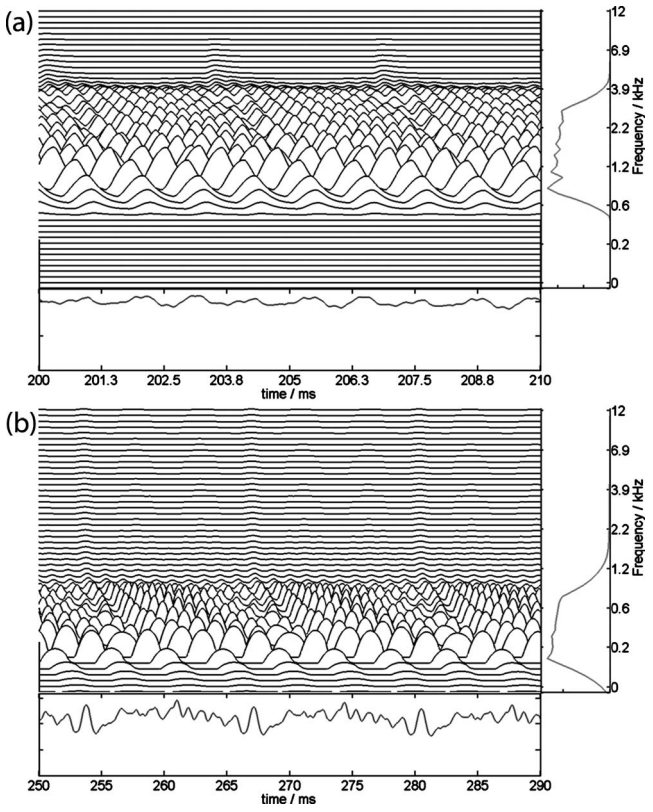

FIG. 1. Neural activity patterns (NAPs) for harmonic complex sounds composed of the third to tenth harmonics of (a) an F0 of 300 Hz, and (b) an F0 of 75 Hz. Side panels show the spectral profiles (vertical) and temporal profiles (horizontal) of the NAP.

The temporal information in the NAP concerning how the sound will be perceived is not coded by time, *per se*, but rather by the time intervals between the peaks of the membrane motion. For this reason, time-domain models include an extra stage, in which autocorrelation (e.g., Slaney and Lyon, 1990) or strobed temporal integration (Patterson *et al.*, 1992) is applied to the NAP to extract and stabilize the phase-locked, repeating neural patterns produced by periodic sounds. Broadly speaking, the time intervals between peaks within a channel are calculated and used to construct a form of time-interval histogram for that channel of the filterbank, and the complete array of time-interval histograms is the correlogram (Slaney and Lyon, 1990), or auditory image (Patterson *et al.*, 1992), of the sound. The histogram is dynamic and events emerge in, and decay from, the histogram with a half life on the order of 30 ms. It is argued that these representations provide a better description of what will be heard than the NAP. They have the stability of auditory perception (Patterson *et al.*, 1992) and they do not contain the between-channel phase information associated with the

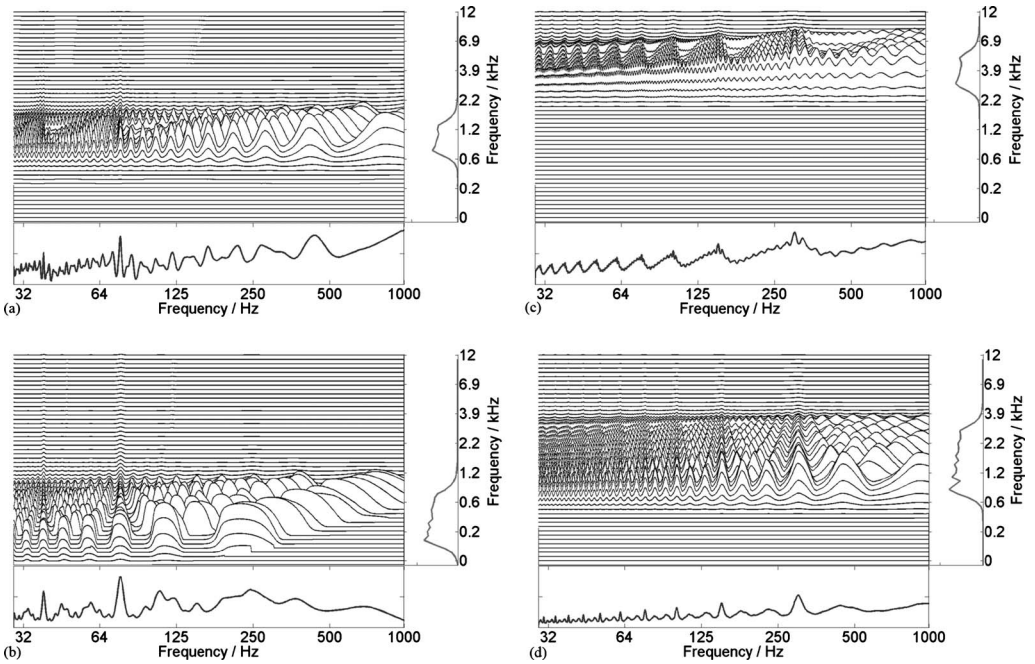

FIG. 2. Stabilized auditory images (SAI) of four harmonic complexes. All stimuli have eight consecutive harmonics; they differ in their fundamentals and lowest components. (a) F0=75 Hz, harmonics 11–18; (b) F0=75 Hz, harmonics 3–10; (c) F0=300 Hz, harmonics 11–18; (d) F0=300 Hz, harmonics 3–10. Side panels show the spectral profiles (vertical) and temporal profiles (horizontal) of the auditory images.

propagation delay which we do not hear (Patterson, 1987). However, all that matters in the current study is that they reveal the precision of the time-interval information in the auditory nerve and make it possible to produce a simple summary of the temporal information in the form of a temporal profile.

The auditory images of four harmonic complexes simulated by AIM are shown in Fig. 2. The stimuli all have eight consecutive harmonics but they differ in fundamental (F0) and/or lowest component (LC) as follows: (a) F0=75 Hz, LC=11; (b) F0=75 Hz, LC=3; (c) F0=300 Hz, LC=11; (d) F0=300 Hz, LC=3. The auditory images corresponding to the NAPs in Figs. 1(a) and 1(b) are shown in Figs. 2(d) and 2(b), respectively. In each channel of all four panels, there is a local maximum at the F0 of the stimulus, and together these peaks produce a vertical ridge in each panel that corresponds to the pitch that the listener hears. In the upper panels [Figs. 2(a) and 2(b)], where the lowest component is the 11th, and the auditory filters are wide relative to component density, the interaction of the components within a filter is clearly manifested by the asymmetric modulation of the pattern at the F0 rate. The corresponding correlograms of Slaney and Lyon (1990) and the autocorrelograms of Meddis and Hewitt (1991) would have a similar form in as much as there would be local peaks at F0 and prominent modulation for the stimuli where the lowest component is the 11th, but the pattern of activity within the period of the sound would be blurred and the envelope of the modulation would be more symmetric.

The vertical and horizontal side panels to the right and below each sub-figure show the average of the activity in the auditory image across one of the dimensions. The average over time interval is shown in the vertical, or spectral, profile; the average over frequency (or channels) is shown in the horizontal, or temporal, profile. The unit on the time-interval axis is the frequency equivalent of time interval, that is, time interval^{-1}. It is used to make the spectral and temporal profiles directly comparable. The spectral profile of the auditory image is very similar to that of the corresponding NAP. The temporal profile of the auditory image shows that the timing information in the neural pattern of these stimuli is very regular, and if the auditory system has access to this information it could be used to explain pitch perception. The advantage of time-domain models of auditory processing is that the spectral and temporal profiles are derived from a common simulation of the information in the auditory nerve, which facilitates comparison of the spectral and temporal pitch models based on such profiles. Moreover, the parameters of the filterbank are derived from separate, masking experiments, so the resulting models have the potential to explain pitch and masking within a unified framework.

In the spectral profile, when the lowest component is increased from three to eleven, the profile ceases to resolve individual components. This is shown by comparing the peaky spectral profile for the stimulus with a LC of 3 in Fig. 2(d), with the smoother profile for the stimulus with a LC of 11 in Fig. 2(c). The effect of increasing LC is similar for the lower F0 in the left column, but the harmonic resolution is reduced in both cases. In the temporal profile, when the lowest component is increased from three to eleven, the pronounced peak at 75 Hz in the left-hand column remains; compare Figs. 2(b) and 2(a). The 300 Hz peak in the temporal profile in the right-hand column becomes much less pronounced relative to the surrounding activity, [compare Figs. 2(d) and 2(c)] but there is still a small peak in Fig. 2(c).

As F0 is increased from 75 to 300 Hz, activity in the spectral profile shifts up along the frequency axis. For the stimuli with higher order components [Figs. 2(a) and 2(c)], there is little change in the resolution of the spectral profile when F0 is changed; the harmonic resolution remains poor. But for the stimuli with lower order components [Figs. 2(b) and 2(d)], the increase from a fundamental of 75 Hz to one of 300 Hz is accompanied by an increase in harmonic resolution, which is due to the increase in the Q of the filter with center frequency. As a result, a model based on spectral profiles would predict (a) that performance for stimuli with higher order components will be poor independent of F0, and (b) that performance for stimuli with lower order components will be better for the higher F0 (300 Hz).

As F0 is increased from 75 to 300 Hz, the peak in the temporal profile shifts to the right along the time-interval axis. For stimuli with lower order components [Figs. 2(b) and 2(d)], the ratio of the magnitude of the F0 peak to the magnitude of the neighboring trough is large, and a model based on temporal profiles would predict good performance in both conditions. For stimuli with higher order components [Figs. 2(a) and 2(c)], the peak to trough ratio is still reasonably large for the lower F0, but it is much reduced for the higher F0. So, a model based on temporal profiles would predict reasonable performance for the low F0 and poorer performance for the higher F0. Thus, there is a clear difference between the predictions of the two classes of model.

II. MAIN EXPERIMENT

The melody task is based on the procedure described previously by Patterson *et al.* (1983) and revived by Pressnitzer *et al.* (2001). Listeners were presented with two successive melodies. The second melody was a repetition of the first but had one of the notes changed by one diatonic interval up or down. The task for the listener was to identify which note had changed in the second melody. Melodies consisted of four notes from the diatonic major scale. The structure of the notes was such that only the residue pitch was consistent with the musical scale, and that sinusoidal pitch could not be used to make judgments. A melody task was used rather than a pitch discrimination task as it is a better measure of pitch strength.

A. Stimuli

The notes in the melodies were synthesized from a harmonic series whose lowest components were missing. The pitch of the note corresponded to the F0 of the harmonic series. The harmonics were attenuated by a low-pass filter with a slope of 6 dB/octave relative to the lowest component present in the complex. Performance on a melody task was measured as a function of three parameters: fundamental frequency (F0); average, lowest component number (ALC); and number of components (NC). There were two nominal F0's 75 and 300 Hz; the F0 was subject to a rove of half an octave. The ALC was 3, 7, 11, or 15. The NC was either 4 or 8. Stimuli were generated using MATLAB; they had a sampling rate of 48 kHz and 16 bit amplitude resolution. They were played using an Audigy-2 soundcard. The duration of each note was 500 ms, which included a 100 ms raised cosine onset and a 333 ms raised cosine offset. Stimuli were presented diotically using AKG K240DF Studio-Monitor headphones at a level of approximately 60 dB SPL. Difference tones in the region of F0 and its immediate harmonics (Pressnitzer and Patterson, 2001) were masked by bandpass filtered white noise; the frequency range was 20–160 Hz for the lower F0 and 50–400 Hz for the higher F0. The level of the noise was 50 dB SPL. Cubic difference tones just below the lowest harmonic were not masked as this would involve inserting a loud noise that would overlap in the spectrum with the stimulus. Cubic difference tones might increase pitch strength slightly in all conditions, but they would not be expected to contribute a distinctive cue to the melody that would affect performance differentially for a particular F0 or lowest harmonic number. The experiment was run in an IAC double-walled, sound-isolated booth.

B. Subjects

Three listeners participated in the first experiment; their ages ranged from 20 to 26 years. All listeners had normal hearing thresholds at 500 Hz, 1, 2, and 4 kHz. Listeners were not chosen on the basis of musical ability, but two of the listeners were trained musicians. All listeners were paid at an hourly rate. Listeners were trained on the melody task over a 2 h period, although they would be allowed to take frequent breaks so the actual training time was somewhat less than 2 h. The training program varied between listeners. Typically it involved starting with an easy condition having eight components, an ALC of three, and no roving of the lowest component. The difficulty of the task was then increased by including stimuli with fewer components (i.e., four), adding the rove, and finally presented stimuli with higher values of ALC. Three potential listeners were rejected after the training period because they were unable to learn the task sufficiently well within the allotted time.

C. Procedure

Listeners were presented with two consecutive four note melodies. The second melody had one of the notes changed, and listeners had to identify the interval with the changed note. The procedure is illustrated schematically in Fig. 3 as four bars of music: The two melodies are presented in the second and fourth bars; the tonic, which defines the scale for the trial, is presented twice before each of the melodies, as a pick up in the third and fourth beats of the first and third bars. After the presentation of the second melody, there was an indefinite response interval, which was terminated by the listener's response. Feedback was then given as to which note actually changed, then another trial begun. In the example shown in Fig. 3, it is the second note that has changed in the second melody as shown by the gray square.

The notes of the melodies were harmonic complexes without their lowest components. The melody was defined as the sequence of fundamentals (that is, the residue pitch) rather than the sequence of intervals associated with any of the component sinusoids. On each trial, the F0 of the tonic was randomly selected from a half-octave range, centered

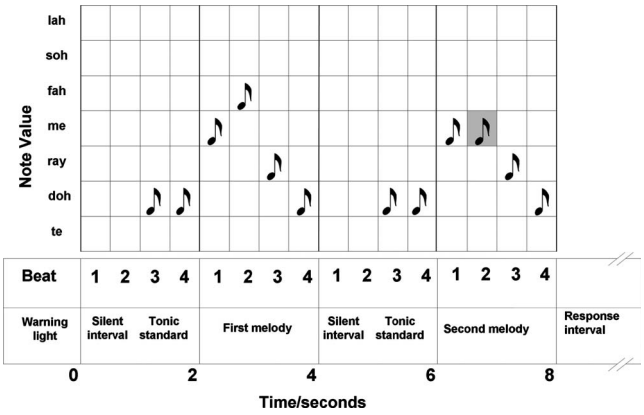

FIG. 3. Schematic of the procedure of the melody task, adapted from Patterson *et al.* (1983). One note changes by a single diatonic interval between the first and second presentations of the melody, and the listener has to identify the changed note, marked here by a grey square.

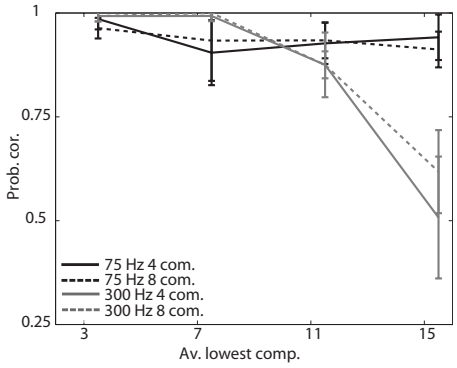

FIG. 4. Performance on the melody task with the 75 and 300 Hz fundamentals. The abscissa shows the average lowest component and the ordinate shows the probability of the listener correctly identifying the note which changed. Performance is plotted for each NC condition as a function of average lowest component. The black and grey lines show the results for the 75 and 300 Hz F0's, respectively. The solid and dashed lines show the results for the four- and eight-harmonic stimuli, respectively.

logarithmically on F0. The actual ranges were 63–89 and 252–357 Hz. The F0's of the other notes in the scale were calculated relative to the F0 of the tonic using the following frequency ratios: $2^{-1/12}$ (te); 1 (doh); $2^{2/12}$(ray); $2^{4/12}$(me); $2^{5/12}$(fah); $2^{7/12}$ (soh); and $2^{9/12}$(lah). Note that a ratio of $2^{1/12}$ produces an increase in frequency of one semitone on the equal temperament scale. The intervals are musical but, due to the randomizing of the F0, the notes of the melodies are only rarely the notes found on the A440 keyboard. The purpose of randomizing the F0 of the tonic was to force the listeners to use musical intervals rather than absolute frequencies to perform the task. The notes of the first melody of a trial were drawn randomly, with replacement, from the first five notes of the diatonic scale based on the randomly chosen tonic for that trial. The melody was repeated in the same key, and one of the notes was shifted up or down by a single diatonic interval. This shift can result in either a tone or a semitone change, since the size of a diatonic interval depends on its position in the scale.

The LC of each note in each melody was subjected to a restricted rove, the purpose of which was to preclude the use of the sinusoidal pitch of one of the components to perform the task. The degree of rove was one component, and so, the LC in each tone was either LC or LC+1. There were two further restrictions on the value of the LC: First, adjacent notes in a melody were precluded from having the same LC; second, each note had a different LC in the second melody from that which it had in the first melody. With these restrictions, it sufficed to alternate between the LC and the one above it using one of the patterns 1–0–1–0 or 0–1–0–1 for the first melody and the other pattern for the second melody.

The note-synthesis parameters were combined to produce 16 conditions ($2\times\mathrm{F0}, 2\times\mathrm{NC}, 4\times\mathrm{ALC}$). The order of these 16 conditions was randomized, and together they constituted one replication of the experiment. The listeners performed three or four replications in a 20 min block, with four or five blocks in a 2 h session. All listeners completed 45 or 46 replications.

D. Results of main experiment

The average results for the three listeners are shown in Fig. 4; the pattern of results was the same for all three listeners as shown by the analysis of variance (ANOVA) in Table I. The abscissa shows the ALC of the harmonic series; the ordinate shows the probability of the listener correctly identifying which of the notes changed in the second melody. Performance is plotted separately for the two NCs and the two F0's. The black and grey lines show the results for the 75 and 300 Hz F0's, respectively. The solid and dashed lines show the results for the four- and eight-harmonic stimuli, respectively. Figure 4 shows that, as ALC is increased, performance decreases, i.e., the probability of identifying which note changed in the second melody decreases in all conditions. However, the effect is much more marked for the 300 Hz F0, where performance decreases abruptly as ALC increases beyond 7. This is the most important result, as it differentiates the spectral and temporal models: Strictly spectral models would predict that there should be no reduction in listener performance when F0 is increased; indeed, performance should improve slightly with increasing F0 because the auditory filter becomes relatively narrower at higher center frequencies. Temporal models predict that there will be a decrease in performance with increasing F0 because of the progressive reduction in the phase locking of nerve fibers. The effect of increasing NC from four to eight had no consistent effect on listener performance.

An ANOVA was performed on the data; the results are presented in Table I, which confirms that the above-described effects are statistically significant at the $P<0.01$ level (bold type in Table I). There is a main effect of ALC, and one interaction, $\mathrm{F0}\times\mathrm{ALC}$. The interaction of F0 with ALC shows that ALC has a greater effect on performance for the higher F0.

III. ANCILLARY EXPERIMENTS

Prior to running the main experiment, two similar ancillary experiments were performed. They are presented briefly here inasmuch as they provide additional data concerning the

TABLE I. Results of an ANOVA of performance data (Dependent variable: SCORE). There is one significant ($P<0.01$) main effect and one significant interaction, both of which are shown in bold type; they are ALC, and F0×ALC.

effects observed in the main experiment, and they provide data on the effects of a larger component rove.

A. Method

The experimental task and the procedure were the same as those described for the main experiment in Sec. II. The design was slightly different. The F0 was 300 Hz in the first ancillary experiment and 75 Hz in the second. The ALC values were the same in the two ancillary experiments and the values were the same as in the main experiment, namely, 3, 7, 11, or 15. The number of components was 4 or 8, as in the main experiment; however, the ancillary experiments also included a condition with just two components. In the ancillary experiments, the lowest-component rove (LCR) was either one component (as in the main experiment) or three components. The LCR was subject to the same restrictions as to those in the main experiment. Specifically, for a rove of three, a random permutation of the four rove values was calculated for the first melody (e.g., 0–2–3–1) and recalculated for the second melody such that none of the notes in the second melody had the same lowest component as the corresponding note in the first melody (e.g., 1–0–2–3). Four listeners participated in each of the ancillary experiments, and three of the listeners were the same in the two experiments.

In the conditions where there were only two components in the sound, the pitch is ambiguous and the form of the ambiguity differs between musical and nonmusical listeners (Seither-Preisler *et al.*, 2007). The problem is that the sinusoidal pitches of the individual components are strong relative to the residue pitch produced by two components; this, in turn, makes it difficult for nonmusical listeners to focus on the residue pitch and not be distracted by the sinusoidal pitches. These problems reduced performance in the two-component conditions; the reduction was larger for the lower F0, and larger for the less musical listeners, but there was not enough data to quantify the interaction of F0 and listener. While it might be interesting to study how the pitch of the residue builds up with number of components, while the sinusoidal pitches of the individual components become less salient, that was not the purpose of these experiments. Consequently, the two-component condition was dropped from the design of the main experiment, and the two-component results from the ancillary experiments are omitted from further discussion.

B. Results

The remaining results of the two ancillary experiments are plotted together in Fig. 5; the pattern of results was the same for the four listeners in each of the experiments, so the figure shows performance averaged across listeners. The ab-

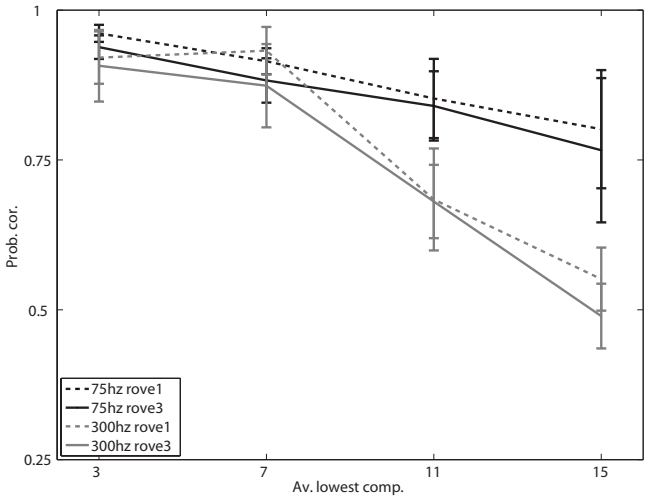

FIG. 5. Performance on the melody task in the ancillary experiments with the 75 Hz fundamental (black lines) and the 300 Hz fundamental (grey lines). The abscissa shows the average lowest component and the ordinate shows the probability of the listener correctly identifying the note which changed. Performance is plotted separately for the two rove conditions. The dashed and solid lines show the results for LCR values of one and three, respectively.

scissa shows the ALC of the harmonic series; the ordinate shows the probability of the listener correctly identifying which of the notes changed in the second melody, as before. Performance is plotted separately for the two LCRs and the two F0's. Performance was averaged over number of components (four and eight) because the variable did not affect performance; the same noneffect was later observed in the main experiment. The black and grey lines show the results for the 75 and 300 Hz F0's, respectively. The dashed and solid lines show the results for LCR values of one and three, respectively.

Consider first, the effect of roving the lowest component; compare the solid lines for a rove of one component with the dashed lines for the rove of three components. Although performance is slightly better for the rove of one, the pattern of results is the same, and the effect of rove magnitude is not significant. With this observation in mind, the results in Fig. 5 are seen to support the conclusions of the main experiment. The overall performance in the ancillary experiments is slightly lower overall, perhaps because two of the three listeners in the main experiment were trained musicians. However, the pattern of results is the same; whereas, performance decreases only slowly with increasing ALC when the F0 is 75 Hz, it decreases rapidly with ALC in the region above seven for an F0 of 300 Hz.

The comparison of performance for the two F0's must be made with some caution in this case, since three of the four listeners were common to the two ancillary experiments, and these three listeners performed the 300 Hz experiment before the 75 Hz experiment. However, there were more than 40 replications of all conditions for each listener in each ancillary experiment, *after* the initial training in the melody task, and an analysis showed that there was essentially no learning over the 40 replications in either experiment. It is also the case that the one listener who only participated in the 75 Hz experiment showed no learning over the course of the experiment, and had the same average level of performance as the other listeners in that experiment, indicating that training on the higher F0 was not required to produce good performance with the lower F0. Thus, it seems likely that the elevation of performance in the 75 Hz experiment for the higher ALC values is not simply due to learning, and probably represents the same effect as observed in the main experiment. Accordingly, in Sec. IV the data from the main and ancillary experiments are combined, so that the performance of the trained musicians is moderated by that of the rest of the listeners to provide the best estimate of what performance would be in the population.

IV. MODELING PITCH STRENGTH WITH DUAL PROFILES

The spectral and temporal profiles of the auditory image both describe aspects of the frequency information in a sound. They can be combined into a dual profile that facilitates comparison of the two kinds of frequency information by inverting the time-interval dimension of the temporal profile (Bleeck and Patterson, 2002). The dual profile for a typical stimulus in the current experiment is shown in Fig. 6. It had the following parameters: NC=4; ALC=3; and F0 =300 Hz. The temporal profile is the blue (darker gray) line with its maximum at 300 Hz; and the spectral profile is the red (lighter gray) line with its maximum at 900 Hz. The peak in the temporal profile at 300 Hz is the F0 of the harmonic series; the position of the peak is independent of the experimental parameters NC and ALC. Should the auditory system have a representation like the temporal profile, it would provide a consistent cue to the temporal pitch of these sounds. The spectral profile has four peaks at 900, 1200, 1500, and 1800 Hz. These peaks are at the four components of the signal, i.e., the third, fourth, fifth, and sixth harmonics of 300 Hz. The spectral profile shows that these four components are resolved, which means that a spectral model would be able to extract the F0 from the component spacing of this stimulus using a more central mechanism that computes subharmonics from a set of spectral peaks. As ALC increases, component resolution decreases and pitch strength decreases. In the following, we use the dual profile to assess the relative value of these spectral and temporal summaries of the sound as predictors of the data from the current experiment.

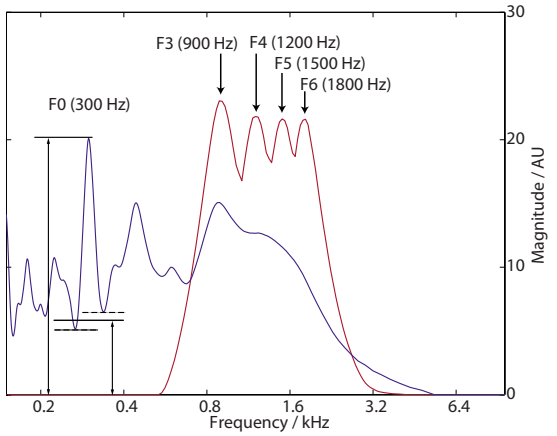

FIG. 6. (Color online) The dual profile for a stimulus with four resolved harmonics: NC=4, ALC=3, and F0=300 Hz. The temporal profile is the blue (dark) line and the spectral profile is the red (light gray) line. The F0 is represented in the temporal profile by the locating of the largest peak. In the spectral profile the F0 is represented by the spacing of the peaks.

A. The gammatone auditory filterbank

The dual profile shown in Fig. 6 was produced using a gammatone auditory filterbank (GT-AFB) (Patterson *et al.*, 1995) and the version of AIM described in Bleeck *et al.* (2004). The GT-AFB provides a linear simulation of the spectral analysis performed in the cochlea by the basilar partition. The dual profiles for all of the stimuli with F0's of 75 and 300 Hz are shown in Fig. 7. Figures 7(a)–7(h) show the profiles for an F0 of 75 Hz and Figs. 7(i)–7(p) show the profiles for an F0 of 300 Hz. Each row in Fig. 7 shows dual profiles with a constant NC; the value is eight for the top row, four for the middle row, eight for the second from bottom row, and four for the bottom row. Each column shows dual profiles for stimuli with a constant ALC, with values of three for the leftmost column, seven and eleven for the middle columns, and fifteen for the rightmost column. Thus, Fig. 7(a) is the dual profile for the stimulus with an F0 of

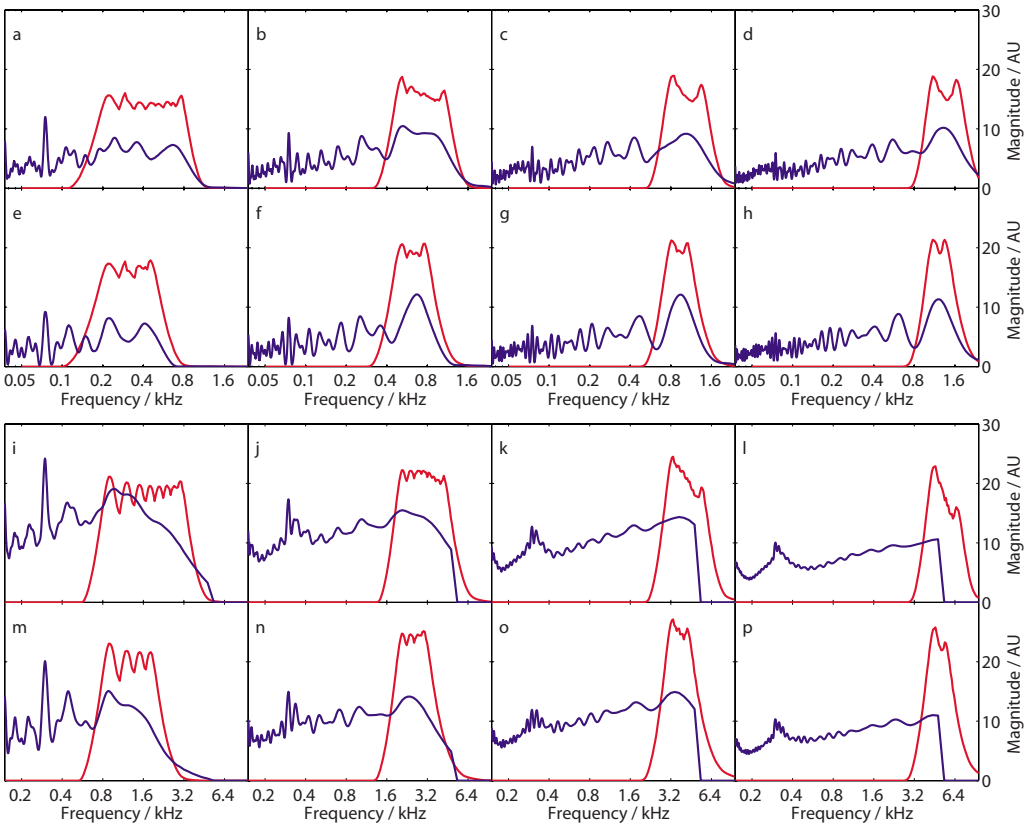

FIG. 7. (Color online) Dual profiles produced with the GT-AFB for stimuli with F0's of 75 and 300 Hz. Panels (a)–(h) Profiles for an F0 of 75 Hz. (i)–(p) Profiles for an F0 of 300 Hz. Each row shows dual profiles with a constant NC; the value is eight for the top row, four for the middle row, eight for the second from bottom row, and four for the bottom row. Each column shows dual profiles for stimuli with a constant ALC, with values of three for the leftmost column, seven and eleven for the middle columns, and fifteen for the rightmost column.

75 Hz, consisting of eight harmonics beginning from the third, and Fig. 7(p) is for an F0 of 300 Hz, consisting of four harmonics beginning from the fifteenth. Figure 7 shows that, generally, the spectral profiles do not contain many resolved harmonics for stimuli with lowest components above seven; this is shown in the three rightmost columns of Fig. 7.

The temporal profile always has a peak at the F0 of the harmonic series, 75 or 300 Hz, depending on the stimulus. The peak at F0 is not always the largest peak in the temporal profile; however, any other large peaks are spaced well away from the F0 in frequency. Sometimes the peaks are up to four octaves away, and as such, are far enough away not to interfere with the F0 peak. The peak used in the modeling was the largest peak within a two octave range centered on the fundamental. Thus, the temporal profile marks the F0 value by the location of a single peak and there is no need for a more central subharmonic generator. The height of the peak relative to the adjacent troughs can be used to estimate the strength of the pitch (Patterson *et al.*, 1996; Patterson *et al.*, 2000) and to explain the lower limit of pitch for complex harmonic sounds (Pressnitzer *et al.*, 2001). The pitch strength metric is illustrated in Fig. 6 by the faint lines; it is the height of the peak at F0, measured from the abscissa, minus the average of the trough values on either side of the peak, again measured from the abscissa. The effect of the loss of phase locking on this metric can be readily observed in the lower two rows of Fig. 7, where the F0 is 300 Hz and NC is either 8 or 4. As ALC increases from panel to panel across each row, the peak to trough ratio decreases progressively. The effect is much smaller in the upper rows where the energy of the stimulus is concentrated in the region below 2000 Hz, where phase locking is more precise.

There is a ceiling effect in the perceptual data at the lowest ALC values (3 and 7). Accordingly, the maximum value of the peak-to-trough ratio was limited to 7 in the modeling of pitch strength. This had the effect of limiting the model's estimate of pitch strength so that it did not rise further as ALC decreased from 7 to 3. The solid black and grey lines in Fig. 8 show the pitch strength estimates as a function of ALC for the 75 and 300-Hz F0's, respectively. The pitch strength values were averaged over the two NC conditions for each value of ALC. Figure 8 also shows the perceptual data for the listeners from both the main and the ancillary experiments averaged over NC for each F0. The perceptual data are presented separately for the two F0's with dashed black and grey lines for 75 and 300 Hz, respectively. Figure 8 shows that the model can explain the more rapid fall off in pitch strength with increasing ALC at the higher F0.

B. The dynamic, compressive gammachirp auditory filterbank

Unoki *et al.* (2006) have argued that the compressive GammaChirp auditory filter (cGC) of Irino and Patterson

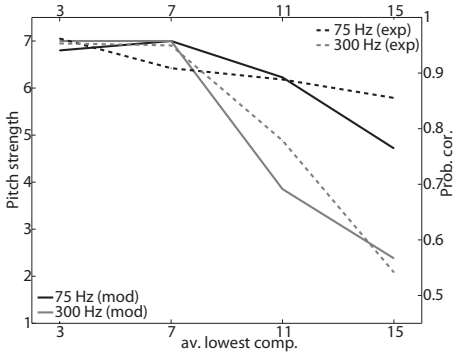

FIG. 8. Comparison of the experimental results with pitch-strength estimates from the dual profile model, based on a gammatone auditory filterbank, for an F0 of 75 Hz (black lines) and 300 Hz (grey lines). Dashed lines are the average experimental data plotted using the right ordinate (probability of correct identification as a function of average lowest component). Solid lines are the model values plotted using the left ordinate (pitch strength as a function of the average lowest component).

(2001) provides a better representation of cochlear filtering than the linear GT auditory filter in models of simultaneous masking. The magnitude characteristic of the cGC filter is asymmetric and level dependent with resolution similar to that described by Ruggero and Temchin (2005). At normal listening levels for speech and music, the bandwidth of the auditory filter is greater than the traditional ERB values reported by Glasberg and Moore (1990) as noted in Unoki *et al.* (2006). Moreover, Irino and Patterson (2006) have recently described a ***d****ynamic* version of the cGC filter with fast-acting compression which suggests that AIM can be extended to explain two-tone suppression and forward masking, as well as simultaneous noise masking. In an effort to increase the generality of the modeling, a version of AIM with the nonlinear dcGC filterbank was used to produce dual profiles for the stimuli in the experiment, to determine the pitch-strength values that would be derived from the temporal profiles of this more realistic time-domain model of auditory processing. The dual profiles produced with the dcGC filterbank were quite similar to those produced with the gammatone filterbank, primarily because the nonlinearities do not distort the time-interval patterns produced in the cochlea simulation as noted in Irino *et al.* (2007). The temporal profiles exhibited somewhat more pronounced peaks for the higher values of ALC, and the spectral profiles contained even less information, as would be expected with a broader auditory. But the differences were not large, and so the pattern of performance predicted for the melodic pitch task is quite similar for AIM with the dcGC filterbank. The results indicate that AIM with the dcGC filterbank would have the distinct advantage of being able to explain temporal pitch, masking, and suppression within one time-domain framework.

V. SUMMARY AND CONCLUSIONS

The decrease in pitch strength that occurs as the components of a harmonic complex are increased in frequency was used to demonstrate the importance of temporal fine structure in pitch perception. Performance on a melodic pitch task was shown to be better when the fundamental was lower (75 Hz) rather than higher (300 Hz), despite the fact that the internal representation of the harmonic complex has more resolved components when the fundamental is higher. A time-domain model of auditory processing (AIM) (Patterson *et al.*, 1995; Bleeck *et al.*, 2004) was used to simulate the neural activity produced by the stimuli in the auditory nerve and to compare the spectral and temporal information in the simulated neural activity in the form of the spectral and temporal profiles of the auditory image. Peaks in the time-interval profile can explain the *decrease* in performance as F0 *increases*. The corresponding spectral profiles show that spectral resolution increases when F0 increases, which suggests that spectral models based on excitation patterns would predict that performance on the melody task would improve as F0 increases, which is not the case.

The temporal profiles produced by the traditional version of AIM with the gammatone filterbank are similar to those produced by the most recent version of AIM, with a dynamic, compressive gammachirp filterbank. The latter model offers the prospect of being able to explain pitch, masking, and two-tone suppression within one time-domain framework.

Speech detection in spatial and nonspatial speech maskers

Uma Balakrishnan[a] and Richard L. Freyman
Department of Communication Disorders, University of Massachusetts, 358 N. Pleasant Street, Amherst, Massachusetts 01003, USA

(Received 22 March 2007; revised 28 February 2008; accepted 3 March 2008)

The effect of perceived spatial differences on masking release was examined using a 4AFC speech detection paradigm. Targets were 20 words produced by a female talker. Maskers were recordings of continuous streams of nonsense sentences spoken by two female talkers and mixed into each of two channels (two talker, and the same masker time reversed). Two masker spatial conditions were employed: "RF" with a 4 ms time lead to the loudspeaker 60° horizontally to the right, and "FR" with the time lead to the front (0°) loudspeaker. The reference nonspatial "F" masker was presented from the front loudspeaker only. Target presentation was always from the front loudspeaker. In Experiment 1, target detection threshold for both natural and time-reversed spatial maskers was 17–20 dB lower than that for the nonspatial masker, suggesting that significant release from informational masking occurs with spatial speech maskers regardless of masker understandability. In Experiment 2, the effectiveness of the FR and RF maskers was evaluated as the right loudspeaker output was attenuated until the two-source maskers were indistinguishable from the F masker, as measured independently in a discrimination task. Results indicated that spatial release from masking can be observed with barely noticeable target-masker spatial differences.

I. INTRODUCTION

The term informational masking has been used in a wide variety of contexts involving both speech and nonspeech signals. The use of this common terminology implies a common basis for this type of masking across speech and nonspeech stimuli. However, some key differences in methodology preclude the development of a global understanding of the concept of informational masking across both classes of signals. Not surprisingly, the majority of work with speech targets and maskers has involved *recognition* tasks (e.g., Carhart *et al.*, 1969; Freyman *et al.* 1999; Brungart, 2001; Arbogast *et al.*, 2005; Rakerd *et al.*, 2006). Some nonspeech studies have employed pattern identification or similar tasks (e.g., Watson *et al.*, 1976; Kidd *et al.*, 1995, 1998) and shown evidence of substantial informational masking. However, most of the work with nonspeech stimuli has involved *detection* experiments where the threshold of a tone is measured in the presence of a spectrally and/or temporally complex masker (e.g., Neff and Green, 1987; Wright and Saberi, 1999; Lutfi, 2003; Richards and Neff, 2004; Durlach *et al.*, 2005).

Only one study that we are aware of (Helfer and Freyman, 2005) examined detection of speech in conditions in which the focus was on informational masking. In that study, detection thresholds of topic-based sentences in the presence of masking sentences were obtained as part of an investigation of audiovisual speech perception. Sentence detection thresholds were obtained for both audiovisual and audio alone conditions for two spatial conditions. In the nonspatial condition the target sentence and the masker were presented from a single loudspeaker directly in front of the listener (the F-F condition). The spatial condition was the same except that an additional copy of the masker was presented 60° to the right and a 4 ms time advance was imposed on the right loudspeaker (the F-RF condition). In this condition, the masker was perceived to be well to the right of the target due to the precedence effect. Detection thresholds improved through the addition of visual cues or target-masker spatial separation only when the masker was speech (two talkers of the same sex as the target talker), not when it was noise. The fact that the F-RF condition produced no improvement for the noise masker was interpreted, as in previous recognition studies (e.g., Freyman *et al.*, 1999) to be evidence that this spatial configuration produced no release from energetic masking. Therefore, the observation of improvement in the F-RF condition with the speech masker was ascribed to release from informational masking. Monaural control experiments conducted by Freyman *et al.* (2001) had shown that, at least with recognition, such improvements were realized only with binaural listening, and presumed to result from perceived spatial differences between target and masker.

Because of the common use of detection for studying informational masking with nonspeech stimuli, its application to speech stimuli may offer improved opportunities to compare informational masking across speech and nonspeech signals. An additional important advantage of studying detection, relative to recognition, is that it would be expected to lower the signal-to-noise (S-N) ratio at which a threshold level of performance can be measured. The classic literature shows the speech detection threshold to be about 9 dB below the speech reception threshold (Thurlow *et al.*, 1948; Chaiklin, 1959). This difference could be useful when release from informational masking is measured in degraded

speech or in hearing-impaired populations. For example, Arbogast *et al.* (2005) showed that release from informational masking, and possibly informational masking itself, was reduced in a group of hearing-impaired subjects relative to normal-hearing listeners. However, the authors found that the base line nonspatial condition was so difficult for the hearing-impaired listeners that speech reception thresholds were often obtained at slightly positive S-N ratios. At positive S-N ratios, the target is louder than the masker, a condition that may not lend itself to informational masking. The vicinity of 0 dB S-N ratio may thus create a ceiling for informational masking, and the nonspatial threshold may have been truncated. Arbogast *et al.* (2005) suggested that because of this truncation it was not possible to determine conclusively whether informational masking differed between normal-hearing and hearing-impaired listeners. A speech detection paradigm could potentially avoid this issue because of the lower S-N ratios at which thresholds can be obtained.

The first experiment in the current paper employed a refined version of the detection paradigm used by Helfer and Freyman (2005) to study spatial release from informational masking. The sentence detection task used in that earlier study was most sensibly limited to single-interval trials because of the duration of the sentence stimuli. In the present study, we used words excised from the sentences and sought to determine whether a 4AFC paradigm could be employed successfully. The shortening of the stimuli from sentences to words also offered better control of stimulus variables and eliminated the potential use of semantic or syntactic connections between words available in sentence-level targets as cues, increasing the potential of making comparisons with nonspeech stimuli. Using this 4AFC paradigm, we investigated release from informational masking by creating target-masker spatial differences that do not produce unmasking with purely energetic maskers. These included the F-RF condition, described above, as well as an F-FR condition, which was identical to F-RF except that the front masker led the right masker by 4 ms. Both natural and time-reversed speech maskers were used.

In the course of Experiment 1 we (1) evaluated the extent to which a word detection paradigm lowered threshold S-N ratios, thereby mitigating the ceiling issues raised by Arbogast *et al.* (2005); (2) compared the amount of the informational masking that this detection paradigm produces relative to existing speech recognition data; (3) determined whether time-reversing the masker reduces spatial release from masking, a typical result in recognition studies; and (4) determined whether there is a difference in spatial release between the F-RF and F-FR conditions, where the former produces a large difference in perceived spatial location and the latter does not.

Experiment 2 explored in further detail the F-RF versus F-FR comparison and addressed the extent and type of spatial differences between target and masker that are essential for releasing informational masking. A classic study (Carhart *et al.*, 1969), as well as several recent studies (Freyman *et al.* 1999; Brungart *et al.*, 2005; Edmonds and Culling, 2005; and Rakerd *et al.*, 2006), have shown strong release from speech-on-speech masking even when spatial separation of target-masker images was not expected to create a clear separation in the centroid of target and masker auditory images. Freyman *et al.* (1999) found that spatial release from masking was almost as large for their F-FR condition as it was for the F-RF condition. The F-FR condition used the same loudspeaker configuration as the F-RF but with the time lead favoring the front loudspeaker. In this case the perceived horizontal location of target and masker was expected to be similar. Brungart *et al.* (2005) and Rakerd *et al.* (2006) explored the effect of masker delay over a wide range and found about the same masking release regardless of whether the time lead was imposed on the front or right loudspeaker. As the conditions where the masker time lead favors the front (target position) are not expected to create large horizontal shifts in the centroid of the masker image, their effectiveness may include or even be dominated by target-masker differences in other spatial properties, such as spatial width and shape. Blauert (1997) used the term "spaciousness" to describe this difference between two-source and single-source stimuli. Inasmuch as our two-loudspeaker spatial maskers simulate a source and a single reflection, the FR masker simulates only a reflection, whereas the RF masker simulates a reflection *and* also moves the masker source. It is not clear at this time whether the added spatial separation of masker source in the RF masker contributes to greater release from informational masking when the task is signal detection as opposed to recognition. In our second study we systematically attenuated the output of the right loudspeaker in both FR and RF spatial conditions and considered the difference in detection in these masking conditions in relation to their discriminability from the front only masker condition.

Finally, we investigated the effects of subject training on detection thresholds in the nonspatial (F-F) condition. This was motivated by the fact that in pilot listening, detection thresholds in the F-F condition showed considerable variability across runs and across listeners. Such variation was minimal in the spatial (F-RF and F-FR) conditions. Our purpose was to tease out any learning effects that might impact the overall amount of informational masking measured in the reference, nonspatial condition, so that we could make more accurate measurements of the release from informational masking provided by the spatial manipulations of the masker.

II. EXPERIMENT 1: RELEASE FROM MASKING IN DETECTION

A. Methods

1. Stimuli

Target stimuli were 20 consonant-vowel-consonant words excised from nonsense sentences recorded by a female talker. This was the same target talker used by Freyman *et al.* in previous studies (e.g., Freyman *et al.*, 1999). The 20 target words were chosen for clarity of production and ease of excision from the continuously produced sentence waveforms. Typically, the target word was the second "content" (meaning loaded) word of each utterance. In those instances where the second word in the sentence was not easy to extract from its surround, content words in other locations (first or third)

within the utterance were taken. The 20 target words were scaled to equate their root-mean-square (rms) amplitude and then padded with zeroes to match the duration of the longest word on the list (500 ms). The 20 words were concatenated to create a single file from which the experimental software randomly selected a single word and played it on each trial.

Two types of maskers were used: two-talker speech ("natural") and two-talker time-reversed speech ("reversed"). These were a 35 s duration mixture of the recording of two female talkers reciting nonsense sentences (see Freyman *et al.*, 2001). The choice of two-talker speech stream was determined by results shown by Freyman *et al.* (2004) that informational masking increased as number of talkers increased from one to two, and diminished thereafter as additional talkers were added. Other investigators have also shown that two to three-talker speech maskers are particularly effective in masking speech targets (Carhart *et al.*, 1975; Yost *et al.*, 1996; Brungart *et al.*, 2001; Hall *et al.*, 2002).

Each stereophonic masker was created by copying the two-talker masker signal into a second channel and imposing a 4 ms pad of zeroes at the beginning of one channel to delay it with respect to the other channel. Another 4 ms pad of zeroes was appended to the end of the second channel, to maintain equal duration of maskers in both channels. Both speech maskers were equated for rms as were the two channels of each masker. Two time-lead conditions were used for the natural masker: right-leading (RF) and front-leading (FR). Only the RF masker condition was used for the reversed speech masker. For comparison, a front-only (F) masker condition was created by turning off the right loudspeaker and playing the masker only from the loudspeaker that produced the target speech (the F-F condition). Thus for the front-only masker condition, the single-channel masker output was 3 dB less than that of the two-channel maskers. The target words always originated from the front loudspeaker. Therefore, for a given listening trial the target-masker configuration could be front-front (F-F), target front and masker right-front (F-RF) or target front and masker front-right (F-FR).

2. Apparatus

The experiments were conducted in an anechoic chamber measuring 4.9 m × 4.1 m × 3.12 m. The walls, floor, and ceiling are lined with 0.72 m foam wedges. Subjects were seated in the center of the room in front of a foam-covered semicircular arc on which two loudspeakers were positioned. The Front loudspeaker was at 0° horizontal azimuth; the Right loudspeaker was at 60° to the right. Both were 1.9 m from the approximate center of the subjects' head and were at ear height for the typical adult.

The target words were delivered via TDT System I instrumentation. The output of the 16 bit digital-to-analog converter (TDT DA1) running at 20 kHz was low-pass filtered at 8.5 kHz (TDT), attenuated (TDT PA3), and mixed with the masker before being delivered to a Crown D40 amplifier and a Realistic Minimus 7 loudspeaker. The masker was delivered from a second computer (Dell Dimension XPD 333) via audio software (Cool Edit Pro). The 35-s-long interference segment was played continuously in the loop mode over the duration of an adaptive track fed through PA4 attenuators (Tucker Davis System II). Calibration of target and maskers was by means of a 1 in. microphone (B&K 4145) fitted with a random incidence corrector and lowered to the position of the subjects' head with the subject absent. A sound level meter (B&K 2204) located outside the chamber measured the microphone output using the C-scale and Fast meter response. The target was calibrated to a sawtooth noise equated for average power to the target word stream. The maskers were calibrated for each channel using a speech-spectrum noise masker (Byrne *et al.*, 1994).

3. Subjects

Listeners were five young adult students. Four of the five subjects had hearing thresholds ≤20 dB hearing level (HL) in the tested frequency range 250–6000 Hz (ANSI S3.6, 1996). The fifth subject (coded as S1 in this paper) had hearing thresholds ≤20 dB HL in the frequency range 250–4000 Hz, and thresholds of 35 and 30 dB HL at 6000 Hz in the left and right ears, respectively, with recovery to within normal limits at 8000 Hz.

4. Procedures

For all conditions, masker level was fixed at 53 dBC in each masker channel while the target level was adapted. A four-alternative forced-choice (4AFC) paradigm with a 2-down 1-up stepping rule was employed to estimate the 70.7% criterion performance (Levitt, 1971). An individual adaptive track consisted of 10 reversals with the threshold computed as the arithmetic mean of the last six reversals. The initial step size for the adaptive track was 16 dB and the final, 2 dB. For all five subjects, data were collected for six listening conditions—two maskers (two-talker natural speech, two-talker reversed speech,) x three loudspeaker configurations (F-F, F-RF, F-FR). The masker was turned on prior to the initiation of each adaptive track and left running in loop play until the end of the track. Subjects responded using a button box with light-emitting diode (LED) lights that marked the four intervals, one of which contained the target. Feedback was provided via an LED, display that illuminated the target interval. For each condition, four adaptive tracks were obtained and threshold determined as the arithmetic mean of the four runs. All five subjects received the same order of listening conditions with two runs per condition before going on to the next. The sequence of presentation is shown in Table I.

At the beginning of the first listening session, subjects were verbally instructed, familiarized with the list of 20 target words (print and audio), and given practice runs in quiet and with the masker in F-F and F-RF loudspeaker conditions to familiarize them with the task. Listeners sat facing the front loudspeaker and were advised to not turn their heads; however, no head restraint was used. Subjects were given a brief break after the first six runs. A total of 12 runs completed the first listening session, with each subject returning for a second session to complete the second set of 12 adaptive tracks, again with a break after the first six runs of the

TABLE I. Order of presentation of listening conditions for Experiment 1. All subjects received the same sequence over two sessions. Maskers were two-talker speech natural and time reversed. Subjects received a final "Quiet" target track without any masker at the end of the second session.

Session 2	13, 14 Reversed F-FR	15, 16 Reversed F-F	17, 18 Reversed F-RF	Break	19, 20 Natural F-FR	21, 22 Natural F-F	23, 24 Natural F-RF	25 Quiet threshold

second session. Following the 12 adaptive tracks run with maskers, a "target only" track was run for each subject without the masker to ensure that target audibility in quiet was well below masker overall level. For all five subjects the quiet threshold was below 10 dBC.

B. Results

Figure 1 displays detection thresholds for the five subjects as well as the group mean for the two speech maskers. An additional set of four adaptive thresholds was obtained for S2 who showed high variability of F-F thresholds on the initial set (standard deviation of the mean=7.75). The second

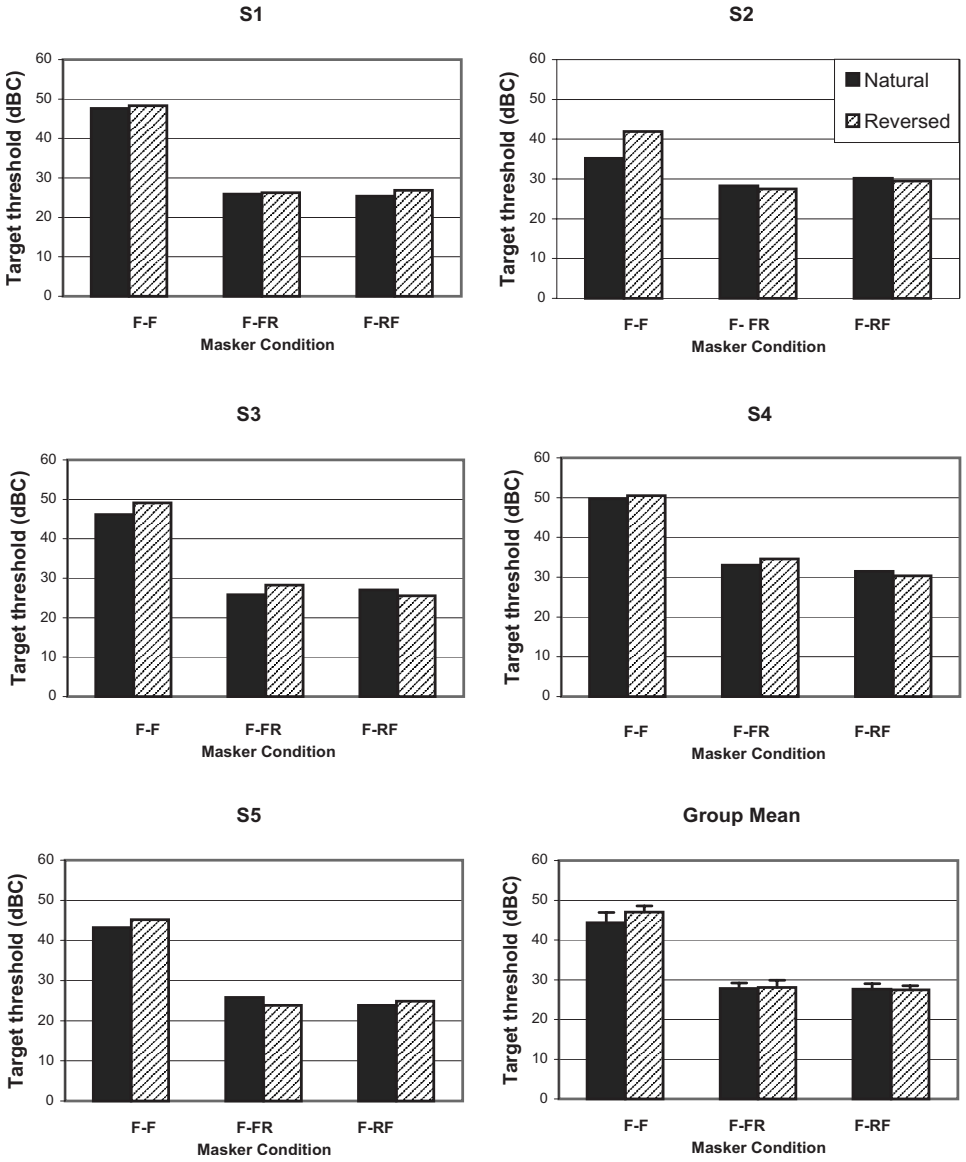

FIG. 1. Target thresholds for five subjects and group mean thresholds for the two-talker maskers in the F-F (nonspatial), F-FR (spatial, front-leading), and F-RF (spatial, right-leading) conditions. Solid bars represent the natural speech masker and the shaded bars represent the time-reversed speech masker. The group mean data (bottom left panel) also display one standard error of the mean.

set of four adaptive tracks also yielded a high standard deviation (6.37). Therefore, final threshold for the F-F condition for this subject was reported as the mean of all eight adaptive tracks.

As indicated earlier, masker output levels were fixed at 53 dBC for each loudspeaker. Threshold signal-to-noise (S-N) ratios are specified as the target level relative to 53 dBC. Across subjects target thresholds ranged from −2 dB S-N ratio for the nonspatial masker condition (S1) to nearly 30 dB below masker level for the RF spatial condition (S5). For individual subjects and the group, clear improvement in thresholds occurred for both spatial speech masker conditions (F-RF and F-FR) as compared to the F-F condition. Mean threshold improvement for the group (bottom right panel) in both spatial conditions relative to F-F was roughly 17 dB for the natural masker and 20 dB for the reversed masker. These values are substantially larger than those observed for nonsense sentence recognition using the same target talker and maskers (Freyman *et al.* 2001). It was also larger than the spatial advantages reported for detection by Helfer and Freyman (2005) for a different set of sentence stimuli using a single-interval task.

A noteworthy finding in the data displayed in Fig. 1 is the fact that both spatial speech masker conditions yielded substantial target threshold improvements, even though one (RF) was perceived well to the right of the target and the other (FR) was not. This is consistent with the findings reported in recognition studies (Freyman *et al.*, 1999; Brungart *et al.*, 2005; Rakerd *et al.*, 2006).

The improvement in the spatial conditions for the speech masker is interpreted here, as before, as indicating a release from informational masking. It is assumed that the high thresholds obtained in the F-F condition reflect approximately the same energetic masking as in the spatial conditions, with the difference of 17–20 dB reflecting informational masking. The fact that detection thresholds in the F-F condition were no better for the time-reversed speech than for the natural speech masker suggests that understandability of the masker is of virtually no importance in this detection experiment. If anything, the unintelligible time-reversed speech was a marginally more effective masker than the natural speech; the difference, however, was nonsignificant $t(4)=-1.962$; $p=0.121$. We suggest that this outcome is logical based on the brevity of the target signal used in this experiment (monosyllabic words) in conjunction with the nature of the detection task itself. That is, for our targets, the informational overlap between the target and masker occurs at the syllabic level, or, even more elementally, at the level of the phoneme. While natural and time-reversed speech streams are clearly differentiable from each other at the sentence level, they may be more similar to each other at the syllabic or phonemic level. For this reason, both types of speech maskers can be equally effective for the targets and the tasks we used. In contrast, when the same two maskers were used in a recognition experiment, the time-reversed masker was shown to be less effective than the natural masker in the F-F condition (Freyman *et al.*, 2001). Similar results have been reported for recognition by others (for example, Rhebergen *et al.*, 2005; Marrone *et al.*, 2007). These differences might suggest that the underlying psychometric functions created by time-reversed speech maskers might be steeper than those generated by natural speech, with the two functions converging at the lower end of the functions, near detection thresholds, and diverging at the higher end, where recognition performance is easier. In Freyman *et al.*, 2001 (Fig. 8, p. 2119) the backward and forward masker recognition performance functions for the F-F condition did converge at low S-N ratios (around −12 dB) while being divergent at high S-N ratios. However, because of the observed floor effects on performance, it is not possible to determine whether the convergence at low S-N ratios reflects an actual difference in the slopes of the two underlying functions.

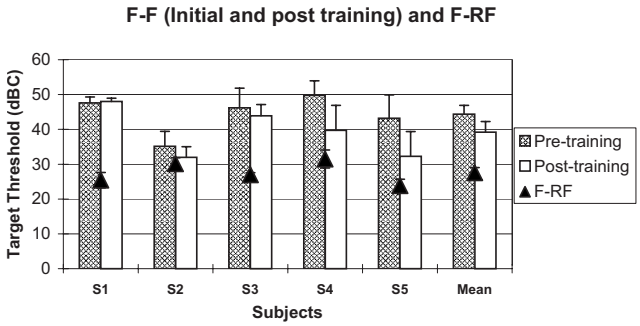

FIG. 2. Comparison of mean target thresholds for the initial four runs of Experiment 1 and the mean of the last four of ten training runs in the presence of the F-F (nonspatial) masker for five subjects and the group. Solid triangles are a replotting of the target thresholds obtained for the F-RF spatial masker condition for the natural speech masker shown in Fig. 1. Vertical bars show one standard deviation for individual subjects across the four pre- and post-training runs, and one standard error of the group mean data.

C. Learning effects in detection

In the F-F listening condition, four of the subjects showed higher variability in thresholds across the four adaptive tracks as compared to the F-RF condition. This raised the issue as to whether listeners could partially resolve the informational masking occurring in the F-F condition under some circumstances. To address this question, all five subjects were given ten successive adaptive tracks for the natural speech masker in the F-F condition. Results revealed variability across listeners, and while most listeners were able to improve performance on a given track, the gains did not carry over to successive tracks in a predictable or consistent manner.

Figure 2 treats the mean of the last four of the 10 runs as "post-training" and compares it to the mean of the initial four F-F runs of Experiment 1 for the five subjects and for the group. S1 shows no improvement, S2 and S3 show modest (less than 3 dB) gains, and S4 and S5 show large gains (about 10 dB). A paired-samples analysis of group mean data did not show a statistically significant difference between the pre- and post-training thresholds [$t(4)=2.316$; $p=.081$].

Also shown in Fig. 2 are the F-RF results for the natural speech masker reproduced from Fig. 1 (filled triangles). With the exception of S2, who did not show much spatial release from masking to begin with, subjects still showed substantial advantages in the F-RF condition even over the post-training

F-F results. Group mean differences between the F-F post-training and F-RF were statistically significant [$t(4)=3.182$; $p=.033$]. These results suggest that for most listeners, the release from masking provided by the spatial maskers was well beyond any improvement resulting from persistent listening and training. Inconsistent or limited responsiveness to extensive training has also been shown for nonspeech stimuli in informational masking tasks (for example, Neff and Callaghan, 1988; Neff and Dethlefs, 1995).

III. EXPERIMENT 2: REDUCING SPATIAL DIFFERENCES THROUGH RIGHT-CHANNEL ATTENUATION

In Experiment 1, listeners were able to benefit nearly equally from both the F-FR and F-RF spatial configurations, despite the fact that the spatial differences created are highly dissimilar. With the RF masker there is a substantial horizontal shift of the masker away from the target. As with any two-source sound, the RF masker is expected to have increased spaciousness relative to the F target, but the horizontal shift stands out as the most obvious difference. With the FR masker, the horizontal shift in position is expected to be fairly small and subjects may indeed use differences in spaciousness as a cue. Here, it may be worth noting an informal impression by the authors that listening to the F-FR condition does not require any special conscious or active effort to sort out how and where the target appears in relation to the masker. One listens for the target directly in front, and, at the relevant S-N ratios, the addition of the right loudspeaker causes it to stand out without any obvious increase in effort by the listener.

In the current experiment, target-masker spatial differences produced in the F-FR configuration were minimized by attenuating the right loudspeaker in graded steps. For comparison, we made the same right-loudspeaker attenuations for the RF masker, although in this case the time-intensity trade could create split or poorly defined spatial impressions. There were two parts to the experiment. In the first part, target words presented from the front loudspeaker were detected in the presence of the two-talker maskers as in Experiment 1, but now as a function of right-loudspeaker attenuation. In the second part, the spatial maskers were discriminated from the nonspatial (F) masker to determine the right-loudspeaker attenuation at which the addition of the right loudspeaker was undetectable. The goal of the combination of the two studies was to determine whether spatial release from masking could be observed with the front-right masker even when it was barely discriminable from the front masker.

A. Methods

Subjects were the same five listeners that completed Experiment 1. The speech target detection experiment used the same procedures as Experiment 1, except that the attenuation of the right loudspeaker in both the F-RF and F-FR conditions was increased from 0 dB (identical to the spatial conditions of Experiment 1) to 16 dB in 4 dB steps. Four adaptive tracks were obtained for each attenuation value. All subjects received the same stepwise order of presentation of conditions, starting with 0 dB and progressing to 16 dB of attenuation. One subject, (S3), received an additional attenuation step of 20 dB due to the fact that for this subject target threshold remained invariant as right loudspeaker attenuation was increased. The target words were the same as those used in Experiment 1 and the masker was the natural two-talker speech. Adaptive procedures and hardware setup were as described in Experiment 1.

For the discrimination task, 20 500 ms segments were randomly excised from a single channel version of the two-talker speech masker. Two kinds of average power relationships between segments were created. One set of 20 segments was allowed to retain the "natural" amplitude variation (N) (rms range=7.55 dB, standard deviation =1.93 dB), and in a second set the 20 segments were equated to each other for rms (Eq). The segments were converted into stereo waveforms by audio software (Cool Edit Pro), 20 ms linear rise/fall times were imposed, and 4 ms delays to one channel were added using zero padding as in Experiment 1. In each of the four intervals within a trial, an independent randomly selected segment was presented from among the 20 segments. In three of the intervals the stimulus was presented only from the front loudspeaker. The right loudspeaker was turned on during only one interval, to be detected by the listener, with feedback provided after each trial. Across trials, the right channel attenuation was adapted using the same tracking criteria and protocol employed in the other experiments described in this paper. Starting level for all stimuli was 40 dBC in both channels. Each subject received four adaptive tracks for each of four conditions in the following sequence: (1) FR-N–front-leading spatial masker with natural amplitude variation across segments; (2) RF-N–right-leading spatial masker with natural amplitude variation; (3) FR-Eq.–front-leading spatial masker rms equated; and (4) RF-Eq.–right-leading spatial masker rms equated. Subjects were the same five individuals who had participated in the previous experiments.

B. Results

The discrimination data are presented first (Fig. 3) so that they can be used to help interpret the target detection results later in Fig. 4. The abscissa marks the four spatial-amplitude combination conditions. The ordinate displays the relative level in the right loudspeaker required for discrimination from the front loudspeaker alone. Only small differences were noted between the results for the naturally roving level and the rms-equated stimuli. The purpose of the using the natural rove was to make the possible use of loudness cues available in the addition of the second loudspeaker less reliable. However, this appeared to have little effect. Because of the similarity across the "N" and "Eq." processing conditions, only the results for the natural rove will be discussed. There was a fairly wide variation across listeners, but the mean data show that the just-noticeable difference (jnd) for FR versus F alone occurred when the right loudspeaker was attenuated by 9 dB, whereas the jnd for the RF masker was obtained at a mean attenuation of approximately 16 dB.

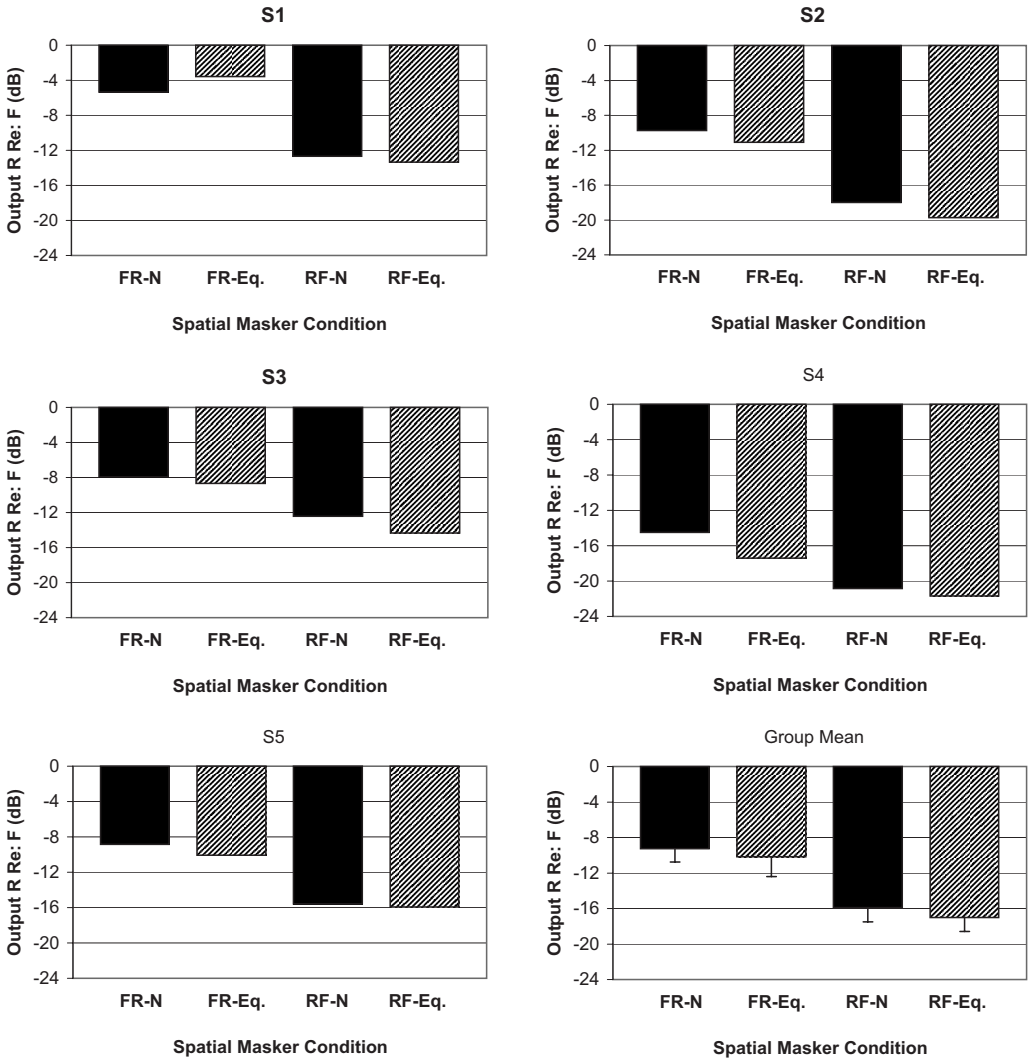

FIG. 3. Just-noticeable difference (jnd) in dB for discrimination of the spatial maskers from the nonspatial masker for five subjects and for the group. Jnd is expressed as right loudspeaker output relative to the fixed front loudspeaker output of 40 dBC. For each spatial masker, data are shown for the natural amplitude varying condition ("N") and the amplitude equated condition ("Eq."). Vertical bars for the group mean data display one standard error.

Paired samples *t*-test results showed that this was a statistically significant difference [$t(4)=10.6$; $p<0.001$]. The fact that the right loudspeaker output could be detected at a lower level for the RF masker may be attributable to a broadened or split spatial impression similar to that reported in lateralization studies in time-intensity trade conditions (Hafter and Jeffress, 1968; Hafter and Carrier, 1971). Rakerd and Hartmann (1985) suggested that the large variations in time-intensity trade data reported in the literature might be attributable to listeners expectations of the reliability and plausibility of conflicting directional cues.

Figure 4 displays target threshold for the two maskers as a function of right loudspeaker attenuation. Also shown for each subject is the F-F mean threshold for the last four of ten training runs (open square), which was assumed to be the value that the thresholds would approach as right loudspeaker output was attenuated and spatial release from informational masking was virtually eliminated. For all but S3, the functions for F-FR progressed from low thresholds averaging about 25 dB sound pressure level at 0 dB attenuation to higher thresholds approaching the F-F results at 16 dB attenuation. Thus, for the most part, 16 dB of attenuation effectively eliminated all effect of the right loudspeaker in producing release from masking. The progression varied among individual listeners. For example, S1's data show a large change between 12 and 16 dB while S4's data show the largest change with the first 4 dB of attenuation. For the other subject, S3, it appears that additional learning took place during the collection of the data such that performance actually improved as the experiment progressed and the attenuations increased. A 5 dB difference between F-FR with 0 dB attenuation (left-most data point) and the most attenuated condition occurred, but this was not nearly as large as the original F-FR versus F-F difference of 19 dB for that subject. The relationships between the F-RF and F-FR results are difficult to summarize on an individual subject basis, except to state that when there was a difference between the two thresholds the F-RF was usually lower. When thresholds were averaged across subjects (bottom-right panel), the RF masker provided a slightly but consistently greater release from masking relative to the FR masker for each right loudspeaker attenuation value (range of 0.55–2.93 dB). How-

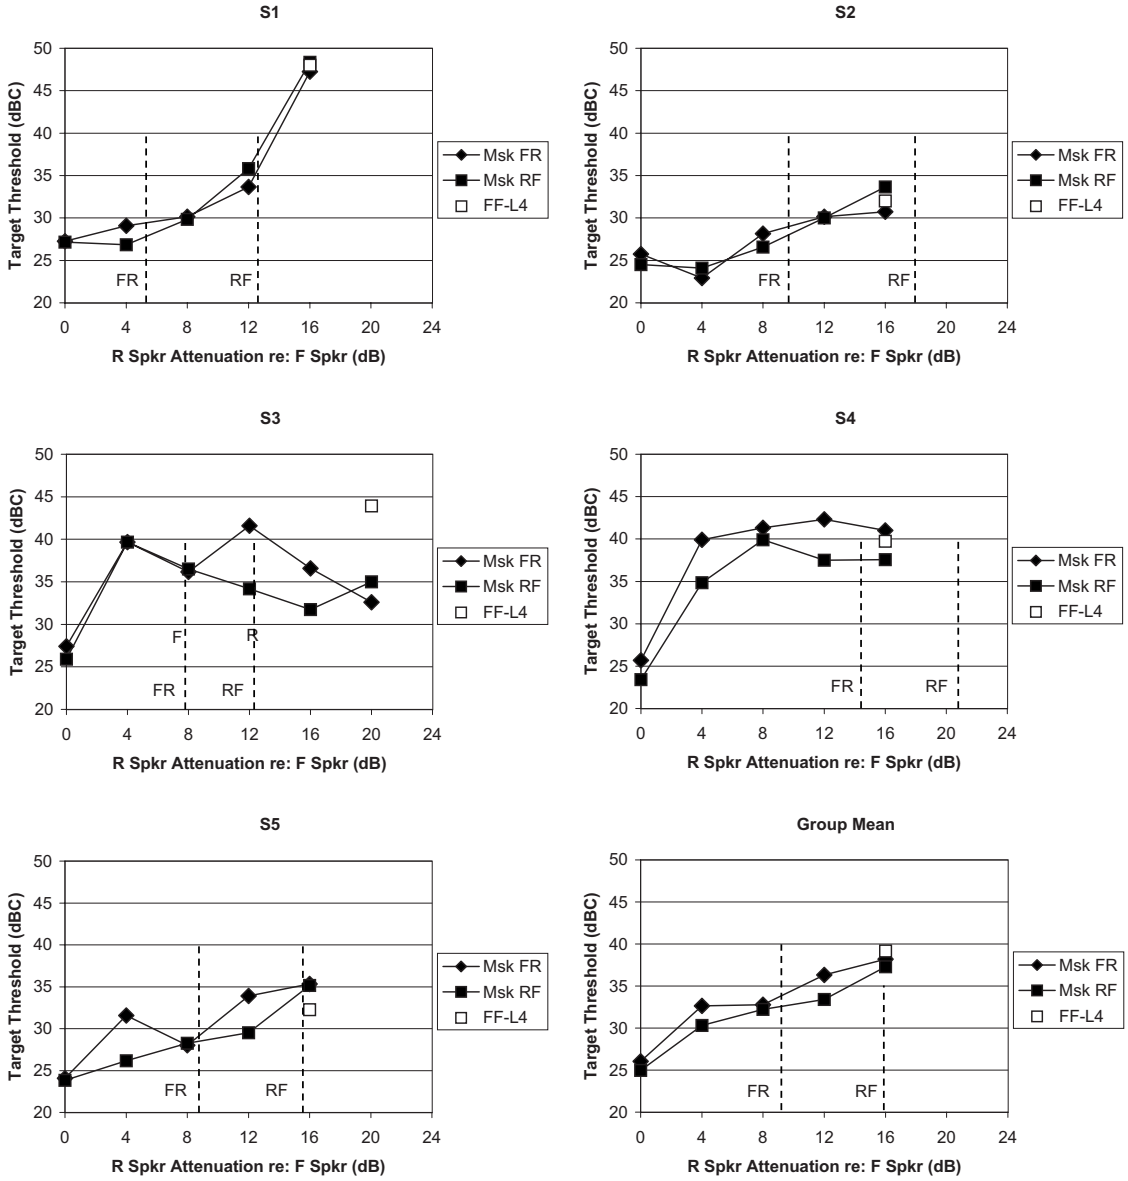

FIG. 4. Target thresholds for two spatial maskers for five subjects and for the group as a function of right loudspeaker attenuation. Dashed lines intersecting the abscissa replot the jnd values for each spatial masker from Fig. 3.

ever, analysis of variance results showed that these were not statistically significant [$F(4,1)=4.5$; $p=0.102$].

For comparison with the discrimination data, the natural-rove data from Fig. 3 are replotted in Fig. 4 as indicated by the dashed lines. These lines indicate the right loudspeaker attenuation values along the abscissa at which the spatial masker was just barely discriminable from the nonspatial. The comparison reveals the relationship between the threshold level of the right loudspeaker presentation and the effectiveness of the addition of the right loudspeaker in releasing masking for the front-only target words. Consider the group data first (bottom-right panel). The average just noticeable difference (jnd) for the F-FR configuration was approximately 9.3 dB of attenuation. Were the FR masker to be used with this right loudspeaker output level, the interpolated target detection threshold would be approximately 33.9 dBC (that is, the point at which the FR dashed line intersects the filled diamond trace depicting the FR threshold function). However, the nonspatial F-F threshold (unfilled square) was actually about 39.2 dBC. This means that 5.3 dB improvement in target detection for the FR masker took place at right loudspeaker attenuation values where the discrimination between FR and F was below 71% correct. In the case of one subject, S1, *most* of the improvement occurred at attenuations where FR and F configurations were less than one jnd apart. Thus, it must be concluded that spatial release from masking can occur with barely discriminable spatial differences between target and masker.

As had been shown in Fig. 3, detection of the signal from the right loudspeaker occurred at lower right loudspeaker output levels for the RF configuration than for FR (distance between the dashed lines along the abscissa). However, when the RF masker was used with the front-only target words, this RF-FR difference did not translate to correspondingly large or consistent changes in release from masking of the target words (difference between squares and

diamonds along the ordinate). This may have been because at low right-loudspeaker levels the RF masker likely produced split images, with one image remaining near the target and creating the same type of confusion caused by the front loudspeaker masking alone. If so, the lack of masking release would not be unlike what was observed by Brungart *et al.* (2005) and Rakerd *et al.* (2006). In those studies, masking release in the spatial maskers disappeared at long delays between the front and right loudspeakers where it was assumed that images were split.

IV. DISCUSSION

In these studies, a standard psychophysical multiple-interval forced-choice detection procedure using monosyllabic words revealed substantial evidence of spatial release from informational masking for speech stimuli. We believe that the general paradigm holds promise for helping to understand the commonalties and differences in what has been called informational masking for both speech and nonspeech stimuli.

In Experiment 1 we gathered basic information about informational masking and masking release using this word detection paradigm. We investigated (1) the S-N ratios at which base line performance could be obtained, (2) the size of the spatial release from informational masking that could be observed, (3) the dependence of informational masking on the understandability of the masker, and (4) the kinds of spatial differences that are required for spatial release from masking.

With regard to (1) above, the detection of words in the presence of two-talker masking was shown to produce thresholds of approximately −25 dB S-N ratio in spatial conditions, where informational masking was presumably minimal. By contrast, threshold *recognition* performance for sentence targets occurred around −10 dB S-N ratio in a recent study also using two-talker speech maskers (Freyman *et al.*, 2007). Others have found low threshold S-N ratios in recognition studies in spatial conditions using single-talker maskers (e.g., Hawley *et al.* 2004); however, less informational masking is expected than with two-talker maskers (e.g., Yost *et al.*, 1996; Freyman *et al.*, 2004). The advantage of the low threshold S-N ratio observed in the present study is that there is ample headroom to observe the effects of informational masking that may occur in nonspatial conditions without bumping into what might be a ceiling for informational masking at around 0 dB S-N ratio. The availability of this headroom could be useful for studying how a variety of stimulus manipulations affect informational masking, and could also make it easier to study informational masking in populations that have higher base line thresholds (see Arbogast *et al.*, 2005).

The second question concerned the size of the spatial release from masking that would be observed with these methods and stimuli. The answer was 17–20 dB for the natural and time-reversed speech maskers, respectively. All of the effect is presumed to be the result of release from informational masking. The basis for this assumption is that the spatial conditions used in this study have not been shown to produce masking release with purely energetic maskers (e.g., Freyman *et al.*, 1999; Brungart *et al.*, 2005; Rakerd *et al.*, 2006), even when using this very same detection paradigm (Freyman *et al.*, 2006). Under the further assumption that informational masking is approximately zero in the spatial conditions, a spatial release of 17–20 dB is indicative of informational masking of the same magnitude. This value is considerably larger than the approximately 5 dB of informational masking estimated with the same maskers for sentence-level target recognition (Helfer and Freyman, 2005; Freyman *et al.*, 2007). Helfer and Freyman (2005) also obtained detection thresholds for sentences against these maskers; the informational masking measured was about 6 dB, suggesting that the use of word level stimuli was a major contributing factor to the greater informational masking seen in the current experiment. A comparison of the word detection thresholds obtained in the current work with the sentence detection thresholds from Helfer and Freyman (2005) revealed that virtually all of the difference occurred in the nonspatial (F-F) condition (−17 dB S-N ratio in the earlier paper, and approximately −7 dB in the current study). This suggests that informational masking was greater for words than for sentences.

In restricting the task to word detection, our results more closely approximated the size of informational masking effects reported for brief nonspeech stimuli by other investigators. For instance, Kidd *et al.* (1998) obtained up to 15 dB of masking release at a spatial separation of 60° for pattern recognition in the presence of informational maskers. Using a detection paradigm, Oxenham *et al.* (2003) found on the average 10 and 25 dB of informational masking for a 1 kHz tone burst for musicians and nonmusicians, respectively. Oh and Lutfi (1999) estimated 11–12 dB informational masking for everyday sound maskers when they were easily recognized by subjects. It is also possible to observe large amounts of informational masking (on the order of 15 dB) in speech recognition studies (e.g., Arbogast *et al.*, 2005). However, these results have been reported for stimuli such as filtered coordinate response measure (CRM) sentences (Bolia *et al.*, 2000) and conditions specifically designed to maximize informational masking and minimize energetic masking.

The fact that spatial release is so large in our detection experiment may reflect a difference in the cues listeners are likely to use in the spatial and nonspatial conditions. In the two spatial conditions, F-RF and F-FR, the spatial image produced by the masker was different from that of the target, and the listener had only to detect the presence of any stimulus appearing to come from the front loudspeaker. By contrast, in the F-F condition both target and masking sounds appeared only from the front. In order to extract the target from the midst of an ongoing two-talker mixture of voices it was necessary to attend to other cues. At a minimum, subjects could have listened for the presence of the words with which they had been familiarized, abrupt amplitude changes, the voice characteristics of the target talker, or other linguistic features that separated the target speech from the masker speech. The threshold S-N ratios in the F-F condition (−7 dB average of natural and time-reversed maskers) suggest that none of these characteristics was easy to extract until the

target was within a few dB of the speech level of the individual talkers within the two-talker masking complex.

The third question considered in Experiment 1 was whether time reversing the masker would affect the amount of informational masking measured with this task. Results showed that masker time reversal produced no reduction in masking in either the spatial or nonspatial conditions. Indeed, a slight (though statistically insignificant) increase of about 2 dB was noted for the time-reversed speech masker. By contrast, sizable reduction of masking efficacy has been shown with masker time reversals for the recognition of short "everyday" sentences (Rhebergen *et al.*, 2005), nonsense sentences (Freyman *et al.*, 2001), and CRM stimuli (Marrone *et al.*, 2007). In recognition tasks, the absence of meaningful words in the masker could eliminate one of the main sources of confusion which, at least for CRM stimuli, is clearly supported by error patterns (Kidd *et al.*, 2005). By contrast, understandability could be less relevant in the detection paradigm used in this study, because any detectable portion of the target (such as a phoneme) can improve performance. The listener is able to use—and may even be dependent on—the phonological or linguistic information present in overlapping masker-target consonant and vowel segments rather than on word meaning and context cues. Thus, time reversing the speech masker does not reduce confusability between target and masker, because the confusion lies not at the word level but at the segmental level.

The absence of an effect of masker time reversal suggests that the speech-on-speech masking measured in the current study could be quite unlike the type of informational masking revealed when, for example, two or three CRM sentences compete with one another for attention (e.g., Ericson and McKinley, 1997; Arbogast *et al.*, 2002; Brungart and Simpson, 2002; Brungart *et al.*, 2005; Kidd *et al.*, 2005; Shinn-Cunningham *et al.*, 2005; Rakerd *et al.*, 2006). The difference may lead to the concern that a common terminology is being applied to different masking processes. However, although it would appear that in this study we measured the effect of a type of auditory confusion that is closer to what is seen in nonspeech informational masking, it would be premature to conclude that the speech-on-speech masking measured in this study had no linguistic basis. Even the time-reversed masker could be clearly recognized as speech. Listeners may have imposed the phonological and lexical rules of English to "extract" the target segment from the speech surround, in both natural and time-reversed speech maskers. It will likely require more work to identify the linguistic and nonlinguistic factors contributing to informational masking in this study.

A final question asked in Experiment 1 concerned the kinds of spatial differences between target and masker that are effective in releasing informational masking. The F-RF condition, where the masker from the right loudspeaker leads the presentation from the front loudspeaker, produces a dramatic target/masker spatial difference in which the masker is heard well to the right of the target. The F-FR condition, in which the front masker leads the right masker, still produces a noticeable spatial difference, but the change is more difficult to characterize. According to accounts from several papers (e.g., Shinn-Cunningham *et al.*, 1993; Litovsky and Macmillan, 1994; Chiang and Freyman, 1998) as well as classic texts on the spatial hearing (Blauert, 1997), the auditory image produced by a two-source masker such as the FR masker is expected to be less punctate than that of the single-source, front-only target, with the center of gravity shifted to the right by perhaps 5–10°. Despite the seemingly less obvious target-masker differences in the F-FR configuration, in *recognition* experiments release from masking relative to F-F was nearly the same for F-RF and F-FR configurations (Freyman *et al.*, 1999; Brungart *et al.*, 2005; Rakerd *et al.*, 2006). The current paper (Fig. 1) shows that this same result is obtained also for the word detection task. This suggests that small differences in spatial separation and/or spatial width cues are no less efficient in releasing informational masking than the dramatic spatial separation provided by the right-leading F-RF masker. The implication is that target-masker perceptual spatial differences other than spatial *separation* can be potent facilitators of release from masking.

In Experiment 2 we exploited the forced-choice word detection technique, and the large spatial release it produces, to explore further the subtlety of spatial difference required for masking release in the F-FR configuration. We titrated the more than 15 dB of difference in thresholds available between F and FR configurations by attenuating the output of the right loudspeaker in F-FR until the results were essentially no different than F-F. The functions were then related to the results of a second portion of the experiment, which determined the threshold of discrimination between F and FR maskers with systematic attenuation of the right loudspeaker in the FR condition. For comparison, all conditions were repeated with the RF masker, but still with attenuation of the right loudspeaker.

The 4AFC task with a two-down one-up stepping rule estimates a d' of 1.53 (Macmillan and Creelman, 1991). Using that threshold criterion, the mean just discriminable difference between FR and F alone occurred when the right loudspeaker was attenuated by 9 dB. With that same 9 dB of attenuation, an average of 5 dB of spatial release from masking still occurred in the F-FR configuration. Thus, it must be concluded that spatial release from masking can be observed with barely discernable target-masker spatial differences. This is consistent with other studies showing that small changes in masker-target spatial relationships can substantially affect target recognition (e.g., Brungart *et al.*, 2005; Gallun *et al.*, 2005).

There are also at least two observations in the literature where the opposite occurred, i.e., presumably large spatial differences between target and masker produced no release from masking (Brungart *et al.*, 2005; Rakerd *et al.*, 2006). In both of these cases release from masking disappeared when the delay in a two-source speech masker was increased from 32 to 64 ms. Presumably, the 64 ms delay produced split images for the masker, one near the front target and one near the lateral masker. Informational masking is attributed to the masker image located near the target. In the current Experiment 2, attenuations applied to the right loudspeaker were much more easily detected in the RF configuration than the FR configuration, but the release from masking created was

only marginally increased (Fig. 4) and did not reach statistical significance. It is possible that the severe attenuation applied to the leading (right) loudspeaker in the RF case produced a split image due to the time-intensity incompatibility and may have failed to produce increased release from masking for the same reasons presumed to occur in the Brungart *et al.* (2005) and Rakerd *et al.* (2006) studies. If this is indeed the explanation, then it is fascinating that listeners cannot use this additional synchronized separated image to inform them of the temporal characteristics of the masker in order better focus on the target. This kind of active study of the masker in order to learn what to ignore does not appear to be used or useful. Rather, barely discriminable differences between the spatial image produced by the target and the most similar image produced by the masker seem to facilitate improved attention on the target.

Relative weights for frequency glide detection using narrowband noise[a)]

Jinyu Qian[b)] and Virginia M. Richards
Department of Psychology, 3401 Walnut Street, Suite 302C, University of Pennsylvania, Philadelphia, Pennsylvania 19104, USA

(Received 18 July 2006; revised 8 February 2008; accepted 18 February 2008)

Narrowband noise stimuli were used to derive relative weights for detecting frequency glides in a yes/no procedure. One stimulus set was restricted to the duration of the glide. For the second stimulus set, there were fringe noise bands preceding and following the glide. For both sets, the center frequency of the linear glide was either fixed at 1000 Hz or randomly chosen on each trial from the range of 800–1200 Hz. Relative weights as a function of time were derived using a linear model and the linear classification method [A. Ahumada, J. Vis., **2**, 121–131 (2002)]. Sensitivity was better for the fixed- than random-frequency conditions, and weight patterns from the random-frequency conditions were less reliable than those obtained from the fixed-frequency conditions. The magnitudes of the relative weights tended to be larger for the second half of the stimulus, suggesting that subjects paid more attention to the later than the earlier parts of stimuli. In the random-frequency conditions, the linear model failed to account for subjects' performance unless the stimuli were expressed in terms of relative changes in frequency rather than absolute frequency. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2897030]

I. INTRODUCTION

Hartmann and Klein (1980) provided a signal-detection theoretical model to evaluate sensitivity to frequency modulation. As they point out, assuming the signal is known exactly, an ideal observer would cross correlate the stimulus with an internal template that is a copy of the signal to be detected. Noting that subjects can detect the modulation at signal levels smaller than those required in order to discriminate between forms of modulation (e.g., sinusoidal versus triangle frequency modulation), Hartmann and Klein suggested that the modulation form cannot be known exactly. Thus, they proposed that subjects sample the pitch of the stimulus, and difference the samples in order to detect the presence of modulation (see also Demany and Semal, 1989).

Here, the signal-detection theoretic approach noted by Hartmann and Klein is revisited with the goal of estimating the internal template for the detection of ascending frequency glides. The psychophysical estimate of the template is relative weights as a function of time, which will be referred to as the temporal weight pattern or TWP. The questions of interest include: What is the form of the TWP? And whether the TWPs can account for the human detection performance.

For the ideal observer model, the template for the detection of an ascending linear frequency glide is itself an ascending linear glide, with negative values for the first half and positive values for the second half of the template. In addition, the relative weights that form the template sum to zero. For each yes/no trial, a decision variable would be the inner product of the template and the stimulus vectors. A decision can be made by comparing the resulting decision variable to a criterion. Therefore, for the ideal observer, the decision variable for a constant-frequency tone (no-glide tone) would be zero and that for an ascending tonal glide would be positive valued. Additionally, the sum-to-zero template would lead to decision variables independent of the central frequency (the frequency at the temporal midpoint of the tonal glide) variation across presentations. Therefore, the ideal template predicts no effect of randomizing the central frequency of the glide stimuli.

Human listeners might likewise make their decisions based on a comparison between an internal template and the stimulus, noting that the template may not be ideal. In addition to the work of Hartmann and Klein (1980), two additional psychophysical results suggest possible deviations of the listeners' actual internal templates from the ideal template. First, several investigators (Madden and Fire, 1996; Moore and Sek, 1998; Sek and Moore, 1999) have reported that the threshold for detecting a change in the frequency extent of tonal linear glides is higher when the central frequencies of the stimuli are random across presentations compared to fixed. Second, Moore and Sek (1998) have shown that the effects of central frequency randomization on thresholds are not always as large as expected if subjects depended on the frequencies solely at the stimulus onset or solely at the stimulus offset.

When the central frequency is drawn at random, neither the beginning nor the ending portion of the stimulus alone indicates whether or not a glide is present. The difference between these two portions, however, is invariant with respect to central frequency randomization. In terms of tem-

plates, "listening" only at the beginning of the stimulus implies non-zero relative weights only at the stimulus onset. As a result, the decision variable would reflect only the initial frequency. For the strategy of "differencing" the beginning and the ending frequencies, similar to the ideal template, the relative weights at the stimulus onset and offset would be of equal magnitude, but opposite sign. On one hand, the available psychophysical data suggest a form of differencing the beginning and ending portions of the stimuli because the listeners' thresholds are superior to those expected if listeners were attending to, for example, just the initial frequency region of the stimuli (Moore and Sek, 1998). On the other hand, the differencing is not perfect; otherwise there would be no effect of frequency randomization at all. It is as though listeners fall between these two extremes, perhaps over weighting the initial or ending portions of the stimuli, but still differencing the frequencies of the initial and ending portions. Such a template would yield decision variables that are only somewhat influenced by central frequency randomization, consistent with the human literature.

Combining intuitions based on the ideal weight pattern and expectations based on psychophysical results, one might suggest the following expectation regarding the form of listeners' internal templates for detecting ascending frequency glides. The estimated internal templates should follow a negative-to-positive form, and the magnitudes of the initial negative and the ending positive regions should not be equal.

This prediction regarding subjects' internal templates suggests variations in the perceptual importance of different temporal segments of the glide stimuli. Since the beginning and ending frequencies are most informative for the detection of glides, they should be weighted heavily and the absolute values of the relative weights associated with these frequencies should be large. To emphasize the beginning and ending frequencies of glides, it is of interest to include conditions where two constant-frequency fringes were added at both ends of the glides to match the beginning and ending frequencies. The expected internal templates in these conditions should have large absolute values associated with the fringes.

In the current study, the internal templates for the detection of frequency glides were estimated when the central frequency of the stimuli were either fixed or randomly chosen across presentations. The stimuli were either frequency glides alone or glides with the beginning and the ending fringes depending on conditions.

The method used to estimate the template is based on Ahumada's (2002) "classification image" approach, where the template is the pattern of relative weights as a function of time. The advantage of Ahumada's approach for estimating relative weights, compared to other methods, is that the method can simply be applied to stimuli that vary continuously in time without requiring temporal "bins" (e.g., Berg and Green, 1990; Dai and Berg, 1992; Buus *et al.*, 1996; Turner *et al.*, 1998; Richards and Tang, 2006).

Ahumada's (2002) approach is, roughly, as follows. In a Yes/No procedure the subject indicates either "yes signal" or "no signal." Normally distributed random perturbations are added to the signal and no-signal stimuli. As an example, for a two-dimensional visual stimulus, the perturbations are added on a pixel-by-pixel case. After data collection, the stimuli are categorized conditioned on listeners' responses, yielding hit, false alarm, miss and correct rejection stimuli. Then, the perturbations for the trials that led to "yes" responses (hits and false alarms) are averaged (pixel-by-pixel) across trials, the perturbations for the trials that led to "no" responses (correct rejections and misses) are averaged across trials, and the latter image is subtracted from the former image. The resulting image provides an estimate of the subject's internal template, or a "classification image."

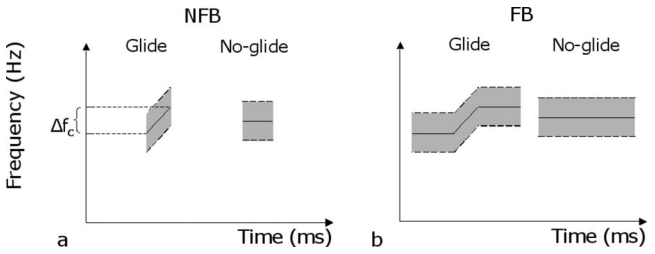

FIG. 1. Schematic spectrograms for the no-fringe-band (NFB, panel a) and fringe-band (FB, panel b) stimulus sets. The abscissa indicates time and the ordinate indicates frequency. Δf_c is the extent of the frequency glide. Solid lines show the carrier frequency of the narrowband of noise as a function of time and dashed lines delineate the 50 Hz noise bandwidth.

To apply this procedure to estimate the internal template for the detection of a frequency glide, perturbations in frequency as a function of time are required.[1] In the current experiment this was achieved by first applying a tonal frequency glide to a carrier tone and then multiplying the resultant glide by low-pass noise. The resulting narrow bands of noise have continuously changing frequencies. The difference, as a function of time, between the carrier frequency and the actual frequency of the narrow band of noise forms the perturbations in frequency as a function of time. Then, applying the method proposed by Ahumada (2002), the perturbations are used to estimate of the relative weights, which in turn provide a psychophysical estimate of the internal template.

II. METHODS

A. Stimuli and procedures

In a Yes/No paradigm, subjects indicated whether a 50-Hz-wide narrowband noise had a carrier with an ascending linear frequency glide (glide stimulus) or a constant-frequency carrier (no-glide stimulus). Two stimulus sets were tested, and both sets are shown in Fig. 1. The abscissa indicates time and the ordinate indicates frequency. The carrier frequency is shown using a solid line and the width of the narrow bands of noise are indicated using gray shading. The first stimulus set had a 120 ms duration, and the duration of the glide, when present, was also 120 ms. Figure 1(a) depicts these stimuli. For the second stimulus set, the glide-bearing 120 ms narrowband noise was preceded and followed by a 200 ms, 50 Hz band of noise [Fig. 1(b)]. The carrier frequencies of these "fringe bands" matched those of the initial and ending carriers of the glide-bearing portion of the band of noise. Thus, for a glide stimulus, the initial fringe band had a

carrier frequency lower than that of the ending fringe band, and for a no-glide stimulus, the initial and ending fringes had the same carriers. As a result, the listener could determine whether a glide was present using only the information in the fringe bands. This latter stimulus set will be referred to as the FB (fringe band) set, and the former stimulus set will be referred to as the NFB set (no fringe band). Note the NFB and FB stimulus sets parallel the "glide only" and "glide" conditions tested by Lyzenga *et al.* (2004), except that they used tonal glides.

The narrowband noise was generated digitally using the "quadrature multiplication" method (Bernstein and Trahiotis, 1992) in which two independent 25 Hz low-pass noises were multiplied by two tonal carriers, one in sine phase and the other in cosine phase, and the products summed to generate a 50-Hz-wide band of noise. For the NFB glide stimuli the 120 ms "sine" and "cosine" carriers varied linearly in frequency, whereas the no-glide stimuli had constant carrier frequencies. For the FB stimuli, stimulus generation was the same, except the carriers included two 200 ms constant carrier frequency fringes. All stimuli had 5 ms raised cosine rise/fall ramps at the stimulus onsets and offsets.

The central frequencies of the stimuli (the frequency at the temporal midpoint of the tonal carrier) were either fixed at 1000 Hz or randomly chosen from a uniform distribution ranging from 800 to 1200 Hz, yielding the *fixed-* or *random-frequency* conditions, respectively. In all, four conditions were tested: The 120 ms NFB stimuli with fixed (NFB-fixed) or random (NFB-random) central frequencies and the 520 ms FB stimuli with fixed (FB-fixed) or random (FB-random) central frequencies.

The extent of the tonal frequency glide, Δf_c, was the independent variable (see Fig. 1). The values of Δf_c ultimately tested were determined during two practice stages. In the first stage the threshold $\Delta f_c$was estimated using an adaptive tracking procedure in the FB-fixed condition (Levitt, 1971). This required approximately 1 h to complete. In the second stage, trials were blocked by condition and fixed Δf_c was used. The value of Δf_c was chosen with the goal of achieving performance of 75–80 percent correct. Depending on the subject and condition, this second practice stage required a total of 200–1300 trials.

Once the values of Δf_c were determined, data collection proceeded in blocks of 5 sets of 50 trials. Listeners rested between blocks. Listeners ran the FB conditions first. The FB-random and the FB-fixed conditions were intermixed such that blocks were tested using a random schedule. A total of five blocks for each condition were tested. Then the NFB conditions were tested using the same procedure. In all, a total of 1250 trials contributed to the final estimate of d' and to the formation of the TWPs.

Three young adults with normal hearing (<15 dB hearing level) served as subjects. The stimuli were presented diotically over Sennheiser HD410 SL headphones at an overall level of 57 dB sound pressure level with visual feedback following subjects' responses. Subjects were tested in a single-walled sound-attenuated booth in a quiet room. The stimuli were generated by TDT system II hardware controlled by MATLAB software.

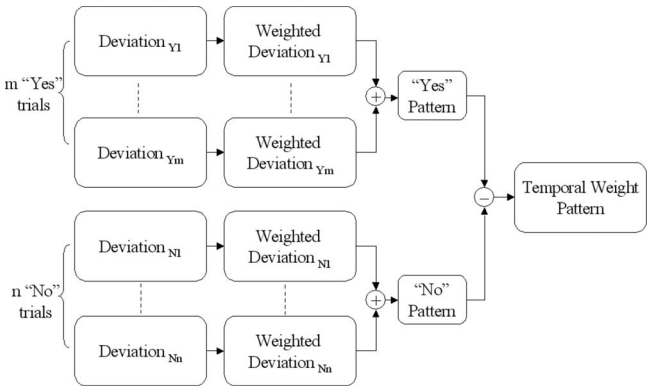

FIG. 2. The procedure for deriving the temporal weight pattern is shown.

B. Computational methods

1. Temporal weight pattern

Figure 2 shows the primary steps used to derive the TWPs. The columns show the computational steps and the rows emphasize that the procedure was applied to each stimulus tested, grouped by listeners' responses ("yes glide" and "no glide"). First, for each stimulus, the instantaneous frequency and envelope were estimated using a Hilbert transform. For stimulus, $x(t)$, with a Hilbert transform $H[x(t)]$, the envelope, $e(t)$, is given by: $e(t)=\sqrt{x(t)^2+H^2[x(t)]}$, and the instantaneous frequency, $f(t)$, is given by:

$$f(t)=\frac{1}{2\pi}\frac{\partial p(t)}{\partial t}, \tag{1}$$

where $p(t)=\tan^{-1}(H[x(t)]/x(t))$ (e.g., Green, 1998). Additionally, it is convenient to define the instantaneous carrier $f_c(t)$:

$$f_c(t)=f_0-\frac{\Delta f_c}{2}g(t), \tag{2}$$

where f_0 is the central frequency of the stimulus, Δf_c is the extent of the frequency glide when present. For the no-glide stimuli, $g(t)$ has a constant value of zero over time. For the glide stimuli in NFB conditions, $g(t)$ increases linearly from −1.0 to +1.0. For the glide stimuli in FB conditions, $g(t)$ has the constant value of −1.0 for the initial fringe, linearly increased values from −1.0 to +1.0 for the glide portion and the constant value of +1.0 for the latter fringe.

Next, the *deviation*, $\Delta f(t)$, of the instantaneous frequency from the instantaneous carrier was calculated as:

$$\Delta f(t)=f(t)-f_c(t). \tag{3}$$

The deviations are depicted in the leftmost column of Fig. 2.

In the third step, the deviations were weighted using a variant of the squared-envelope-weighted average of instantaneous frequency (SEWAIF) of Anantharaman *et al.* (1993; see also Dai, 1993), a model developed to predict pitch estimates for dynamically changing stimuli. In parallel with the SEWAIF model, the deviations of the instantaneous frequency from the carrier were weighted by the squared instantaneous envelope and then divided by the mean value of the squared instantaneous envelope, $\overline{e^2(t)}$:

$$\Delta f_w(t) = \frac{e(t)^2 \Delta f(t)}{\overline{e(t)^2}}, \quad (4)$$

The resulting *weighted deviations* are depicted in the second column of Fig. 2. The weighted deviations, $\Delta f_w(t)$, as a function of time formed the "perturbations" from the carrier frequency and allowed the estimation of the internal template or TWP using Ahumada's (2002) approach.

To form the TWP, i.e., relative weights as a function of time, the weighted deviations ($\Delta f_w(t)$) were categorized in accordance with subjects' responses (Ahumada, 2002). A "Yes" pattern was obtained by averaging the weighted deviations over all trials where the subject responded "Yes" the glide is present. Likewise, a "No" pattern was obtained by averaging the weighted deviations over the trials where the subject responded "No" glide. The ultimate TWP was subsequently formed by subtracting the "No" pattern from the "Yes" pattern, where the "Yes" and "No" patterns were weighted in proportion to the number of "Yes" and "No" responses[2] (final column of Fig. 2). Keep in mind that the estimated TWPs did not depend on the presence or absence of the glide because it was the deviations from the carrier frequency that were being averaged. However, the TWPs did depend on the responses, and therefore reflected subjects' decision processes.

This procedure for estimating the relative weights (Ahumada, 2002) assumes that the perturbations ($\Delta f_w(t)$ in this application) added to the stimulus (the carrier frequency) are normally distributed and statistically independent. The assumption of normal distribution was reasonably met,[3] but the assumption of independence was not. Evaluations of the autocorrelation functions of the $\Delta f_w(t)$ for several of the stimuli suggested consistent non-zero correlations for delays less than 40–50 ms. This represents a significant limitation in the current approach—changes in the estimated TWPs should be viewed with a conservative eye appreciating that there may be correlations in the TWPs that last 40 ms or so.

2. Model evaluation

The TWPs were evaluated from three perspectives. First, were the derived TWPs statistically discernable from zero? Second, was there sufficient information in the TWPs to account for subjects' performance? Third, were the magnitudes of relative weights corresponding to the initial and ending portions of the stimuli approximately the same? The procedures used to address these questions will be addressed in turn.

a. Bootstrap estimate: Are the TWPs statistically different from zero? A bootstrap procedure (Efron and Tibshirani, 1993) was used to evaluate whether the obtained TWPs were statistically different from those patterns based on random responses. For each subject and condition 1250 weighted deviations ($\Delta f_w(t)$) were drawn, with replacement, from the 1250 trials encountered by the subject. Responses of "Yes" and "No" were randomly assigned to each stimulus using proportions consistent with the "Yes" and "No" responses of the subject. Then a TWP was generated. This simulated TWP provided an estimated function for the null hypothesis that the subject-based TWPs contained no information concerning the internal template. The formation of a meaningful TWP requires that subjects' responses be systematically influenced by the perturbations, a relationship not present when responses were randomly assigned. The bootstrap simulation was repeated 100 times. Across the 100 repetitions, the average TWP were near zero. For each point in time, 96% confidence intervals about the average were estimated. The confidence intervals for all points were then averaged across time to form a single 96% confidence interval for each TWP. To the degree the psychophysically derived TWPs exceed the 96% confidence intervals, it would indicate that the obtained TWPs reflected properties of the subjects' responses (and so decision processes), not properties of the stimuli.

b. d' based on estimated TWPs. Values of d' based on TWPs (d'_{wgt}) were compared with the psychophysically obtained values of d' (d'_{obs}). The d'_{wgt} represents the best possible d'_{obs} subjects can reach if the derived TWPs were their exact internal templates on every trial, and there was no added "internal noise". Should the d'_{obs} exceed the d'_{wgt}, the linear model (specified below by Eq. 5) would fail to account for the psychophysical data. An opposite pattern would indicate that the TWPs contained enough information to account for subjects' performance. The approach used was similar to that used by Berg (1990).

The procedure used to estimate d'_{wgt} was as follows, and was repeated for each subject and condition. First, a decision variable β was computed for each trial. The decision variable was the inner product of the TWP (indicated as $W(t)$ below) and the weighted instantaneous frequency (i.e., $f_w(t) = \Delta f_w(t) + f_c(t)$) of the stimulus on that trial (trial i):

$$\beta_i = W(t) \bullet f_w(t)_i. \quad (5)$$

Equation (5) defines a linear detection model, in which the values of the decision variable β are a linear combination of the stimulus and the TWP. For a zero-mean TWP that resembled the form of the tonal carrier of the glide stimulus [see Fig. 1, solid lines] the βs for the glide stimuli would have a positive mean and the βs for the no-glide stimuli would have a zero mean.

Next, the βs were categorized depending on whether the stimulus was a glide or no-glide stimulus (β_g and β_{ng}, respectively). The distribution of the resulting βs was close to a normal distribution. Then, the two distributions of β_g and β_{ng} were fitted using a Gaussian distribution, $\hat{\beta}_g \sim N(\mu_g, \sigma_g^2)$ and $\hat{\beta}_{ng} \sim N(\mu_{ng}, \sigma_{ng}^2)$, where μ and σ^2 represent the mean and the variance of the estimated distributions. Finally, the d'_{wgt} was estimated as

$$\mathrm{d}'_{\mathrm{wgt}} = \frac{\mu_g - \mu_{ng}}{\sqrt{\frac{\sigma_g^2 + \sigma_{ng}^2}{2}}}. \quad (6)$$

A second model was also applied to the results of the random-frequency conditions. It was assumed that subjects formed representations of the frequency glides independent of the central frequency. For this model, the stimuli were translated to have the same central frequency, and the model was applied to the resulting stimuli. This model will be referred to as the *frequency-translation model*. The resulting values of d'_{wgt} will be indicated as $\tilde{d}'_{wgt}$ for this model. This model allows the determination of whether the predicted sensitivity improved when frequency randomization

TABLE I. For each subject and each condition, values of Δf_c (in Hz) and d' are listed.

		NFB			FB		
Conditions		S1	S2	S3	S1	S2	S3
Fixed frequency	Δf_c	46	44	42	16	18	20
	d'_{obs}	1.52	1.38	1.51	1.76	1.72	1.62
Random frequency	Δf_c	46	64	60	24	18	26
	d'_{obs}	1.60	1.42	1.72	1.76	1.49	1.52

was removed. The procedures used to estimate $\tilde{d}'_{wgt}$ were the same as those described above, except the central frequencies were translated to 1000 Hz prior to the formation of the decision variables, the β_is.

c. Comparisons of the magnitudes of the initial and ending portions of TWPs. As will be presented in the Results section, the TWPs derived from the current study were consistent with the expectations based on previous psychophysical results (Madden and Fire, 1996; Moore and Sek, 1998; Sek and Moore, 1999): The TWPs shared a negative-to-positive form, and unlike the ideal template, the magnitudes of the negative and positive weights tended to be different. That result led to two questions: (1) Whether subjects relied relatively more on the initial or the ending portion of the stimuli in order to make their detection decisions, and (2) was there a relation between the subjects' relative reliance on the initial/ending portion and their sensitivity? To address these questions, the ratio of the magnitudes of the relative weights from the ending *re*. initial portions of the TWPs was computed. If the ratio was approximately unity it would suggest equal weighting of the initial and ending portions of the stimuli. Additionally, consistent with the ideal template, should the TWP follow the negative-to-positive form, the initial negative and the latter positive portions would "cancel" the influence of the central frequency on decision variable β. This TWP would predict little or no effect of central frequency randomization. In contrast, a ratio either larger or smaller than unity would suggest subjects relied more on either the ending or initial portion of the stimuli, respectively. This result would predict a detrimental effect of central frequency randomization because the initial negative and the latter positive portions could not fully "cancel" the influence of the central frequency randomization.

These ratios of the magnitudes of the ending *re*. initial relative weights were estimated using different methods depending on the stimulus set. For the NFB conditions, the values were calculated by taking the ratio of the absolute values of the maximal (which occurred at toward the end of the TWP) *re*. the minimal (which occurred toward the initial part of the TWP) relative weights. For the FB conditions the relative weights from the initial and ending 200 ms fringe regions of the stimuli were separately averaged, and the ratio of the magnitudes of the averaged ending *re*. initial relative weights was computed.

To provide a statistical evaluation of the magnitude ratios, additional simulations were run. In each condition, the assumed TWP had the same form as the carrier frequency of the glide stimuli (see Fig. 1, solid lines), but the relative weight of the temporal middle of the TWP was zero. The stimuli from subject 2 (S2) were used for the simulation. First the 1250 stimuli were drawn, with replacement, from among the 1250 stimuli tested. Then, the inner product of the assumed TWP and $f_w(t)$ for each stimulus was obtained [Eq. (5)] and a zero-mean normal deviate was added to form the decision variable. The standard deviation of the zero-mean deviate was adjusted so as to approximate d'_{obs} for S2 in each condition. Simulated responses of "Yes" or "No" were assigned depending on whether the resulting decision variable was above or below the criterion, respectively. The criterion was the average decision variable across all trials. Once simulated responses were obtained, simulated TWPs were generated using the same methods as for the human subjects. This process was repeated 40 times, yielding 40 simulated TWPs for each of the four conditions. The ratio of the magnitudes of the ending and initial relative weights was calculated for each of the 40 replicate simulations. In each condition, the higher and lower boundaries of the 96% confidence interval of the ratios for the simulated TWPs were determined by adding or subtracting 2.054 times the standard deviations from the mean ratio across the 40 replicate indices.

III. RESULT AND DISCUSSION

A. Psychoacoustic results

Table I shows the frequency extents (Δf_c) used for each subject in each condition. The measured values of d'_{obs} are also listed. Given that the values were obtained from a Yes/No procedure, relative criteria (response bias) were also estimated (Macmillan and Creelman, 1991). The relative criteria were near zero, ranging from −0.1 to 0.2 across subjects and conditions, with S1 producing the largest relative criteria. For approximately equal values of d'_{obs}, Δf_cs were larger in the NFB than the FB conditions, and typically larger for random- than fixed-frequency conditions. These results were consistent with past work demonstrating the advantage of the fringe portions (e.g., Lyzenga *et al.*, 2004) and the disadvantages of frequency randomization (e.g., Madden and Fire, 1996; Moore and Sek, 1998; Sek and Moore, 1999), although in those studies the frequency extents at threshold were substantially smaller because the stimuli were tones rather than narrow bands of noises.

B. Estimated temporal weight patterns

The bold curves in Fig. 3 show the TWPs (relative weights as a function of time) for S1, whose results are as representative as any other subject. These results are shown separately to provide an example of the derived TWPs and the 96% confidence intervals associated with random responses. The left panels show the results for the NFB conditions and the right panels are for the FB conditions. Upper panels are for the fixed-frequency conditions and lower panels are for the random-frequency conditions. The shaded areas show the 96% of confidence intervals for TWPs derived

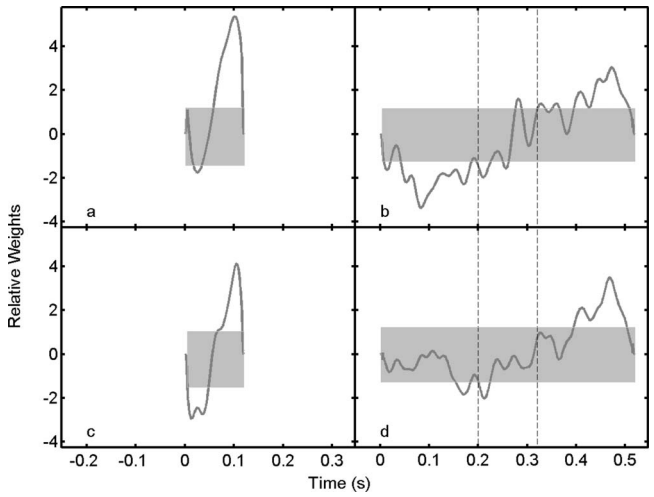

FIG. 3. Temporal weight patterns, i.e., relative weights as a function of time, derived from S1's responses for (a) NFB-fixed, (b) FB-fixed, (c) NFB-random and (d) FB-random conditions. The shaded areas specify the 96% confidence interval about the pattern derived from random responses. The vertical dashed lines in the right panels indicate the temporal regions associated with the glide-bearing portions of the stimuli.

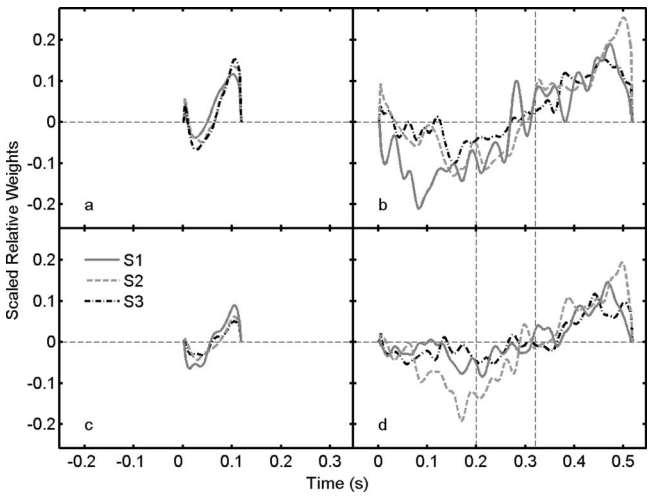

FIG. 4. Temporal weight patterns scaled by the inverse of Δf_c in (a) NFB-fixed, (b) FB-fixed, (c) NFB-random and (d) FB-random conditions. Data from different subjects (S1, S2, S3) are plotted using different line types. Weights of zero are specified by the horizontal dashed lines. The vertical dashed lines in the right panels indicate the temporal regions associated with the glide-bearing portions of the stimuli.

from unrelated to the presence/absence of the glide. The vertical dashed lines in the right panels indicate the temporal regions associated with the glide-bearing portions of the stimuli. The TWPs shifted from negative to positive values. This suggested that S1 contrasted the early and later frequencies rather than relying exclusively on just one or the other in making detection decisions. Moreover, there were substantial regions where the TWPs exceeded the confidence intervals, indicating that the obtained TWPs contained reliable information regarding S1's decision process. Note that the TWPs were constrained to start and end at zero.

The TWPs were scaled by the inverse of Δf_c in an effort to provide a direct comparison of the TWPs across conditions and subjects. For an ideal observer (assuming the linear model specified by Eq. (5) was correct and assuming the hypothetical observer maximized percent correct), such scaling would provide TWPs independent of Δf_c. In the current experiment the results were unlikely to be ideal, and so a slight error was assumed for this scaling procedure. Even so, this approach allowed a means of comparing the magnitudes of the relative weights across conditions and subjects.

Figure 4 shows subjects' individual TWPs scaled by the inverse of Δf_c for all conditions. The panels are arranged as in Fig. 3. The vertical dashed lines in the right panels indicate the temporal regions associated with the frequency glide. The results for different subjects are plotted using different line types. The results from Fig. 3, after scaling, are reproduced using the solid gray lines.

1. Comparisons of TWPs across conditions

Two common features were apparent in the obtained TWPs: (1) There was a clear negative-to-positive pattern in all TWPs, and (2) Most of the negative weights were in the first half of the TWPs and most of the positive weights were in the second half. Subjects' processing strategies were consistent with a linear model in which the first and second halves of the stimuli were differenced.

A third feature of the TWPs, not apparent in Fig. 4, was that for all but the FB-random conditions, the 96% confidence intervals were exceeded in both the beginning and ending portions of the TWPs. In the FB-random condition, the TWPs generally exceeded the confidence intervals only in the latter portion. This result might indicate a failure of the linear model in providing a reliable description of subjects' strategies in the FB-random condition, a possibility that will be considered more fully below (Sec. III B 2). Overall, however, the approach appears to have been successful in providing reliable and meaningful patterns of relative weights across time.

Across conditions, differences among TWPs were apparent. First consider the differences between the TWPs derived in the fixed- and random-frequency conditions. The magnitudes of the scaled weights were larger for the fixed than the random conditions. Moreover, the magnitudes of the weights were larger in the latter portion than the beginning portion of the TWPs. These greater magnitudes of the weights in the latter portion were clearer in the TWPs derived from the fixed- than random-frequency conditions. This suggested that, for the fixed-frequency conditions subjects relied more heavily on the ending frequency than the starting frequencies in decisions regarding the presence of a frequency glide. The relative magnitudes of the beginning and ending portions of the TWPs are considered more fully below (Sec. III B 3).

Next, consider the TWPs derived in the NFB and FB conditions. Restricting the comparison to just the glide portion of the TWPs, the extent of the scaled weights were roughly similar in the FB and NFB conditions, but the proportion of the TWP that fell outside the 96% confidence interval was much larger for the NFB condition (see Fig. 3 for an example). This suggests that subjects may have at-

TABLE II. Values of d'_{obs}, d'_{wgt}, and $\tilde{d}'_{wgt}$ are listed for each subject in fixed- and random-frequency conditions.

		NFB			FB		
Conditions/model		S1	S2	S3	S1	S2	S3
Fixed frequency	d'_{obs}	1.52	1.38	1.51	1.76	1.72	1.62
	d'_{wgt}	1.73	1.72	2.02	2.53	2.43	2.76
Random frequency	d'_{obs}	1.60	1.42	1.72	1.76	1.49	1.52
	d'_{wgt}	1.48	2.70	1.40	0.58	0.47	0.76
Random frequency - translated	$\tilde{d}'_{wgt}$	2.44	2.94	2.95	3.22	2.44	3.37

tended less to the glide portion in the FB conditions compared to the NFB conditions because there was additional information available in the fringe bands (Lyzenga *et al.*, 2004).

2. Comparison of d′ from observers and TWPs

The first four rows of Table II show the d'_{obs} and the d'_{wgt} for the four experimental conditions. The final row indicates the values of $\tilde{d}'_{wgt}$ for the frequency-translation model applied in the random conditions. The values of d'_{obs} are reproduced from Table I. For the NFB- and FB-fixed conditions, the values of d'_{wgt} were larger than the corresponding values of d'_{obs}, and this difference was magnified in the FB-fixed condition compared to the NFB-fixed condition. Because the TWP predicted better-than-obtained performance, the information in the TWPs was sufficient to describe subjects' performance in the fixed conditions.

Next, consider the random conditions. Except for S2 in the NFB-random condition, values of d'_{wgt} were smaller than the corresponding d'_{obs}. This indicated a failure of the linear model without frequency translation [i.e., Eq. (5)] because the model predicted lower-than-obtained values of d'. For the FB-random condition, the values of d'_{wgt} were even poorer. When Eq. (5) was altered to include frequency translation, the resulting predictions, $\tilde{d}'_{wgt}$, were much larger than the corresponding d'_{obs}. This result has two implications. First, the failure of the linear model in the random-frequency conditions does not reflect poorly estimated TWPs: $\tilde{d}'_{wgt}$ is much larger than d'_{obs} meaning that there was sufficient information in the TWPs to account for performance when frequency translation was applied. Second, there might be a psychophysical process corresponding to frequency translation but not captured by the linear detection model [in Eq. (5)], which allows the d'_{obs} to be higher than d'_{wgt}. By one potential process, the subject would form an internal representation of the stimulus distinct from the central frequency. This is simply the frequency translation model and predicts no effect of central frequency randomization, which is inconsistent with the data shown in Table I. If however, subjects failed to *completely* extract the stimuli away from the central frequencies, there would be on the one hand an effect of central frequency randomization, and on the other hand, a TWP that was successful in accounting for subjects' performance only after frequency translation.

3. Comparisons of the magnitudes of the initial and ending portions of TWPs

For TWPs in the fixed conditions, visual inspection suggested a tendency for the magnitudes of the weights to be smaller at the beginning than the end of the TWPs. This is consistent with the expectations of TWPs based on the previous psychophysical data (Madden and Fire, 1996; Moore and Sek, 1998; Sek and Moore, 1999): The unequal magnitudes of the initial negative and ending positive weights. Table III shows the ratio of the magnitudes of the ending *re.* initial portions of the TWPs. For the NFB conditions the ratio was based on the absolute values of the maximal and minimal weights and for the FB conditions the ratio was based on the absolute averaged values of the TWP associated with the ending *re*. initial fringe bands. The ratios in the first and second rows of Table III are from the fixed- and random-frequency conditions, respectively, and the columns are for the individual subjects in the NFB and FB conditions, respectively.

For the fixed-frequency conditions (first row) computer simulations indicated 96% confidence intervals surrounding unity of [0.58, 1.44] for the NFB-fixed condition and [0.75, 1.76] for the FB-fixed condition. In five of the six comparisons, the obtained ratios exceeded the 96% confidence intervals indicating that magnitudes of relative weights were larger at the ending than the initial portions of the TWPs. Subjects appeared to rely more heavily on the ending than the beginning portions of the stimuli in making their detection decisions. For the subjects with higher (lower) values of Δf_c the ratios were greater than (nearer) unity, although the comparisons are based on relatively few subjects and small differences.

For the random-frequency conditions (second row) computer simulations indicated the following 96% confidence intervals about a ratio of unity: [0.13, 1.74] for the NFB-random condition and [0.62, 1.55] for the FB-random condition. For the NFB condition, none of the ratios exceeded the

TABLE III. For each subject and each condition, the ratio of the magnitudes of the ending *re*. initial portions of the TWP are listed. Values in bold exceed the 96% confidence intervals about a ratio of unity.

	NFB			FB		
Conditions	S1	S2	S3	S1	S2	S3
Fixed frequency	**3.07**	**2.74**	**2.26**	0.82	**2.90**	**3.45**
Random frequency	1.40	1.43	1.59	**2.29**	1.09	**1.94**

96% confidence intervals and for the FB condition, the ratios for S1 and S3 exceeded the 96% confidence intervals. As in the fixed-frequency conditions, for the random-FB condition the two subjects with the larger ratios also had the poorer performance (greater values of Δf_c), but this reflects only three comparisons.

Subjects' reliance on the ending portion of the stimuli rather than the initial portion was stronger for the fixed- than random-frequency conditions. Potentially, in an effort to counteract the effect of central frequency randomization, subjects attempted to more equally rely on the initial and ending portions of the stimuli when the central frequency was random. However, to the degree subjects altered their strategies under the pressures of frequency randomization, they were not wholly successful. Such a strategy might, for example, introduce instability in their internal templates, which would potentially cause a failure of the linear model [outlined in Eq. (5)] to accurately estimate the TWPs in the random-frequency conditions.

C. Summary of computational results

The obtained TWPs were significantly different from the patterns associated with random responses for all three subjects in all four conditions, indicating that the patterns contained information regarding subjects' decision strategies. In the fixed-frequency conditions the TWPs indicated that subjects relied on both the starting and ending portions of the stimuli, although more so on the ending portion. In the random-frequency conditions, the stronger dependence on the ending portion was less apparent. Moreover, for the random-frequency conditions the linear detection model indicated by Eq. (5) failed to account for subjects' sensitivity. When frequency translation was applied to the stimuli, the model could at least account for subjects' sensitivity. Together, these results suggested that subjects altered their decision processes depending on whether the central frequency was randomized so as to more effectively difference the initial and ending portions of the stimuli.

IV. SUMMARY AND CONCLUSIONS

A linear classification model (Ahumada, 2002) was successfully used to derive relative weights as a function of time for the detection of an ascending frequency glide applied to 50-Hz-wide narrowband noise. Four conditions were tested, depending on whether the glide had onset and offset fringes or not (FB versus NFB) and depending on whether the central frequencies of the stimuli were fixed or random. Sensitivity to changes in frequency were superior in the FB relative to the NFB conditions, and for both the NFB and FB conditions sensitivity was superior for the fixed- than the random-frequency conditions. Although the current psychophysical data were obtained using narrow bands of noise, the pattern of results was consistent with previous results using tonal stimuli (Madden and Fire, 1996; Moore and Sek, 1998; Sek and Moore, 1999; Lyzenga *et al.*, 2004).

The pattern of relative weights as a function of time (TWPs), were derived for all four conditions. The estimated TWPs went from negative to positive, consistent with the ideal template. This negative-to-positive pattern also suggested that subjects did not rely on just the beginning or ending portion of the stimuli in detecting the glide. In most cases, the relative weights associated with the TWPs had larger magnitudes in the latter portion of the stimuli, especially for the fixed-frequency conditions. An analysis of d' based on the obtained TWPs indicated that the linear model could at least account for subjects' sensitivity in the fixed-frequency conditions. For the random-frequency conditions, although the estimated TWPs have the forms consistent with the expectations from the previous psychophysical results (Madden and Fire, 1996; Moore and Sek, 1998; Sek and Moore, 1999), the linear detection model [specified by Eq. (5)] nevertheless failed. An additional model representing the stimuli as changes in frequency (i.e., not actual frequencies) could account for subjects' sensitivity.

Dr. Daniel Shub and Rong Huang also provided very helpful comments on earlier versions of the manuscript.

[1]Note that the frequency perturbations introduce variations in the decision variable, which results in more overlap between the two distributions of the decision variable for the glide and no-glide stimuli. This additional overlap due to the perturbations would make the glide more difficult to detect, and might cause the no-glide stimulus sound as though there is a glide.

[2]Ahumada (2002) derived a scaling procedure by which hit rates and false alarm rates are used to minimize the error in the weight patterns. Here, a somewhat less optimal scaling scheme, the proportion of "Yes" and "No" trials, is used. This approach ensures that the resulting weight patterns are in similar units (akin to deviations in Hz) across conditions.

[3]The distribution of the weighted deviations ($\Delta f_w(t)$) is roughly normal, with a mean near zero and a standard deviation of approximately 10. The kurtosis and skewness of the distribution are approximately the same as for a normal distribution.

This study examined the perception and cortical representation of harmonic complex tones, from the perspective of the spectral fusion evoked by such sounds. Experiment 1 tested whether ferrets spontaneously distinguish harmonic from inharmonic tones. In baseline sessions, ferrets detected a pure tone terminating a sequence of inharmonic tones. After they reached proficiency, a small fraction of the inharmonic tones were replaced with harmonic tones. Some of the animals confused the harmonic tones with the pure tones at twice the false-alarm rate. Experiment 2 sought correlates of harmonic fusion in single neurons of primary auditory cortex and anterior auditory field, by comparing responses to harmonic tones with those to inharmonic tones in the awake alert ferret. The effects of spectro-temporal filtering were accounted for by using the measured spectrotemporal receptive field to predict responses and by seeking correlates of fusion in the predictability of responses. Only 12% of units sampled distinguished harmonic tones from inharmonic tones, a small percentage that is consistent with the relatively weak ability of the ferrets to spontaneously discriminate harmonic tones from inharmonic tones in Experiment 1.

I. INTRODUCTION

Two fundamentally important auditory perceptual phenomena, spectral fusion and virtual pitch, are intimately associated with sounds having harmonic spectra. The importance of harmonic sounds in auditory perception is such that auditory theory for at least 150 years has been driven in part by a quest for understanding the mechanisms underlying pitch perception (von Helmholtz, 1954). Despite intense investigation, many aspects of pitch perception have resisted explanation. One such problem is identifying its cortical neural correlates. More generally, not just pitch but the cortical encoding of harmonic sounds is not well understood, and forms the topic of this paper.

Listeners typically hear a harmonic complex tone as a coherent unitary entity with a clear pitch; this perceptual fusion due to harmonicity is used by the brain to organize complex acoustic environments into separate auditory objects (Bregman, 1990). An example of this brain function is the improvement obtained in the ability to distinguish two talkers when a fundamental frequency difference is imposed (Brokx and Nooteboom, 1980). This study focuses on fusion of tone components due to harmonic relationships, seeking correlates of this fusion in single cortical neurons. The highly salient pitch evoked by spectrally resolved harmonic complex tones, known as virtual pitch (when there can be no actual energy at the frequency of the perceived pitch), makes this study relevant for understanding cortical neural coding of pitch. We distinguish this pitch due to spectrally resolved harmonics from that due to spectrally unresolved harmonics, and use the term residue pitch to refer to the latter in this paper. The pitch due to spectrally resolved harmonics is the most important of the many distinct percepts that come under the rubric of pitch, because it underlies speakers' voices and speech prosody, as well as musical intervals and melody.

The percepts of virtual pitch and the spectral fusion of complex tones are closely related. There are a great many perceptual parallels, as in their similar insensitivity to the phases of low harmonics (Hartmann *et al.*, 1993; Houtsma and Smurzynski, 1990; Moore and Glasberg, 1985). Moreover, models for virtual pitch apply well to harmonic spectral fusion as well (Duifhuis *et al.*, 1982). For instance, in pattern recognition models, the pitch of a complex tone is equal to the fundamental frequency of the harmonic template that best fits the evoked neural activity arrayed along the tonotopic axis of the cochlea. In such models, template matching operates on the neural activity due to the resolved components of the complex tone (e.g., Goldstein, 1973; Srulovicz and Goldstein, 1983; Terhardt, 1974, 1979; Wightman, 1973). Such models predict well that the pitch of harmonic complex tones is not changed by the absence of the fundamental component: this is an important attribute for a model

[a)]Author to whom correspondence should be addressed. Current address: Starkey Hearing Research Center, 2150 Shattuck Ave., Suite 408, Berkeley, California 94704. Electronic mail: sridhar_kalluri@alum.mit.edu.

of pitch to possess (de Cheveigne, 2005). There is evidence that a template-matching operation also underlies the perceptual fusion of harmonically related components of a complex tone (Brunstrom and Roberts, 1998, 2000; Lin and Hartmann, 1998). However, the two processes are not entirely congruent, with virtual pitch depending on harmonic relations between components and perceptual fusion being due to spectral regularity (Roberts and Brunstrom, 1998, 2001, 2003). Nevertheless, the similarities of fusion and virtual pitch for harmonic stimuli suggest common mechanisms underlying the two and enable findings of one to be applied to the other. The study seeks to identify the neural basis for the special perceptual status of harmonicity; it approaches this issue from the perspective of the fusion or perceptual coherence of harmonic tones, and in the process it sheds light on the pitch evoked by such tones.

While spectral fusion and virtual pitch of complex tones are closely related, previous studies of the cortical coding of harmonic sounds have focused on the latter. One of the few studies that examined the role of human auditory cortex in harmonic fusion found support in measurements of event related potentials for the involvement of primary cortical areas (Dyson and Alain, 2004). Lesion studies show that the auditory cortex is needed for the perception of virtual pitch (Whitfield, 1980; Zatorre, 1988). Primary auditory cortex (AI) has failed, on the whole, to yield compelling correlates of virtual pitch. However, a study by Bendor and Wang (2005) in nonprimary auditory cortex of marmosets has yielded promising results that remain to be independently replicated and confirmed. See also further reservations discussed in McAlpine (2004).

In recordings from single neurons, Bendor and Wang (2005) found responses in rostral field tuned to the fundamental frequency of harmonic complex tones with and without the missing fundamental component. Such tuning to the fundamental frequency regardless of the physical presence of that component is suggestive of these neurons being tuned to pitch. Nevertheless, it is unclear if these neurons respond differently to harmonic tones than to inharmonic tones, as a pitch-selective or harmonicity-selective neuron might be expected to do.

Many studies of AI have examined pitch coding, and failed to yield harmonicity-selective neurons. Recordings from single units (Schwarz and Tomlinson, 1990) and multiple units (Fishman *et al.*, 1998) of monkey AI in response to missing-fundamental harmonic complex tones failed to show any rate tuning to the fundamental frequency. Multiunit activity and current-source-density patterns recorded in high-frequency areas of monkey AI directly encode the click rate of same- and alternating-polarity click trains in the temporal pattern of response (Steinschneider *et al.*, 1998); this click rate corresponds to the weak residue pitch. Consistent with observations from single-unit recordings (Schwarz and Tomlinson, 1990), resolved harmonics were represented as local maxima of activity determined by the tonotopic organization of the recording sites. However, the virtual pitch that would be derived from these local maxima was not encoded directly, in that neither the temporal pattern of response nor spatial distribution of activity reflected the fundamental frequency. Finally, several studies have reported mapping of the envelope periodicity of amplitude-modulated tones on an axis orthogonal to the tonotopic axis in AI of Mongolian gerbils (Schulze *et al.*, 2002; Schulze and Langner, 1997a, 1997b) and of humans (Langner *et al.*, 1997). These findings may indicate the presence of a map of virtual pitch, but three aspects of the experiments make the assertion inconclusive. First, the neurons forming the map of envelope periodicity were primarily sensitive to high-frequency energy (>5 kHz), a frequency region that does not evoke virtual pitch in human and cats (Heffner and Whitfield, 1976). Second, an extensive body of psychoacoustical literature shows that envelope periodicity, in general, is not predictive of the virtual pitch evoked by a stimulus (e.g., de Boer, 1956, 1976; Flanagan and Gutman, 1960). Third, rather than reflecting the virtual pitch due to the spectrally resolved components of the stimulus, the findings could instead be a mapping of the fundamental frequency (or modulation frequency for an amplitude-modulated tone) reintroduced by nonlinear distortion in the cochlea (McAlpine, 2002, 2004).

The lattermost of these reservations is also applicable to observations in monkey AI of similar responses to a pure tone and a missing-fundamental harmonic complex of the same pitch (Riquimaroux, 1995; Riquimaroux and Kosaki, 1995). Sensitivity to harmonic combinations of resolved components that would show tuning to the fundamental frequency of complex tones has been found in marmoset AI (Kadia and Wang, 2003) (also in bats, Suga *et al.*, 1983). Such neurons may underlie spectral fusion of harmonic complex tones. However, because these neurons preferred high frequencies and very high fundamental frequencies (typically greater than 4 kHz), the role of such neurons in the computation of virtual pitch and spectral fusion is unclear for sounds having predominantly low-frequency spectra such as speech, music, and many animal vocalizations.

In summary, previous studies of the cortical encoding of harmonic sounds have focused on correlates of virtual pitch. Several studies have yielded promising candidate neurons that encode pitch and may encode harmonic fusion, although these findings need to be further understood and replicated.

In this paper, we report experiments in domestic ferrets (*Mustela putorius*) aimed at understanding the cortical neural coding of harmonic sounds from the perspective of spectral fusion rather than virtual pitch. By comparing the neural representation of perceptually fused harmonic complex tones with that of perceptually unfused inharmonic complex tones in single AI and anterior auditory field (AAF) neurons, we expect to uncover neural computations specifically elicited by harmonic fusion in subcortical or primary cortical structures. The presence of such harmonicity-specific processing would have been missed by previous studies that employed harmonic sounds exclusively.

An assumption underlying the neurophysiology experiment is that ferrets automatically fuse components of harmonic complex tones, like humans do in typical listening conditions. Many animals can hear the pitch of the missing fundamental, including cats and monkeys (Heffner and Whitfield, 1976; Tomlinson and Schwartz, 1988), so it is not unreasonable to assume that ferrets might do the same. In order

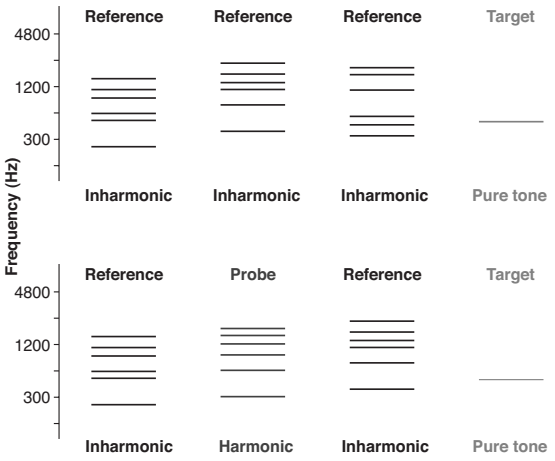

FIG. 1. Stimulus protocols for testing if ferrets automatically distinguish harmonic complex tones from inharmonic complex tones. (Top) In baseline sessions, ferrets were trained to detect pure-tone targets terminating a one-to-six-stimulus sequence of inharmonic complex tone reference sounds. Cues available for distinguishing the targets from the references were (i) differences in the quality of perceptual fusion and (ii) differences in timbre. (Bottom) In probe sessions conducted after ferrets attained proficiency in baseline sessions, a small fraction of the reference sounds were replaced by harmonic complex tone probe sounds. If harmonic complex tones were perceptually fused, then they might have been confused occasionally with the pure-tone targets, thereby indicating that ferrets can automatically distinguish harmonic tones from inharmonic tones.

to hear the pitch of the missing fundamental, the feline and primate subjects must have been able to estimate the fundamental from the components that were actually present in the stimuli. However, the animals did not necessarily fuse these components into a unitary entity.[1] The first experiment in this paper uses a conditioned avoidance behavioral-testing paradigm to study whether ferrets spontaneously fuse harmonic components of complex tones. Experiment 2 seeks neural correlates of harmonic fusion in ferret auditory cortex, specifically in areas AI and in AAF.

II. EXPERIMENT 1: PERCEPTION OF HARMONIC COMPLEX TONES

A. Rationale

In order to address whether ferrets can automatically fuse components of a harmonic complex, we asked if they can distinguish inharmonic complex tones from harmonic complex tones without receiving training on the distinction between the two classes of sounds. The experiment was performed in two stages comprising baseline sessions and probe sessions (Fig. 1). In baseline sessions, the ferrets were trained to detect pure-tone targets in a sequence of inharmonic complex tone reference sounds. By eliminating or making unreliable the differences in frequency range, level, and roughness, we left two cues available for reliably distinguishing targets from references: (i) differences in the degree of perceptual fusion, and (ii) differences in timbre.

When ferrets attained proficiency in these baseline sessions, probe sessions were conducted in which 10% of the reference sounds were replaced with harmonic complex tone probe sounds that were identical to the inharmonic complex tone references in every way except in the frequency relations between components. Because the timbre of the complex tones differs greatly from that of the pure tones, ferrets were expected, in most cases, to categorize the harmonic complex tones with the inharmonic complex tones based on similarity of timbre. This should be the case even if the ferrets heard the harmonic complex tones as fused. However, occasionally the putative fused nature of the harmonic complex tone might be confused with the unitary quality of the pure tone, prompting the ferret to respond to the harmonic probes as if it heard the pure-tone target. Therefore, detecting the probes at a rate greater than the false-alarm rate (i.e., the rate at which references were inadvertently detected as if they were targets) indicates that harmonic complex tones are heard differently than inharmonic complex tones. In contrast, failure to detect the probes in this experiment does not mean that the ferrets could not distinguish harmonic tones from inharmonic tones; they could simply have been using timbre exclusively to categorize the stimuli.

B. Methods

1. Behavioral testing

A conditioned-avoidance paradigm was used for testing how ferrets hear complex tones. The paradigm has been successfully used with many animals and it is described in detail by Heffner and Heffner (1995). We give a brief overview here.

A water-restricted ferret licked water from a continuously dripping spout while listening to reference sounds. At random intervals, an easily distinguishable target sound was presented followed by a light shock to the tongue delivered through the reward spout. Such pairings of stimulus and shock helped the ferret learn to break contact with the spout when it heard a target. The continuous water reward encouraged the ferret to maintain contact with the spout, providing a baseline behavior against which to measure responses. From the perspective of a ferret, the reference stimuli constituted safe trials because it could drink from the spout without getting shocked. On the other hand, target stimuli were warning trials, because they warned the ferret to break contact with the spout.

A computer registered successful withdrawal from the spout following a target as a *hit* and failure to withdraw as a *miss*. Because the animal occasionally withdrew in the absence of a target, a *false-alarm* rate was determined by registering how often it withdrew from the reward spout for reference trials. Both target and reference trials were ignored when the ferret did not contact the reward spout just before the trial; this was done in order to ensure that performance was evaluated only for trials on which the ferret attended to the stimuli. Figure 2 helps understand these measures by illustrating the presentation of trials and the timing of response intervals, while Table I shows which behaviors led to the different response categories.

During testing, two kinds of trial sequences were presented: (i) One to six reference trials followed by a target trial, and (ii) seven consecutive reference trials constituting a sham sequence. The number of reference trials in a given sequence was randomized such that the probability of the

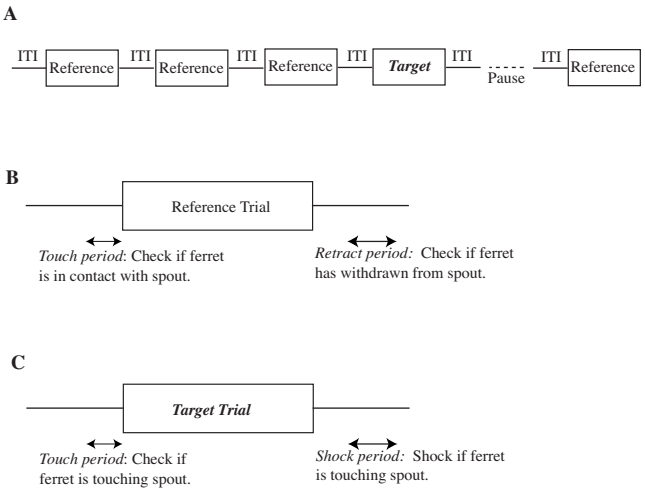

FIG. 2. (A) Schematic representation of a trial sequence, where the target sound was presented on trial 4. The presentation of trials was paused after a target trial until the ferret returned to the spout. (B) Schematic representation of a reference trial shows two time intervals, one before the stimulus onset and the second after stimulus offset. During the second interval, the ferret's contact with a reward spout determined the response class for the trial. If the ferret was not in contact with the spout during the first interval (the *touch* period), the response was classified as an "early" withdrawal and not counted toward overall performance on the experiment. If the ferret failed to contact the spout during the second interval (the *retract* period), the trial performance was scored as a "false alarm." (C) Schematic representation of a target trial shows the same two intervals of time. The first interval played the same role as on a reference trial. The second interval (the *shock* period) was a period when contact with the spout elicited a shock, and the trial performance was scored as a "miss." The *touch* period was 0.2 s while the *retract* and *shock* periods were 0.4 s in the experiment. The interval between the end of the stimulus and the start of the *retract* and *shock* periods was 0.2 s. Based on a figure from Heffner and Heffner (1995).

target sound occurring in trial position 2 through 7 was constant. This randomization was done so that the ferret could not preferentially respond on trials occurring at any given position. Sham sequences were interspersed between target sequences to discourage the ferrets from responding at regular intervals regardless of whether a target was presented. During probe sessions, probe trials were presented in exactly the same way as reference trials by replacing 10% of reference sounds by probe sounds; this percentage amounted, on average, to 40 probe sounds per session. Responses on the probe trials were scored in the same way as those on the reference trials. *Probe hits* and *probe misses* were equivalent to false alarms and safe responses respectively on reference trials.

TABLE I. Relationship between stimulus timing, ferret response, and performance measures.

Trial type	Spout contact (touch period)	Spout contact (retract/shock period)	Response class
Reference	Contact	No contact	Safe
Reference	Contact	Contact	False alarm
Reference	No contact	N/A	Early
Target	Contact	No contact	Hit
Target	Contact	Contact	Miss
Target	No contact	N/A	Early

2. Stimuli

For any given reference, target, or probe trial, stimuli were chosen randomly from a collection of inharmonic, pure-tone, and harmonic sounds that were synthesized and stored in memory just before placing a ferret in the testing cage. The stimuli were all 0.5 s long. Pure tones ranged in frequency from 150 to 4800 Hz. These frequencies were also the lower and upper bounds of the spectra of the complex tones, which had six components. To comply with these frequency limits, harmonic complex tones with components in random phase had fundamental frequencies between 150 and 800 Hz.

We constructed inharmonic complex tones by maintaining the same ratios or log spacings between consecutive components as in harmonic tones but reordering them to occur in different sequences than in harmonic tones. For example, a six-component harmonic tone had ratios between consecutive components of [2 3/2 4/3 5/4 6/5], and an exemplar inharmonic complex tone with lowest component at 200 Hz had components [200 267 320 480 960 1200] Hz corresponding to an ordering of the ratios of [4/3 6/5 3/2 2 5/4]. We constructed inharmonic complex tones in this manner so that these stimuli, if perceived as rough by ferrets, would have comparable roughness to the harmonic tones. The reasoning was that roughness is proportional to envelope fluctuations resulting from interactions between tone components within an auditory filter, and such interactions are comparable between harmonic complex tones and inharmonic complex tones constructed as above (Plomp and Levelt, 1965; Terhardt, 1974). The lowest component of the inharmonic complex tones was constrained between 150 and 800 Hz, so that any pitch cues from the edge of the spectrum were not reliably different from those generated by the spectral edge of the harmonic complex tones.

The levels of all stimuli were roved over a 6 dB range to prevent the use of intensity cues. Stimuli were played at a nominal level of 70 dB sound pressure level; this was the overall level of the complex tones, so individual components were lower in level. Levels were calibrated in an empty testing cage at the position occupied by the ferret's head with a sound level meter (Bruel and Kjaer). All stimulus parameters were restricted to narrower ranges during training sessions to help the ferrets learn the task.

3. Experimental apparatus

Behavior of the ferrets was tested in a custom-designed cage mounted inside a Sonex-foam lined and single-walled soundproof booth (Industrial Acoustics, Inc.). Sound was delivered through a speaker (Manger) mounted in the front of the cage at approximately the same height above the testing cage as the metal spout that delivered the water reward.

The testing cage had a metal floor so that the ferret formed a low-resistance electrical pathway between the spout and the floor when licking. The lowered resistance between floor and spout was used by a custom "touch" circuit to register when the ferret contacted the spout. Electromechanical relays switched between the touch circuit and a fence charger in order to deliver shocks to the ferret's

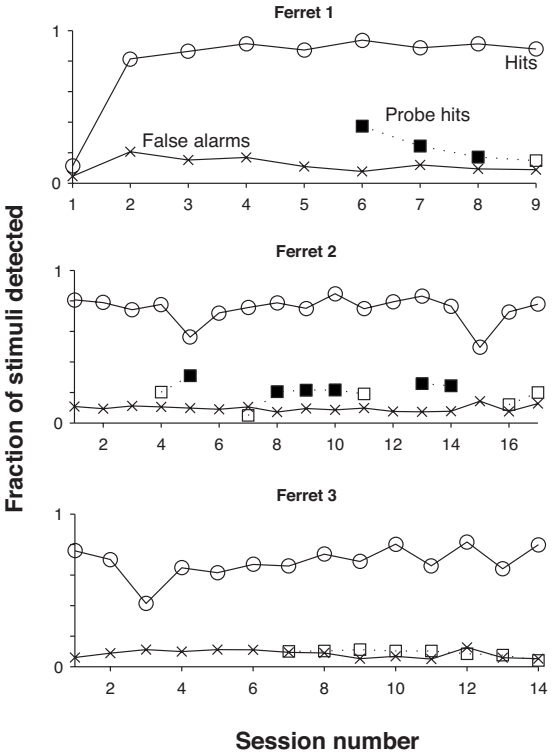

FIG. 3. Performance of three ferrets on baseline and probe sessions of experiment. Several training sessions occurred prior to the first session indicated on the abscissa of the figure for each of the ferrets. All three ferrets attained proficiency at the baseline task of distinguishing pure-tone targets from inharmonic complex tone references, as indicated by the hit rate exceeding 70% and the false-alarm rate not exceeding 20%. Two ferrets (top two panels) had probe hit rates that were significantly greater than the false-alarm rate during probe sessions (statistically significantly greater probe hit rates are indicated with a filled symbol), indicating that they sometimes heard harmonic complex tones as being different from inharmonic complex tones.

tongue. All procedures for behavioral testing of ferrets were approved by the institutional animal care and use committee (IACUC) of the University of Maryland, College Park.

C. Results: Ferrets can weakly distinguish harmonic tones from inharmonic tones during spontaneous behavior

Results from testing three female ferrets, in Fig. 3, indicate that ferrets automatically distinguish harmonic complex tones from inharmonic complex tones on about 20% of trials. The figure shows performance on consecutive sessions after a training period lasting 15–75 sessions had been completed. Hit rates greater than 70% and false-alarm rates less than 20% show that all three ferrets attained proficiency at the baseline task of distinguishing pure-tone targets from inharmonic complex tone references. Two ferrets (top two panels) out of three also detected harmonic complex tone probes at a significantly higher rate than the false-alarm rate, especially in the earliest probe sessions. For the sessions indicated with filled symbols for the probe hit rate, the null hypothesis of no difference between the probe hit rate and the false-alarm rate was rejected ($p < 0.05$) with a two-sided z test for independent proportions applied separately for each session and animal. The z test is a nonparametric test that is applicable when comparing two treatments (harmonic tones and inharmonic tones) and classifying measurements into two mutually exclusive types (hits and misses). Therefore, the ferrets, without receiving training on the distinction, occasionally heard harmonic complex tones to be different than inharmonic complex tones. Nevertheless, the considerable difference between the probe hit rate and the target hit rate indicates that harmonic tones were not treated equivalently to the pure tones.

D. Discussion

It is worth noting three points from the results. First, two ferrets heard harmonic complex tones to be different from inharmonic complex tones in about 15–20% of all trials. In these cases, they confused harmonic probes with pure-tone targets by responding to them as if they were pure tones, although the considerable difference between the hit rates for probes and targets suggests that these ferrets did not treat the two sound classes equivalently. A possible objection to the interpretation that probes and targets were confused, is that the ferrets simply heard the harmonic targets as a new kind of sound and responded (due to surprise) by withdrawing from the reward spout. This objection does not hold for two reasons. First, the parameters of the harmonic complex tones were matched in every way to those of the inharmonic complex tones. Thus, if harmonic probes were heard as a new category of sounds, it underscores the point that the ferrets could hear them to be different from inharmonic tones. Second, a novelty response should have declined rapidly as the ferret became accustomed to the harmonic probes. However, the elevated probe hit rate persisted for several sessions, especially in ferret 2.

Based on these results, we suggest that the ferrets sometimes distinguish harmonic tones from inharmonic tones on the basis of differences in perceived fusion. The results do not directly demonstrate that fusion was the relevant dimension for their judgments. However, we think it is a probable explanation because the harmonic and inharmonic complex tones were constructed to have no consistent differences in timbre or roughness. In analogy with human perception, we think perceptual fusion may be the logical dimension along which ferrets distinguish these two classes of sound. The results of the experiment also indicate that the ferrets occasionally distinguished harmonic tones from inharmonic tones automatically; it was automatic in the sense that they did not have to be taught the difference between these sound classes. In fact, the animals were not rewarded for making the distinction.

Second, the failure of ferret 3 to detect probes at a higher rate than the false-alarm rate does not necessarily indicate that it could not hear a difference between harmonic and inharmonic complex tones. Instead, the ferret may have learned to focus on the timbre cue in order to perform the baseline task. It may have continued to use the same cue during probe sessions and thus correctly categorized the harmonic probes to be similar to the inharmonic references along the perceptual dimension of timbre, while ignoring audible differences in fusion.

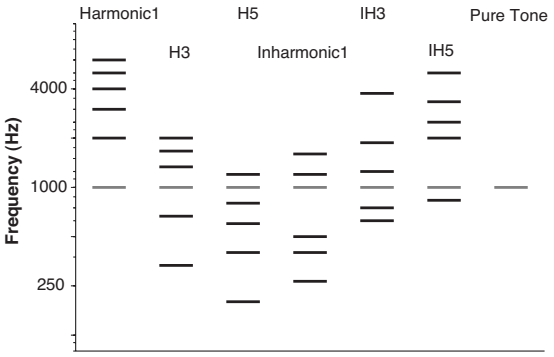

FIG. 4. Stimulus protocol for investigating cortical neural correlates of harmonicity in ferrets. Neural activity is recorded for a sequence of complex tones and a pure tone (*anchored tone sequence*), all of which share a component at the BF of the neuron under investigation. If cortical (or upstream) neurons treat harmonic sounds in a special manner, then the component at BF should elicit a qualitatively different response when presented in a harmonic context compared to an inharmonic context.

Finally, the probe hit rate for ferret 1 declined steadily after the first probe session. A probable reason is that the ferret, gradually learning that the harmonic probes were not associated with the shock, adjusted its judgments to use timbre exclusively rather than timbre in conjunction with fusion. Ferret 2, on the other hand, might not have adjusted its judgments simply because it more slowly learned that harmonic probes were not associated with the shock. Given more probe sessions, the ferret might have exhibited such a learning effect. Indeed, consistent with the notion that learning ability might underlie the difference between the declining probe hit rate for ferret 1 and the lack of such decline for ferret 2, the latter animal took almost five times more sessions than the former to attain proficiency at the baseline task.

In summary, two out of three ferrets discriminated harmonic tones from inharmonic tones. However, the low detection rate (15–20%) of harmonic tones was not comparable enough to that of pure tones to warrant a conclusion that these sound classes were perceptually equivalent to the animals.

III. EXPERIMENT 2: CORRELATES OF HARMONIC FUSION IN AUDITORY CORTICAL NEURONS

A. Rationale

To seek neural correlates of harmonic fusion, we recorded single-unit activity from primary auditory cortex (AI) and auditory anterior field (AAF) to a sequence of harmonic and inharmonic complex tones where all the sounds in the sequence shared a component at the best frequency (BF) of the unit under investigation (Fig. 4). The frequency of this shared component is known as the *anchor frequency* (AF) and the sequence is known as an *anchored tone sequence* in the rest of the paper. The anchor component was placed at the BF to ensure a robust response from the neuron for every complex tone. Any special cortical or upstream (subcortical) neural computation on harmonic sounds would be expected to result in a difference in the responses to the harmonic complex tones compared to those for inharmonic complex tones.

The effect of a harmonic context on the responses can be confused with the effects of spectro-temporal integration of stimulus spectrum by the spectro-temporal tuning of a cortical neuron (e.g., interaction of inhibitory sidebands with balance of spectrum above and below BF) (Depireux *et al.*, 2001; Kowalski *et al.*, 1996; Schreiner and Calhoun, 1994; Shamma *et al.*, 1995). To account for spectrotemporal filtering, we measured a neuron's spectro-temporal receptive field (STRF) and used it to predict the responses to the stimuli in the anchored tone sequences. An effect of harmonic context should then appear as a difference in the predictability of the responses to harmonic complex tones compared to those for inharmonic complex tones, because the predictions using the STRF account for the effect of the spectral context. The STRF is the best-fitting linear model for the transformation of the stimulus spectro-temporal envelope by a neuron. Because we measured STRFs using spectro-temporal envelopes imposed upon broadband noise (inharmonic) carriers, any effect of harmonic fusion is expected to manifest itself as a reduction in the predictability of responses to harmonic tones compared to that for inharmonic tones. A reduction is expected because the STRF, by definition, gives the best possible linear estimate of the response; any modification due to harmonicity must result in a degradation of this best estimate.

B. Methods

1. Experimental apparatus and methods

Experiments were performed at the University of Maryland, College Park and the University of Maryland, Baltimore. Animal preparation and neural-recording procedures were approved by the IACUCs of both institutions. Surgical procedures are described in detail in other publications (Dobbins *et al.*, 2007; Fritz *et al.*, 2003). We give a brief outline of the recording procedure here. During daily recording sessions lasting 3–6 h, ferrets were trained to lie motionless in a custom apparatus that restrained them. The auditory cortex was accessed through craniotomies of diameters in the range 0.5–6 mm. We took precautions to maintain sterility of the craniotomies at all times.

- In some experiments, the auditory cortex was accessed through a small hole of diameter less than 0.5 mm. Each hole was used for 5–7 days after which it was sealed with dental cement. The small size of the hole afforded stable recordings and lowered chances of infection. Closely spaced holes were made over auditory cortex, with particular focus on low-frequency areas for this study. Recordings were attributed to AI based on tonotopic organization and response properties (strong response to tones and relatively short response latency), but a few penetrations might have been from adjacent areas.
- In other experiments, we obtained recordings from both AAF and AI. In these experiments, the recordings were through relatively large craniotomies of diameter 5–6 mm. Larger craniotomies permitted us to identify recording locations as being from AI or AAF based on position relative to sulcal landmarks on the surface of the brain (Kowalski

et al., 1995). Such attribution of location would not have been possible with microcraniotomies because sulcal landmarks are not readily visible.

A variety of different methods were used for the recordings. These methods are described below, but they are not distinguished in the reporting of results because they did not lead to noticeably different findings. Most of the recordings were with single parylene-coated tungsten microelectrodes having impedance ranging from 2 to 7 MΩ at 1 kHz. Electrode penetrations were perpendicular to the surface of the cortex. We used a hydraulic microdrive under visual guidance via an operating microscope to position the electrodes. A few recordings were made with NeuroNexus Technologies silicon-substrate linear electrode arrays (four arrays, with each array having four electrodes in a straight line) or silicon-substrate tetrode arrays (four tetrode arrays, with each array having four closely spaced electrodes in a diamond-shaped configuration). Recordings yielded spikes from 1–3 neurons on a single electrode that were sorted offline with a combination of automatic spike-sorting algorithms (Lewicki, 1994; MClust-3.3, A. D. Redish *et al.*; KlustaKwik, K. Harris) and manual techniques. A spike class was included as a single unit for further analysis if less than 5% of interspike intervals were smaller than 1 ms, the putative absolute refractory period, and the spike waveform had a bipolar shape.

In some experiments, sounds were delivered with an Etymotic ER-2 earphone inserted into the entrance of the ear canal on the contralateral side of the cortex being investigated. All stimuli were generated by computer and fed through equalizers to the earphone. An Etymotic ER-7C probe-tube microphone was used to calibrate the sound system *in situ* for every recording session. An automatic calibration procedure gave flat frequency responses below 20 000 Hz. In other experiments, sounds were delivered by a speaker (Manger) placed 1 m straight above the head of the ferret. Stimuli were generated by a computer and sound levels were calibrated at the position of the ferret's head. Apart from a handful of cases, most of the recordings in these latter experiments were obtained without the sound system having been equalized to a flat frequency response, because the frequency response was flat even when not equalized.

2. Stimuli and analysis

a. Stimuli. After a cluster of single units was isolated using pure-tone and complex-tone search stimuli, its response area was measured with pure tones to get an estimate of the BF. The discharge rate was measured as a function of the level of pure tones at BF in order to estimate the threshold. Responses to a tone sequence anchored at the BF (as in Fig. 4) were measured at approximately 20 dB above BF-tone threshold. Finally, the neuron's spectro-temporal filtering characteristics were estimated at the same level as the anchored-tone sequence by measuring the STRF with temporally orthogonal-ripple-combination (TORC) stimuli (Klein *et al.*, 2000), which are described below.

b. Anchored tone sequences. Anchored-tone sequences consisted of six-component harmonic and inharmonic complex tones. Up to six different harmonic complex tones with components in random phase were part of the sequence, where each tone had a different component number at the anchor frequency. For most units, the first through sixth components were at the anchor frequency, but a few units had only the second through fifth or first through fifth components at the anchor frequency.

Inharmonic complex tones in the sequences were formed by reordering ratios between consecutive components of a harmonic complex tone, as in Experiment 1. The same sequences of ratios were used for almost all units.

In our later recording sessions, we imposed a slow sinusoidal amplitude modulation (4–20 Hz) with a modulation depth of 0.5 (peak to mean) upon the complex tones. All components were modulated coherently. We imposed this modulation to ensure that neurons responded vigorously throughout the complex tone, because cortical neurons are often unresponsive during the sustained portions of static stimuli (Clarey *et al.*, 1992; Shamma *et al.*, 1995) as was indeed the case for the majority of single units recorded during our early recording sessions. In contrast, most units responded vigorously to the amplitude-modulated complex tones. Sinusoidal amplitude modulation at slow rates may provide an additional grouping cue beyond that of harmonicity. However, this cue is in fact relatively weak compared to the unavoidable powerful (and quite similar) cue of the common rapid onset and offset of all (harmonic and inharmonic) tones. Since our goal is to compare the responses to the harmonic versus inharmonic complexes, then as they are treated the same, amplitude modulation should not confer any advantage to one complex over the other.

All components of the harmonic and inharmonic complex tones were presented at the same level.

c. Characterizing linear processing of spectro-temporal envelopes with STRFs. Underlying the measurement of a STRF is the observation (Kowalski *et al.*, 1996; Schreiner and Calhoun, 1994; Shamma *et al.*, 1995) that responses of many AI neurons have a large linear component with respect to the spectro-temporal envelope of sounds. The STRF (t,x), a two-dimensional function of time t and log frequency $x = \log(f/f_0)$, describes the linear component of the transformation between the spectro-temporal envelope of an acoustic stimulus and the neural response. This response component is given by

$$r(t) = \int \int \mathrm{STRF}(\tau,x) \cdot S(t-\tau,x) d\tau dx, \qquad (1)$$

where $r(t)$ is the instantaneous discharge rate of the neuron and $S(t,x)$ is the spectro-temporal envelope (or dynamic spectrum) of the stimulus; the equation describes a convolution in time and a correlation in log frequency. Intuitively, the neural response r at time t is the correlation of the STRF with the time-reversed dynamic spectrum of the stimulus S around that moment. This operation can be viewed as similar to a matched-filtering operation whereby the maximum response of the neuron occurs when the time-reversed dynamic spectrum most resembles the STRF.

The theory and practice of measuring STRFs with TORC stimuli are in Klein *et al.* (2000). A brief outline is given in the appendix. TORCs are composed of *moving*

ripples (Depireux *et al.*, 2001; Kowalski *et al.*, 1996), which are broadband sounds having sinusoidal temporal and spectral envelopes. Moving ripples are basis functions of the spectro-temporal domain, in that arbitrary spectro-temporal envelopes can be most efficiently expressed as combinations of these stimuli. The accumulated phase-locked responses to individual moving ripples give a spectro-temporal modulation transfer function (parameterized by ripple periodicity and ripple spectral density) whose two-dimensional inverse Fourier transform is the STRF. TORCs are special superpositions of moving ripples such that two components having different ripple spectral densities do not share the same ripple periodicity. This special combination of moving ripples enables rapid measurement of the STRF. We used random-phase tones densely spaced on a log-frequency axis as carriers (100 tones/octave, spanning 5–7 octaves) for the envelope of the TORC stimuli.

It is worth noting two properties of our STRF measurements.

1. Underlying our measurement of the STRF is an assumption that the neuronal system has reached a steady state (Schechter and Depireux, 2007). Consequently, the STRF quantifies changes of the discharge rate above and below a steady-state rate.
2. The mean of the STRFs is set to zero because the STRF is designed to predict response modulations, not the steady-state response. In order to predict the steady-state discharge rate, it is necessary to measure the terms of the STRF at a ripple periodicity of 0 Hz (i.e., static ripples). These responses cannot be measured by directly incorporating static ripples into TORC stimuli because responses to the static ripples are difficult to disambiguate from nonlinear responses to the moving ripples resulting from, for example, spiking rate saturation and positivity of spike rates. The 0 Hz ripple periodicity terms can be estimated separately using static ripples presented at a range of phases. We estimated such terms of the STRF for 13 units in some of the later recording sessions. However, because results from these units did not differ from other units, we do not distinguish them in the results.

d. Quantifying the effects of spectro-temporal filtering on responses to complex tones. In order to account for the effect of spectro-temporal filtering on responses of a unit to the anchored-tone sequence, we predicted the peri-stimulus time (PST) histogram of the response to each stimulus from the measured STRF. The lack of predictability of the PST histogram then served as a measure of the response to each stimulus that was not explainable by spectrotemporal filtering. Correlates of harmonic fusion were expected to show up as systematic differences in the predictabilities of the response for harmonic stimuli compared to those for inharmonic stimuli. In other words, the prediction of responses from the STRF accounts for the processing of slow spectrotemporal envelopes in the stimulus, a feature that has little to do with harmonic fusion and pitch. Any effects of harmonicity have to be in the remaining unpredicted portion of the response.

A discrete-time implementation of Eq. (1) was used to predict the response to each stimulus in the anchored tone sequence (visualized in Fig. 5). The predicted PST histogram ($p[n]$) for a stimulus was a function of the sum of two terms, one term due to spectrotemporal filtering ($p_{\text{strf}}[n]$) and a second term representing the steady-state discharge rate (p_{ss}). For a complex tone having L components, we used a two-step process to determine $p_{\text{strf}}[n]$, which is simply the convolution of the stimulus spectrogram with the STRF.

1. Convolve stimulus envelope $e[n]$ (flat in the early experiments that used unmodulated complex tones and sinusoidal in the later experiments that used modulated complex tones, both having 10 ms cosine-squared onset and offset ramps) with horizontal slices of the STRF at the frequencies x^i of the tone components, STRF $[n,x^i]$, to get the contributions of individual components to the overall prediction.

$$p^i_{\text{strf}}[n] = \frac{1}{N}(\text{STRF}[n,x^i] * e[n]), \tag{2}$$

where N is the length of $\text{STRF}^i[n]$ and $*$ indicates convolution in time.

2. Combine contributions of individual components to get the overall prediction from the STRF as the mean of the individual contributions.

$$p_{\text{strf}}[n] = \frac{1}{L}\sum_{i=1}^{L} p^i_{\text{strf}}[n]. \tag{3}$$

Finally, the predicted PST histogram was

$$p[n] = g(p_{\text{strf}}[n] + p_{\text{ss}}), \tag{4}$$

where $g(\cdot)$ indicates half-wave rectification representing the positivity of spike rates. Because the STRF does not predict the steady-state discharge rate (except in the handful of measurements where we measured responses to static ripples), we used the measured steady-state discharge rate r_{ss} instead of p_{ss}. In Fig. 5(E), shading is used to indicate one standard deviation above and below the mean prediction,[2] where the standard deviation is estimated by resampling the measured STRF using the bootstrap technique (Efron and Tibshirani, 1993; Klein *et al.*, 2006). Figures 5(C) and 5(D) show raster and PST histograms of the actual response of the cell to the same stimulus, demonstrating the relatively high quality of the prediction in this case.

We quantified the quality of the prediction with the cross-covariance between the response $r[n]$ and the prediction $p[n]$, defining it to be

$$\rho[m] = \frac{cov(r[n+m]\cdot p[n])}{\sigma_r \cdot \sigma_p}. \tag{5}$$

Because the covariance in the numerator is normalized by the standard deviations, $\rho[m]$ is insensitive to the magnitudes of $r[n]$ and $p[n]$ but it captures the similarity of the waveform shapes. We used $\rho = \max(\rho[m])$ to summarize the relationship of prediction and response independent of temporal misalignments between the waveforms; this quantity served

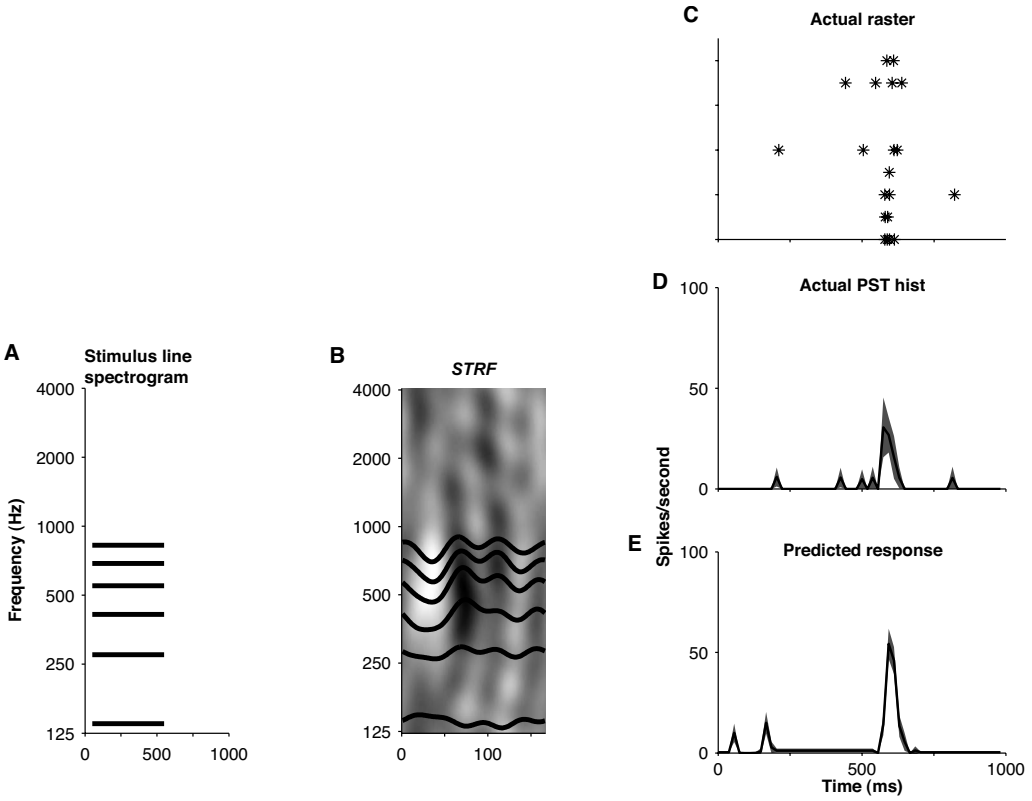

FIG. 5. Predicting responses to complex tones using STRFs. The predicted response (E) is the convolution of the spectrotemporal envelope of the stimulus (A, schematic spectrogram for complex tone having six components) with the STRF (B). More specifically, the operation can be seen as comprising two steps: (1) One-dimensional convolutions between the stimulus envelope (trapezoid-like with 10 ms cosine-squared onset and offset ramps) and horizontal slices of the STRF corresponding to the frequencies of each tone component; (2) Average of the results of the convolutions. These steps form part of an implementation of Eq. (4). Shown for comparison with the prediction are a raster plot (C) and a PST histogram (D) of the actual response of the neuron for ten stimulus presentations. Shading in D and E indicates one standard deviation above and below the mean prediction and the mean PST histogram, respectively, obtained with the bootstrap technique. The units of the STRF depicted in B are spikes/s/Pa. White pixels in the STRF indicate suppression, gray pixels indicate no change, and black pixels indicate elevation of discharge rate. Unit *d-46d*, *class 1*.

as a measure of the neuron's response after accounting for the effects of spectrotemporal filtering.

To quantify the extent to which a neuron distinguished a harmonic tone from each of the inharmonic stimuli, we used a measure analogous to the *d-prime* statistic from signal detection theory. We defined this measure to be the difference between the means of the distributions of ρ for each of the stimuli normalized by the geometric means of the standard deviations of the distributions, with the distributions having been generated by bootstrap replication.

$$d'_{\rho}(Hx,IHx) = \frac{\overline{\rho(Hx)} - \overline{\rho(IHx)}}{\sqrt{\sigma_{\rho(Hx)} \cdot \sigma_{\rho(IHx)}}}. \quad (6)$$

We did not compute this quantity when either stimulus of a *Hx*, *IHx* pair (denoting harmonic and inharmonic tones, respectively) did not evoke a change in discharge rate or a change in phase-locked response by visual inspection because predictability of the temporal pattern of discharge of a no response is not meaningful. Figure 7(B) gives an example of distributions of ρ generated by bootstrap resampling for a harmonic tone and several inharmonic tones. We take $d' = 1$ as the threshold at which the two distributions are significantly different (equivalent to 76% correct identification in a two-alternative forced-choice discrimination task) to determine if a neuron reliably distinguished a harmonic tone from all of the inharmonic stimuli. We revisit this example in the Results section below.

C. Results: A small fraction of cortical neurons distinguished harmonic complex tones from inharmonic complex tones

We selected data from 86 units in nine ferrets for this report, with many units rejected due to not having high enough signal-to-noise ratios. None of the nine ferrets were used in the behavioral study. The BFs of the units ranged from 210 to 13 600 Hz, with 11 having BF greater than 5000 Hz, 20 having BF greater than 3000 Hz, and 36 having BF greater than 1500 Hz. Of these units, 51 were from AI, 22 were from AAF, and 13 units were of uncertain location either in AI or AAF.

Figure 6 shows the responses of a single unit to unmodulated harmonic and inharmonic tones constituting the anchored tone sequences. Harmonic tones are labeled with the prefix "H" and the inharmonic tones are labeled with the prefix "IH;" the numerical suffix for the harmonic tones indicates the component at the AF (anchor frequency) while for inharmonic tones it is an arbitrary label not indicative of any status for the component at AF. The spectral context clearly influenced the responses of this unit to the different tones. For example, the harmonic tones labeled H3 and H4

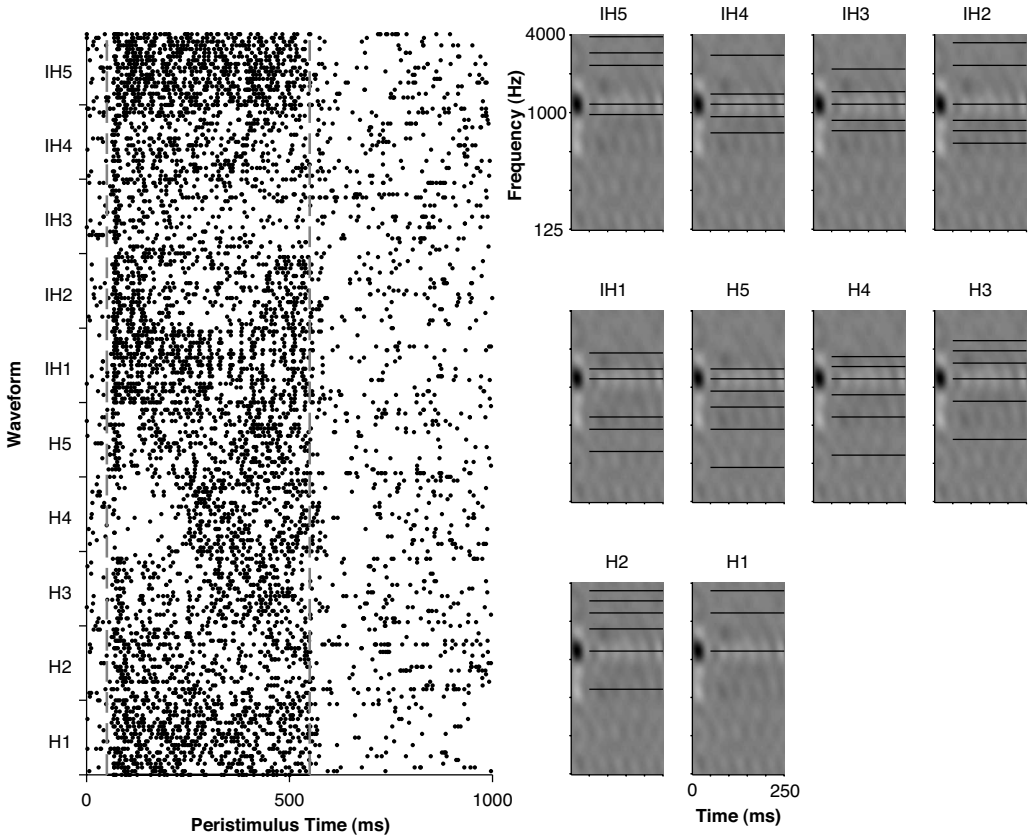

FIG. 6. Response of a unit to an anchored-tone sequence. Dot rasters (left) and schematic spectrograms of each tone in the anchored tone sequence overlayed on the STRF of the unit (right). Stimuli labeled as *Hx* (where *x* indicates the component number at *BF*) are harmonic tones. Those labeled as *IHx* are inharmonic tones, but in contrast to that for the harmonic tones, the numerical suffix is an arbitrary label not indicative of any status for the component at anchor frequency. Unit *d*-76*b*, *class 1*.

(third and fourth components at the AF, respectively) were inhibited for the first half of stimulus presentation, while none of the other stimuli elicited such a response. Similarly, the unit responded far more weakly to the inharmonic tones labeled IH3 and IH4 than to any of the other stimuli.

Interestingly for this unit, the response to stimulus IH1 shows temporal structure in the discharge pattern. This temporal structure reflects synchronization of discharges to envelope modulations resulting from interaction between tone components. Responses to all stimuli showed such synchronization to tone interactions up to 250 Hz. As a result of this 250 Hz upper limit, the temporal envelope for harmonic tones H1 through H4, where the fundamentals exceeded 250 Hz, was not reflected in the neural discharge patterns but the temporal envelope for H5 did produce synchronized discharges. The rate limit also makes such units unsuitable for encoding the virtual pitch of harmonic complex tones via synchronization to the envelope; instead, they are better suited for encoding residue pitch. A similar limit for synchronizing to the stimulus temporal envelope has been observed in previous studies of auditory cortex in awake animals (Bieser and Muller-Preuss, 1996; de Ribaupierre *et al.*, 1972; Elhilali *et al.*, 2004; Fishman *et al.*, 2000; Liang *et al.*, 2001; Steinschneider *et al.*, 1998). No other unit in our population exhibited such discharge patterns.

In order to account for the effect of spectrotemporal filtering in this unit, we used the STRF to predict PST histograms for the complex tones. Figure 7(A) shows actual PST histograms overlayed on predictions for the unit of Fig. 6. The response was better predicted for the inharmonic stimuli than for stimuli H3 and H4 because the STRF was unable to predict the late response to these harmonic stimuli. We summarized the linear predictability of the response using the maximum cross-covariance ρ (see Methods), between the response PST histogram and the predicted wave-form. Figure 7(B) shows distributions of ρ for stimulus H4 and for all the inharmonic stimuli. We quantified the extent to which this neuron distinguished H4 from each of the inharmonic stimuli using d'_ρ (see Methods). If we take $d'=1$ to be the threshold at which two distributions are significantly different, then this neuron reliably distinguished H4 from all of the inharmonic stimuli. Figure 7(C) summarizes d'_ρ for each of the harmonic stimuli compared to all of the inharmonic stimuli. The minimum d'_ρ for a given harmonic tone is a convenient measure of how well the neuron discriminated that harmonic tone from the inharmonic tone having the most similar response. This measure is greatest for H4 of all the harmonic tones, which means that this neuron was best at discriminating H4 from inharmonic tones.

Figure 8 shows an example of responses and predictions from a unit for amplitude-modulated complex-tone stimuli. Figure 8(A) shows period histograms of responses to a harmonic (H3) and an inharmonic tone[3] along with a single period of predictions for the same stimuli. Both the magnitudes and phases of the responses are predicted well by the STRF of this neuron. Figure 8(B) shows histograms of

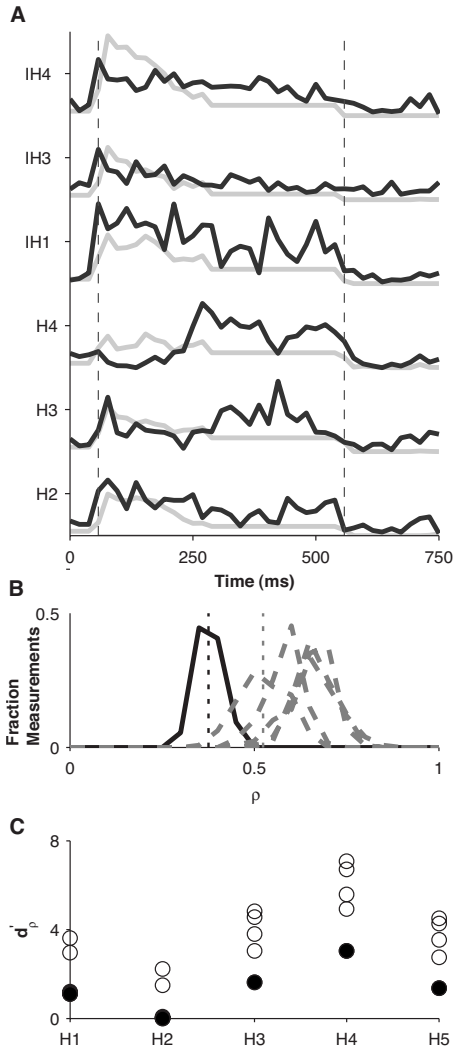

FIG. 7. Predictability of temporal patterns of discharge for unit of Fig. 6. (A) Actual (solid) PST histograms overlayed on predicted (dotted) PST histograms for some select stimuli in the anchored-tone sequence. Dashed vertical gray lines indicate stimulus onset and offset. Predictions are normalized by the maximum across stimuli of all prediction waveforms and actual PST histograms are normalized by the maximum across stimuli of all actual responses, because the magnitudes of the predictions are consistently greater than the magnitudes of the PST histograms. (B) Histograms of the correlation coefficient (ρ) between predicted and actual PST histograms for harmonic stimulus H4 (solid) and histograms of ρ for each of the inharmonic stimuli (dashed), where histograms are obtained from 128 bootstrap replicates of predicted and actual responses. Dotted vertical lines indicate means of the distributions of ρ for stimulus H4 and for the inharmonic stimulus whose response predictability was closest to that of H4. d'_ρ is the difference between such means normalized by the geometric mean of their standard deviations. (C) d'_ρ for each of the harmonic tones relative to each of the inharmonic tones. The minimum d'_ρ for a given harmonic number (solid circles) is a measure of how discriminable that particular harmonic tone is from the most similar inharmonic tone in terms of the predictability of the temporal discharge pattern.

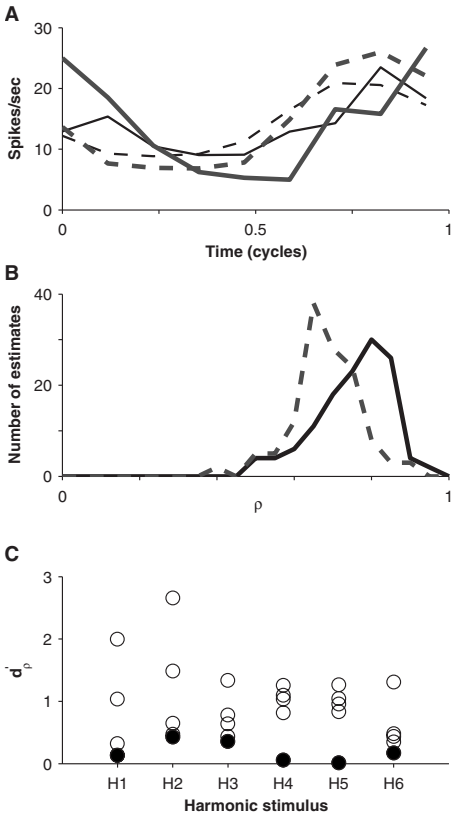

FIG. 8. Predictability of temporal patterns of discharge in a unit driven by amplitude-modulated complex tones. (A) A single period of predicted (dashed) and actual (solid) responses for harmonic tone H3 (thick gray) and an inharmonic tone (thin black). (B) Histograms of correlation coefficients between 128 bootstrap replicates of predicted and actual responses from panel (A). (C) d'_ρ for each of the harmonic tones relative to each of the inharmonic tones, with solid circles indicating the smallest d'_ρ for a given harmonic tone.

bootstrap-replicate ρ for stimulus H3 and the inharmonic tone of panel A. The distributions of ρ for these stimuli overlap a great deal, suggesting that the predictability of temporal discharge pattern does not readily distinguish H3 from the inharmonic tone. Figure 8(C) summarizes d'_ρ for each of the harmonic tones compared to all of the inharmonic tones. The minimum d'_ρ for each harmonic tone is less than 1, confirming the observation for stimulus H3 that this neuron was not effective at discriminating any of the harmonic tones from inharmonic tones.

Neurons were no more effective at discriminating harmonic tones from inharmonic tones when the stimuli were unmodulated compared to when they were amplitude modulated. Distributions of d'_ρ for responses to unmodulated tones overlapped greatly with those for responses to modulated tones. A large-sample normal approximation of the Wald–Wolfowitz runs test, a nonparameteric test for determining whether two samples are identically distributed, yielded a test statistic $z=1.42$. At this value of the test statistic, the null hypothesis of d'_ρ for modulated stimuli and d'_ρ for unmodulated stimuli being identically distributed cannot be rejected ($p>0.05$).

Most units in the population were ineffective at discriminating the harmonic tones from the inharmonic tones; that is, they were mostly like the unit of Fig. 8 rather than the unit of Fig. 7. Figure 9 summarizes for our entire population of neurons how well the predictability of the temporal pattern of discharge discriminated the harmonic tones from the inharmonic tones. Histograms of minimum d'_ρ in Fig. 9(A) show that values exceeding 1 were infrequently observed, indicating that few neurons discriminated any of the harmonic tones from inharmonic tones. Figure 9(B) gives an-

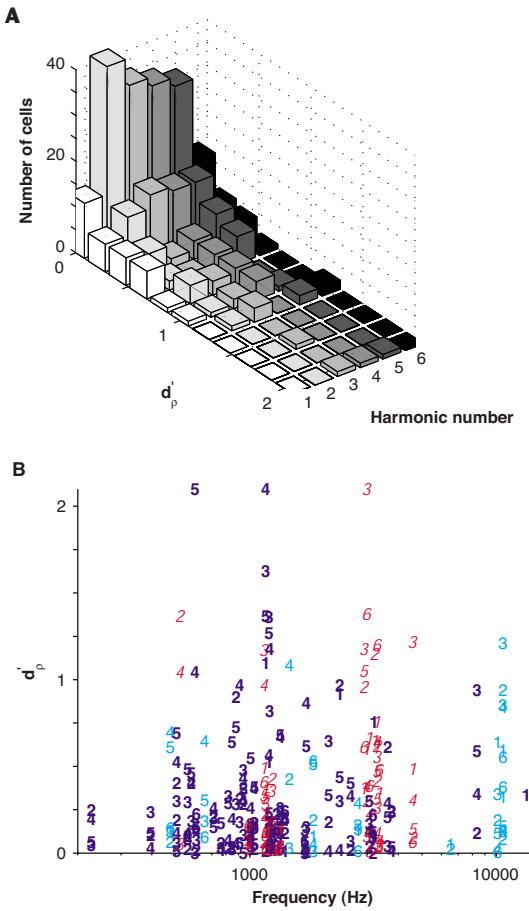

FIG. 9. (Color online) Summary of how distinguishable harmonic tones are from inharmonic tones across all recordings. (A) Histograms of the minimum d'_ρ for each harmonic tone across all recordings. (B) Minimum d'_ρ for each harmonic tone as a function of the best frequency for the recording. The recording location is indicated by font style (bold: AI, italic: AAF, plain: undetermined) and the identity of the harmonic tone is indicated by the numeric symbol.

other view of the same information. The figure shows the minimum d'_ρ for each harmonic tone as a function of the BF of the unit, while identifying the harmonic tone by digits corresponding to the number of the anchor component. The 13 units that had a minimum d'_ρ greater than 1 had BFs between 500 and 10 000 Hz (all but one unit having BFs less than 4400 Hz). Location of the units (indicated by the font style of the symbol) that discriminated harmonic tones from inharmonic tones could be either AI or AAF. In summary, these few discriminative units were not likely to occur in a particular cortical location nor biased to a particular range of BFs within the 500–4400 Hz range.

The maximum cross-covariance quantifies the similarity of the shapes of the predicted waveforms and the PST histograms. However, this measure fails to account for how the magnitude of the predicted waveform compares to the magnitude of the time-varying component of PST histograms, or any differences in latencies of the prediction and actual response. For modulated complex tones it fails to quantify synchronization of response to the amplitude modulation. Moreover, the steady-state discharge rate is not predicted by the STRF, but it must be affected by the interaction of the stimulus spectrum with the frequency tuning of the neuron. We accounted for these various other properties of response predictability in a manner similar to our examination of the maximum cross covariance (not shown). Our conclusions based on the maximum cross covariance were not significantly altered—between 10% and 15% of the units were capable of discriminating one of the harmonic tones from the inharmonic tones with these other measures.

D. Discussion

About 10%–15% of units in AI and AAF responded differently to harmonic tones than to inharmonic tones, so that they may be said to be sensitive to harmonicity. This relatively small fraction of harmonicity-encoding neurons may account for the weak ability of ferrets in Experiment 1 to discriminate harmonic tones from inharmonic tones.

The failure to find a robust neural discrimination of harmonic tones from inharmonic tones is consistent with the conclusion of previous studies that single AI neurons in naive animals for the most part are not concerned with the coding of harmonicity. On the other hand, the failure to find harmonicity coding in AAF neurons may be at odds with other studies. The correspondence of AAF in ferrets to cortical fields in other animals in uncertain (Bizley *et al.*, 2005). If AAF corresponds to the rostral field in primates, then our failure to find a significant percentage of neurons to be selective for harmonicity may be surprising given the promising observations of neurons tuned to the fundamental frequency of harmonic tones in marmosets (Bendor and Wang, 2005).

There are several possible reasons for the lack of congruence between the marmoset data and the ferret data. One possible reason is that AAF in ferrets may not correspond to rostral field in marmosets or that the marmoset data were mostly at very low frequencies (<0.8 kHz), while our data are at higher frequencies [mostly between 1 and 5 kHz—see Fig. 9(B)]. Another reason might be that the marmoset neurons were not harmonicity selective but instead were selective to waveform modulation rate. Future ferret studies having more recordings from the low-frequency region of AAF may yield data that are in line with the marmoset data. Moreover, there are some caveats to our conclusion that there are few harmonicity-sensitive neurons in AI and AAF of ferrets. First, our recordings were from multiple cortical layers and we had relatively few recordings per cortex. These characteristics may lead to a false conclusion that single AI and AAF neurons do not encode harmonicity if a population of harmonicity-selective neurons is concentrated in a specific subfield and layer of auditory cortex that we failed to sample. Second, different animals were used for the physiology and the behavior and it is possible that the physiology animals were incapable of spontaneously distinguishing harmonic tones from inharmonic tones. Finally, it is of course conceivable that our criteria for identifying harmonicity-sensitive cells are simply inadequate. Other formulations in the future may prove successful, such as distributed coding requiring comparison of spike timing across nearby neurons.

On the whole, our failure to find a robust encoding of harmonicity is not inconsistent with most previous studies

that have examined the encoding of harmonic sounds from the perspective of virtual pitch. Single-unit and multi-unit recordings have failed to reveal neurons selective to virtual pitch in AI (Fishman *et al.*, 1998; Schwarz and Tomlinson, 1990). Recent neuromagnetic and functional magnetic resonance imaging studies also support the conclusion that virtual pitch is not extracted in AI. Instead, investigations with regular-interval noise and filtered harmonic complex tones suggest that pitch is extracted at the anterolateral border of AI in humans (Krumbholz *et al.*, 2003; Patterson *et al.*, 2003; Penagos *et al.*, 2003; Warren *et al.*, 2003). Nevertheless, this conclusion about the role of the anterolateral border of AI has also recently come under doubt (Hall and Plack, 2006, 2007).

Several studies have investigated neural coding of harmonic fusion by seeking correlates of the perceptual popout of a mistuned component from an otherwise harmonic complex tone. Sinex *et al.* (2002, 2005) found that single inferior colliculus neurons in chinchilla could distinguish harmonic tones from mistuned-component harmonic tones based on distinctive temporal patterns of discharge. These temporal discharge patterns were understood as arising from envelope modulations due to interaction between adjacent tone components. This finding of a neural correlate for harmonicity in inferior colliculus is not inconsistent with our failure to find a robust correlate in auditory cortex, because the majority of cortical neurons do not encode first-order envelopes (modulations due to tone-tone interactions) but instead encode slower second-order envelopes (modulation of the first-order envelope) (Elhilali *et al.*, 2004).

The neural basis of the perceptual popout of a mistuned harmonic has also been investigated in human listeners with event-related brain potentials. These studies have found long latency (150–250 ms after stimulus onset) responses that are correlated with perceptual popout (Alain *et al.*, 2002; Hiraumi *et al.*, 2005; McDonald and Alain, 2005); such latencies imply an involvement of secondary auditory cortical areas. Involvement of primary auditory cortex is also suggested by small differences in middle latency responses between harmonic stimuli and mistuned-harmonic stimuli (Dyson and Alain, 2004). While these middle and long latency responses may reflect harmonicity processing, it is also possible that they indicate, more generally, the perception of concurrent auditory objects; this possibility may underlie our failure to find significant evidence for encoding of harmonicity.

In general, the present study differs in outlook from most previous single-unit and multi-unit neurophysiology studies of the cortical neural coding of harmonicity. Previous studies have sought correlates of harmonicity by focusing on two characteristics of the pitch percept: (1) virtual pitch is at the common fundamental of a sequence of harmonics, and (2) the pitch corresponds to that of a pure tone at the fundamental frequency. The former property is expected to endow the putative pitch neuron with inputs across a broad range of frequencies, while the latter property is expected to endow the neuron's tuning to pure tones to be at low frequencies below 1100 Hz (the range of virtual pitch in humans). These studies may be seen as employing a *pitch-equivalence method*.

The present study, employing a *fusion-based method*, exploits the fact that the brain uses harmonicity as a cue for grouping spectral components of a sound. It assumes that the fusion of harmonic components leaves an imprint on the neural representation of the individual components themselves; i.e., the brain maintains a pitch- or harmonicity-tagged representation of sound that is a by-product of the harmonic fusion process. Neurons that have an imprint of this harmonicity tagging would span a broad frequency range of best tuning up to 5000 Hz, the existence region for virtual pitch (Ritsma, 1962). This frequency range is greater than the expected frequency range of tuning for neurons whose selectivity to fundamental frequency corresponds to the pure-tone best frequency. The larger candidate pool of neurons in the fusion-based method compared to the pitch-equivalence method can be seen as an advantage when seeking correlates of harmonicity processing. On the other hand, a desirable feature of the latter method is that it can better reveal the actual neurons that combine harmonic components across frequency. A further advantage of the fusion-based method over the pitch-equivalence method is the potential for distortion products and combination tones to complicate interpretation of data in the latter method (McAlpine, 2004). Distortion and combination tones can regenerate missing components of missing-fundamental harmonic tones used in pitch-equivalence experiments; such nonlinearities are not a problem for the fusion-based method because it does not use missing-fundamental stimuli.

IV. GENERAL DISCUSSION

Our results show that ferrets can spontaneously distinguish harmonic tones from inharmonic tones, albeit weakly. We found relatively few neurons in AI and AAF that encoded harmonicity, which may explain the weak spontaneous behavior.

Perhaps one reason we did not find a large number of harmonicity-encoding neurons is that ferrets are not good at spontaneously distinguishing harmonic tones from inharmonic tones. Animals trained to discriminate harmonic tones from inharmonic tones may turn out to have significantly more harmonicity-encoding neurons. It is worth noting, however, that physiology studies that succeeded in finding candidate harmonicity-selective neurons were done on untrained animals (Bendor and Wang, 2005; Riquimaroux, 1995). Another possible explanation for finding few harmonicity-encoding neurons in AI and AAF is that such neurons exist aplenty, but elsewhere in the brain. If such is the case, then the relatively weak spontaneous behavior in Experiment 1 may be explainable if training is a necessary prerequisite for a strong behavioral response.

In conclusion, the neurons that confer a special perceptual status to harmonic sounds remain to be conclusively identified. Perhaps the puzzle of the cortical encoding of harmonicity will be unraveled by experiments having neural recordings coupled closely with functional brain imaging and behavioral measures in trained animals.

We thank Shantanu Ray for expert programming and electronics assistance, Yadong Ji, Tamar Vardi, and Sarah Newman for help with training animals, as well as Heather Dobbins and Barak Shechter for assistance with physiological recordings. We are grateful to the three anonymous reviewers and the associate editor for helpful comments that greatly improved the manuscript.

APPENDIX: MEASURING THE STRF OF A NEURON WITH TORC STIMULI

The TORC stimulus is a particular combination of broadband stimuli known as *moving ripples*, whose spectrotemporal envelope is given by

$$S(t,x) = a_0 + a\cos[2\pi(\omega t + \Omega x) + \psi]. \quad \text{(A1)}$$

At each frequency location, the function describes a sinusoidal modulation of sound level at a rate of ω cycles/s around a mean a_0 and amplitude a; the relative phases of these modulations at different log frequency, $x=\log(f/f_0)$, produce a sinusoidal or rippled profile of density Ω cycles/octave. The rippled profile drifts across the spectral axis in time, hence leading to the name of moving ripples for these stimuli. Analogous to sinusoids for one-dimensional signals, moving ripples are basis functions of the spectrotemporal domain in that any arbitrary spectrotemporal profile can be constructed from a combination of them. And analogous to estimating the impulse response of a one-dimensional system using reverse correlation with white noise stimuli that have equal representation of all sinusoidal frequencies within the system bandwidth (de Boer and de Jongh, 1978), it is possible to estimate the STRF by reverse correlation with spectrotemporal white noise (STWN), which is a stimulus that has an equal representation of all moving ripples within the spectrotemporal bandwidth of the system[4] (Klein *et al.*, 2000, 2006).

However, because the STRF (x,t) transforms a two-dimensional input to a one-dimensional output, moving-ripple components of STWN that are spectrally orthogonal (different ripple densities, Ω, but same ripple periodicities, ω) can evoke overlapping response components that cannot be disambiguated; reverse correlation with such stimuli can result in inaccurate and noisy estimates of the STRF. The TORC stimulus overcomes this problem by ensuring that each moving ripple in the stimulus has a different absolute ripple periodicity $|\omega|$, so that each linear response component is uncorrelated with every ripple component of the stimulus except for the one evoking it. Therefore, when using reverse correlation with a TORC stimulus, response components of a given ripple periodicity contribute only to a single $[\omega,\Omega]$ component of the STRF.

[1]Spectral fusion of components and their contribution to virtual pitch are not entirely congruent in human listeners as well. For example, a component must be mistuned from a harmonic relation by 1.5%–2% in order to hear it apart from the remaining components, whereas it must be mistuned by 8% to stop contributing to the pitch of the complex (Ciocca and Darwin, 1993; Darwin and Ciocca, 1992; Moore *et al.*, 1986; Moore and Kitzes, 1985).

[2]The predictions are stochastic quantities because they are derived from STRFs that are estimated from spike train measurements having inherent variability.

[3]The period histogram accumulates the number of spikes occurring at a given phase of the modulation period of the amplitude-modulated complex tone. We accumulate all spikes occurring between 100 ms after stimulus onset and the end of the stimulus.

[4]For the cortical neurons investigated in this paper, ripple periodicities were less than 32 Hz and ripple densities were less than 1.4 cycles/octave.

(Received 20 December 2006; revised 25 February 2008; accepted 28 February 2008)

Pathologic changes within the organic constitution of vocal folds or a functional impairment of the larynx may result in disturbed or even irregular vocal fold vibrations. The consequences are perturbations of the acoustic speech signal which are perceived as a hoarse voice. By means of appropriate image processing techniques, the vocal fold dynamics are extracted from digital high-speed videos. This study addresses the approach to obtain a parametric description of the spatio-temporal characteristics of the vocal fold oscillations for the aim of classification. For this purpose a biomechanical vocal fold model is introduced. An automatic optimization procedure is developed for fitting the model dynamics to the observed vocal fold oscillations. Thus, the resulting parameter values represent a specific vibration pattern and serve as an objective quantification measure. Performance and reliability of the optimization procedure are validated with synthetically generated data sets. The high-speed videos of two normal voice subjects and six patients suffering from different voice disorders are processed. The resulting model parameters represent a rough approximation of physiological parameters along the entire vocal folds.

I. INTRODUCTION

Supporting clinical diagnosis and classification of voice pathologies by means of objective measurements is an important issue in medical voice assessment. A widely used approach is the analysis of the acoustic speech signal.[1–3] However, voice signals provide only symptomatic information about the laryngeal dysfunction. Predications about the voice disorder itself are thus ambiguous.[4]

The reasons for perturbations of the acoustic speech signal are asymmetric or even irregular vocal fold vibrations which result from pathologic changes within the organic constitution of the vocal folds or an impairment of the laryngeal function.[5,6] For evaluating the direct effect of the laryngeal pathology, the observation of the vibrating vocal folds is an important method in clinical investigation of voice abnormalities.[7,8] Using state of the art digital high-speed imaging techniques, normal and pathologic vocal fold vibrations are observable during voice production with sufficient spatial and temporal resolution.[9,10] The analysis of high-speed recorded vocal fold vibrations has proven to be useful to study pathological and normal voice production.[9] The vocal folds are delineated by appropriate image processing algorithms.[11–14] For a quantitative analysis it is useful to derive a concise description of the vocal fold dynamics from the segmentation results.

One common approach is to compute the glottal area wave form, a plot of the area of the vocal fold opening, or glottal area, as a function of time.[15,16] Using the glottal area function, oscillation amplitude and frequency are commonly analyzed, as well as the ratio between open and closed duration of the glottis.[17] As a main shortcoming, this function does not distinguish between the influence of the left and the right vocal fold. Asymmetries concerning oscillation directions, velocities and amplitudes between the dynamics of the left and the right vocal fold are not evaluated. Local disturbances of the vibration pattern due to organic disorders are not incorporated sufficiently.

Further approaches for a quantitative analysis of segmented high-speed videos are deflection measurements of the vocal fold oscillations.[11,17] Here, the time-dependent distance of a specific point on the medial vocal fold edge to the longitudinal glottal axis is extracted (single-line kymography). In this way, the dynamic of each vocal fold is described by a one-dimensional trajectory. For a direct analysis of these trajectories, symmetry measures such as amplitude ratio or phase shift between left and right oscillation are introduced.[9,18] An alternative for evaluating the deflection measurements is a model-based approach.[6,19] The vocal fold dynamics can be reproduced with lumped-element models, such as the so-called two-mass model (2MM).[20] By means of automatic parameter optimization, the model oscillations are fitted to the bilateral motion curves.[19,21,22] The optimized model parameters enable an objective quantification of the vocal fold dynamics. The model-based method is advanta-

[a)]Author to whom correspondence should be addressed. Electronic mail: raphael.r.schwarz@googlemail.com

geous, as besides temporal oscillation properties like frequency, amplitude, and phase, also the specific wave forms of the oscillations are incorporated for the quantification. Additionally, the resulting model configurations facilitate further research into normal and pathologic human voice production by means of model simulations.[23] The model-based approach was successfully applied for an objective classification of vocal fold vibrations.[21,22]

Besides left-right asymmetries, alteration of wave forms also in longitudinal direction are observable as a consequence of voice disorders (e.g., due to organic impairments of the vocal folds). For analyzing such vibration patterns the deflection measurements by means of single-line kymography need to be extended. In Tigges *et al.*[24] and Neubauer *et al.*[10] the distances of the vocal fold edges from the longitudinal glottal axis are evaluated at multiple specific points (multi-line kymography). In this way a set of one-dimensional trajectories is obtained, describing the vocal fold vibrations at different points along each vocal fold. One method to analyze the trajectories is the evaluation of different symmetry measures.[25] In this way, amplitude differences and phase shifts between the left and the right vocal fold for the multiple longitudinal positions are evaluated. However, details concerning the time-varying shape of the vocal fold edges are not incorporated.

In this work a new model-based approach is proposed to enable an objective quantification of vocal fold vibration patterns that also takes longitudinal vibration modes into account. The so-called multi-mass model (MMM) based on Wong *et al.*,[26] a longitudinal extension of the 2MM as used in Schwarz *et al.*[21] and Wurzbacher *et al.*,[22] is introduced. Compared to other complex and high-dimensional models, ranging from multi-mass models with different surface modeling[27,28] to finite-element approaches,[29,30] the MMM allows to describe the pathologic vocal fold vibrations using only a limited parameter set.[26,31,32] This property enables a parameter optimization with suitable computing time. The MMM is combined with a new automatic optimization procedure based on a genetic algorithm. The performance of the model-based approach is validated with synthetic and clinical data sets. It is shown, that besides a spatio-temporal quantification, the proposed method allows to infer an estimation of physiological vocal fold parameters.

II. METHODS

A. Videoendoscopy and clinical data

High-speed videos are recorded during stationary sustained phonation of a vowel /a/ in a comfortable way (stationary phonation paradigm). The vocal fold vibrations are observed from a top-view position with a digital high-speed camera system (High-Speed Endocam, Wolf Corp., Knittlingen, Germany, temporal resolution 4000 frames/s, spatial resolution 256×256 pixels) which is coupled to a rigid endoscope, illuminated by a 250 W Xe light. Figure 1 shows the recording situation (left) and a single image from a high-speed video (right). From each high-speed video a sequence of $N=351$ frames (87.5 ms) is evaluated. The vocal fold edges are segmented, using the method after Lohscheller *et al.*[14] Within Fig. 1 (right) the segmented vocal fold edges are depicted as a dotted white line. The opening between the vocal folds is called glottis with opening area $a_v[n]$ for frame n. Posterior (pc) and anterior commissure (ac) mark the dorsal and ventral endings of the glottal axis. Within the short intervals of a high-speed sequence (less than 100 ms), changes of the vocal fold length are negligible due to the stationary phonation paradigm. Thus, the distance between the anterior and posterior commissure can be assumed to be constant during the evaluated sequence. In Fig. 1 (right), the points $\mathbf{g}_j$, with $j=1,\ldots,3$, are positioned at 25%, 50%, and 75% of the glottal axis length, starting from the posterior commissure. The dashed lines k_j are perpendicular to the glottal axis (intersection points $\mathbf{g}_j$). The intersection points $\mathbf{p}_j$ (right vocal fold) and $\mathbf{p}_{j+3}$ (left vocal fold), $j=1,\ldots,3$, of the vocal fold edges and the lines k_j are determined in each frame. For frame n, the distances $c_{v,j}[n]$ (right vocal fold) and $c_{v,j+3}[n]$ (left vocal fold) are calculated after

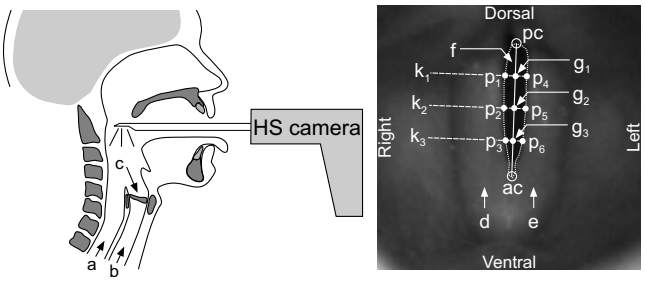

FIG. 1. Laryngeal high-speed videoendoscopy. Left: a rigid 90° endoscope connected to a digital high-speed camera is placed into the oropharynx (a–esophagus, b–trachea, c–vocal folds). Right: single image from a high-speed video (d,e–right and left vocal fold, f–glottis, ac–anterior commissure, pc–posterior commissure). The segmented vocal fold edges (dotted white line) and the glottal axis (solid white line from ac to pc) are shown.

$$c_{v,j}[n]=(-1)^{\kappa}\|\mathbf{p}_j-\mathbf{g}_j\|_2, \tag{1}$$

$$c_{v,j+3}[n]=(-1)^{\kappa+1}\|\mathbf{p}_{j+3}-\mathbf{g}_j\|_2, \tag{2}$$

with

$$\kappa=\begin{cases}1, & \text{mass crosses glottal axis}\\ 2, & \text{otherwise}\end{cases}. \tag{3}$$

In the sense of multi-line kymography, the vocal fold deflections are described by the *experimental curves* comprising the one-dimensional trajectories $c_{v,i}[n]$ and the glottal area function $a_v[n]$, with $i=1,\ldots,6$ and $n=1,\ldots,N$.

A reduced quality of the endoscopic images results in errors of the segmentation process. The applied image processing algorithm uses a threshold value to decide whether a certain pixel is part of the glottis or the vocal fold edges. If the transition between the glottis and the vocal folds is blurred within the high-speed data, the uncertainty of the edge segmentation increases. This uncertainty takes effect on the amplitudes of the extracted experimental curves. In this study, the typical deflection at medial position is about 10 pixels. The accuracy of the segmentation algorithm is about 1.5 pixel in lateral direction,[14] i.e., the relative segmentation error ϵ_s is about 15%. This error is mainly due to

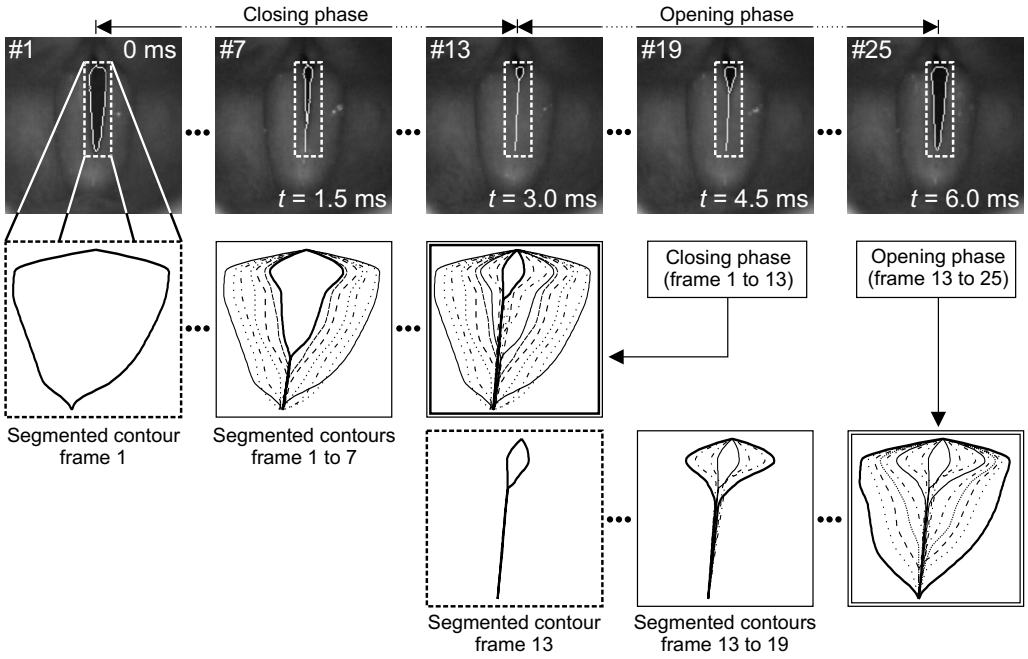

FIG. 2. Image sequence from a digital high-speed video. An oscillation cycle for normal vocal fold vibration is shown (first row). An alternative illustration of the vocal fold dynamics is depicted in the second (closing phase) and the third (opening phase) row.

the limited spatial resolution of the charge coupled device chip of the camera rather than from inaccurate segmentation of the glottal edges.

Figure 2 (first row) depicts an oscillation cycle in case of normal voice. The segmentation result is shown as a white line in each image. Here, the cycle starts with a maximum opening (frame 1). The glottal closing occurs with a longitudinal phase shift starting from the ventral part of the vocal folds (frame 7, after 1.5 ms). The minimum glottal area is achieved after 3 ms with a minor glottal closure insufficiency at the dorsal end (frame 13). After 6 ms the maximum opening is reached again (frame 25). The lower two rows show the construction of a compact illustration of the vocal fold dynamics. The first image of the second row represents the segmented contour of the first frame. The subsequent segmentation results are also drawn in the same figure (second image). In the third image (doubled border) the contours of the whole closing phase are depicted. For the opening phase, a second image is produced in the same way (third row). The resulting figure for the closing phase is shown in the third image of the third row. In the following, this compact illustration is used to represent the spatio-temporal characteristics of clinical data.

Within this study high-speed videos from two normal voice subjects (S1, S2) and six subjects (S3–S8) suffering from voice disorders are evaluated. Figures 3 and 4 give a survey of the corresponding vibration patterns. The left column shows a closing phase from each video. For subject S1, the sampling points of the trajectory $c_{v,2}$ (i.e., the dynamics of the right vocal fold at medial position) derived from the segmented contours are shown. For S1–S8 the intersection points $\mathbf{p}_2[n]$ of line k_2 and the right vocal fold edge are shown. The right column depicts the opening phase. It follows a brief description of the specific vibration characteristics:

- **S1**. Normal male voice. Left and right vocal fold oscillation are almost symmetric with respect to the glottal axis. Duration $\Delta t_c = 2.5$ ms of the closing phase is greater than the opening phase duration $\Delta t_o = 1.5$ ms. The glottal closure starts at the ventral end.
- **S2**. Normal female voice. Left and right vocal fold oscillation are almost symmetric. The closing phase is slightly longer ($\Delta t_c = 2.5$ ms) than the opening phase ($\Delta t_o = 2.0$ ms). The glottal closure starts at the ventral end. There is a glottal closure insufficiency at the dorsal end.
- **S3**. Functional dysphonia. The vibrational amplitude of the left vocal fold is reduced. The glottal closure is insufficient.
- **S4**. Unilateral paralysis (right sided). The glottal closure is insufficient and there is a phase shift between the left and right vocal fold oscillation. The left vocal fold reveals a longitudinal vibration mode.
- **S5**. Spasmodic dysphonia. The vocal fold oscillations are almost symmetric as for the normal voice subjects. However, spasms cause the vocal folds to slam together and stiffen. As a consequence Δt_c and Δt_o are decreased (1.0 and 0.75 ms, respectively) compared to the duration of the glottal closure (2.25 ms). The glottis is closed for more than half of the oscillation cycle.
- **S6**. Vocal fold scar (right sided). The right vocal fold shows a longitudinal vibration mode. The right oscillation amplitude is decreased compared to the left side. The du-

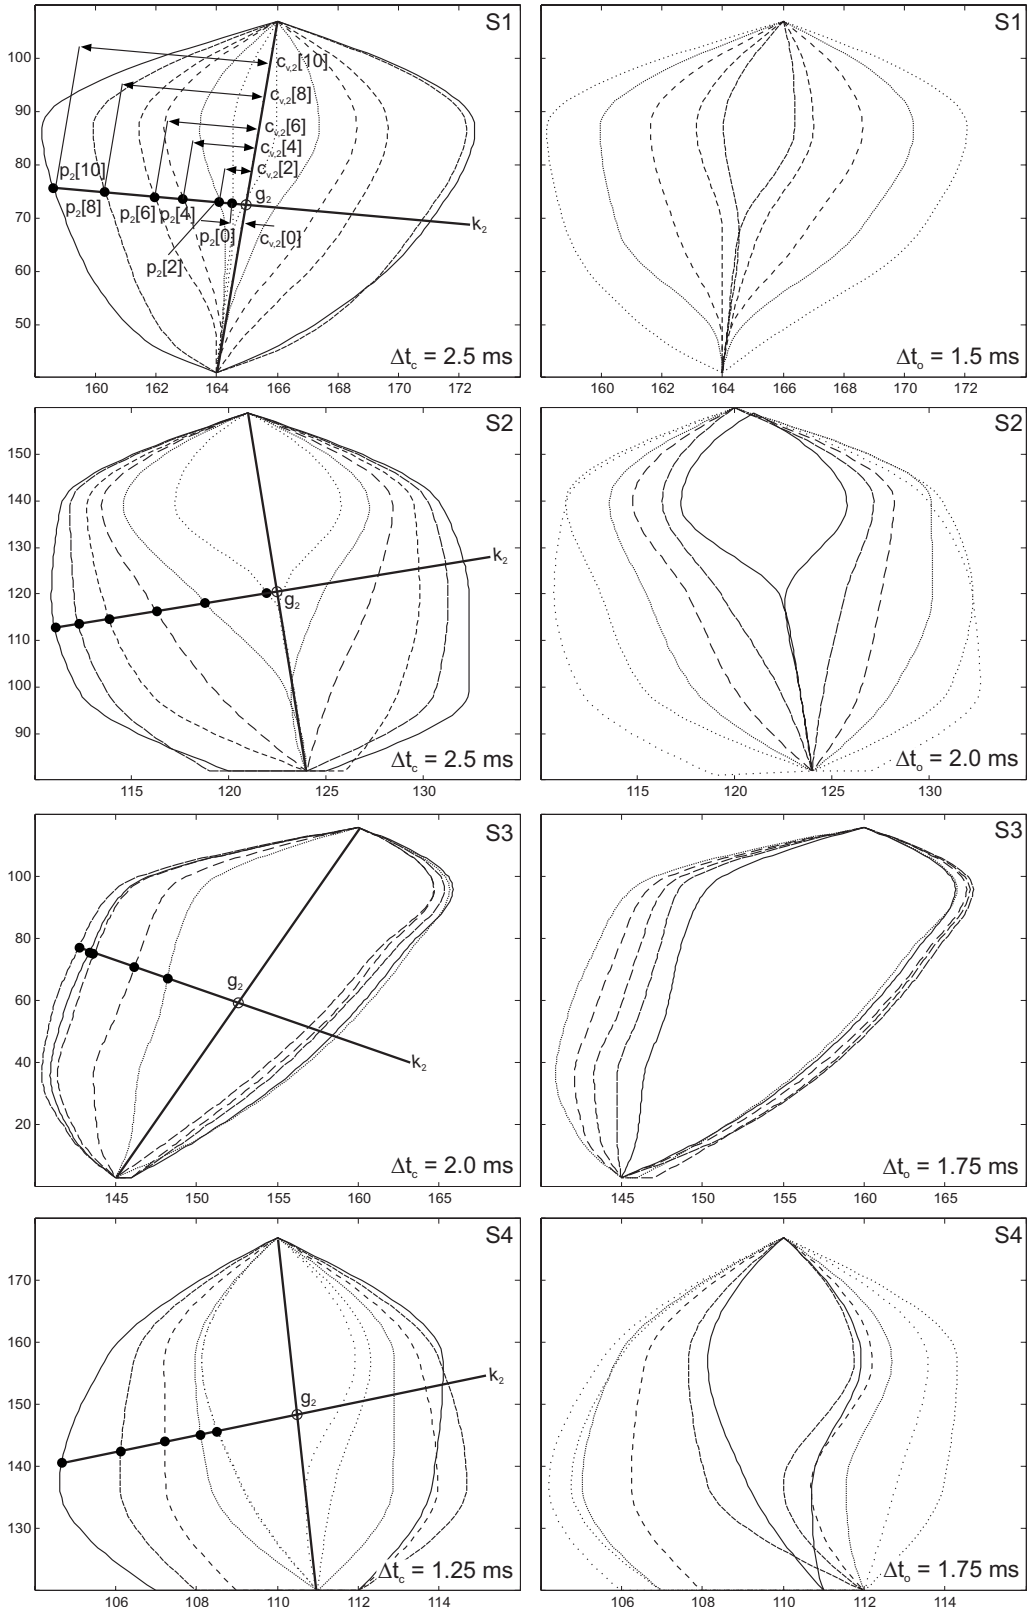

FIG. 3. Vocal fold vibration patterns for the subjects S1–S4. The left column shows the closing phase (duration Δt_c), the right column the opening phase (duration Δt_o). For subject S1, the sampling points of the experimental trajectory $c_{v,2}$ extracted during the closing phase from even-numbered frames are depicted.

ration of the glottal closure is short (0.5 ms) compared to the opening and closing phase (1.5 ms each).

- **S7**. Reinke's edema. The edema at the ventral end of the right vocal fold decreases the right oscillation amplitude. The glottal closure at the dorsal end is insufficient.
- **S8**. Nodules. The nodules are at medial position, symmetrical on both vocal folds. The glottal closure at the dorsal end is insufficient.

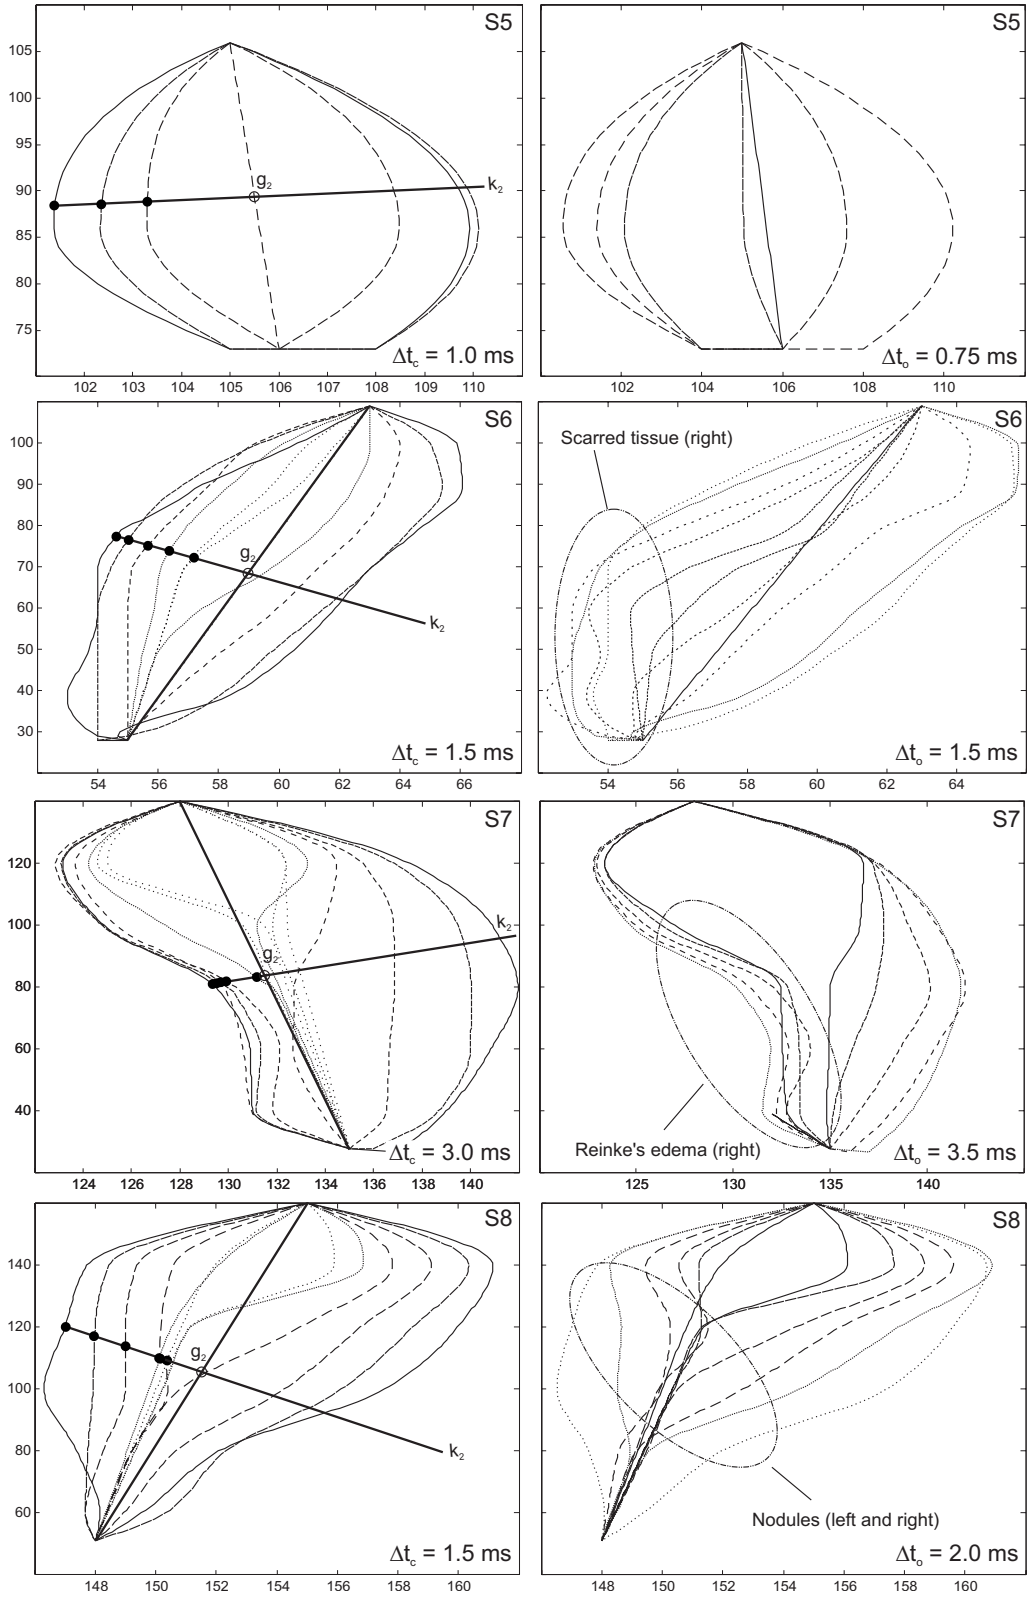

FIG. 4. Vocal fold vibration patterns for the subjects S5–S8. The left column shows the closing phase, the right column the opening phase.

B. Multi-mass model

For modeling the vocal fold dynamics a multi-mass model (MMM), similar to the model proposed in Wong *et al.*[26] (hereafter called the WO91 model), is used. Figure 5 shows a perspective view of the MMM. The coupled mass-spring oscillators numbered with $i=1,\ldots,6$ are the vibrating elements. In accordance to the view from the high-speed videos, the elements on the left ($i=1,\ldots,3$) model the dynamics of the right vocal fold, the elements on the right ($i=4,\ldots,6$) model the left vocal fold vibrations. Towards the posterior commissure, the vibrating elements are coupled to two fixed positions. These fixed positions correspond to the

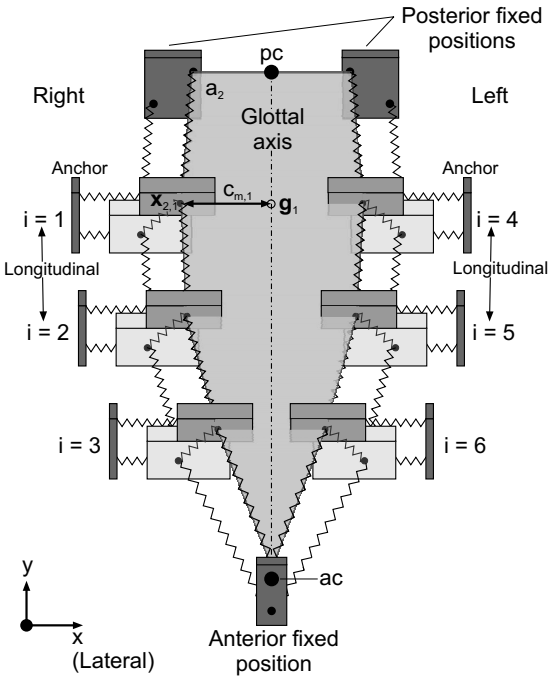

FIG. 5. Schematic representation of the multi-mass model of the vocal folds. The left model side represents the right vocal fold, the right side the left vocal fold. The minimum opening formed by the positions of the masses and fixed positions of both planes represents the glottal area (a_2). Posterior (pc) and anterior commissure (ac) define the glottal axis.

stiffened nonvibrating transition between the vocal cord and the arytenoid cartilage, the so-called vocal process.[33] At the ventral ending of the glottis the two model sides join together at a single fixed position (anterior commissure). In the following, the indices $s=1$ and $s=2$ denote the lower and the upper horizontal model plane. The vector $\mathbf{x}_{s,i}=(x_{s,i},y_{s,i})^T$, where $(\cdot)^T$ denotes the transposed vector, defines the position of the mass element $m_{s,i}$, with velocity $\dot{\mathbf{x}}_{s,i}$ and acceleration $\ddot{\mathbf{x}}_{s,i}$. Together with the fixed positions, the mass positions $\mathbf{x}_{s,i}$ define the model opening $a_s[n]$ of the horizontal plane s for the nth time step.

Compared to the WO91 model the following extensions are introduced for the MMM:

1. Besides different values of the anchor spring constances along each model side, variations of the longitudinal coupling stiffnesses are also considered.
2. The mass elements are allowed to move within the whole xy plane in longitudinal and lateral directions. This means a fully two-dimensional extension of the WO91 model.
3. The flow is calculated for the entire opening formed by the mass positions in each horizontal plane. Within the WO91 model, the glottal air flow is constricted to the sum of the parallel flows through each opposing pair of mass-spring oscillators.

The first extension is introduced to model alterations of the longitudinal stiffness within the vocal fold tissue, especially due to local tissue impairments. The applied image processing algorithm delivers a two-dimensional projection of the vocal fold movements. Following the second extension these

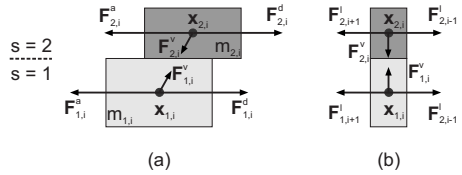

FIG. 6. Free body diagram of an oscillating element in lateral view (a) and frontal view (b).

movements can be reproduced by the MMM. The third extension of the WO91 model is necessary due to the second extension.

The equation of motion for a mass element $m_{s,i}$ is defined as

$$\mathbf{0}=m_{s,i}\ddot{\mathbf{x}}_{s,i}+\mathbf{F}^a_{s,i}+\mathbf{F}^v_{s,i}+\mathbf{F}^l_{s,i}+\mathbf{F}^c_{s,i}+\mathbf{F}^d_{s,i} \tag{4}$$

with the following forces:

$\mathbf{F}^a_{s,i}$ – force due to the anchor spring,

$\mathbf{F}^v_{s,i}$ – vertical coupling force,

$\mathbf{F}^l_{s,i}$ – longitudinal coupling force,

$\mathbf{F}^c_{s,i}$ – force due to collision with other masses or longitudinal coupling springs,

$\mathbf{F}^d_{s,i}$ – driving force generated by glottal flow.

Figure 6 shows a free body diagram of a single oscillator element with the acting forces. Compared with the WO91 model a more general definition of the forces is required according to the two-dimensional model extensions.

1. Anchor force

With stiffness $k^a_{s,i}$ and damping $r^a_{s,i}$ of the anchor spring as well as the rest position $\mathbf{x}^r_{s,i}$ of mass $m_{s,i}$ the anchor force $\mathbf{F}^a_{s,i}$ is defined as

$$\mathbf{F}^a_{s,i}:=k^a_{s,i}\|\mathbf{x}^r_{s,i}-\mathbf{x}_{s,i}\|_2\mathbf{u}^a_{s,i}+r^a_{s,i}(\mathbf{u}^a_{s,i})^T\dot{\mathbf{x}}_{s,i}\mathbf{u}^a_{s,i}. \tag{5}$$

For the definition of the unit vector $\mathbf{u}^a_{s,i}$, see Fig. 7.

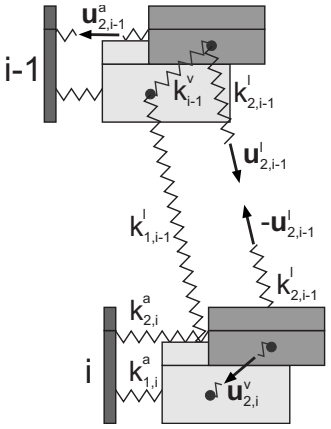

FIG. 7. Graphical definition of the unit vectors $\mathbf{u}^a_{s,i}$, $\mathbf{u}^l_{s,i}$, and $\mathbf{u}^v_{s,i}$ for the anchor force, longitudinal and vertical coupling.

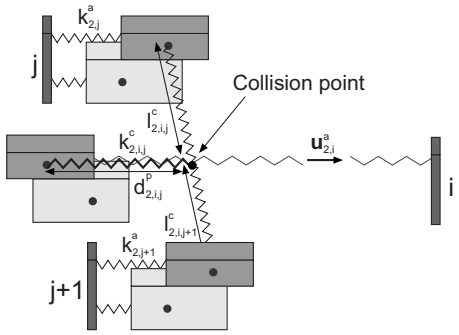

FIG. 8. Illustration of a single impact within the multi-mass model.

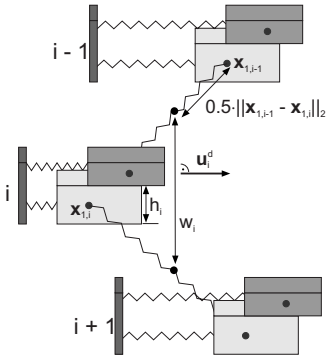

FIG. 9. Graphical definition of the unit vector $\mathbf{u}_{s,i}^{d}$ and the effective side length w_i for the driving force.

2. Vertical coupling force

The vertical coupling force $\mathbf{F}_{s,i}^{v}$ is calculated after

$$\mathbf{F}_{s,i}^{v} := k_i^{v}(\|\mathbf{x}_{s,i}^{r} - \mathbf{x}_{s^*,i}^{r}\|_2 - \|\mathbf{x}_{s,i} - \mathbf{x}_{s^*,i}\|_2)\mathbf{u}_{s,i}^{v} + r_i^{v}(\mathbf{u}_{s,i}^{v})^T(\dot{\mathbf{x}}_{s,i} - \dot{\mathbf{x}}_{s^*,i})\mathbf{u}_{s,i}^{v} \quad (6)$$

with the stiffness and damping coefficients k_i^{v} and r_i^{v} of the vertical coupling spring connecting masses $m_{1,i}$ and $m_{2,i}$. Index $s^*=1$ for $s=2$, otherwise $s^*=2$ is used. For the definition of the unit vector $\mathbf{u}_{s,i}^{v}$, see Fig. 7.

3. Longitudinal coupling force

The force $\mathbf{F}_{s,i}^{l}$ acting on mass $m_{s,i}$ due to the longitudinal coupling to $m_{s,i-1}$ and $m_{s,i+1}$ is defined as

$$\begin{aligned}\mathbf{F}_{s,i}^{l} := {} & k_{s,i-1}^{l}(\|\mathbf{x}_{s,i}^{r} - \mathbf{x}_{s,i-1}^{r}\|_2 - \|\mathbf{x}_{s,i} - \mathbf{x}_{s,i-1}\|_2)(-\mathbf{u}_{s,i-1}^{l}) \\ & + r_{s,i-1}^{l}(-\mathbf{u}_{s,i-1}^{l})^T(\dot{\mathbf{x}}_{s,i} - \dot{\mathbf{x}}_{s,i-1})(-\mathbf{u}_{s,i-1}^{l}) \\ & + k_{s,i}^{l}(\|\mathbf{x}_{s,i}^{r} - \mathbf{x}_{s,i+1}^{r}\|_2 - \|\mathbf{x}_{s,i} - \mathbf{x}_{s,i+1}\|_2)\mathbf{u}_{s,i}^{l} \\ & + r_{s,i}^{l}(\mathbf{u}_{s,i}^{l})^T(\dot{\mathbf{x}}_{s,i} - \dot{\mathbf{x}}_{s,i+1})\mathbf{u}_{s,i}^{l}, \end{aligned} \quad (7)$$

where $k_{s,i-1}^{l}$, $k_{s,i}^{l}$ and $r_{s,i-1}^{l}$, $r_{s,i}^{l}$ are the stiffness and damping coefficients of the longitudinal coupling springs, see Fig. 7.

4. Collision force

In case of collision an additional restoring force $\mathbf{F}_{s,i}^{c}$ acts on the mass $m_{s,i}$.[34] A collision is defined for $m_{s,i}$ if its anchor spring crosses the longitudinal coupling spring between two adjacent masses $m_{s,j}$ and $m_{s,j+1}$, as illustrated in Fig. 8. For the general case that $m_{s,i}$ causes more than one collision, the resulting collision force is given by

$$\mathbf{F}_{s,i}^{c} := \sum_{\forall j} k_{s,i,j}^{c} d_{s,i,j}^{p} \mathbf{u}_{s,i}^{a}, \quad (8)$$

with the stiffness of the restoring spring $k_{s,i,j}^{c}$ and the penetration depth $d_{s,i,j}^{p}$, defined as in Fig. 8. Derived from the 2MM[35] $k_{s,i,j}^{c}$ is calculated after

$$k_{s,i,j}^{c} := 3 \cdot \left(\frac{l_{s,i,j}^{c}}{l_{s,i,j}^{c} + l_{s,i,j+1}^{c}} k_{s,j}^{a} + \frac{l_{s,i,j+1}^{c}}{l_{s,i,j}^{c} + l_{s,i,j+1}^{c}} k_{s,j+1}^{a} \right), \quad (9)$$

where $l_{s,i,j}^{c}$ denotes the distance between the collision point and the position of the mass $m_{s,j}$, see Fig. 8.

5. Driving force

$\mathbf{F}_{s,i}^{d}$ is the driving force for the self-sustained MMM oscillation. It results from the pressure drop within the glottis. As the air flow is calculated for the entire model opening, the calculation of $\mathbf{F}_{s,i}^{d}$ differs from the definition in the WO91 model. The aerodynamic forces are described by the Bernoulli law and based on the following assumptions:[19,21–23,36,37]

- The subglottal pressure P^{sub} and the supraglottal pressure P^{supra} are constant with $P^{\text{supra}}=0$.[35]
- The interaction of the glottal flow with the subglottal and supraglottal vocal tract is neglected.[23,36]
- Pressure drop due to viscous losses within the glottis is neglected.[28]
- The Bernoulli force acts only below the narrowest part of the constriction and therefore only within the lower plane of the MMM.[19,38]

Following these assumptions the driving force is calculated as

$$\mathbf{F}_{s,i}^{d} = \begin{cases} P \cdot w_i \cdot h_i \cdot \mathbf{u}_i^{d}, & s=1 \\ \mathbf{0}, & s=2 \end{cases}, \quad (10)$$

with the height h_i of mass $m_{1,i}$ and the effective side length

$$w_i = \tfrac{1}{2} \cdot \|\mathbf{x}_{s,i+1} - \mathbf{x}_{s,i-1}\|_2. \quad (11)$$

The unit vector $\mathbf{u}_i^{d}$ indicates the direction of $\mathbf{F}_{s,i}^{d}$, see Fig. 9. The pressure P within the lower plane is calculated in accordance to Steinecke and Herzel[35] as

$$P = \begin{cases} P^{\text{sub}} \cdot \left(1 - \left(\dfrac{\min(a_1,a_2)}{a_1}\right)^2\right), & a_1 > 0 \\ 0, & a_1 \leqslant 0 \end{cases}. \quad (12)$$

The driving pressure P depends on the ratio of the areas a_s.

For the integration of the equations of motion a fourth-order Runge-Kutta algorithm is used. The step size is set to 0.25 ms. Due to the sampling frequency of the high-speed camera of 4000 frames/s no resampling is needed. The model runs with a computing time to real-time ratio of almost 1:1 (C# Pentium 4, 3 GHz).

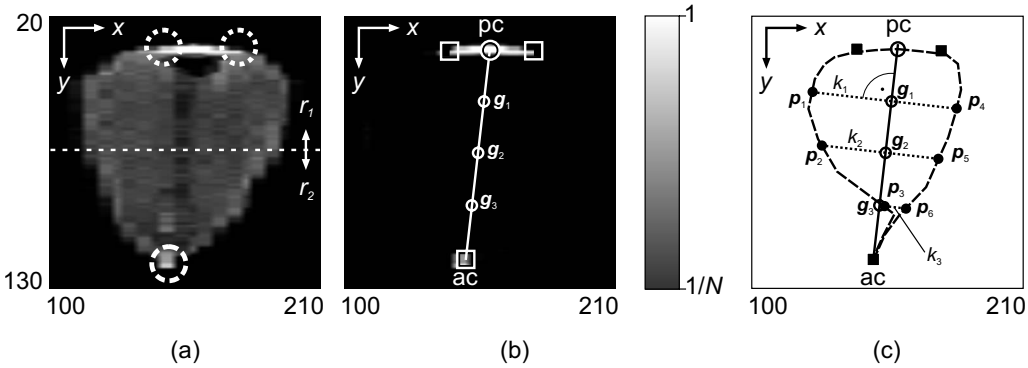

FIG. 10. (a) Representation of the histogram matrix H. The estimated positions of the anterior commissure (dashed circle) and the vocal processes (dotted circles) are shown. (b) Segmented regions at the anterior and the posterior commissure. The white squares represent the identified coordinates for the three fixed positions. The points $\mathbf{g}_j$ mark the dorsal, medial, and ventral position on the glottal axis. (c) The rest positions $\mathbf{p}_i$ for the oscillating elements are derived from the glottal contour with mean opening area (dashed line).

C. Automatic parameter optimization

The optimization procedure is constructed to simulate real vocal fold vibrations as exact as possible. For this aim, a model initialization, optimization parameters and an objective function consisting of two measures evaluating the fitting quality to the vocal fold vibrations are introduced in the following. The optimization parameters which result into the best fitting represent a quantitative description of the vocal fold vibrations patterns.

1. Model initialization

Precondition for the parameter optimization is a proper initialization of the MMM depending on the evaluated high-speed video. The applied image processing algorithm delivers the time-variant glottal contour but no information about the positions of the left and right vocal process which correspond to the two fixed positions near the posterior ending of the MMM. Also the anterior commissure where both vocal folds merge together is not determined. These fixed positions and subsequently the rest positions $\mathbf{x}_{s,i}^r$ for the masses are calculated with the following procedure: A histogram matrix $H(x,y)$ with 256×256 entries is derived from the segmentation results. The value of each entry $H(x,y)$ equals the number of time steps in which the corresponding pixel position (x,y) is part of the segmented glottal contour, normalized to the number of time steps N. For the pixel coordinates which are not passed by vocal fold edges the matrix entry is 0. Figure 10(a) depicts the matrix H for the high-speed video from a healthy voice subject (see Fig. 2). The black areas show the pixels which never belong to the segmented contour. The triangular-shaped region comprises the pixels contacted by the glottal edges during vocal fold oscillations. The boundary to the black area marks the maximum opening of the glottal area. The positions of the anterior commissure (dashed circle at the lower tip of the glottal area) as well as the left and right vocal process (dotted circles at the upper boundary of the glottal area) are represented by increased values within H. Thus, the characteristic positions can be identified by segmenting these parts of H which show maximum matrix entries. For this purpose, H is subdivided in the regions r_1 and r_2 as shown in Fig. 10(a). By definition the posterior commissure is located in r_1 while the anterior commissure can be found in r_2. Within each region a specific maximum $\eta_l=\max(H(x,y))$ with $(x,y)\in r_l$ and $l\in\{1,2\}$ occurs. Using threshold $\tau=\min(\eta_1,\eta_2)$, i.e., $H(x,y)=0$ if $H(x,y)<\tau$, the Matrix H can be segmented resulting in Fig. 10(b). Here, only matrix elements remain which are located near the posterior and anterior commissure. The pixel with minimum x within r_1 is used for the left posterior fixed position and the pixel with maximum x for the right one. The posterior commissure (pc) is on half way between these two points. The pixel with maximum y within r_2 defines the anterior commissure (ac). The three points $\mathbf{g}_j$ are defined as in Sec. II A. The frame n^* with the glottal area nearest to the mean opening is identified after

$$n^* = \underset{n}{\operatorname{argmin}} \left| a_u[n] - \frac{1}{N}\sum_{k=1}^{N} a_u[k] \right|. \tag{13}$$

Using the segmentation result of frame n^*, the contour points $\mathbf{p}_i$, $i=1,\ldots,6$, are determined, see Fig. 10(c). The initial rest positions of the upper plane are assigned with $\mathbf{x}_{2,i}^r-\mathbf{p}_i$ $(i=1,\ldots,6)$ and for the lower plane following

$$\mathbf{x}_{1,i}^r = \begin{cases} \begin{pmatrix} 0.95\cdot x_{2,i}^r \\ y_{2,i}^r \end{pmatrix}, & i=1,\ldots,3 \\ \begin{pmatrix} 1.05\cdot x_{2,i}^r \\ y_{2,i}^r \end{pmatrix}, & i=4,\ldots,6 \end{cases}. \tag{14}$$

2. Optimization parameters

Certain vibration patterns of the MMM can be simulated by means of modifying specific model parameters. According to model-based approaches[19,21,22] the variable model parameters are P^{sub}, $m_{s,i}$, $k_{s,i}$ and the rest positions $\mathbf{x}_{s,i}^r$. These variable model parameters are initialized by the standard parameter values as used in the WO91 model. A set of eight optimization parameters Q_p, $Q_1,\ldots,Q_6$, and Q_r is defined for modifying the standard values. By means of this set the actual model parameters $\hat{P}^{\text{sub}}$, $\hat{m}_{s,i}$, $\hat{k}_{s,i}$ and rest positions $\hat{\mathbf{x}}_{s,i}^r$ are derived from the initial values as follows:[19,21,22]

$$\hat{P}^{\text{sub}} = P^{\text{sub}}\cdot Q_p, \tag{15}$$

$$\hat{m}_{s,i} = m_{s,i}/Q_i, \tag{16}$$

$$\hat{k}_{s,i} = k_{s,i} \cdot Q_i, \tag{17}$$

$$\hat{\mathbf{x}}^r_{s,i} = \begin{pmatrix} g_{x,i} \mp Q_r \cdot |g_{x,i} - x^r_{s,i}| \\ y^r_{s,i} \end{pmatrix}, \quad \text{with } \mathbf{g}_i = \begin{pmatrix} g_{x,i} \\ g_{y,i} \end{pmatrix}. \tag{18}$$

In Eq. (18) the "−" sign is used for $i=1,\ldots,3$ and "+" for $i=4,\ldots,6$. The scaling of upper and lower springs and masses with Q_i couples four model parameters in one single optimization parameter for each oscillating element. The reciprocal coupling of spring stiffness and magnitude of mass was proposed and justified in former works.[19,31] In this way, the number of free optimization parameters is reduced, which assures a unique association between Q_i and the model dynamics.[39]

3. Objective function

For evaluating the adaptation quality achieved with the parameters $\hat{P}^{\text{sub}}$, $\hat{m}_{s,i}$ and $\hat{k}_{s,i}$, the consistency between the dynamics of the MMM and the vocal folds needs to be quantitatively described. For this aim first the model dynamics needs to be described in a way comparable with the vocal fold dynamics, i.e., *theoretical curves* have to be defined in accordance with the experimental curves. Second, criteria are defined for comparing the model dynamics with the vocal fold oscillations.

3.1 Definition of the theoretical curves

In this work the vocal fold dynamics is captured by means of the time-varying contours of the segmented glottis, see Fig. 2. These two-dimensional vibration patterns are presented in the model as time-variant polygons. The polygons are spanned by the anterior and posterior fixed positions and the mass positions $\mathbf{x}_i$ of the plane s with minimum opening, calculated after

$$\mathbf{x}_i[n] = \begin{cases} \mathbf{x}_{1,i}[n], & \text{for } a_1[n] < a_2[n] \\ \mathbf{x}_{2,i}[n], & \text{otherwise} \end{cases}. \tag{19}$$

From these polygons with opening area $a_m[n] = \min(a_1[n], a_2[n])$, one-dimensional model trajectories $c_{m,i}[n]$ with $i=1,\ldots,6$ and $n=1,\ldots,N$ are derived as described for the vocal folds, see Eqs. (1)–(3) and Fig. 1. Opening area a_m and trajectories $c_{m,i}$ define the theoretical curves.

3.2 Comparison between model dynamics and vocal fold dynamics

For quantifying the consistency between experimental and theoretical curves, two criteria are defined:

1. **Area consistency measure**. The energy Δa of the difference between the area functions of the MMM $a_m[n]$ and the vocal folds $a_v[n]$, $n=1,\ldots,N$, normalized to the energy of $a_v[n]$ is calculated after

$$\Delta a = \frac{\frac{1}{N}\Sigma_{n=1}^{N}(|a_m[n] - a_v[n]|)^2}{\frac{1}{N}\Sigma_{n=1}^{N}(|a_v[n]|)^2}. \tag{20}$$

2. **Trajectory consistency measure**. For each position i the trajectory $c_{m,i}$ is compared with the trajectory of the corresponding point at the vocal fold edge $c_{v,i}$ and the energy of the difference signal is calculated after

$$\Delta c_i = \frac{1}{N}\sum_{n=1}^{N}(|c_{m,i}[n] - c_{v,i}[n]|)^2,$$

$$\Delta c = \frac{\frac{1}{6}\Sigma_{j=1}^{6}\Delta c_j}{\frac{1}{6}\Sigma_{k=1}^{6}\frac{1}{N}\Sigma_{n=1}^{N}(|c_{v,k}[n]|)^2}, \tag{21}$$

with Δc normalized to the mean energy of the trajectories $c_{v,i}$.

For bounding the ranges of the two measures, the function $f(x)$ is introduced as

$$f(x) := \begin{cases} x, & 0 \leqslant x \leqslant 1 \\ 1, & x > 1 \end{cases}. \tag{22}$$

By means of $f(x)$ the values Δa and Δc are limited to values $\leqslant 1$. The two measures are combined to the objective function ϕ:

$$\phi := f(\Delta a) + f(\Delta c). \tag{23}$$

The smaller the value ϕ the better is the achieved fitting of the model oscillations to the vocal fold vibrations. In the following a method is introduced which uses the optimization parameters and the objective function ϕ for an automatic fitting of the model dynamics.

4. Optimization procedure

The objective function ϕ is a nonconvex function within the search space spanned by the introduced optimization parameters. Stochastic sampling methods as genetic algorithms (GA) are an appropriate technique solving optimization problems with such objective functions.[40,41] Therefore, the proposed procedure for the parameter optimization is based on a GA and in principle works as follows:[41]

1. Optimization parameters—the interface between GA and the variable model parameters—are combined in a group herein after referred to as *individual*. A set of M individuals forms the actual *population*.
2. Using the parameters of an individual, the variable model parameters are calculated from the standard values and a simulation is carried out with the modified MMM. This step is performed for each member of the population.
3. The match between the resulting model dynamics and the vocal fold vibrations is quantified with the objective function.
4. Using the parameter values of the individuals and their corresponding values of the objective function, the GA calculates the new population. This procedure is iterated from step 2 until a termination condition is fulfilled. The

fittest individual of the final population, i.e., the individual which results in the best adaptation, is the optimization result.

A general description of genetic algorithms can be found in Goldberg.[40] The termination of the optimization procedure can be obtained in two ways. Either a maximum number of iterations is passed through or all individuals of the actual population are located close to the fittest one. Due to the negligible diversity of the population the GA generates no more individuals with significantly differing values for the optimization parameters. Improvements for the fitness values no longer occur.

Applied in the described manner, the GA delivers no unique results, because of the extensive search space for the optimization parameters. Thus, the optimization procedure consists of three parts, the pre-, the coarse, and the fine optimization. For each part the steps 1–4 are passed through once. The aim of the first and the second part is a sufficient limitation of the search space and part 3 determines the final result of the optimization:

1. **Pre-optimization**. In this step, the theoretical area function a_m is fitted in frequency and amplitude to a_v. Longitudinal vibration properties are not evaluated in this part. Therefore, parameters $Q_{\text{left}}=Q_{1,\ldots,3}$ and $Q_{\text{right}}=Q_{4,\ldots,6}$ are used. All springs and masses representing one vocal fold are scaled with the same value following Eqs. (17) and (16). As initial search range [0.3,…,3] is used for each parameter. The parameter ranges are appropriate for simulating normal and pathologic vocal fold vibration patterns. Within the objective function it is sufficient to use only the measure Δa. The pre-optimization delivers the values Q_p^{pre}, $Q_{\text{left}}^{\text{pre}}$, $Q_{\text{right}}^{\text{pre}}$, and Q_r^{pre}.
2. **Coarse optimization**. The complete parameter set $Q_p, Q_1, \ldots, Q_6, Q_r$ is used. The search ranges for the eight parameters are derived from the pre-optimization results: $Q \in [Q^{\text{pre}}/1.2, \ldots, Q^{\text{pre}}/0.8]$. In consequence of the homogeneous scaling with Q_{left} and Q_{right} within the pre-optimization large deviations Δc_i occur, if the vocal fold dynamics demands a Q_i distinct from the other two values of the same model side. It is the aim of the coarse optimization to detect this situation as follows: For the left $(\alpha=l)$ and right $(\alpha=r)$ model side, the pair $(i,j)_\alpha$ with the least difference between the energies of the trajectory difference signals is identified after

$$(i,j)_\alpha = \underset{(i,j)}{\operatorname{argmin}} |\Delta c_i - \Delta c_j| \quad i,j \in \begin{cases} 1,\ldots,3, & \alpha = l \\ 4,\ldots,6, & \alpha = r \end{cases} \tag{24}$$

and the mean values $\Delta c_{\text{mean}}^{\alpha} = \frac{1}{2}(\Delta c_i + \Delta c_j)$ are calculated. The remaining difference energy Δc_k, $k \neq i,j$, for each side is assigned to $\Delta c_{\text{max}}^{\alpha} = \Delta c_k$. For $\Delta c_{\text{max}}^{\alpha} > 4 \cdot \Delta c_{\text{mean}}^{\alpha}$ the search range for the corresponding parameter Q_k is extended to [0.3,…,3]. The factor 4 avoids an unnecessary extension of the search space in case of small deviations. Due to the local search space extension, distinct values for Q_k compared to the remaining both vales (Q_i, Q_j) of a single model side are enabled. Within the objective function, Δa and Δc are evaluated.

3. **Fine optimization**. For this step, the optimization is coupled with a regularization. Besides the model dynamics, the mass and stiffness distributions along each model side are evaluated. For this aim, a further regularization condition is introduced in addition to the objective function ϕ.

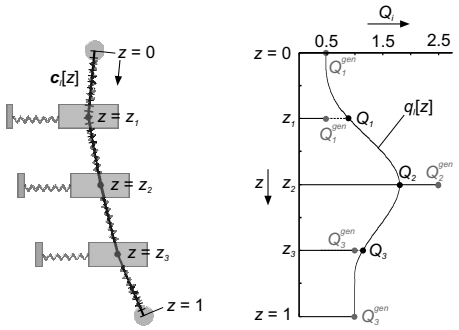

FIG. 11. Calculation of the longitudinal distribution $q_l[z]$ of the values Q_i $(i=1,\ldots,3)$ for the left model side.

For each model side (all masses are at rest position) contour lines $\mathbf{c}_\alpha[z]=(x[z],y[z])$ with the parametric domain $z \in [0,1]$ are determined as shown in Fig. 11. By means of approximation using cubic B splines, $q_\alpha[z]$ are derived from the sampling points $Q_j^{\text{gen}}(\alpha=l)$ and $Q_{j+3}^{\text{gen}}(\alpha=r)$, with $j=1,\ldots,3$. Thereby, Q_i^{gen} are the values for the optimization parameters delivered by the GA. Instead of using Q_i^{gen} for scaling the variable model parameters, the approximated values $Q_i=q_\alpha[z=z_i]$ are applied.

According to Eqs. (16) and (17) the function q_α approximates the mass and stiffness distributions along the model contour $\mathbf{c}_\alpha$. Following Hess *et al.*,[42] the mass and stiffness distributions along a vocal fold reveal a smooth course, i.e., a continuous behavior without excursive changes. To take this into consideration, the local smoothness s_i at position z_i is estimated as

$$s_i = \sum_{z=z_i-1}^{z_{i+1}} \left(\frac{q_\alpha[z-\Delta z] - 2q_\alpha[z] + q_\alpha[z+\Delta z]}{(\Delta z)^2} \right)^2, \tag{25}$$

the squared sum of the second order difference quotient with $\Delta z=0.01$. A mean value $\bar{s}$ of the s_i is calculated, whereby positions i with an extended search range during the coarse optimization are not considered:

$$\bar{s} = \frac{1}{\sum_{j=1}^{6} k_j} \sum_{i=1}^{6} k_i \cdot s_i,$$

with

$$k_i = \begin{cases} 0, & \Delta c_i = \Delta c_{\text{max}}^{\alpha} > 4 \cdot \Delta c_{\text{mean}}^{\alpha} \\ 1, & \text{else} \end{cases}. \tag{26}$$

For the regularization, a value $\bar{s}$ as low as possible, i.e., a function q_α as smooth as possible, is demanded. Extending the optimization procedure with the regularization, the final results $Q_p^*, Q_1^*, \ldots, Q_6^*$, and Q_r^* of the parameter optimization are calculated after

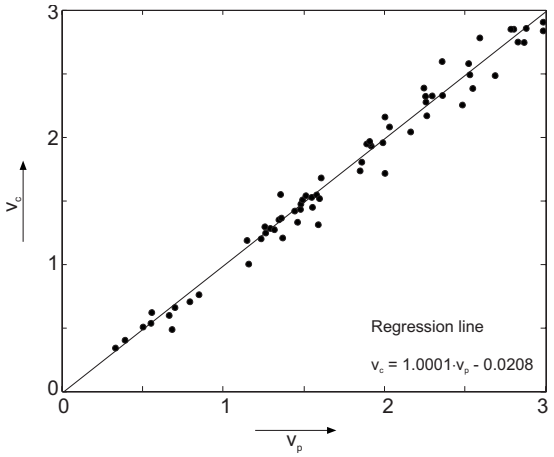

FIG. 12. Calculated parameter values v_c over the predefined parameter values v_p used for generating the synthetic vibration patterns.

$$\min_{Q_p,Q_1,\ldots,Q_6,Q_r}\left(\phi+\frac{\bar{s}}{\max_i(s_i)}\right). \tag{27}$$

The search spaces for the optimization parameters are derived from the results of the coarse optimization after $[Q^{\text{coarse}}/1.2,\ldots,Q^{\text{coarse}}/0.8]$.

5. Validation

Due to the nonconvex objective function ϕ with many local minima, it cannot be guaranteed to localize the global minimum. The different local minima of ϕ correspond to theoretical curves resulting from different values for the optimization parameters which fit more or less the experimental curves. In addition, the GA used for the optimization procedure is a stochastic approach and thus the calculated parameter values are not unique. Exact parameter values cannot be assured, as the results of the GA scatter within a certain interval. Therefore, the effects of the local minima of the objective function and the scattering of the optimization results has to be assessed. For this aim, the optimization procedure is applied to synthetic data sets. These data sets are generated by simulations with predefined model configurations. Eight model configurations are constructed, which simulate vibration patterns as observed for normal and pathologic voices as shown in Fig. 3 and 4. The time-variant contours formed by the modeled vocal fold edges are used as synthetic image processing results. For validation purposes, the parameter values resulting from the fitting of the MMM dynamics to the synthetic vibration patterns are compared with the predefined values. In this way, the reliability and performance of the optimization procedure is evaluated. Concerning the reproducibility of the optimization results, the parameter optimization is applied five times to each synthetic vibration pattern in addition to the first run. In this way, the scattering of the obtained parameter values and thus the reproducibility of the optimization results can be estimated.

TABLE I. Error between predefined and calculated parameter values averaged over all synthetic cases.

III. RESULTS

A. Validation of stability and reliability

In Fig. 12 the calculated parameter values v_c (comprising $Q_p^*,Q_1^*,\ldots,Q_6^*,Q_r^*$) resulting from the fitting to the eight synthetic vibration patterns are plotted over the predefined parameter values v_p. The correlation amounts 98%. The mean deviation of the predefined parameters from the values determined by the optimization are summarized in Table I. The error averaged over all eight parameters is 5.1%. The smallest error is achieved for parameter Q_1 with a mean error of 3.10%. The parameter Q_3 has the largest deviation with a mean error of 8.78%.

For the validation of the stability, the optimization procedure is applied additionally five times to each synthetic vibration pattern. The results are compared with the parameter values obtained in the first processing of the synthetic data. The variation of the resulting optimization parameters facilitates an appraisal of the stability of the proposed method. The mean deviation amounts to 5.5%, averaged across all parameters, see Table II. The smallest deviation is achieved for parameter Q_4 with a mean error of 3.36%. The greatest deviation reveals Q_1 with a mean error of 9.16%.

B. Application to real vocal fold oscillations

The automatic optimization procedure is applied to the eight digital high-speed videos of the subjects S1–S8. In Fig. 13 the vibration patterns of the optimized models are summarized. For each subject one entire closing phase is depicted. For comparison with the processed high-speed data, the corresponding vocal fold vibrations from Figs. 3 and 4 are also shown (gray lines). The frequency and amplitude of the vocal fold dynamics, as well as the time-varying shape of the glottis are reproduced by the MMM.

For giving a survey over the achieved fitting quality in all eight subjects, Table III summarizes the correlations between the area functions a_m and a_v (ρ_a) as well as the individual trajectories $c_{m,i}$ and $c_{v,i}$ (ρ_i). Concerning ρ_a a correlation of at least 0.89 is achieved with a mean value of 0.94. The correlation between the individual theoretical trajectories $c_{m,i}$ and the experimental trajectories $c_{v,i}$ amounts to (mean $\pm$ standard deviation (sd), averaged across all positions and subjects) 0.88 ± 0.09. The worst correlation is obtained at the position $i=3$ for S1 and at $i=5$ for S7, each with

TABLE II. Mean deviation of the optimization results from the predefined values after five additional applications of the optimization procedure to the same synthetic vibration patterns (averaged over all synthetic data sets).

procedure are summarized in Table V and Fig. 14. Table V shows the values for the parameters Q_p and Q_r. Figure 14 shows the determined values for the optimization parameters Q_i (marked with small circles) and the interpolated distributions $q_\alpha[z]$, which represents an approximated distribution of mass and stiffness along left and right model side. In Fig. 14, q_l and q_r of each subject are graphically related to the morphology of the vibrating part of the vocal folds. Thereby, the normalized values $\hat{q}_\alpha[z]=q_\alpha[z]/\max_z(q_l[z],q_r[z])$ are plotted to facilitate a comparison between different subjects. In addition, μ_α indicates mean $\pm$ sd of $\hat{q}_\alpha$. For assessing the characteristics of the distributions q_α, Table VI summarizes the correlation ρ_q between q_r and q_l as well as mean and standard deviation of $\Delta q=|q_l-q_r|$ for each subject. For the normal voice subject S1 ρ_q is reduced to 0.12. Subject S6 shows a negative correlation with $\rho_q=-0.67$. For the normal voice subjects the mean for the difference Δq is 0.01 (S1) and 0.02 (S2), respectively. For the pathological subjects this value is at least three times increased to 0.06 for subject S6 (up to 0.27 in case of S3).

IV. DISCUSSION

The primary voice signal is generated by vocal fold vibrations and thus its temporal characteristics can also be found in the vocal fold dynamics. Therefore, the objective quantification of the vocal fold oscillations is an important precondition for supporting the clinical diagnosis of voice disorders. For quantification purpose, in this work a model-based method is proposed. Objective parameters representing the spatio-temporal properties of the vocal fold dynamics are identified by modeling vocal fold vibrations by means of the biomechanical MMM. The model is fitted to the vocal fold oscillations by modifying a set of model parameters. Appro-

S7	0.39	0.15 ± 0.12
S8	0.98	0.06 ± 0.02

priate values for the model parameters are determined with an automatic optimization procedure. In this way parameter values are identifiable which describe the time-varying two-dimensional contour of the vocal fold edges. In addition, the resulting parameter values serve for an approximation of physiological properties of the vocal fold as stiffness and mass distribution.

The applicability of our method was validated using eight synthetic model configurations, generated with predefined parameter values. The synthetic data sets were analyzed with the optimization procedure. A comparison of the calculated parameter values with the predefined values reveals a mean error of only 5.1% ± 3.8% (Table I) which represents a sufficient accuracy for the assessment of vocal fold vibrations extracted from high-speed videos. The resulting model deflection difference of less than 5%[22] is in the same range as the accuracy of the applied image processing for the vocal fold edge detection.[14]

The optimization procedure is based on a random-based search algorithm and thus the calculated parameter values are not unique with an immanent uncertainty. Thus, a certain resulting value cannot be guaranteed. To analyze the effect of the scattering, the procedure was applied six times to each synthetic data set. The mean deviation from the predefined values was 5.5% ± 4.3% (Table II). Following this, the uncertainty due to the scattering of the random-based optimization procedure is in the same range as the uncertainty of the segmentation algorithm with approximately 15% (see Sec. II A).

Besides a quantification of vocal fold dynamics, it is an additional motivation for the model-based approach to gain an estimation of physiological vocal fold properties. Primarily, these physiological parameters are stiffness and mass distribution along each vocal fold due to their influence on the vocal fold dynamics and the phonation process. To analyze the applicability of the optimization procedure and the interpretability of the obtained optimization results, clinical data of eight subjects are evaluated. The vibration patterns range from almost symmetric and regular oscillations for the normal voice subjects S1 and S2 to clearly asymmetric vibrations concerning the left and the right vocal fold (e.g., S3 and S4) and irregular shapes as for subject S6 and S7. Although the subjects show this high variability, the optimization procedure is capable of fitting the model dynamics to the vocal fold oscillations as indicated by the values in Tables III and IV. The mean relative error between the experimental and theoretical trajectories amounts to 10% which reflects the same accuracy as for the applied image processing algorithm. This result accounts for a sufficient accuracy of the model fitting.

For the aim of regularization within the fine optimization, distributions q_l and q_r are approximated using the values of the optimization parameters Q_j and $Q_{j+3}(j=1,\ldots,3)$ as sampling points. Following Eqs. (17) and (16) q_α describes the stiffness distribution and inverse mass distribution respectively along each model side. In Fig. 14 the normalized distributions $\hat{q}_\alpha$ derived from the final optimization result are related graphically to the morphology of the vocal folds. This allows a discussion of the optimized biomechanical model of the vocal folds with respect to the analyzed laryngeal configuration. The processed clinical data can be categorized in three groups: normal voice subjects, subjects with functional or paralytic voice disorders and voice disorders which result in local organic impairments on one or both vocal folds.

A. Normal voice subjects

For the normal voice subjects S1 and S2 the distributions q_α are almost symmetric for the left and the right side which results in mean difference between both sides of 1% (S1) and 2% (S2) of the maximum value of q_α. The standard deviation of only 3% and 2% of q_r and q_l for S1 and S2 reflects a low variability in longitudinal direction. Consequently, masses as well as stiffnesses vary only slightly along each model side with an obvious left/right symmetry. This result corresponds to the vocal fold constitution expected for normal voice subjects.

B. Functional and paralytic voice disorders

For the subjects with functional and paralytic voice disorders (S3, S4, S5) asymmetric model configurations are obtained. The mean difference between q_l and q_r is at least 0.13 (S5) which is about six times more than for the normal voice subjects. The correlation between q_l and q_r is at least 0.91 (S3). These high correlations result from almost identical courses in longitudinal direction for q_l and q_r.

The functional voice disorder of subject S3 results in a decreased stiffness and increased vibrating mass for the right side. The value for q_α increases towards the anterior commissure, but there is no distinct extremum for both sides. This is in accordance to the underlying functional voice disorder: a symmetric positioning and muscle activation is impeded, but there are no local changes of the tissue.[43]

In subject S4, the values of q_l, which models the right vocal fold, are reduced compared to the values of q_r (left vocal fold), especially towards the anterior commissure. Consequently, the stiffness for the side representing the paralyzed vocal fold is decreased compared to the unaffected side. This reflects the reduced muscle activation due to the unilateral paralysis. Towards the posterior commissure q_l and q_r increase symmetrically, thus the stiffness is increased. This result can be explained by reduced oscillation amplitudes of the vocal fold edges towards the dorsal endings.

In the case of spasmodic dysphonia (S5) spasms and involuntary muscle activations result in an asymmetric strain on the left and right vocal fold during phonation.[44] In accordance to this, the model configuration for subject S5 results in a decreased stiffness and increased vibrating mass for the left side.

C. Organic voice disorders

For the subjects S6, S7, and S8 with organic voice disorders, the distributions q_α reflect the local changes of the organic constitutions of the vocal folds. For S6 and S7 the standard deviation of Δq reaches the maximum compared to the other subjects due to the local effect of the tissue impairment. For both subjects the correlations between q_l and q_r are reduced compared to the normal voice subjects and the subjects with functional voice disorders. Along the scar on the right vocal fold (S6) the values for q_l are increased compared to the adjacent values. The localized stiffened scared tissue corresponds to an increased stiffness within the model. For the unaffected left vocal fold the behavior of q_r is comparable to the results of the normal voice subjects. The edema on the right vocal fold at ventral position for subject S7 corresponds to a maximum of q_l at this position. The symmetrical positioned nodules of subject S8 result in symmetrically increased values for q_α at medial position ($z=z_2$). Thus the standard deviation of the distribution q_α is increased compared to the normal voice subjects. However, as both vocal folds are effected symmetrically by tissue impairments, the symmetry between q_l and q_r is comparable to the normal voice subjects: The standard deviation of Δq is 0.02 as for S1 and the mean value is the minimum among the pathologic subjects.

The resulting model configurations reflect individual properties of the vocal fold vibrations and morphologic constitutions. The obtained distributions q_α are comprehensible by accounting physiological vocal fold properties as the longitudinal mass and stiffness distribution of the evaluated clinical cases: For the normal voice subjects a symmetric mass and stiffness distribution concerning left and right vocal fold with only a slight variance in longitudinal direction is approximated. The functional voice disorders result in an increased left to right asymmetry. For local tissue impairments in case of the organic voice disorders local changes of the stiffnesses and masses are obtained.

The proposed method enables a first approximation of physiological parameters along the entire vocal fold *in vivo*. This is an extension compared to other model-based approaches[21,22,45,46] or direct measurement techniques as proposed in Goodyer *et al.*,[47] where only global values for the vocal fold properties are derived *in vivo*. However, the relationship between the calculated parameters of the multi-mass model and the actual values of the corresponding vocal fold properties needs further investigation. In several works the measurement of biomechanical properties of the vocal folds using excised cadaver larynges were presented.[48–52] In Hess *et al.*[42] even local variations of the elasticity parallel and perpendicular to the vocal fold edge were measured *ex vivo*. Doellinger and Berry[32] comprises experiments with excised vocal folds and the high-speed imaging technique. Combining these methods with the proposed optimization procedure offers the possibility to investigate the relationship between the model parameters and the physiological vocal fold properties.

V. CONCLUSION

The observation of the vibrating vocal folds is essential for the clinical assessment of voice disorders. Videoendoscopic high-speed systems allow the recording of vocal fold vibrations during phonation. A comprehensive investigation of voice pathologies demands an objective and quantitative description of the observed vocal fold dynamics. In this work, a model-based approach is proposed, which allows to infer an approximation of the stiffness and mass distribution along the vocal folds. The validation with synthetic data sets shows the reliability and stability of the optimization procedure. In a study comprising a larger amount of clinical data sets with more different voice pathologies, the clinical significance of our proposed method has to be analyzed.

(Received 2 August 2007; revised 10 December 2007; accepted 14 December 2007)

A theory of interaction between the source of sound in phonation and the vocal tract filter is developed. The degree of interaction is controlled by the cross-sectional area of the laryngeal vestibule (epilarynx tube), which raises the inertive reactance of the supraglottal vocal tract. Both subglottal and supraglottal reactances can enhance the driving pressures of the vocal folds and the glottal flow, thereby increasing the energy level at the source. The theory predicts that instabilities in vibration modes may occur when harmonics pass through formants during pitch or vowel changes. Unlike in most musical instruments (e.g., woodwinds and brasses), a stable harmonic source spectrum is not obtained by tuning harmonics to vocal tract resonances, but rather by placing harmonics into favorable reactance regions. This allows for positive reinforcement of the harmonics by supraglottal inertive reactance (and to a lesser degree by subglottal compliant reactance) without the risk of instability. The traditional linear source–filter theory is encumbered with possible inconsistencies in the glottal flow spectrum, which is shown to be influenced by interaction. In addition, the linear theory does not predict bifurcations in the dynamical behavior of vocal fold vibration due to acoustic loading by the vocal tract. © *2008 Acoustical Society of America.*

I. INTRODUCTION

The acoustic features of all vowel productions, and many consonant productions, have generally been described by a linear source–filter theory (Chiba and Kajiyama, 1958; Fant, 1960; Flanagan, 1972; Stevens, 1999). This linear theory is based on the assumption that the source of sound for vowels and voiced consonants (pulsatile airflow in the larynx) is independent of the filter, an acoustic resonator formed by airways known as the vocal tract. It is traditionally assumed that the source–filter combination can be characterized by mathematical convolution of source and filter functions in the time domain or by multiplication of Fourier-transformed source and filter functions in the frequency domain. Time domain convolution and frequency domain multiplication are linear mathematical operations that carry with them the superposition assumption; that is, the output of any combination of inputs is the linear combination of all the individual outputs. Stated another way, the output of any and all input frequencies can at most be an amplitude and phase changed version of these input frequencies. The filter cannot influence the source to produce new frequencies or change the overall energy level of the source. We will show here that this assumption is generally not valid, but under certain conditions is an appropriate simplification.

Many aspects of speech production have been successfully described by a linear source–filter theory. In particular, linear prediction of speech (Markel and Gray, 1976; Atal and Schroeder, 1978) has been the flagship of speech analysis, synthesis, and processing for over 30 years. But it has been recognized all along, however, that the linear theory is more applicable to male speech than female and child speech (e.g., Klatt and Klatt, 1990). As long as the dominant source frequencies lie well below the formant frequencies of the vocal tract, the source is influenced only in simple ways by the filter, mainly in terms of glottal flow pulse skewing and pulse ripple. This mild interaction occurs for most male adult speech, but greater interaction occurs for female and child speech, and even more for singing, where the fundamental frequency range spans more than two octaves and the lower partials of the source cross the formants. In these more intense interactions, bifurcations in the dynamics of vocal fold vibration can occur that may generate sudden F_0 jumps, subharmonic frequencies, or changes in the overall energy level at the source. The earliest computer simulations of source–filter coupling (Flanagan, 1968; Flanagan and Landgraf, 1968; Ishizaka and Flanagan, 1972) showed the interactivity clearly. The one-mass vocal fold model did not self-sustain oscillation without a vocal tract (a highly exaggerated coupling effect), and the two-mass model showed sudden frequency discontinuities when F_0 passed through the first formant frequency F_1. In human phonation, as our companion paper shows, the frequency discontinuities are clearly observable, but to a lesser extent than in these earlier models.

The purpose of this paper is to elucidate the underlying mechanisms of source–filter interaction, both with simple analytical models and with a highly sophisticated computational model. Specific questions of interest are: (1) what is the primary parameter that regulates the degree of interaction, (2) can new frequencies and greater output power be produced with increased interaction, (3) are there regions of

harmonic stability and instability that can be exploited by a vocalist, (4) are sudden F_0 discontinuities (reported in a companion paper on human subjects) always triggered by F_0 interactions with F_1, the first formant frequency, or can higher harmonic-formant interactions contribute as well, and (5) how does the subglottal system contribute to nonlinear coupling differently from the supraglottal system?

It is hypothesized that humans (and perhaps many animals) have the ability to operate their source–filter system with either linear or nonlinear coupling. One way to express the degree of coupling is through the relative impedances of the source and filter. For linear source–filter coupling, the source impedance (transglottal pressure divided by glottal flow) is kept much higher than the input impedance to the vocal tract (vocal tract input pressure divided by the airflow into the vocal tract). This linear coupling is accomplished by adducting the vocal folds firmly and widening the epilarynx tube (a normally narrow region of the vocal tract above the vocal folds also known as the laryngeal vestibule). The glottal flow is then determined strictly by aerodynamics, while acoustic pressures above and below the glottis have little influence on either the transglottal pressure (which drives the glottal flow) or the intraglottal pressure (which drives the vocal folds). For nonlinear source–filter coupling, the glottal impedance is adjusted to be comparable to the vocal tract input impedance, making the glottal flow highly dependent on acoustic pressures in the vocal tracts (above and below the glottis). This is accomplished by setting specific adduction levels of the vocal folds that match a narrower epilarynx tube. Evidence of nonlinear coupling is the production of new frequencies in the form of distortion products, lowering of the oscillation threshold pressure (the Hopf bifurcation), production of subharmonics or modulation frequencies, sudden F_0 jumps, or chaotic vibrations, as either vowel or F_0 are changed (companion paper).

In many attempts to model the glottal airflow with explicit mathematical formulas (e.g., Rosenberg, 1971; Fant *et al.*, 1985; Fant and Lin, 1987), nonlinear source–filter coupling in the form of distortion products had already been introduced implicitly by making the glottal flow pulse shape different from the glottal area pulse shape. Usually, the peak of the flow pulse was delayed with respect to the area pulse shape. But such a delay (referred to as flow pulse skewing) cannot be justified if only quasisteady aerodynamic calculations are carried out (i.e., linear source–filter coupling). Rothenberg (1981) showed that the peak delay of the glottal flow pulse is a result of low-frequency source–filter interaction. Zhao *et al.* (2002) make a case for intraglottal pressure skewing for different glottal shapes based on an aerodynamic treatment that involves flow separation and vortex shedding, but the effect on glottal flow is likely to be small in comparison to the vocal tract loading effect, which has recently been further explored by this author (Titze, 2001; 2004a; b; 2006a). There is now strong evidence that glottal flow pulse skewing always involves the vocal tract, explicitly or implicitly. Constructing a glottal flow pulse shape without consideration of the vocal tract load can lead to inconsistencies in combining the source with the filter.

Source–filter interactions that involve changes in vocal fold vibration have been demonstrated by several investigators. Sudden changes in vocal fold vibration can be triggered by vocal tract length changes (Hatzikirou *et al.*, 2006), a good example of source–filter interaction. Further observations about source–filter coupling were reported by Švec *et al.* (1999) on human subjects and excised larynges, Mergell and Herzel (1997) on a female subject, Miller and Schutte (2005) on singers, Neumann *et al.* (2005) on male opera singers, Zhang et al. (2006a,b) on a physically constructed model, Zañartu *et al.*, (2007) with a computer simulation model, and Jiang and Tao (2007) with analytical mathematic methods. Some of these studies will be referred to in more detail later. In singing, vowel modifications (e.g., changing /u/ to /U/ or /i/ to /I/) are used routinely to strengthen a vowel on a certain pitch (Appelman, 1967; Coffin, 1987). Entire singing styles (operatic, musical theatre, yodeling) are based on the concept that certain vowels and voice qualities work best with certain pitches, a concept that would have no explanation if the source–filter system were linear. The entire voice register terminology is based on observed phenomena related to interaction within the source–filter building blocks, which includes the subglottal system (Titze, 2000; Chap. 10). Vocal pedagogues who invented terms like chest voice and head voice were not so naive to suggest that the source of sound moves from location to location, but rather that interactions with certain parts of the airway are stronger with certain source–filter adjustments and lead to special sensations along the airway. The role of the subglottal system for chest voice was implicated years ago by Van Den Berg (1957) and Vennard (1967). Chest voice production has both a glottal feature (a relatively long closed phase) and significant acoustic coupling to the trachea. For head voice, there appears to be more of an interaction with the supraglottal tract.

In an accompanying paper (Titze *et al.*, 2008), a primary objective is to differentiate purely source-generated bifurcations, including F_0 jumps, from vocal tract induced bifurcations. Three vocal exercises are designed in the accompanying paper to deliberately cross the fundamental frequency with the first formant frequency and to observe the resultant nonlinear effects in nine normal males and nine normal females. It is hypothesized that crossing F_0 with F_1 changes the acoustic load dramatically and that this crossing can destabilize vocal fold vibration. The main goal is to determine the proportion of irregularities that are due to nonlinear source–tract interactions. Expected manifestations of nonlinearity are sudden pitch jumps, subharmonic generation, or chaotic vocal fold vibration. Results indicate that the most frequent bifurcation is a sudden F_0 jump, as predicted by Fletcher (1993) for pressure-controlled valves in gas flows. The objective in this paper is to provide a theoretical framework for the bifurcation phenomena in vocal fold vibration with a nonlinear source–filter construct.

II. INTERACTION BASED ON VOCAL TRACT REACTANCE

Because the vocal tract is relatively short in comparison to a wavelength at typical speech fundamental frequencies

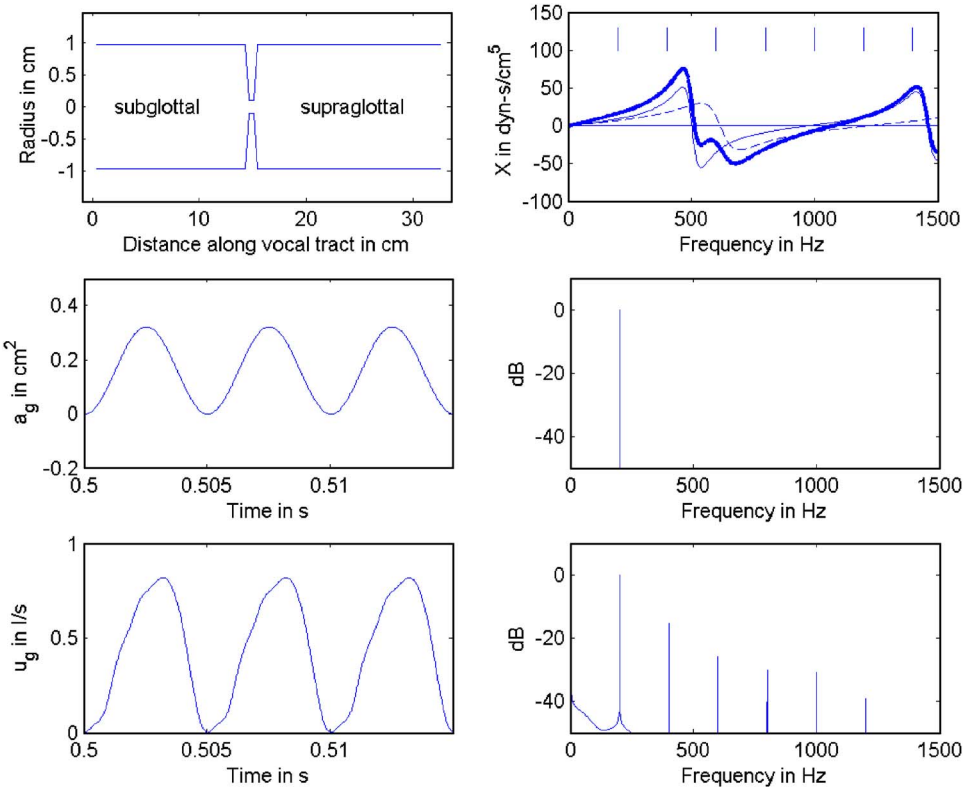

FIG. 1. (Color online) Harmonic frequency generation by source–filter interaction; (top left) vocal tract shape; (top right) reactance curves, thin solid line for supraglottal, dashed line for subglottal, and thick solid line for combined; (middle left) sinusoidal glottal area function; (middle right) spectrum of glottal area; (bottom left) glottal flow; (bottom right) spectrum of glottal flow.

(e.g., at F_0=200 Hz the vocal tract contains less than 1/8 of a wavelength), and because a speaker or singer wishes to convey all the phonetic variations of a spoken language, the length and shape of the vocal tract cannot be adjusted to resonate many of the source frequencies simultaneously. Thus, unlike in most musical instruments, for which the length and shape of the horn or bore is carefully designed to resonate the dominant source frequencies simultaneously, lining up source frequencies with vocal tract filter resonances is highly selective and rare in human phonation. Apparent "formant-harmonic tuning" occurs in high soprano singing (Sundberg, 1977; Joliveau *et al.*, 2004), but close inspection of the data reveals that F_0 is usually slightly less than the formant frequency F_1. In some cases, at very high F_0, oscillation occurs for $F_0 > F_1$. We will show that this is more likely for a falsetto-like vibration regime. Exact tuning of F_1 with a harmonic seems to occur only in so-called *overtone singing*, where a high frequency harmonic is reinforced by a formant that is tuned precisely to its frequency (Rachele, 1996).

For low-pitched speech or singing, the dominant source harmonics (typically F_0 through $3F_0$) are below the first resonance (formant) frequency F_1 of the vocal tract. For example, a bass or baritone speaking or singing a note G_2 (98 Hz) will reach the first formant of an /i/ or a /u/ vowel only with the third harmonic. For an /a/ vowel, source harmonics higher than the seventh are needed to reach the first formant. Because these higher harmonics often do not have a great influence on the nature of vocal fold vibration, their interaction with a formant is perceived as a vowel or voice quality characteristic, not a source change. But the flow pulse may nevertheless be influenced by higher harmonic source–filter interaction, as will be shown next.

A. Level 1 interaction: Flow pulse dependency on the subglottal and supraglottal vocal tract pressures

A first level of interaction is described in which vocal fold vibration is not significantly disturbed by oscillating pressures above or below the glottis, but glottal flow is. This level occurs in all speech and is therefore worthy of special consideration.

What is common about harmonics whose frequencies are less than F_1 is that they all experience positive (inertive) reactance from the vocal tract.[1] Figure 1 (top left) shows a uniform vocal tract (subglottal and supraglottal) separated by the glottis. The top right panel shows the reactance curves (subglottal as a dashed line, supraglottal as a thin solid line, and combined reactance as a thick solid line) up to 1500 Hz. The reactance curves were calculated with cascade transmission line matrices as originally outlined by Sondhi and Schroeter (1987) and further developed by Story *et al.* (2000). From 0 to 500 Hz, the supraglottal reactance is positive (inertive), whereas from 500 to 1000 Hz it is negative (compliant). The subglottal reactance stays inertive up to 600 Hz for this configuration.

Inertive reactance has been shown to skew the flow pulse (delay its peak relative to that of the glottal area), whether it is subglottal (X_1) or supraglottal (X_2). For a review of this flow pulse skewing, see Rothenberg (1981), Fant (1986), Fant and Lin (1987), or Titze (2006a). Note the delay in the peak of U_g in Fig. 1 (bottom left) in relation to a_g (middle left). Further discussion of these graphs will follow. For glottal flow calculation, the subglottal input impedance and the supraglottal input impedance add together algebraically (in complex form) to produce the effective load imped-

ance for the glottis. This can be shown by letting the input pressure to the vocal tract (epilarynx tube) be

$$P_e = Z_2 U_g, \tag{1}$$

where U_g is the complex (Fourier transformed) glottal flow and Z_2 is the complex supraglottal impedance. Similarly, the subglottal pressure is

$$P_s = Z_1(-U_g), \tag{2}$$

where Z_1 is the subglottal impedance. The transglottal pressure is then

$$P_s - P_e = -(Z_1 + Z_2)U_g = -(R_1 + R_2)U_g - i(X_1 + X_2)U_g, \tag{3}$$

where R_1 and R_2 are the subglottal and supraglottal resistances, $i = \sqrt{-1}$, and X_1 and X_2 are the corresponding reactances. Note that the combined reactance $X_1 + X_2$ shown in Fig. 1 (top right, thick line) is not necessarily symmetric about the horizontal axis because the subglottal and supraglottal peaks do not occur at identical frequencies.

For incompressible, quasisteady glottal flow, the transglottal pressure can also be expressed aerodynamically as

$$P_s - P_e = k_{t\frac{1}{2}} \rho u_g^2 / a_g^2, \tag{4}$$

where k_t is an empirically-determined transglottal pressure coefficient with an average value of about 1.1 (Scherer *et al.*, 1983; Alipour and Scherer, 2007; Fulcher *et al.*, 2006), ρ is the air density, u_g is the time-dependent flow, and a_g is the time-varying glottal area. Equation (4) is nonlinear in u_g and cannot easily be Fourier transformed, and since the resistances and reactances in Eq. (3) are in the frequency domain, Eqs. (3) and (4) cannot be equated. In previous work with a wave-reflection analog of the vocal tract (Titze, 1984), it was shown that the flow had the following closed-form solution:

$$u_g = \frac{a_g c}{k_t}\left\{-\left(\frac{a_g}{A^*}\right) \pm \left[\left(\frac{a_g}{A^*}\right)^2 + \frac{4k_t}{\rho c^2}(p_s^+ - p_e^-)\right]^{1/2}\right\}, \tag{5}$$

where c is the sound velocity, and A^* is an equivalent vocal tract area defined as

$$A^* = A_s A_e/(A_s + A_e), \tag{6}$$

with A_s and A_e being the subglottal and supraglottal (epilaryngeal) entry areas, respectively. Further, in the wave-reflection algorithm (Kelly and Lochbaum, 1962; Liljencrants, 1985; Story, 1995; Titze, 2006b) p_s^+ is the incident partial wave pressure arriving from the subglottis and p_e^- is the incident partial wave pressure arriving from the supraglottis. It should be noted that the wave-reflection analogs do not include the exact near-field pressures (Zhao *et al.*, 2002: Zhang *et al.*, 2002), but capture the most important fields for wave propagation in the vocal tract.

Equation (5) is critically important for understanding source–filter interaction because it defines explicitly a coupling parameter, a_g/A^*. Note that when a_g/A^* is small, the flow reduces to

$$u_g = a_g\left[\frac{4(p_s^+ - p_e^-)}{k_t \rho}\right]^{1/2}, \tag{7}$$

which becomes a direct proportion to the glottal area a_g. If a constant subglottal pressure were to be applied to produce the glottal flow, the incident partial pressure wave p_s^+ in the wave-reflection algorithm would be replaced by half of the lung pressure P_L with a +1 reflection coefficient, so that the subglottal pressure would then be $P_s = p_s^+ (1+r) = 2p_s^+ = P_L$ (Titze, 1984; Story, 1995). Furthermore, if the incident supraglottal pressure p_e^- were set to zero, then

$$u_g = a_g\left[\frac{2P_L}{k_t \rho}\right]^{1/2}, \tag{8}$$

which is the asymptotic condition for linear (noninteractive) source–filter coupling. For linear coupling, the relative phase delays between p_s^+ and p_e^- due to wave propagation are responsible for the nonproportionality between u_g and a_g.

The skewing of the flow pulse as a result of an overall inertive reactance produces new harmonic frequencies in the glottal airflow that are not part of the glottal area waveform. This result is not new (Rothenberg, 1981; Fant and Lin, 1987; Koizumi *et al.*, 1985), but most previous analyses have underestimated the amount of skewing because the exact geometry of the epilarynx tube was not known. The magnetic resonance images produced by Story (1995; 2005) have been the key data sets to validate strong source–filter interaction. The uniform tubes in Fig. 1 produce relatively weak interactions. In the middle panels, a sinusoidal a_g waveform is shown on the left and its corresponding single line spectrum is shown on the right. With this sinusoidal area (forced oscillation), glottal flow was produced (bottom left panel) with 0.8 kPa lung pressure in a voice simulator that could be switched between forced oscillation and flow-induced self-sustained oscillation. Equation (5) was combined with a 44 section uniform vocal tract with energy losses and the appropriate radiation impedance was used as previously described (Titze, 2006b). Note that the flow waveform is slightly skewed and has an entire spectrum of frequencies (bottom right). Wave propagation occurred in both subglottal and supraglottal tracts. The source–filter coupling is nonlinear because new frequencies (harmonic distortion frequencies) are created by the vocal tract.

The skewing of the flow pulse guarantees a dominant excitation near glottal closing and raises the energy in the harmonics (Fant, 1986). In the past it has been assumed that the harmonic spectrum of the source comes primarily from vocal fold collision. This may be true for many phonations, but this example shows that vocal fold collision is not essential to produce source harmonics. Nonlinear source–filter coupling can produce a spectrum of source frequencies, with a spectral slope of about −15 dB per octave in this case. Furthermore, the harmonic amplitudes are affected by the reactance curve. The short vertical lines in the top right panel above the reactance curves show the location of the harmonics in the bottom right figure. Note that harmonics 3 and 4 are in negative reactance territory and are depressed slightly in amplitude, relative to harmonics 2 and 5. The simplest explanation for this amplitude depression is that negative

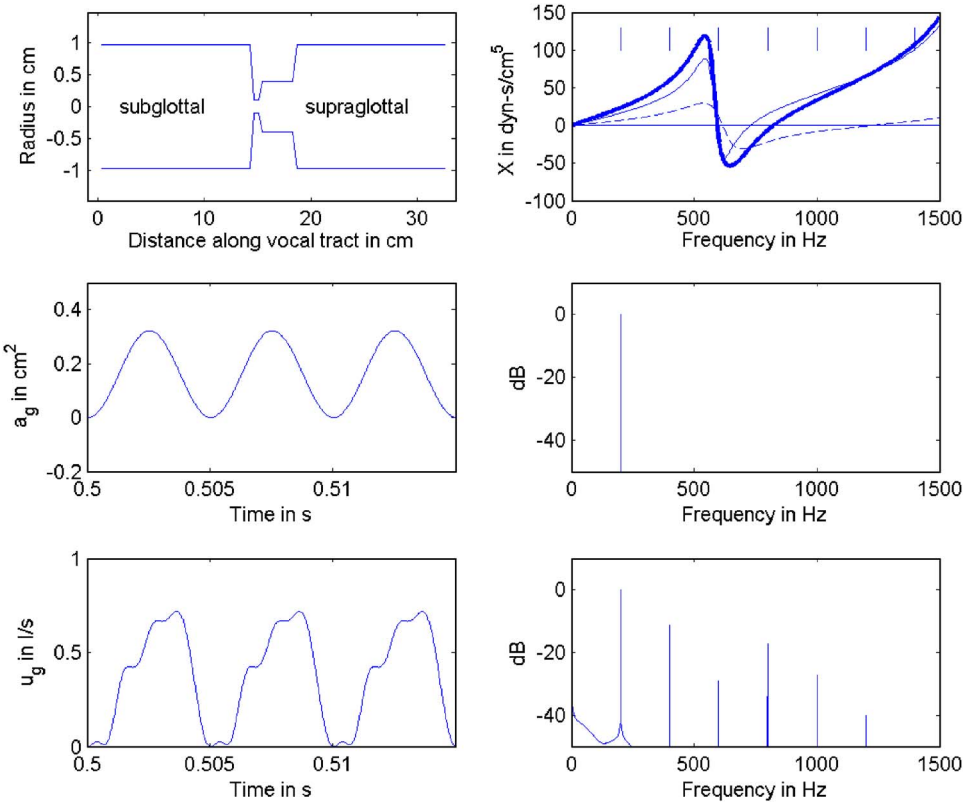

FIG. 2. (Color online) Harmonic frequency generation by source–filter generation with stronger coupling (A_e=0.5 cm^2); (top left) vocal tract shape; (top right) reactance curves, thin solid line for supraglottal, dashed line for subglottal, and thick solid line for combined; (middle left) sinusoidal glottal area function; (middle right) spectrum of glottal area; (bottom left) glottal flow; (bottom right) spectrum of glottal flow.

(compliant) reactance integrates the downstream flow and builds up an opposing pressure that reduces the flow at a given frequency. If negative reactance were present at all frequencies, the flow pulse would be skewed to the left because more flow would be accepted during glottal opening than glottal closing as the back pressure builds up. With frequency dependent reactance, selective components that would skew the pulse to the left are reduced in amplitude because, overall, the pulse is still skewed to the right. A more detailed discussion would require the consideration of all the phases of the components and how they are affected by variable reactance.

Figure 2 shows the same set of curves as in Fig. 1, but now the coupling between the source and the filter is increased to a more realistic value. By reducing the epilarynx tube cross-sectional area A_e from 3.0 cm^2 in Fig. 1 to 0.5 cm^2 in Fig. 2 (compare upper left graphs), the input impedance to the vocal tract has been increased. This input impedance is scaled by $\rho c/A_e$, the characteristic acoustic impedance of the first section of a tube, where ρ is the density of air and c is the sound velocity. The coupling parameter a_g/A^* in Eq. (5) was correspondingly increased from 0.1 to 0.35 because it contains A_e in the formula for A^* in Eq. (6). The mean glottal area a_g was held constant at 0.15 cm^2 and the subglottal area was held constant at 3.0 cm^2. Hence, the glottal source impedance remained the same. Note that the combined reactance curve (thick line, upper right in Fig. 2) now has a net upward shift toward positive (inertive) values. Specifically, over the entire 0–1500 Hz frequency range, negative (compliant) reactance occurs only between 600 and 800 Hz.

The harmonic frequencies produced in the flow wave form (bottom left panel of Fig. 2) reflect this increase in coupling strength. An apparent "closed phase" is seen, even though there was no glottal closure. As in Fig. 1, the area function a_g was sinusoidal and always remained above zero (no truncation). This brings into question that whole enterprise of inferring vocal fold vibration patterns from inverse-filtered glottal flow, especially in terms of an open phase and a closed phase. Rothenberg and Zahorian (1977) showed that inverse filtering to obtain the glottal area from mouth flow is fundamentally a nonlinear process. Linear prediction cannot accomplish this task.

Comparing the harmonic spectra (bottom right) across Figs. 1 and 2, we see that the strength of the harmonics is again related to the amount of inertive reactance present at the harmonic frequency. For the F_0 selected here (200 Hz), the third harmonic gained no strength with increased coupling because it still resides in negative (compliant) reactance territory, as in Fig. 1. The second and the fourth harmonics, however, both experience a slight amplitude increase due to higher reactance. In particular, the fourth harmonic, which was in negative territory, now experiences about zero reactance. This stronger fourth harmonic is responsible for the ripple seen in the flow waveform at the bottom left. (Only three ripple cycles are seen on the increasing flow; the fourth ripple cycle is hidden on the downward slope and on the flat portion near zero flow). The spectral slope is now only on the order of −10 dB per octave.

Because the source spectrum can be affected by vocal tract reactance, and because this reactance is frequency dependent, a spectrogram with an F_0 glide at constant vocal tract shape (identical to the shape shown in Fig. 2, top left) was investigated. This type of a pitch–glide spectrogram was

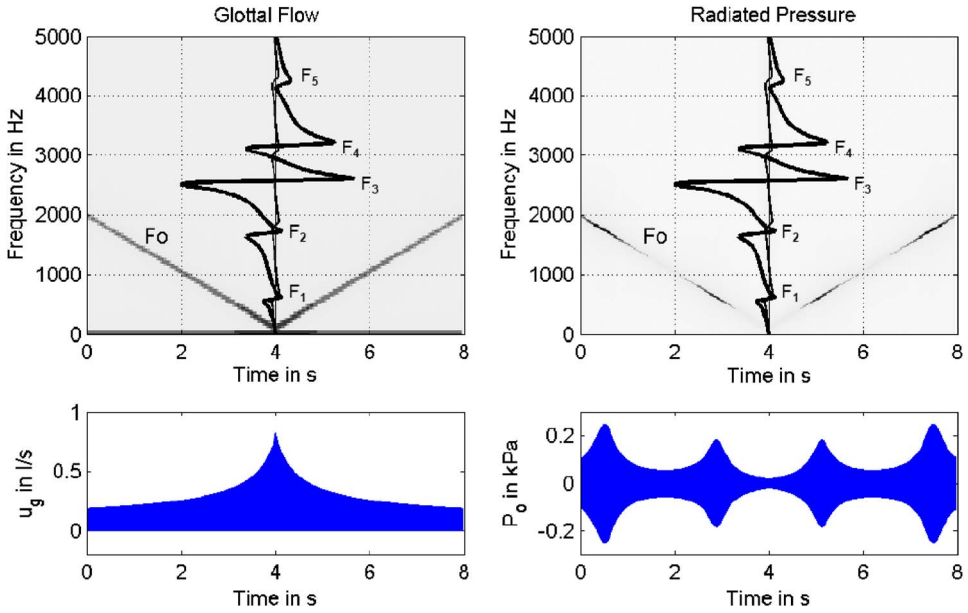

FIG. 3. (Color online) F_0 glide produced with a driven sinusoidal glottal area function with no source–filter interaction; (top left) spectrogram for glottal flow based on sinusoidal glottal area, with reactance curves overlaid vertically; (top right) spectrogram for radiated mouth pressure P_0; (bottom left) amplitude envelope of glottal flow; (bottom right) amplitude envelope of radiated mouth pressure.

analyzed for recordings of human subjects in the companion paper (Titze *et al.*, 2008). Figure 3 shows the noninteractive (linear) case as a control for later interactive cases. No interaction with tissue vibration was allowed because the vibration was still forced with a sinusoidal area rather than self-sustained. At the top left we see a spectrogram of the F_0 glide (straight sloping line), from 2000 to 100 Hz and back to 2000 Hz. The signal used in the spectrogram was the glottal flow u_g, a purely sinusoidal function derived from the sinusoidal area function a_g according to Eq. (8). The amplitude envelope of this sinusoidal flow is shown below the spectrogram on the left. Its peak at 4.0 s comes from the fact that the glottal area function (not shown) was programmed to vary inversely with the square root of frequency to approximate realistic amplitudes of vibration.

The spectrogram (top left panel) also shows the reactance curves of Fig. 2, now superimposed on the center of the spectrogram such that they are displayed vertically from 0 to 5000 Hz. Positive reactance is to the left and negative reactance is to the right of center. The reactance fluctuation in the third and fourth formant region (around 3000 Hz) is so large that the subglottal reactance is barely visible on the same scale. This large fluctuation is attributed to the epilarynx tube, which begins to establish its own characteristic quarter-wave resonance near the third formant at 2500–3000 Hz (Titze and Story, 1997).

Note again that no harmonic distortion frequencies are created by the vocal tract for this noninteractive F_0 glide, the control case. The single frequency component of the flow (F_0, sloping downward from 0.0 to 4.0 s and then upward from 4.0 to 8.0 s) is unaffected by the filter. What is affected by the filter is the oral radiated pressure P_o, shown on the right side of Fig. 3. As expected, P_o increases near 0.6 s when F_0 passes through F_2 and near 3.0 s when F_0 passes through F_1. These increases (and decreases on the other side of a formant) would be perfectly symmetric if the radiation at the mouth were independent of frequency. High frequencies radiate better than low frequencies, however, which produces a greater P_o at 2000 than at 100 Hz, even though the peak glottal flow was 0.2 vs 0.8 l/s at these extremes.

Figure 4 shows the flow-interactive case, with A_e remaining at 0.5 cm^2. Vocal fold vibration still remained forced (no interaction with tissue vibration). The confirming observation is that a series of extra harmonics ($2F_0$ through $4F_0$) is again created in u_g by vocal tract coupling. These harmonics are reinforced when there is positive reactance (positive reactance curve is left of the vertical center line) rather than at the center of the formants. This is especially noticeable in the second harmonic. [The dependence on reactance is also present in the fundamental, but the spectrogram gray scale was deliberately saturated for F_0 so that the higher harmonics could be seen.] At the formants, where the reactance changes suddenly from positive to slightly negative, the source harmonics are diminished in their amplitudes. This is further evidenced by the envelope of the flow wave form u_g, which is modulated by an uneven treatment of the harmonics by this reactance (note the valleys at 0.8 and 3.0 s in the bottom left panel). The peaks and valleys in the amplitude envelope are unmistakable evidence of nonlinear source–filter coupling because the glottal area and lung pressure were identical to the control case. As a result, the overall peak-to-valley ripple in the P_o waveform (bottom right) is less severe than in the linear case of Fig. 3. The dips in the u_g amplitude at the formants partially cancel the increase in energy transmission through the vocal tract at the formants (Rothenberg, 1987). Thus, the effect of nonlinear formant–harmonic coupling in the glottal flow (level 1 interaction) is to distribute the acoustic energy over the entire spectrum rather than to accentuate it at the center of a formant.

In summary, rather than attempting to resonate several source harmonics by tuning them to the tube resonances, as is done in many musical instrument designs, a vocalist may attempt to reinforce a cluster of several harmonics with favorable reactance. In most cases, as many harmonics as possible are placed on the lower frequency side of a formant (below the resonance frequency). For high-pitched singing,

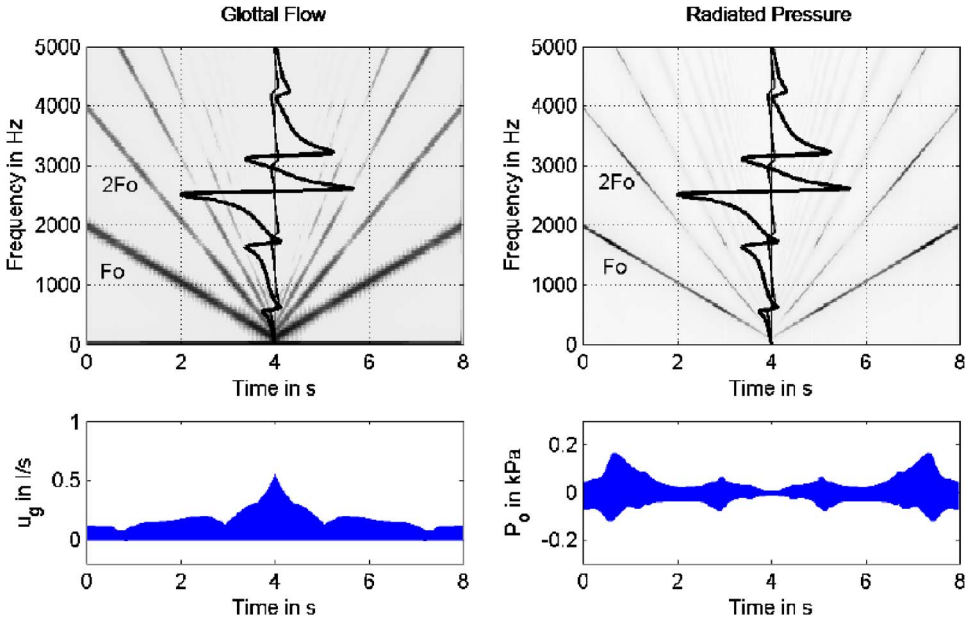

FIG. 4. (Color online) F_0 glide produced with a driven sinusoidal glottal area function with source–filter interaction (A_e=0.5 cm^2); (top left) spectrogram for glottal flow based on sinusoidal glottal area, with reactance curves overlaid vertically; (top right) spectrogram for radiated mouth pressure P_0; (bottom left) amplitude envelope of glottal flow; (bottom right) amplitude envelope of radiated mouth pressure.

this often requires a special vowel, so that at least F_0, $2F_0$, and $3F_0$ can all be reinforced over a reasonable pitch range. An example is shown in Fig. 5, where subglottal reactance is now shown by the thin line and supraglottal reactance by the thick line. Note the ranges of F_0, $2F_0$, and $3F_0$ below the reactance curves at the bottom of Fig. 5. Only the subglottal reactance is negative in the $2F_0$ range, but in the next discussion it will be shown that the combination of a compliant (negative) subglottal reactance and an inertive (positive) reactance provides ideal reinforcement of vocal fold vibration. So, the loss in level 1 interaction may in part be overcome by a gain in level 2 interaction. This example suggests that certain vowels will be favored over other vowels. The utility of this type of interaction is that source and filter frequencies do not need to match exactly, leaving some degree of freedom for articulation and vowel migration with the general goal of strengthening the dominant low-frequency harmonics.

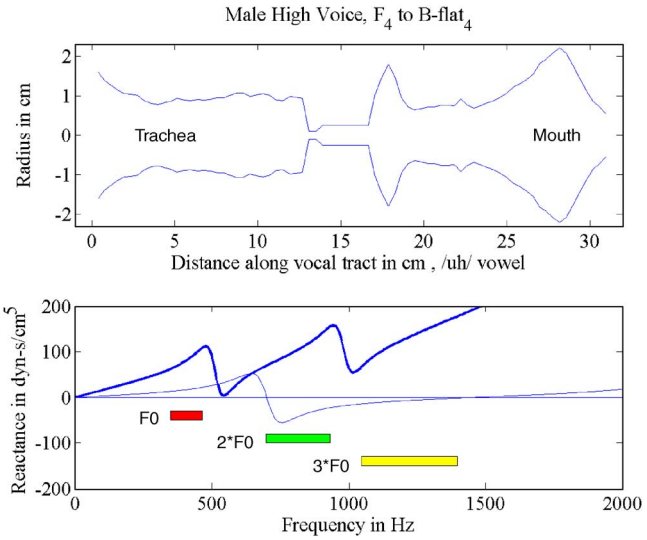

FIG. 5. (Color online) (Top) Vocal tract shape for the vowel /U/; (bottom) reactance curves, thick line supraglottal and thin line subglottal, and favorable ranges for F_0, $2F_0$, and $3F_0$ shown underneath.

B. Level 2 interaction: Mode of vibration dependency on vocal tract reactance

There is another level of interaction, identified as level 2, which involves a change of the vibration pattern of the vocal folds as a result of vocal tract changes. For this level of interaction, subglottal reactance and supraglottal reactance affect vocal fold vibration differently. While supraglottal reactance is generally most favorable when it remains inertive (positive), the subglottal reactance is sometimes more favorable if it is compliant (negative). The complicating factor is the geometry of the vocal folds, or shape of the glottis, in direct analogy to Fletcher's (1993) differentiation of inward, outward, and lateral striking valves that can self-sustain oscillation in a pipe. An added complexity, not discussed by Fletcher, is that vocal folds can propagate a surface wave in their tissue, which changes the shape of the valve dynamically. Based on this surface wave, a relation for the mean intraglottal driving pressure on the vocal fold surface was derived previously (Titze, 1988),

$$P_g = P_s\left(1 - \frac{a_2}{a_1}\right) + P_e\frac{a_2}{a_1}, \tag{9}$$

where P_g is the mean (entry to exit) intraglottal driving pressure, P_s is the subglottal pressure, P_e is the supraglottal (epilarynx tube) input pressure, a_1 is the glottal entry area (lower margin of the vibrating portion of the vocal folds), and a_2 is the glottal exit area (upper margin of the vibrating portion of the vocal folds). In deriving Eq. (9), the pressure profile in the glottis was assumed to follow the Bernoulli energy conservation law, the glottal area was assumed to vary linearly from bottom to top, the acoustic pressure P_e was assumed to be the only pressure recovery at glottal exit, and the transglottal pressure coefficient was set to 1.0 for simplicity. (For details of the full derivation, see Titze (1988), p. 1542.)

As a valve, the vocal folds are closest to the (+,+) case described by Fletcher (1993). In his notation, the valve is

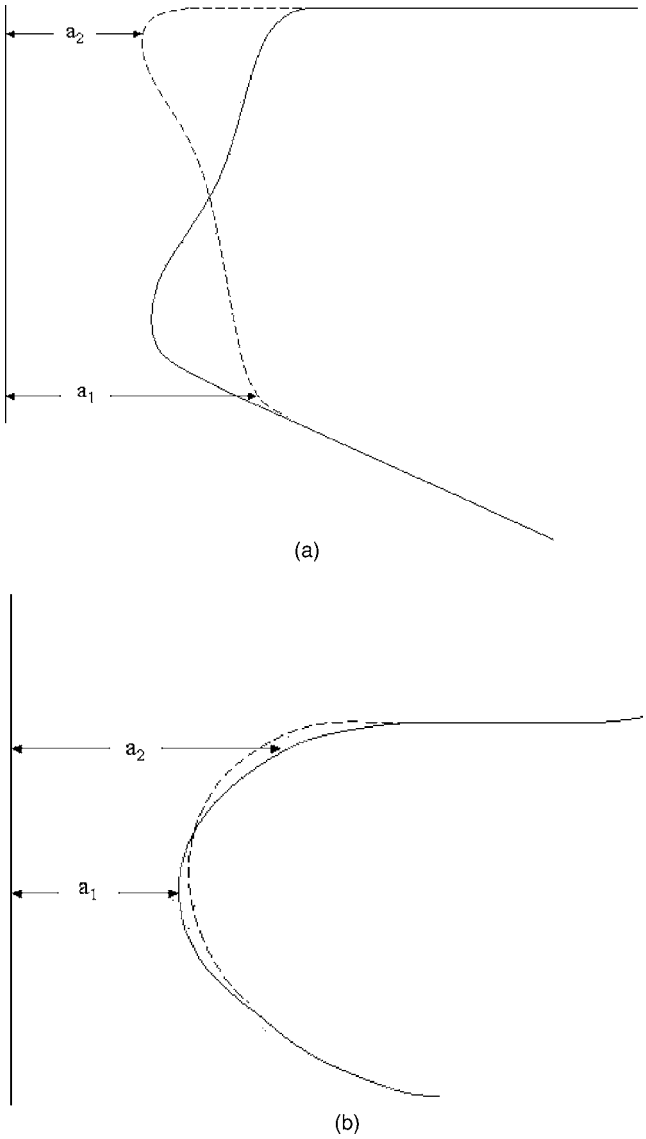

FIG. 6. Sketches of right vocal fold tissue displacement from the glottal midplane in coronal view of (a) modal register and (b) falsetto register. After Hirano, 1975.

(+,+) if tissue moves laterally with both increasing subglottal pressure (first +) and increasing supraglottal pressure (second +). But, as Eq. (9) indicates, intraglottal pressure is greater for a convergent glottis than for a divergent glottis. Tissue surface waves on the vocal folds (i.e., standing waves, or modes of vibration) can be excited by the airflow to produce self-sustained oscillation, even without vocal tract interaction (Titze, 1988). Note that, even if P_s is a constant and P_e is zero in Eq. (9), an alternating push–pull pressure can be created by an a_2/a_1 ratio that is less than 1.0 for lateral movement and greater than 1.0 for medial movement. Vocal tract interaction is therefore an important, but not a necessary, condition for self-sustained vocal fold oscillation.

Figure 6 shows a sketch of how the medial surface of the vocal folds may change during vibration, both in terms of the static and the time varying configuration. The sketch is patterned after Hirano (1975). Two different registers of phonation are identified. In the so-called modal register [Fig. 6(a)], vibration is observed over much of the thickness of the vocal folds, so that the entry area a_1, where vibration begins, is low in the glottis vertically. To the contrary, in the so-called falsetto register [Fig. 6(b)], vibration is confined mainly to the upper portion of the vocal folds, with a_1 being much higher in the glottis. (The point where vibration effectively begins vertically in the glottis has been called the mucosal upheaval point; Yumoto and Kadota, 1998). If we approximate the vibrating portion of the medial surface with a straight line, then the prephonatory shape is both convergent ($a_2<a_1$) and divergent ($a_2>a_1$) for the modal register but mainly divergent ($a_2>a_1$) for the falsetto register. Physiologically, the thyroarytenoid (TA) muscle controls this medial surface shape. When the TA muscle contracts, it thickens and bulges out the lower part of the vocal fold, thereby "squaring up" the glottis and producing modal register. When the TA muscle is relaxed, the bottom of the vocal fold retracts and only the top remains engaged in vibration. The medial surface is more rounded. The vocal ligament is used for adductory positioning and tensing of the vocal fold tissues.

It will now be shown how vocal tract pressures can assist or hinder vibration in these basic two registers. Neglecting vocal tract resistance and steady pressures for the first part of the discussion, basic acoustic theory would predict the vocal tract pressures to be

$$P_s = -I_1\frac{du}{dt} \quad \text{inertive subglottal tract} \tag{10}$$

$$= P_1 - \frac{1}{C_1}\int u\,dt \quad \text{compliant subglottal tract,} \tag{11}$$

$$P_e = +I_2\frac{du}{dt} \quad \text{inertive supraglottal tract} \tag{12}$$

$$= P_2 + \frac{1}{C_2}\int u\,dt \quad \text{compliant supraglottal tract,} \tag{13}$$

where P_1 and P_2 are constants of integration. With these relations, the intraglottal pressure of Eq. (9) has four possible forms:

$$P_g = -I_1\left(1-\frac{a_2}{a_1}\right)\frac{du}{dt} + I_2\frac{a_2}{a_1}\frac{du}{dt} \quad \text{inertive – inertive} \tag{14}$$

$$= P_1 - \frac{1}{C_1}\left(1-\frac{a_2}{a_1}\right)\int u\,dt + I_2\frac{a_2}{a_1}\frac{du}{dt} \quad \text{compliant – inertive,} \tag{15}$$

$$= -I_1\left(1-\frac{a_2}{a_1}\right)\frac{du}{dt} + P_2 + \frac{1}{C_2}\frac{a_2}{a_1}\int u\,dt \quad \text{inertive – compliant,} \tag{16}$$

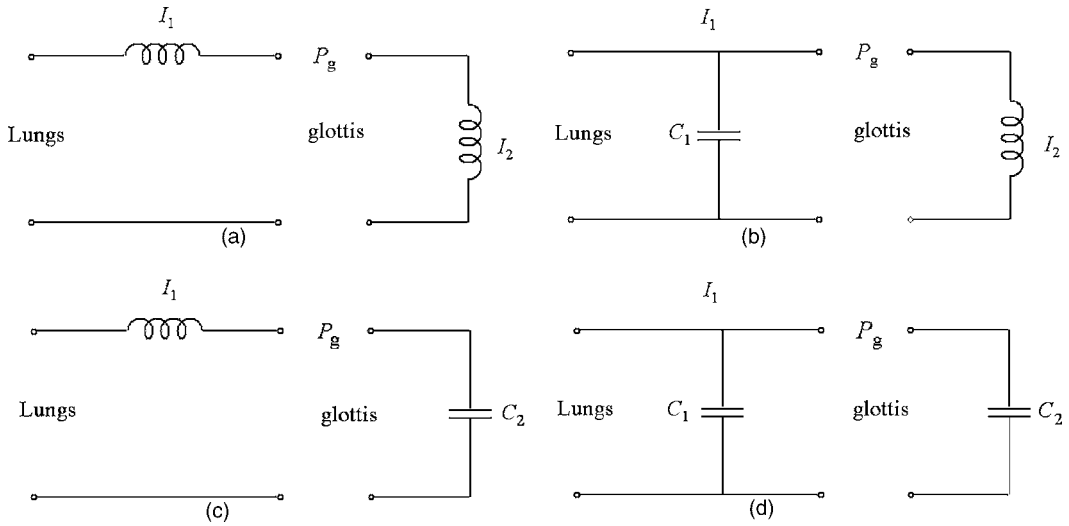

FIG. 7. Acoustic circuit diagrams for subglottal and supraglottal reactance, (a) inertive–inertive, (b) compliant–inertive, (c) inertive–compliant, and (d) compliant–compliant.

$$= P_1 - \frac{1}{C_2}\left(1 - \frac{a_2}{a_1}\right)\int udt + P_2 + \frac{1}{C_2}\frac{a_2}{a_1}\int udt \qquad \text{compliant – compliant.} \qquad (17)$$

These cases are basically the same as the four cases described by Fletcher (1993). An acoustic "circuit" representation of these relations is shown in Fig. 7. Inertance is represented by coils I_1 and I_2 and compliance is represented by parallel plates C_1 and C_2, following the symbolism of electric circuitry for inductance and capacitance, respectively. The driving pressure P_g from the above-presented mathematical expressions is also labeled in Fig. 7. For maximum reinforcement of vocal fold vibration, the driving pressure P_g should provide an alternating push–pull on the vocal fold tissue, a push when the glottis is opening and a pull when the glottis is closing. Thus, when du/dt is positive (flow is increasing during glottal opening), P_g should be positive; when du/dt is negative (flow is decreasing during glottal closing), P_g should be negative.

Consider first the *inertive – inertive* case [Eq. (14) and Fig. 7(a)]. Both coefficients in front of du/dt in Eq. (14) should be positive for the push–pull condition. The only way this can occur is if $a_2/a_1 > 1.0$ over most of the open portion of the glottal cycle, which means the glottis must be mainly divergent. Falsetto register may provide this configuration quite readily, referring to Fig. 6(b). It is known that the top of the vocal folds spread apart slightly in falsetto register. A net divergent glottis at the top created by this spread would appear to be beneficial to both terms in Eq. (14). For modal register, the divergent configuration occurs over a smaller fraction of the glottal cycle, prior to closure. But maximum pressures occur in this fraction of the cycle, yielding strong excitation in a pulse-like manner. Thus, subglottal inertance I_1 generally provides both a help and a hindrance to vocal fold vibration in modal register. On the other hand, supraglottal inertance I_2 always provides the favorable push–pull condition, for both registrations and both glottal configurations. The Flanagan and Landgraf (1968) and Ishizaka and Flanagan (1972) simulations had no subglottal tract. Hence, their vocal tract interaction effects were probably exaggerated. The Zhang *et al.* (2006a, b) investigations had only a subglottal tract, which could underestimate the overall interaction. The Zañartu *et al.* (2007) simulations included both a subglottal and a supraglottal tract. Given that their vocal fold model was composed of only a single mass, the results can be considered an excellent correction to the Flanagan and Landgraf (1968) model. In a later section, it will be shown that neglect of the subglottal reactance can be dramatic, even with greater degrees of freedom in tissue movement.

The *compliant–inertive* tract appears to be the most favorable for vocal fold vibration in modal register [Eq. (15) and Fig. 7(b)]. If the glottis is mostly convergent, with divergence occurring only over a small fraction of the cycle prior to closure, the integration of the flow in Eq. (15) produces a steady decrease in intraglottal pressure over the open portion of the glottal cycle (because $a_2 < a_1$). This gradual decrease in pressure (stronger during opening and weaker during closing) adds to the dominant push–pull produced by the inertive supraglottal tract, as described before. Tongue-tip trills (McGowan, 1992) have also been shown to be sustained by an upstream compliant reactance. The dominant compliance in tongue trills is a wall compliance (rather than an air compliance), but the effect is similar.

The *inertive – compliant* tract [Eq. (16) and Fig. 7(c)] is the least favorable for modal register. Supraglottal integration of the flow u raises the intraglottal pressure throughout the open portion of the cycle, creating a greater push during closing than during opening. This is contrary to the desired push–pull condition. In addition, when the glottis is convergent ($a_2/a_1 < 1.0$), the inertive subglottal tract further hinders oscillation, as discussed earlier. But some assistance is possible from subglottal inertance in falsetto register, if $a_2 > a_1$, also as discussed earlier.

Finally, a *compliant – compliant* tract [Eq. (17) and Fig. 7(d)] is also not favorable to modal register, but a little more

so than the inertive–compliant combination just discussed. For convergence, although the gradual pressure reduction from the first integration in Eq. (17) is favorable, the second integration is detrimental. The worst of all situations exists for divergence. The glottis is simply blown apart by a uniformly increasing intraglottal pressure. Thus a *compliant–compliant* vocal tract squelches phonation when the glottis diverges.

To determine how the above-noted driving pressures affect the frequency and amplitude of self-sustained oscillation, it is typical to develop an autonomous differential equation of motion for tissue displacement in terms of flow-dependent driving pressures. Fletcher's (1993) small amplitude analysis of autonomous vibration of simple pressure-controlled valves in gas flows is relevant to vocal fold vibrations, but the alternating convergent–divergent glottis created by surface waves on the tissues were not modeled. Hence, the analysis was basically for a one-mass model (or the x_{10} mode in the abbreviated mode nomenclature of Titze (2006b, Chap. 4). Adachi and Sato's (1996) treatment of two-dimensional lip vibration (transverse and longitudinal to the flow) captured a z_{10} mode in addition to the x_{10} mode, but also did not include the surface wave. Titze's earlier (1988) analysis did include the surface wave, but considered only downstream inertive reactance of the tract (the most typical for low F_0 speech). In Chan and Titze (2006) and in Titze (2006b, Chap. 7), upstream inertive reactance was also considered, but not compliant reactance. Thus, to date nobody has derived an autonomous differential equation that includes both inertive and compliant reactance, upstream and downstream, with the inclusion of a surface wave on the tissue.

Given that Fletcher's (1993) closed-form (analytical) solutions contain both subglottal and supraglottal reactance explicitly, his equations are utilized here to approximate frequency and amplitude changes for autonomous (self-sustained) oscillation. Equations (19) and (20), from Fletcher (1993) p. 2176, were solved with the following parameters (Fletcher's notation) that are relevant for human phonation: $\sigma_1=\sigma_2=+1$ (Fletcher's overpressure parameters that define the valve type); $W=1.0$ cm (vocal fold length); $m=0.05$ g (vocal fold mass in vibration); $S_1=S_2=S_3=0.5$ cm^2 (inferior, medial, superior surfaces of vocal folds, respectively); $x_0=0.03$ cm (neutral glottal half-width); $\bar{p}_2=10\,000$ dyn/cm^2 ≈ 1 kPa (mean subglottal pressure); $\theta=30°$=entry and exit angles into glottis; $k=(0.05)\,(2\pi F_0)$=tissue resonance bandwidth (157 Hz at $F_0=500$ Hz); X_1, X_2=subglottal and supraglottal reactances, respectively (variables).

Both X_1 and X_2 were varied according to the reactance curves of Fig. 2 (top right). They are redrawn for comparison at the top of Fig. 8. Recall that these reactances apply to a uniform 3.0 cm^2 subglottal tract and a uniform 3.0 cm^2 supraglottal tract that has a narrowed 0.5 cm^2 epilarynx tube.

Fletcher's analytical equations allow for direct specification of the natural frequency F_0 of the vocal fold oscillator in a no-load condition. This frequency was varied from 0 to 1500 Hz as a pitch glide to correspond to human ranges of F_0 and to predict the F_0 jumps observed in the data of the companion paper (Titze *et al.*, 2008). F was defined to be the

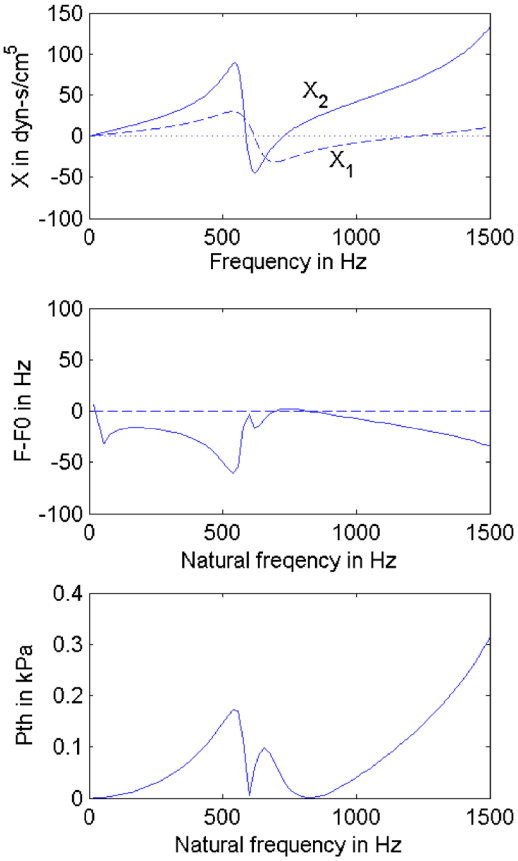

FIG. 8. (Color online) Fletcher's (1993) small oscillation analysis; (top) reactance curves; (middle) the difference between the oscillation frequency F and the no load frequency F_0; (bottom) oscillation threshold pressure P_{th}.

true oscillating frequency for any applied load. Figure 8 (middle graph) shows calculations for $F-F_0$, the difference in oscillation frequency from the no-interaction fundamental frequency. In the bottom graph we see the corresponding oscillation threshold pressure P_{th}.

Consider first some general trends. The oscillation frequency tends to be mostly below the no-interaction resonance frequency F_0. This is because inertive reactance dominates in airways that have a constricted region (the epilarynx tube in this case), creating effectively an increase in the mass of the oscillating system (tissue and air columns collectively). Note that there is a general inverse relation between $F-F_0$ and the supraglottal reactance X_2. The highest frequency is at 750 Hz, where $X_1=-30$ dyn s/cm^5 (compliant) and $X_2=0$. This frequency is slightly greater than F_0. The most notable drop in frequency (−50 Hz) occurs just above 500 Hz, where both X_1 and X_2 are highly positive. The small peak around 600 Hz is for $X_1=X_2=0$, the no-interaction condition for which $F=F_0$.

The threshold pressure P_{th} basically follows the sum of the reactance curves. Aside from a narrow dip near the tube resonances, where $X_1+X_2=0$, the lowest threshold pressure is found in the 750–1000 Hz region, where X_1 is negative (compliant) and X_2 is positive (inertive). Thus, as stated earlier, the *compliant – inertive* acoustic load is the most favorable to vocal fold oscillation. Titze and Sundberg (1992) have shown that every doubling of lung pressure above threshold raises the source intensity by about 6 dB. In addi-

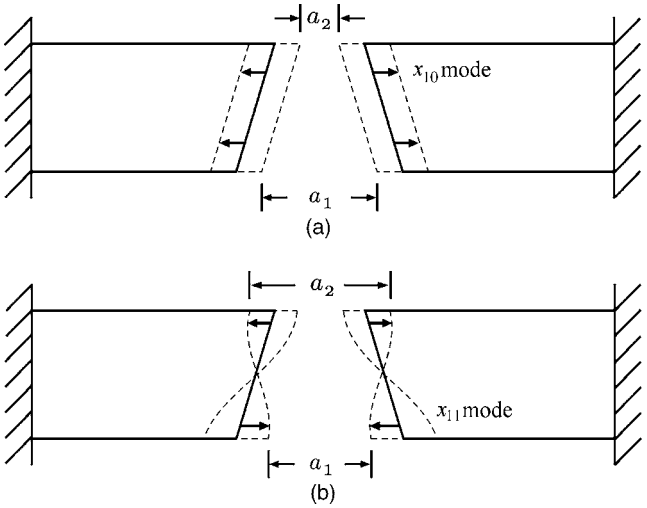

FIG. 9. Sketches of a convergent glottis with two vibrational modes, (a) the x_{10} mode and (b) the x_{11} mode.

tion, Alipour *et al.* (2001) showed that an approximate 6 dB increase in intensity was obtained in an excised larynx when a vocal tract was added by way of a physical tube that lowered the threshold pressure. Given that the threshold pressure in Fig. 8 varies from below 0.1 to above 0.3 kPa, and given that typical lung pressures for speech range between 0.5 and 1.0 kPa, it is possible that more than one doubling of P_{th} or 6–12dB in source intensity could be realized in the lower threshold regions with normal lung pressures. But a word of caution is in order. The Fletcher (1993) equations used for the Fig. 8 calculations did not contain vocal tract losses. Hence, the P_{th} fluctuations are probably overestimated. Nevertheless, significant changes in source energy are likely with only a few tenths of a kPa reduction in P_{th}.

In any vocal fold model other than the one-mass model, the a_2/a_1 ratio is variable throughout the glottal cycle. The amount of dynamic a_2/a_1 variation can be explained in terms of two dominant modes of vibration of vocal fold tissues (Fig. 9). For prephonatory (static) convergence, an x_{10} mode has no vertical variation in tissue displacement, as shown in Fig. 9(a). It produces less variation in the a_2/a_1 ratio than an x_{11} mode, which has a 180° phase difference between top and bottom displacement, as shown in Fig. 9(b). [For a complete description of tissue modes and their nomenclature, see Titze (2006b), Chap. 4]. The a_2/a_1 ratio for the x_{10} mode gradually increases and decreases over the open portion of the glottal cycle, but stays between 0.0 and 1.0. For the x_{11} mode, however, both convergence and divergence can be experienced over the cycle. Thus, the x_{11} mode is less dependent on vocal tract interaction than the x_{10} mode because the pushes and pulls from vocal tract pressures tend to cancel each other over the glottal cycle. This conclusion agrees with what Flanagan and Landgraf (1968) observed with a one-mass model, which only supports an x_{10} mode, and what Zhang *et al.* (2006a, b) observed on a physical model. It is also the reason why Zañartu *et al.* (2007) focused their recent analysis on the one-mass model. All models with a dominant x_{10} mode are highly affected by vocal tract reactance. In the two-mass model of Ishizaka and Flanagan (1972), the x_{11} mode was present and vocal tract interaction was reduced. Thus, the percentage of x_{11} mode excitation (relative to x_{10}) serves as a decoupler of vocal tract interaction, in direct opposition to the narrowing of the epilarynx tube. It offers a vocal tract-independence mechanism of self-sustained oscillation (Titze, 1988; Lucero and Koenig, 2007; Chan and Titze, 2006; Jiang and Tao, 2007). Speakers and singers who adjust their source and filter for linear coupling rely heavily on this mechanism of self-sustained oscillation.

III. SOURCE–FILTER INTERACTIONS WITH COMPUTER SIMULATIONS

Because of the many simplifications and limitations imposed by the low-dimensional vocal fold models and analytical treatments, it is important to balance the above-presented results with computer simulation models that are capable of handling all levels of interaction and many degrees of freedom in tissue movement.

A. Methods

An $L \times M \times N$ point-mass model of the vocal folds was used for simulation of flow-induced, self-sustained oscillation. The details of this model are beyond the scope of any single article, but are well documented in Titze (2006b, Chap. 4). L is the number of masses in the medio-lateral direction (7 in this simulation), M is the number of masses in the anterior–posterior direction (5 in this simulation), and N is the number of masses in the inferio–superior direction (5 in this simulation). Thus, the model had 175 point masses, each with two degrees of freedom (horizontal and vertical). Tissue properties were defined with a fiber-gel construct, where the fibers carried the nonlinear stress–strain characteristics of muscle, ligament, and mucosa, and the gel properties were defined with Young's moduli, shear moduli, and Poisson's ratios (Titze, 2006b; Chaps. 2–4). Aerodynamic pressures and glottal flow were calculated with a modified Bernoulli equation that included flow separation and jet formulation by rule (Titze, 2006b, Chap. 5). All vocal tract pressures were computed with the well-known wave-reflection analog (Liljencrants, 1985; Story *et al.*, 1996; Titze, 2006b, Chap. 6).

Based on the foregoing autonomous differential equation analyses, it was important to include both a subglottal and a supraglottal vocal tract to assess the individual and combined interaction effects. As in the previous section on level 1 interaction with forced oscillation, the subglottal system had 36 cylindrical sections, each 0.398 cm long, for a total length of 14.33 cm. The supraglottal system had 44 cylindrical sections, each of the same length, for a total of 17.51 cm. The first eight sections of the supraglottal tract again constituted the epilarynx tube, the diameter of which was kept uniform so that a single parameter (A_e) could be varied for coupling strength. The sampling frequency was 44.1 kHz. The medial surface of the vocal folds was nearly flat, with a slight convergence in the inferio–superior direction and a similar convergence (tapering) in the posterio–

FIG. 10. anterior direction. Dynamically, the shape of the glottis assumed a variety of mode configurations due to surface wave propagation.

Control parameters for this model were lung pressure P_L and simulated muscle activations of the intrinsic laryngeal muscles of the larynx: cricothyroid (CT), thyroarytenoid (TA), lateral cricoarytenoid (LCA), posterior cricoarytenoid (PCA), and interarytenoid (IA). These muscle activations (ranging from 0.0 for no activation to 1.0 for 100% activation) positioned the vocal folds (Titze, 2006b, Chap. 3; Titze and Hunter, 2007) and determined all of the tissue properties. Specific values will be given in the following sections.

B. Results

1. Simulation 1

A no-interaction case was first investigated as a control case. A high–low–high pitch glide was simulated under self-sustained oscillation, following the pattern produced earlier for level 1 interaction and produced by human subjects in the companion paper. Figure 10 shows a spectrogram for the glottal flow waveform, with both the subglottal reactance (thin white solid line) and the supraglottal reactance (thick white line) superimposed vertically. These reactances are the same as in previous figures (Figs. 2–4 and 8) for the uniform tubes with a 0.5 cm^2 epilarynx tube. The zero line for the reactance curves is set at time=4 s, and the scaling of the reactance magnitude can be obtained from Fig. 2. Underneath the spectrogram, the amplitude envelope for the glottal flow u_g is shown in the middle panel and the amplitude envelope for the glottal area a_g is shown in the bottom panel. The following parameters of the model were held constant in the simulations: P_L=1.5 kPa, LCA activity=31%, IA activity =30%, PCA activity=0.0%, vowel=uniform tube with narrowed epilarynx tube as in Fig. 2, with no nasal coupling. CT activity was varied from 90-0-90% and TA activity from 0-10-0%. Details of how these activities affect laryngeal posturing in a speech-like gesture can be found in Titze and Hunter (2007).

To simulate no vocal tract interaction, the pressures in the glottis were programmed as described previously in the forced oscillation case (level 1 interaction). Waves propagated through the vocal tract and were radiated from the mouth, but this propagation produced no load on the glottis because the incident pressures (traveling waves) were nullified by programming for glottal flow and pressure calculation. Only aerodynamic pressures and flows were retained. Note that this caused glottal flow and glottal area envelopes to be proportional, as in the forced oscillation case. The glottal area spectrogram (not shown) was identical to the glottal flow spectrogram, indicating that there was no interaction. Both spectrograms showed harmonics; however, these resulted from vocal fold collision in this case instead of flow pulse skewing. (It is difficult to obtain a perfectly sinusoidal area with no collision with self-sustained oscillation.) The broad peak in the center of the u_g and a_g envelopes was due to greater laxness of the tissue, which caused greater vibrational amplitude when F_0 was low. The fundamental frequency (F_0) in the glide ranged from 700 to 330 Hz. Note that F_0 passed through the positive peak of the reactance curve at about 1.0 s and again at about 7.0 s, but this had no effect on the flow or area waveforms, indicating linear source–filter coupling for this control case.

2. Simulation 2

For the next simulation, subglottal interaction alone was investigated. To uncouple the supraglottal tract, the supraglottal pressure was set to zero in the program for the purpose of glottal flow and intraglottal pressure calculation, but not for wave propagation. Figure 11 shows the result. Note first that the overall signal strength is a little less than for no interaction, judged by height of the a_g and u_g envelopes, and there is not an exact proportionality between the glottal area and glottal flow. More important, new frequencies have been created due to bifurcations in tissue movement, as seen in the spectrogram on top. At 0.8 s, a period-3 subharmonic occurs, which changes to a period-5 subharmonic at 1.6 s. The timing of the period-3 bifurcation agrees with F_0 being in the maximum negative reactance dip and the period-5 bifurcation occurs when $2F_0$ enters the negative reactance region. Much needs to be understood about the nature and onset of these subharmonic bifurcations, but this is a topic for subsequent research. Suffice it to say here that individual harmonics passing through rapidly changing reactance regions can destabilize the vibration regimes, as the foregoing analysis

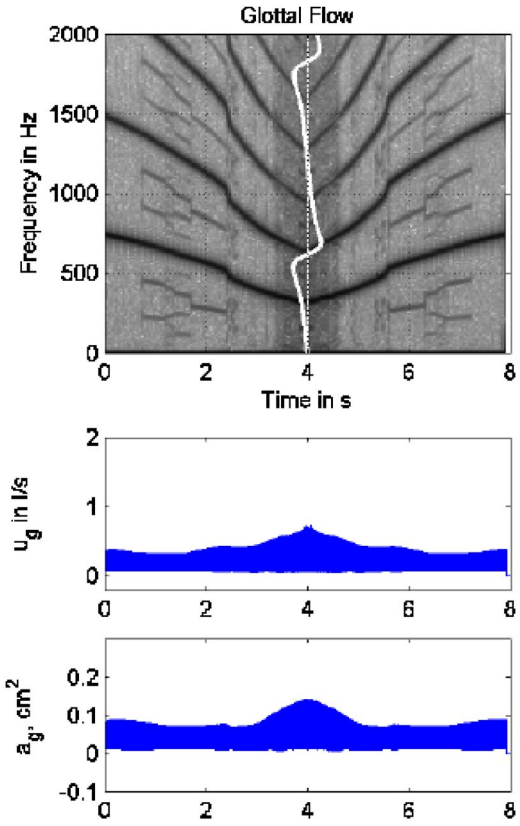

FIG. 11. (Color online) Simulation of downward and upward F_0 glide produced with a 175 point-mass self-oscillating biomechanical model of the vocal folds with subglottal interaction only; (top) spectrogram, with subglottal reactance superimposed vertically with white line; (middle) glottal flow envelope; (bottom) glottal area envelope.

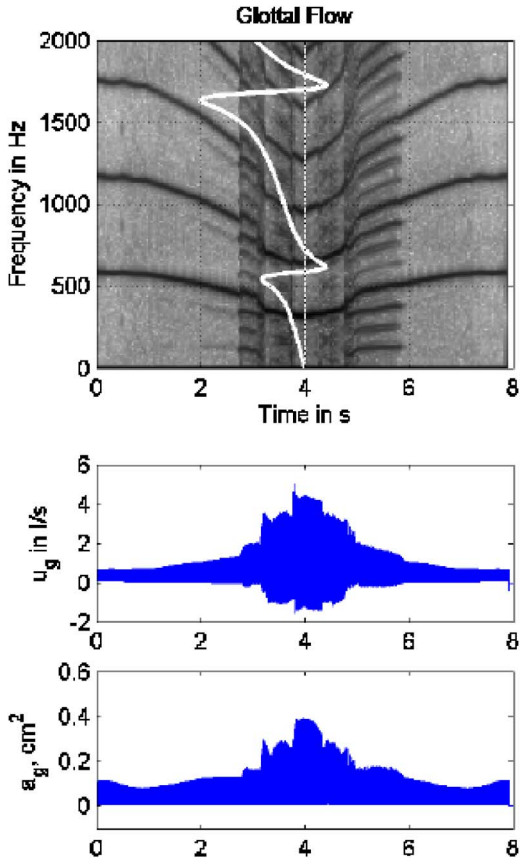

FIG. 12. (Color online) Simulation of downward and upward F_0 glide produced with a 175 point-mass self-oscillating biomechanical model of the vocal folds with supraglottal interaction only; (top) spectrogram, with supraglottal reactance superimposed vertically with white line; (middle) glottal flow envelope; (bottom) glottal area envelope.

demonstrated. Our quantitative interest here is in F_0 drops, because they are the most predictable instabilities and the most prevalent in our companion paper on human phonation.

An F_0 drop of about 50 Hz occurs at 2.4 s. This F_0 drop, predicted well by the foregoing small oscillation analysis with Fletcher's (1993) model (Fig. 8) and by Zhang *et al.* (2006a,b) on a physical laboratory model that had only subglottal interaction, was a "correction" from a higher F_0 that prevailed in the compliant reactance region. The starting F_0 was 750 Hz rather than the no-interaction F_0 of 700 Hz seen in Fig. 10. Compliance basically adds stiffness to the interactive vibrating system, thereby raising F_0, whereas inertance adds mass, thereby lowering F_0. An interesting observation is that the 50 Hz pitch jump occurred below the positive peak of the reactance curve. This may be related to the fact that the second harmonic $2F_0$ entered the compliant region at about 2.4 s, which could have delayed the jump by adding some stiffness to the system before inertive reactance took over. At 3.2 s in Fig. 11, some perturbed vibration occurred, as indicated by the darker (noisier) background. This aperiodic vibration is related to an impedance mismatch instability, i.e., the source impedance became lower, on average, than the vocal tract input impedance, and highly variable due to oscillation. The F_0 upglide showed a slight asymmetry in the duration of another brief noisy regime at 5.6 s, indicating a small hysteresis effect.

3. Simulation 3

The next simulation was for supraglottal interaction alone. Here subglottal pressure was set to the lung pressure, but supraglottal traveling waves were kept intact. Results are shown in Fig. 12. The waveform envelopes show that this case has the greatest overall signal energy. (The scale of u_g has been increased by a factor of 3 and the scale of a_g by a factor of 2 with respect to Figs. 10 and 11). A weak period-4 bifurcation occurred at 2.0 s, followed by a stronger one at 2.7 s. F_0 and $2F_0$ both went from higher to lower inertive reactance in this bifurcation region. With regard to fundamental frequency changes, note that F_0 started lower than in the noninteractive case, 570 Hz instead of 700 Hz. This "pulling down" of F_0 toward F_1, even when all muscle activities were the same as before, resulted from the inertive reactance of the vocal tract, which (as stated earlier) adds mass to the interactive oscillating system. A very small F_0 rise (10–20 Hz) is then seen at the beginning of the strong period-4 bifurcation, correlated with diminished reactance for both $2F_0$. This small rise, together with the subharmonic regime, delays the eventual larger drop in F_0 of about 100 Hz in positive reactance territory. Finally, the vocal fold vibrational amplitude became disproportionably large and slightly unstable in the 3.0–5.0 s region. A hysteresis effect was also seen in that the bifurcations were delayed on the upslope of the glide. Given that these bifurcations did not appear in the

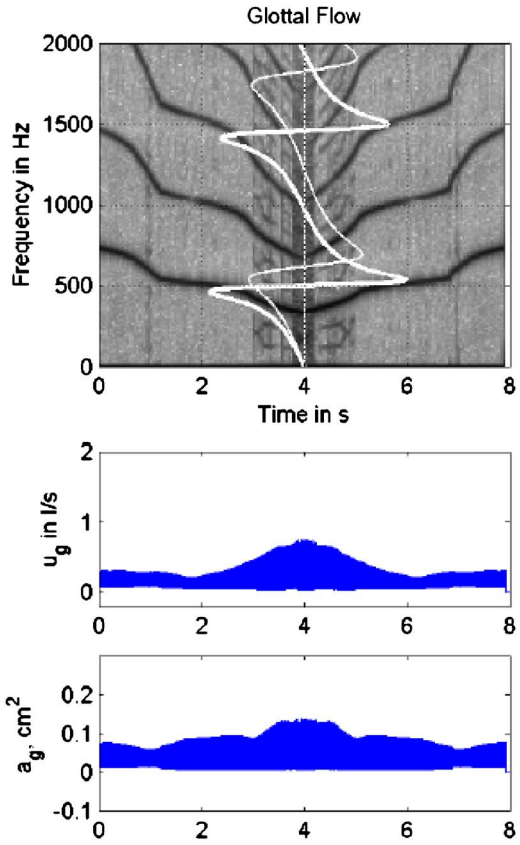

FIG. 13. (Color online) Simulation of downward and upward F_0 glide produced with a 175 point-mass self-oscillating biomechanical model of the vocal folds with both subglottal and supraglottal interaction, A_e=3.0 cm^2; (top) spectrogram, with subglottal reactance (thin white line) and supraglottal reactance (thick white line) superimposed; (middle) glottal flow envelope; (bottom) glottal area envelope.

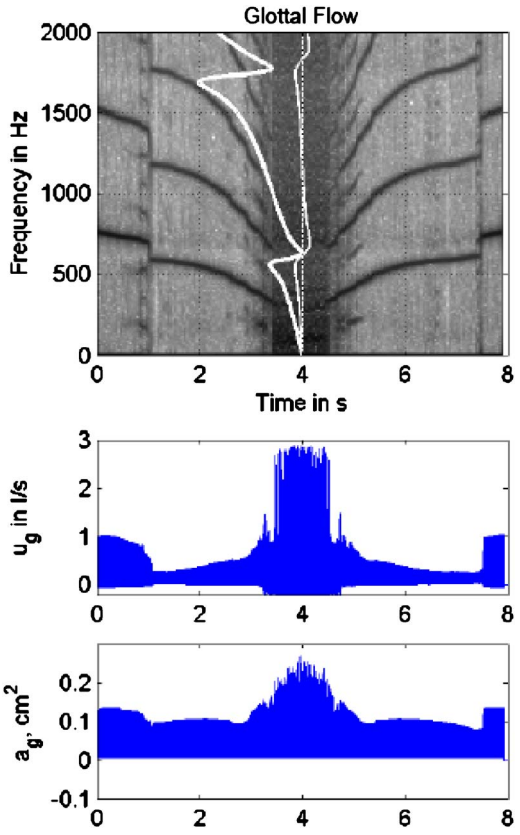

FIG. 14. (Color online) Simulation of downward and upward F_0 glide produced with a 175 point-mass self-oscillating biomechanical model of the vocal folds with both subglottal and supraglottal interaction, A_e=0.2 cm^2; (top) spectrogram, with subglottal reactance (thin white line) and supraglottal reactance (thick white line) superimposed; (middle) glottal flow envelope; (bottom) glottal area envelope.

noninteractive case (Fig. 10), we conclude that they are the result of supraglottal source–filter interaction.

4. Simulation 4

The next simulation was with combined subglottal and supraglottal interactions. Thus, it represented a realistic (nonrestricted) situation. The degree of supraglottal interaction was controlled by two separate values of the cross-sectional area of the epilarynx tube A_e. For the lowest degree of interaction (A_e=3.0 cm^2) the epilarynx tube diameter was equal to that of the uniform tube (recall Fig. 1, top left). Figure 13 shows the simulation results for this configuration. Both subglottal and supraglottal reactance curves are shown in white on the spectrogram, supraglottal being the thicker line. Again the scales are arbitrary, but the relative magnitudes between subglottal and supraglottal reactance are correct. There were two F_0 drops, one at about 0.8 s, where F_0 entered a region of rapidly changing overall F_1 reactance and $2F_0$ entered a region of positive supraglottal reactance, and another at drop about 3.0 s, where F_0 entered the region of positive supraglottal F_1 reactance. Also, $2F_0$ entered the *compliant–compliant* region at the second drop, and a period-3 bifurcation occurred when $2F_0$ entered this region, similar to what was seen in Fig. 12. Some evidence of chaotic vibration was seen near 4.0 s, where the lowest F_0 and the highest vibration amplitude occurred. The overall signal strength was slightly less than that of the noninteractive case (the scale for the signal envelopes was set back to that of Figs. 10 and 11).

5. Simulation 5

Figure 14 shows results for a severe case of epilaryngeal constriction (A_e=0.2 cm^2). The overall signal strength was much higher (scale on the glottal flow envelope was changed to 3.0 l/s), and stronger bifurcations occurred. A 100 Hz F_0 jump occurred at 1.0 s, which was preceded by a period-4 subharmonic, again as F_0 entered the rapidly changing reactance region. When $2F_0$ entered the minimum reactance regions, around 3.0 s, destabilization occurred in the vibration, as evidenced by further bifurcations. Strong hysteresis effects were also evident in that reverse bifurcations occurred at higher frequencies. Of particular significance is the fact that vibrational amplitude increased and decreased sharply (and irregularly) near the lowest F_0 (middle graph), while the flow amplitude reached a plateau (bottom graph). This plateau is attributed to the fact that the input impedance to the vocal tract became higher than the glottal impedance for A_e=0.2 cm^2, thus limiting the flow.

6. Changes in energy levels

Table I shows numerical results for a selected group of dynamical variables at all levels of interaction discussed earlier. (An intermediate case for A_e=0.5 cm^2 was added to

TABLE I. Output quantities for various degrees of interaction.

	Mean glottal area (cm^2)	Mean glottal flow (l/s)	Aerodynamic power (w)	Radiated power (w)	Efficiency (%)
No interaction	0.0381	0.3284	0.4825	0.0117	2.42
Subglottal only	0.0336	0.1835	0.2264	0.0033	1.44
Supraglottal only (A_e=0.5 cm^2)	0.0579	0.5014	0.7408	0.0523	7.07
Subglottal and supraglottal (A_e=3.0 cm^2)	0.0347	0.1717	0.2226	0.0014	0.62
Subglottal and supraglottal (A_e=0.5 cm^2)	0.0405	0.1860	0.2228	0.0035	1.59
Subglottal and supraglottal (A_e=0.2 cm^2)	0.0534	0.3200	0.2604	0.0143	5.49

show the progression with increased nonlinear coupling.) The output quantities for comparison are mean glottal area, mean glottal flow, aerodynamic power at the glottis, acoustic power radiated at the mouth, and glottal efficiency (the ratio of radiated power to aerodynamic power). The numbers represent time averages over the entire 8.0 s pitch glide. The "no interaction case" (top row) produced self-sustained oscillation by excitation of the x_{11} mode with aerodynamic pressures only. It serves as the control case. Consider first the "subglottal only" interaction case (row 2). In comparison to "no interaction," every dynamic quantity was reduced in magnitude. This is consistent with the expectation that subglottal inertance generally hinders vocal fold vibration, and such inertance was present over most of the F_0 glide. To the contrary, for the supraglottal only interaction case (row 3), every dynamic variable was increased, again consistent with previous predictions and discussions. Most variables increased by a factor of about 2 with supraglottal interaction only, but acoustic radiated power increased by a factor of more than 4. Glottal efficiency (the ratio of acoustic radiated power to glottal aerodynamic power) increased by a factor of about 3. Thus, supraglottal interaction alone would be a highly favored condition. Unfortunately, the trachea is always present in human phonation. Its effect cannot be removed, but perhaps altered for better reinforcement of vocal fold vibration by larynx lowering or raising.

With both subglottal and supraglottal interaction (rows 4–6), the results were dependent on the degree of interaction, which was controlled by the parameter A_e, the epilarynx tube area. For A_e=3.0 cm^2, the same as the area of the rest of the uniform tube, the radiated acoustic power was only 0.0014 W, nearly an order of magnitude less than for no interaction. This suggests that interaction is not necessarily an advantage. If the impedances are not well matched, more power can be absorbed internally in the system (Titze, 2002). Efficiency was only 0.62% compared to 2.43% for no interaction. Mean glottal flow was about half, as was the aerodynamic power. Mean glottal area remained about the same.

As the degree of interaction increased with a decrease in the epilarynx tube area A_e (rows 5 and 6), all dynamical variables increased. For the greatest interaction, A_e =0.2 cm^2, all quantities except aerodynamic power were greater than those for the "no interaction" case. This suggests a double advantage, getting more radiated power for less aerodynamic power used. Hence, the glottal efficiency had doubled, with the same lung pressure. Comparing mild interaction (A_e=3.0 cm^2) to strong interaction (A_e=0.2 cm^2), all variables increased categorically. The radiated acoustic power increased by a factor of 10, as did the glottal efficiency. We made no attempt to optimize the output variables by choosing the best value of A_e for the given glottal conditions, but we expect that such an optimization would yield an even higher efficiency.

IV. DISCUSSION AND CONCLUSIONS

Source–filter interaction has been divided into two levels. Level 1 is the interaction of glottal airflow with acoustic vocal tract pressures, even if vocal fold vibration is undisturbed. The interaction parameter is the mean glottal area divided by the effective (parallel combination) tube area of the subglottis and supraglottis. For constant adduction of the vocal folds and constant large tracheal diameters, the coupling parameter becomes the cross-sectional area of the epilarynx tube. Level 1 interaction produces harmonic distortion frequencies that contribute to the source spectrum. This interaction is present in all speech and singing, male and female. It has been described for nearly three decades, but generally underestimated in magnitude because details of the lower vocal tract were unknown. Level 1 interaction contributes to the spectral slope and the spectral ripple in the glottal sound source, even when the spectrum is purely harmonic and no bifurcations in vocal fold vibration occur. The supraglottal and subglottal impedances are additive for this interaction. If both impedances are inertive (positive), a maximum skewing of the flow pulse is achieved, which increases the maximum flow declination rate and thereby vocal intensity. Individual harmonics can be enhanced or suppressed by frequency-dependent reactances that change from positive to negative.

An interesting discovery was made in this investigation with regard to level 1 interaction. The entire spectrum of source frequencies can (theoretically) be produced without vocal fold collision. This finding could have an impact on voice therapy, particularly for vocal fold pathologies resulting from excessive tissue collision stress. With a sinusoidally varying glottal area and no vocal fold contact, a

−12 dB/octave spectral slope was shown here to be achievable with an epilarynx tube cross-sectional area of 0.5 cm^2.

Level 2 interaction is realized more in high F_0 productions for which the dominant harmonics $(F_0, 2F_0, 3F_0, \ldots)$ are near the formants. Frequency jumps and a variety of new source frequencies or instabilities can be produced, including subharmonics and non-random noise. The instabilities occur mostly when one of the dominant harmonics encounters sudden changes in reactance, destabilizing the modes of vibration of the tissue that are affected differently by reactance. The control parameter for these phenomena is the same as for level 1 interaction. Computer simulations with a high-dimensional model showed that vocal efficiency, the ratio of radiated acoustic power to aerodynamic power, can increase by an order of magnitude when the epilarynx tube area is narrowed from 3.0 to 0.2 cm^2, but this narrowing also produced greater instabilities when dominant harmonics were in unfavorable reactance regions (i.e., near formants).

A thick and pliable mucosal layer on the vocal folds can lead to self-sustained oscillation without much reliance on vocal tract reactance. A parameter for this is the strength of the x_{11} mode of vibration (characterized by large vertical phase differences) relative to the x_{10} mode. Some vocalists may have the choice to operate in either a nearly linear region, with maximum harmonic stability, or in a nonlinear region with greater output power and greater efficiency but at the expense of less harmonic stability.

In the companion paper (Titze *et al.*, 2008), the most frequently occurring instabilities in human subjects were F_0 jumps, in magnitude on the order of 30–40 Hz. But not all subjects exhibited these instabilities, suggesting that nonlinear interaction varies across subjects, and perhaps even within subjects for repeated vocalizations. The theoretical analyses here predicted the F_0 jumps, both with analytical treatments and with simulation. They are mostly triggered when F_0 passes through F_1, but occasionally when $2F_0$ passes through F_1, as both theory and measurement showed. Larger F_0 jumps tend to occur with greater coupling (i.e., a narrower epilarynx tube).

For the modal voice register, used largely in speech at relatively low F_0, the ideal vocal tract load for self-sustained oscillation would be subglottal compliance and supraglottal inertance. The x_{10} mode would get maximum reinforcement. Unfortunately, this combination does not exist at low F_0 in the human voice. Both reactances tend to be inertive because the trachea and the supraglottal tract are roughly of equal length. Although this *inertive–inertive* combination has been shown to be less favorable for self-sustained oscillation than the *compliant–inertive* combination, flow pulse skewing (level 1 interaction) benefits from dual inertive reactance. Hence the two effects are offsetting. The worst combination for self-sustained oscillation in the modal register is an inertive subglottal tract and a compliant supraglottal tract. This combination can occur in speech for low F_1 vowels such as /i/ and /u/. For example, if $F_0 = 300$ Hz, $F_1 = 250$ Hz, and $F_1^1 = 600$ Hz (first subglottal formant), then the *inertive–compliant* condition exists. If interaction is high (narrow epilarynx tube), the register can flip from modal to falsetto, which is more sustainable with this acoustic load. Females may have cultivated a mixed register for speech to avoid this instability, given that a 300 Hz fundamental frequency is well within their speaking range. The companion paper shows the females exhibit fewer instabilities on a pitch glide than males, even though the likelihood of $F_0 - F_1$ crossing is greater.

A great amount of future work is needed to determine the extent to which combinations of subglottal and supraglottal reactance can be exploited, especially in high-pitched speech, loud speech, and singing on a variety of vowels. In this paper, all discussions pertained to a neutral-shaped vocal tract. Detailed interaction effects need to be developed for all vowels and consonants. Finally, although humans do not have much control over tracheal diameters, tracheal lengths can be changed with larynx raising and lowering. Perhaps the subglottal entry configuration can also be changed for more compliance, and the soft wall construct of the trachea (the portion in contact with the esophagus) may be useful for introducing subglottal compliance.

[1]Reactance is the energy-storing part of impedance, in contrast to resistance, which is the energy-dissipating part. These two parts of impedance are written as a complex number (real and imaginary part), with reactance being the imaginary part of the impedance. Positive reactance is labeled inertive (because the acoustic flow lags behind the pressure in phase) and negative reactance is labeled compliant (because the acoustic flow leads the pressure in phase).

Amplitude variations in coarticulated vowels

Ewa Jacewicz[a] and Robert Allen Fox
Department of Speech and Hearing Science, The Ohio State University, Columbus, Ohio 43210-1002

(Received 19 February 2007; revised 13 February 2008; accepted 19 February 2008)

This paper seeks to characterize the nature, size, and range of acoustic amplitude variation in naturally produced coarticulated vowels in order to determine its potential contribution and relevance to vowel perception. The study is a partial replication and extension of the pioneering work by House and Fairbanks [J. Acoust. Soc. Am. **22**, 105–113 (1953)], who reported large variation in vowel amplitude as a function of consonantal context. Eight American English vowels spoken by men and women were recorded in ten symmetrical CVC consonantal contexts. Acoustic amplitude measures included overall rms amplitude, amplitude of the rms peak along with its relative location in the CVC-word, and the amplitudes of individual formants F1–F4 along with their frequencies. House and Fairbanks' amplitude results were not replicated: Neither the overall rms nor the rms peak varied appreciably as a function of consonantal context. However, consonantal context was shown to affect significantly and systematically the amplitudes of individual formants at the vowel nucleus. These effects persisted in the auditory representation of the vowel signal. Auditory spectra showed that the pattern of spectral amplitude variation as a function of contextual effects may still be encoded and represented at early stages of processing by the peripheral auditory system. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2897034]

I. INTRODUCTION

This paper examines acoustic amplitude variation in naturally produced vowels as a function of vowel quality and its immediate consonantal context. Usually, formant frequencies are considered to be the primary factors determining vowel identity. However, although "secondary" acoustic cues such as duration, fundamental frequency (f_0), and amplitude have also been shown to contribute significantly to the phonetic identity of vowels, particularly little is known about the role of vowel amplitude. There is an extensive body of work supporting the linguistic use of vowel length distinctions and the perceptual importance of duration in vowel identification (e.g., Ainsworth, 1972, 1981; Mermelstein, 1978; Gottfried and Beddor, 1988; Whalen, 1989). The significance of f_0 to vowel quality has also been established (e.g., Nearey, 1989; Whalen and Levitt, 1995; Katz and Assmann, 2001). Yet, over the years, neither vowel amplitude nor the amplitudes of individual formants have been studied as systematically as have the other two secondary cues. Understandably, the literature on the subject, whether pertaining to vowel production or perception, is sparse.

Perhaps the best known set of studies exploring the role of formant amplitude comes from early speech perception research. Given the possibility of independent control over the formant amplitudes of static vowels using the parallel synthesis method, a number of experiments demonstrated that manipulations of the amplitudes of particular formants affected the perceived quality of the vowel (Lindqvist and Pauli, 1968; Carlson *et al.*, 1970; Ainsworth and Millar, 1972; Aaltonen, 1985; Schwartz and Escudier, 1987). If formant amplitudes indeed contribute to the perception of vowel quality, the question arises whether the auditory system is also sensitive to possible variations in formant amplitudes arising from coarticulation effects. However, before this question is addressed, we need to have a much better understanding of the nature, size, and range of such variation in naturally produced speech, especially in terms of the effect of immediate context. That is, given that naturally produced vowels are rarely static and dynamic cues such as formant transitions are coded primarily in the frequency domain, what is the nature and acceptable size of formant amplitude variation that may covary with dynamic frequency information? A better understanding of the nature and permissible range of such variation can help define more precisely the appropriate values in creating synthetic versions of vowels. In turn, by providing better controls, we may find that the contribution of formant amplitude to vowel perception may involve percepts other than phonetic quality, most likely vowel naturalness and timbre.

It needs to be pointed out that over the years, the primary interest in studying vowel amplitude was in determining its role in signaling linguistic prominence distinctions such as stress and accent (e.g., Fry, 1955; Lehiste and Peterson, 1959; Beckman, 1986; Sluijter and Van Heuven, 1996; Fant *et al.*, 2000a, b). However, this type of variation is fundamentally different in that it involves speaker-intended modification of vocal intensity. With regard to the basic amplitude variation, there is essentially one study which showed that vowel amplitude also varied as a function of its immediate consonantal context: House and Fairbanks (1953).

House and Fairbanks (1953) reported measurements of relative power for six American English vowels /i, e, æ, ɑ, o, u/ along with their duration and f_0. These vowels were produced in symmetrical stressed CVC syllables with twelve consonants /p, t, k, b, d, g, f, v, s, z, m, n/ differing in

[a]Electronic mail: jacewicz.1@osu.edu

 0001-4966/2008/123(5)/2750/19/$23.00 © 2008 Acoustical Society of America

voicing, manner, and place of articulation. Averaged across all consonantal contexts, the vowels fell in two groups: greater in relative power (/o, e, u/) and lesser in relative power (/i, æ, ɑ/). The differences within each group were not significant. A surprising result was that low vowels /æ, ɑ/ were the weakest in the entire set, contrary to what might have been expected given the greatest openness of both vowels. Another striking finding was that consonant voicing had a substantial effect on the vowel's amplitude: Vowels embedded in voiced consonants were more than twice as strong as vowels in the context of voiceless consonants. Considerable differences were also found as a function of consonant manner: Vowels in the context of fricatives were about 60% stronger than vowels in the context of stops. The effects of consonant place were small, showing that vowels in the contexts of velars were only slightly weaker that those in the contexts of either labials or alveolars.

These findings motivated the present study of the variation in formant amplitude in consonantal context. If specific contexts introduce such considerable changes to the overall vowel amplitude, we may expect these changes to be manifested also in the vowel spectrum. Furthermore, they may still be present at the vowel nucleus and not only at the vowel margins. There is a lack of empirical acoustic data which would relate the variability in the overall vowel amplitude as a function of consonantal context to the corresponding changes in amplitudes of particular formants. It is also unknown how the context affects formant amplitude of vowels differing in their articulation with respect to the tongue body position and degree of openness. We may only infer that context effects may be different for different vowel spectra, introducing local changes that might enhance a particular portion of the spectrum to which the perceptual system might be sensitive and may utilize it in processing and recognizing the vowel at the lexical level.

The contribution of formant amplitudes to the perception of vowel quality was recently examined in terms of manipulation of the global spectral tilt of synthetic vowels, based on the rules of formant amplitude in cascade filter model of the vocal tract (Ito *et al.*, 2001; Kiefte and Kluender, 2005). However, as demonstrated by Kiefte and Kluender (2005), spectral tilt seems to be more effective for steady-state vowels than for vowels with inherent spectral change. It becomes even more difficult to specify the synthesis values and to predict the perceptual efficacy of the global spectral tilt that may additionally vary as a function of the immediate phonetic context of the vowel.

In acoustic phonetic theory, it is generally accepted that the spectrum of a vowel is the spectrum of the glottal source filtered by the vocal tract and the vocal tract acts as a composite filter of several bandpass filters, one for each formant (e.g., Stevens, 1998; Titze, 2000). Although the vowel-specific spectral slope can be predicted from the complex interaction between glottal source and vocal tract filtering (e.g., Fant, 1956; Fant *et al.*, 1963; Fant and Lin, 1987), the size of the filter-related size variation in formant amplitude such as that found in vowels in context has not yet been integrated into the models. Yet, such spectral details may bolster speech production models, leading also to improved speech recognition schemes.

The present acoustic study is a partial replication and extension of House and Fairbanks (1953) to individual formants. The purpose of the replication is to verify the general patterns of amplitude variation in that study using current speech analysis tools. The investigation of the amplitude of individual formants, extending the original House and Fairbanks study, aims to relate the variability in the vowel spectrum to the changes in the overall vowel amplitude in consonantal context. The overall goal of this study is to characterize the nature, size, and range of acoustic amplitude variation in coarticulated vowels in order to determine its contribution and relevance to vowel perception.

II. METHODS

A. Speakers

Twenty speakers (ten men and ten women) of Midwestern American English with no known history of speech disorders participated in the present study—fourteen were born and raised in Ohio, four in Michigan, and two in Wisconsin. They were students aged 18–36 years enrolled in a variety of majors at The Ohio State University and were phonetically untrained.

B. Speech materials

Eight relatively monophthongal American English vowels were selected: /i, ɪ, ɛ, æ, ɑ, ɔ, ʊ, u/. Four of the vowels /i, æ, ɑ, u/ were among those studied by House and Fairbanks (HF), and four /ɪ, ɛ, ɔ, ʊ/ were new. Since the set in HF did not include short vowels, the vowels /ɪ, ʊ/ were added as the lax counterparts to the tense /i, u/ and the two diphthongal vowels /e, o/ were replaced by the relatively monophthongal vowels /ɛ, ɔ/. Consistent with HF, each vowel was embedded in a symmetrical C_1VC_1 context. The selected consonant set consisted of ten oral consonants /p, t, k, b, d, g, f, v, s, z/ as in HF. The two nasal consonants /m, n/ were not included in the present set. We decided to concentrate on oral vowels only because vowels in a symmetrical nasal context would have been produced with a significant degree of nasalization which would have introduced both nasal formants and nasal zeroes into the vowel spectra. In the present study, the CVCs were produced as monosyllables in a stressed position in a short phrase "It's a _____" [ɪtsə_____] and not as disyllables as in HF, in which each CVC was prefixed by unstressed [hə] (e.g., *hupeep*, *hudeed*, *hukeek*, etc.). This modification was introduced merely for practical reasons as the phonetically untrained subjects found it difficult to read a nonsense word with the above-mentioned prefix. However, in both HF and the present study the stressed target syllable was preceded by an unstressed schwa. The complete set of stimulus materials in the orthographic form presented to the speakers is listed in Table I. Each speaker recorded 240 utterances in a single session lasting approximately 1 h (8 vowels × 10 consonants × 3 repetitions). The data for /ɔ/ from three subjects and for /ɑ/ from three other subjects were subsequently discarded because it was determined during the

TABLE I. Orthographic representation of the recorded stimulus set.

Context	/i/ (heat)	/ɪ/ (hit)	/ɛ/ (bed)	/æ/ (bad)	/ɑ/ (lot)	/ɔ/ (law)	/ʊ/ (good)	/u/ (who)
[p]	peep	pip	pep	pap	pop	pawp	poup	poop

analysis phase that these speakers had a complete merger of /ɔ/ and /ɑ/ (this was not true for the other speakers).

C. Procedure

Recordings were controlled by a program in MATLAB. The speaker was seated in a sound-attenuated IAC booth and was facing a LCD monitor placed outside the booth's window. A head-mounted Shure SM10A dynamic microphone was used, positioned at a distance of 2 in. from the speaker's lips. Speech samples were recorded and digitized at a 44.1 kHz sampling rate directly onto a hard disc drive. A model example word containing the vowel of interest was first displayed on the screen (e.g., "heat"). Next to the word, the stimulus sentence appeared (e.g, "It's a **beeb**"). The speaker read the sentence placing stress on the CVC word and producing the vowel quality as in the displayed word. To overcome any orthographic uncertainties, the presentation was blocked by vowel type. The order of consonantal contexts for each vowel type and the order of vowels themselves were randomized for each speaker. There was a short practice set completed before the start of each vowel category to assure that the speaker was comfortable with the spelling of the CVCs. After recording each sentence, the experimenter either accepted and saved the sentence or re-recorded it in the case of any mispronunciations. Speakers took short breaks upon request and the position of the microphone was monitored by the experimenter throughout the recording session to assure its constant distance from the speaker's lips.

D. Acoustic measurements

The set of measurements included overall rms amplitude, amplitude of the rms peak along with its location in the vowel, the amplitudes of individual formants F1–F4 along with their frequencies, vowel duration, and f_0. Prior to acoustic analysis, the tokens were digitally filtered and downsampled to 11.025 kHz. Measurements of both vowel duration and the duration of the whole CVC word served as input for subsequent automated measurements of rms peak location and the entire set of amplitude and frequency measurements. Standard measures of vowel duration were used (Peterson and Lehiste, 1960; Hillenbrand *et al.*, 1995). Vowel onsets and offsets were located by hand, primarily on the basis of a wave form display with segmentation decisions checked against a spectrogram. For vowels in the context of fricatives, vowel onset was measured from the cessation of noise in the periodic wave form following a frication offset and vowel offset was determined by the onset of noise in the wave form signaling the start of final frication. For vowels in the context of stops, vowel onset was measured from onset of periodicity (at a zero crossing) following the release burst. Vowel offset for voiceless stops was defined at the point at which the amplitude of the vowel dropped to near zero (which was also coincident with elimination of all periodicity in the wave form). The vowel offset for voiced stops was defined as that point when the amplitude dropped to near zero and any periodicity in the wave form contained no high frequency components (as expected for voicing produced during the stop closure). Because vowel amplitude was the primary focus, we eliminated those portions of the vowel near offset that were produced with creaky voice. This happened in about 20% of productions from three speakers who had a tendency to use irregular phonation at word offsets. All segmentation decisions were later checked and corrected (and then rechecked) by both experimenters using a MATLAB program that displayed the segmentation marks superimposed over a display of the CVC's wave form (in two different views—a view that included the entire CVC and an expanded view that concentrated on the vowel portion only).

Two measures of vowel amplitude were used in this study, the peak rms and the overall rms. The peak rms measure estimates the peak energy of the vowel, i.e., the highest amplitude of the vocalic portion or syllable nucleus. The overall rms (the quadratic mean) is a measure of vowel amplitude calculated from vowel onset to vowel offset. The choice of both measures instead of one was dictated by our desire to replicate the HF results choosing the amplitude values that would correspond most closely to the "maximum level for each syllable." HF measured the maximum level of each stressed syllable, defined as the point of maximum intensity reached during the production of the stressed vowel as indicated on an analog sound level meter and recorded graphically on paper. However, in reporting their result, HF used another measure called "relative power," which was a manipulation "to facilitate arithmetic treatment" (p. 110). Namely, each measurement for each subject was expressed in decibels above the lowest value for that subject and the difference N between the two values ($N_{\max} - N_{\min}$) was con-

verted to relative power for this subject which was equal to $\text{antilog}_{10} N/10$. Calculated in this way, each of these relative power values is a simple ratio value and there is no specific measure unit that can be assigned to them. In reporting their results as relative power, HF did not use any specific unit as they did in reporting their duration (in seconds) and f_0 (in Hz) measurements (see, for example, their Table 5). Their vowels were simply comparatively greater or smaller in relative power, which might be thought of as greater or smaller in magnitude, as all values were reported in relative power.

From the HF report, we do not know the exact decibel values for their "syllable maximum" measurements. Since our present focus was to relate the measures of overall vowel amplitude and the amplitude of individual formants, we measured both the peak rms and the overall rms amplitude to observe their relationship for individual vowels and consonantal contexts. The amplitudes of individual formants were then measured at the temporal location of the rms peak, which gives the best estimate of how spectral energy is distributed in the most "intense" region in the vowel. We expected higher decibel values for the peak rms measure as compared to the overall rms, but whether the effects of consonantal context would be the same for both measures could not be determined without empirical investigation. Based on how the analyses were done using the experimental apparatus available to HF, the overall rms measure may correspond more closely to HF measurements. Yet, examination of the overall rms measure alone would be problematic for the present focus which investigates changes to the amplitude spectrum in addition to the more "global" amplitude variation as a function of consonantal context. It was therefore decided to report the results for the overall rms in addition to the results for rms peak amplitude.

To find the location and size of the amplitude peak, the rms values of a series of overlapping 25 ms windows were calculated whose number varied with the duration of the vowel. The temporal location of the center of the 25 ms window with the highest rms value was defined as the location of the rms peak. The location of the rms peak was expressed as its relative position (with values ranging from 0 to 100%) with regard to the duration of the word.[1]

Formant frequency values and amplitudes of the first four formant peaks based on 14-pole LPC analysis were extracted automatically using a MATLAB program which determined the location of the rms peak. The program displayed these values along with the FFT and LPC spectrum and provided a wideband spectrogram of the entire vowel. No preemphasis was applied. In some cases, the formant frequency values obtained were compared to the formant peaks identified using smoothed FFT spectra and from the wideband spectrograms with formant tracks displayed (using the program TF32, Milenkovic, 2003). Errors in formant estimation in LPC analysis were then hand-corrected. The effects of consonantal context on formant amplitude were assessed by first examining the variation of A1, the strongest formant of each vowel. The decibel values for A1 (and for the higher formants A2, A3, and A4) were measured relative to the reference level of the speech analysis program (written in MATLAB), which is the lowest nonzero instantaneous amplitude that is coded by the A/D conversion. The differences between the amplitude of each higher formant and that of A1 were then analyzed. Because amplitude spectrum varies as a function of vowel category, the amplitude variation of the higher formants became more apparent when reported relative to A1. The (negative) decibel differences reflect the strength of the higher formant relative to A1. Smaller negative decibel difference values here denote a stronger higher formant. Conversely, greater negative decibel difference values imply its relative weakness.

The f_0 of the rms peak window was computed using cepstral analysis (Oppenheimer and Willsky, 1977) and hand-corrected when the method measured the frequency of a higher harmonic.

E. Statistical treatment of the amplitude results

In the HF study, the amplitude measures for each subject were expressed relative to the lowest value for that subject. A primary reason for this expression was to control for individual variation (in vocal characteristics, general amplitude levels, etc.). However, as HF note, the results of their analysis of variance (ANOVA) tests indicated that subject variation had not been "completely obliterated." The current study took the approach of using within-subject (also called repeated-measures) designs for all inferential statistical tests. The advantage of a within-subject design is that idiosyncratic variations among subjects (which is commonly found in phonetic experiments but is of no interest here) can be controlled for. In particular, in within-subject designs the differences among subjects are measured and separated from the error terms in the calculation of the test statistic (e.g., t and F values).

We used within-subject ANOVAs to assess the significance of amplitude variation. For each amplitude-related measure (i.e., location of rms peak, amplitude of rms peak, overall amplitude, and amplitudes of formants) an overall ANOVA was first completed with the within-subject factors vowel and consonantal context. Speaker gender was included as a between-subjects factor. To further explore significant consonant effects for each measure, separate repeated-measures ANOVAs were completed on individual vowels for the factors manner, voicing and place for the /b, p, d, t, v, f, z, s/ set, and for the factors place and voicing for the /b, p, d, t, g, k/ set. In each of these additional analyses, speaker gender was included as a between-subjects factor. For all reported significant main effects and interactions, the degrees of freedom for the F-tests were Greenhouse–Geisser adjusted when there were significant violations of sphericity. In addition to the significance values, a measure of the effect size—partial eta squared is reported (η^2, whose value can range from 0.0 to 1.0, should be considered a measure of the proportion of variance explained by a dependent variable when controlling for other factors). Post hoc analyses were completed using either additional ANOVAs on selected subsets of the data (with appropriate F tests) or Bonferroni-adjusted t-tests.

The results for vowel duration were assessed by within-subject ANOVAs and Bonferroni-adjusted t-tests. f_0 results

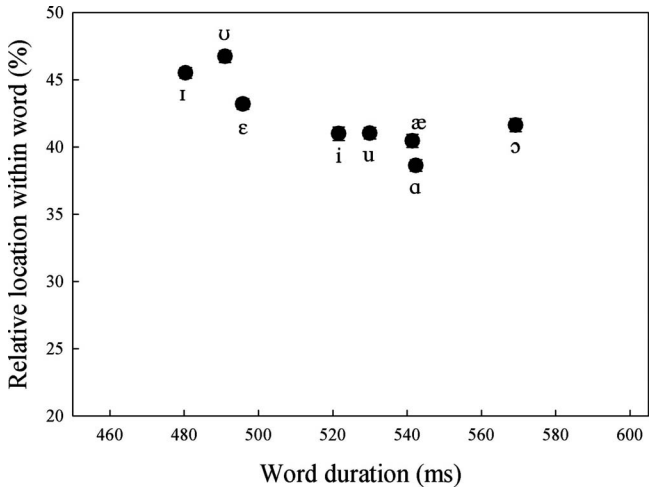

FIG. 1. Mean relative location of rms peak within a word as a function of each word's mean duration averaged across ten consonantal contexts.

were not assessed statistically because they are reported here merely to establish consistency with the HF data for all three secondary cues, including vowel amplitude, vowel duration, and f_0. At present, vowel duration and f_0 do not constitute a focus of the study.

III. RESULTS

A. Amplitude of rms peak and overall rms amplitude

The amplitude of rms peak was measured at its temporal location within the CVC word which varied for individual vowels. Despite the variation, the mean peak values for all vowels were still before vowel midpoint (Fig. 1). In general, the peaks of the short vowels /ɪ, ɛ, ʊ/ occurred later than the peaks of the remaining longer vowels.

The variation in the relative positions of rms peak within word as a function of consonantal context is summarized in Fig. 2. The peaks in the context of stops occurred later than in the context of fricatives and, statistically, the effect of manner was strong $[F(117)=306.16, p<0.001, \eta^2=0.947]$. The peaks were also significantly later in the context of

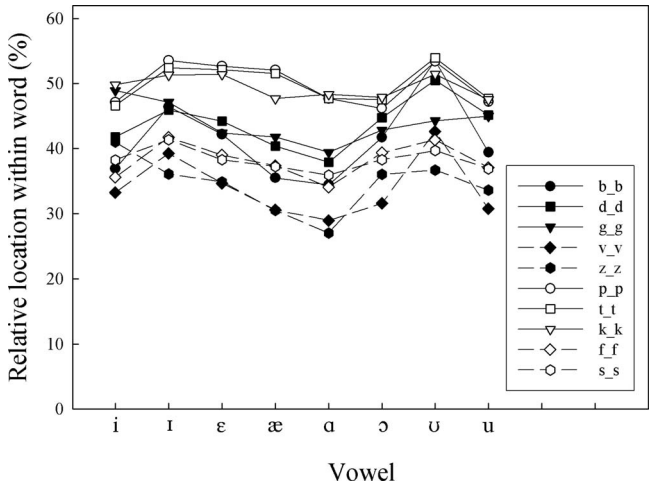

FIG. 2. Mean relative location of rms peak within a word shown for each vowel and for each individual consonantal context.

TABLE II. Mean vowel amplitude at rms peak and overall rms amplitude (in decibels) (s.d.) in consonantal contexts grouped by voicing, manner, and place of articulation. All vowels are pooled.

Grouped consonant environments	rms peak	Overall rms
Voicing		
Voiceless	−15.58 (3.89)	−18.26 (3.76)
Voiced	−15.45 (3.72)	−18.26 (3.62)
Manner of articulation		
Stop	−15.68 (3.79)	−18.28 (3.65)
Fricative	−15.27 (3.83)	−18.22 (3.74)
Place of articulation		
Labial	−15.01 (3.80)	−17.71 (3.69)
Alveolar	−15.79 (3.84)	−18.62 (3.72)
Velar	−15.97 (3.66)	−18.63 (3.50)

voiceless consonants than voiced $[F(1,17)=82.09, p<0.001, \eta^2=0.828]$. The effects of place were more variable and were mostly not significant.

Table II shows, following HF, means for amplitude of rms peak and overall rms amplitude grouped by consonant voicing, manner, and place across all vowels pooled. The mean amplitudes at rms peaks were consistently higher (2.74 dB) than the mean overall rms amplitudes. As is evident, however, neither amplitude values varied appreciably as a function of the consonantal features. This is in sharp contrast to HF results, particularly for voicing and manner.

Figure 3, drawn after HF, shows rms means for individual consonantal contexts (stops and fricatives) across all vowels pooled. Unlike the HF data, there is no sharp division

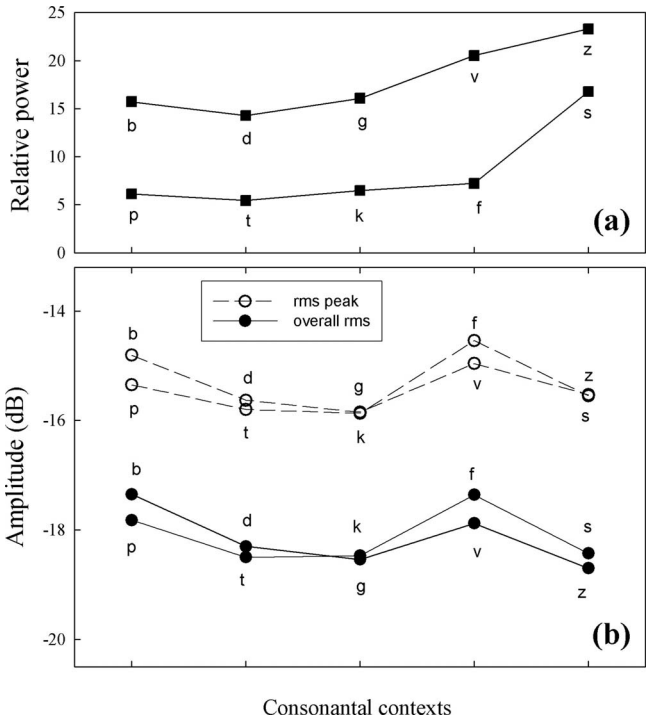

FIG. 3. Consonantal context effects on vowel amplitude pooled across all vowels. (a) Data from House and Fairbanks (1953) for their relative power measure (see the text). (b) Mean amplitudes (in decibels) of rms peak and overall rms in the present study.

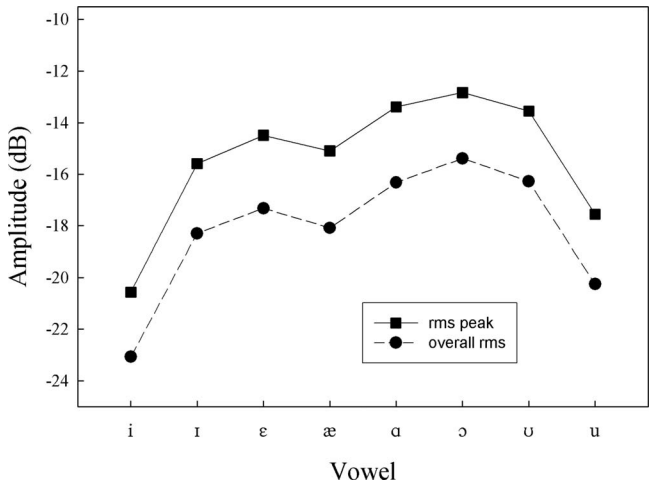

FIG. 4. Mean amplitudes of rms peak and overall rms for individual vowels averaged across all consonantal contexts.

between vowel amplitude in voiced and voiceless contexts. Although the general trends for all stops and the fricatives /v, f/ are consistent with HF, the results for the fricatives /z, s/ differ rather drastically. Unlike the HF results, the amplitudes of vowels in the environments of either /z/ or /s/ were not the greatest in the entire consonant set and did not differ appreciably from those in the context of alveolar stops. As shown in Table II, all amplitude values at rms peaks were about 3 dB higher than were overall rms amplitudes.

The amplitudes of individual vowels averaged across all consonantal contexts are shown in Fig. 4. Consistently with the trend already observed, amplitudes at rms peaks were about 3 dB higher than overall rms amplitudes. Back vowels had higher amplitude than front vowels. At rms peak, the overall mean for back vowels was −14.33 dB as opposed to −16.44 dB for front vowels. For overall rms, the mean values for back and front vowels were −17.06 and −19.19 dB, respectively. There was general regularity in the relationship between the degree of vowel openness and vowel amplitude: The two most closed vowels /i/ and /u/ had the lowest amplitudes while the most open back vowels /ɑ/ and /ɔ/ had the highest. However, the correspondence between greater openness of a vowel and its increased amplitude was less consistent for the remaining vowels. In particular, it was surprising that the amplitudes for both /ɪ/ and /ʊ/ were relatively high and comparable with those for /æ/ and /ɑ/, respectively. Paired two-tailed *t*-tests confirmed these observations, showing that there was no statistical difference in the amplitudes of the vowels /ɪ/ and /æ/ and the vowels /ʊ/ and /ɑ/. The difference was also not significant between /ʊ/ and /ɔ/. The differences for all remaining vowel pairs were significant for both rms peak and overall rms amplitude.

It may be recalled that the vowels /æ/ and /ɑ/ were drastically low in relative power in the HF study, approximating the relative power of the vowel /i/. Although various explanations for this unexpected outcome were offered, HF admitted that "a confident explanation of the atypical finding for

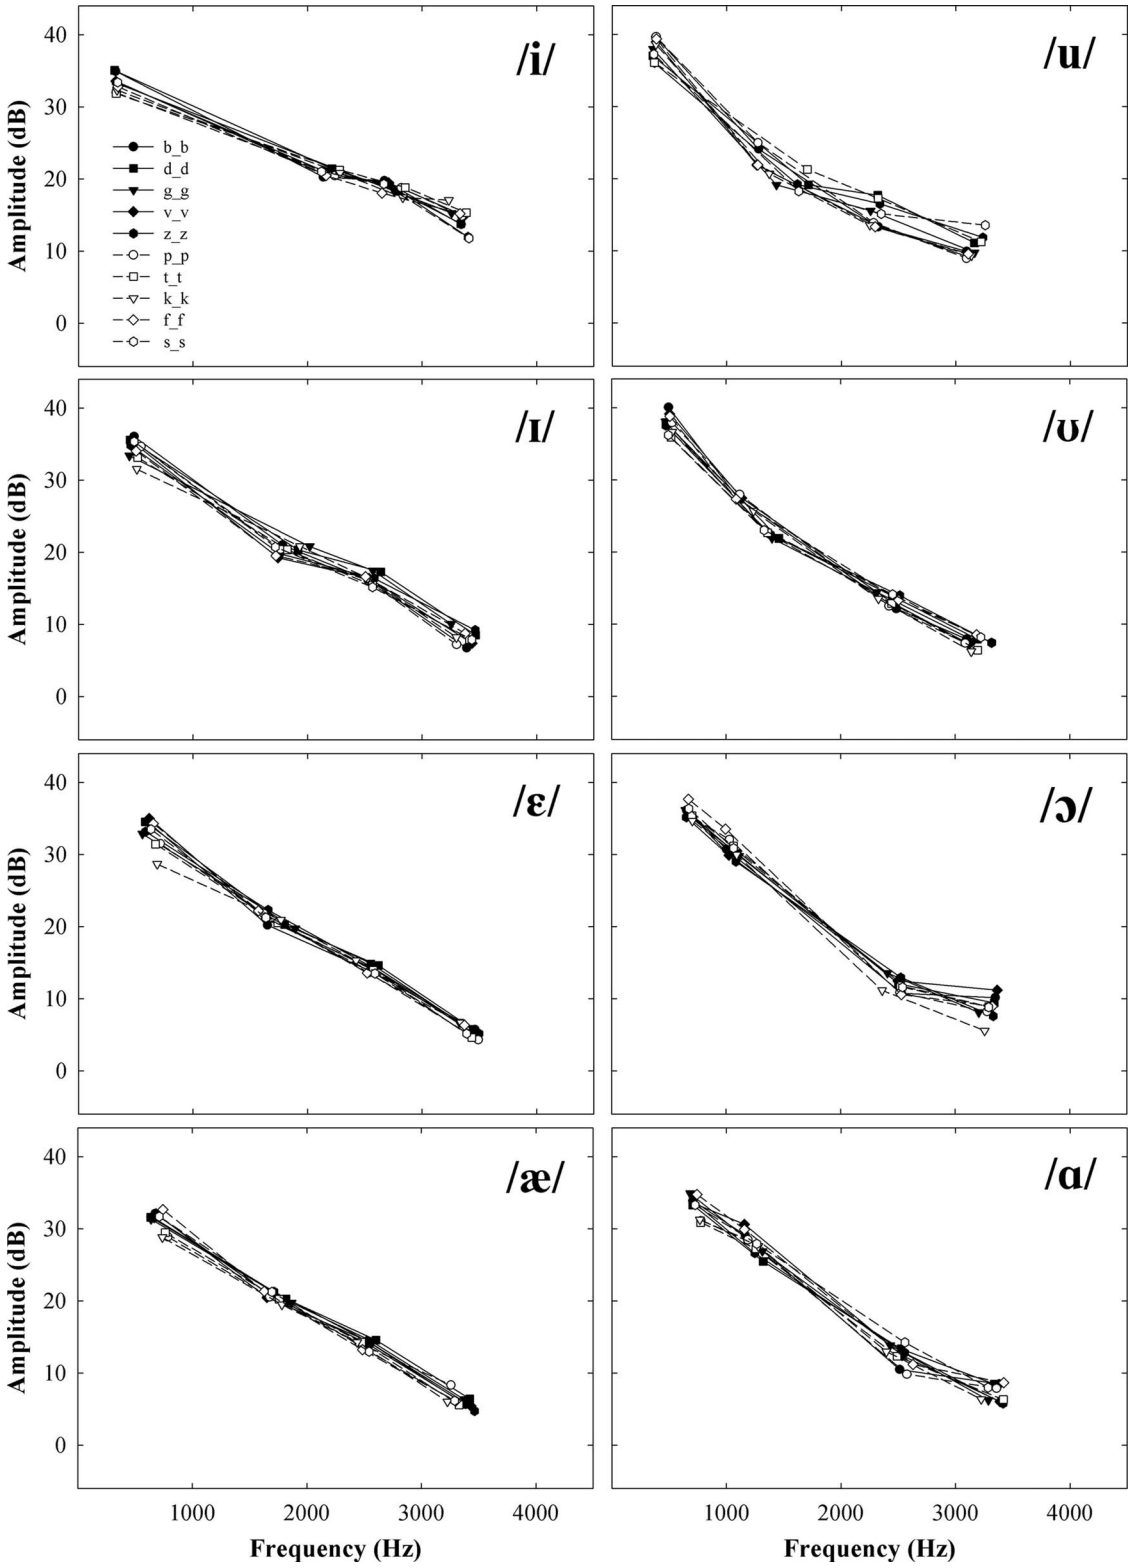

FIG. 5. Frequency and amplitude of formants 1–4 for individual vowels in ten consonantal contexts averaged for male speakers.

relative power cannot be advanced" (p. 112). The present results did not replicate this finding and did not provide any additional explanation for such atypically low amplitude values. However, in the current study, the amplitudes of these two vowels were not different from those for /ɪ/ and /ʊ/ within each front and back series, indicating that the greatest degree of opening may not automatically imply highest vowel amplitude.

Considering the consonantal context effects of voicing, manner, and place on amplitudes of individual vowels, the amplitude values did not differ greatly as a function of either voicing or manner. However, notable variation was found for consonant place: All vowels had higher amplitudes in the context of labials. The statistical assessments of the consonantal context effects are summarized in Table III. Table III lists the significant main effects only because significant in-

teractions were sparse and did not contribute greatly to the interpretation of the results. The main effect of voicing reached significance only for selected vowels (see Table III), and amplitude values were usually higher in the context of voiced stops. The main effect of manner was significant for the vowels /ɛ, æ, ɑ/ at rms peak. In each case, the peaks were higher in the context of fricatives. This tendency was consistent with HF results although decibel differences in the present data were much smaller, ranging from 0.5 to 0.7 dB, as compared to their relative power values. The effect of manner for the overall rms amplitude, however, produced greater amplitude in the context of stops. Overall, these results suggest that, generally, vowel amplitude does not change drastically as a function of either voicing or manner of articulation of the surrounding consonants.

To the contrary, the main effect of place was significant for all vowels except for /i/ for the stops-only analysis. Uniformly, the rms peaks were higher in the context of labial consonants as opposed to alveolar. The size of the place effects were greater too, with η^2 values ranging from 0.311 to 0.839. However, no consistent trend was found with respect to the alveolar and velar contexts (see Table III). The effects for the overall rms amplitude generally paralleled those at rms peak. The effect size of place was even stronger for the overall rms as evident from higher η^2 values listed in Table III. As a whole, the results for place do not match HF results, however, where vowels were greatest in relative power in the context of alveolars.

The main effect of gender was significant only for the vowel /i/ for both rms peak and overall rms, showing that male vowels had significantly higher amplitudes than female vowels. Given the relatively large degrees of freedom involved in the analyses, several interaction effects with gender as a factor were significant but had extremely low effect sizes ($\eta^2 < 0.10$), suggesting relatively unimportant (and, perhaps, even spurious) effects. They are not discussed here.

B. Relative amplitude of vowel formants

To get an overall picture of spectral variation for the present vowels in terms of both consonantal context and speaker gender, the mean frequency and amplitude values for the first four formants for each vowel in all ten consonantal contexts were plotted separately for males in Fig. 5 and for females in Fig. 6. As can be seen, consonantal context variously affected the amplitudes of individual formants and individual vowels. Frequency shifts are also detectable. Of particular note are the generally high F2 values for the vowel /u/ for both males and females which were additionally fronted in the context of alveolars. This is an outcome of regional variation in the vowel system of American English. The majority of the speakers for this study grew up in Ohio, where the variant of /u/ is significantly fronted. More acoustic evidence for the variation of F2 in the vowel /u/ as a function of speaker dialect can be found in Jacewicz *et al.* (2007a).

Figure 7 shows the mean differences between A2 and A1 (RelA2), A3 and A1 (RelA3), and A4 and A1 (RelA4) for each individual vowel and for each consonantal context. Because the first ANOVA showed that speaker gender was not significant for measure RelA2, RelA3, or RelA4, the display in Fig. 7 reflects amplitude values taken from Figs. 5 and 6 collapsed across speaker gender. As can be seen, mean RelA2 values remained rather steady for each front vowel (about −10 dB) whereas they were more variable for back vowels. In particular, they tended to increase with vowel openness, so that RelA2 for /u/ was about −18 dB and for /ɔ, ɑ/ was −5 dB. The variation as a function of consonantal context was quite extensive for most vowels although it was smaller for /u, ɑ/ and only minimal for /i, ɔ/.

Mean RelA3 values, although lower in general, tended to be higher for front vowels than for back (about −15 and −20 dB and lower, respectively). For back vowels, they were clearly the lowest for the vowel /ɔ/. The context-related variation was again evident for most vowels with the exception of /i, ɔ, ɑ/. The means for RelA4 again showed a sizeable variation as a function of consonantal context for some of the vowels.

The formant amplitude differences (RelA2, RelA3, and RelA4) were examined using separate ANOVAs which, for each vowel, assessed the effects of manner, voicing, and place separately for stops and fricatives sharing the same place of articulation (/b, d, p, t, v, z, f, s/) and for stops only differing in voicing and place (/b, d, g, p, t, k/) with gender as a between-subject factor. In the whole series of ANOVAs, the effect of speaker gender was significant only for the vowel /æ/ for RelA2 [$F(1,18)=6.65$, $p=0.019$, $\eta^2=0.270$] and RelA3 [$F(1,18)=7.76$, $p=0.012$, $\eta^2=0.301$] for the stops and fricatives analysis and for RelA2 [$F(1,18)=5.46$, $p=0.031$, $\eta^2=0.233$], RelA3 [$F(1,18)=8.97$, $p=0.008$, $\eta^2=0.333$], and RelA4 [$F(1,18)=4.77$, $p=0.042$, $\eta^2=0.210$] for the stops-only analysis, in each case indicating smaller decibel difference values for males. We therefore have chosen to exclude speaker gender as a factor for further consideration.

1. Variation of A1

In a separate analysis, we examined the variation of A1 as a function of consonantal context which is summarized in Fig. 8 for both male and female speakers.

The overall mean A1 values for male speakers were about 3 dB higher as compared to females (35 vs 32 dB). This relation was found in most vowels except for /i/ and /ʊ/ where the differences were greater (about 5 dB) and for /æ/, where mean male A1 was only 1 dB higher. As Fig. 8 shows, the variation as a function of consonantal context is particularly great for the vowels /ɪ, u/ for females and for /ɪ, ɛ/ for males.

We used separate ANOVAs with the within-subject factors manner, voicing, place, and gender as a between-subject factor to determine the significance of the A1 variations. A summary of significant effects is shown in Table IV.

The amplitude of A1, the strongest peak of a vowel, was affected by consonantal context to a relatively large extent. As can be seen, voicing had a significant effect on a number of vowels and was particularly strong for the short vowels /ɪ, ɛ, ʊ/. Unlike for the higher formants, all A1 peaks were higher in the context of voiced consonants and not voiceless. There were also significant effects of manner for three vow-

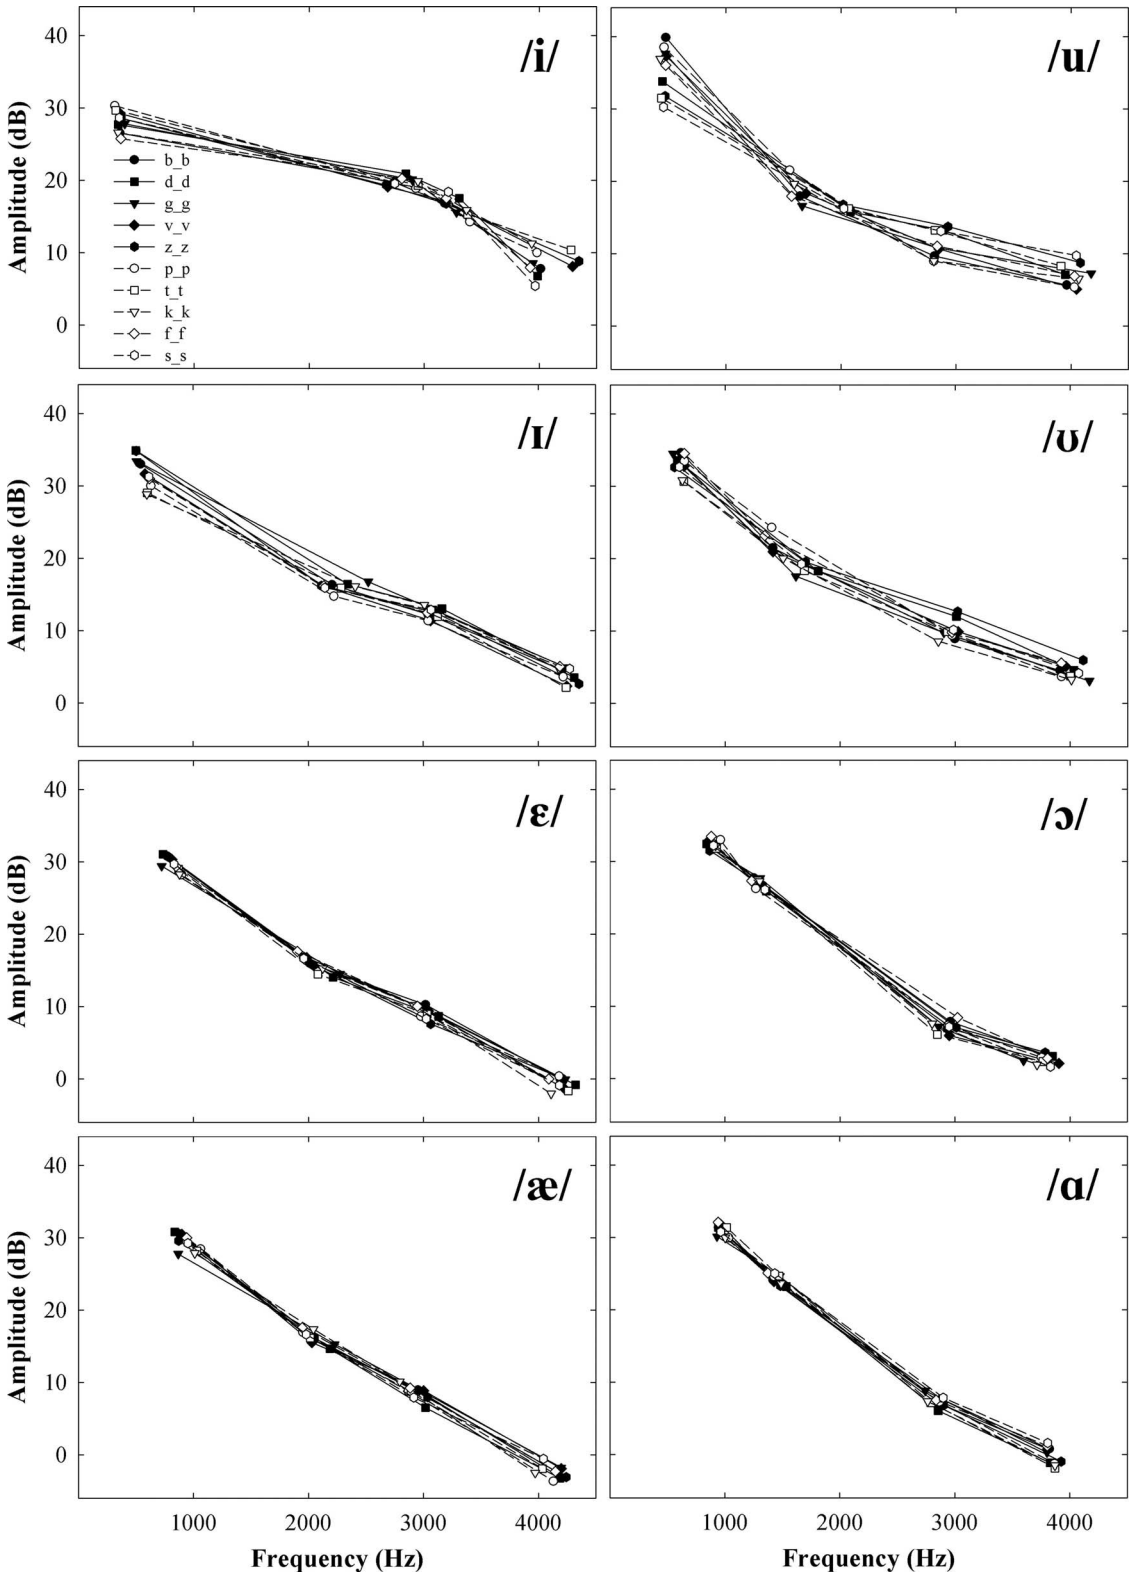

FIG. 6. Frequency and amplitude of formants 1–4 for individual vowels in ten consonantal contexts averaged for female speakers.

els /ɛ, æ, ɑ/, showing that A1 peaks were about 0.6–1.0 dB higher in the context of fricatives as opposed to stops. Place was significant for /ʊ, u/ for fricatives and stops, indicating that A1 in the context of labials was higher than in alveolars. For /u/, this effect was particularly strong (η^2=0.642) and A1 peaks were 4.4 dB higher. For the stops-only analysis, the results were variable. In general, the peaks in labial and alveolar contexts were higher as compared to velars. There were significant effects of gender for four vowels /i, ɛ, ɔ, ʊ/. In each case, A1 values for male speakers were higher than for female. One significant interaction deserves a mention here because it involved most of the vowels and showed a

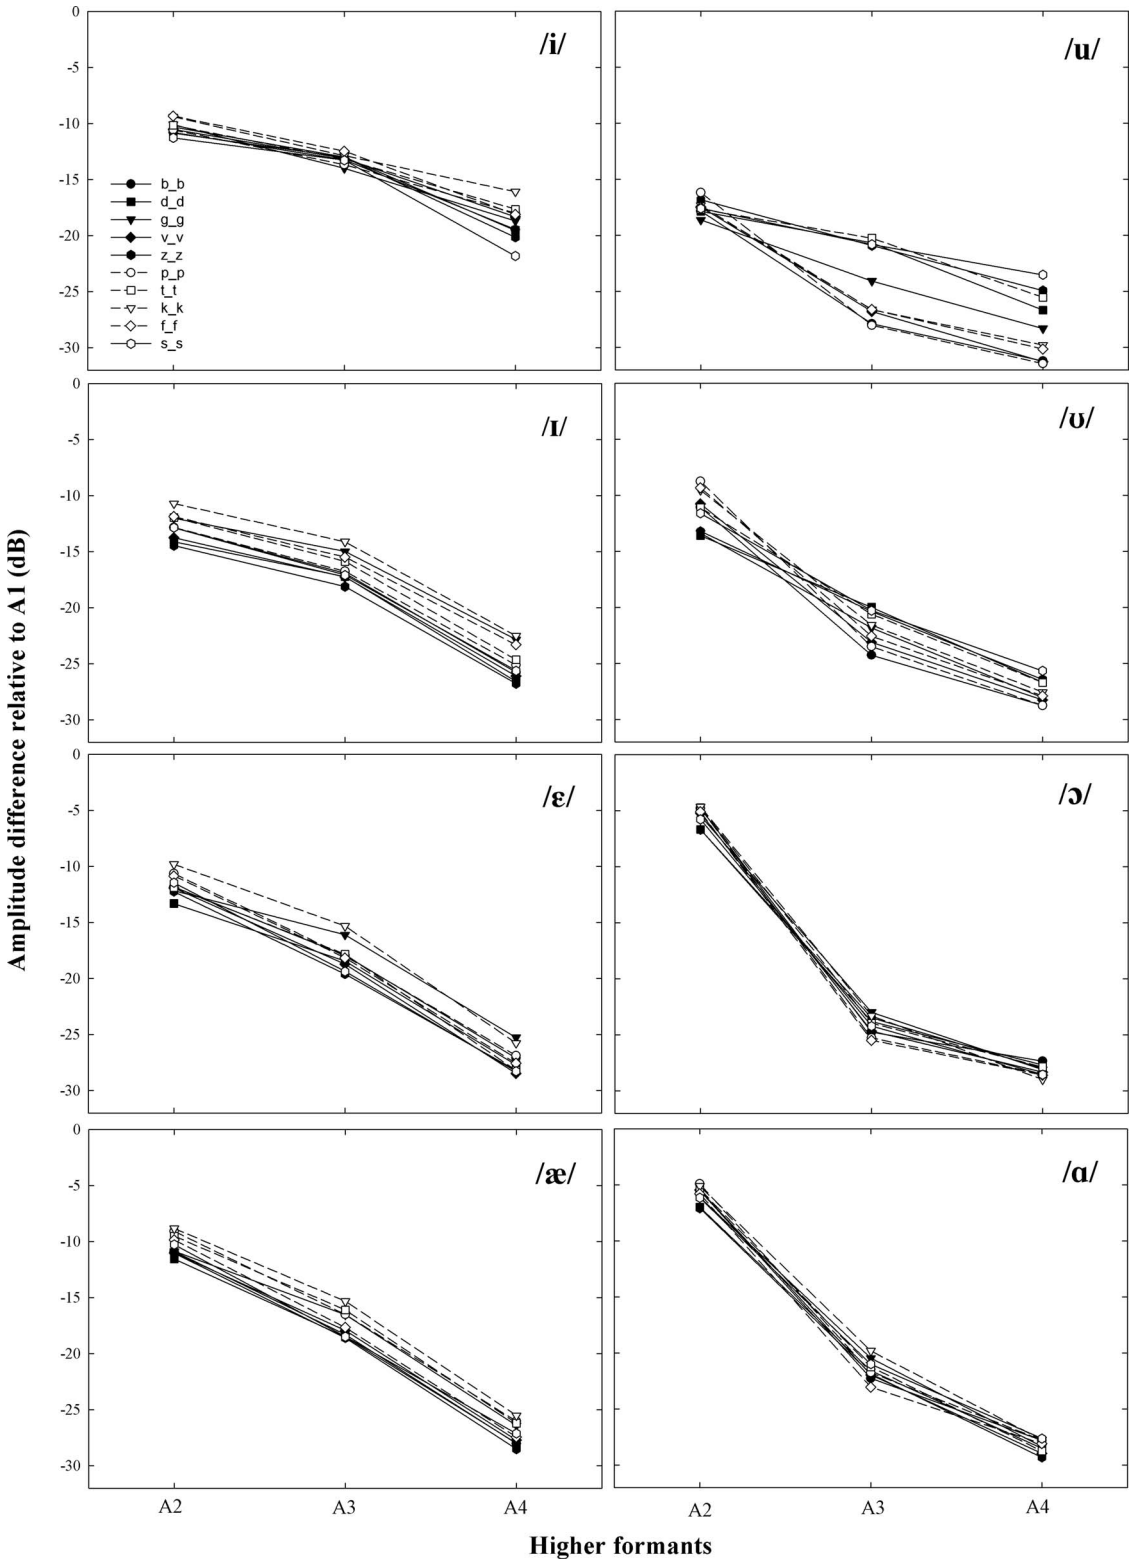

FIG. 7. Amplitude differences for each higher formant (A2, A3, A4) relative to A1 for individual vowels in ten consonantal contexts averaged across speaker gender.

consistent, relatively strong effect. The significant manner × voicing interaction arose from the fact that, for each affected vowel, the decibel difference between the higher A1 peak for voiced stops and the weaker A1 peak for voiceless stops was significantly greater (ranging from 2.18 to 2.88 dB) than the decibel difference between the A1 peaks for voiced and voiceless fricatives (ranging from −0.08 to 1.02 dB).

2. Results for RelA2, RelA3, and RelA4

Table V summarizes the statistical results for amplitude variations of the A2 and A3 relative to A1, i.e., RelA2 and RelA3. As can be seen, significant contextual effects were evident for all vowels except for /i/ and /ɔ/ for RelA2 and for /i, ɔ, ɑ/ for RelA3 analysis. In particular, the effect of voicing

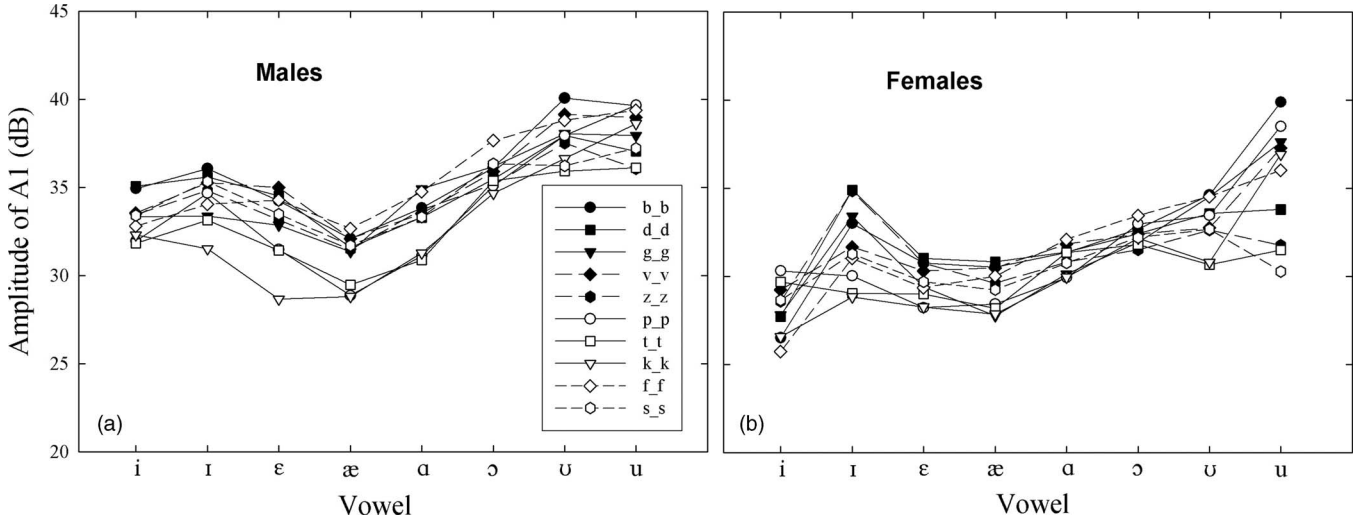

FIG. 8. Variation in the amplitude of the first formant (A1) for individual vowels in ten consonantal contexts averaged for male speakers (a) and for female speakers (b).

showed that the negative decibel differences were significantly smaller (about 2 to 3 dB) in the context of voiceless consonants as opposed to voiced, indicating that A2 was higher when surrounded by voiceless consonants. Consonant place introduced more variable results and affected primarily vowels in the context of stops. For front vowels, post-hoc analyses for stops revealed that decibel differences for both RelA2 and RelA3 were smallest in the context of velars, although this was not true for back vowels (compare Table V). The main effect of manner was not significant for any of the vowels. Significant interactions were sparse in the entire set and their small effects did not warrant a separate discussion.

While not necessarily related to consonantal context effects, visual inspection of Fig. 7 suggested that it was worthwhile to compare RelA3 values for front and back vowels. Across all contexts, these values tended to be smaller for front vowels than for back, indicating relatively stronger F3 peaks in front vowels. Results from a series of *t*-tests for RelA3 completed for all pairwise comparisons between vowels collapsed across all consonantal contexts confirmed these observations. There were no significant differences among the back vowels /u, ʊ, ɔ, ɑ/ except for /ɔ/ and /ɑ/ [$t(12) = -2.85$, $p = 0.015$]. For the front vowels, the differences among /ɪ, ɛ, æ/ were not significant. However, all pairwise comparisons with /i/ were significant, indicating that F3 for the vowel /i/ was significantly stronger than F3s for the remaining front vowels. No such consistency was found for all paired RelA2 and RelA4 comparisons, indicating that it is the relative amplitude of the third formant that most clearly marks the differences in spectral tilt between the front and back vowels.

The context effects for RelA4 were comparatively smaller as shown in Table VI. The two high vowels /i, u/ were affected the most. Interestingly, place effects were different for each vowel. For /i/, the decibel difference was 1.3 dB smaller for the labial contexts as opposed to alveolar. The effect of place was particularly strong for the vowel /u/. For the stops and fricatives analysis, RelA4 was 7.5 dB higher in the context of alveolars as opposed to labials and the same tendency was also found for the stops-only analysis. Significant effects of place were also found for /ʊ/. For stops-only analyses, place was significant for /ɪ, ɛ, æ/ and the decibel differences were smallest in the context of velars, and for /u/, where the smallest decibel difference occurred in the context of alveolars. The effect of manner was significant for /u/ and /ɔ/, although showing opposite effects in that the decibel differences were smaller in the context of fricatives for /u/ (2.2 dB) and in the context of stops for /ɔ/ (1.4 dB). Voicing was significant for two vowels only, for /ɪ/ for fricatives and stops, and for /i/ for the stops-only analysis. In each case, the differences were about 2.5 dB smaller in the voiceless contexts as opposed to voiced.

Summarizing the results for formant amplitude, the consonantal context effects varied with vowel category and with a particular formant. For example, almost no significant effects were found for the vowel /ɔ/ across all three measures whereas numerous effects and interactions occurred for the short vowels /ɪ, ɛ, ʊ/. Similarly, there were no context effects for the vowel /i/ for RelA2 whereas they were abundant for

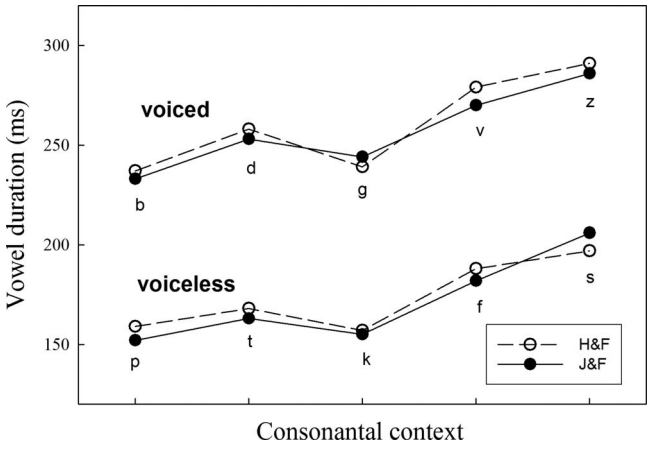

FIG. 9. Consonantal context effects on vowel duration pooled across all vowels. The present results, marked as JF, are compared with the data from House and Fairbanks (1953), marked as HF.

RelA4. Conversely, context affected RelA2 for /ɑ/ but not RelA3 or RelA4. Turning to the significant effects of consonantal features on formant amplitude variation, manner of articulation had almost no influence on amplitude changes except for a few interactions and main effects for RelA4. Both voicing and place affected formant amplitude variation to a much greater extent, as evident in a greater number of significant main effects. The effects of voicing were very consistent, showing uniformly that the formant peaks were higher in the voiceless contexts as opposed to voiced. Consonant voicing affected the greatest number of vowels and formants. The effects of place were more variable, although formant peaks tended to be higher in the context of labials as compared to alveolars. For stops only, the peaks were highest in the context of velars for front vowels whereas more variability was found in back vowels. Overall, there were more significant context-related main effects and interactions for front vowels (32) than for back (20).

C. Vowel duration

Although vowel duration was not of central interest to the study, this measure can be informative in light of the differences in amplitude results obtained between the HF study and the present report. Specifically, could differences in the articulation rates between the speakers in the two studies account for some of the discrepancies?

Table VII lists the duration values as a function of consonant environment grouped by voicing, manner, and place of articulation for all vowels pooled separately for males and females. With regard to the male data, the consistency with HF is remarkable given that only four vowels studied by HF were included in the present set.[2] The match is almost perfect despite the apparent differences in the way the material was recorded, i.e., as isolated disyllabic words in HF and as monosyllables in a short phrase in the present study. As might be expected, durations of female vowels were longer as compared to males (e.g., Adank *et al.*, 2007; Jacewicz *et al.*, 2007b).

Following HF, Fig. 9 displays mean durations for each individual consonantal context across all vowels pooled. Since the present focus was to compare the duration material with HF data,[3] only duration values from male speakers were included in Fig. 9. Again, the obtained pattern agrees remarkably with that found in HF. These results suggest that the articulation rates for the speakers in both the HF study and the present report were very similar.

As might be expected, the most robust duration differ-

TABLE VIII. Mean durations of individual vowels (in milliseconds) (s.d.) shown for voiced (Vd_Vd) and voiceless (Vl_Vl) environments and for all consonantal contexts pooled. Shown are also mean f_0 values (in hertz) (s.d.) for vowels for all consonantal contexts pooled.

Vowel	Duration Vd_Vd males	Duration Vl_Vl males	Duration Vd_Vd females	Duration Vl_Vl females	f_0 males	f_0 females
/ɪ/	204 (42)	125 (30)	250 (45)	142 (44)	138 (17)	217 (20)
/ʊ/	221 (43)	136 (35)	253 (42)	163 (47)	138 (16)	220 (23)
/ɛ/	225 (47)	153 (43)	277 (53)	172 (55)	131 (14)	213 (18)
/i/	257 (57)	173 (54)	305 (53)	205 (74)	145 (17)	237 (25)
/u/	267 (60)	166 (36)	309 (58)	209 (59)	144 (16)	235 (24)
/ɑ/	287 (70)	198 (56)	342 (58)	234 (68)	125 (14)	212 (19)
/ɔ/	300 (68)	211 (67)	374 (57)	246 (88)	129 (15)	207 (19)
/æ/	305 (66)	217 (62)	352 (63)	242 (69)	127 (15)	210 (18)

ences among the vowels came from the effects of consonant voicing. Table VIII lists durations of individual vowels (in ascending order) for male and female speakers, showing that vowels in the context of voiced consonants were longer than in the voiceless contexts. Also significantly longer vowels (18% longer) were produced by females [$F(1,10)=6.17$, $p=0.032$, $\eta^2=0.382$]. The main effect of consonant voicing was strong [$F(1,10)=134.7$, $p<0.001$, $\eta^2=0.931$] and the differences were very consistent within each gender group. On average, vowels in the context of voiced consonants produced by males were 36% longer than vowels in the voiceless contexts whereas the difference for female speakers was 37%. Comparing the present results with more recent published data, we found consistency with vowel duration material in Hillenbrand *et al.* (2001).

Considering the durations of individual vowels, the results for the voiced contexts were less variable than for the voiceless. In particular, paired two-tailed *t*-tests showed that there were no significant differences between /ɔ/ and /æ/ or between /æ/ and /ɑ/—the longest vowels or between the vowels /i/ and /u/—vowels of intermediate length. There were also no significant differences between /ɪ/ and /ʊ/ nor /ɛ/ and /ʊ/ —short vowels. All other differences were significant.

D. Variation in f_0

Although f_0 measure was also not of central interest to this study, the present f_0 values were compared with the results of HF for consistency. Following HF, f_0 values at the rms peak averaged across all vowels were plotted for each of the ten individual consonantal contexts (the plots are not included here). Although the present f_0 values for males were slightly higher than those in HF (on the order of 9%), the general trends were strikingly similar. Most important, f_0's of vowels in voiceless contexts were higher than those in voiced ones. As in HF, the difference in f_0 values as a function of voicing of the surrounding consonants tended to be greater for stops than for fricatives. These results match rather closely the f_0 material presented in HF. f_0 values for individual vowels averaged across all consonantal contexts and split by speaker gender are listed in Table VIII. The general tendency reflects the widely observed phenomenon that high vowels have higher intrinsic f_0 than low vowels (e.g., Whalen and Levitt, 1995).

IV. GENERAL DISCUSSION

The aim of this study was to characterize the nature, size, and range of acoustic amplitude variation in coarticulated vowels. Expecting large variation based on the findings in the House and Fairbanks (1953) study, we examined the changes to the amplitudes of the rms peak and the overall rms amplitude as a function of the consonantal features voicing, manner, and place. Contrary to the HF results, we found no systematic changes in vowel amplitude as a function of either consonant voicing or manner.

Both the present study and HF found significant effects of consonant place of articulation. However, although the small size of the amplitude variation was comparable, the directions of the effects for the place distinction differed. In particular, vowels in the context of alveolars were greater in relative power than labials in the HF data whereas the present results show the opposite: Both rms peak and overall rms amplitude were higher in the context of labials and not alveolars. In a similar fashion, vowels in the context of velars were lesser in relative power than in the context of alveolars in the HF study whereas no difference was found for these two contexts in the present study. On the whole, the present results show that consonantal context of a vowel does not introduce sizeable acoustic variation in vowel amplitude for either rms peak measure or overall rms amplitude.

A. Accounting for the discrepancy between the two sets of results

In attempting to explain the discrepancy between the central results of the HF study and the present results, we first considered the differences in the experimental protocol. Since the speech material in HF consisted of isolated words and the present stimuli were recorded in a short phrase, the possible differences in the articulation rate were a primary candidate for accounting for the discrepancy. As it turned out, the durations of vowels in the consonantal contexts in HF and in the present study were almost identical, indicating that the discrepancy was not due to a more formal or more casual speaking mode used in the recordings of the two sets of stimuli. We then turned to the equipment used in both studies and, although some slight incompatibilities might have been expected due to the analog and digital recordings, we considered each experimental setup to be adequate for the experimental purpose it served. The third possibility was in the way the acoustic measurements were made then and now. As will be shown in the following, the differences between the results of the two studies can probably be explained, at least to a great extent, by the different measurement techniques used.

Perhaps the greatest single discrepancy between the HF results and those presented here involves the voicing difference. In particular, HF's measurements indicated that vowels produced in the context of voiced consonants had twice the relative power of vowels produced in the context of voiceless consonants. One possible explanation for the difference lies in suggesting that the HF vowel measurements included some portion of the consonantal context, especially for voiceless consonants. In particular, we must assume that there was an integration window associated with their apparatus and associated measurement of intensity. If this window was large enough, then it might also have included a portion of the voiceless consonant context (syllable-initial, syllable-final, or both) since vowels produced in a voiceless context are significantly shorter than those in a voiced context. This account would explain many of the consonant context differences in relative power seen in HF (see their Fig. 3).

For example, we could expect that the voiced stops would show greater relative power than voiceless stops because the relative power measures for the vowels in a voiceless context would include portions of the voiceless stop itself. We would also expect vowels in the context of /s/ to

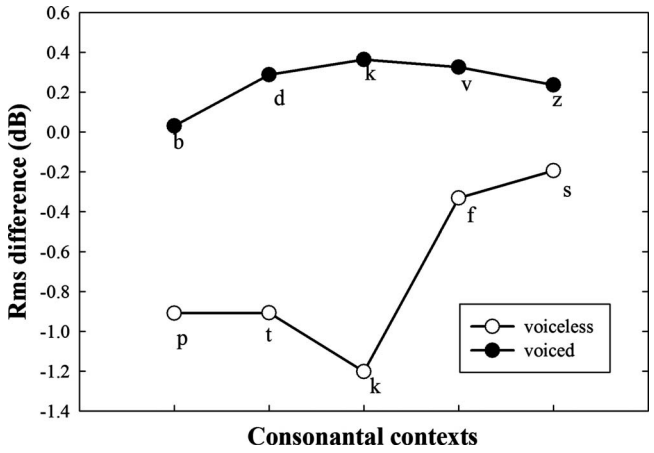

FIG. 10. Mean differences between overall rms (calculated from vowel onset to offset) and the rms from a 200 ms section of the utterance centered on the vowel across the ten consonantal contexts. Data are collapsed across two speakers and eight vowels.

show greater relative power than in the context of /f/ (since the relative power of the /s/ consonant, a portion of which is included in calculation of the vowel's power, is greater than that of the /f/). In turn, we would expect vowels in the context of /f/ to be slightly greater in relative power than when they occur in the context of /p, t, k/. This approach would thus also account for some of the differences between HF and the current study related to consonant manner. These patterns of consonantal feature differences were not found in the present study simply because our method only measured that portion of the speech signal that corresponded to the vowel.

As a test to determine whether this explanation is, in fact, plausible, the recordings from two speakers (one male, one female) were randomly selected and the rms of their vowels were analyzed in two separate ways. First, the rms of the target vowel, alone, was measured (this corresponded to the overall rms measure). Next, the rms of a 200-ms-long section of each utterance—centered on the midpoint of the target vowel—was measured. This 200 ms section of the utterance included portions of the initial and final consonants (which would lower the rms when the vowel was relatively short). Finally, the difference between the overall rms and the rms of the 200 ms section for each token was calculated. Shown in Fig. 10 are the mean rms differences collapsed across both speakers and all eight vowels. The pattern of the consonant context differences (between the voiced and voiceless contexts, and between the /p, t, k/ and /f, s/ context) shown in Fig. 10 bear a striking resemblance to HF (Fig. 3) suggesting the viability of this explanation for the obtained discrepancies.

B. Consonantal context effects on formant amplitude variation

Turning to the present results, we explored the possibility that significant context-related amplitude variations may affect specific spectral regions in a vowel (such as individual formants) rather than its overall energy. The changes in the amplitude of vowel formants were first examined by measuring amplitude of each higher formant relative to each vowel's strongest spectral peak, i.e., the amplitude of F1. This analysis revealed several systematic effects for each formant.

For F2, variation in A2 relative to A1 (RelA2) was significant for all vowels except for /i/ and /ɔ/. RelA2 was affected primarily by consonant voicing and place. For each vowel, the RelA2 values were uniformly smaller in the context of voiceless consonants as opposed to voiced, and they were variably affected by consonantal place. The variation ranged from 0.8 to 3.8 dB.

For F3, the RelA3 values did not vary greatly for the analysis involving labial and alveolar stops and fricatives. A large difference of 7.7 dB was found for the vowel /u/ as a function of place. However, more significant effects were found for the stops-only analysis. The RelA3 values were again smaller in the context of voiceless stops as opposed to voiced and the effects of place were variable. In general, the RelA3 variation was of the range 1.5–3.3 dB. The vowels /i, ɔ, ɑ/ remained unaffected by consonantal context. However, the place effects for the vowel /u/ were very strong. For this vowel, the decibel differences produced by context were large: 6.7 dB between alveolars and velars, and 8.7 dB between alveolars and labials. The consonant place effects for the vowel /u/ were thus the strongest in the entire set of vowels studied here. A3 peaks in the context of alveolars were higher than in the context of labials.

Finally, variation in the amplitude of F4, typically the weakest formant of a vowel, turned out significant for several vowels. Interestingly, the effects of place and voicing were significant for RelA4 for the vowel /i/ (1.3–2.6 dB) which otherwise was unaffected by contextual variation. The place effects for /u/ were again strong, reaching 7.5 dB difference for alveolars as opposed to labials for the contexts of stops and fricatives. For the stops-only analysis, A4 was 4.4 dB higher for alveolars as compared to velars and 7.3 dB higher in comparison with labials.

For the amplitude of F1 (A1), there was a significant effect of consonant voicing. A1 peaks had greater amplitude (ranging from 1.0 to 3.2 dB) in the voiced contexts than in the voiceless contexts. This was different from the patterns for the higher formants suggesting that A1 may be affected by other source characteristics. The results for place lead to the same conclusion. Although the amplitudes of higher formants were uniformly greater in the context of alveolars, A1 values were mostly greater in the context of labials. This was true for high vowels /u, ʊ, ɪ/ whose F1 frequency is low. For the vowels /ɛ, æ/ however, whose F1 frequencies are higher, A1 values were greater in the context of alveolars. This result was significant for the stops-only analysis. For the stop and fricatives analysis, the effect of place was not significant for these vowels.

C. Context-induced variation in relation to "basic rules of formant amplitude"

The observed amplitude variations as a function of consonantal context need to be situated within a well-established theoretical frame which lets us anticipate a substantial proportion of the effects found here. As Fant (1956) first noted,

formant frequencies and formant amplitudes are "intimately related" to the extent that two vowels differing in the frequency of F1 must also differ in the overall amplitude. This relation is carried over to the higher formants. Stevens 1998, (pp. 133–135) illustrates the three general rules of formant amplitude as stemming from the principles of linear resonances in series. All three rules are well represented in the present set of results, as shown in Figs. 4–6. In particular, the greater overall rms of back vowels as compared to front was due to the greater amplitude of F1 in back vowels. This can be accounted for by the first rule, which expresses the relation between the greater amplitude of F1 or higher frequency of F1 and the increased overall amplitude. Also, consistent with the first rule, the overall rms of the vowels increased as F1 rose in frequency. Although the overall rms of the vowels /æ, ɑ/ was slightly smaller than /ɛ, ɔ/ despite their higher F1 frequencies, this effect can be accounted for by the fact that the amplitude of F1 was on average about 2 dB greater for /ɛ, ɔ/ than for /æ, ɑ/.

A clear manifestation of the second rule, which states that increasing a particular formant frequency raises the amplitude of the spectrum at frequencies above that formant, can be found in front vowels. In the present set, the amplitude of F3 rose as a result of the increase in the frequency of F2 for the front series. This rule also explains the greater A3 for the vowel /u/ whose frequency of F2 rises in its variant spoken in Ohio. Finally, there is also an indication of the appearance of the third rule in the present set, which points to an increase in the amplitude spectrum in the vicinity of two or more formants coming close together. The increased amplitude of F2 in /ɔ, ɑ/ and of the F2–F3–F4 cluster in /i/ can be interpreted in light of the third rule.

The consonantal context effects on variation in formant amplitude observed in this study cannot be interpreted without reference to this pattern of expected changes to the amplitude spectrum. For example, consonant voicing did affect the amplitude of F1 but, apparently, the effect was not strong enough to influence the overall vowel amplitude and the first rule failed to apply. However, the context-induced variation in the frequency of a higher formant could in principle introduce changes to the amplitude spectrum at frequencies above that formant. The consonantal context effects on the vowel /u/ are the most illustrative example in the present set, where operation of the second and third rules cannot be excluded.

D. The role of formant amplitude variation in vowel perception

The size of variation in the amplitude of each higher formant observed here leads to the question of how relevant are these changes to the perception of vowel quality. In particular, one would not necessarily expect a vowel category change as a function of amplitude variation related to the place of articulation or voicing of consonants surrounding the vowel. In the typical speech perception paradigm involving isolated synthetic stimuli, the experiments demonstrated that adjustments made to formant amplitudes can change the perceived vowel quality (e.g., Miller, 1953; Lindqvist and Pauli, 1968; Carlson *et al.*, 1970; Ainsworth and Millar, 1972) and that a 8 dB change in the amplitude of A3 can be sufficient for the listener to perceive a different vowel category (Aaltonen, 1985). A much smaller difference limen was reported by Flanagan (1957) in a discrimination task, in which the 50%-crossover point for F2 of the vowel /æ/ was reached when the amplitude of this formant increased by 3 dB. Furthermore, listeners were shown to be equally sensitive to amplitude adjustments in F4 and in F2 for /ɪ/ and again, a 8 dB change caused a vowel category shift (Jacewicz, 2005).

These reports point to the potential role of variation in formant amplitudes in vowel perception. However, the variation ranging from 0.8 to 3.8 dB which was found in naturally produced vowels in this study is less likely to introduce a vowel quality change. After all, listeners do not depend on formant amplitude relations in making vowel quality distinctions to the extent that they rely on formant frequency pattern. Yet, the large 8.7 dB difference for the vowel /u/ produced by coarticulatory context as reported here has a great potential to affect the perception of vowel quality. In most cases, however, the sensitivity to formant amplitude variations may reflect listeners' experience with more subtle spectral changes which may contribute to the perceived vowel naturalness or timbre differences rather than vowel quality per se.

E. Consonantal context effects on amplitude spectrum at the auditory periphery

Before any expectations about the relevance of formant amplitude variation to vowel perception can be advanced, it is important to know whether such variation is still present in the auditory representation of the speech signal, at least at the auditory periphery. To estimate how the spectral amplitude variation may be encoded and represented at early stages of processing by the peripheral auditory system, we used the first level of the Perceptual Auditory Spectral Centroid model (Anantharaman, 1998) which simulates the peripheral processing through three psychoacoustically motivated stages corresponding to the middle-ear transduction, the filtering mechanism exhibited by basilar membrane, and hair cell activity transmitted in the auditory nerve which contributes to the sensation of loudness. Auditory spectra were calculated by passing the vowel spectra (as a positive time-frequency representation of the vowel signal) through the three stages of peripheral auditory processing: (1) equal-loudness preemphasis curve (provides a weighting along the frequency axis), (2) auditory filter bank (passes the output of the previous stage through 33 gammatone filters centered at each bin of the fft, center frequencies in ERBs), and (3) intensity-loudness compression (raises the output of the previous stage to the 0.3 power).

Figure 11 (bottom) shows the average auditory spectra of the vowel /ɪ/ in the contexts of labial, alveolar, and velar stops which were calculated from the productions of the present ten male speakers. For the same speakers, the corresponding measured mean frequencies of formants F1–F4 along with their amplitudes are included in the top panel. The formant peaks are situated within the four contiguous broad frequency bands B1–B4 [one band per octave, in kilohertz B1 (0–0.5), B2 (0.5–1.0), B3 (1.0–2.0), and B4 (2.0–

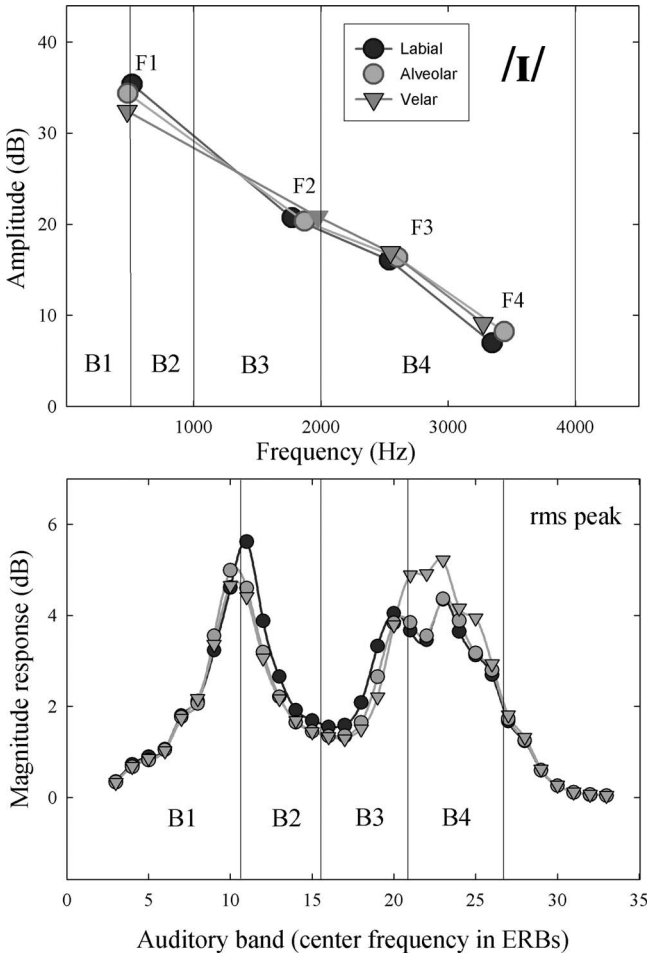

FIG. 11. Mean formant amplitude of the vowel /ɪ/ in the context of stops averaged across ten male speakers in this study (top) and the calculated auditory spectra based on the magnitude response of a gammatone filter bank (bottom).

4.0)]. These bands are also included in the auditory spectrum display to relate the two representations, i.e. acoustic (linear) and auditory (nonlinear), to one another. As evident, the acoustic amplitude variation is carried on through the early stages of auditory processing and the magnitude response in the auditory spectrum is remarkably consistent with the acoustic pattern. In particular, the specific significant consonantal context effects for the vowel /ɪ/ for the measures RelA2, RelA3, RelA4, and A1 summarized in Tables IV–VI can be clearly traced in the auditory spectrum. That is, the statistically strong place effects for RelA2, RelA3, RelA4 (see the results for the stops-only analysis for the vowel /ɪ/), indicating higher amplitude peaks in the context of velars are manifested in the auditory spectrum at the juncture of the bands B3 and B4 and throughout band B4. Clearly, the second peak in the auditory spectrum (which corresponds to the F2, F3, and F4 peaks) is highest in the context of velars. A close correspondence between the acoustic amplitude variations can also be found in the lower frequency region, representing F1 in the acoustic representation and the first peak in the auditory spectrum. The statistically strong effect of place for the A1 measure showing higher amplitude in the context of labials is also evident in the auditory spectrum.

The auditory spectra calculated from the measurements at rms peak show that two spectral regions—corresponding to the lower and higher parts of the measured acoustic spectrum—are emphasized. The question arises as to which spectral region contributes more to the overall vowel amplitude. In Table III, we observe that the significant effect of place for the vowel /ɪ/ for both the rms peak and the overall rms shows higher amplitude values in the context of labials. Relating this effect to the place effects within the spectral regions, we again find higher amplitude values in the context of labials for the lower spectral region (A1) but not for the higher (RelA2, RelA3, and RelA4), where the amplitude is greater in the context of velars. This may indicate that the lower spectral region dominates the vowel spectrum and the contribution of the higher region is comparatively smaller. However, despite the existing evidence (based upon psychophysical tuning) that in the region below 1000 Hz the ability to process spectral contrasts increases (e.g., Healy and Bacon, 2006), this interpretation needs to be tested in a series of further experiments.

At present, any generalization should be drawn with caution due to the large number of vowels and consonantal contexts used in this study. A more focused investigation should concentrate on selected vowels and contexts to gain more insight into the exact causes of differences in the size of amplitude variation found here. A detailed analysis deeply rooted in the acoustic theory of speech production is especially desirable in explaining some of the consonantal context effects on vowel amplitude variation. For example, spectral amplitude variations reflect a complex relation between the characteristics of the sound in the low-frequency region and acoustic attributes at frequencies above the first formant. These include the timing of acoustic events which depend on the length and the place of the consonantal constriction preceding the vowel. These events, such as rate of movement of F1 after the stop release and rate of movement of trajectories of higher formants following the release have an effect on amplitude spectrum (Stevens, 1998).

The significant effects of consonantal context on formant amplitude variations examined here were found at a time window relatively late in a vowel, i.e., at rms peak. This shows that significant variations do not occur only at vowel onsets and offsets (the vowel margins) whose formant frequencies are affected most by surrounding consonants but such effects can also be manifested at vowel nuclei. However, given the variable durations of the vowels and, understandably, variable locations of the rms peaks, it was not surprising to find different degrees of their susceptibility to the context effects. For example, the long vowels in the set such as /ɔ/ and /ɑ/ were relatively unaffected by contextual variation. This would indicate a greater temporal separation of their nuclei from syllable margins. However, this interpretation may not be true with respect to the vowel /æ/ which was the longest in the present set and exhibited more contextual effects than either /ɔ/ or /ɑ/. Also, the vowel /i/, being of intermediate length, was unaffected by contextual variation except for the variation in A4. These mixed results indicate that differences in vowel duration alone cannot entirely explain the varying degrees of context effects found at

vowel nucleus. Finally, there may also be a source variation in the vowel as a function of consonantal context—a study of contextual variations of the voice source can be found in Fant (1997). Fine-grained analyses of the voice source have shown that the influences on the vowel's mode of phonation depend on the manner of articulation of the consonant (Gobl and Ní Chasaide, 1999) and consonant voicing (Gobl and Ní Chasaide, 1993). The source variation in consonantal context may also have a profound effect on variation in the amplitudes of formants.

The type of variation in formant amplitude found in coarticulated vowels in the present study naturally co-occurs with speaker-intended changes to vocal intensity to convey emphasis, linguistic stress, emotions, or to communicate in noisy environments or over a longer distance. How listener deals with such complex interaction between several factors influencing vowel perception is a rich area for future research.

ACKNOWLEDGMENTS

This study was supported by the research Grant No. R03 DC005560 from the National Institute of Deafness and Other Communication Disorders, National Institutes of Health, to the first author. The authors would like to thank Chiung-Yun Chang for assistance at various stages of this research and Jeff Murray for editorial help. The comments and suggestions of the Associate Editor Anders Löfqvist and two anonymous reviewers on an earlier version of the paper are greatly appreciated.

[1]The location of the rms peak can be expressed in several ways. First, the peak rms position can be determined in terms of its absolute distance (in milliseconds) from vowel onset or CVC-word onset. Alternatively, the peak rms position can be expressed in terms of its relative position (with values ranging from 0 to 100%) with regard to the duration of the vowel or duration of the word. We experimented with each of these approaches to determine which measure best characterized the variation in the location of rms peak as a function of vowel category and consonantal context. Based on the statistical results, it became clear that the two relative positions (i.e., within the vowel and within the word) yielded the most comparable patterns. We therefore decided to present only the results for the most dependable measure.

[2]In the HF study, the voiced environments included the nasals /m, n/ which were absent in the present report. Also, in their Table 2, HF listed vowel durations separately for bilabial (/p, b, m/) and labiodental (/f, v/) consonants. In the present study, the HF's values for bilabials and labiodentals were averaged and listed in Table VII as labials. Also, postdental consonants in HF included /n/ which was absent in the present alveolar environments.

[3]HF data displayed in their Fig. 1 are taken from their Table 2.

Focus, prosodic context, and phonological feature specification: Patterns of variation in fricative production

Noah Silbert[a] and Kenneth de Jong
Department of Linguistics and Department of Cognitive Science, Indiana University, Memorial Hall, Room 322, 1021 E. Third Street, Bloomington, Indiana 47405

(Received 12 March 2007; revised 6 February 2008; accepted 7 February 2008)

Because they consist, in large part, of random turbulent noise, fricatives present a challenge to attempts to specify the phonetic correlates of phonological features. Previous research has focused on temporal properties, acoustic power, and a variety of spectral properties of fricatives in a number of contexts [Jongman *et al.*, J. Acoust. Soc. Am. **108**, 1252–1263 (2000); Jesus and Shadle, J. Phonet. **30**, 437–467 (2002); Crystal and House, J. Acoust. Soc. Am. **83**, 1553–1573 (1988a)]. However, no systematic investigation of the effects of focus and prosodic context on fricative production has been carried out. Manipulation of explicit focus can serve to selectively exaggerate linguistically relevant properties of speech in much the same manner as stress [de Jong, J. Acoust. Soc. Am. **97**, 491–504 (1995); de Jong, J. Phonet. **32**, 493–516 (2004); de Jong and Zawaydeh, J. Phonet. **30**, 53–75 (2002)]. This experimental technique was exploited to investigate acoustic power along with temporal and spectral characteristics of American English fricatives in two prosodic contexts, to probe whether native speakers selectively attend to subsegmental features, and to consider variability in fricative production across speakers. While focus in general increased noise power and duration, speakers did not selectively enhance spectral features of the target fricatives.

I. INTRODUCTION

A. Stress, focus, strengthening, and reduction

Reduction is a pervasive property of motor behavior in speech. The extent of reduction of a speech action varies according to the context in which an utterance is produced, the position of the action within the utterance, the nature of surrounding actions, and the properties of the action itself. To create a framework in which to analyze this kind of variation, Lindblom (1990) formulated H&H Theory, in which speech production is constrained by the conflicting demands of motor economization and acoustic distinctiveness. Motor economization causes hypoarticulation, in which a production system "cuts corners," resulting in reduction effects (Lindblom *et al.*, 1971; Lindblom, 1963). However, according to the H&H framework, such effects are held in check by countervailing pressures to produce signs that are reliably recoverable by the hearer. Such shifts toward "output oriented" speech are called hyperarticulation. Various utterance contexts impose these opposing constraints to varying degrees, producing variation in the amount of reduction found in different contexts.

In concordaonce with the predictions of the H&H framework, the frequency of a lexical item seems to be correlated with weakening of output oriented constraints. High frequency words are shorter in overall duration than lower frequency items (Bell *et al.*, 2003), contain shorter consonantal segments in various positions (Umeda, 1977; Jurafsky *et al.*, 2001), and exhibit more extensive contextual assimilation (Ernestus *et al.*, 2006). However, such results need to be interpreted in light of other factors that also affect degree of reduction.

For example, the location of linguistic stress and focus affects degree of reduction. Linguistic stress is a conventional aspect of some languages that increases the prominence of certain syllables within a given word. Focus is the more general aspect of speech such that talkers mark particular items as centers of attention. de Jong (1995) used x-ray microbeam traces to investigate the effects of linguistic stress and focus on the articulation of a number of different vowels and consonants, arguing that stress functions as syllable-localized hyperarticulation (cf., Lindblom, 1990); phonological contrast effects are more apparent in stressed than unstressed syllables, and reduction is a general property of unstressed syllables. Although stress-induced hyperarticulation is generally taken to be localized to the syllable (at least in English), focus-induced hyperarticulation might apply to units larger than the syllable (Lindblom, 1990), and possibly those smaller than the syllable (van Heuven, 1994). The degree to which a segment is reduced also differs depending on the nature of the segment. For example, while both consonants and vowels tend to shorten, and vowels tend to exhibit centralized values of F2, coronal consonants are subject to exceptionally large amounts of reduction in poststress position (Umeda, 1977; de Jong, 1998).

The current study builds on previous work on the effects of linguistic stress and focus. The fact that stress accentuates local cues to linguistic contrasts was exploited in a pair of experiments probing cross-linguistic differences in vowel duration and consonant voicing (de Jong, 2004; de Jong and Zawaydeh, 2002). de Jong (2004) found stress and focus

[a]Electronic mail: nosilber@indiana.edu

both exaggerate durational differences between vowels and voicing-induced vowel duration differences, de Jong and Zawaydeh (2002) found similar effects on the duration difference between long and short vowels in Arabic, but no effect of voicing-induced durational differences.

These studies employed two types of focus, one in which talkers contrasted phonologically unrelated lexical items (lexical focus), and one in which talkers disambiguated particular segments (phonological focus). Lexical focus seems to operate primarily in locations picked out by linguistically specified stress, whereas phonological focus also serves to selectively enhance localized phonologically relevant features. de Jong (2004) also found a general effect on focus on vowel quality and less differentiation of vowel quality as a result of phonological focus; phonological focus effects on vowel quality were not significantly different than lexical focus effects.

The current paper extends this research program to an investigation of the effects of focus on place of articulation and voicing contrasts in American English fricatives. Less is known about the acoustic effects of focus and stress on consonants than on vowels, though several findings have been repeated in the literature. For example, stress and focus tend to create larger and more rapid transitions from a fricative into a following vowel (e.g., Tjaden, 1999). In addition, obstruents have greater duration in stressed position, though such increases in duration are smaller than those found in vowels (Crystal and House, 1988b).

No study to our knowledge has examined the effect of focus on the duration and quality of fricative productions, although the effects of low level prosodic context and stress on European Portuguese fricatives has been studied (Jesus and Shadle, 2002). Mooshammer *et al.*, (2006) similarly examined the effect of increased loudness on articulation of a variety of consonants, focusing on the relations of the jaw and tongue for different manners of articulation. While this study found sizable differences between loud and nonloud vowels, and some small positional differences for other consonants, they found very few differences between loud and nonloud sibilant fricatives, suggesting that the sibilant production exerts stringent requirements on jaw position, reducing variability in the loud and nonloud productions. It is also important to note that, while Jesus and Shadle (2002) found strong spectral tilt effects of increased airflow on sustained fricatives, they also showed that stress is not simply equivalent to increased effort.

In addition, there is evidence that levels of prosodic structure are distinguished by the "strength" of articulation of initial consonants in a number of languages; articulatory strengthening is similar to hyperarticulation, though it is not necessarily listener-oriented (Fougeron 2001; Keating *et al.* 2003). The current research examines strengthening and reduction patterns in the acoustics of fricatives in two (low level) prosodic contexts. While much research of this type has been applied to vowels and stop consonants, there is relatively little work on fricatives. In fact, aside from duration measures of sibilants in a variety of prosodic contexts (e.g., Klatt, 1974), duration and devoicing measures of European Portuguese fricatives in a variety of word positions and stress contexts (Jesus and Shadle, 2003a, b), and devoicing and spectral measures of sustained fricatives produced at various effort levels (Jesus and Shadle, 2002), the nature of prosodically induced acoustic variability in fricatives is relatively understudied.

B. Properties of fricatives

While vowels have been extensively examined, the physical properties of fricatives are less well understood. This may be due, in part, to the nature of fricatives. Because fricatives consist largely of turbulent noise, the wave form of a given fricative varies considerably from token to token. Because the characteristics of frication noise depend to an unknown degree on the unique shape of a given speaker's vocal tract, fricatives can also vary from speaker to speaker. Nonetheless, research indicates that fricatives do have a number of stable properties that vary consistently with phonological features. Broadly speaking, these may be categorized as temporal, spectral, and power properties.

1. Temporal properties

Although a number of factors may affect the duration of a given speech sound (see, e.g., Klatt, 1976) the effects of phonological feature specification and prosodic context are of interest here. The duration of the frication noise for voiceless fricatives at a given place of articulation is much greater than the duration of their voiced cognates (Crystal and House, 1988a, c; Klatt, 1976; Pirello *et al.*, 1997; Stevens, 1998; Stevens *et al.*, 1992). Stevens (1998) and Stevens *et al.* (1992) present a physiological explanation for this difference, arguing that the maintenance of voicing during the articulation of a fricative constriction results in later onset, earlier offset, and lower amplitude of frication noise. In addition, it is common to find that phonologically voiced fricatives undergo substantial devoicing (Haggard, 1978; Stevens *et al.* 1992). It is also possible that duration differences in fricatives may be "phonologized," or taken by speakers to be linguistically specified (as opposed to being a merely physiological byproduct of articulation).

Differences in place of articulation and prosodic context also correspond to duration differences, although place effects are typically much smaller than voicing effects. Voiceless coronal fricatives [s] and [ʃ] tend to be longer than voiceless interdentals [θ] and labiodentals [f] (Behrens and Blumstein, 1988; Jongman *et al.*, 2000), and phrase final segments tend to be lengthened (Klatt, 1976). Syllable affiliation (i.e., onset versus coda position) does not appear to correspond to reliable duration differences.

2. Spectral properties

Spectral properties of fricatives change with place of articulation, less so with voicing, across a number of languages (Hughes and Halle, 1956; Jassem, 1965; Jesus and Shadle, 2002; Jongman *et al.*, 2000; Stevens, 1998). Voicing seems to affect the spectra of fricatives primarily by reducing the amplitude of the noise (see, e.g., Jesus and Shadle, 2002; Stevens *et al.*, 1992). Differences in place of articulation can have drastic effects on the spectra of fricatives, largely be-

cause the noise source mechanism can change drastically with place: Labiodental and interdental frication noise is produced by airflow through a narrow constriction, whereas coronal frieation noise is produced both by this and the channeling of the air stream into the lower teeth (Shadle, 1990, 1991). In addition, the spectra of coronal fricatives are shaped by the resonant frequencies of the cavity anterior to the constriction (Stevens, 1998).

Because frication noise is highly variable, statistical techniques have proven to be especially useful in investigations of place of articulation differences in fricative spectra. For example, Jesus and Shadle (2002) fit two regression lines to the spectra of a number of European Portuguese fricatives. One regression line was fit to the spectra from the mean frequency of the highest amplitude peak up to 20 kHz, the other from 500 Hz to that mean frequency. Other work has exclusively employed so-called "spectral moments," in which the spectral representation of (a portion of) an obstruent is treated as a probability distribution. The first four (central) moments—the mean, variance, skewness, and kurtosis—are then taken as measures of the central tendency, variation, symmetry, and peakedness of the spectrum, respectively. Forrest *et al.* (1988) pioneered the use of spectral moments in a study of spectral differences in voiceless obstruents. Jongman *et al.* (2000) extended the use of these measures to a larger set of place of articulation distinctions in English fricatives, finding that interdental and labiodental fricatives tended to have lower spectral means and kurtosis than [s] and [z], higher spectral means and kurtosis than [ʃ] and [ʒ], higher spectral variance than either of the coron alpairs, and skewness higher than [s] and [z], but lower than [ʃ] and [ʒ]. Jesus and Shadle (2002) found similar, consistent changes in spectral shape across place of articulation in European Portuguese fricatives.

Although prosodic context has been studied with regard to articulatory measures (Fougeron, 2001; Keating *et al.*, 2003) as well as measures of duration and devoicing (Jesus and Shadle, 2003a; b), the spectral effects of prosodic context are unknown. Insofar as onset position is "stronger" than coda position, and insofar as strength corresponds to increased airflow, we should expect coda fricatives to exhibit a steeper spectral drop-off at higher frequencies (see Sec. I B 3). This will have predictable consequences for spectral measurements (see spectral measure hypotheses stated in Sec. II).

3. Power properties

As described earlier, the presence of voicing in a fricative tends to lower the overall amplitude of the frication noise. Noise amplitude can also be affected by place of articulation. For example, coronal fricatives have higher amplitude than labiodental or interdental fricatives (Jongman *et al.*, 2000). In addition, glottal excitation produces energy primarily at low frequencies (e.g., below 750 Hz). Finally, mechanical models of human vocal tracts show that increases in the volume velocity of air flowing through a constriction increase the power more at higher frequencies than at lower frequencies (Shadle, 1990, 1991).

4. Speaker-specific properties

Because many of the properties of fricatives are dependent on physiological features, the possibility of interspeaker variation must be allowed for. For example, the source spectrum for coronal fricatives depends in part on the shape and position of the lower teeth; the source spectrum for labiodental fricatives depends in part on the shape and size of the constriction between the lower lip and upper teeth; the resonant frequencies of a cavity vary with its size, which is itself variable. In addition, speaker gender has been shown to interact with, e.g., spectral peak location (Jongman *et al.*, 2000).

II. RESEARCH QUESTIONS AND HYPOTHESES

The present research seeks to probe the effects of focus on a subset of phonological contrasts in fricatives using a number of acoustic measures. Native speakers participated in an interactive fricative production experiment in which voicing and place of articulation distinctions in fricatives were explicitly disambiguated. Posed generally, the research questions to be investigated are as follows: What are the effects of focus on fricative production? How does prosodic context (i.e., syllable affiliation) modulate the effects of focus? Do native speakers selectively attend to subsegmental (i.e., contrastive) features in production? Answers to these questions were pursued by analyzing productions of singleton voiced and voiceless labiodental and coronal fricatives in onset and coda position in focus and neutral conditions.

Methods: *1. Corpus and materials.* The fricatives of interest were the labiodental [f] and [v], interdental [ɵ] and [ð], and coronal [s] and [z] in onset and coda positions in nonsense syllables. Every target syllable contained the same low vowel, [ɑ]. The exclusive use of "minimal pair" nonsense syllables was imposed to control for spectral and duration differences between English vowels, as well as potential confounds relating to differences in word frequency.

All fricative productions were elicited with orthographic representations. Both of the interdental fricatives were represented with the letters "th" accompanied by key words cuing the intended voicing specification. Because all but one participant exhibited considerable confusion with the interdental fricatives, trials involving these consonants were exempted from measurement and analysis.

Each recording was made with the first author present in a sound-attenuating booth. Target fricative productions were elicited in frame sentences in neutral, voicing disambiguation, and place disambiguation contexts. The neutral productions occurred in postfocus position, while the voicing and place disambiguation productions occurred in focus position. In each condition, a 3 by 5 in. card with a nonsense target syllable was displayed and the participants were instructed to read this nonsense syllable aloud. In the neutral (unfocused) condition, the experimenter then asked the participant "Did you say [target syllable]?" The participants were instructed to respond to this question with the frame sentence "No, Jeff/Jane said [target syllable]." The name in the response frame was fixed to match the gender of the participant.

In the voicing disambiguation and place disambiguation conditions, the experimenter asked "Did you say [disambiguation syllable]?" where [disambiguation syllable] indicates a syllable identical to the target syllable except for a difference in either voicing or place specification (i.e., the target syllable and the disambiguation syllable form a "minimal pair" contrastive in either voicing or place alone). The participants were instructed to respond to these questions with the frame sentence "No, I said [target syllable]." For example, for trials in which the target syllable was [fa], the voicing disambiguation question would be "Did you say [va]?," while the place disambiguation question would be "Did you say [sa]?" ln either case, the participant's response would be "No, I said [fa]."

For each talker, each target syllable was produced and recorded six times in each condition. Productions were blocked by repetition and partially blocked by focus condition. The disambiguation contexts, prosodic context, and target voicing and place specifications were randomized within blocks. Thus, for each repetition block, all of the neutral productions were elicited first, followed by all voicing and place disambiguation productions. The corpus consisted of six repetitions of four target fricatives produced in two prosodic contexts and three disambiguation conditions by four speakers. Thus, 576 tokens were measured and analyzed.

2. Participants. Four native speakers of Midwestern American English—two male and two female—were recorded in a single-walled sound attenuated booth using a head-mounted microphone. The participants' ages ranged from 18 to 21. At the time of recording, all participants were enrolled at a large Midwestern university. None reported any history of speech or hearing pathology, and all had limited, adult experience with at least one second language.

3. Recording. The microphone, a Shure SM10A (with frequency response from 50 to 15 000 Hz), was placed approximately 2 in. to the left and 2 in. below each participant's lips. Recordings were captured on digital audio tape (using a Panasonic SV3800) at a sampling rate of 44.1 kHz The participants' recordings were transferred to hard drive as wav files with a sampling frequency of 44.1 kHz and bit depth of 16 bits. These wav files were edited and subjected to acoustic analysis.

4. Measurement. Each target fricative alone and each full target syllable were manually extracted and saved as separate files using both wave form and spectrogram displays. All editing made use of two visual cues: high levels of energy in the frequency region above about 3 kHz relative to surrounding (vowel) regions in the spectrogram display, and the presence of noise (i.e., lack of periodicity) in the wave form display. The edited signals were preemphasized via a first-difference filter [as in Forrest *et al.* (1988) and Jongman *et al.* (2000)]. All measurements were taken automatically via a MATLAB script. Prior to measurement, all files were resampled to 30 000 Hz, fixing the highest frequency available for spectral analysis at 15 000 Hz. This value was chosen to match the upper bound of the frequency response of the microphone used to make the recordings.

Two temporal measurements were taken. Syllable duration was measured in milliseconds, and fricative duration was measured as a proportion of the syllable duration, in part to mitigate the effects of differences in speech rate across subjects (see Jongman *et al.*, 2000), in part to reduce as much as possible any correlation between the two temporal measures so as to increase the power of the multivariate statistical tests performed (Tabachnick and Fidell, 2001).

Four spectral measurements were taken. Twelve 17 ms (512 sample) sections were taken from each fricative. A full Hamming window was applied to each section, and a spectrum was calculated via fast fourier transform. All spectral moment measurements were taken from a single spectrum time-averaged across 12 individual spectra calculated from equally spaced windows. [See Jesus and Shadle (2002) for a discussion of time versus token averaging of fricative spectra.] Spectral moment measurements were restricted to frequencies above 750 Hz, as these were intended as descriptors of the noise component of the fricatives, and energy produced by glottal pulsing is located predominantly in the low frequency range. The energy below 750 Hz was used to measure the amount of glottal energy (see the following). The cutoff was chosen as 750 Hz based on visual inspection of the spectra analyzed here and on criteria used in other research (e.g., Jesus and Shadle (2002)).

The first four (central) spectral moments were calculated based on the formulas used in Forrest *et al.* (1988). Spectral moments were calculated using the portion above 750 Hz of a single spectrum (time) averaged across all 12 individual spectra taken from each fricative.

The noise power measurement for a given fricative was also taken from a single time-averaged spectrum and was also restricted to frequencies above 750 Hz. Glottal power measurements (i.e., power below 750 Hz) for each fricative were taken at three intervals, each based on a single spectrum averaged over four spectra. Thus, four 17 ms sections in the first third of a fricative were windowed, transformed, and averaged and the power below 750 Hz was calculated; the same was done for the middle third and final third of each fricative. All power measurements were decibel transformed with reference to a single bit.

5. Analysis. Each set of measures (two temporal measures, four spectral measures, and four power measures) was subjected to repeated measures multivariate analyses using the SPSS GLM algorithm. Plots and tables in Sec. III are based on a subset of the statistically significant results from the multivariate tests of between and within subject effects, as determined by the following hypotheses.

Temporal measures. Previous research leads us to expect the following hypotheses to hold. Regardless of prosodic context, phonologically voiceless fricatives will be longer than phonologically voiced fricatives, and coronal fricatives will be longer than labiodental fricatives. Phonologically voiced coda fricatives will be preceded by longer vowels than will phonologically voiceless coda fricatives. Phonological voicing in onset position will have no effect on vowel duration, so overall syllable duration will not vary across fricative voicing in coda position, but phonologically voiceless onset fricatives will appear in longer syllables than their voiced cognates.

If focus involves a general shift toward listener-oriented speech, syllables in focus position will have longer overall durations than will those in the nonfocus (neutral) position, as will individual fricatives. If focus involves adjustments in production specifically targeting contrastive dimensions, voicing disambiguation will selectively exaggerate duration differences due to phonological voicing. Although focus will generally increase fricative duration, phonologically voiceless fricatives will be lengthened more than phonologically voiced fricatives. Also, voiced-coda induced increases in vowel duration will be exaggerated by focus on voicing.

Note that, although the effect of voicing specification of coda obstruents on preceding vowel durations is quite large when found (see, e.g., Klatt, 1976, de Jong, 2004), it is not always found (see, e.g., Crystal and House, 1988a). Also, because all of the target syllables are in prepausal, phrase final position, coda fricatives will be longer than their onset counterparts (see, e.g., Klatt, 1976).

Spectral measures. Previous research leads us to expect that coronal fricatives will have higher spectral means, lower spectral standard deviations, higher spectral kurtosis, and lower spectral skewness than labiodental fricatives. More specifically, coronals will have negative spectral skewness, while labiodentals will have spectral skewness near zero. Phonologically voiced fricatives will have higher spectral standard deviations, lower (i.e., more negative) spectral skewness, and lower spectral kurtosis, regardless of prosodic context.

Although the effects of changes in cross-sectional area due to changes in place of articulation are well understood, relatively little is known about the acoustic effects of changes in cross-sectional area and shape of a fricative constriction within a given place of articulation (e.g., due to hyperarticulation). Because of this, all of the general focus hypotheses for spectral effects pertain to the effects of increase in volume velocity airflow. In order to state any such hypotheses, then, it is assumed that explicit focus will induce an increase in volume velocity airflow due to a general increase in articulatory effort. Because increased volume velocity airflow through a constriction with the same area increases the power more at higher frequencies than at low frequencies, fricatives in focus position will have higher spectral means than those in the neutral position, within each place of articulation and in any prosodic context. Coronal fricatives in focus position will have higher spectral standard deviation than those in the neutral position, while labiodental fricatives in focus position will have lower spectral standard deviation than those in the neutral position. Coronal fricatives in focus position will have lower (i.e., more negative) spectral skewness than those in the neutral position. Labiodental fricatives in focus conditions will also have lower (i.e., more negative) skewness and higher spectral kurtosis than those in the neutral position. If onsets are "stronger" than codas, and if articulatory strength is implemented, at least in part, through increased airflow, we expect the same general (focus) effects in onset but not in coda position.

If focus involves adjustments in production specifically targeting contrastive dimensions, place disambiguation will selectively exaggerate place differences as found in all four spectral moments. Insofar as voicing disambiguation increases the amount of glottal excitation, changes in the noise power will induce lower spectral mean, skewness, and kurtosis, higher spectral standard deviation for voiced fricatives.

Power measures. Based on previous research, we expect phonologically voiced fricatives to have more low-frequency power (near the co-syllabic vowel) than phonologically voiceless fricatives, regardless of prosodic context. Due to phrase and word edge effects, phonologically voiced coda fricatives will be devoiced more than their onset counterparts. Coronal fricatives will have higher noise power than labiodental fricatives. Phonologically voiced fricatives will have lower noise power than phonologically voiceless fricatives, although this effect may be modulated by the phrase edge effects discussed earlier.

If focus effects reflect a general increase in vocal output, fricatives in focus position will have higher noise power than those in the neutral position, regardless of place of articulation, voicing specification, and prosodic context. Phonologically voiced fricatives in focus position will have more low-frequency power (near the vowel in time) than those in the neutral position, regardless of place of articulation or prosodic context. Phonologically voiceless labial fricatives in focus position will have more low-frequency power (at all times) than those in the neutral position, whereas, due to zeros associated with the coronal place of articulation, phonologically voiceless coronal fricatives in focus position will have less low-frequency power than those in neutral position; we expect the same general pattern in onset and coda position. If focus effects are tuned to specific contrastive dimensions, voicing disambiguation will selectively increase the amount of low-frequency power in phonologically voiced fricatives.

III. RESULTS

A. Temporal measurements

Due to the large number of statistical tests carried out, a relatively conservative criterion ($\alpha=0.01$) was adopted. There were statistically significant main effects of voicing [$F(2,47)=120.15, p<0.001$], disambiguation condition [$F(2,96)=3.65, p=0.008$], prosodic context [$F(2,47)=106.92, p<0.001$], and speaker gender [$F(2,47)=12.90, p<0.001$]. Between-subject main described in detail in Table I. There were statistically significant interactions between voicing and prosodic context [$F(2,47)=6.35, p=0.004$] and between prosodic context and speaker gender [$F(2,47)=6.413, p=0.003$]. These interactions are illustrated in Fig. 1.

Phonologically voiced fricatives were shorter than phonologically voiceless fricatives, as shown by the main effect of voicing. However, there was no statistically significant main effect of place. The general focus prediction regarding temporal measures was confirmed, as shown by the main effect of disambiguation condition: In both focus conditions, overall syllable duration was increased by roughly the same amount. The disambiguation-specific predictions, however, were disconfirmed. Both focus conditions induced an approximately equal increase in consonant duration proportion.

TABLE I. Main effects, temporal DVs. Fricative duration is expressed as a proportion of syllable duration. Numbers indicate means (standard deviations).

Independent variable	Fricative duration		Syllable duration (ms)	
Voiced	0.302	(0.078)	409.876	(76.938)
Voiceless	0.426	(0.099)	428.843	(83.997)
Neutral	0.341	(0.104)	378.006	(75.899)
Voicing	0.376	(0.110)	440.605	(74.572)
Place	0.375	(0.108)	439.468	(76.595)
Onset	0.303	(0.072)	399.017	(84.437)
Coda	0.426	(0.104)	439.702	(72.079)
Female	0.341	(0.093)	400.373	(78.446)
Male	0.387	(0.118)	438.346	(79.236)

The main effect of prosodic condition was caused by the overall greater duration of coda fricatives. The voicing by prosodic context and prosodic context by gender interactions are depicted in Fig. 1. The gender main effect was caused by the male speakers' slightly longer syllables and fricatives. Both interactions are due to the male speakers' particularly long voiceless coda fricatives.

B. Spectral measurements

There were statistically significant main effects of voicing $[F(4,45)=7.41, p<0.001]$, place of articulation $[F(4,45)=363.49, p<0.001]$, prosodic context $[F(4,45)=11.26, p<0.001]$, speaker gender $[F(4,45)=25.34, p<0.001]$, and (within subjects) experimental block $[F(20,29)=3.40, p=0.001]$. Between-subject main effects are described in Table II. There were statistically significant interactions between voicing and place of articulation $[F(4,45)=6.54, p<0.001]$, place and speaker gender $[F(4,45)=38.90, p<0.001]$, place and prosodic context $[F(4,45)=5.29, p<0.001]$, voicing and prosodic context $[F(4,45)=4.08, p=0.007]$, experimental block and speaker gender $[F(20,29)=3.391, p=0.001]$, and between experimental block and place of articulation $[F(20,29)=2.837, p=0.005]$. Interactions involving only between-subjects effects are illustrated in Figs. 2–4.

TABLE II. Main effects, spectral DVs. M_s= spectral mean; s.d.$_s$= spectral standard deviation; S_s= spectral skewness; K_s= spectral kurtosis. Numbers indicate means (standard deviations). Spectral means and standard deviations are given in hertz. Spectral skewness and kurtosis are expressed in reference to spectral standard deviation (see formulas in Forrest *et al.*, 1988).

Independent variable	M_s		s.d.$_s$		S_s		K_s	
Voiceless	7049	(864)	2694	(505)	0.371	(0.372)	0.162	(0.758)
Voiced	6979	(885)	2820	(673)	0.369	(0.364)	0.143	(0.961)
Labiodental	6745	(707)	3302	(290)	0.337	(0.249)	−0.564	(0.317)
Coronal	7283	(942)	2212	(192)	0.403	(0.426)	0.870	(0.606)
Onset	7324	(851)	2770	(668)	0.284	(0.338)	0.123	(0.979)
Coda	6704	(785)	2744	(519)	0.456	(0.342)	0.182	(0.735)
Female	7274	(1012)	2689	(638)	0.237	(0.319)	0.301	(0.943)
Male	6754	(612)	2825	(548)	0.503	(0.330)	0.004	(0.752)

The main effect of place was as expected on three of the four of the spectral moments: coronal fricatives had higher spectral means, lower spectral standard deviations, and higher spectral kurtosis than did the labiodentals. The hypothesis concerning the effect of phonological voicing specification was only partially confirmed. While voicing does generally correspond to lower noise power in fricatives (see Sec. III C), this did not have the expected effect on the first, third, or fourth spectral moments. As can be seen in Fig. 2, phonologically voiced labiodental fricatives (diamond with solid variance axes) have higher spectral standard deviations (y axis) than do phonologically voiceless fricatives (star with solid variance axes), but no such effect was found for coronal fricatives (star and diamond with broken variance axes).

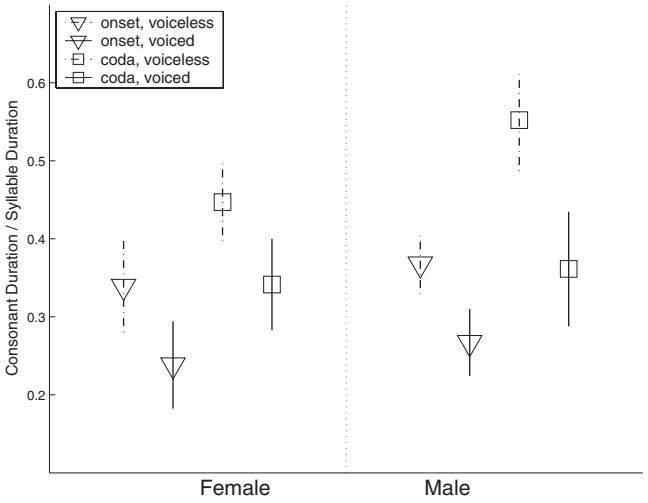

FIG. 1. Fricative duration (divided by syllable duration) as a function of fricative voicing, prosodic context, and speaker gender. Triangles indicate mean consonant duration for onset fricatives, squares for coda fricatives. Solid error bars indicate ±1 s.d. for voiced fricatives; broken error bars for voiceless fricatives. Values for female participants appear on the left, values for male participants on the right.

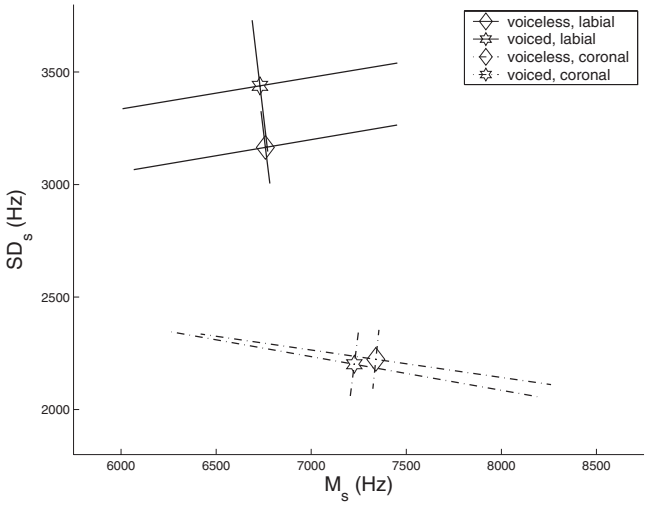

FIG. 2. The first and second spectral moments as a function of fricative voicing and place of articulation. The x axis indicates spectral mean values. The y axis indicates spectral standard deviation values. Diamonds indicate mean spectral moment values for voiceless fricatives, stars for voiced fricatives. Solid error bars indicate the major and minor axes of the variance ellipses for labial fricatives, broken error bars for coronal fricatives.

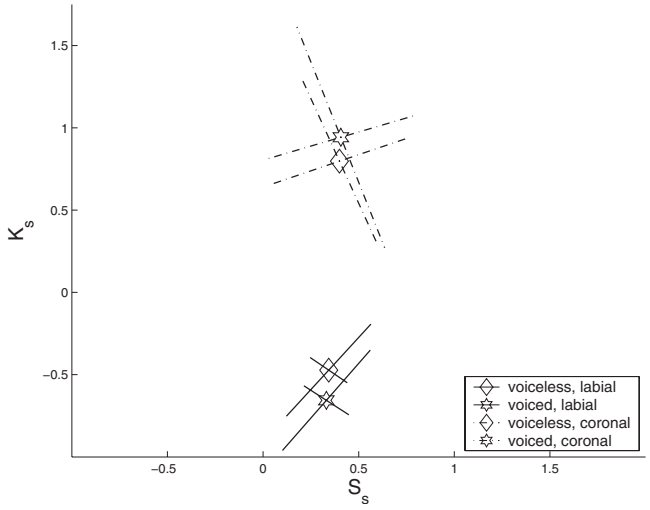

FIG. 3. The third and fourth spectral moments as a function of fricative voicing and place of articulation. The *x* axis indicates spectral skewness values. The *y* axis indicates spectral kurtosis values. Diamonds indicate mean spectral moment values for voiceless fricatives, stars for voiced fricatives. Solid error bars indicate the major and minor axes of the variance ellipses for labial fricatives, broken error bars for coronal fricatives.

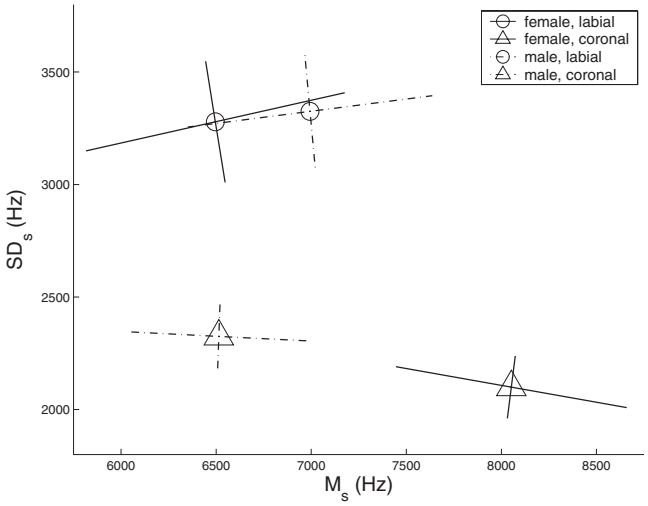

FIG. 5. The first and second spectral moments as a function of speaker gender and place of articulation. The *x* axis indicates spectral mean values. The *y* axis indicates spectral standard deviation values. Circles indicate mean values for labials, triangles for coronals. Solid error bars indicate the major and minor axes of the variance ellipse for female speakers, broken error bars for male speakers.

While the first and third moments were unaffected by phonological voicing, the difference in kurtosis between voiced labiodentals and coronals was larger than that between voiceless labiodentals and coronals (see Fig. 3). These two voicing-induced differences account for the place by voicing interaction.

All of the general focus and disambiguation-specific hypotheses were disproven, though the lack of statistical significance of the focus conditions was not due to a high degree of random variation in the fricatives, since there are a number of subtle prosodic and voicing differences that were statistically significant in the spectral measures. The main effect of prosodic context is due to higher spectral means in onset fricatives; the second, third, and fourth spectral moments are essentially identical across syllable position (see Table II). This main effect is due to an upward shift in spectral mean in voiceless onset fricatives and a larger difference in spectral standard deviation between labiodentals and coronals in onset position than in coda position. These differences are also responsible for the voicing by prosodic context interaction.

Place of articulation also interacts with prosodic context. The difference in spectral kurtosis between labiodentals and coronals is larger in onset position than in coda position, as depicted in Fig. 4.

Gender also affected the spectral measures. Both of the female speakers exhibited the expected patterns—coronal fricatives with high first and fourth but low second and third spectral moments, and labiodental fricatives with low first, third, and fourth spectral moments, and high spectral standard deviation. Both of the male speakers produced unexpectedly low first and fourth spectral moments and unexpectedly high second and third spectral moments in their coronal fricatives, although their labiodental fricatives conformed to expectations (see Figs. 5 and 6). All of the labiodental spectra are relatively flat across the four speakers, with small, idiosyncratic peaks in the spectra at various frequencies. The average coronal spectra, by contrast, all show energy concentrations in relatively narrow frequency bands. The lowest frequency of the concentrated energy is at approximately 5 kHz for the male speakers, and well above 6 kHz for the female speakers, consistent with a presumably shorter resonator for the female speakers. The difference between male and female speakers may also be due to idiosyncratic differences in (within category) place of articulation (e.g., differences in how far forward/back coronal fricatives are articulated). The different location of this peak relative to the center frequency of the spectral distribution explains the gender-based difference in skewness.

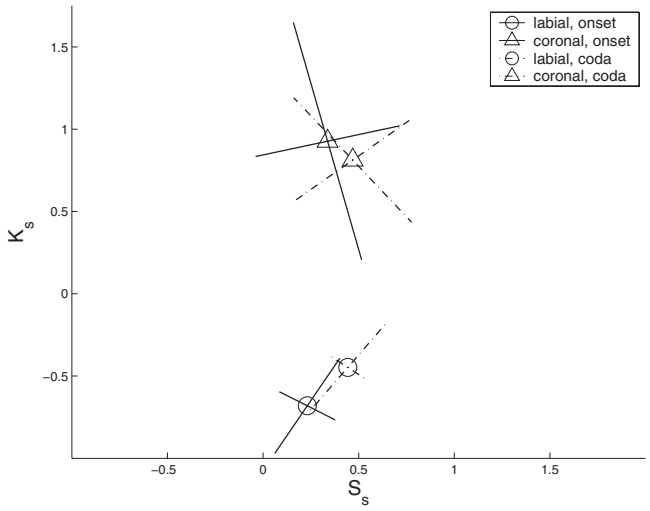

FIG. 4. The third and fourth spectral moments as a function of place of articulation and prosodic context. The *x* axis indicates spectral skewness values. The *y* axis indicates spectral kurtosis values. Triangles indicate mean spectral moment values for coronals, circles for labials. Solid error bars indicate the major and minor axes of the variance ellipses for onset fricatives, broken error bars for coda fricatives.

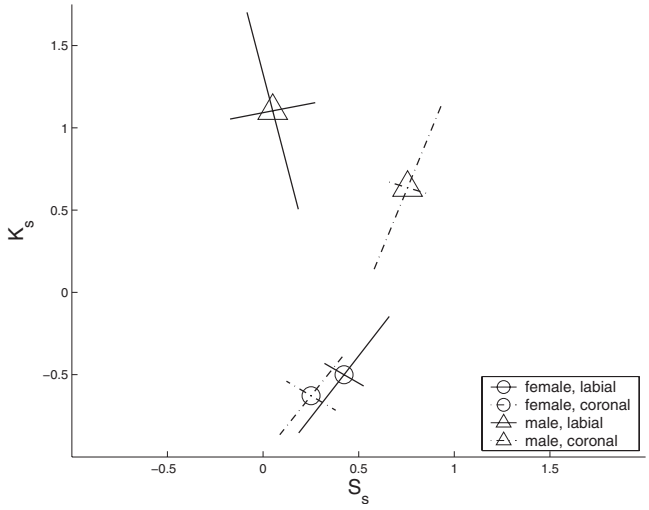

FIG. 6. The third and fourth spectral moments as a function of speaker gender and place of articulation. The *x* axis indicates spectral skewness values. The *y* axis indicates spectral kurtosis values. Circles indicate mean values for labials, triangles for coronals. Solid error bars indicate the major and minor axes of the variance ellipse for female speakers, broken error bars for male speakers.

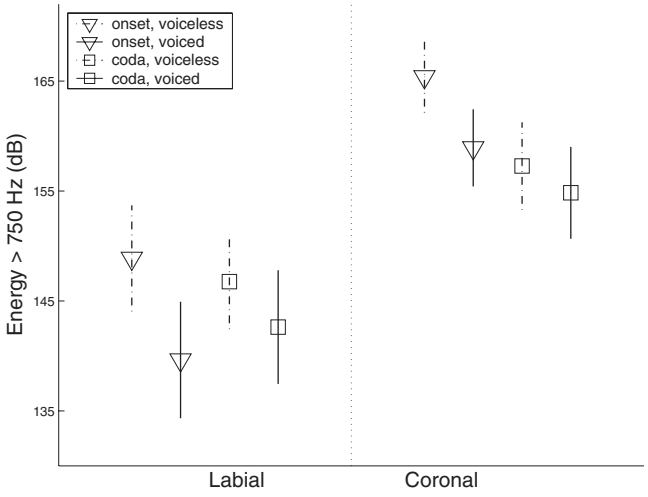

FIG. 7. Noise power (in dB re: 1 bit) as a function of voicing, prosodic context, and place of articulation. Triangles indicate mean noise power for onset fricatives, squares for coda fricatives. Solid error bars indicate ±/s.d. for voiced fricatives, broken error bars for voiceless fricatives. Noise power for labial fricatives is in the left panel, for coronals in the right.

Although these differences correspond with the gender of the speakers here, the small number of subjects in the present study and the apparent consistency across gender in other studies (e.g., Jongman *et al.*, 2000) limit the generality of the "gender" effect on spectral moments observed here. The "statistical" measures of the spectral properties of fricatives employed here cannot distinguish between plausible systematic (e.g., vocal tract size) and idiosyncratic (within-category place of articulation differences) causes for the observed gender difference.

The main effect of experimental block is due to an increase in spectral means, a decrease in spectral standard deviation and skewness, and general, nonmonotonic increase in spectral kurtosis over the course of the experiment. The experimental block by place interaction is due to nonmonotonic shifts in spectral means and skewness over the course of the experiment. All other spectral measurements remained more or less stable over the course of the six blocks.

C. Power measurements

There were statistically significant main effects of voicing $[F(4,45)=104.10, p<0.001]$, place of articulation $[F(4,45)=179.45, p<0.001]$, prosodic context $[F(4,45)=59.02, p<0.001]$, and experimental block $[F(20,29)=3.219, p=0.002]$. Between-subject main effects are described in detail in Table III. There were statistically significant interactions between voicing and prosodic context $[F(4,45)=18.039, p<0.001]$, place and prosodic context $[F(4,45)=29.03, p<0.001]$, voicing and speaker gender $[F(4,45)=8.03, p>0.001]$, and between experimental block and speaker $[F(20,29)=3.52, p=0.001]$. Interactions involving only between-subjects factors are illustrated in Figs. 7–9.

Phonologically voiceless fricatives have higher noise power than do phonologically voiced fricatives, as shown by the main effect of voicing on noise power in Table III. The main effect of place due to the higher noise power in coronals than labiodentals was also expected. Figure 7 illustrates the place by prosodic context and voicing by prosodic context interaction effects on noise power. The noise portion of the place by prosodic context interaction is due to the overall higher power for onset coronals relative to coda coronals, while labiodentals have roughly the same power across prosodic context (compare triangles to squares within each half of Fig. 7). The voicing by prosodic context interaction is due

TABLE III. Main effects, power DVs. Noise=power (dB) above 750 Hz. Voicing *N*=power (dB) below 750 Hz at *N*th third of the fricative. Numbers indicate means (standard deviations).

Independent variable	Noise	Voice 1	Voice 2	Voice 3
Voiceless	154.57 (8.46)	105.09 (4.75)	102.98 (4.93)	103.50 (5.58)
Voiced	149.00 (9.30)	114.58 (7.05)	108.92 (8.35)	109.36 (9.00)
Labiodental	144.47 (6.07)	110.21 (7.34)	106.70 (7.60)	106.69 (7.58)
Coronal	159.10 (5.41)	109.46 (7.95)	106.21 (7.78)	106.16 (8.84)
Onset	153.20 (10.71)	108.90 (8.56)	108.98 (8.45)	110.04 (8.60)
Coda	150.37 (7.40)	110.77 (6.51)	103.92 (5.83)	102.82 (5.43)
Neutral	150.30 (8.77)	108.64 (7.03)	105.28 (7.58)	105.87 (8.41)
Voicing	152.64 (9.51)	110.06 (8.23)	106.83 (7.66)	106.49 (7.61)
Place	152.42 (9.48)	110.80 (7.53)	107.24 (7.71)	106.91 (8.09)

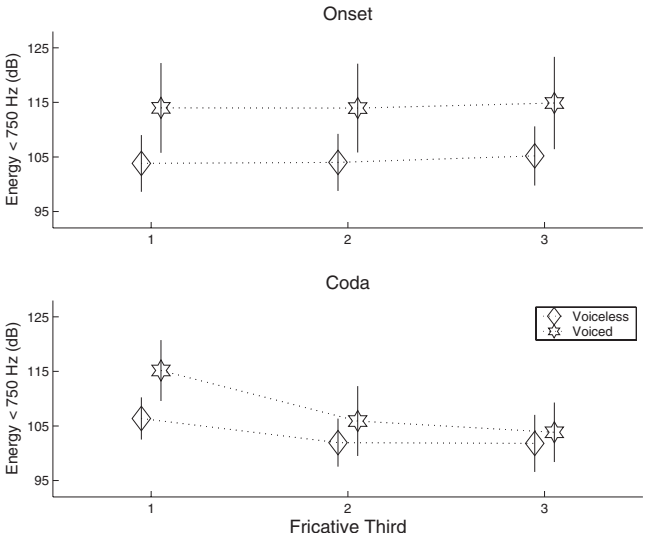

FIG. 8. Voicing power (in dB re: 1 bit) as a function of voicing, prosodic context, and fricative third. The *x* axis indicates "time," or the first, second, and middle third of the fricative. They *y* axis indicates power in decibels relative to one bit. Diamonds indicate mean voicing power for voiceless fricatives, stars for voiced fricatives. Solid error bars indicate ±1 s.d. The top panel indicates values for onset fricatives, the bottom panel for coda fricatives. The plots are staggered and nonvertical lines are plotted to ease comparison across voicing specification.

to the fact that, although the expected ordering is found between phonologically voiceless and voiced segments within each prosodic context, the difference between voiceless and voiced segments is larger in onset than in coda position (compare the difference between triangles with broken error bars and triangles with solid error bars to the difference between squares with broken error bars and squares with solid error bars in Fig. 7).

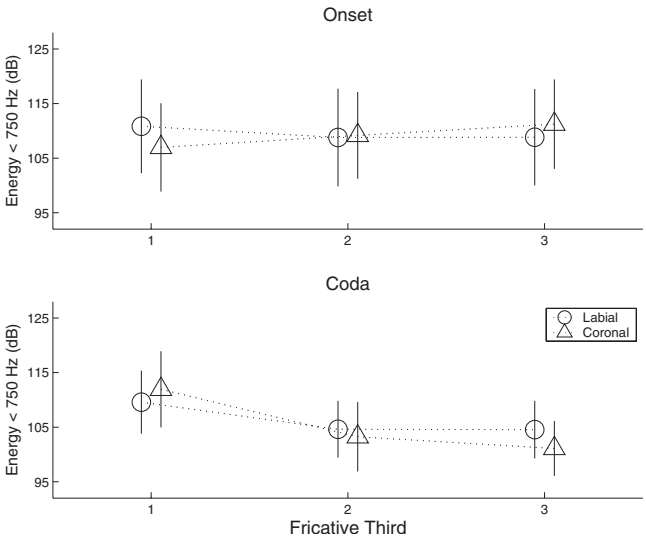

FIG. 9. Voicing power (in dB re: 1 bit) as a function of place of articulation, prosodic context, and fricative third. The *x* axis indicates time, or the first, second, and middle third of the fricative. The *y* axis indicates power in decibels relative to one bit. Circles indicate mean voicing power for labial fricatives, triangles for coronal fricatives. Solid error bars indicate ±1 s.d. The top panel indicates values for onset fricatives, the bottom panel for coda fricatives. The plots are staggered and nonvertical lines are plotted to ease comparison across voicing specification.

None of the general focus or disambiguation-specific power measure predictions were confirmed, though, as predicted, both of the focus conditions produced slightly higher noise and voicing power, as can be seen in Table 3.

Higher degree of voicing near the vowel should exhibit itself as a voicing by prosodic context interaction—onset fricatives should have higher power at the last measurement, whereas coda fricatives should have higher power at the first measurement. Figure 8 shows that, while phonologically voiced fricatives had higher low-frequency power than did phonologically voiceless fricatives, and while coda fricatives did indeed exhibit considerably more low-frequency power in the first third than at either of the other two thirds, onset fricatives had a more or less constant, perhaps slightly increasing level of low-frequency power.

The place by prosodic context interaction is also evident in the low frequency power measures. Figure 9 shows that voicing power in labiodentals decreased slightly over the three measurements (to a greater extent in coda than in onset position), whereas low frequency power increased for onset coronals and decreased for coda coronals.

The gender by voicing interaction is due to a much larger difference between phonologically voiced and phonologically voiceless fricatives in the first, and to a lesser degree the second, low-frequency power measurement in the productions of the male speakers than in productions of the female speakers. This is likely due, at least in part, to the fact that female speakers with higher fundamental frequencies would have fewer harmonics present below the 750 Hz cutoff employed.

IV. DISCUSSION AND CONCLUSION

Many previously documented differences between fricatives were observed here. The phonologically voiced fricatives were shorter than their voiceless counterparts. Coronal fricatives had higher spectral means, lower spectral standard deviations, higher spectral kurtosis, and had substantially more acoustic power than their labiodental counterparts. Phonological voicing increased the amount of low frequency power and reduced the acoustic power of frication noise, and had some, though not all, of the expected effects on the spectral moment measurements (e.g., voiced fricatives tended to have lower spectral means than their voiceless counterparts). The coda fricatives tended to be devoiced and lengthened.

Some expected properties of the fricatives were absent in the present data, however. Voiced coda fricatives were not preceded by longer vowels than their voiceless counterparts. For the male speakers, spectral skewness was higher for coronals than for labiodentals, and spectral means, while higher for coronals than for labiodentals, were much lower than expected. The duration of coronals was not statistically significantly different than the duration of labiodentals. Place of articulation also interacted with prosodic context with regard to the three low frequency power measurements—coronals had more low frequency power near the associated vowel (i.e., at the third time slice in onset position, at the first in coda position), whereas labiodentals in both prosodic contexts tended to decrease in low frequency power.

With regard to reduction effects, the general picture that is suggested by comparing onset and coda fricatives is that, as in vowels, fricative reduction is reflected, in part, in changes in acoustic power. However, unlike typical reduction effects, the coda fricatives in this corpus were longer than their onset counterparts, probably due to phrase-final lengthening. Interestingly, in coda position all spectral means are lower, while the spectral standard deviations take values intermediate between those of onset position. This suggests an acoustic characterization of reduction as consisting of a loss of higher frequency noise energy and the presence of relatively undifferentiated shaping effects.

The most obvious effect of focus was an increase in both fricative and syllable durations. Recall that fricative durations are expressed here as a proportion of syllable duration. The spectral mean increased slightly and spectral skewness decreased slightly in both focus conditions, and focus induced small increases in both noise and voicing power. All of these effects suggest that speakers were simply increasing articulatory effort. None of the disambiguation-specific predictions were borne out; both disambiguation conditions induced essentially the same general focus behavior.

The present results contrast with previous findings that focus induces hyperarticulation, which, in turn, selectively exaggerates linguistically important cues (de Jong, 2004; de Jong and Zawaydeh, 2002). A key difference between the present project and those reported in the above-mentioned papers is the nature of the segments under investigation, de Jong (2004) and de Jong and Zawaydeh (2002) studied the effects of focus (and stress) on vowel production, whereas this paper addresses fricatives. The differences in findings regarding the effects of focus between this and previous projects suggest that fricatives and vowels are subject to very different production pressures; vowels seem to be more malleable than fricatives. This finding is consistent with earlier articulatory research on prosodic position effects in which fricatives seem to be more resistant to changes in articulatory strength (Fougeron, 2001).

Although it is speculative to suggest a link, this idea is also consistent with work on word recognition wherein Dutch and Spanish native speakers were found to be more accurate and faster when required to change a vowel than when required to change a consonant, and more apt to change a vowel than a consonant when given a choice, in order to form real words from nonwords (Cutler *et al.*, 2000). Insofar as the present results reflect a difference in malleability between vowels and fricatives, we may conclude that the most one can hope for in cue-enhancing hyperarticulation in fricatives is increases in length and power. Longer and louder fricatives likely offer more and better opportunities to hear the relatively static phonetic cues for features like voicing and place of articulation.

However, one must be cautious in generalizing the current results to fricatives in general. The small set of fricatives examined here likely does not display the full range of variation in fricative production. For example, it is possible that the alveolar and palato-alveolar sibilants, which differ not just in lingual articulation but also secondary rounding, might exhibit focus-induced changes. If the lack of focus effects on fricative spectra depends on relatively stringent articulatory constraints on labial and lingual contact, it is still possible that the relatively free use of lip rounding might allow for focus variation. An obvious next step would be to extend the current approach to other segments and languages with different fricative inventories.

There are other possible reasons for the lack of focus effects here. Perhaps most obviously, while desirable for the control over extraneous factors (e.g., elimination of variables that were not of interest, such as word frequency), the use of nonwords as target syllables potentially reduces the communicative load of the carrier utterances. Because phonological contrasts function as cues to differences in meaning, by removing semantics from the picture (along with word frequency effects), the voicing and place contrasts' function was eliminated. Of course, it may also be the case that speakers are unable to attend selectively to subsegmental properties of speech sounds. The use of real words in a task in which a premium is placed on accurate communication of those words may better probe the speaker's ability and willingness to focus on the low-level characteristics that cue one contrast or another. Assuming that an appropriate set can be found, real words also offer the possibility of comparing current results with previous work, e.g., the effects of stress and focus in de Jong (2004) and the irregular differences in patterns of devoicing between real and nonwords in Jesus and Shadle (2002).

Finally, although an examination of within-subject variability is not the primary focus of the present research, it is noteworthy that statistically significant within-subjects main effects and interactions were found in the spectral measurements. Although some of these effects may be attributable to, e.g., changes in behavior over the course of the experiment, it seems that much of the variability across blocks is not due to task variables, but is a stable indicator of the different talkers. Of course, the existence of within-speaker and within-category variation is to be expected. However, given the differences in the variability of the spectral moments across place of articulation and speaker gender, a systematic investigation of this variation is called for, since such acoustic variation is a potentially important indicator of indexical differentiation in the face of linguistically specified aspects of the signal.

ACKNOWLEDGMENTS

This work was supported by the NSF Grant No. BCS-04406540. We would also like to thank Professor Diane Kewley-Port for her assistance in conducting this research, Dr. Christine Shadle for her comments and suggestions in her capacity as Associate Editor, and three anonymous reviewers for their helpful comments, all which have improved this work considerably.

What marks the beat of speech?

Greg Kochanski[a] and Christina Orphanidou
Phonetics Laboratory, University of Oxford, 41 Wellington Square, Oxford OX1 2JF, United Kingdom

(Received 4 December 2006; revised 7 February 2008; accepted 8 February 2008)

Which acoustic properties of the speech signal differ between rhythmically prominent syllables and non-prominent ones? A production experiment was conducted to identify these acoustic properties. Subjects read out repetitive text to a metronome, trying to match stressed syllables to its beat. The analysis searched for the function of the speech signal that best predicts the timing of the metronome ticks. The most important factor in this function is found to be the contrast in loudness between a syllable and its neighbors. The prominence of a syllable can be deduced from the specific loudness in an (approximately) 360 ms window centered on the syllable in question relative to an (approximately) 800-ms-wide symmetric window. © *2008 Acoustical Society of America.*

I. INTRODUCTION

Patterns of prominence define the rhythmicity of speech, which is an important characteristic of stress-timed languages, English among them. The purpose of this study is to find which acoustic properties of the speech signal mark rhythmic prominence. We investigate this with a new production-based experiment; it involves auditory perception only to the extent that subjects extract a beat from a metronome tick.

While a number of papers have studied acoustic correlates of prominence, human perception of speech has played a central part in most of them, with listeners being asked to identify prominent units in speech. The prototypical experiments are those of Fry (1955, 1958), who synthesized isolated disyllabic words and asked listeners to choose which syllable was stressed (≈ prominent). These papers are mostly of historic interest because the synthesis may not have been very realistic and the stimuli were very simple compared to natural speech.

Other workers (Beckman, 1986; Streefkerk *et al.*, 1999; Brenier *et al.*, 2005; Silipo and Greenberg, 2000; Kochanski *et al.*, 2005) have studied more realistic speech, some using actual conversations. These studies investigated the relative importance of a variety of acoustic factors to prominence. Streefkerk *et al.* (1999) tested several acoustic features such as duration, loudness, spectral slope of vowels, as well as median f_0 over a syllable, and the range of f_0 over a syllable. They concluded that all but the spectral slope had promise as predictors of prominence.

Brenier *et al.* (2005) tested 12 acoustic and lexical features and found that the maximum intensity was the most effective for emphasis detection, followed by duration and f_0. Silipo and Greenberg (2000) found that a combination of intensity and syllable duration was the best predictor of their "prosodic stress" (prominence by our definition). Kochanski *et al.* (2005) tested syllable prominence in seven dialects of British and Irish English and concluded that loudness and duration primarily marked prominence in speech, with f_0 relatively unimportant. The experimental consensus is that louder and longer syllables tend to be heard as prominent.

Most of these papers suffer from a common problem: The task used to define prominence is highly artificial and unnatural. Prominence was evaluated by a variant of the following experimental procedure:

(1) Display the speech wave form and f_0 trace on a computer monitor.
(2) Allow the subject (typically a linguist) to listen to the utterance or parts thereof many times.
(3) Have the subject find and mark prominent syllables on the computer screen.

Participants in a conversation normally do not see a graphical representation of their speech, and they hear each utterance only once. Further, they do not consciously classify each syllable as prominent or not,[1] nor is a mouse click the normal behavioral response to speech. Consequently, it is important to see if one would get similar results with a different task.

In our experiment, we employ a more natural approach by giving subjects a production rather than a perception task. The classic production experiment is that of Lieberman (1960), who built a machine classifier to study acoustic properties of prominence. He made perceptual judgments unimportant by selecting sentences that had unambiguous prominence patterns, at the cost of studying utterances that were presumably much more carefully articulated than normal speech. Fear *et al.* (1995) is a noteworthy modern representative of such experiments. Rhythmic speech, often spoken to a metronome, has been extensively studied in relation to stress in speech production and perception (Fowler, 1979; Cummins and Port, 1998; Lehiste, 1973). Boutsen *et al.* (2000) is a recent production experiment; they concluded that speakers use intensity to mark stress patterns, in agreement with the majority of perception-based experiments. Our experiment is most closely related to Cooper and Allen (1977), who collect very similar data, however we use a different analysis to look at the loudness contrasts in more

detail. They focus on the differences between normal subjects and stutterers; we look at what aspects of the speech of normal speakers most accurately reflect the metronome rhythm.

We ask subjects to read text to a metronome, matching their reading to the beat. Before the experimental part of the task, there is a training part which is intended to accustom the subjects to treating metronome ticks as proxies for prominence. We then analyze the speech to find stable timing relationships between acoustic properties and the metronome ticks.

One important feature of our work is that we use naive native speakers, rather than linguists. This reduces the possibility that the prominence marks may be influenced by theoretical expectations. No conscious judgments of prominence are required and no visual cues are involved in this experiment. This experiment provides a different experimental view of prominence, with different biases and limitations from the classical technique.

One could argue that the task is not ideal in that the phrases must be spoken repetitively, which brings in the risk that repetitive speech is different from more natural speech. However, we have checked this possible problem in other, more recent work (Kochanski and Orphanidou, 2007). We found that spectral differences between repetitive speech and speech from a list of randomized phrases are not large, so one would expect other aspects of speech, like prominence, to be similarly unaffected.

Work has been published in the related field of music analysis, where algorithms have been designed to extract the beat and/or metrical pattern of music using metronomic stimulation. See Scheirer (1998), Klapuri *et al.* (2006), Todd and Brown (1996), Large and Palmer (2002), and references therein. The techniques differ from ours for various reasons, for instance, unlike speech, many musical sounds have sharp onsets (e.g., drums, pianos). Further, algorithms can exploit the fact that the beat of music is very nearly periodic; they can keep long-term correlations and use them to help predict the next beat. Conversely, our algorithm is designed to be applicable to normal speech, which is not very periodic. It therefore operates on a small window of time, with no explicit memory of previous prominences.

II. EXPERIMENTAL METHODS

The experiment involved several tasks and lasted for approximately 1 h; only some of the later tasks are analyzed. The earlier tasks were intended to train the subjects to put the metronome beat on metrically prominent syllables.[2]

A set of 53 short phrases (4–6 syllables) were central to the experiment (see Appendix B for a list). The phrases had four different metrical patterns: 12 of *SuSu*, 12 of *uSuS*, 13 of *SuuSuu*, and 16 of *SuuS*, where *S* denotes a stressed syllable and *u* unstressed.[3] The phrases were selected from Project Gutenberg (Hart *et al.*, 2006), based on patterns of stress predicted by UNISYN (Fitt and Isard, 1999; Fitt, 2002).[4] Phrases were selected for broad coverage of phonemes, minimal repetition of words, and a lack of obsolete and unusual vocabulary. They were reviewed to confirm that the UNISYN stress assignments led to a reasonable reading. All phrases have at least one polysyllabic word and they have an average of 1.4 monosyllabic words.

As a warm-up, subjects read out a poem (Nesbitt, 2001, "My Excuse") and then read it out again while tapping their finger to what they considered to be stressed syllables.

Next, a metronome was connected to an earphone, and subjects were asked to choose the two most comfortable rates at which they could read text with a strong metrical pattern. To pick a comfortable metronome rate, the metronome was started and the subject was asked to read the poem again. After a few lines, the subject was asked "faster, slower, or is that OK?" If necessary, the metronome was adjusted by one click (typically 4 beats per minute) and the process continued until the subject said "OK." They were then asked to pick a second rate, either four beats faster or slower than the first one. They then read the poem at both rates, matching their reading to the beats of the metronome.

In the next tasks, subjects read 48 short paragraphs from which the phrases had been extracted, then read a randomized list of 264 phrases, which included five repetitions each of the above-mentioned set of phrases.[5]

In the final set of tasks, subjects were presented with the above-mentioned set of phrases, from which four groups of 12 were randomly selected, with the groups balanced by metrical pattern. Subjects were asked to read out ten consecutive repetitions of each phrase. The repetitive task was intended to allow the subject to settle upon the easiest (perhaps the most natural) metrical pattern. The number of repetitions was intended to allow subjects to conveniently say them all in one breath. The first group of 12 was simply read out. For the second group, the subject was asked to read and simultaneously "Tap your finger to what you consider a stressed syllable."

We analyzed the data from the third and fourth groups of 12 phrases, which were read out to metronome ticks. One group was read at each of the two rates that the subjects chose earlier. Subjects were instructed to "Read, trying to follow the beat of the metronome." The metronome rates were 86 ± 7 beats per min (0.71 ± 0.06 s intervals between beats), and the mean length of ten repetitions of the phrase was 13.4 ± 2.4 s. (In this paper, means and standard deviations are given in the form $\mu \pm \sigma$, where σ is the standard deviation of the distribution, not the standard error of the mean.) There were 0.91 ± 0.15 metronome ticks per stressed syllable (assuming stress as predicted by UNISYN).

Participants were linguistically naive speakers of Standard Southern British English. All were either undergraduate or graduate students at Oxford University. Five females and four males were recruited by mailing list advertisements.

Each subject was recorded with an electret microphone positioned approximately 10 cm from his/her mouth, to the side of the breath stream. Recordings were taken in a acoustically insulated recording booth. The audio signals were sampled at 32 kHz with 16 bit resolution.

Metronome ticks were fed to the subjects through an "ear-bud" style earphone on the opposite side from the microphone that recorded their speech. It was adjusted to a comfortable loudness level for each subject. The metronome

ticks were recorded on one channel of a stereo recording and cannot be heard in the other channel which carries the microphone signal.

The start and end points of the speech were automatically determined by an algorithm that finds the borders of a loud interval, surrounded by quiet regions on both edges. It is a modified version of techniques used in Kochanski *et al.* (2005). All end points were manually checked at the same time we checked the tick marks. Fewer than 10% were adjusted. In total, approximately 3000 syllables (and tick positions) were examined.

III. ANALYSIS TECHNIQUES

In the analysis, we search for the function of the speech data that is best at predicting the metronome ticks. The function is expressed as a simple algorithm that has several adjustable parameters. It takes a wave form and yields a set of predictions; we compute the timing accuracy of the predictions and adjust the parameters to maximize that accuracy. We can then interpret the parameters to see how the subjects express rhythmical prominence.

A. The algorithm

The algorithm computes a signal from the speech wave form, convolves the signal with a kernel, and picks maxima of the result. Large maxima become predictions of metronome ticks. The signal we use is related to the perceived loudness of the speech, but we also try modifications that include information from the pitch of the speech, voicing, and the overall slope of the local speech spectrum.

It is motivated by perception experiments (Kochanski *et al.*, 2005) showing that prominent syllables are typically louder. The algorithm begins by computing a time series of the specific loudness, $L(t)$, from Kochanski *et al.* (2005),[6] derived originally from Stevens (1971). This specific loudness is then convolved with a kernel K to yield $x(t)$ as an intermediate result. We use[7]

$$x = K^*(Lg). \tag{1}$$

Other acoustic properties of the speech will be included via g, and will be described in more detail in Sec. III B. We will test different values for g, beginning with $g=1$, then functions of f_0, voicing periodicity, and spectral slope.

We chose a product form in Eq. (1) to express the fact that the other acoustic parameters become irrelevant as L approaches zero. For instance, if the signal is quiet enough relative to nearby regions, the pitch of the quiet region will be perceptually unimportant.

We chose a convolution kernel, K, which has a zero mean and is the difference between two Gaussians:

$$K(\tau) = e^{-(\tau - a\sigma)^2/2(b\sigma)^2} - be^{-\tau^2/2\sigma^2}, \tag{2}$$

where τ is the time delay, σ controls the overall width of the kernel, b (which is typically less than 1) is the relative width of the positive Gaussian, and a controls where the positive Gaussian sits. If $a=0$, K is symmetric in time and corresponds to the difference between a syllable and both of its neighbors; if $a \neq 0$, then the contrast with either the left or the right neighbor is more important. One can interpret σ as the width of the region that is used to normalize the local loudness information.

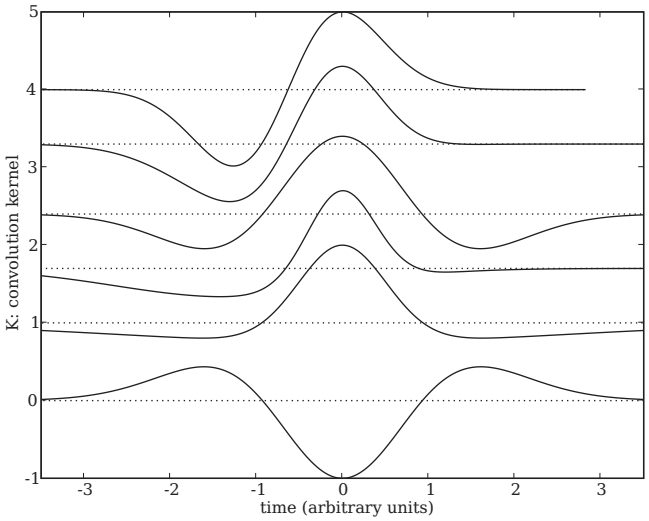

FIG. 1. Possible shapes for the convolution kernel, $K(\tau)$. More possible shapes can be obtained by reversing the time (delay) axis or the vertical axis.

Figure 1 shows the range of shapes that $K(\tau)$ can take. The top two would respond best to stepwise increases in Lg, the next down responds to the contrast of a syllable with the nearest syllable on each side. The next two show contrasts against broader regions than the nearest neighbor(s), and the lowest curve shows a kernel that responds to a local minimum in Lg.

In the next step, we consider regions where $x(t)$ is positive and take the time of the largest value in each region, $t_i^{\max}$. The final set of syllable times, T, is then computed by dropping any values of $t_i^{\max}$ where either $x(t_i^{\max}) < rx(t_{i-1}^{\max})$ or $x(t_i^{\max}) < rx(t_{i+1}^{\max})$. In other words, one drops t-values whose x is substantially smaller than their neighbors. The process is controlled by the adjustable parameter r: If $r \ll 1$ all the maxima are preserved, while if r is close to 1 only the largest few maxima in each utterance survive.

B. Acoustic properties beyond loudness

As there is some evidence that acoustic properties other than L contribute to prominence judgments, we investigated a set of alternatives for g in Eq. (1). They were as follows:

(1)

$$g_1 = 1. \tag{3}$$

The resulting timing estimates are based only on L.

(2)

$$g_2(t) = 1 + \eta V(t)\left(\frac{f_0(t)}{\langle f_0 \rangle} - 1\right), \tag{4}$$

where $f_0(t)$ is the speech fundamental frequency, as determined by the GET_F0 program from the ESPS package (Entropic Corp.). $V(t)$ is 1 or 0, indicating whether or not the speech is voiced (it also is produced by GET_F0), and $\langle f_0 \rangle$ is the average f_0 over the voiced parts of the utterance. Thus, if

$\eta > 0$, voiced sounds with relatively high f_0 are emphasized, while if $\eta < 0$, voiced sounds with relatively low f_0 would be treated as louder.

(3)

$$g_3(t) = 1 + \zeta V(t) \left| \frac{f_0(t)}{\langle f_0 \rangle} - 1 \right|, \tag{5}$$

with variables as noted earlier. Thus, if $\zeta > 0$, voiced sounds with either high or low f_0 are emphasized relative to those with f_0 near average. Conversely, if $\zeta < 0$, voiced sounds with near-average f_0 or unvoiced sounds would be treated as more important.

(4)

$$g_4(t) = 1 - \alpha A(t), \tag{6}$$

where $A(t)$ is the aperiodicity measure from Kochanski *et al.* (2005). [Related measures have been developed by de Krom (1993) and Boersma (1993).] Vowels have small aperiodicities (typically less than 0.5), while fricatives have aperiodicities near 1, so α controls how important fricatives (and other consonants) are in the expression of prominence.

(5)

$$g_5(t) = 1 - \gamma S(t), \tag{7}$$

where S is a measure of the average slope of the speech spectrum. It is related to the ratio of power below 1 kHz to the power above 1 kHz, and is described in detail in Appendix A. Related measures have been developed by Heldner (2001); Sluijter and van Heuven (1996), and references therein.

We define S so that its histogram is approximately centered around zero, and positive S corresponds to excess high-frequency power. Consequently, a positive γ would cause sounds with more high frequency power (like fricatives and harshly spoken vowels) to be treated as louder; on the other hand, sounds like /m/ and gently spoken vowels would be treated as emphasized if $\gamma < 0$.

(6)

$$g_6(t) = g_2(t) g_4(t) g_5(t). \tag{8}$$

We conduct an analysis where g is the product of Eqs. (4), (6), and (7). This allowed for prominence to be determined by an arbitrary combination of voicing irregularity, spectral slope, and f_0.

C. Optimizing the parameters

We based our analysis on the metaphor of coupled oscillators (Large and Kolen, 1994; Saltzman and Byrd, 2000; Port, 2003). Following that metaphor, we constructed a time series of phase for both the tick sequence and for the set of syllable times T produced by the algorithm. The phase is 0, 2π, 4π,… at successive ticks, linearly increasing in between. The metronome phase $\phi(t)$ is then a linear function of time, with a slope equal to 2π divided by the interval. A similar phase function, called $\psi(t)$, is defined from T; it increases by 2π for each element of T. It is defined between the first and last elements of T that fall within the speech.

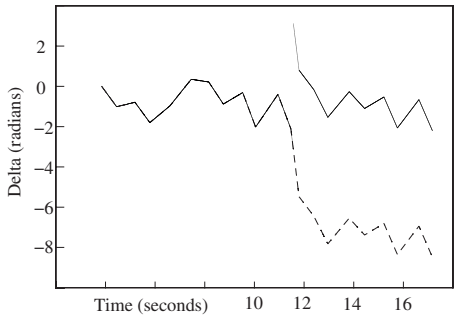

FIG. 2. The phase $\Delta(t)$ for a typical utterance plotted against time. The algorithm missed a prediction near $t = 10.8$ s, then behaved well for the rest of the utterance (dashed line). The solid line shows Δ, wrapped into the range from $-\pi$ to π to simulate the behavior of Eq. (10).

If the algorithm produced a periodic series of predictions in T, then $\psi(t)$ would also be a straight line. For a regular pattern with ticks and predictions coming at the same average rate, the slopes of ϕ and ψ will be equal, and the difference,

$$\Delta(t) = \phi(t) - \psi(t), \tag{9}$$

will be a constant. At each moment, Δ can be interpreted as a phase difference between the stream of ticks and the stream of predictions in T.

One could use the variance of $\Delta(t)$ as a measure of how well the two sequences are related, but it would be extremely sensitive to missed events. One missing or extra element in T would change Δ by 2π for the remainder of the utterance. Thus a single missed prediction could dramatically increase the variance, as can be seen from the dashed line of Fig. 2.

Instead, we compute[8]

$$I = \frac{1}{\mathbb{L}} \int \exp(i\Delta(t)) dt, \tag{10}$$

where the integral is taken over the part of the utterance where ψ and ϕ are both defined; $\mathbb{L}$ is the integral's length (in seconds).

If the times in T match the metronome ticks so that $\Delta(t)$ is constant, then the exponential will be a complex number of constant phase and unit magnitude, and the magnitude of I will be unity. This gives the largest possible magnitude for I; any mismatches will reduce it. So, $|I|$ tells how well the two sequences match, and the phase of I describes when the ticks occur relative to T.

Putting $\Delta(t)$ into an exponential makes the analysis relatively insensitive to dropping or adding one prediction. In either case, the argument to the exponential changes by 2π radians during the gap, but the value of the exponential swings around and returns to the value it had before the gap.[9] In such a case, $|I|$ would be reduced from 1 to about 0.9 for our conditions. The solid line in Fig. 2 shows the effect of the exponential, wrapping together values of Δ that differ by 2π.

We can interpret I in two related ways. Starting with $I = 1$ as implying perfect correlation, I is reduced whenever there is a missing or extra prediction. Alternatively, we note that when var(Δ) is much less than 1, $I \approx 1 - \text{var}(\Delta)$, so that a

decrease in I can be interpreted as an increase in the variance of Δ and thus as increased timing errors between the ticks and T.

Now we can compute I for an utterance, given the parameters that control the algorithm. Then, for a corpus, we can compute the average of the magnitude of I, i.e., $\langle|I|\rangle$. $\langle|I|\rangle$ is thus a function of the algorithm's parameters. It is an overall figure of merit for how well the algorithm's predictions match the ticks.

We then find the optimal parameters for the algorithm by evaluating $\langle|I|\rangle$ for 90 000 randomly chosen combinations of parameters and taking the one that produces the largest absolute value. This simple technique for finding the best parameters was chosen because I, and thus $\langle|I|\rangle$, is a discontinuous function of the algorithm's parameters. (More efficient optimization algorithms are not applicable, as they typically assume that the function to be optimized is continuous, and often that it has continuous first derivatives.)

By optimizing in this way, we are explicitly searching for acoustic properties that repeat with the same periodicity as the metronome ticks. The resulting parameters will be most representative of those utterances with one nominally stressed syllable per metronome tick.

D. Bootstrap resampling and confidence intervals

The above-presented technique is good for finding the parameters that give the best match to the data but it needs to be extended to find error bars and confidence intervals. For this purpose, we use a bootstrap resampling scheme (Davison and Hinkley, 1997). We compute 3400 artificial corpora, constructed by choosing utterances from the real corpus, sampling randomly with replacement. In each artificial corpus, most utterances appear once, but some do not appear at all and some appear several times. The same analysis procedure can then be repeated for each artificial corpus, leading to optimal parameters for each. In practice, we use a mathematically equivalent but faster technique. We compute the values of I for each combination of utterance and parameters, then the bootstrap resampling is implemented as a weighted average in the computation of $\langle|I|\rangle$. (Each weight is just equal to the number of times that datum was chosen.)

The resulting distribution of optimal parameters then approximates what one would get by replicating the entire experiment with new subjects drawn from the same pool. So, if one wishes to estimate the probability that some parameter p exceeds a threshold, X, one can simply count the fraction of artificial corpora where the optimal $p>X$. Thus, we use bootstrap resampling to generate confidence intervals for $|I|$ and the algorithm's parameters.

E. Timing data

We processed both the metronome and speech channels with the same algorithm (Sec. III A). Its use on the speech channel is a major focus of this paper; we used it to find the metronome ticks merely out of convenience. The metronome data are short bursts of oscillation amid silence, and almost any algorithm will be equally successful at finding the ticks.

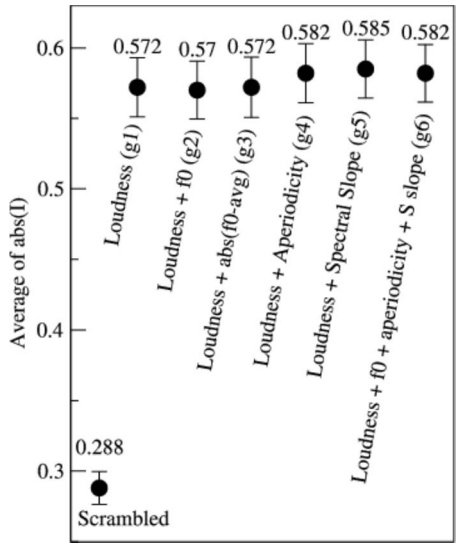

FIG. 3. Values if $|I|$, averaged over the corpus. The lower left measurement is the baseline, where acoustic data are shuffled with respect to ticks. Other conditions correspond to the six cases of Sec. III B, in order: running the analysis only on L ($g=g_1$), and L enhanced by other acoustical properties ($g=g_{2,\ldots,6}$).

For the metronome channel, rather than computing L (see Sec. III A), we used the rms power above 100 Hz in the metronome output, averaged over a 15 ms window. This signal was then used in Eq. (1) in place of L to yield an initial set of tick times. The algorithm's parameters were set by informal experiment to $g=1$, $a=0$, $\sigma=0.110$ s, $b\sigma=0.015$ s, and $r=0.5$. The result was inspected and no errors were found.

IV. RESULTS AND DISCUSSION

A. Relevant acoustic measures

We first confirm that the algorithm performs better when given acoustic data than it would without any data. This is the basic check that it can usefully predict anything. To do this, we first perform the analysis with $g=1$ and find $\langle|I|\rangle=0.572\pm0.02$. Then, we repeat the analysis, except we shuffle the data so that we use ticks from one utterance and acoustic data from another. Comparing, the shuffled results are substantially poorer than the actual analysis, with $\langle|I|\rangle$ only 0.290 ± 0.013. The difference between normal and shuffled analyses is statistically significant at $z>9$ or $P\ll10^{-5}$. Thus, based on L, metronome ticks can be predicted at much better than chance levels. All choices of g show similarly large and significant changes.

Next, we investigate which acoustic properties carry the most information, as shown by an improvement in the tick prediction. Can adding other information to L improve the tick prediction? To do this, we insert different choices of g from Sec. III B into Eq. (1) and see if $\langle|I|\rangle$ increases. The results are displayed in Fig. 3. Changing g to bring in other acoustic data gives little or no improvement over $g=1$.

Because the analysis with $g=g_6$ involves more parameters, it might be argued that we do not sample densely enough in the higher-dimensional parameter space to find the

maximum. While an exhaustive test is not practical, we did check for this possibility by recomputing the $g=g_6$ case with ten times as many samples (9×10^5 sets of parameters). This makes only a modest change: $\langle|I|\rangle$ increases by just 0.01. Since the change is small, it suggests that we have indeed sampled parameters close to the maximum even in the higher dimensional $g=g_6$ parameter space, and that little further increase would be expected even with more samples.

Figure 3 shows that L is an important correlate of the ticks, but it would not exclude the possibility that g is of comparable importance to L, if g and L marked the same locations. We can check that by looking at the distribution of α, γ, η, and ζ in suitable optimizations. If an acoustic measurement (e.g., f_0) were important, we would expect that the distributions of, e.g., η (which indicates changes in f_0—see Sec. III B) would be narrow. Assume, for instance, that ticks are marked by high f_0. In that case, we would expect a positive η so that the contributions of f_0 and L would reinforce each other. Running the algorithm with negative η would cause the contributions to cancel. L would then cancel the main effect of f_0 and vice versa, leaving only the fluctuations; one would not then expect the peaks of x to be correlated with either metronome ticks, L or f_0.

Similarly, if f_0 and L were anticorrelated, the same logic would apply and η would be negative. (If η were near zero, it would imply that the best tick predictions are done without the use of f_0, which contradicts the hypothesis that f_0 is important.) Either way, if f_0 were important, we would expect that η would have a reasonably narrow distribution, on one side or the other of zero. A broad distribution of η, roughly centered on zero, is thus evidence that the algorithm gets no useful information from f_0 via Eq. (4). The same logic applies to α, γ, and ζ.

For α, η, and ζ the distribution is broad and overlaps zero. The optimal values of η for the $g=g_2$ analysis is 0.0 ± 0.5. This provides additional evidence that f_0 does not usefully contribute to the prediction of metronome ticks (i.e., rhythmic prominence),[10] since the distribution includes $\eta=0$. The deviation of f_0 from the average ($g=g_3$) is also unimportant, with $\zeta=0.2\pm0.9$: subjects do not reliably mark prominent syllables by pushing f_0 away from the utterance mean. Likewise, the aperiodicity is not important; optimal $\alpha=-0.3\pm0.7$.

On the other hand, the spectral slope has some relationship to the ticks. The distribution of optimal values is $\gamma=0.6\pm0.3$, so that distribution overlaps zero only slightly: just 1% of the sets of optimal parameters are negative. So, syllables on the beat have some excess high frequency power. However, it is not a large effect; we estimate that $g_5(t)$ gives the same effect as a 20% change in L (roughly equivalent to a 5 dB change in acoustic power). (Perceptually, a 20% change in loudness is not large.) This is consistent with our result that $\langle|I|\rangle$ does not substantially increase when spectral slope information is added to L (Fig. 3). The small size of the effect is further confirmed by computing the correlation coefficient between $L(t)$ and $S(t)$, the spectral slope measure defined in Appendix A: It is just 0.03.

The straightforward interpretation of this is just that the specific loudnesses at frequencies over 1 kHz go up more, on the beat, than the specific loudnesses at lower frequencies. Such a shift in the spectral balance for vowels was measured by Glave and Rietveld (1975) and Gauffin and Sundberg (1989).

This weak correlation of a spectral slope measure with metronome ticks is in general agreement with the results of Kochanski *et al.* (2005), though the spectral slope computations differ. A comparison with Sluijter and van Heuven (1996) is not simple; they analyzed dependencies on focus (i.e., accent) and stress separately, while we effectively compare [+focus, +stress] with the neighboring syllables which are either [−focus] or [−stress]. Heldner (2001) showed that his measure, called "spectral emphasis," is a good predictor of accent. Our results do not support this (but are not inconsistent as his spectral emphasis measure is substantially different).

TABLE I. Parameters that yield the largest $\langle|I|\rangle$. The analysis operates on L only ($g=1$). The right column shows the distribution of values that were tested in the optimization procedure (90 000 samples), and the center column shows the distribution of optimal values that were found (3400 bootstrap corpora).

Parameter	Optimal value	Distribution of test evaluations: mean ± s.d.
σ	0.176 ± 0.028	Gaussian 0.19 ± 0.07
a	-0.01 ± 0.03	Gaussian 0 ± 0.4
b	0.83 ± 0.07	Uniform on [0.5,1]; thus 0.75 ± 0.16
r	0.04 ± 0.04	Uniform on [0,0.4]; thus 0.20 ± 0.12

B. How localized is prominence?

Since the primary acoustic marker of rhythmical prominence is L, we now focus on that case ($g=1$) and describe the remaining parameters. Three parameters (a,b,σ) define the shape of the convolution kernel K, and one (r) controls the rejection of small peaks. Table I shows optimal parameters. The rightmost column shows the distribution of parameters we sampled; in each case, the distribution of optimal parameters can be seen to be narrow and not too far off center, so our choice of sampling distribution is not seriously constraining the distribution of optimal parameters.

We also check that our analysis is not simply detecting the gap between repetitions. This is confirmed by noting that the median spacings between predictions in T (0.67 s for metronome for $g=1$) is substantially smaller than the median length of a repetition (1.30 s). Thus, we are not locked onto a single prediction per repetition; in fact, we are seeing close to one prediction per stress, or two predictions per repetition. Also, we note that the average integral over *uSuS* patterns is essentially the same as that for *SuSu* patterns (0.549 vs 0.558, not significantly different) while we might expect a substantial difference if predictions were tied to the beginning of each repetition but the metronome ticks followed the stresses.

The optimal values of r are small, so that the last step of the algorithm is almost moot; it rejects very few candidates.

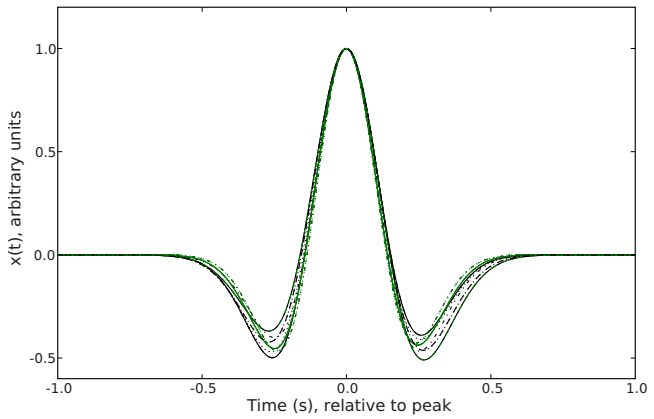

FIG. 4. (Color online) Convolution kernels, $K(\tau)$, that are optimal for bootstrap samples of the data. The maxima of the curves are aligned at $t=0$. (These kernels maximize $\langle|I|\rangle$, and have α, γ, and η zero, corresponding to $g=1$.)

The other three parameters are closely coupled, and can most easily be interpreted visually, by plotting $K(\tau)$. Figure 4 shows a set of convolution kernels that are computed from sets of (a,b,σ) which are optimal parameters for bootstrap corpora. The curves show examples of $K(\tau)$ that are consistent with the data, analyzed assuming $g=1$. Since the analysis procedure is invariant with respect to shifts of the peaks of x, we can align the peaks of K for clarity without changing $\langle|I|\rangle$. The shape of K is important because it tells us which contrasts are important for predicting a tick. In this case, the contrast is approximately symmetrical: the syllables preceding and following the metronome tick are equally quiet.

Figure 5 shows convolution kernels that are optimal for the $\langle|I|\rangle$, $g=g_6$ analysis. The analysis is entirely consistent with Fig. 4, but with somewhat larger scatter as we are fitting a more complex model to the data.

The widths and relative spacings of the peaks are remarkably consistent. Values for σ, which is related to the overall width of the kernel, are in Table I. The full-width at half-maximum (FWHM) for the highest peak in K is 0.184 ± 0.008 s, and the magnitude of the time interval between the most positive and most negative peaks is 0.31 ± 0.04 s for the $g=1$ analysis, so the entire window of relevant speech data spans approximately 800 ms. The numbers are similar for the $g=g_6$ analysis, 0.183 ± 0.01 for the FWHM and 0.26 ± 0.01 for the peak spacing.

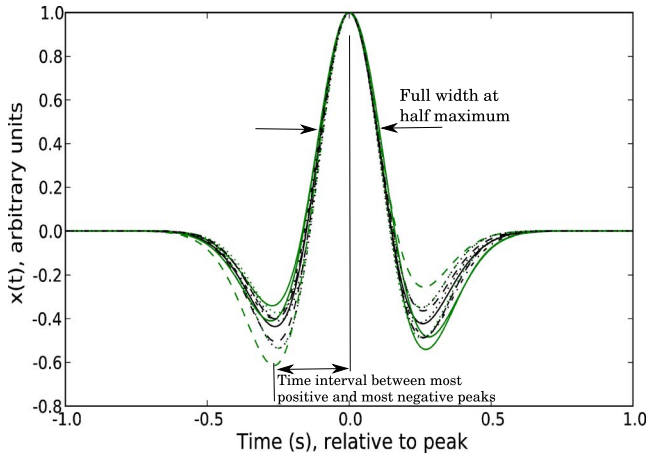

FIG. 5. (Color online) Optimal bootstrap samples of the convolution kernel, $K(\tau)$, for the $g=g_6$ analysis. The maxima of the curves are aligned at $t=0$. (These kernels maximize $\langle|I|\rangle$, and allow α, γ, and η to be nonzero.)

The positive peaks of the kernel are as wide or wider than a typical vowel, and about two-thirds of the mean syllable spacing, 0.27 s. The full extent of the kernel, given by $2\sigma\approx0.34$ s, is wider than the mean syllable spacing, and the time interval between the positive and negative peaks is just about equal to the mean syllable spacing. Ticks are thus correlated with the properties of a region larger than a single syllable. Our analysis is consistent with the hypothesis that ticks are related to a large loudness contrast between a syllable and its nearest neighbor(s).

This conclusion is consistent with findings by Kochanski *et al.* (2005), who show an (approximately) symmetric loudness pattern around syllables that were judged to be prominent. The loudness pattern observed there was somewhat narrower, as might be expected, given the faster speech in that study. There are some differences in detail, however. Kochanski *et al.* (2005) reported small but significant correlations of f_0 and A with prominence; but we see none here. The difference may be due to the different tasks (e.g., production versus perception).

An interesting feature of the these results is that the algorithm unifies loudness and duration changes into a single time series, $x(t)$. For vowel durations shorter than K's positive peak, an increase in duration has much the same effect as an increase in loudness; the convolution can be approximated as an integral of loudness over about 0.2 s. It can then be further approximated as the vowel's loudness times the vowel duration. Thus, peaks of $x(t)$ and consequently predictions in T will tend to occur on longer syllables, rather than shorter ones.

An analogous effect, but occurring in speech perception rather than production, can be found in the psychophysics literature. Munson (1947) showed that perceived loudness is a generally increasing function of duration, and Plomp and Bouman (1959) modeled the effect as a convolution of the specific loudness with a kernel. They obtained equivalent widths of their kernel near 0.25 s. This is sufficiently close to our results to support the idea that speech production should be matched to speech perception; the peak value of our $x(t)$ may simply be related to the perceived loudness of the syllable.

Our results are similar to those of Beckman (1986), who found strong correlations of prominence with a similar combination of amplitude and duration, and Silipo and Greenberg (1999, 2000), who had the best success at predicting prominence with a product of syllable-averaged amplitude and vowel duration. It also parallels (on the production side) at least one claim of Turk and Sawusch (1996)—viz. that duration and loudness are perceived together as a single percept.

This agreement with other work is perhaps remarkable, given the differences in experimental technique. Not least because the above-mentioned experiments involve percep-

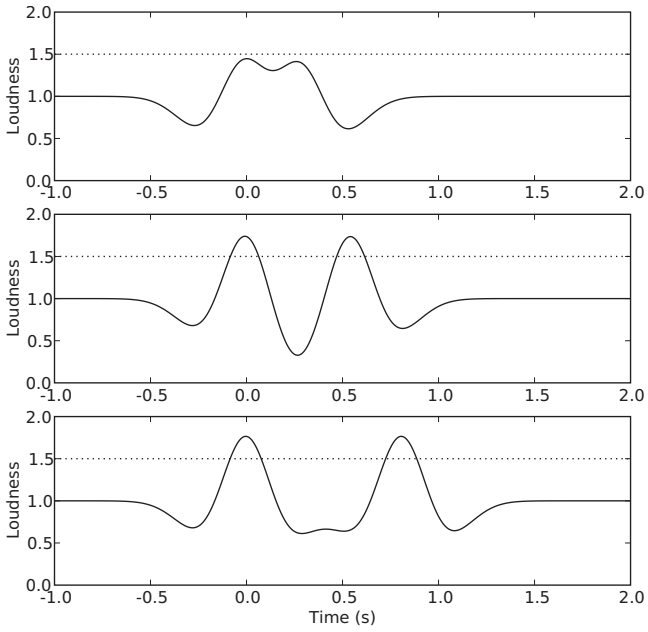

FIG. 6. Theoretical loudness contours based on this work for prominences that are (top) on adjacent syllables, (middle) separated by one, and (bottom) by two syllables. The dashed line is a loudness reference.

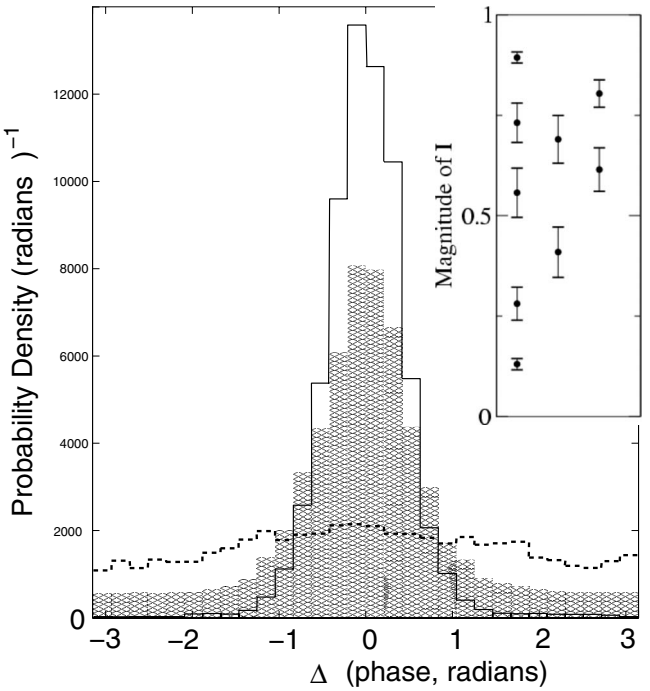

FIG. 7. Phase histograms (Δ, relative to the phase of I) for three different subjects. The subjects shown have (reading from top to bottom, in the center) the largest, median, and smallest value of $\langle|I|\rangle$. The sub-figure shows values of $\langle|I|\rangle$ for each subject, with 1 s.d. error bars on the average. (The horizontal axis in the subfigure has no meaning—it just separates subjects.)

tual judgments (e.g., which syllables are prominent), while our experiment is strictly a production experiment.

C. Alternating metrical patterns and implications for phonology

This result that prominence is expressed by a contrast between a syllable and its neighbors is interesting because it may provide a reductionist explanation of the alternating metrical patterns that are common in many languages.

Consider a loudness pattern like Fig. 4, and place it on a uniform background corresponding to the average loudness of speech. For the sake of argument, suppose that loudness patterns of different syllables add. Then, Fig. 6 shows the resulting loudness patterns for prominences that are separated by one, two, and three syllables.

One can see that the loudness patterns interfere with one another when the prominent syllables are adjacent, and the resulting loudness peaks are then not as dramatic as when the syllables are farther apart. If, hypothetically, the listener had a loudness threshold for the perception of prominence, the case of adjacent syllables would not be perceived as prominent.

To make the adjacent case appear prominent, the speaker would have to make those syllables unusually loud, and/or to push the syllables farther apart so that the loudness patterns would not interfere so strongly. We suggest that speakers may avoid this case because of the extra effort and complexity needed to ensure that a listener will perceive the correct prominences. Over time, this avoidance may become enshrined in phonological rules that reduce the number of adjacent stresses. If speakers avoid one-syllable feet because they are hard to produce clearly, the next simplest foot is two syllable and this potentially might help explain the cross language preference for an alternating metrical pattern.

D. Performance variation between subjects

Subjects differ substantially in terms of how consistently they follow the metronome. This performance variability is seen in Fig. 7, which shows the phase histograms for three speakers. Histograms for the other speakers are similar, displaying the same properties: Large $\langle|I|\rangle$ is correlated with a tall, narrow peak and a low background level, while small $\langle|I|\rangle$ implies a short broad peak sitting on a higher background.

From subject to subject, $\langle|I|\rangle$ varies from 0.13 to 0.90, while the uncertainty in each subject's mean due to intra-subject variation is just 0.05. This is a large range, as the possible range of $\langle|I|\rangle$ is just from 0 to 1.

Analysis of variance rejects the hypothesis that the subject means are equal with $P<10^{-6}$ $[F(9,214)=7.5]$. Some subjects are therefore speaking reliably along with the metronome, while the speech of some others has little consistent relationship to the ticks. By observation, the subjects with the lower values of $\langle|I|\rangle$ show a mixture of two problems: irregular pauses that lead to jumps in Δ, and speech that is simply not synchronized with the metronome rate, leading to a gradual drift in Δ.

For instance, if we select utterances that were spoken with approximately 1 tick per stressed syllable (i.e., 19–21 metronome ticks within the ten repetitions or 0.95–1.05 ticks per stressed syllable), we compute $\langle|I|\rangle=0.69\pm0.28$ for those utterances ($n=119$). This contrasts sharply with $\langle|I|\rangle=0.25\pm0.2$ for utterances which are apparently unsynchronized with the metronome, having 0.65–0.85 ticks per

stress ($n=44$). The three subjects who have the largest number of these unsynchronized utterances are also the three subjects with the smallest values of $\langle|I|\rangle$.

Because of the large range of subject performance, and because it can be automated, this task may be useful as a measure of the ability to process metrical patterns. One possible application is an evaluation tool for stuttering [e.g., Boutsen *et al.* (2000) and Cooper and Allen (1977) showed that stutterers had much larger timing variance in repetitive speech than normal subjects]. The wide range of intersubject performances that we have observed (cf. Fig. 7) parallels the results of Cooper and Allen (1977) for normal subjects, who found that some subjects had timing variances roughly ten times larger than others.

E. Analysis of high-performing subjects

Our analysis is designed on the assumption that metronome ticks are proxies for prominence. But, ticks are clearly not perfect proxies, especially for some subjects. This raises the possibility that our results are affected by utterances that are unsynchronized with the metronome or that have other synchronizations (e.g., two ticks per prominence).

The majority of the utterances were spoken with approximately a 1:1 ratio between metronome ticks and nominal stresses: 56% of the utterances contained 19–21 metronome ticks for their 20 nominally stressed syllables. A total of 18% were near other small-integer ratios that might suggest different patterns of synchronization: 5% contained 9–11 ticks (near a 1:2 ratio), 11% contained 14–16 (near a 2:3 ratio, but informal investigation shows that many of these utterances have no obvious synchronization), 1% contained 29–31 (3:2), and 1% contained 39–41 ticks (2:1). The ratios of the remaining 26% do not suggest synchronization between the speech and the metronome.

To check that possibility, we repeated our analysis on the subjects that gave us the five largest values of $\langle|I|\rangle$. These subjects generally produced utterances that are well synchronized, with one prominence per metronome tick, and thus are particularly well adapted to our analysis. By comparing the analysis on this subset to our main results (Sec. IV A), we can check that our results are robust.

As expected, the value of $\langle|I|\rangle$ for the shuffled analysis is statistically indistinguishable from the shuffled analysis for the full data set. Also, as expected, the values for the $g_{1,\ldots,6}$ analyses have increased: For the g_1 analysis, $\langle|I|\rangle$ has increased from 0.572 ± 0.02 to 0.739 ± 0.02. Even so, there are no differences among the various $\langle|I|\rangle$ values for the $g_{1,\ldots,6}$ analyses that are larger than the corresponding standard deviations. This supports our contention that the other acoustic properties are not very important.

Likewise, α, η, and ζ still have distributions that strongly overlap zero, providing further confirmation that f_0 does not play a role in the sense of Eqs. (4) and (5), and that $A(t)$ is likewise unimportant. The spectral slope remains weakly important, with just 4% of the optimal parameter sets having $\gamma<0$.

The shapes of K do not change substantially from those shown in Fig. 5; neither σ, a, b, nor r show changes larger than the error bars shown in Table I. This supports our use of the metronome tick as a proxy for rhythmic prominences.

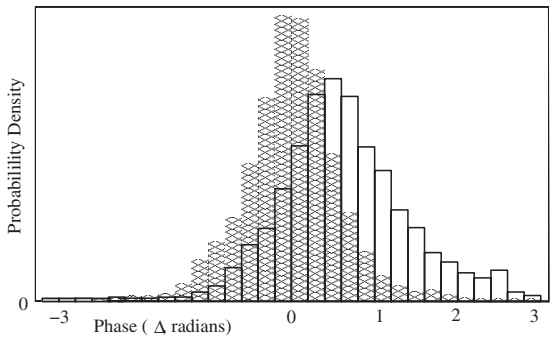

FIG. 8. Phase histogram (Δ) for a typical speaker (outline) and the histogram of Δ relative to the average phase of each utterance (filled). The peak of the dashed histogram shows the typical phase relationship between metronome ticks and the algorithm's predictions for that subject. The width of the histograms show timing inconsistencies between the subject's speech and the metronome.

F. Phase variation between utterances

The analysis so far only considers how stable the predictions (T) are, in relation to the ticks. Any uniform phase shift between the ticks and T will just change the phase of I but not its magnitude, so $|I|$ and $\langle|I|\rangle$ are insensitive to the average phase relation within an utterance. Our analysis essentially minimizes the variance of the difference between the predicted and actual tick positions. Thus, our analysis differs from that of Allen (1972), who assumes that the moment when the tick happens is the critical part of the syllable.

However, because the optimal K happens to be symmetrical and fairly compact, we can use it to identify the point in each phrase where $x(t)$ is maximal. The loudness contour in a region around this point gives the most consistent prediction of the metronome ticks. We computed this for $g=1$ and optimized parameters; peaks in $x(t)$ thus correspond fairly accurately to peaks in $L(t)$.

Figure 8 shows the histogram of Δ for all utterances produced by one subject. It also displays the histogram of Δ relative to the phase of I for the corresponding utterance. We display data from the subject who had the median value of $\langle|I|\rangle$. The histogram of relative phase is noticeably narrower and taller, as might be expected, indicating that different utterances have somewhat different alignments between the speech and the metronome.

For this subject, the peak of the Δ histogram (outline) is not at zero, indicating that the peak of $x(t)$ is not aligned with the metronome ticks, but that the metronome ticks occur somewhat before the peaks of $x(t)$. In other words, this subject speaks with the ticks early in the syllable, before the vowel's loudness peak. However, subjects differ in their average alignment.

Figure 9 shows a vector plot of the phases per utterance, for all subjects. The phases are distributed around zero, indicating that on average, subjects align the peaks of $x(t)$ [and thus $L(t)$] with the metronome ticks. If we wished to discuss a "pr(oduction)-center" in analogy to Allen's (1972) p(ercep-

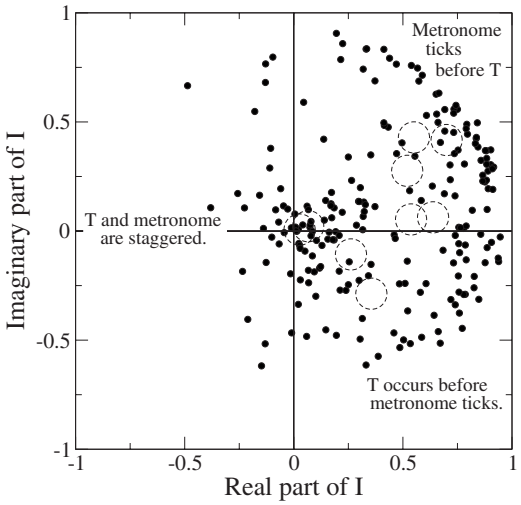

FIG. 9. The phase relationship between the metronome ticks and peaks of $x(t)$ (loudness, loosely speaking). Each utterance (i.e., ten repetitions of one text by one speaker) is represented by a dot at the (complex) value of I, with the real part on the horizontal axis and the imaginary part on the vertical axis. The distance from the origin is thus proportional to $|I|$ for that utterance. Dots near the origin represent utterances that did not have a consistent phase relationship between loudness and the metronome; dots on the unit circle would have a perfectly consistent phase relationship. The angle of the point, when viewed from the origin matches the phase of I, and dots just to the right of the origin come from utterances where the peak in $x(t)$ is aligned with the metronome ticks. Dashed circles represent the average of each subject's utterances.

tual) centers, the pr-center appears to be near the syllable's peak in L: the mean phase of the peak is $13 \pm 44°$ before the tick. The concept of pr-centers has been discussed by Morton, Marcus, and Frankish (1976), who have argued that P-centers are ambiguous and could possibly be exerting an influence on the production as well as the perception of words. However, there is substantial intersubject variation.[11] In Fig. 9, the dashed circles show averages of I for each subject. Apart from the two that are near zero and thus have no consistent phase relationship to the ticks, some subjects place the loudness peak before the tick, some almost on the tick, and some place it after the tick.

V. CONCLUSIONS

In English, the beat of repetitive speech is marked by an increase in the loudness relative to the immediate neighborhood. This neighborhood is approximately one syllable on either side of the beat, at the speech rates we studied.

The critical factor-appears to be the average loudness over an approximately 360 ms interval, so that as the vowel is shortened below 200–300 ms, the duration reduction will play the same role as a reduction in loudness. Other acoustical properties such as f_0 are not strongly correlated with the beat; one exception is that, on average, speakers produce somewhat more high frequency power on the beat than off.

We suggest that this preference for loudness contrasts as a marker of the beat may provide a partial explanation for the relative rarity of adjacent, prominent syllables. We note also that the width of the region over which prominence is expressed is well matched to human auditory perception, as might be expected.

We conducted a production experiment that had minimal involvement of speech perception, in contrast to much prior work on prominence. Despite that our results are in general agreement with prior experiments. Prominence seems a broadly useful idea, one that is shared both by linguists and naive speakers of English, and one that has a straightforward relationship to measureable acoustic quantities.

APPENDIX A: DEFINITION OF SPECTRAL SLOPE MEASURE

The spectral slope measure we use is based on a comparison of specific loudnesses at high and low frequencies. The computation begins by filtering the speech into bands that are 1 Erb (see Moore and Glasberg, 1983) wide, on 1/2 Erb centers, between 50 and 6000 Hz. [We use the filterbank recommended by Baumgarte (2002).] Then, we half-wave rectify each filter output and take the cube root of the local intensity to approximate the nonlinear response of the ear. This yields a set of specific loudness measures, $\ell_k(t)$, where k indexes the frequency band. The center frequency of the kth band is $f(k)$ Hz.

Next, we low-pass filter these with a frequency-dependent time constant derived from Plomp and Bouman (1959) to yield $\tilde{\ell}_k(t)$. We approximate their time constants as

$$\tau(f) = 0.4 - 0.27\frac{\log(f/200)}{\log(10^4/200)}, \tag{A1}$$

where $\tau(f)$ is in seconds.

We sum the result into two broadband specific loudnesses,

$$L^H(t) = \sum_k \tilde{\ell}_k(t)$$

where

$$f(k) > 1000 \text{ Hz}, \tag{A2}$$

and

$$L^L(t) = \sum_k \tilde{\ell}_k(t)$$

where

$$f(k) < 1000 \text{ Hz}. \tag{A3}$$

Finally, we combine L^L and L^H into a spectral slope measure by computing

$$S(t) = \frac{cL^H(t) - L^L(t)}{\hat{s}}, \tag{A4}$$

where $c = 2.8$ is a constant chosen so that the average of $S(t)$ is approximately zero, and $\hat{s}$ (defined in the following) is a factor to normalize out the average loudness. This form for

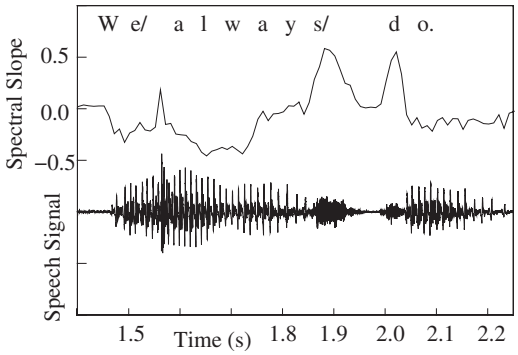

FIG. 10. Sample audio data along with the spectral slope, $S(t)$. This shows one repetition of "We always do."

$S(t)$ has the advantage that it is well-behaved in and near pauses, unlike measures based on intensity ratios of two frequency bands (Boersma, 1993; de Krom, 1993; Sluijter and van Heuven, 1996; Streefkerk *et al.*, 1999; Kochanski *et al.*, 2005). Also, it is well-behaved in regions of uncertain or no voicing, unlike the measure used by Heldner (2001).

We use

$$\hat{s} = c\frac{\Sigma_t s^2(t)}{\Sigma_t s(t)}, \tag{A5}$$

where $s(t)=cL^H(t)+L^L(t)$ and the sum over time is computed over the entire data file containing the utterance. (Typically, the data file contains about 20% silence, counting pauses between repetitions and a few hundred milliseconds at each end. We chose this form for $\hat{s}$ because it relatively insensitive to the amount of silence in the data file.) An example of $S(t)$ is shown in Fig. 10.

APPENDIX B: LIST OF PHRASES

Exactly so. Another time.
We always do. It surely is.
You never will. I understand.
Upon my word. She goes away.
They lie apart. The business here.
Indeed it had. I noticed that.
Nothing matters. Checker players.
William Roper. Scarlet Letter.
Goodness gracious! Lightning presses.
Worldly wisdom. Banking systems.
Phosphorescence. None whatever.
Good beginning. This is funny.
Testing the instruments. Philip was conquered
Love and integrity. Spare me your history.
Let us experiment. Notes on the editing.
Like you suggested. Here are the banners.
Not to my knowledge. Run for the cellar
Not that it mattered. Talking of wandering.
Wendy was scandalised. Going away.
Always ahead. Then I refuse.
Nothing at all. Open the door.
Maybe she had. Probably not.
Only a mouse. Say it again.
Billy was there. Under the desk.
Carrots and greens. Shirley declared.
That ruined me. Freddy Observed.
Tracy announced.

[1]As discussed in Kochanski (2006), it is not obvious to what extent people have accurate conscious access to the process of speech perception and understanding. For instance, several papers have raised the possibility (Dyde and Milner, 2002; Haffenden and Goodale, 1998; Aglioti *et al.*, 1995) that visual processing for perception is substantially different than processing for action. If so, reported perceptions could disagree on the actions we take in response to the same stimuli. If a similar effect occurs in speech, our reports of what we hear might not reflect our conversational behavior. Hickok and Poeppel (2000) argue for a similar distinction between tasks that require sublexical awareness and those that do not.

[2]Part of these data was intended for a similar finger-tapping experiment, but we dropped its analysis when we found that the finger-taps were too loud in the speech channel. However, the tapping parts of the experiment nicely serve the purpose of training the subjects to associate the beat with prominence.

[3]One male was accidentally given *uuSuuS* phrases instead of *SuuS*; these data were included in the analysis as we did not find any strong differences between metrical patterns. We do not include those phrases in the appendix because they were only used once.

[4]UNISYN is a software package for predicting pronunciation in a variety of English dialects. It is based on a lexicon and includes transformation rules.

[5]This part of the data was designed to check that the repetitive speech as not too different from a more typical laboratory experiment. See (Kochanski and Orphanidou, 2007) and the discussion in Sec. I.

[6]Note that calling $L(t)$ loudness as was done by Kochanski *et al.* (2005) is somewhat of a misnomer. $L(t)$ is closer to the sum of all the specific loudnesses at each moment, to use Zwicker's (1977) terminology. Munson (1947) and Plomp and Bouman (1959) showed that perceived loudness is an average of the specific loudness over approximately a 250 ms interval, while the Kochanski *et al.* (2005) measure averages only over a 25 ms (FWHM) window. Averaging $L(t)$ over a 250 ms window should approximate perceived loudness.

[7]The convolution $a*b$ is the integral $\int a(\tau)b(t-\tau)d\tau$. It can be thought of as taking a time-series b, and filtering it in a way specified by function a. If this were a perception experiment, this equation would correspond to Munson's (1947) sensation integral.

[8]Recall that $\exp(i\Delta)=\cos(\Delta)+i\sin(\Delta)$, so that it is periodic, not rapidly increasing as one would get by taking exp( ) of a real argument. If one plots the real and imaginary parts of $\exp(i\Delta)$, one finds that they trace out a unit circle, centered at zero.

[9]We rely on the fact that $\exp(i\Delta)=\exp(i(\Delta+2\pi))$ for any Δ.

[10]We recognize that f_0 *can* induce the perception of prominence, as shown by Gussenhoven *et al.* (1997); Rietveld and Gussenhoven (1985); Terken (1991). However, as shown in Kochanski *et al.* (2005), f_0 swings in speech are frequently not large enough to induce a prominence judgment. Consequently, f_0 is potentially important to prominence, but apparently not important in practice.

[11]Unfortunately a direct comparison to the p-center location is not practical in this experiment.

Differential contribution of envelope fluctuations across frequency to consonant identification in quiet

Frédéric Apoux[a] and Sid P. Bacon
Psychoacoustics Laboratory, Department of Speech and Hearing Science, Arizona State University, P.O. Box 870102, Tempe, Arizona 85287-0102

(Received 3 November 2006; revised 22 January 2008; accepted 25 February 2008)

Two experiments investigated the effects of critical bandwidth and frequency region on the use of temporal envelope cues for speech. In both experiments, spectral details were reduced using vocoder processing. In experiment 1, consonant identification scores were measured in a condition for which the cutoff frequency of the envelope extractor was half the critical bandwidth (HCB) of the auditory filters centered on each analysis band. Results showed that performance is similar to those obtained in conditions for which the envelope cutoff was set to 160 Hz or above. Experiment 2 evaluated the impact of setting the cutoff frequency of the envelope extractor to values of 4, 8, and 16 Hz or to HCB in one or two contiguous bands for an eight-band vocoder. The cutoff was set to 16 Hz for all the other bands. Overall, consonant identification was not affected by removing envelope fluctuations above 4 Hz in the low- and high-frequency bands. In contrast, speech intelligibility decreased as the cutoff frequency was decreased in the midfrequency region from 16 to 4 Hz. The behavioral results were fairly consistent with a physical analysis of the stimuli, suggesting that clearly measurable envelope fluctuations cannot be attenuated without affecting speech intelligibility. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2897916]

I. INTRODUCTION

For continuous speech in quiet, the dominant components of the modulation spectrum—the spectral representation of the temporal envelope—lie between 1 and 16 Hz with a peak around 4 Hz, reflecting the average syllable rate in speech (Arai and Greenberg, 1997; Greenberg, 1999). The speech modulation spectrum, however, also contains amplitude components above 16 Hz (Plomp, 1983; Houtgast and Steeneken, 1985). Consistent with the physical characteristics of the temporal structure of speech, a number of behavioral studies have demonstrated that speech intelligibility is only affected by reducing or removing modulation frequencies below a few tens of hertz, suggesting that higher envelope fluctuations do not contribute to overall intelligibility (Drullman *et al.*, 1994; Shannon *et al.*, 1995; Arai *et al.*, 1999; Xu *et al.*, 2005).

Although both physical and behavioral data suggest a limited role of high-frequency envelope fluctuations in speech intelligibility, listeners have been provided with envelope frequencies well beyond a few tens of hertz in many speech studies (Eisenberg *et al.*, 2000; Qin and Oxenham, 2003; Apoux and Bacon, 2004; Gonzales and Oliver, 2005). One motivation for this is related to the relative uncertainty about precisely which envelope frequencies are most important for speech. Another motivation is that some speech information (e.g., periodicity cues) has been associated with envelope fluctuations between 50 and 500 Hz (Rosen, 1992). In studies simulating hearing via a cochlear implant (CI), listeners are commonly provided fast envelope fluctuations (Dorman *et al.*, 1997, 1998; Friesen *et al.*, 2001; Faulkner *et al.*, 2003; Fu and Galvin, 2003; Baskent and Shannon, 2006). In this case, high-frequency cutoffs of the envelope filter (i.e., the low-pass filter used to extract the envelope) are used to conform to the cutoff frequencies commonly used in CI speech processors.

A. Factors affecting the bandwidth of the modulation spectrum

While it might seem reasonable to preserve high-frequency envelope fluctuations, it is unclear whether listeners can extract information from them. Even though humans are able to detect rates of amplitude modulation (AM) imposed on a broadband carrier as high as about 1000 Hz (Viemeister, 1979), filtering in the peripheral auditory system may limit the ability of the listeners to use high-frequency envelope cues in any given spectral region, as the maximum modulation frequency in a band-limited signal cannot exceed half the bandwidth of that band (see Lawson and Uhlenbeck, 1950). Modulation frequencies greater than half the bandwidth will be attenuated by the filter. Therefore, high-frequency AM should be available primarily from the high-frequency region of the speech spectrum. Similar limitations are also true for processing mimicking the resonant properties of the peripheral auditory system such as the analysis filters in CI and CI simulations (i.e., the filters used to decompose input signal spectra into a number of directly adjacent frequency bands for further processing). For example, Xu *et al.* (2005) examined the relative contribution of spectral and temporal cues for phoneme recognition by systematically varying the number of bands (1–16) and the cutoff frequency of the envelope low-pass filter (1–512 Hz) of a

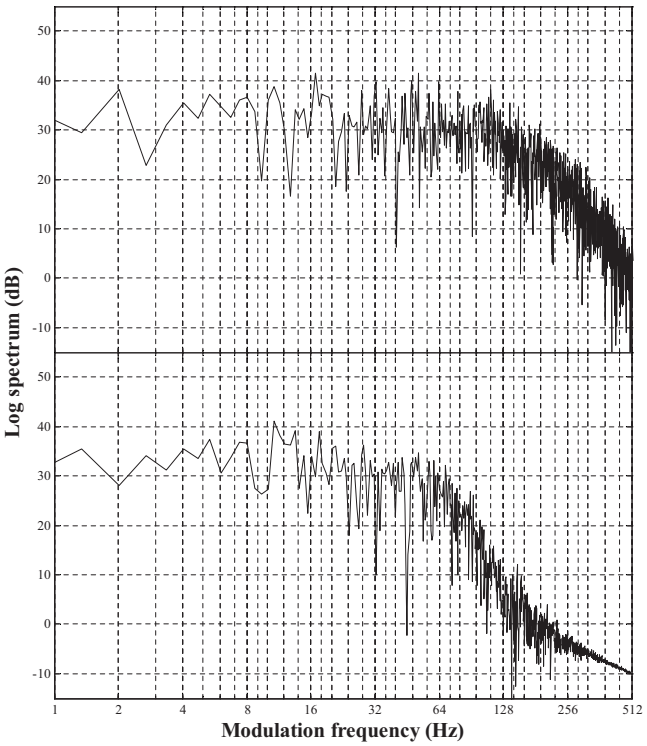

FIG. 1. Logarithm of the amplitude components of the modulation spectrum of a Gaussian noise, as computed at the output of a bandpass filter centered at 1000 Hz. The bandwidths of the bandpass filter were 1024 and 128 Hz for the upper and the lower panels, respectively. Prior to computation, the envelope of each band of noise was low pass filtered at 128 Hz.

noise-excited vocoder. According to their Table I, the bandwidth of the analysis filters ranged from 62 to 936 Hz in the 16-band condition. Therefore, it is clear that most, if not all, of the 16 unfiltered narrow-band envelopes could not exhibit fluctuations as high as 512 Hz. Moreover, if sidebands were introduced outside the passband of the analysis filter by AM, they would be significantly reduced by filtering after modulation (Eddins, 1993, 1999; Strickland and Viemeister, 1997). The effect of the bandwidth of the analysis filter is illustrated in Fig. 1. The two panels show the modulation spectrum of a Gaussian noise derived from the output of a bandpass filter centered at 1000 Hz. The bandwidth of the filter was 1024 Hz (upper panel) or 128 Hz (lower panel). The cutoff frequency of the envelope low-pass filter was 128 Hz in each condition. In the upper panel, it can be seen that only modulation frequencies above the cutoff of the envelope filter were attenuated. In contrast, modulation frequencies well below 128 Hz were attenuated when the bandwidth of the analysis filter was 128 Hz (lower panel). Only the modulation frequencies below half the bandwidth of the analysis filter (i.e., 64 Hz) were left intact.

B. Differential contribution of temporal envelope cues across frequency

From the above, it is apparent that the range of available envelope frequencies should differ across frequency because of the characteristics of the auditory filters and/or the analysis filters. Moreover, it is well established that the shape of the modulation spectrum of speech differs significantly across frequency. Greenberg *et al.* (1998) indicated that the high-frequency spectral region of speech contains a significantly greater amount of energy in the midfrequency modulation spectrum (10–25 Hz) than does the lower frequency spectral region. More recently, Crouzet and Ainsworth (2001) showed that temporal envelopes extracted from distant frequency regions are only partially correlated. Consistent with previous reports (Plomp, 1983; Houtgast and Steeneken, 1985), the results of Crouzet and Ainsworth indicate that for very low-frequency envelope modulations ($\leqslant$4 Hz) the correlation of envelope information between frequency bands is very high ($>$0.8). This high correlation reflects the syllabic rate in speech (i.e., syllables onsets and offsets are similar across the speech spectrum). For higher frequency envelope modulations ($>$8 Hz), the correlation remains significant only for adjacent spectral bands. Taken together, the fact that the shape of the modulation spectrum is not similar across spectral frequency and that narrow-band envelopes are only partially correlated across all spectral regions strongly suggest that temporal cues extracted from remote regions do not convey the same information.

Several behavioral studies with normal-hearing listeners reported data that are in good agreement with the above physical analysis. Grant *et al.* (1991) evaluated the benefits of the auditory presentation of envelope cues as a supplement to lip reading. Among the parameters assessed in this study, the authors investigated the effect of the frequency of the envelope low-pass filter and the effect of the center frequency of the analysis band. When the analysis band was located in the low-frequency region (500 Hz, 1 octave wide), some benefits to lip reading were observed for envelope cutoff frequencies up to 50 Hz. Benefits were observed up to 200 Hz when the analysis band was located in the high-frequency region (3150 Hz, 1 octave wide), suggesting a differential contribution of envelope cues across frequency. This result, however, may simply reflect the influence of auditory filters on the bandwidth of the modulation spectrum. More recently, Silipo *et al.* (1999) measured the intelligibility of one to four $\frac{1}{3}$-octave-wide bands of speech (sentences) presented simultaneously. The envelope of one or two of the bands was low pass filtered in a systematic fashion, allowing the authors to assess the importance of low-, mid-, and high-frequency modulations at different spectral regions. Their results indicated that (i) only modulation rates below 12 Hz play a significant role in the low spectral region and (ii) modulation rates between 10 and 25 Hz are of particular importance for encoding speech information in the spectral region above 1.5 kHz. Finally, Apoux and Bacon (2004) assessed the relative importance of temporal information in broad spectral regions for consonant identification. For the purpose of forcing listeners to use primarily temporal envelope cues, speech sounds were spectrally degraded using four noise-band vocoder processing. Frequency-weighting functions were determined using two methods. The first consisted of measuring the intelligibility of speech with a hole in the spectrum either in quiet or in noise. The second consisted of correlating performance with the randomly and independently varied signal-to-noise ratio within each band. Results demonstrated that all bands contributed equally to consonant

identification when presented in quiet. In noise, however, both methods indicated that listeners consistently placed relatively more weight on the highest frequency band.

The first experiment of the present study was designed to demonstrate the effect of auditory filter bandwidth on the transmission of high-frequency AM. As discussed above, modulation frequencies greater than half the critical bandwidth (see Zwicker *et al.*, 1957) are presumably attenuated. Therefore, it is inappropriate to discuss the effects of envelope cutoff frequency when the effective modulation bandwidth is, in fact, limited by the bandwidth of the auditory filters. To evaluate the effect of the auditory filter bandwidth on the transmission of high-frequency AM, a vocoder-like processor with the cutoff frequency of the envelope low-pass filter in each band proportional to the critical bandwidth of the auditory filter corresponding to that band was implemented. More specifically, envelope cutoffs were independently determined for each band so that, in theory, the desired modulation frequencies in a particular band could not be attenuated by the auditory filters (or the analysis filters). The results were compared with those obtained using a single high-frequency envelope cutoff for all bands. For completeness, low-frequency envelope cutoff frequencies were also tested.

The second experiment was designed to independently establish for different frequency regions which AM rates are critical for speech intelligibility. Previous studies evaluating the importance of low- and high-frequency amplitude fluctuations for speech intelligibility always filtered the temporal envelope in each speech band homogeneously across frequency (i.e., the same envelope cutoff frequency was used for each band). In one study, however, the authors investigated the critical AM for speech in three broad frequency regions independently (Christiansen and Greenberg, 2007). The three bands were centered at 750, 1500, and 3000 Hz and were presented either in isolation or combined with one or two other bands. The envelope cutoff frequency in each band was 3, 6, 12, or 24 Hz and was always the same across bands when two or more bands were simultaneously presented. From the data reported in their Table I, it seems that the effect of the envelope filter was similar across bands when presented in isolation. The authors, however, did not perform a statistical analysis of their percent correct data, making it difficult to determine whether or not the same range of AM was critical in each spectral region. In the second experiment of the present study, the envelope cutoff frequency in one band was systematically varied while keeping the envelope cutoff frequency for all the other bands fixed. Because it was anticipated that performance may not be affected by the manipulation of the envelope cutoff frequency in a single band, the cutoff frequency in two adjacent bands was also systematically and uniformly varied while keeping the envelope cutoff frequency for all the other bands fixed.

A potential complicating factor in the interpretation of the results may arise from recent studies suggesting that envelope filtering techniques might be inappropriate to estimate the range of the pertinent fluctuation rates in speech. Indeed, a series of theoretical and behavioral studies indicated that envelope filtering techniques might introduce artifacts when the speech fine structure is preserved (Ghitza, 2001; Atlas *et al.*, 2004). The exact reasons why envelope filtering techniques might be inappropriate are beyond the scope of the present study and, therefore, the reader is referred to a recent paper by Atlas *et al.* (2004) for further details. In short, it has been demonstrated that part of the original envelope information remains in the speech fine structure and that listeners are able to extract and use this information (Zeng *et al.*, 2004; Gilbert and Lorenzi, 2006). Accordingly, the possibility exists that listeners were, in fact, presented with rich envelope information in studies where the speech fine structure was preserved. Therefore, the speech fine structure was replaced by sinusoids in the present experiments. The use of spectrally degraded stimuli should also force listeners to primarily use temporal cues and, therefore, listeners likely should be more sensitive to modifications applied to the temporal structure of speech.

II. EXPERIMENT 1

A. Methods

1. Subjects

Six normal-hearing subjects participated—five females and one male [one of the authors, Apoux (S1), participated]. Their ages ranged from 20 to 32 years (average=23 years). Normal hearing was defined as having pure-tone air-conduction thresholds of 20 dB HL or better (ANSI, 1996) for octave frequencies from 250 to 8000 Hz. All participants, who, except for Apoux, were native American English speakers, had about 2 h of previous experience identifying spectrally degraded speech sounds and were paid an hourly wage for their participation.

2. Speech processing

The frequency range of speech stimuli was initially restricted to 0.1–5 kHz. The fine structure was replaced by sinusoidal carriers in the following manner. Each vowel-consonant-vowel (VCV) was first band passed in to N semi-logarithmic[1] frequency bands using 24th-order Butterworth filters (N=4, 8, 12, or 16). At the output of each analysis filter, the envelope was extracted by half-wave rectification and low-pass filtering at cf_m (eighth-order Butterworth). In all conditions but one, the envelope low-pass filter cutoff frequency was identical for each band (cf_m=4, 8, 16, 160, or 400 Hz). In the last condition, cf_m was independently computed for each band so that it was equal to half the critical bandwidth (HCB) of the auditory filter centered at the sinusoidal carrier frequency (Glasberg and Moore, 1990). The center frequency of each band and the corresponding envelope filter cutoff frequency in the HCB condition are given in Table I. The filtered envelopes were then used to modulate sinusoids with frequencies equal to the center frequencies of the bands. Each modulated sinusoid was passed through the same bandpass filter used in the original analysis band and the outputs of each band were finally combined. The overall level of each stimulus was normalized and calibrated to produce an average A-weighted output level of 70 dB.

TABLE I. Center frequencies of the analysis bands (in Hz). The envelope cutoff frequency—half the critical bandwidth—used for each band in the HCB condition is shown in italics.

Number of bands	Band															
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16

3. Speech material and procedure

The stimuli consisted of 16 consonants in /a/-consonant-/a/ environment recorded by four speakers (two for each gender) for a total of 64 VCV disyllables (Kwon and Turner, 2001). Each run or block presented the entire set of VCV stimuli and corresponded to a given combination between a band condition (4, 8, 12, or 16 bands) and an envelope cutoff condition (4, 8, 16, 160, 400 Hz or HCB). Therefore, each listener completed 24 blocks in which the 64 VCV stimuli were presented in random order. All conditions were presented in random order to avoid order effects. Stimulus presentation was computer controlled. Percent correct identification was measured using a single-interval, 16-alternative forced-choice procedure. The listeners were instructed to report the perceived consonant and responded using the computer mouse to select 1 of 16 buttons on the computer screen. Prior to data collection, each listener received 2 h of practice. No feedback was given during the practice or the experimental sessions. The listeners were tested individually in a double-walled, sound-attenuated booth. Stimuli were played to the listeners binaurally through Sennheiser HD 250 Linear II circumaural headphones.

B. Results and discussion

Figure 2 shows the percent correct identification score as a function of the number of bands averaged across listeners for each of the six envelope cutoff frequency conditions. The standard deviation across listeners was calculated for each condition, but for clarity these are not displayed. The standard deviation ranged from 6 to 21 percentage points (mean=13 percentage points). It generally increased with both increasing envelope cutoff and number of bands. Overall, the percent correct identification scores were slightly lower than in previous experiments. This apparent discrepancy, however, can be accounted for by differences in terms of the amount of practice. For example, Shannon *et al.* (1995) obtained about 90% correct but their subjects received between 8 and 10 h of practice. In studies with a similar amount of practice (e.g., 3 h in Xu *et al.*, 2005), the results were much more comparable. Other differences such as speech material and number of speakers may also account for these small discrepancies. Consistent with previous reports, consonant identification generally improved as a function of the number of bands. Intelligibility also improved as the envelope cutoff frequency increased. Beyond 160 Hz, however, performance seemed to reach an asymptote: scores in the 160- and 400-Hz conditions were within 5 percentage points of one another. Although it was systematically lower, performance in the HCB condition was very similar to that in the 160- and 400-Hz conditions. Overall, the envelope cutoff frequency exerted a more dominant effect on consonant identification than did the number of bands. A repeated measure analysis of variance (ANOVA) with factors of number of bands and envelope cutoff frequency revealed a significant effect for both factors ($p<0.001$). The interaction between the number of bands and the envelope cutoff frequency was also significant [$F(15,143)=2.21$, $p<0.05$]. *Post hoc* (Tukey) comparisons confirmed that increasing the envelope cutoff frequency from 4 to 8 Hz, from 8 to 16 Hz, and from 16 to 160 Hz significantly improved the performance of the listeners ($p<0.001$). Performance in the 400-Hz and HCB conditions did not differ significantly ($p=0.30$). The difference between the 4-band and the 8-band conditions was significant ($p<0.02$). The difference between the 8-band and the 12-band conditions was also significant ($p=0.04$), while

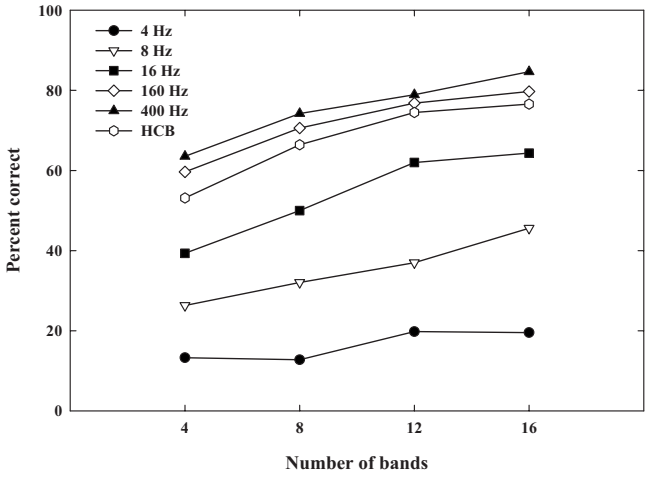

FIG. 2. Mean percent scores for consonant identification as a function of the number of bands. The parameter is the cutoff frequency of the envelope low-pass filter.

the difference between the 12-band and the 16-band conditions was not ($p=0.47$). This last result is fairly consistent with previous reports showing that asymptotic performance is usually achieved with eight bands for VCV stimuli presented in quiet (Dorman *et al.*, 1997).

Also consistent with previous research (van Tasell *et al.*, 1987; Shannon *et al.*, 1995), our results indicate that usable speech information is contained in fluctuation rates above 16 Hz. Indeed, providing modulation frequencies above 16 Hz markedly improved performance, irrespective of the number of bands that was available. Asymptotic performance was reached in the 160-Hz condition for all number of band conditions, suggesting that AM rates between 160 and 400 Hz do not play a significant role in speech intelligibility. Results in the HCB condition showed that consonant identification is not affected by eliminating AM rates greater than half the bandwidth of an auditory filter and, therefore, well below 160 Hz in some regions of the speech spectrum (see Table I).

Because performance did not improve when envelope fluctuations above HCB were provided to the listeners, it is reasonable to assume that, at least in quiet, the transmission of envelope fluctuations can be limited to those frequencies below half the bandwidth of the auditory filter in CI and CI simulations. The present results, however, do not provide much indication about the possible influence of those frequencies above half the bandwidth of the auditory filter when speech is presented against a background noise. Possibly, the intelligibility of speech presented in noise might even decrease when fluctuation rates above half the bandwidth of the auditory filter are provided. First, our results showed that fluctuation rates above half the bandwidth of the auditory filter do not convey any usable information in terms of intelligibility. Therefore, limiting the transmission of nonpertinent envelope fluctuations should help reduce the amount of noise in CI users *without affecting intelligibility*. Second, interference in the modulation domain has been demonstrated for speech in at least two studies (Kwon and Turner, 2001; Apoux and Bacon, 2008). Accordingly, fluctuation rates *above* half the bandwidth of the auditory filter pertaining to the noise background might interfere with fluctuation rates *below* half the bandwidth of the auditory filter pertaining to the target. Since the latter play a role in speech intelligibility, performance might be adversely affected by such interference. In view of the above, we suggest that the transmission of envelope fluctuations should be limited to those frequencies below half the bandwidth of the auditory filter in CI and CI simulations, particularly when background noise is present.

III. EXPERIMENT 2

A. Conditions

Twelve new subjects participated in the second experiment (11 females and 1 male). Their ages ranged from 20 to 40 years (average=25 years). All participants were native American English speakers and had pure-tone air-conduction thresholds of 20 dB HL or better for octave frequencies from 250 to 8000 Hz. Subjects were paid an hourly wage for their participation. The stimuli and processing were the same as for experiment 1 with the following exceptions.

(1) Speech stimuli were processed through an eight-band processor only. This condition was chosen (i) to allow a reasonable spectral resolution (i.e., a large number of bands) while limiting redundancy of information between bands and (ii) because results from experiment 1 indicated that consonant identification should be around 50% correct in this condition with the 16 Hz envelope cutoff and, therefore, base line scores should be sufficiently removed from ceiling and floor effects.
(2) In one condition (SING), the envelope cutoff frequency was set to 16 Hz for all but one band and the envelope in that single (test) band was low pass filtered at 4 Hz, 8 Hz, or HCB to quantify the range of modulation frequencies relevant for consonant identification in that particular band.
(3) In the other condition (CONT), the envelope cutoff frequency was set to 16 Hz for all but two contiguous bands (1 and 2, 2 and 3, 3 and 4, and so on) and the envelope in each of these two (test) bands was low pass filtered at 4 Hz, 8 Hz, or HCB.
(4) A baseline condition in which all narrow-band envelopes were filtered at 16 Hz was added. For comparison, a condition in which all eight narrow-band envelopes were filtered at half the critical bandwidth was also tested (HCB8).

The 12 listeners were divided into two groups. Each group first completed a series of seven blocks for practice. The first block corresponded to an unprocessed condition. The following six blocks corresponded to the conditions for which all bands were filtered at 16 Hz. We chose to train subjects in this particular condition because it was the reference condition. Then, the two speech band conditions were administrated separately. Six listeners completed the SING condition first and six completed the CONT condition first. The presentation order for the test band conditions was chosen randomly to avoid order effects. In addition, each listener completed three blocks in the 16-Hz condition and three blocks in the HCB8 condition. These 6 blocks were randomly dispersed among the 90 experimental blocks with the constraint to have at least one block for each condition in each part of the experiment.

B. Results and discussion

Figures 3 and 4 show the results for the SING and the CONT conditions, respectively. Each figure shows the performance averaged across the 12 listeners as a function of the test band(s) for each envelope cutoff condition. For reference, results for the baseline (all band at 16 Hz) and the HCB8 conditions are also reported. Note that individual performance in these two conditions corresponds to the average of 192 instead of 64 trials. The standard deviation across listeners was calculated for each condition, but for clarity these are not displayed. Overall, the standard deviation for a given condition was typically about 10 percentage points and did not vary systematically across conditions. Consistent

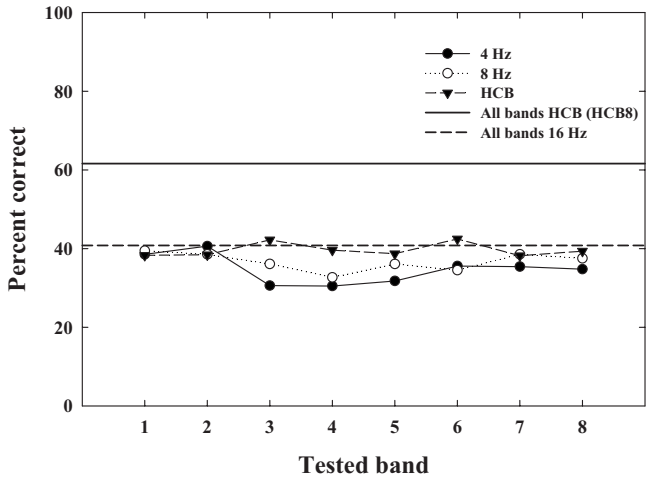

FIG. 3. Mean percent scores for consonant identification as a function of the band tested (SING condition). The parameter is the cutoff frequency of the envelope low-pass filter used for the tested band. Dashed and solid lines show the mean percent scores when the envelope filter for all bands was set to the same cutoff frequency, either 16 Hz or half the critical bandwidth (HCB8), respectively.

with our earlier finding, performance in the baseline condition was about 40% correct and increased up to about 60% correct in the HCB8 condition. First, consider the results for the SING condition (Fig. 3). Overall, the effects of test band frequency and envelope cutoff frequency were rather small. The latter had no influence on performance in the lower frequency region (test bands 1 and 2) for the most part. When the envelope cutoff was manipulated in test bands 3–8, some differences were observed. As a general rule, performance was only slightly reduced when the cutoff frequency was set to 4 or 8 Hz, while no effect was observed in the HCB condition. A repeated measures ANOVA with factors of test band frequency and envelope cutoff frequency showed a significant effect of test band frequency [$F(7,154)=2.84$, $p<0.020$] and envelope cutoff frequency [$F(2,154)=14.11$, $p<0.001$]. The interaction was also significant [$F(14,154)=2.47$, $p<0.005$]. *Post hoc* (Tukey) comparisons confirmed that the 4- and 8-Hz conditions did not differ significantly ($p=0.129$). However, performance in these two conditions was significantly lower than in the HCB condition ($p<0.001$ and $p<0.01$, respectively). *Post hoc* comparisons also revealed that scores for test bands 1 and 2 both differed significantly from performance for test band 4, indicating an effect of the frequency region ($p<0.03$ and $p<0.02$, respectively).

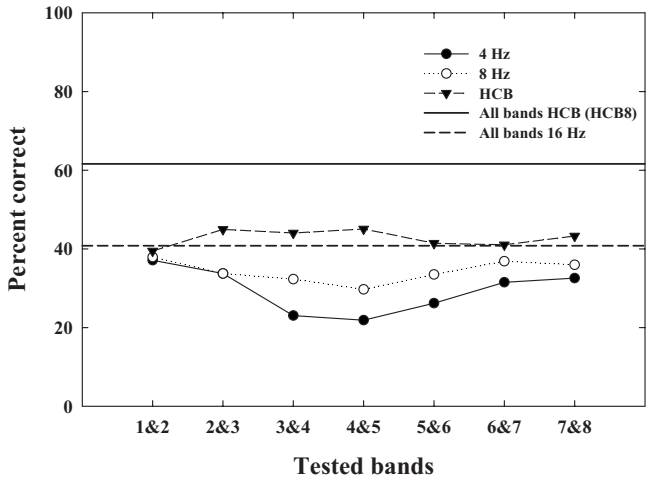

FIG. 4. Mean percent scores for consonant identification as a function of the bands tested (CONT condition). The parameter is the cutoff frequency of the envelope low-pass filter used for the tested bands. Dashed and solid lines show the mean percent scores when the envelope filter for all bands was set to the same cutoff frequency, either 16 Hz or half the critical bandwidth (HCB8), respectively.

By comparing Figs. 3 and 4, it is apparent that the same general pattern was observed in the CONT condition. However, the effects were noticeably amplified by the manipulation of two contiguous bands simultaneously. Again, no difference was observed between the three envelope cutoff conditions in the low-frequency region (test bands 1&2). In the other test band conditions, restricting envelope fluctuations to frequencies below 4 or 8 Hz typically deteriorated performance relative to the base line condition with the 4-Hz condition leading systematically to poorer scores. In this latter condition, percent correct may be reduced by as much as about 20 percentage points (test bands 3&4 and 4&5). In a few band conditions, consonant identification scores in the HCB condition increased relative to those in the baseline condition. However, the difference did not exceed 5 percentage points. A repeated measure ANOVA with factors of test band frequency and envelope cutoff frequency showed a significant effect of test band frequency [$F(6,132)=7.79$, $p<0.001$] and envelope cutoff [$F(2,132)=54.55$, $p<0.001$]. The interaction was also significant [$F(12,132)=5.06$, $p<0.001$]. *Post hoc* comparisons indicated that all three envelope cutoff conditions differed significantly from each other. They also indicated that consonant identification scores in the test band 4&5 condition differed from test band 1&2, 2&3, 6&7, and 7&8 conditions.

Increasing the cutoff of the envelope low-pass filter to half the critical band of an auditory filter in one band only (SING) did not lead to any substantial improvement in intelligibility. This finding may seem surprising at first given the 20 percentage points advantage observed when all eight narrow-band envelopes were filtered at half the critical bandwidth (compare solid and dashed lines in Fig. 3). One likely explanation is that envelope information in each band interacted in a way that was not simply additive. Such synergistic interactions have been reported previously for narrow bands of speech. For example, Warren *et al.* (1995) examined the intelligibility of $\frac{1}{20}$-octave-wide bands of speech presented either in isolation or in pairs. The authors found that two widely separated narrow bands of speech have intelligibility scores well above what would be predicted from the simple addition of their intelligibility scores when presented separately. The difference between the observed and the predicted performance, the synergistic effect, was about 17 percentage points in their study. To assess whether synergistic interactions also occurred in the CONT condition, the difference relative to the baseline condition in each test band condition was computed for both band conditions. A new condition, Sum Sing, was created in which the sum of differences ob-

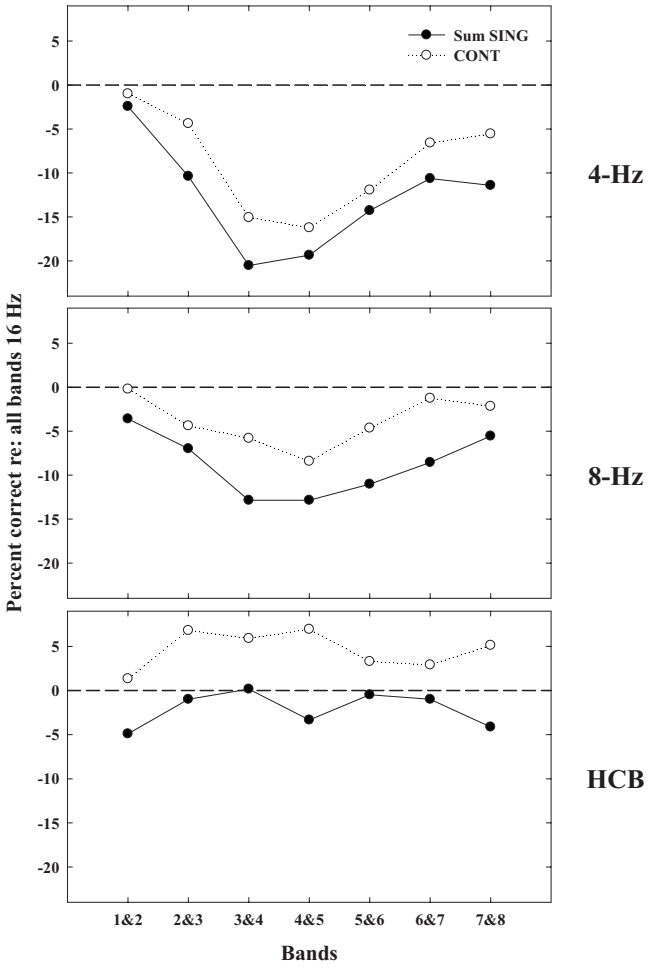

FIG. 5. The upper, middle, and lower panels show the percent correct relative to the base line condition (all bands at 16 Hz) in the 4 Hz, 8 Hz, and HCB conditions respectively, as a function of the tested bands. In each panel, the filled and unfilled circles show the results for the sum Sing and the CONT condition, respectively.

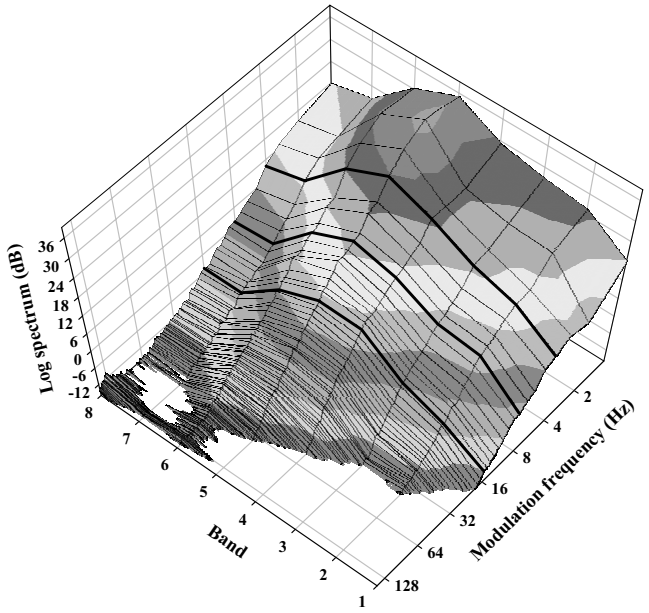

FIG. 6. Logarithm of the amplitude components of the modulation spectrum computed for all 64 VCVs used in the experiments as a function of the analysis band. The same eight bandpass filters used in the HCB condition were used for the analysis (i.e., the envelope low-pass filter cutoff frequency was equal to half the bandwidth of an auditory filter). Levels of gray indicate a 6 dB amplitude range. For clarity, lines on the modulation frequency axis corresponding to an envelope cutoff condition are in bold (4, 8, and 16 Hz).

tained for two bands was calculated for each pair of contiguous bands. For example, in the 1&2 band condition, the difference relative to the baseline condition computed for bands 1 and 2 was added together. This new condition allowed estimating the effect of manipulating two bands simultaneously (i.e., the synergistic effect). Figure 5 presents the results this way for the Sum Sing and the CONT conditions. The upper, middle, and lower panels show the results for the 4-Hz, 8-Hz, and HCB conditions, respectively. Positive values indicate an improvement over the baseline condition (cutoff frequency in all bands of 16 Hz). Statistical analyses were performed separately for each envelope cutoff frequency using repeated measures ANOVA with factors of test band frequency and "synergy" (i.e., Sum Sing versus CONT). The results indicated a significant effect of test band frequency for the 4- and 8-Hz conditions (all $p<0.001$), confirming a differential contribution of rate between 4 and 8 and between 8 and 16 Hz to consonant identification. In contrast, the effect of test band frequency was not significant for the HCB condition. All three analyses indicated no significant synergistic effect. In other words, the improvement observed with two contiguous bands (CONT) was not larger than the summed increase measured individually for each band (Sum Sing). The interaction between the two main factors was not significant in all three analyses. A likely explanation for the absence of synergistic interactions with two contiguous bands is that adjacent bands provide highly correlated information. Therefore, the 20 percentage points advantage observed when all eight narrow-band envelopes were filtered at half the critical bandwidth most likely reflects the synergistic interaction of distant bands. This assumption is consistent with the results of a recent study by Healy and Warren (2003). In this study, the authors measured the intelligibility of band pairs presented either contiguously or separated by 1, 2, 3, or 4 octaves. Their results showed an improvement in sentence intelligibility as band pairs were moved apart. Although a band separation of 3 and 4 octaves resulted in no improvement relative to the contiguous condition, a 20 percentage points improvement was observed for band separation of 1 and 2 octaves.

An interesting question that emerges is how the present results can be related to the amount of "temporal information" that was physically present in each band. The modulation spectrum associated with each band is illustrated in Fig. 6, as computed for all 64 VCV stimuli at the output of the analysis filters used in the HCB condition. For clarity, the modulation frequencies corresponding to envelope cutoff conditions used in experiment 2 are marked by a bold line (4, 8, and 16 Hz). As can be seen, the peak of the spectrum lies around 2 Hz in all bands and the energy decreases rapidly with increasing modulation frequency beyond this value. The frequency of the peak presumably reflects the average duration of the stimuli. At most modulation frequencies, the

amount of energy is greatest in band 5 (cf=930 Hz) and lowest in bands 1, 7, and 8. The four remaining bands have an intermediate amount of energy with bands 4 and 6 being in the upper end of this intermediate range and bands 2 and 3 in the lower end. This pattern is fairly consistent with the effects of the envelope filter's cutoff frequency on consonant identification in that behavioral data indicated a primary role of modulation frequencies between 4 and 16 Hz in the midfrequency region of the speech spectrum and a negligible contribution of these rates in the lower and upper frequency regions. Minor discrepancies may have resulted from at least two factors. First, it should be noted that a seven-point drop in percent correct can result from the deterioration of intelligibility for one VCV only. Therefore, the average identification scores may have been influenced by the results for a particular VCV or subset of VCVs and this effect might not be apparent when averaged behavioral and physical data are compared. Second, as discussed in the Introduction, the correlation of envelope information between adjacent bands is very high and, therefore, one can reasonably assume a certain degree of redundancy across bands. Accordingly, the loss of envelope information in a restricted frequency region may have been compensated by the presence of similar information in an adjacent band, reducing the observed effect. Comparisons across SING and CONT conditions provide at least some indirect support for this interpretation in that a larger effect of envelope cutoff was observed when the envelope cutoff was manipulated in two adjacent bands.

Results from experiment 2 suggest that the accuracy of methods developed for the prediction of speech intelligibility such as the speech transmission index (STI) (Steeneken and Houtgast, 1980) might be increased by measuring independently for different frequency regions which AM rates are critical for speech intelligibility. The STI is based on a weighted sum of modulation transfer functions, each of which specifies how modulation depth in seven octave-wide frequency bands is affected by interference or signal processing. This reduction in modulation depth of a test signal (Houtgast and Steeneken, 1985) or speech signal (Payton and Braida, 1999; Steeneken and Houtgast, 1999) has been shown to be highly correlated with intelligibility. Because STI calculation is based on the transmission of AM, one important parameter is the range of modulation frequencies considered. Based on the modulation spectra of octave-band filtered speech, modulation frequencies of 0.63–12.5 Hz in $\frac{1}{3}$-octave steps have been typically used. According to our data, however, the upper limit of the pertinent fluctuations rates for speech intelligibility varies across the speech spectrum. Although our results were obtained with VCVs, it is reasonable to assume that the same range of modulation frequencies should not be used for each of the seven-octave-wide bands. In some bands, only the modulation frequencies below a few hertz should be considered. Conversely, modulation frequencies well above 12.5 Hz should be considered in other bands.

IV. SUMMARY AND CONCLUSIONS

The goal of the present study was to determine which modulation frequencies contribute significantly to the identification of spectrally degraded speech in specific frequency regions. The results from experiment 1 suggest that envelope fluctuations above 16 Hz play a critical role in consonant identification. They also demonstrate that the preservation of modulation frequencies greater than half the bandwidth of an auditory filter has no significant effect on consonant identification in quiet. Taken together, these findings indicate that most of the temporal information necessary to preserve accurate consonant identification is conveyed by envelope fluctuations equal or lower than half the critical bandwidth of an auditory filter. Although not surprising, this result stands out against the use of a high envelope cutoff frequency as typically used in CI and CI simulations.

The second experiment indicates that the range of critical modulation frequencies for consonant identification depends on the region of the speech spectrum. Behavioral data showed a primary role of modulation frequencies between 4 and 16 Hz in the midfrequency region of the speech spectrum and a negligible contribution of these rates in the lower and upper frequency region of the speech spectrum. Accordingly, previous studies showing that the removal of modulation frequencies between 4 and 16 Hz significantly affects speech intelligibility (Drullman *et al.*, 1994; Arai *et al.*, 1999) only reflect the importance of these rates *in a specific region of the speech spectrum*. A comparison between the analysis of the speech stimuli used in the present experiment and the behavioral data obtained with these stimuli suggests that understanding spectrally reduced speech (eight-band vocoder) relies on most, if not all, the *available* envelope fluctuations in each band. In other words, envelope fluctuations present in narrow bands of speech *with enough power* cannot be attenuated without affecting intelligibility.

ACKNOWLEDGMENTS

This research was supported by a grant from the National Institute of Deafness and Other Communication Disorders (NIDCD Grant No. DC01376). We thank Ken Grant and two anonymous reviewers for their helpful comments on a previous version of the manuscript.

[1]The upper cutoff frequency f_n of the nth band was computed according to the equation

$$f_n = F_{\mathrm{lo}} \times 10^{\log_{10}(F_{\mathrm{up}}/F_{\mathrm{lo}})(1/N)n},$$

where F_{lo} and F_{up} are, respectively, the lower and upper limits of the filterbank in hertz (i.e., 100 and 5 000 Hz) and N is the total number of bands.

A method to identify noise-robust perceptual features: Application for consonant /t/

Marion S. Régnier and Jont B. Allen[a)]

(Received 11 August 2007; revised 24 February 2008; accepted 25 February 2008)

This study focuses on correlating speech *confusion patterns*, defined as consonant-vowel confusion as a function of the speech-to-noise ratio, and a model acoustic feature (AF) representation called the *AI gram*, defined as the *articulation index density* in the spectrotemporal domain. By collecting many responses from many talkers and listeners, the AF and psychophysical feature (*event*) is shown to be correlated via the AI-gram model and the confusion matrices at the utterance level, thereby explaining the listener confusion. Consonant /t/ is used as an example to identify its primary robust-to-noise feature, and a precise correlation of the acoustic information with the listeners' confusions is used to label the event. The main spectrotemporal cue defining the /t/ event is an across-frequency temporal coincidence, wherein frequency spread and robustness vary across utterances, while the event remains invariant. The cross-frequency timing event is shown to be the key perceptual feature for consonants in a vowel following context. Coincidences are found to form the basic element of the auditory object. Neural circuits used for coincidence in binaural processing for localization across ears are proposed to be used within one ear across channels. It is further concluded that the event is based on the audibility of the /t/ burst rather than on any superthreshold property. © *2008 Acoustical Society of America.* [DOI: 10.1121/1.2897915]

I. INTRODUCTION

After 50 years of work, even a basic understanding of speech's robustness to masking noise remains a mystery. Having a theory of human speech recognition (HSR) is critical for the development of new hearing aids and cochlear implants, and for automatic (machine) speech recognition (ASR). Given the importance of such a theory, other than a hand full of papers, little attention has been paid to the basic relations between acoustic and perceptual speech features. To research this long-standing problem, we measured a large number of listeners' responses to individual consonant-vowel (CV) syllables in noise and then correlated the confusions with each utterances' acoustic cues. *Utterances* are defined as CV sounds spoken by a particular talker, whereas a *token* is an utterance specified by its signal-to-noise ratio. We can prove the existence of these perceptual cues, denoted here as *events*, by identifying the spectrotemporal features used by listeners to discriminate consonants in noise.

Our approach is to correlate tokens to listeners's responses. By assuming that human communication is an "information channel" in the Shannon (1948) sense, we use Shannon's receiver to model the robust detection of speech cues in noise. We specifically show that across-frequency onset timing plays a crucial role in speech perception (Heil, 2003).

One might reasonably wonder why we study CV phonology rather than meaningful sounds having context. Context effects are critical when decoding natural language. However, with very limited context, listeners are still able to discriminate nonsense CV speech sounds below −16 dB speech-to-noise ratio (SNR) (Allen, 2005a; Phatak and Allen, 2007). This is now clear from our analysis of confusion matrices (CMs) of CV sounds, measured by Miller and Nicely (1955) (denoted MN55), as emphasized by Allen (2005a, 2005b) and Phatak and Allen (2007). Noise robustness has been a major area of debate in both the HSR and ASR literature (Hermansky, 1998).

Other than in a handful of studies (Blumstein and Stevens, 1979; Delattre *et al.*, 1955; Repp *et al.*, 1978; Kewley-Port, 1983; Lisker, 1985; Stevens and Klatt, 1974; Klunder *et al.*, 1995) little is known about the specific spectrotemporal information present in each wave form that causes (or prevents) specific confusions. Much remains to be done. Only a few studies (Fletcher and Galt, 1950; Summerfield and Haggard, 1977; Dubno and Levitt, 1981; Dubno *et al.*, 1987; Kamm *et al.*, 1985; Hant and Alwan, 2003) have used masking noise on real speech signals to study the confusions via the confusion matrix method. To explore the effects of noise and its spectrum, the University of Illinois at Urbana-Champaign (UIUC) Human Speech Recognition Group at the Beckman Institute conducted two basic studies, denoted PA07 and PA05 (Lovitt and Allen, 2006) and analyzed by Phatak and Allen (2007). PA05 used the same CVs as MN55 presented in white noise but expanded the MN55 experiment by including more vowels, talkers, and listeners and by updating the testing methodology. The present paper extends the analysis of Phatak and Allen (2007) by correlating the audible speech information with the scores for individual utterances from these two experiments. Our goal is to identify and label the common robust-to-noise features in the spectrotemporal domain (Strope and Alwan, 1997).

[a)]Electronic mail: jontalle@uiuc.edu.

Previous studies [Cooper *et al.*, 1952; Delattre *et al.*, 1955; see Hawkins, 2003; Nguyen and Hawkin, 2003 for reviews] pioneered the analysis of spectrotemporal cues discriminating consonants. Their goal was to study the acoustic properties of consonants /p/, /t/, and /k/ in different vowel contexts. One of their main results is the empirical establishment of a physical to perceptual map, derived from the presentation of synthetic CVs to human listeners. These synthetic "speech sounds" consisted of a short noise burst (10 ms, 400 Hz bandwidth), representing the consonant, followed by artificial formant transitions composed of tones, simulating the vowel. They discovered that for each of these synthetic voiceless stops, the spectral position of the noise burst was vowel dependent. This *coarticulation* was mostly obvious for /p/ and /k/, with bursts above 3 kHz giving the percept of /t/ for all vowel contexts. A burst located at the second formant frequency or slightly above would create a percept of /k/, and that below would create /p/. Consonant /t/ could therefore be considered to have less coarticulation. No information was provided about the robustness of their synthetic speech samples to masking noise nor about the importance of the presumed features relative to other cues that are present in natural speech but missing in their synthetic speech samples.

The spectrotemporal location of events has been found to vary due to the natural variability of speech. Cooper *et al.* (1952) determined the most relevant parts of the speech based on perceptual criterion. We have done the same. However, unlike Cooper *et al.* (1952), our results depend on natural speech and variable amounts of masking noise (Miller and Nicely, 1955; Allen, 2005a; Phatak and Allen, 2007; Régnier and Allen, 2007a, 2007b).

In summary, by collecting many responses from many talkers and listeners, we were able to build a large database of CPs (Allen, 2005b; Phatak and Allen, 2007). We relate the perceptual and physical domains at the utterance level via our measurement of speech audibility, the articulation index (AI) model (Fletcher and Galt, 1950; French and Steinberg, 1947), and thereby explain listeners' confusions via the spectrotemporal acoustic perceptual features. Throughout this paper, we will take the example of consonant /t/ and show how we can reliably identify its primary robust-to-noise feature. In order to identify and label events, we precisely correlate the acoustic information with the listeners' confusions. We show that the main spectrotemporal cue defining the /t/ event is composed of across-frequency temporal coincidence (perceptual features), which is represented by correlated acoustic properties (acoustic features). These can vary on an utterance basis. Our observations support these coincidences as a basic element of the auditory object formation, the cross-frequency timing event being the main perceptual feature for consonants in a vowel context. It seems reasonable that similar neural circuits used for coincidence in binaural processing for localization across ears (Joris *et al.*, 1998) could be used within one ear across channels (Delgutte *et al.*, 1998).

II. THE ARTICULATION INDEX: AN AUDIBILITY MODEL

The *articulation* is defined as the score P_c(SNR) for nonsense sound. The *articulation index* is the foundation stone of speech perception, laid down by Fletcher and Galt (1950) and French and Steinberg (1947). The AI is a *sufficient statistics* of the articulation (Allen, 2005a). It follows that the score is a function of the AI, giving P_c(AI). The basic concept of the AI is to quantify maximum entropy (MaxEnt, also called nonsense speech) average phone scores. It is based on the SNR in critical bands, expressed in decibel sensation level, scaled by the dynamic range of speech (30 dB) (Allen, 1994, 2005a; Phatak and Allen, 2007).

Allen (2005a) showed that French and Steinberg's (1947) expression for the maximum entropy average phone score P_c(AI), corrected for chance, may be written as

$$P_c(\mathrm{AI}) = 1 - P_e = 1 - e_{\mathrm{chance}} e_{\mathrm{min}}^{\mathrm{AI}}, \tag{1}$$

where the recognition error e_{min} is the minimum error at AI=1, and the error $e_{\mathrm{chance}}=1-1/16=15/16$ at chance performance (AI=0) for the 16 consonant case (Kamm *et al.*, 1985).

The articulation index is the basis of many standards, and its long history and utility, as discussed in length in several papers and books (French and Stemberg, 1947; Allen, 1994; Fletcher, 1995; Allen, 1996, 2005a, 2000b). Phatak and Allen (2007) extended the AI formula following French and Steinberg (1947) to account for the peak-to-rms [root-mean-squared $x_{\mathrm{rms}}=\sqrt{\overline{(x-\bar{x})^2}}$] ratio for the speech r_k in each band as

$$\mathrm{AI}_k = \min\left(\tfrac{1}{3}\log_{10}(1 + r_k^2 \mathrm{SNR}_k^2), 1\right), \tag{2}$$

where AI_k is called the *specific AI*, and SNR_k is the SNR (i.e., the ratio of the rms of the speech to the rms of the noise) in the kth articulation band. The total AI is then the average over the specific AI:

$$\mathrm{AI} = \frac{1}{K}\sum_{k=1}^{K} \mathrm{AI}_k. \tag{3}$$

The parameter $K=20$ bands defines the number of articulation bands and is determined empirically to give an equal band contribution in score for consonant-vowel materials (French and Steinberg, 1947). Each of these 20 bands corresponds to 1 mm along the basilar membrane, from about 0.3 to 7.5 kHz (Fletcher and Galt, 1950).

We denote the AI density over time and place (frequency) as the *AI gram* and noted it as $\mathrm{AI}(t, X_k)$. This is a simple graphical extension of the AI, as defined by French and Steinberg (1947). This function of time and *place* (defined as the distance X along the basilar membrane) is computed from a cochlear model or cochlear filter bank, with bandwidths equal to human critical bands, followed by a simple model of the auditory nerve (Lobdell and Allen, 2006). Figure 1 shows the block diagram of how the AI gram is computed from a masked speech signal $s(t)$. As a practical matter, the noise spectrum $\sigma_n^2(f)$ is based on the noise in isolation, but if necessary, it may be estimated directly from the noisy speech but with some loss of accuracy. The AI gram includes a conversion of the basilar membrane vibration to a neural firing rate via an envelope detector representing the mean rate of the neural firing pattern across the cochlear output. The speech+noise signal is scaled by the long-

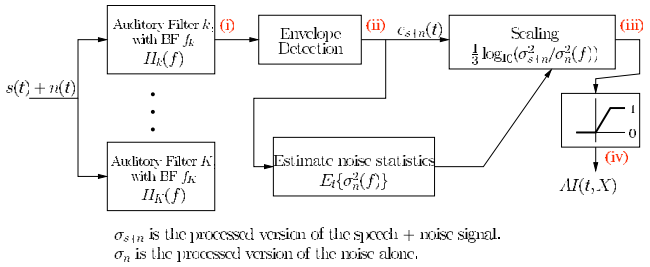

FIG. 1. (Color online) AI-gram block diagram. Derived from the work of French and Steinberg (1947) and Fletcher (1995), the output of the AI gram relates to the audibility of a sound. When a speech signal is visible in different degrees of black on the AI gram, it is above the masked threshold (i.e., audible). It follows that all noise and inaudible sounds having a SNR less than 0 dB appear in white due to the band normalization by the noise.

term average noise power $\sigma_n^2(f)$ so that the power SNR in each frequency band is $\mathrm{SNR}_k^2=\sigma_{s+n}^2/\sigma_n^2\approx 1+\sigma_s^2/\sigma_n^2$. The scaled value of SNR_k (in decibels) [as defined by Eq. (2)] yields the AI density $\mathrm{AI}(t,X)$. The audible speech modulations across frequency give a spectrotemporal representation in the form of the AI gram (Lobdell and Allen, 2006), as shown in Fig. 2.

The AI gram represents a simple *perceptual model*, and based on the pioneering work of French and Steinberg (1947) and Fletcher and Galt (1950), its output is assumed to be correlated with our psychophysical experiments. Different degrees of black on the AI gram are correlated with the audibility of the region of interest. Noise and inaudible speech sounds are represented by white (where the SNR is less than 0 dB), while audible speech is dark. The greater the $\mathrm{AI}(t,X)$, the darker the corresponding region.

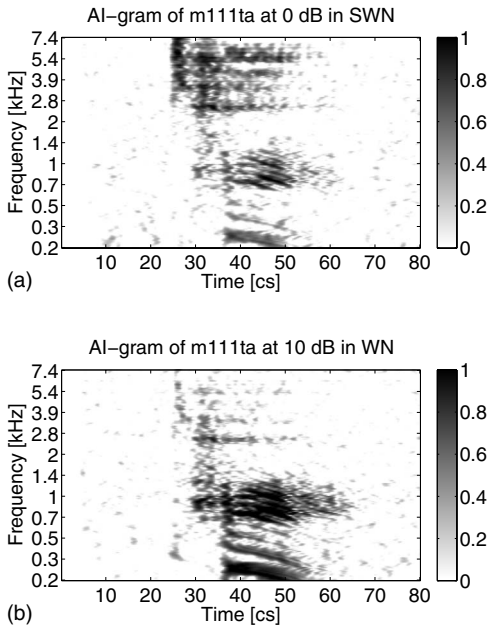

FIG. 2. AI gram of male speaker 111 speaking /tɑ/ in (a) SWN at 0 dB SNR and (b) WN at 10 dB SNR. The audible speech information is dark, the different levels representing the degrees of audibility. Since the two different noises have different spectra, the speech is masked differently. Speech-weighted noise masks low frequencies and high frequencies equally on average. One may clearly see the strong masking due to WN at high frequencies. The AI gram is an important tool used here to explain the differences in CPs observed in many studies to connect the physical and perceptual domains.

Figure 2 provides two AI grams of utterance /tɑ/ in (a) speech-weighted noise (SWN) and (b) white noise (WN). We shall demonstrate that this model of audibility is useful when explaining the decrease of recognition and for identifying the correlated masked events.

III. PILOT EXPERIMENTS

The purpose of this pilot study section is to draw out previously unpublished results from two major studies, called PA05 and PA07 here. PA05 is a modern version of the study of Miller and Nicely (1955). Results are unpublished. It uses 16 consonants and a single vowel with white noise. PA07 is an extension of MN55, with 64 CVs (16 consonants and 4 vowels), using speech-weighted noise (Phatak and Allen, 2007). Both experiments are further analyzed here in terms of confusion patterns (CPs) $P_{h|s}(\mathrm{SNR})$ (Allen, 2005b) and then correlated against AI grams. We have carried out this analysis on the consonant /t/ using an analysis tool denoted the *four-step method*. This novel detailed analysis will provide some useful insights that we believe to be new.

The next section describes the methods and results of these Miller-Nicely-type experiments, PA07 and PA05, run by members of the Human Speech Recognition Group in 2004 (Phatak and Allen, 2007).

A. PA07 and PA05

Experiment PA07 measured normal hearing listeners' responses to 64 CV sounds (16 C × 4 V, spoken by 18 talkers). PA05 included the subset of these CVs containing vowel /ɑ/, to match MN55's CVs.

B. Methods

For PA07, the masking noise was SWN having SNRs of $[Q,12,-2,-10,-16,-20,-22]$ (Q for quiet), and that for PA05 WN was used with SNRs of $[Q,12,6,0,-6,-12,-15,-18,-21]$. All conditions were randomized and presented only once to each of the approximately 20 listeners. The CV speech stimuli for all experiments described in this paper are taken from the Linguistic Data Consortium at the University of Pennsylvania (corpus LDC-2005S22) (Fousek, *et al.* 2004) database composed of a large number of CV, VC, CCV, and VVC utterances, spoken by 20 talkers having different language backgrounds. Talkers' labels start with a talker gender label (f, m), followed by the talker ID (a three-digit number) and the sound label (e.g., m115pa).

The experiments were implemented using MATLAB©. The presentation program was written by student Andrew Lovitt, run on a desktop PC with a Linux kernel 2.4 (Mandrake 9) located outside an acoustic booth (Acoustic Systems model number 27930). Only the keyboard, liquid crystal display monitor, headphones, and mouse were inside the booth. Subjects sitting in the booth are presented with the speech files via a 16 bit PC sound card (Soundblaster Live) and Sennheiser HD280 headphones. Subjects responded as to which CV they heard via a graphical interface.

1. SNR calculations

To set the rms level, the following procedure was used. The rms level for the speech and the noise was set to 1 by computing the rms level for each, and dividing each waveform by that number. Second, the SNR was converted to a decimal value using the formula $g=10^{\text{snr}/20}$, where SNR is the decibel value. Third, the speech and noise were added according to the formula $\text{fix}(S=s+g*n)$ where s,n are the vector speech and noise wave forms. Finally, the absolute peak was found and the vector signal S was converted to an integer wave form, in preparation for outputting to the codec. This transformation is $KS(t)/S_{\max}$ where $K=32\,767=2^{15}-1$ is the maximum positive integer supported by the codec corresponding to the maximum codec voltage.

The rms for the speech was based on either a Volume Unit (VU) calculation (Lobdell and Allen, 2007) or a true rms calculation depending on the data set in question (Phatak and Allen, 2007). The rms of the noise was based on a true rms calculation.

To prevent loud sounds, the maximum allowed rms pressure was limited to 80 dB sound pressure level (SPL) by a hardware attenuator box located between the sound card and the headphones. This limit was based on a 1 kHz long-duration pure tone. The earphone sensitivity calibration (in Pa/V) was based on a 1 kHz tone SPL level on a flat plate coupler using an Etymotic ER7C probe microphone. When frequently asked, the subjects never requested any further level adjustment.

Subjects were volunteers from the University of Illinois student and staff population who had normal hearing (self-reported) and were native English speakers. They were compensated for their participation. Further details on methods may be found in the references.

C. Confusion pattern analysis

CPs [a row of the CM versus SNR, $P_{h|s}(\text{SNR})$] corresponding to a specific CV "spoken" (s) versus "heard" (h) utterance provide the representation of the scores as a function of SNR. CPs may be made for individual utterances or averaged over all talkers/utterances of the same CV. In the following analysis, we shall look at CPs for specific utterances.

Examples of CP plots for an individual /tɑ/ utterance from PA05 and PA07 are shown in Fig. 3, averaging data for 14 listeners for PA07 and 24 for PA05. Many important observations are supported by these charts.

1. Utterance variability

As SNR is reduced (noise increased), the target consonant score starts to measurably decrease at the *saturation threshold*, denoted SNR_s. This *robustness threshold* is defined as the SNR at which the consonant had an error equal to chance performance (6.25%). For example, in Fig. 3, corresponding to utterance f105ta, SNR_s is located at −16 dB SNR for SWN [left panel (a)] and at 0 dB SNR in WN [right panel (b)]. Each utterance presents a different threshold depending on its physical properties. This dependence will be explored in detail in the next section, Sec. III D, and then discussed in Sec. III E.

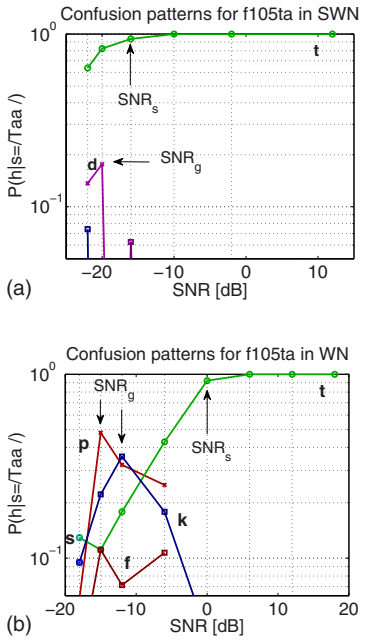

FIG. 3. (Color online) Confusion patterns for /tɑ/ spoken by female talker 105 in (a) SWN and (b) white noise. Note the significant robustness difference depending on the noise spectrum. In SWN, /t/ is correctly identified down to −16 dB SNR, whereas it starts to decrease at 0 dB in WN. SNR_s corresponds to the SNR at which the error starts to increase. The confusions are also more significant in WN, with the scores for /p/ and /k/ overcoming that of /t/ below −6 dB. We call this surprising observation morphing. The maximum confusion score is denoted SNR_g. The reasons for this robustness difference depend on the audibility of the /t/ event, which will be analyzed in the next section.

2. Spectral effects

It is clear from Fig. 3 that the noise spectrum (WN or SWN) strongly influences both SNR_s and the confusions occurring well below the saturation threshold. The *confusion group* of this /tɑ/ utterance in WN [Fig. 3(b)] is [/p/, /t/, /k/]. The SNR corresponding to the maximum in the confusion score is denoted SNR_g, and for this example is located close to (indicated with arrows) −18 dB SNR for /p/ and −15 dB for /k/, with respective scores of 50% and 35%. In SWN (a), /d/ is the only significant competitor (at a 20% level. $\text{SNR}_s=-16$ dB, $\text{SNR}_g=-20$ dB) due to its natural robustness to SWN. Summarizing then, the same utterance presents different robustness and confusion thresholds depending on the masking noise and the consonant spectral support. We shall further explore this in Sec. III D.

3. Morphing

As WN is mixed with utterance f105ta, /t/ *morphs* to /p/ or /k/, meaning that the probability of recognizing /t/ drops while that of /p/ and /k/ increases above that of /t/. At a SNR of −9 dB (WN), the /p/ and /k/ confusions overcome the target /t/ score. As shown in the CP plot of Fig. 3(b), the recognition of /p/ is maximum $[P_{/p/|/t/}(\text{SNR}_g=-16)=50\%]$, that of /k/ peaks at 35% at −12 dB, whereas the score for /t/ is about 10%. This morphing effect, while at first surprising,

is typical in our database for many consonant in white noise but much less common in SWN. The robustness of /t/ to SWN makes morphing rare in PA07 (SWN), as will be exampled later on, due the large difference in SNR spectral balance.

4. Priming

Listening experiments show that when the scores for consonants of a confusion group are similar, listeners can *prime* between these phones. Priming is defined as the ability to mentally select the consonant heard by making a conscious choice between several possibilities having neighboring scores. As a result of priming, given random presentations, a listener must randomly choose one of several priming consonants. The SNR range for which priming takes place is listener dependent; the CPs presented here are averaged across listeners and, therefore, are representative of an average priming range. At a given SNR, each listener has a bias toward one or the other sound, causing score differences. However, most listeners prime between /t/, /p/, and /k/ at around −10 dB SNR, whereas they typically have a bias for /p/ at −16 dB SNR and for /t/ above −5 dB. Based on our studies, we suspect that priming occurs when events, shared by consonants of a confusion group, are at the threshold of audibility, and when the distinguishing feature is at its masked threshold.

In summary, four major observations may be drawn from our analysis of many CPs of CVs similar to those of Fig. 3: (i) *robustness variability across utterances* as measured by SNR_s, (ii) *confusion group variability across noise spectra and utterances*, (iii) *morphing*, and (iv) *priming*. We conclude that each utterance presents different *saturation thresholds*, different *confusion groups, morphs* (or not), and may be subject to *priming* in some SNR range, depending on the masking noise spectrum and the consonant.

Our approach is to take advantage of this natural variability across tokens. As exampled in the above discussion, we will quantitatively relate the confusion patterns and robustness to the audible cues at a given SNR. Finding such relations enables us to identify events, namely, to label the acoustic features that map to "perceptual space."

Using the four-step method, described in the next section, we demonstrate that events are common across utterances of a particular consonant, whereas the *acoustic correlation* of the events, namely, the spectrotemporal and energetic properties, depends on the utterances, the noise spectrum, and the SNR. That is, while the acoustic features are highly variable, events are not. While in this report we only study /t/ and its confusions, we believe that /t/ is representative of other sounds in this regard.

5. Conclusion of confusion pattern analysis

We have used an AI-gram analysis on a large number of responses to many CV sounds in noise and related the scores to the audible speech features, with the end goal of finding events. These events represent the acoustic features that are robust to noise since they survive at very low SNRs (typically much less than 0 dB). Several features of the CPs have been defined, such as morphing, priming, and utterance variability in noise. The identification of a saturation threshold SNR_s (Fig. 3), located at the 93.75% point, is a quantitative measure of utterance robustness, and is a function of the noise spectrum. The natural utterance variability, quantified by this robustness threshold, causes utterances of the same phone category to behave differently with different types of noise.

The existence of morphing demonstrates that noise can mask an essential feature for the recognition of a sound, leading to consistent confusions among our subjects. However, such morphing is not ubiquitous, as it depends on the type and amount of masking noise. Different morphs are observed for different noise spectra. Morphing demonstrates that consonants are not uniquely characterized by independent features, but that they share *common cues* that appear to be weighted differently in perceptual space. This conclusion is supported by CP plots for /k/ and /p/ utterances, showing a well defined [/p/, /t/, /k/] confusion group structure in WN.

From the strong confusions, it seems clear that [/t/, /p/, /k/] share common perceptual features. A similar conclusion can (arguably) be derived from the results observed by Miller and Nicely (1955) (Allen, 2005b). The /t/ event is more easily masked by WN than by SWN, and the usual [/k/, /p/] confusion for /t/ in WN demonstrates that when the /t/ burst is masked, the remaining features are shared by all three voiceless stop consonants. As exampled in the next section, in Fig. 4(a), when the primary /t/ event is masked at high SNRs in SWN, we see strong [/p/, /t/, /k/] confusion groups. Our working hypothesis is that the common features shared by this group are masked by speech-weighted noise due to their localization in frequency, whereas the /t/ burst itself is usually robust in SWN.

We shall further show in Sec. III that this *common feature* hypothesis is also supported by temporal truncation experiments, similar to those of Furui (1986). It is shown that confusions take place when the acoustic features defining the primary /t/ event are inaudible due to noise or truncation, and that the remaining cues are part of what perceptually characterizes /t/'s competitors (/p/, /k/).

D. Four-step method to identify events

Our four-step method (steps 1–4) is an analysis that uses the perceptual models and correlates them with the CPs. This leads to the development of the *event gram*, derived from the AI gram, and uses human confusion responses to identify the relevant acoustic features. Here, we used the four-step method to draw conclusions about the /t/ event. There is some evidence that we may be able to explain other stop consonants using the four-step method. This will be studied in the near future. In Fig. 4(a), we identify and analyze the spectral support of the primary /t/ perceptual feature for two /tɛ/ utterances in SWN spoken by different talkers.

1. Step 1: CPs and robustness

Step 1 of our four-step analysis consists of the collection of confusion patterns described in the previous section, as in the bottom right panels of Figs. 4(a) and 4(b).

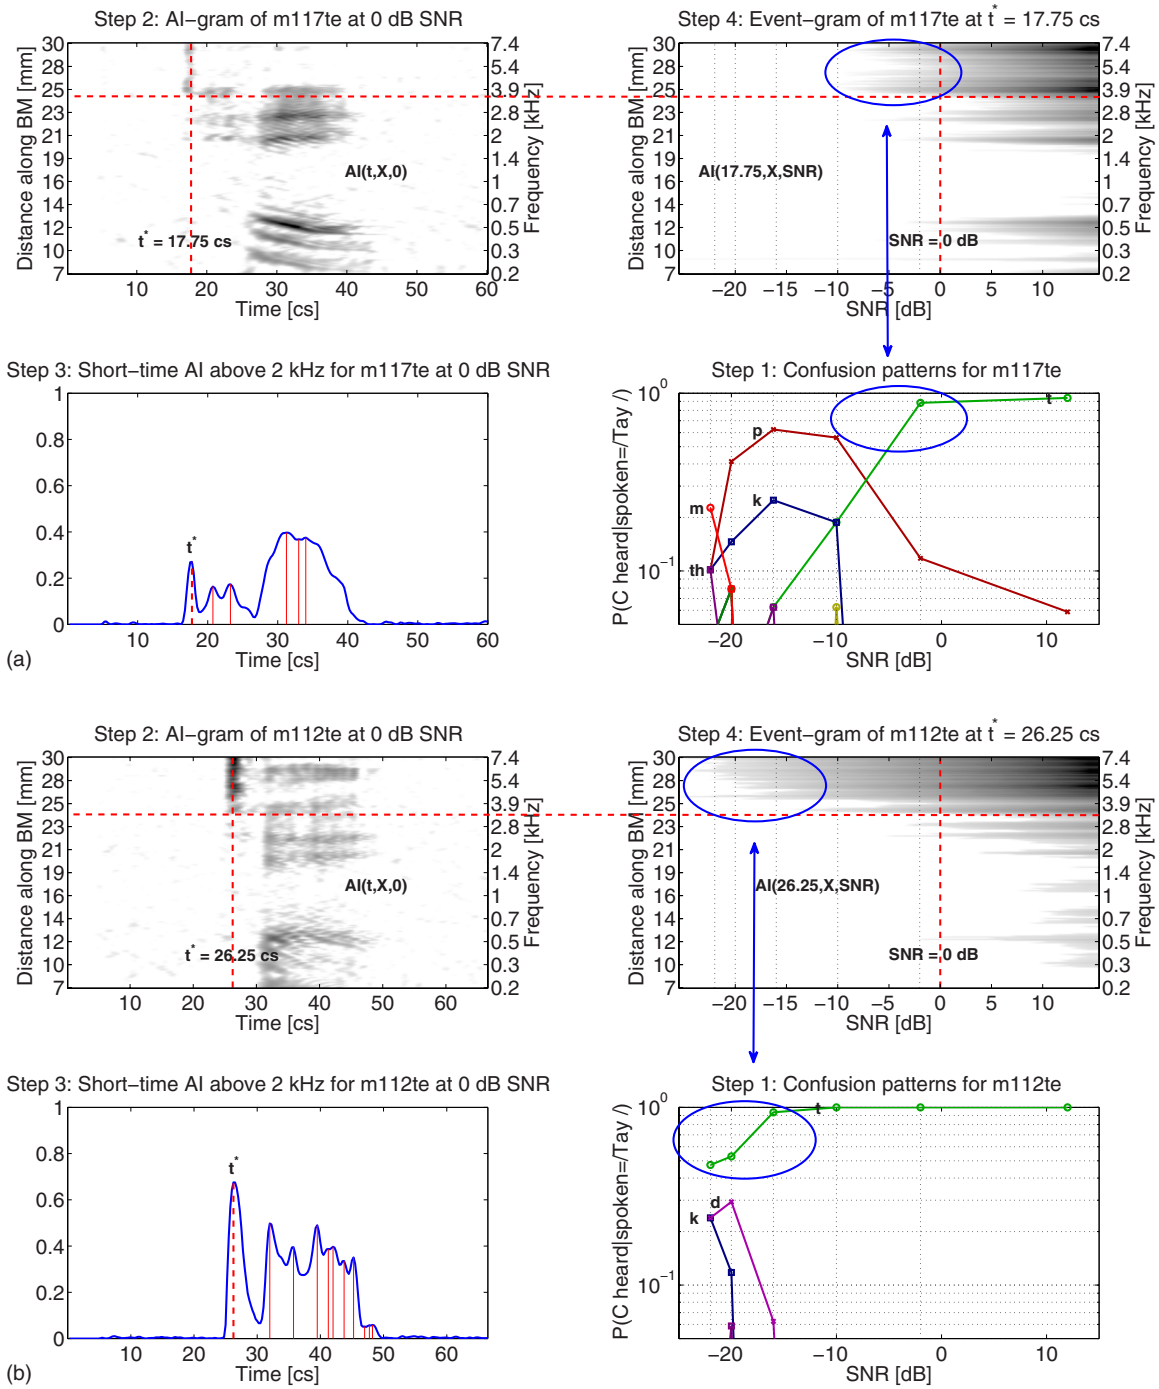

FIG. 4. (Color online) Comparison between a "weak" (top, m117te) and a "strong" (robust) (bottom, m112te) /tɛ/. The arrangement of the four panes is optimized for inner subfigure comparisons. Step 1 provides to the CPs (bottom right), step 2 to the AI gram at 0 dB SNR in SWN, step 3 to the mean AI above 2 kHz where the local maximum t^* in the burst is identified, leading to step 4, the event gram (vertical slice through AI grams at t^*). Note that for the same SWN masking noise, these utterances behave differently and present different competitors. Utterance m117te strongly morphs to /pɛ/. Many of these differences can be explained by the AI gram and more specifically by the event gram which quantifies the /t/-burst threshold, and therefore its robustness to noise. This threshold is precisely correlated with the human responses (encircled). This leads to the conclusion that this 2–8 kHz across-frequency onset transient is the primary /t/ event. (a) Analysis of sound /tɛ/ spoken by male talker 117 in SWN. This utterance is not robust to noise since the /t/ recognition starts to decrease at −2 dB SNR. Identifying t^*, time of the burst maximum at 0 dB SNR in the AI gram (top left), and its mean in the 2–8 kHz range (bottom left), leads to the event gram (top right). The vertical dashed line on the AI gram shows t^*. On the event gram, the dashed line shows the SNR at which the AI gram was displaced (similar to a vertical slice). In both cases, the horizontal dashed line marks the lower frequency limit of the burst (here 3.7 kHz) This representation of the audible phone /t/ burst information at time t^* is highly correlated with SNR_s and the CPs: when the burst information becomes inaudible (white on the AI gram), /t/ score decreases, as indicated by the ellipses. (b) Analysis of sound /tɛ/ spoken by male talker 112 in SWN. Unlike the case of m117te, this utterance is robust to SWN and identified down to −16 dB SNR. Again, the burst threshold defined by the event gram (top right) is related to SNR_s defined by the CP, accounting for the robustness of consonant /t/.

For male talker 117 speaking /tɛ/ [Fig. 4(a), bottom right panel], the saturation threshold is ≈−6 dB SNR (ellipsed), forming the /p/, /t/, /k/ confusion group. This weak /t/ morphs to /p/ [Fig. 4(a)]: the recognition of /p/ is maximum $[P_{/p/|/t/}(\mathrm{SNR}_g)=60\%]$ at a $\mathrm{SNR}_g=-16$ dB, where the score for /t/ is 6%. Morphing not only occurs in WN (Fig. 3

f105ta) but also in SWN for this weaker /tɛ/ sound (m117te). Confusion patterns and robustness vary dramatically across utterances of a given CV masked by the same noise: unlike for talker m117, /te/ spoken by talker m112 does not morph to /p/ or /k/, and its score is higher [Fig. 4(b), bottom right panel]. For this more robust utterance, /t/ was accurately identified down to $SNR_s = -16$ dB SNR (ellipsed) and was still well above chance performance (1/16) at −22 dB. Its main competitors /d/ and /k/ have 25%–30% scores and which only appear well below SNR_s.

It is clear that these two /tɛ/ sounds are dramatically different. Note that utterance differences are only seen with the addition of a masking noise. There is confusion pattern variability not only across noise spectra but also within a masking noise category (e.g., WN versus SWN). These two /tɛ/'s are an example of *utterance variability*, as shown by the analysis of step 1: two sounds are heard the same when it is quiet, but they are heard quite differently as the SNR is varied. The next section will detail the physical properties of consonant /t/ in order to relate spectrotemporal features to the score using our audibility model.

2. Steps 2 and 3: Utilization of a perceptual model

For talker 117, Fig. 4(a) (top left panel) shows the AI gram at 0 dB SNR. We observe that the high-frequency burst having a sharp energy onset, stretches from 2.8 to 7.4 kHz and runs in time from 16 to 18 cs (a duration of 20 ms). According to the CPs previously discussed [Fig. 4(a), bottom right panel], at 0 dB SNR consonant, /t/ is recognized 88% of the time. The burst for talker 112 has higher intensity and spreads from 3 kHz up, as shown by the AI gram for this utterance [Fig. 4(b), top left panel], which results in a 100% recognition at and above −10 dB SNR.

These observations lead us to step 3, the integration of the AI gram over frequency [bottom right panels of Figs. 4(a) and 4(b)]. One obtains a representation of the average audible speech information over a particular frequency range Δf as a function of time, denoted the short-time AI, AI(t) (Rhebergen *et al.*, 2006). Here, AI(t) is computed in the 2–8 kHz bands, corresponding to the limits of this high-frequency /t/ burst. In contrast, the traditional AI is the area under the entire frequency range. (In this case, if we integrated over all frequencies, there would be only a very small difference.) The first maximum, AI(t^*) [vertical dashed line on the top and bottom left panels of Figs. 4(a) and 4(b)] is an indicator of the audibility of the consonant /t/ burst. Since the frequency content is collapsed, t^* indicates the time of the relevant perceptual information for /t/.

3. Step 4: The event gram

The identification of t^* allows step 4 of our correlation analysis. The top right panels of Figs. 4(a) and 4(b) represent the event grams for the two utterances. The event gram, AI(t^*, X, SNR), is defined as a cochlear place (or frequency, via Greenwood's cochlear map) versus SNR slice at one instant of time. The event gram is the link between the CPs and the AI gram. The event gram represents the AI density as a function of SNR at a given time t^* (determined in step 3). If several AI grams computed at different SNRs were stacked, the event gram would be a vertical slice through this stack. In summary, the event grams displayed in the top right panels of Figs. 4(a) and 4(b), plotted at t^*, characterize the /t/ burst's threshold. A horizontal dashed line, from the bottom of the burst on the AI gram to the bottom of the burst on the event gram at SNR=0 dB, provides the visual link between the two plots.

The significant result visible on the event gram is that for these two utterances, the event gram is correlated with the average normal listener score, as seen in the ellipses linked by a double arrow. Indeed, for utterance 117te, the recognition of consonant /t/ starts to drop at −2 dB SNR, when the burst above 3 kHz is completely masked by the noise [top right panel of Fig. 4(a)]. On the event gram, below −2 dB SNR (circle), one can note that the energy of the burst at t^* decreases, and the burst becomes inaudible (white). A similar relation is seen for utterance 112, but since the energy of the burst is much higher, the /t/ recognition starts to fall at −15 dB SNR, at which point the energy above 3 kHz becomes sparse and decreases, as seen in the top right panel of Fig. 4(b) and highlighted by the circles.

There is an obvious correlation in this example between the variable /t/ confusions and the score for /t/ [step 1, bottom right panel of Figs. 4(a) and 4(b)], the strength of the /t/ burst in the AI gram (step 2, top left panels), and the short-time AI value (step 3, bottom left panels), all quantifying the event gram (step 4, top right panels). Because these panels are correlated with the human score, the burst constitutes our model of the perceptual cue (the event), upon which listeners rely to identify consonant /t/ in noise.

A systematic quantification of this correlation for a large number of consonants will be described in the next section, where we analyze the effect of the noise spectrum on the perceptual relevance of the /t/ burst in noise to account for the differences previously observed across noise spectra.

4. Effect of the noise samples

A classical question is the difference between internal and external noises in masking (Allen and Neely, 1997). Internal noise is due to the internal representation of the signal in a critical band while external noise is due to the uncertainty from the external noise added to the signal. Given this classical classification scheme, it was natural to wonder about the significance of the different ensemble noise samples on the variability of the event gram. Our experiment procedure was designed so that a new noise sample was used for each token presentation, so listeners never hear a signal (speech sound) mixed with the same masker (noise) even when presented at the same SNR.

To study this effect, we analyzed the variance using different noise samples having the same spectrum (the phase of the noise varied from trial to trial) and computed event grams for ten different noise samples. The resulting variance is shown in Fig. 5 for utterance f103ta in SWN. The result is that both regions of high and low SNRs show a small variance. Only where the SNR is near zero do the speech and noise interact, giving a finite variance. It makes sense that the only noticeable variance is seen near threshold. The

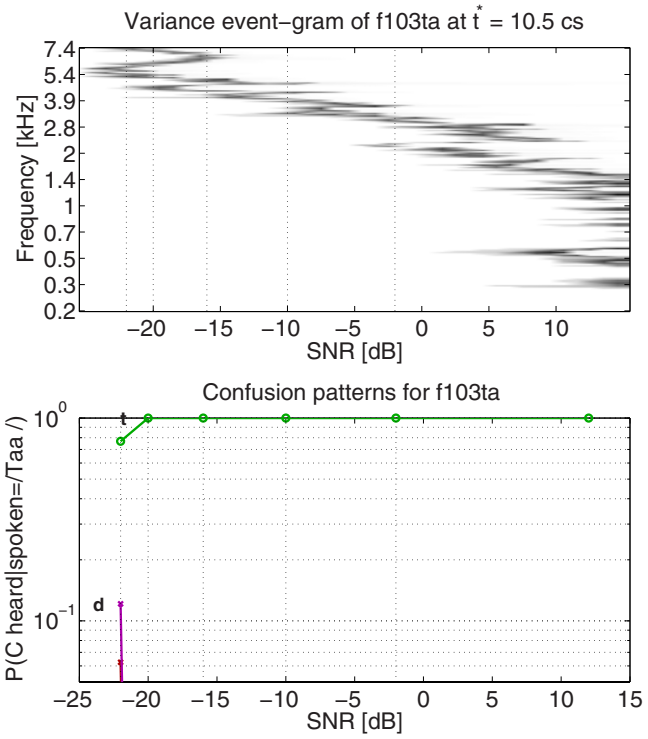

FIG. 5. (Color online) This variance event gram was computed by taking event grams of a /tɑ/ utterance for ten different noise samples in SWN (PA07). We can see that all the variance is located on the edges of the audible speech energy, where the noise and speech have similar level, located between regions of high audibility and regions of noise. However, the spread is thin, showing that the use of different noise samples will not significantly impact the perceptual scores.

thickness of the line is a measure of the trial variance. The small spread of the line indicates that using a new noise on every trial has little impact on the scores of our psychophysical experiment, and the correlation between noise and speech is unlikely to impact the features significantly, and to the extent it does, only over a small SNR range.

E. Discussion: Relating CPs and audibility for /t/

Using a four-step method analysis, we found that the discrimination of /t/ is due to its robustness, defined by a sharp onset burst from 2 to 8 kHz. Robustness, measured by SNR_s and CPs (confusion groups), are highly dependent on the specific utterance due to variations in this burst. Each instance of the /t/ burst typically presents different characteristics. As shown in Fig. 3, SNR_s changes with the noise type for a given sound. This correlation demonstrates that a consonant presents different perceptual thresholds. Additionally, in Fig. 4, we found that the /t/ event is invariant for two utterances and is masked at different SNRs and correlated with SNR_s.

As compared to SWN, WN provides more masking at high frequencies, accounting for the decrease of the /t/ at high SNR recognition. Once the burst starts being masked, at SNR_s, the /t/ score quickly drops below 100%. The acoustic representations in the physical domain of the perceptual features is highly variable (e.g., 16 dB in our example), while the perceptual features themselves (events) remain invariant.

We wish to more precisely quantify the /t/ event in the physical domain; however, improved characterization of the spectrotemporal location of the burst is needed to fully quantify its impact on robustness across utterances.

To further quantify the correlation between the audible speech information from the event gram and the perceptual information given by our listeners, we have correlated *event-gram thresholds*, denoted SNR_e, with the 90% score SNR, denoted SNR_{90}. Based on our regressions between SNR_e and the score, the 90% score point represents the /t/ feature with a smaller residual error over the wide range of conditions we studied. Thus, the onset drop in score appears to be more highly correlated with SNR_e than SNR_s. Here, we wish to identify the optimal set of parameters that will maximize the correlation between SNR_e and SNR_{90}). Our previous results, based on the four-step method, enable us to limit the search above 2 kHz, a frequency ranged *assumed* to be most relevant to /t/ recognition.

The parameters used here are an AI density threshold T and an adaptive bandwidth B. For given values of T,B, we determined the SNR range where there is continuous speech information in frequency above AI threshold T. To start the search for the optimum values of T and B, a set of values of SNR_e is determined for different pairs of parameters, within 5 Hz steps for the bandwidth and steps of 0.005 for the threshold. The value corresponding to the lowest mean square error for the correlation with SNR_{90} gives SNR_e. The procedure was followed independently for PA05 and PA07 and gave two slightly different optimized parameters, namely, $B=570$ Hz in SWN for $T=0.335$, and $B=450$ Hz for $T=0.125$ in WN.

Fourteen of the /ɑ/ utterances tested in PA07 were also in PA05; therefore, sound common to both experiments appears twice on the scatter plot. Scatter plots for PA05 (in WN) are at higher SNRs than those for PA07 (in SWN) due to the stronger masking of the /t/ burst in WN, leading to higher SNR_e and SNR_{90}.

The high correlation between SNR_{90} and the event-gram thresholds for the parameters used, represented by their proximity to the 45° line, proves that our AI-gram audibility model and the event gram are good predictors of the average normal listener score. The 120 Hz difference between optimal bandwidths for WN and SWN seems insignificant. The identification of an intermediate value for both noise spectra would be the basis of additional work. The difference in optimal AI thresholds T is likely due to the spectral emphasis of each noise (low frequencies in SWN and high frequencies in WN). The lower value obtained in WN could also be the result of other cues at lower frequencies, contributing to the score, when the burst is weak. More research will be needed to identify the optimal parameters and to precisely characterize the correlation between the scores and the event-gram model.

Figure 6(b) shows an event gram in SWN, for utterance f106ta, with the optimal bandwidth between the two horizontal dashed lines, leading to the identification of SNR_e. Below

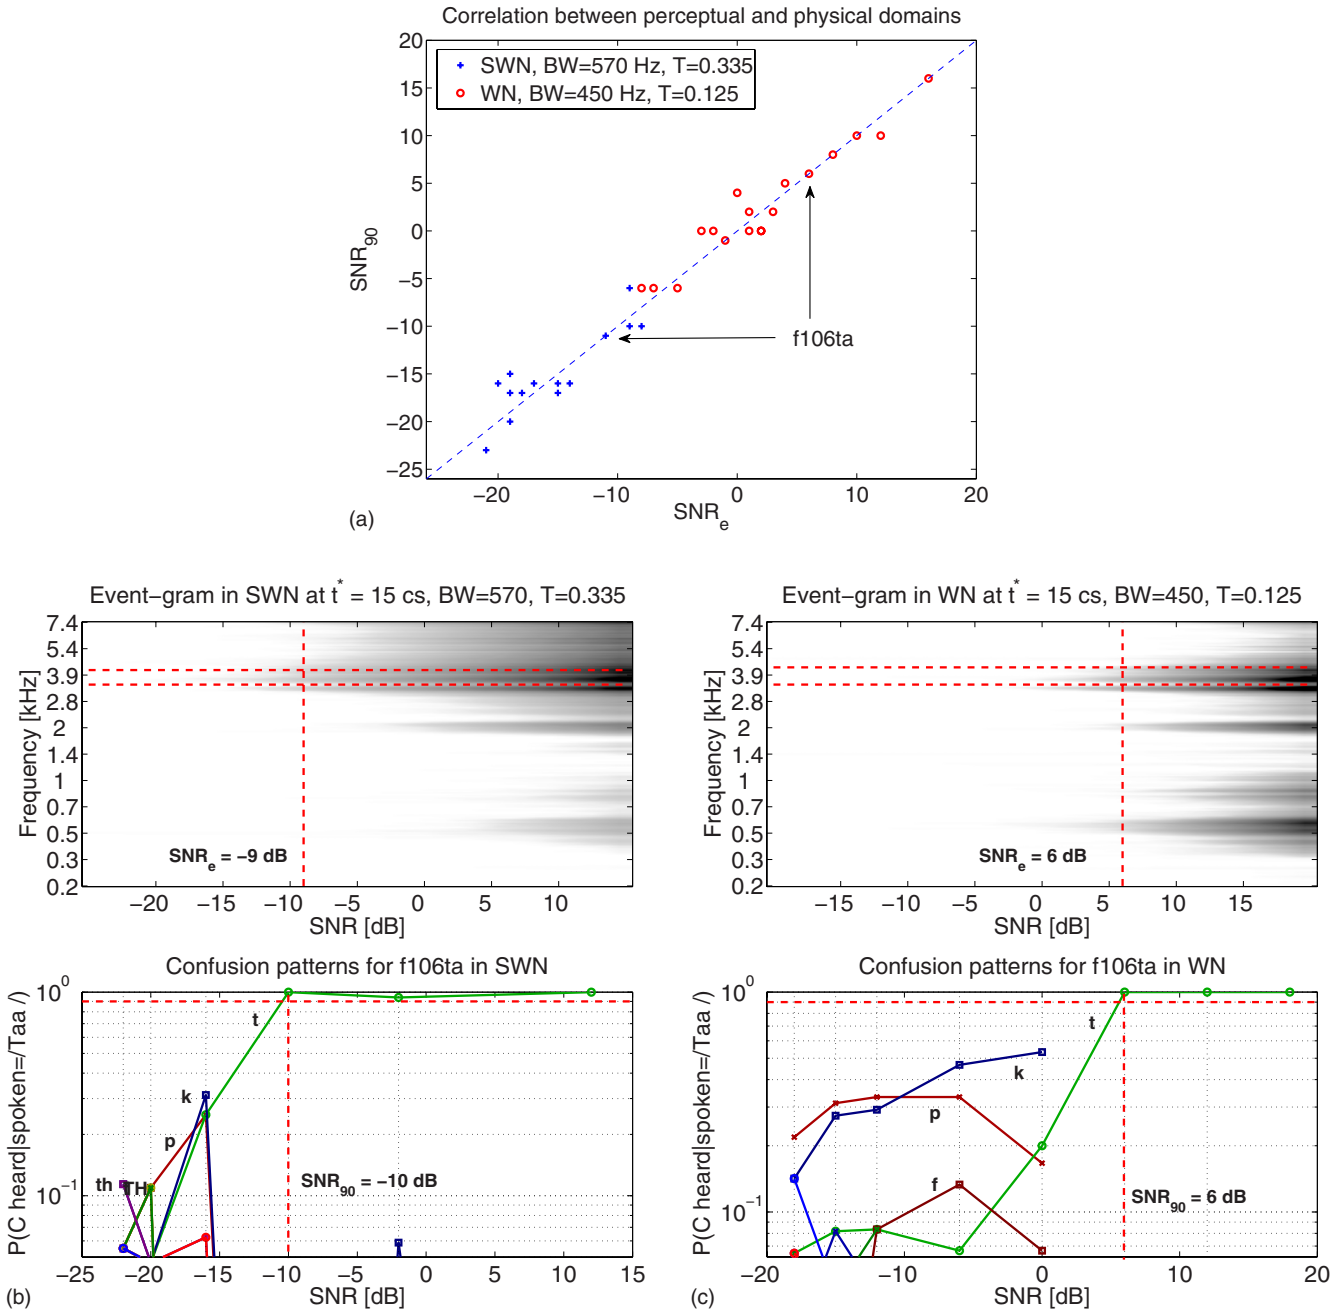

FIG. 6. (Color online) (a) Scatter plot of the event-gram thresholds SNR_e above 2 kHz, computed for the optimal burst bandwidth B having an AI density greater than the optimal threshold T compared to the SNR of 90% score. Utterances in SWN (+) are more robust than those in WN (○), accounting for the large spread in SNR. We can see that most utterances are close to the 45° line, showing the high correlation between the AI-gram audibility model (middle pane) and the event gram (right pane). The detection of the event-gram threshold SNR_e is shown on the event gram in SWN [top pane of (b)] and WN [top pane of (c)], between the two horizontal lines, for f106ta, and placed above their corresponding CPs. SNR_e is located at the lowest SNR where there is continuous energy above 2 kHz and spread in frequency with a width of B above AI threshold T. We can notice the effect of the noise spectrum on the event gram, accounting for the difference in robustness between WN and SWN.

are the CPs where $SNR_{90}=-10$ dB is shown by a vertical dashed line (thresholds are chosen in 1 dB steps, and the closest SNR integer value above 90% is chosen for SNR_{90}). Panel (c) shows the event gram and CPs for the same utterance in WN. The points corresponding to utterance f106ta are denoted by arrows.

Regardless of the noise type, we can see on the event grams the relation between the audibility of the 2–8 kHz range at t^* (in dark) and the correct recognition of /t/ even though the thresholds are much lower in SWN than in WN. More specifically, the strong masking of WN at high frequencies accounts for the early loss of the /t/ audibility as compared to SWN.

We conclude that the burst, as a high-frequency coinciding onset, is the main event accounting for the robustness of consonant /t/ independent of the noise spectrum. It presents different physical properties depending on the masker spectrum, but its audibility is strongly related to human responses in both cases. The event is therefore based on the audibility of the /t/ burst, not on any superthreshold property.

To further amplify the conclusions of the four-step method, we decided to run a psychophysical experiment where the /t/ burst would be truncated and study the resulting responses under lower noise conditions. We hypothesize that since the /t/ burst is the most robust-to-noise event, it is the strongest feature cuing the /t/ percept even at higher SNRs. A truncation experiment would therefore remove this crucial /t/ information.

IV. EXPERIMENT 2: TIME TRUNCATION

We next strengthen our conclusions drawn from Fig. 4 based on a confusion pattern and the event-gram analysis. Inspired by the work of Furui (1986), we truncated CV sounds in 5 ms steps and studied the resulting morphs. Our goal is to answer a fundamental research question raised by the four-step analysis of /t/: can the truncation of /t/ cause a morph to /p/, implying that the /t/ event is prefixed to consonant /p/, thereby showing that they share common features? Such a conclusion would be consistent with our observation that many /t/'s strongly morph to /p/ when the energy at high frequencies around t^* is masked by the noise.

A. Methods

Two SNR conditions, 0 and 12 dB SNRs, were used with SWN. The noise spectrum was identical to that used in PA07 (Phatak and Allen, 2007). In preliminary pilot studies, we identified the most common responses, and 22 were chosen that seem to accommodate our subjects. The final response task was then a forced choice among the 22 possible consonant CV responses or vowel only. A "vowel only" button was provided for those cases where no consonant could be identified. When queried, our subjects never expressed a need to add more response choices. Ten subjects participated in the final experiment.

1. Stimuli

The six tested CVs were /tɑ/, /pɑ/, /sɑ/, /zɑ/, /ʃɑ/, and /ʒɑ/ spoken by ten different talkers, for a total of 60 utterances. The times of the onset of each consonant and vowel were hand labeled. Onset truncations were generated automatically from these timing markers every 5 ms, including a "no truncation" condition and a "total" truncation condition, where only the vowel was played. One-half second of noise was prefixed to the CVs. The truncation was created by ramping the clean speech with half of a 10 ms Hamming window (5 ms ramp). The noise was added following the ramping. We only report the /t/ results here.

B. Results

The main conclusion of the /tɑ/ truncation experiment is the strong morph obtained for *all* of our stimuli when less than 30 ms of the /t/ burst are removed relative to the hand-labeled onset of the consonant. When presented with our truncated /tɑ/ sounds, listeners most commonly reported hearing /p/. Occasionally, /k/ or /h/ is reported, but when so, they have much lower average scores than /p/. In all cases, transitions took place within a 5–10 ms time frame. Specifically, the /t/ recognition abruptly dropped from above 90% at the onset of morphing to less than 10% within 5–10 ms.

Two main trends can be observed. Four out of ten utterances followed a hierarchical $/t/ \rightarrow /p/ \rightarrow /b/$ morphing pattern (group 1). In these cases, the consonant was first identified as /t/ for truncation times less than 30 ms; then /p/ is reported over a period spreading from 30 to 110 ms (one extreme case) and to finally reported as /b/.

The results (all four utterances) of group 1 are shown in Fig. 7. Note the significant variability in the crossover truncation times (the duration that the target and the morph scores overlap). This is due to both the natural variability in the /t/ burst duration and variation in the subject's responses. We have not analyzed the relative magnitudes of these two sources of variation. As a rule, the change in SNR from 12 to 0 dB had only a negligible impact on the scores (see Fig. 7).

The second trend (group 2) consisted of utterances that morph from $/t/ \rightarrow /p/$ but are also confused with /h/ and /k/. Five out of ten utterances (shown in Figs. 8 and 9) are in this group. The /h/ confusion is represented by the black dashed line and is stronger for the two top utterances, m102ta and m104ta [Figs. 8(a) and 8(b)]. A decrease in SNR from 12 to 0 dB caused a small increase in the /h/ score, almost bringing scores to chance performance (e.g., 50%) between those two consonants for the top two panels. This suggests a priming situation between these two sounds. The four lower panels show results for talkers m107 and m117, where a decrease in SNR causes a /k/ confusion which is as strong as the /h/ confusion but which differs from the 12 dB case, where competitor /k/ was not reported. The final example for the truncation of utterance f113ta (Fig. 9) shows a weak /h/ confusion to the /p/ morph, not significantly affected by a SNR change.

A noticeable difference of group 2 from group 1 is the absence of /b/ as a significant competitor. This discrepancy could simply be due to the limit of the truncation times. Utterances m104ta and m117ta [Figs. 8(b) and 8(d)] show weak /b/ confusions at the last truncation time tested. More test conditions would be needed to confirm this. Alternatively, since /p/ is a midstate between /t/ and /b/, we might simply study /pɑ/ truncations. In our /pɑ/ truncation data (not shown), not all /pɑ/s morph to /bɑ/; in most cases, no consonant is heard for the maximum truncation condition (i.e., only the vowel is reported). Therefore, if our $/t/ \rightarrow /p/$ results suggest that /p/ could be a precursor for /t/, we have not yet drawn this conclusion for $/p/ \rightarrow /b/$. More experiments will be required to resolve this apparent discrepancy. Of course, it is possible that the confusions with /h/ play a role in the loss of /b/ confusions.

In the figures, notice that for both groups 1 and 2, the onset time of the /t/ confusion depends on SNR. In most of the 0 dB case, the score for /t/ drops 5 ms earlier than for the 12 dB cases. This is likely due to masking of both sides of the burst energy, making them less audible and more difficult to be heard as an onset cue. When we study the AI grams for these cases, we see that the /t/-burst energy is weaker at t^*

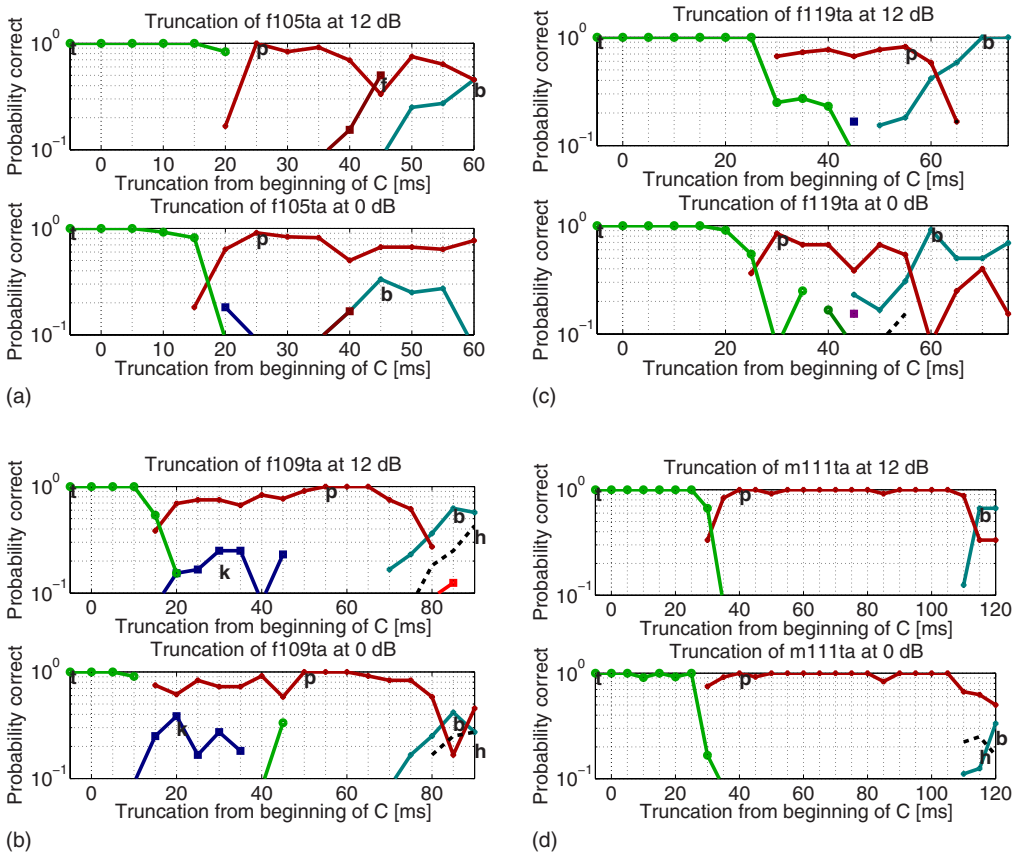

FIG. 7. (Color online) Group 1 utterances are defined as those which morph as /t/ → /p/ → /b/. For each panel, the top plot represents responses at 12 dB SNR and the lower those at 0 dB SNR. There is no significant SNR effect for these sounds. (a) Truncation of f105ta at 12 (top) and 0 dB SNRs (bottom). (b) Truncation of f109ta at 12 (top) and 0 dB SNRs (bottom). (c) Truncation of f119ta at 12 (top) and 0 dB SNRs (bottom). (d) Truncation of m111ta at 12 (top) and 0 dB SNRs (bottom).

(where the /t/ burst energy has its maximum). The best example of this somewhat subtle SNR effect is shown in Fig. 7(d).

As shown in Fig. 10, the pattern for the truncation of utterance m120ta was totally different from the other nine utterances included in the experiment. First, the score for /t/ did not decrease significantly after 30 ms of truncation. Second, /k/ confusions were present at 12 but not at 0 dB SNR, causing the /p/ score to reach 100% only at 0 dB. Third, the effect of SNR was pronounced. Figure 10 shows AI grams of this /tɑ/ at 12 (a) and 0 (b) dB SNRs. We can see that the burst is very strong for about 35 ms for both SNRs, which accounts for the high /t/ recognition in this range. For truncation times greater than 35 ms, /t/ is still identified with an average probability of 30%. This effect appears to be due to the level of high-frequency energy following the onset. As a result of the truncation, a coinciding onset of energy in the /t/-burst event frequency range is created, the duration of which is close to the natural /t/ burst.

For the 12 dB SNR case and for truncation times greater than 4 cs, this artificial /t/ burst appears to be weaker than the original strong onset burst. This explains the lower /t/ score compared to that in the untruncated version.

An unanticipated score inversion appears at 55 ms for the 0 dB SNR case. This /t/ peak is also weakly visible at 12 dB (left). We hypothesize that midfrequency energy, most likely around 0.7 kHz, is cuing /p/ at 12 dB but being masked at 0 dB SNR, enabling the /t/ recognition to rise. For the first 30 ms of truncation, this behavior is similar to that of the other utterances. The pattern observed for later truncation times is a demonstration of utterance variability, and can thus be explained without violating the /t/ burst event hypothesis. As shown by the truncation plots, when the /t/ burst is gone, beyond 80 ms, the /t/ score finally drops.

We conclude from the CV-truncation data that the *consonant duration* is an important timing cue used by listeners to distinguish /t/ from /p/. This duration depends on the natural duration of the /t/ burst. When only 5–10 ms more are truncated, the scores can drop dramatically. This demonstrates the high temporal sensitivity of the /t/ burst. As discussed earlier, we found in additional results (not shown) on truncated /pɑ/ that utterances are frequently confused with /bɑ/. This is consistent with the idea of a hierarchy of speech sounds, clearly present in our group 1 /tɑ/ examples. At the core of this hierarchy is /p/. By prefixing a short-duration burst, this can become /tɑ/ or /kɑ/. We have limited preliminary data that show that this works for several other vowels as well.

In summary, using our truncation procedure, we have independently verified that the high-frequency burst accounts for the noise-robust event corresponding to the discrimination between /t/ and /p/ even in moderate noisy conditions. Thus, we confirm that our approach of adding noise to iden-

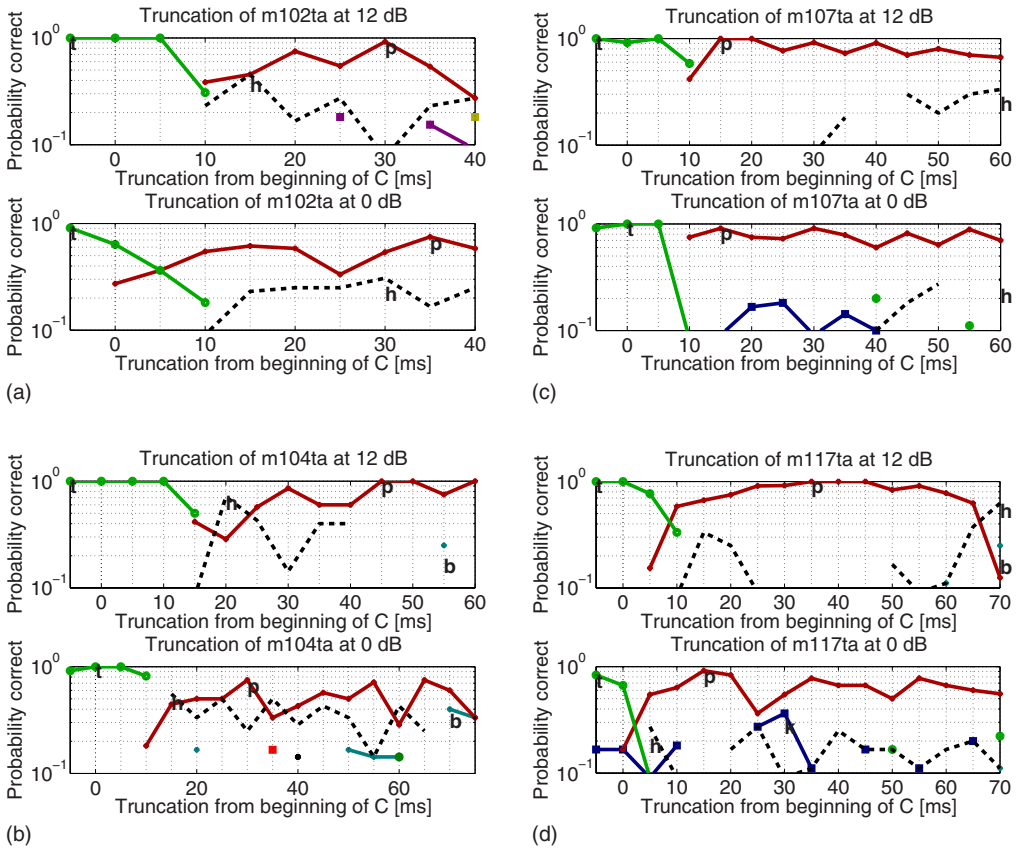

FIG. 8. (Color online) Utterances of group 2: Consonant /h/ strongly competes with /p/ (top), along with /k/ (bottom). For the top right and left panels: increasing the noise to 0 dB SNR causes an increase in the /h/ confusion in the /p/ morph range. For the two bottom utterances, decreasing the SNR causes a /k/ confusion that was nonexistent at 12 dB, equating the scores for competitors /k/ and /h/. (a) Truncation of m102ta at 12 (top) and 0 dB SNRs (bottom). (b) Truncation of m104ta at 12 (top) and 0 dB SNRs (bottom). (c) Truncation of m107ta at 12 (top) and 0 dB SNRs (bottom). (d) Truncation of m117ta at 12 (top) and 0 dB SNRs (bottom).

tify the most robust, and therefore crucial perceptual information, enables us to identify the primary feature responsible for the correct recognition of /t/.

C. Discussion

The results of our truncation experiment demonstrate that the /t/ recognition is masked after 30 ms for nine out of ten of our stimuli. This is in locked agreement with our analysis of the AI gram and event gram emphasized by our four-step analysis. We proved, therefore, that the leading edge of the /t/ burst from 2 to 8 kHz is used by our listeners to identify /t/ at all SNRs. We conclude that this burst is an across-frequency coincidence over a specific frequency range, and it plays the key role in the robust recognition of /t/.

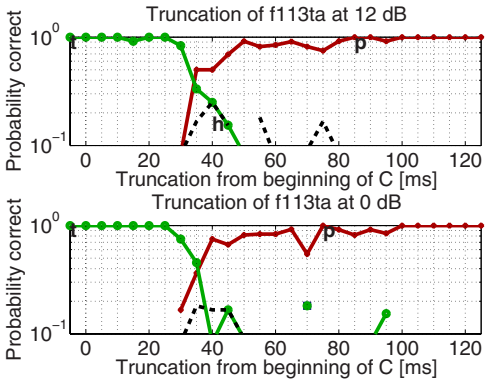

FIG. 9. (Color online) Truncation of f113ta at 12 (top) and 0 dB SNRs (bottom): Consonant /t/ morphs to /p/, which is slightly confused with /h/. There is no significant SNR effect.

Moreover, the /p/ morph that consistently occurs when the /t/ burst is truncated shows that consonants are not perceptual independent; thus, they share common cues. This hypothesis leads to the possible existence of "root" consonants. We presently view /p/ as a voiceless stop consonant root containing raw but crucial spectrotemporal information to which primary robust-to-noise cues can be added to form the various consonant of /p/'s confusion group. We have only demonstrated this here for the case of /t/. When CVs are mixed with masking noise morphing and priming are important empirical observations that are correlated with this conclusion.

Future work would need to verify that the /t/ recognition significantly drops when 30 ms of *only* the above 2 kHz burst region is removed. Such an experiment would further prove that it is an exclusively high-frequency /t/-burst event, making it not just sufficient but a necessary condition.

Dynamically modifying such timing events using signal processing techniques could lead to a new family of hearing

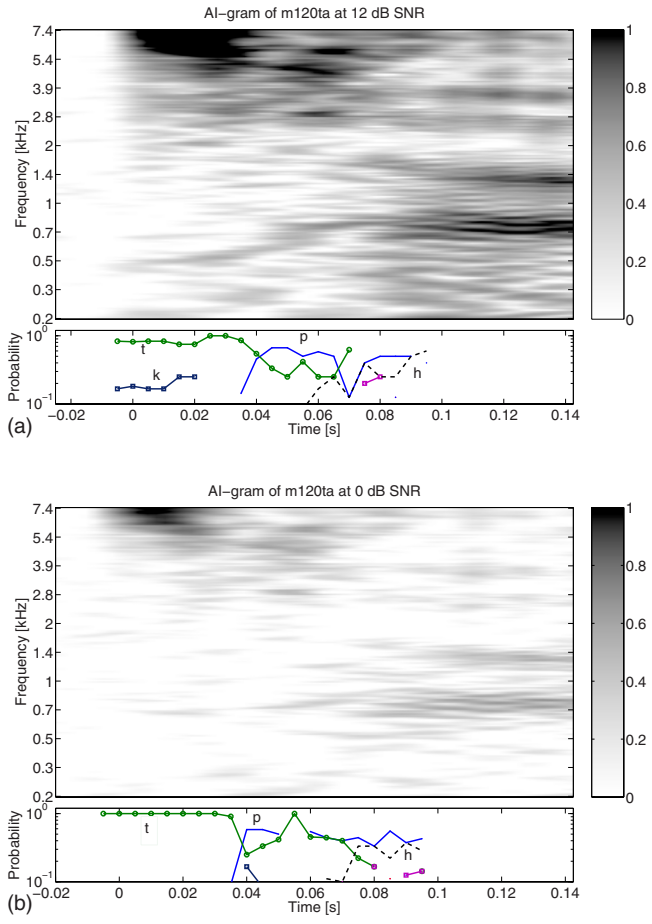

FIG. 10. (Color online) (a) 12 dB SNR zoomed AI gram. (b) 0 dB SNR zoomed AI gram. AI grams of m120ta, zoomed to a duration of 160 ms, in the consonant and transition regions at (a) 12 dB SNR and (b) 0 dB SNR. Below each AI gram are plotted the listener responses as a function of the truncation time, time synchronized. Uniquely for this utterance, the /t/ identification is still high after 30 ms of truncation, presumably because of the long-duration residual high-frequency (i.e., 2–8 kHz) energy. The target probability even overcomes the score for /p/ at 0 dB SNR at a truncation time of 55 ms, most likely because of a strong relative /p/ event present at 12 dB but weaker at 0 dB.

aids (Braida *et al.*, 1979), cochlear implants (Rabinowitz *et al.*, 1992; Shannon *et al.*, 1995), and robust automatic speech recognition (Hermansky, 1998).

Making automatic speech recognizers robust to noise, based on knowledge of human speech recognition, would be a tremendous breakthrough in an area where significant improvement is sorely needed (Lippmann, 1997; Dusan and Rabiner, 2005).

V. CONCLUSION

Our overall approach aims at directly relating our model of *speech audibility* in noise, the AI gram, a generalization of the AI, to the *confusion pattern discrimination measure* for consonant /t/. The AI gram represents an "input" measure, while the CPs are the "output" measure of the auditory speech processing system. Our approach is novel and represents a significant contribution toward solving the speech robustness problem as it has successfully led to the identification of the /t/ event as a synchronous 2–8 kHz temporal burst. This event is common across CVs identified with /t/ even if its physical properties widely vary across utterances. The strength of this acoustic feature leads to different degrees of robustness to noise. We have harnessed its natural variability to allow us to establish a correlation between the acoustic features and the scores. The correlation we observed between event-gram thresholds and 90% CP scores [Fig. 6(a)] confirms our hypothesis. This nearly perfect correlation between the /t/ burst strength and /t/ masked threshold scores has been demonstrated in a systematic manner across a large number of utterances.

Our results are consistent with the idea that the auditory brain is listening for onset transients. There is a small but significant literature on the importance of onset transients in both cortical research (Heil, 1997; Oertel, 2005; Heil, 2003; Shamma, 2003) and in the music perception research where timing onsets are known to carry important information about instrument identity.

Our onset-timing interpretation of speech cues resulted in a second experiment where we truncated the sounds from the onset and to the concept of a hierarchy of consonants forming the confusion group. It confirms our hypothesis that consonants forming a confusion group share common events. Finally, we have clearly shown that the /t/ burst is the primary feature for the identification of /t/ even in small amounts of noise. Primary events, along with a shared base of perceptual features, are used to discriminate consonants and characterize the consonant's degree of robustness to masking noise.

We have concluded that the event is therefore based on the audibility of the /t/ burst, not on any superthreshold property.

We believe that a hearing aid, tuned to such onset transients, could extract these cues and amplify them on a listener basis, resulting in significant improvement of speech identification in noisy environments for hearing impaired (HI) listeners.

ACKNOWLEDGMENTS

The authors wish to acknowledge the support of the Human Speech Recognition Group for the valuable comments and data collection. The authors would like to thank Etymotic Research and Starkey Laboratories for the financial support used to pay the subjects in the many experiments. Financial support was mostly provided by the ECE Department, UIUC. This work constitutes a portion of the first author's MS thesis.

(Received 5 January 2007; revised 14 February 2008; accepted 14 February 2008)

The present study systematically manipulated three acoustic cues—fundamental frequency (f0), amplitude envelope, and duration—to investigate their contributions to tonal contrasts in Mandarin. Simplified stimuli with all possible combinations of these three cues were presented for identification to eight normal-hearing listeners, all native speakers of Mandarin from Taiwan. The f0 information was conveyed either by an f0-controlled sawtooth carrier or a modulated noise so as to compare the performance achievable by a clear indication of voice f0 and what is possible with purely temporal coding of f0. Tone recognition performance with explicit f0 was much better than that with any combination of other acoustic cues (consistently greater than 90% correct compared to 33%–65%; chance is 25%). In the absence of explicit f0, the temporal coding of f0 and amplitude envelope both contributed somewhat to tone recognition, while duration had only a marginal effect. Performance based on these secondary cues varied greatly across listeners. These results explain the relatively poor perception of tone in cochlear implant users, given that cochlear implants currently provide only weak cues to f0, so that users must rely upon the purely temporal (and secondary) features for the perception of tone. © *2008 Acoustical Society of America.*

I. INTRODUCTION

In Mandarin Chinese, four tones are one of the phonetic determinants of lexical meaning (e.g., Chao, 1948; 1968; Yip, 1980). These four tones are mainly distinguished by their variations in fundamental frequency (e.g., Howie, 1976; Lin, 1988). The four tonal patterns are often described in terms of the pitch range of the particular speaker. Tone 1, the level tone, starts within a speaker's high pitch range and maintains approximately the same pitch to the end of the syllable. Tone 2, the rising tone, starts in a middle pitch range, then shows a rise, which is sometimes preceded by a small dip. Tone 3, the falling–rising tone, also starts in a middle pitch range, falls gradually toward a low pitch and then rises. Tone 4, the falling tone, starts at a high pitch, and drops to a low one. A syllable with different tones represents different words. For example, the syllable *ba* expressed with tones 1, 2, 3, and 4 means "eight," "to pull," "to hold," and "father," respectively.

Although tone 3 is often referred to as a falling–rising pattern, it also appears in other forms (e.g., Chao, 1948; 1968; Shih, 1988; Chen, 2000). This variation is due to phonological processes that are described by the third tone sandhi rule. A falling–rising pattern appears in isolated words and in sentence-final position. However, in nonfinal positions, a low-falling pattern occurs. In addition, if a syllable with tone 3 is followed by another syllable with the same tone, the first syllable will be pronounced as tone 2, a rising tone. Therefore, tone 3 appears in three patterns: the falling–rising pattern, the low-falling pattern, and the rising pattern. Previous studies have shown that tone 3 was sometimes misidentified as the falling tone (tone 4) or the rising tone (tone 2) (Gårding *et al.*, 1986; Shen and Lin, 1991).

The usage of the falling–rising and the low–falling patterns also varies according to dialect and/or speaking style (Shih, 1988). Northern Chinese speakers use the falling–rising pattern in sentence-final position in all speech. By contrast, southern speakers use the low-falling pattern even in the final position in casual speech, and use the falling–rising pattern in emphatic speech and in yes–no questions. Dialect may also influence Mandarin tone. Fon and Chiang (2000) reported that Taiwan Mandarin showed a narrower tonal range, lower tonal heights, and more conservative tonal contours compared to Beijing Mandarin. This could be attributed to an influence from Taiwanese, which has a lower tonal register than Mandarin (Lin and Repp, 1989).

While the four tones are mainly distinguished by fundamental frequency, other acoustic characteristics such as overall intensity and duration tend to vary systematically with tone (Howie, 1976; Zee, 1978; Blicher *et al.*, 1990; Tseng, 1990; Whalen and Xu, 1992; Fu and Zeng, 2000). Tone 4 is often the most intense one and has the shortest duration,

[a)]Electronic mail: ykuo@tmue.edu.tw

while tone 3 is the least intense with the longest duration. However, different patterns of tone 3 differ in duration as well as in pitch contour. While the falling–rising pattern shows the longest duration among the four tones, the low-falling pattern has the shortest duration (Shih, 1988). Amplitude envelope has also been found to be highly correlated with f0 contour for tones 3 and 4 (Whalen and Xu, 1992; Fu and Zeng, 2000).

Several studies have investigated tone perception from purely temporal cues using various noise stimuli modulated by envelopes derived from natural speech stimuli. Three temporal envelope cues were defined by Fu and Zeng (2000): periodicity, amplitude contour, and duration. As in Rosen (1992), "periodicity" referred to fluctuations in the overall amplitude at a rate between 50 and 500 Hz, whereas "amplitude contour" referred to fluctuations at a rate between 2 and 50 Hz. Although percepts of pitch are strongest for truly periodic sounds, they can also be elicited by temporal fluctuations in amplitude-modulated noise (Burns and Viemeister, 1976). When the temporal envelope of speech is derived from rectified speech with an envelope-smoothing filter which includes the voice f0 range, listeners can perceive the quasiperiodic amplitude modulations imposed on a noise carrier as pitch changes. The temporal regularities in the modulated noise can be referred to as periodicity information (Rosen, 1992). However, when the cutoff frequency of an envelope-smoothing filter falls below the fundamental frequency range, the periodicity information is not included in the envelope signal.

Whalen and Xu (1992) used signal-correlated-noise (SCN) to investigate the extent to which tone recognition can be aided by amplitude contour and duration. Their results showed high recognition scores for tones 2–4, averaging 87.6%, but only 38.5% correct for tone 1. To further examine the contribution of amplitude contour, they used stimuli with controlled duration, and found that recognition scores were still well above chance in the absence of the duration cue (45%, 55.3%, 69.5%, and 92.3% for tones 1, 2, 3, and 4, respectively). However, SCN is equivalent to wide-band noise modulated with an envelope extracted using a smoothing filter with a very high cut-off frequency on full-wave rectified speech. Therefore, SCN stimuli contain not only amplitude contour and duration cues, but also the periodicity of the natural tokens on which they were based, albeit in weakened form. Green *et al.* (2002) showed listeners to have some ability to label glides in fundamental frequency at low frequency ranges in stimuli that were similar to, although not identical to, SCN. Thus, periodicity information, directly related to the change in fundamental frequency, was likely to influence subject performance as well (Rosen, 1992; Van Tasell *et al.*, 1987).

Fu *et al.*, 1998 investigated the importance of periodicity and amplitude envelope to tone recognition by using amplitude-modulated noise. In this study, duration was not examined and retained its natural variations. When no spectral information was available (1-band condition), recognition scores of up to 80% could be achieved in a condition that preserved amplitude envelope, periodicity, and duration information, while accuracy was about 67% in a condition preserving only amplitude envelope and duration information. Tones 3 and 4 were identified best, nearly twice as well as tone 1 and tone 2. In another study, Fu and Zeng (2000) used SCN to further explore the contribution of periodicity, amplitude contour, and duration to tone recognition. These three cues were manipulated in isolation, in pairs, and all together. Results showed that the highest score, nearly 70%, was achieved in the condition with all three cues. Around 55% correct recognition was shown in conditions that preserved either the amplitude contour or periodicity cues. A condition preserving only the duration cue had the lowest recognition score of about 35% correct. The duration cue was found to contribute to recognition of tone 3, and the amplitude cue contributed to the recognition of both tones 3 and 4. The periodicity cue contributed to recognition of all four tones.

In a recent study by Xu *et al.* (2002), amplitude envelope and periodicity were manipulated by varying the low-pass cutoff frequency of an envelope-smoothing filter from 1 to 512 Hz in 1 octave steps. Tone recognition improved slightly but consistently as cutoff frequency increased in the 1-channel condition in which there was no spectral information available. Consistent with the results of Fu *et al.* (1998), around 50% correct recognition was achieved with only amplitude envelope and duration cues (when the envelope cutoff frequency was as low as 1 or 2 Hz), while accuracy approached 65% when periodicity cues were also available (with an envelope cutoff frequency at 512 Hz). When the duration cue was removed, scores dropped significantly, with tones 3 and 4 affected the most (the decreases were by 12.5, 8.5, 19.5, and 19.7 percentage points for tones 1, 2, 3, and 4, respectively). These decreases in performance indicated that duration did show a significant effect on tone recognition mainly on tones 3 and 4.

To sum up, results from the above-mentioned studies confirm that tone recognition can be assisted by temporal envelope cues. Although the pitch from modulated noise is considerably less salient than the pitch of harmonic signals for which there are spectral cues to pitch, listeners can perceive the periodicity information in the modulated noise and use it to recognize tone (Burns and Viemeister, 1976). The amplitude and duration cues also play significant roles for tone recognition, and contribute to tones 3 and 4 the most. The studies showed an inconsistency of effects of duration. Duration contributed to the identification of both tones 3 and 4 in Xu *et al.* (2002), but only affected tone 3 in Fu and Zeng (2000). It appears that duration did not consistently contribute to tone 4 recognition in the latter study because tone 4 was not significantly different from tone 1 in duration. In Xu *et al.*, tone 4 was the shortest tone. Therefore, although duration can sometimes be used to aid tone recognition, it varies in natural tokens so it may not always be a reliable cue.

The aim of the current study was to investigate the extent to which tonal contrasts can be recognized with different acoustic cues. Although these three main cues to tonal contrasts in Mandarin (f0, amplitude envelope, and duration) have been investigated in several studies, only the study by Fu and Zeng (2000) systematically combined different cues to examine their contributions. Modulated noises were used

to carry all possible combinations of the three cues. However, the pitch information was conveyed by the temporal fluctuations in the speech envelope which is a far less salient cue than that which arises from true periodic sounds. Here, we introduce a sawtooth wave form created period by period to match the f0 of original speech, and used this to carry pitch information. The f0-controlled sawtooth wave form contains both spectral and temporal cues to pitch, and was expected to give a clearer indication of voice pitch than would be possible from the temporal envelope of noise alone. The same three cues in all combinations were conveyed both by sawtooth and noise carriers [the latter as in Fu and Zeng (2000), but with some modifications in signal processing]. With the same testing materials, the results of the present study allow the comparisons of the level of correct tone recognition with different combinations of acoustic cues.

Stimuli with explicit f0 information (f0 carried by sawtooth carriers) were expected to be recognized the best among all stimuli. For stimuli with the relatively weak temporal f0 information (f0 carried by temporal fluctuations of noise carriers), listeners were expected to be able to identify some tonal information, but their performance would not be as good as the performance when f0 was represented explicitly. It is well known that amplitude-modulated noise stimuli, with no regularity in fine structure, lead to weak pitch sensations. According to Lin's (1988) study, when explicit f0 is presented, amplitude envelope and duration are unlikely to contribute much to the recognition of tonal contrasts. However, when f0 information is absent or presented in a rather weak form, as in Whalen and Xu (1992) and Fu *et al.* (1998), amplitude envelope and/or duration could be of use. Even so, the effect of amplitude envelope and/or duration would be less significant.

II. METHODS

A. Speech stimuli

Four syllables (/i/, /ba/, /fu/ and /tɕʰi/) with each of four tones were used as stimuli. Four different syllable structures (vowel only, three point vowels with initial plosive, fricative, and affricative consonants) were included, so as to contain more variability and be more representative of the information in real life. All these syllables were Mandarin words with a high frequency of occurrence. Natural models for the stimuli were produced by two young adults, one male and one female, who were native speakers of Mandarin from Taiwan. All stimuli were randomized and produced in the carrier phrase "qǐ tiao chu-" ("Please choose—") to avoid inconsistency in pitch range. Six repetitions were produced for the four syllables with each of the four tones. The recording was conducted in an anechoic chamber with speech and laryngograph signals (*Lx*) recorded at the same time using a Sony DAT recorder at a 44.1 kHz sampling rate. The first two tokens sounded natural and contained no creaky voice, as judged by a native speaker of Mandarin (the first author), and so were selected as stimuli. There were a total of 64 speech stimuli (4 syllables X 4 tones X 2 tokens X 2 speakers).

TABLE I. Mean fundamental frequency (Hz), rms amplitude (dB re 1, where all amplitudes are within the range ±1), and duration for the four tones (standard deviations in parentheses).

		Fundamental frequency (Hz)				rms amplitude (dB re 1)	Duration (ms)
		Male		Female			
Tone 1	Average	158	(6)	257	(12)	−23.5 (3.5)	308.8 (38)
Tone 2	Initial	121	(16)	201	(11)	−27.7 (2.9)	347.7 (47)
	Final	143	(15)	222	(15)		
Tone 3	Initial	120	(13)	198	(15)	−30.7 (2.5)	323.7 (66)
	Turning point	91	(9)	113	(41)		
	Final	119	(9)	147	(37)		
Tone 4	Initial	171	(32)	264	(18)	−25.0 (3.0)	256.2 (72)
	Final	108	(14)	150	(42)		
Average						−26.7 (3.6)	309 (65)

B. Acoustic analysis of speech stimuli

Table I shows the f0 values of average pitch curves, mean rms amplitude, and duration for the four tones.

1. F0 contour

Figure 1 shows pitch contours for all speech tokens by the male and female speakers. Note that the pitch contours of tone 3 for the female appeared to be more variable. While the male speaker used the falling–rising pattern consistently, the female speaker used both falling–rising and low-falling patterns. Some of the pitch contours kept falling throughout while others rose slightly at the end.

2. Overall intensity

An analysis of variance (ANOVA) showed a significant difference of rms amplitude of the four tones [$F(3,60)=17.22$, $p<0.001$]. *Post-hoc* comparisons revealed that tone 3 was the least intense tone with significantly lower intensity than the other three tones. Tones 1 and 4 had no significant difference between their overall intensities, and both had significantly higher levels than tone 2.

3. Duration

Tone 2 had the longest duration, followed by tone 3, then tone 1, and finally tone 4. An ANOVA showed a significant effect of duration [$F(3,60)=7.3$, $p<0.001$]. *Post-hoc* comparisons revealed that tones 2 and 3 were significantly longer than tone 4.

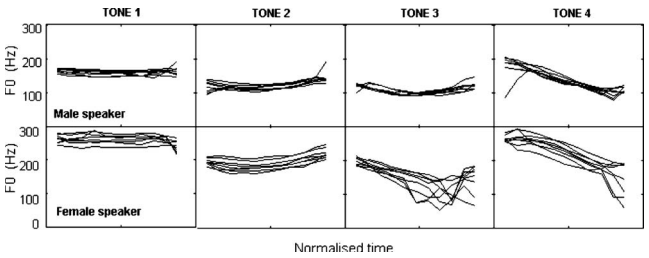

FIG. 1. F0 contours for speech stimuli from the two speakers (all the pitch contours were normalized using a linear time scaling to give the same duration).

TABLE II. Summary of stimuli used in the present study and the study of Fu and Zeng (2000). Cues *A*, *F*, and *D* represent amplitude contour, f0, and duration, respectively.

Cues		Carrier		
		Present study		Fu and Zeng 2000
		Sawtooth carrier	*Noise* carrier	*Noise* carrier
Natural duration	*AFD*	f0-controlled sawtooth carrier envelope extracted at 30 Hz	*AFDcis* Noise carrier × envelope extracted at 400 Hz *AFD* f0-controlled sinusoidal modulated noise × envelope extracted at 30 Hz	Noise carrier × envelope extracted at 500 Hz
	AD	Random-frequency sawtooth carrier envelop extracted at 30 Hz	Noise carrier × envelope extracted at 30 Hz	Noise carrier × envelope extracted at 50 Hz
	FD	f0-controlled sawtooth carrier	f0-controlled sinusoidal modulated noise	f0-controlled 100% amplitude modulated noise (no further detials provided)
Duration fixed at 309 ms	*AF*	Sawtooth carrier controlled by the 309 ms time-scaled f0 contour × time-scaled envelope extracted at 30 Hz	Time-scaled f0-controlled sinusoidal modulated noise × time-scaled envelope extracted at 30 Hz	Linear interpolation was applied to AFD-stimulito give a fixed duration at 400 ms (the range of f0 variation may change althoughthe same percentile of f0 change remains)
	A	309 ms random-frequency sawtooth carrier × time-scaled envelope extracted at 30 Hz	Noise carrier × time-scaled envelope extracted at 30 Hz	Linear interpolation was applied to *AD* stimuli togive a fixed duration at 400 ms (the range of f0 variation may change)
	F	Sawtooth carrier controlled by the 309 ms time-scaled f0 contour	Time-scaled f0-controlled sinusoidal modulatednoise	Linear interpolation was applied to *FD* stimuli(the range of f0 variation may change)
Duration cue only	*D*	Random-frequency sawtooth carrier with original duration	Noise carrier with original duration	Noise carrier with original duration

While tone 3 was often reported as the longest tone in many early studies (e.g., Howie, 1976; Tseng, 1990; Whalen and Xu, 1992; Fu and Zeng, 2000), tone 3 had a shorter duration than tone 2 in this study (348 and 324 ms for tones 2 and 3, respectively). The short tone 3 might be due to the female speaker using both falling–rising and low-falling patterns. As mentioned in Sec. I, the falling–rising tone 3 had the longest duration and the low-falling tone 3 had the shortest duration. Both our speakers were native Mandarin speakers from Taiwan, while most speakers in earlier studies were native speakers from Beijing. The short tone 3 might be a dialect difference between Beijing and Taiwan.

Another possible reason for the short tone 3 was the speech stimuli used in the current study. The speech stimuli in our study included vowels in four different phonetic contexts (vowels only and with different initial consonants), while stimuli in most of early studies used vowels only. The potential effects of the four phonetic contexts might result in the differences in duration relative to other studies. A short tone 3 can also be found in previous studies. For instance, Howie (1976) reported some of the recorded syllables had longer tone 2 than tone 3 (e.g., syllable /hu/ had 260 and 235 ms vowel duration for tones 2 and 3, respectively; syllable /yan/ had 190 and 180 ms vowel duration for tones 2 and 3, respectively).

C. Signal processing

All stimuli in this study were simplified from the originally recorded speech stimuli. Table II summarizes the method used to generate these stimuli, compared to Fu and Zeng's (2000) study. Each speech stimulus was used to produce 15 simplified stimuli with all possible combinations of f0 (*F*), amplitude envelope (*A*), and duration (*D*) in isolation, pairs, and all together, and carried by either sawtooth or noise carriers. Figure 2 shows some examples of the simplified stimuli.

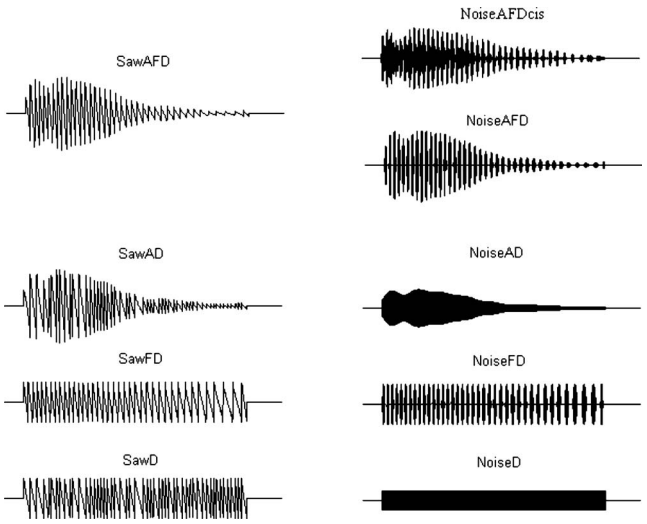

FIG. 2. Examples of some simplified stimuli (conditions *AFD*, *AD*, *FD*, and *D*, using both sawtooth and noise carriers and *NoiseAFDcis*) for the syllable /ba/ with tone 4 produced by the male speaker. Other simplified stimuli *AF*, *A*, and *F* are similar to *AFD*, *AD*, and *FD*, respectively, except with duration fixed at 309 m.

1. AFD (amplitude envelope, f0, and duration)

a. Sawtooth carrier The times between successive regular vocal fold closures (referred to as *Tx*) were measured from laryngograph signals, and used to generate a sawtooth wave form period by period. The f0-controlled sawtooth wave form preserved the f0 contour of the original speech with constant amplitude contour. The amplitude envelope was extracted by full-wave rectification, followed by forward and backward filtering with a 30 Hz cutoff frequency fourth-order elliptical low-pass filter. The f0-controlled sawtooth carrier was then multiplied by the amplitude envelope to generate the *SawAFD* stimulus.

b. Noise carrier In the present study, the signal processing used to generate the *AFD* stimulus by a noise carrier was different from that used in Fu and Zeng's study (2000). A sinusoidal wave form was generated from *Tx* values period by period, half-wave rectified, and then used to modulate a noise carrier. The *NoiseAFD* stimulus contained all three cues, but the temporal cue to pitch was expected to be rather weak. Another condition, which was almost the same as one used by Fu and Zeng (2000), except using a slightly different cutoff frequency (see Table II), was also generated. A noise carrier was multiplied by a speech envelope extracted by half-wave rectification and low-pass filtering with a 400 Hz cutoff frequency to generate the *NoiseAFDcis* stimulus ("cis" refers to "continuous interleaved sampling, CIS," one commonly used speech coding strategy in current cochlear implant systems). Since the range of voice pitch was included, the envelope with 400 Hz cutoff frequency would be expected to preserve some pitch information. The *NoiseAFD* stimulus, because of its clearer pattern of f0-related modulations, might contain slightly better pitch information than the *NoiseAFDcis* stimulus, although the difference should not be large (Green *et al.*, 2002). In any case, the use of an explicit modulator based on f0 allowed condition *NoiseAFD* to be comparable to condition *NoiseFD*, and also to make the f0 information contained in the noise conditions more comparable to that contained in the sawtooth carriers.

2. AD (amplitude envelope and duration)

a. Sawtooth carrier. A random-frequency sawtooth carrier was generated by taking *Tx* randomly from the *Tx* values of the 64 original speech signals across four tones and two speakers, with the same duration as the original speech. The random-frequency sawtooth carrier eliminated the f0 cue to tonal contrasts. A fixed frequency sawtooth carrier was not used because a constant f0 would sound like tone 1, the level tone. The random-frequency sawtooth carrier was then multiplied by the amplitude envelope to generate the *SawAD* stimulus.

b. Noise carrier. A noise carrier was multiplied by the amplitude envelope extracted at 30 Hz to generate the *NoiseAD* stimulus.

3. FD (f0 and duration)

a. Sawtooth carrier. The *SawFD* stimulus was the f0-controlled sawtooth carrier, which preserved the f0 contour and the duration of the original speech but no variation in amplitude.

b. Noise carrier. The *NoiseFD* stimulus was the f0-controlled sinusoidally modulated noise. This stimulus contained the temporal cue to pitch with constant amplitude envelope.

4. AF (amplitude envelope and f0)

a. Sawtooth carrier. A linear time scaling was applied to the f0 contour so as to give a constant duration of 309 ms (the average duration of the voiced parts of all original speech signals), thus eliminating the duration cue. To create a sawtooth wave form with the original f0 contour but a fixed duration at 309 ms, the following procedure was used. The fundamental periods measured from the larygograph signal were converted to a pitch contour first. Then, a linear time scaling was applied to the pitch contour to produce a new pitch contour with the same shape but duration fixed at 309 ms. The new pitch contour was converted back to a new set of *Tx* periods. The first *Tx* period was the same as that in the original speech. The second *Tx* period was determined by the f0 value in the time-scaled pitch contour at the end of this first period. Similarly, the third and subsequent *Tx* periods were determined from the f0 value of the time-scaled contour at the end of the immediately preceding period. The new sets of *Tx* values preserved the original pitch contours without changing the overall f0 range.

The amplitude envelopes extracted at 30 Hz were also scaled in time to give the 309 ms duration, and then multiplied against the sawtooth carriers controlled by time-scaled f0 contour. The *SawAF* stimulus preserved both the f0 and amplitude contours in the original speech but with duration fixed at 309 ms.

b. Noise carrier. A sinusoidal wave form was generated from the time-scaled *Tx* values and half-wave rectified, and then used to modulate a noise carrier. The time-scaled f0-controlled sinusoidal wave form was then multiplied by the time-scaled amplitude envelopes extracted at 30 Hz. The *NoiseAF* stimulus contained the same temporal pitch and amplitude information as in *NoiseAFD* stimulus but without the duration cue.

5. A (amplitude envelope only)

a. Sawtooth carrier. A random-frequency sawtooth carrier with duration fixed at 309 ms was multiplied by the time-scaled amplitude envelope extracted at 30 Hz, resulting

in the *SawA* stimulus.

b. Noise carrier. A noise carrier was multiplied by the time-scaled amplitude envelope extracted at 30 Hz, resulting in *NoiseA* stimulus.

6. F (f0 only)

a. Sawtooth carrier. The *SawF* stimulus was the constant amplitude sawtooth carrier generated from the time-scaled *Tx* values.

b. Noise carrier. The *NoiseF* stimulus was the time-scaled f0-controlled sinusoidal modulated noise. This stimulus contained the temporal cue to pitch with a constant amplitude envelope and a fixed duration.

7. D (duration only)

a. Sawtooth carrier. The *SawD* stimulus was a fixed-amplitude random-frequency sawtooth carrier with duration varied as in the original speech.

b. Noise carrier. The *NoiseD* stimulus was a noise carrier with the duration of the original speech.

D. Subjects

Eight normal hearing adults, three male and five female, participated in the experiment. All were native speakers of Mandarin from Taiwan, aged between 27 and 35.

E. Procedure

Stimuli were blocked by condition, so were presented in 15 blocks. A graphical user interface built in MATLAB was used for running the experiment. In each block, a learning session and a training session were given before a testing session started. Subjects were given sample stimuli for all 15 processing conditions in the learning session, and these stimuli were played randomly in the training session with feedback given. Subjects were allowed to spend as much time as desired in these two sessions. No stimuli used for familiarization were used in the testing session. In the testing session, the four corresponding Mandarin characters of the stimulus were shown first, and the stimulus was played. The Mandarin characters with the Chinese phonetic alphabet, the jùyīnfúhaù, were also shown on the screen. Four push buttons labeled with Tone 1 to Tone 4 were presented below the corresponding characters. Subjects made their identification response using a computer mouse to click one of the four buttons. Then the four corresponding characters of the next stimulus were shown, and the next stimulus was played. No feedback was given in the testing session.

Stimuli were presented through Sennheiser HD 414X headphones, with intensity varied randomly within a 3 dB range around the original level on each trial to reduce cues derived from the overall intensity of the stimuli. The 3 dB range was chosen as it approximated the standard deviation of the rms amplitude of the natural tokens. The order of the 15 processing conditions was randomized and counterbalanced across subjects. In each block, stimuli from male and female speakers were presented in a randomized order. The 15 blocks with 64 simplified stimuli in each resulted in a total of 960 stimuli.

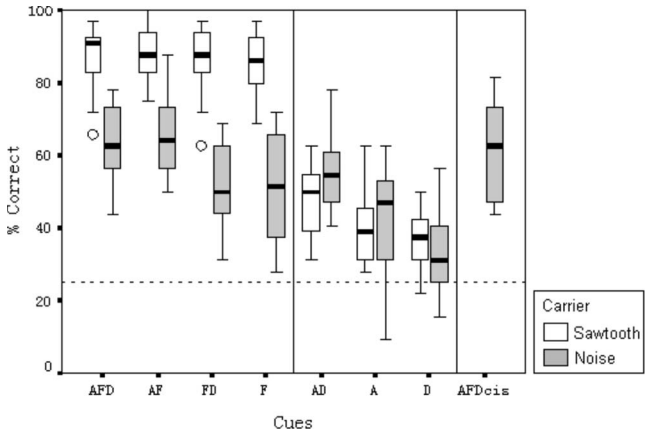

FIG. 3. Boxplots of percentage of correct tone recognition across conditions of different acoustic cues carried by sawtooth or noise carriers. The box represents the 25 to 75 percentile range of the data over subjects and speakers, and the bar within each box represents the median. The whiskers represent the range of data points, except for outliers which are shown as asterisks (more than 3 box lengths from the box edge) or open circles (more than 1.5 box lengths). The dashed line represents chance performance (25% correct).

III. RESULTS AND DISCUSSION

A. Contribution of f0, amplitude envelope, and duration

For stimuli in which f0 information is conveyed by sawtooth carriers (*SawAFD*, *SawAF*, *SawFD*, and *SawF*), a pitch percept can be evoked from both resolved lower harmonics and unresolved higher harmonics. For stimuli with f0 carried by noise carriers (*NoiseAFD*, *NoiseAF*, *NoiseFD*, *NoiseF*, and *NoiseAFDcis*), pitch can only be derived from regular fluctuations in the amplitude of the noise. Since pitch perception in the normal auditory system is mainly determined by resolved lower frequency harmonics (e.g., Moore and Peters, 1992; Ritsma, 1967), stimuli *SawAFD*, *SawAF*, *SawFD*, and *SawF* would be expected to give the most clear information about tonal contrasts. Figure 3 shows the percentage correct tone recognition for the various acoustic cues. Conditions with f0-controlled sawtooth carriers (*SawAFD*, *SawAF*, *SawFD*, and *SawF*) led to the highest levels of performance (around 90% correct), but conditions with other acoustic cues also allowed tone recognition to some extent (varying between 33% and 65%). Performance on all conditions was significantly above chance, except marginal effects for conditions with the duration cue only (36.3% and 33.6% for conditions *SawD* and *NoiseD*; a binomial distribution reveals that scores of 23 or more out of 64, or over 35.9%, are statistically different from chance performance, $p < 0.05$).

Conditions *NoiseAFDcis* and *NoiseAFD* would be expected to carry similar information for tonal contrasts, and an *a priori* comparison confirmed that there was no significant difference between performances on these two conditions. *A priori* comparisons were also carried out to examine the effect of periodicity, amplitude envelope, and duration, by using contrasts of conditions with and without one of these three cues (for instance, comparison of conditions *NoiseAFD/NoiseAF/NoiseFD* vs *NoiseAD/NoiseA/NoiseD* was used to examine the effect of periodicity; contrasts of

TABLE III. Results of Bonferroni post hoc comparisons for pairs of conditions with different acoustic cues. An asterisk indicates a significance level of 0.05.

	Sawtooth Carrier							Noise Carrier						
	AFD	AF	FD	F	AD	A	D	AFD	AF	FD	F	AD	A	D
AFD														
AF	-							-						
FD	-	-						-	*					
F	-	-	-					-	*	-				
AD	*	*	*	*				-	-	-	-			
A	*	*	*	*	-			-	-	-	-	-		
D	*	*	*	*	*	*		*	*	-	-	-	-	

NoiseAFD/AF/AD vs *NoiseFD/F/D*, and *NoiseAFD/FD/AD* vs *NoiseAF/F/A* were used for amplitude envelope and duration, respectively). These revealed that there were significant differences for the periodicity and amplitude envelope cues ($[F(1,7)=20.3,\ p<0.01]$ and $[F(1,7)=48.8,\ p<0.01]$, respectively), but not for the duration cue.

A repeated-measures ANOVA was performed for factors of cue, carrier, and speaker. This showed significant effects of carrier $[F(1,7)=131.3,\ p<0.001]$ and cue $[F(6,42)=51.3,\ p<0.001]$, and significant interactions of carrier by cue $[F(6,42)=27.3,\ p<0.001]$ and speaker by carrier $[F(1,7)=15.0,\ p<0.05]$. No other two-way or three-way interaction was significant.

The interaction of carrier by cue was almost certainly due to performance with the two carriers differing greatly only in those conditions in which f0 information was presented (*AFD*, *AF*, *FD*, and *F*). Bonferroni-corrected *post-hoc* comparisons, with an alpha of 0.05, were used to examine the effect of the two different carriers on each of seven conditions, revealing that this was indeed the case. All conditions involving f0 information (*AFD*, *AF*, *FD*, and *F*) were significantly different according to carrier, whereas conditions which had no f0 information (*AD*, *A*, and *D*) were statistically equal. This confirmed our expectation that a sawtooth carrier generated period by period from f0 provided better information for tone recognition than could possibly be conveyed by a modulated noise, with no significant difference for using a random-frequency sawtooth carrier and a noise carrier for conveying information about amplitude envelope and duration.

To examine the relative importance of the different acoustic cues to tonal contrasts, the effect of different combinations of cues on tone recognition was also compared, with sawtooth and noise carriers separately. Table III summarizes the results. For the sawtooth carrier, no significant difference was found between the four conditions with salient f0 (*SawAFD*, *SawAF*, *SawFD*, and *SawF*), and they were all significantly higher than the three conditions without f0 information. There was no significant difference between the two conditions with amplitude envelope cue presented (*SawAD* and *SawA*), and they were significantly higher than the condition with duration only (*SawD*). This indicated that information about f0 conveyed by a periodic sound contributed to tone recognition the most, and neither amplitude envelope nor duration affected tone recognition

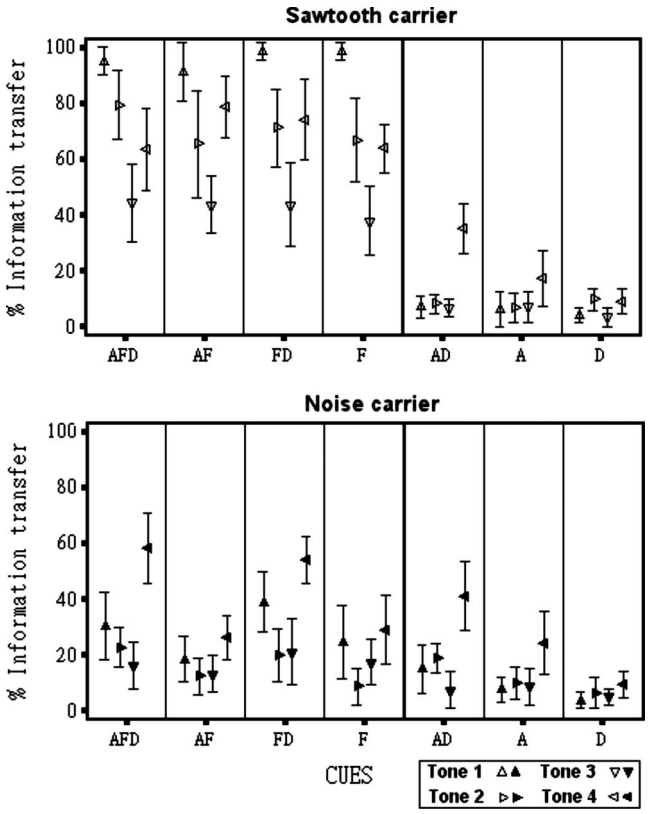

FIG. 4. Percentage of information transfer score of tone recognition for four tones across conditions with different combinations of three acoustic cues. Performance on conditions using the sawtooth carrier is displayed in the upper panel, and performance on conditions using the noise carrier is displayed in the lower panel. Error bars indicate the 95% confidence interval for the means averaging over 16 data points (8 subjects × 2 speakers).

performance while f0 was present. In the absence of salient f0, amplitude envelope appeared to contribute more to tone recognition than duration.

For noise carriers, only a few comparisons showed significant effects, even though several pairs of conditions had considerably different means (for instance, the mean score of *NoiseAFD* was more than 20% higher than that of *NoiseD*, yet, not significant). This was due to there being larger variations in some conditions than others, and the Bonferroni correction leads to relatively conservative tests.

B. Performance for the four tones

Previous studies have shown that the recognition for the four tones in Mandarin can vary with different acoustic cues available (e.g., Whalen and Xu, 1992; Fu *et al.*, 1998; Fu and Zeng, 2000). Here, performance for the four tones in conditions with different combinations of cues was further examined. To give an unbiased measure of identification performance for individual tones, information transfer scores were computed using the procedures of Miller and Nicely (1955) from tone confusion matrices (e.g., a 2 × 2 matrix classifying stimuli as tone 1 versus all other tones, and responses in the same way). The percentage of information transferred for the four tones across conditions is shown in Fig. 4.

A repeated-measures ANOVA was performed for factors of tone and condition, demonstrating a significant interac-

TABLE IV. (a) Response matrices (in percentage) for stimuli with the amplitude envelope cue only (results were summed over conditions *SawA* and *NoiseA*). (b) Cross correlations between amplitude contours and pitch contours for male and female speakers.

(a)		Response to male speaker				Response to female speaker			
	Stimulus	1	2	3	4	1	2	3	4
	Tone 1	31.3	43.0	16.5	9.4	35.9	28.9	16.4	18.8
	Tone 2	15.6	48.4	25.8	9.4	19.5	42.2	26.6	11.7
	Tone 3	7.8	44.5	38.3	9.4	17.2	19.5	25.8	37.5
	Tone 4	23.4	10.2	13.3	53.3	17.2	9.4	16.4	57.0
(b)	Amp	Male speaker F0				Female speaker F0			
		1	2	3	4	1	2	3	4
	Tone 1	0.38	−0.07	0.22	0.69	0.62	−0.01	0.69	0.72
	Tone 2	0.34	0.68	0.45	0.04	0.33	0.45	0.33	0.25
	Tone 3	0.43	0.40	0.78	0.51	0.43	−0.02	0.79	0.85
	Tone 4	0.41	−0.01	0.37	0.77	0.49	−0.19	0.88	0.89

tion $[F(39,273)=18.2,\ p<0.001]$, and significant main effects for condition $[F(13,91)=96.5,\ p<0.001]$ and tone $[F(3,21)=65.7,\ p<0.001]$. Bonferroni-corrected *post-hoc* comparisons were used to examine performance of the four tones on conditions with different combinations of cues. For conditions with explicit f0 included (*SawAFD*, *SawAF*, *SawFD*, and *SawF*), information transfer scores for the four tones showed similar patterns: Tone 1 was significantly higher than tones 2 and 4, and there was no significant difference between these two tones. All these three tones were significantly higher than tone 3. Tone 1 might be recognized best because it had a higher and more distinct frequency range compared to the other three tones. As for tone 3, the variation of its realization presumably was responsible for its relatively low scores. In the two conditions with the duration cue only (*SawD* and *NoiseD*), information transfer scores were all very low, with not much difference among the four tones. For the rest of conditions with little or no f0 presented, tone 4 was generally recognized well compared to the other three tones.

C. The use of amplitude envelope for tone recognition

Table IV(a) shows subject response for stimuli with the amplitude envelope cue only. The confusion matrices were summed over conditions *SawA* and *NoiseA* for male and female speakers separately. Percent correct for each of the four tones is shown along the diagonal of each table. Results from previous studies have shown that listeners were able to use the amplitude cue to label tones to some extent, though performance based on the amplitude envelope cue was often highly variable across tones and speakers. Whalen and Xu (1992) suggested that listeners either recognized the consistent correlation between pitch and amplitude contours or interpreted amplitude change as f0 change. The variation in performance might arise from the fact that a significant correlation between pitch and amplitude contours was only found for certain tones and speakers (Whalen and Xu, 1992; Fu and Zeng, 2000). To examine if subject responses could be explained by the similarity of pitch and amplitude contours, the correlations between pitch and amplitude contours were calculated and compared with the frequency of subject response for stimuli with the amplitude envelope cue only.

The similarity of the amplitude contour of one tone to the pitch contour of each of the four tones was examined by calculating a cross correlation. The average pitch and amplitude contours, averaged over eight normalized contours with the duration of 309 ms of the four tones for the male and female speaker, were used (see Fig. 5). To obtain approximately independent samples, points along a contour were sampled separated by an interval determined by calculating autocorrelation coefficients for pitch and amplitude contours of several sentences. Since a sample point and its neighbor become less related to each other when they are further apart,

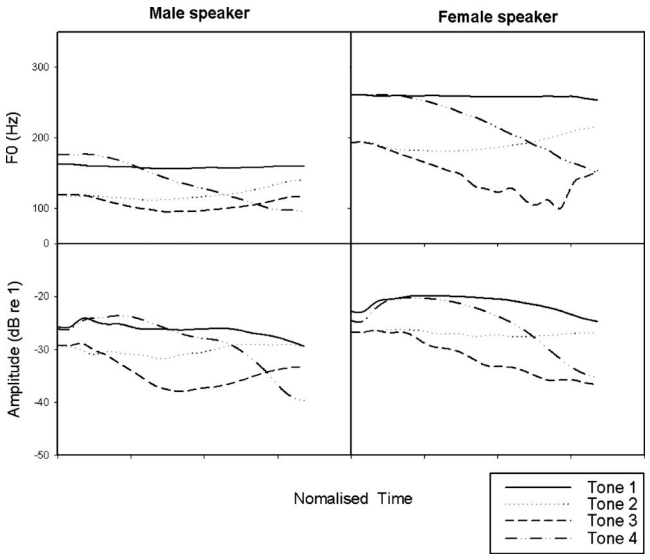

FIG. 5. Average pitch and amplitude contours for the four tones for the two speakers. Each line was averaged over eight speech tokens after a linear time scaling.

the autocorrelation coefficients were often not significant when the time lag was over 55 ms. Therefore, six samples for each of normalized amplitude and pitch contours were calculated by dividing one contour into six sections and taking the average value in each section. Correlations for the lags of −1, 0, and +1 were calculated, and the maximum value was selected. Table IV(b) shows the average correlation between the amplitude contour of one tone and the pitch contours of the four tones. The amplitude contour of a tone did not always correlate most highly with the pitch contour of that same tone. For instance, the amplitude contour of tone 1 for the male speaker was highly correlated to the pitch contour of tone 4 (r=0.69) rather than that of tone 1 (r =0.38). Also, for the female speaker, the amplitude contour of tone 3 was highly correlated with the pitch contours of both tone 3 and tone 4 (r=0.79 and 0.85, respectively), so as the amplitude contour of tone 4 to the pitch contours of tone 4 and tone 3 (r=0.89 and 0.88, respectively). This might be due to, as shown in Fig. 1, the female tone 3 sometimes appeared as low-falling pattern which could correlated well with tone 4, the falling tone.

To further investigate whether response frequencies to stimuli with only the amplitude envelope cue [Table IV(a)] could be explained by the similarity between pitch and amplitude contours [Table IV(b)], the relationship between subject responses and the correlation of pitch and amplitude was examined. Generally speaking, high response frequencies were associated with high correlation coefficients. Although a high correlation coefficient did not always lead to a high proportion of subject responses, a low correlation coefficient seldom did. This indicated that a certain relationship between identification responses and the correlation between amplitude and pitch contour exists.

IV. GENERAL DISCUSSION

While lexical tones are mainly distinguished by their f0 patterns, early studies often suggested that other acoustic cues such as amplitude and duration were of little importance for tone recognition. Recent studies have reported that these temporal cues have a more substantial contribution when f0 information is weak or completely absent. However, results from the present study clearly demonstrate that performance with any combination of these temporal cues was still much lower than with explicit f0 information. The results here might be used to indicate the extent to which information about tonal contrasts could possibly be obtained by current cochlear implant users with CIS-like speech processors, and what may possibly be achieved in future devices. While voice f0 is indubitably the most essential cue for recognizing tonal contrasts, it is not transmitted sufficiently well through current implants. The f0 information available in implant systems is very similar to that conveyed by temporal fluctuations of a noise carrier in the present study. Without the presence of explicit f0 information, this temporal pitch information could help tone recognition, as could amplitude envelope and duration. However, even with all available temporal cues, tone recognition performance was hardly above 70% correct. This is consistent with clinical results, which have reported that users of tonal languages often encounter great difficulty in tone recognition (e.g., Barry *et al.*, 2002; Peng *et al.*, 2004, Wei *et al.*, 2004).

While these temporal cues (temporal coding of f0, amplitude envelope, and duration) could aid in tone recognition to a certain extent and could be used by implant users, none of them is always reliable. Listeners often vary greatly in their ability to make use of these temporal cues, as shown in this study (see Fig. 3) and in previous research. For instance, in Green *et al.* (2002), glide labeling performance based on temporal envelope cues was limited and varied greatly across subjects. Also, the amplitude envelope and duration cues in Mandarin have been reported to be highly variable across speakers and different tones (Fu and Zeng, 2000). The performance in those conditions with noise carriers may represent what can be achieved when listeners are able to perceive one, two, or all of these three cues. The average performance across conditions varies greatly between 35% and 65%, and this low level is about what has been observed in many implant users. Furthermore, these temporal cues are likely to be even less salient in a real life situation of running speech in less-than-ideal acoustic environments.

V. SUMMARY

As would be expected, the explicit f0 cue contributed to tone recognition the most, irrespective of the presence of amplitude envelope and/or duration cues. In the absence of explicit f0, the temporal f0, amplitude envelope, and duration cues also contributed to tone recognition to different extents: the temporal coding of f0 and amplitude envelope both demonstrated substantial contributions to tone recognition, while duration had only a marginal effect. The differences in the utility of duration relative to other studies might be due to: (a) a dialect difference between Beijing and Taiwan and/or (2) the speech syllables used here including different phonetic contexts (vowels only and with different initial consonants). Performance based on these secondary cues varied greatly across subjects, indicating listener variability in perceiving these temporal cues. The contribution of the amplitude envelope cue to the identification of certain tones, especially for tone 4, might be explained by the relatively high correlation between their amplitude and pitch contours.

Compensation for coarticulation, /u/-fronting, and sound change in standard southern British: An acoustic and perceptual study

Jonathan Harrington,[a] Felicitas Kleber, and Ulrich Reubold
Institute of Phonetics and Speech Processing (IPS), University of Munich, Munich, Germany

(Received 17 September 2007; revised 10 February 2008; accepted 21 February 2008)

The aim of the study was to establish whether /u/-fronting, a sound change in progress in standard southern British, could be linked synchronically to the fronting effects of a preceding anterior consonant both in speech production and speech perception. For the production study, which consisted of acoustic analyses of isolated monosyllables produced by two different age groups, it was shown for younger speakers that /u/ was phonetically fronted and that the coarticulatory influence of consonants on /u/ was less than in older speakers. For the perception study, responses were elicited from the same subjects to two minimal word-pair continua that differed in the direction of the consonants' coarticulatory fronting effects on /u/. Consistent with their speech production, young listeners' /u/ category boundary was shifted toward /i/ and they compensated perceptually less for the fronting effects of the consonants on /u/ than older listeners. The findings support Ohala's model in which certain sound changes can be linked to the listener's failure to compensate for coarticulation. The results are also shown to be consistent with episodic models of speech perception in which phonological frequency effects bring about a realignment of the variants of a phonological category in speech production and perception. © *2008 Acoustical Society of America.*

I. INTRODUCTION

Many studies in recent years have shown that /u/ (lexical set GOOSE in Wells, 1982) of the standard accent of England, Received Pronunciation (RP) has become phonetically fronted. One of the earliest reports of this phenomenon was in Gimson (1966) and some 30 years later, Roach and Hartman (1997) described RP /u/-fronting as a radical shift that had taken place in the last 20–30 years. These and other similar auditory impressions (e.g., Wells, 1982, 1997) have been supported by various acoustic studies showing that the second formant frequency of /u/ both in RP and in standard southern British (SSB), a variety spoken by the majority of RP speakers, is raised for young compared with older speakers (e.g., Bauer, 1985; de Jong *et al.*, 2007; Hawkins and Midgley, 2005; Henton, 1983; McDougall and Nolan, 2007).

Diachronic /u/-fronting has also been found in longitudinal studies of Queen Elizabeth II (Harrington *et al.*, 2000a, b) who speaks a variety of the standard accent known as U-RP [see also Wells (1982, 1997) for the distinction between mainstream RP, or SSB, and U-RP and their relationship to Estuary English]. In these acoustic analyses of the Christmas broadcasts, /u/ was shown to have fronted between the 1950s and 1980s, but the Queen's 1980s /u/ was not as front as /u/ that was typical of SSB speakers of the 1980s. Harrington (2007) suggests that this sound change could be related to the prevalence with which RP /u/ follows consonants with a high F2 locus, both after alveolars in words like *noon*, *soon*, and after /j/, the latter context being somewhat more frequent in RP and SSB (and other related accents such as Australian and New Zealand English in which GOOSE is a high central vowel) because of the additional contexts with /coronal+j/ like *duty*, *news*, *tune* which are without /j/ in general American.

Thus, it is possible that the synchronic vowel fronting caused by consonant-on-vowel perseverative coarticulation in these contexts is related to diachronic /u/ -fronting in the last 50 years. Some evidence for this was provided in Harrington (2007), who showed that the distance between the F2 locus of the preceding consonant and the F2 target of /u/ had progressively diminished over a 50 year period in the Queen's Christmas broadcasts suggesting an increase in the influence of the preceding consonant on /u/ which, for various reasons that are also discussed in Harrington (2006), could not be explained away by a waning of the formality of speaking style leading to greater coarticulation and a shrinkage of the vowel space.

The above-provided explanation gives emphasis to speaker-hypoarticulation and speech production as a basis for diachronic change, but as argued by Ohala in a number of studies concerned with establishing a relationship between synchronic variability and diachronic change, there is also experimental evidence to show that the origin of sound changes is often as likely to be in the ear of the listener as in the mouth of the speaker (e.g., Ohala 1981, 1990, 1993, 2005; Ohala and Feder, 1994). For Ohala, the source of many hypoarticulation-induced sound changes—that is those that

[a]Author to whom correspondence should be addressed at Institut für Phonetik und Sprachverarbeitung, Ludwig-Maximilans Universität München, Schellingstraße 3, D 80799 München, Germany. Electronic mail: jmh@phonetik.uni-muenchen.de

can be related to contextual influences synchronically—is an unintentional error on the part of the listener that comes about because of a failure to compensate for the effects of coarticulation. Central to this idea is that listeners may incorrectly parse phonetic events from one phoneme that are temporally distributed and interwoven with those of another. For example, in a dissociation parsing error, two events in speech production that should be associated or parsed together are not (Ohala and Busà, 1995). Thus, as argued in Hombert *et al.* (1979), the development of phonological tone in certain daughter dialects of middle Chinese and some Southeast Asian languages can be attributed to listeners parsing the speaker's unintended f0 microperturbation not with the voicing status of the preceding consonant, but with tonal properties of the following vowel. The extension of Ohala's model to the analysis in the present study is that /u/-fronting may have come about because listeners fail to parse the fronting effect on /u/ either with a preceding palatal consonant or with a preceding coronal consonant that has a high F2 locus.

The evidence that listeners compensate for coarticulation at all has been demonstrated in various studies (see, e.g., Fujisaki and Kunisaki, 1976; Lindblom and Studdert-Kennedy, 1967; Mann and Repp, 1980 for some of the earliest of these) in which listeners are shown to categorize differently exactly the same acoustic token when it is embedded in two contexts that are known to exert different influences on its phonetic structure. Consider a hypothetical example which is entirely relevant to the present study from Lindblom *et al.* (1995), in which speakers are presumed to produce a back vowel as a fronted variant in an alveolar context because of consonant-on-vowel coarticulation: thus /tut/ which in the speaker's phonological plan is specified with a back vowel may be produced as [tʉt] with a central vowel due to the phonetic fronting effects of the flanking alveolars. However, assuming that listeners have an internalized knowledge of such rules of coarticulation, they can nevertheless recover the speaker's planned /tut/ by factoring out the proportion of /u/-fronting that they assume to be attributable to the alveolar context: that is they undo or compensate perceptually for coarticulation. However, if (for whatever reason) compensation for coarticulation should fail to apply, then the listener recovers not /tut/ but /tʉt/: that is, the listener assumes that a central /ʉ/ formed part of the speaker's phonological (rather than phonetic) speech production plan. A minisound change would then occur according to Ohala, if the listener turned speaker replaces /u/ with /ʉ/, especially if this is done in contexts like *move* in which a phonetically advanced /u/ has no coarticulatory *raison d'être*.

One of the main aims of the present study was to investigate whether there was any evidence for this relationship between the failure to compensate for coarticulation and /u/-fronting that has been taking place in SSB over the last 50 years. We reasoned that if young listeners are more likely to interpret a fronted production of /u/ as intended (i.e., as part of the speaker's phonological speech production plan), then they should show less evidence of compensation for the coarticulatory effects of fronting compared with older listeners from the same SSB-speaking community. A second and related aim was to assess whether, commensurate with the studies cited earlier showing /u/-fronting as a change in progress in SSB, the perceptual boundary along an /i-u/ continuum is shifted to the left for younger listeners—that is, whether young listeners are more likely to label a given token from an /i-u/ continuum as /u/ compared with older listeners from the same community.

In the present study, these perceptual effects were investigated by embedding /i-u/ continua in two sets of minimal pairs: *yeast-used* (*used*, past tense, as in "they used to study"), /jist-just/; and *sweep-swoop*, /swip-swup/.

Based on the foregoing discussion, we made the following predictions.

(1) The /i-u/ boundary should be left-shifted (greater proportion of /u/-responses) for younger listeners in both contexts. This is because, if young listeners' /u/ category boundary has fronted, then it is likely that they will interpret a greater number of stimuli with high F2 on an /i-u/ continuum as /u/.
(2) The /i-u/ boundary should be left-shifted for *yeast-used* compared with *sweep-swoop* for both young and old listeners, if a certain degree of variation in /u/ is interpreted as due to the different coarticulatory influences of the initial consonants. This follows entirely from the theory of, and experimental findings for, perceptual compensation for coarticulation (Beddor *et al.*, 2002; Beddor and Krakow, 1999; Fujisaki and Kunisaki, 1976; Kawasaki, 1986; Mann and Repp, 1980).
(3) The difference in the responses between these two sets of minimal pairs should be less for younger listeners. This is because, if young listeners compensate less for coarticulation—i.e., if they tend to ignore perceptually the influence of the consonant on /u/—then their responses to the same synthetic token whether embedded in a fronting or nonfronting context should be fairly similar, whereas they are predicted to diverge much more for older listeners, assuming that they compensate perceptually to a greater extent for the effects of coarticulation.

Another aim of this study was to relate these predictions from speech perception to speech production in two ways. First (and trivially), younger listeners should show evidence of a left-shifted category boundary in production, i.e., /u/ is expected to be phonetically fronted compared with that of an older group of speakers. Second, if perceptual compensation for coarticulation has weakened in younger listeners, then evidently the perceptual influence of the consonant on /u/ is reduced. We might then expect the coarticulatory influences of the consonant on /u/ also to be reduced in their speech production compared with that of older speakers. Thus we would expect diphones in which the consonant does (e.g., /ju/) and does not (e.g, /wu/) have a fronting effect on the vowel to be phonetically less divergent in the younger than in the older speakers.

In summary, then, there are five hypotheses to be tested, two in production and three in perception:

H1: /u/ is fronted in the production of young SSB speakers.

H2: The coarticulatory consonant-on-vowel influences in /Cu/ are less in younger SSB speakers.

H3: The /i-u/ perceptual boundary is left-shifted (greater proportion of /u/-responses) in younger listeners.

H4: Listeners (young and old) compensate perceptually for the expected coarticulatory influence of a consonant on /u/.

H5: Young listeners compensate less for the influence of a consonant on /u/ compared with older listeners.

II. SPEECH PRODUCTION

A. Method

1. Subjects

The subjects were recruited from the University of Cambridge and through the University College London and included 30 speakers of SSB. The subjects were recruited into a Young and an Old group. The Young group included 14 subjects (3 male, 11 female) aged between 18 and 20 and with an average age of 18.9 years; and the Old group 17 subjects (10 male, 7 female) over the age of 50 and with an average age of 69.2 years. Seven members of the Old group had been taken from the same subject pool as in Hawkins and Midgley (2005). Due to various scheduling difficulties, one subject from the Old group participated only in the production experiment (II) but not in the perception experiment (III); and four other subjects from the Old group participated only in the perception experiment (III) but not in the production experiment. Most of the subjects were tested and recorded in quiet rooms in the Phonetics Laboratory of the University of Cambridge, but some of the older subjects were tested and recorded in a quiet room at their homes. There were no apparent differences in the quality of the recorded speech signal and no differences in the subjects' performance related to the testing location. The equipment (for both the production and the perception experiment) was the same (Sennheiser stereo headset pc165 USB and a Toshiba Tecra notebook) for all recordings.

2. Materials, procedure, and parameters

Subjects produced a number of isolated monosyllabic words with different vowel nuclei to cover most of the RP vowel space. The words were displayed individually on a notebook computer screen in a quiet room and recordings were made with the "SpeechRecorder" software that is routinely used at the University of Munich for speech recording outside the laboratory (Draxler and Jänsch, 2004). A total of 540 words were produced in this way from a randomized list of 10 repetitions of 54 words. Any words that were mispronounced were excluded from the analysis.

The words that were analyzed in the present study included only a subset of these: /i/ (lexical set FLEECE), /u/ (lexical set GOOSE), and /ɑ/ (lexical set START) nuclei. The words with other types of nuclei, of which some will be analyzed in a future study, served mainly as filler and distractor items as far as the present study was concerned. The design of the words with /u/ and /i/ nuclei was shaped by five main criteria:

(1) The two sets of minimal word pairs used in the perception experiment *yeast*, *used*, *sweep*, *swoop* were included.
(2) There was a matched set of /Cu/ and /Cju/ words (e.g., *cooed* and *queued*)
(3) Words were included whose initial consonants had a minimal (*food*, *who'd*), a fronting (*soup*), and a backing (*cooed*) influence on /u/.
(4) There were matched minimal word-pairs between /Cid/ and /Cud/ (e.g. *keyed*, *cooed*)
(5) The final consonant was /d/ as far as possible.

A total of 4296 words were analyzed in this study including 2412 with /u/ nuclei, 1614 with /i/ nuclei, and 270 with /ɑ/ nuclei all taken from the word *hard*. The purpose of including /ɑ/, which in SSB is phonetically open, a monophthong (SSB is nonrhotic), and slightly fronter than cardinal vowel 5, was to provide a relative quantitative measure of /u/-fronting, as described in further detail in Sec. II A 2. The distribution of these 4296 words by age and gender is shown in Table I.

The words were digitized at 44.1 kHz and the first four formant frequencies were calculated using the EMU speech database analysis system (Cassidy and Harrington, 2001). The parameters for formant calculation were: LPC order of 10, a preemphasis of 0.95, and a 30 ms Blackman window with a frame shift of 5 ms. All of the data were segmented and labeled into phonetic segments.

The first two formant frequencies of all vowels in the words in Table I were checked manually both by inspecting the trajectories on the spectrogram and by identifying outliers from ellipse plots in the F1 × F2 formant plane. All the formant frequencies were converted to bark using the formula in Traunmüller (1990).

The quantitative analysis of /u/-fronting was carried out in a three-dimensional space formed from the first three coefficients of the discrete cosine transformation (DCT) applied separately to the Bark-scaled F2 trajectory between the onset and offset of each vowel. The DCT breaks down any trajectory into $\frac{1}{2}$ cycle cosine waves which, if summed, reconstruct the original signal [Watson and Harrington (1999); see also Nossair and Zahorian (1991) and Milner and Shao (2006) for the relationship between DCT and cepstral coefficients]. For an N-point F2-trajectory, $x(n)$, extending in time from $n=0$ to $N-1$ points, the mth DCT coefficient, C_m $(m=0,1,2)$ was calculated with

$$C_m = \frac{2k_m}{N}\sum_{n=0}^{N-1} x(n)\cos\left(\frac{(2n+1)m\pi}{2N}\right)$$

$$k_m = \frac{1}{\sqrt{2}},\ m=0, \quad k_m = 1,\ m \neq 0 \tag{1}$$

Thus the F2 trajectory between the acoustic onset and offset of each vowel was represented by a single point in a three-dimensional space whose axes were formed from the first three DCT coefficients or equivalently from the amplitudes of the cosine waves at frequencies $k=0$, 0.5, and 1 cycles. Since these first three DCT coefficients are proportional to

the trajectory's mean, linear slope, and curvature, respectively (Guzik and Harrington, 2007), this form of data reduction encodes a significant amount of dynamic information of the F2 trajectory's changing shape in time.

Using a methodology in Harrington (2006) and Guzik and Harrington (2007) we quantified the extent of /u/-fronting by calculating separately for each speaker the relative Euclidean distances of all the speaker's /u/ tokens to the same speaker's /ɑ/ (a back vowel) and /i/ (a front vowel) centroids in the three-dimensional DCT-space described earlier. This is illustrated in Fig. 1 in two dimensions, in which E_1 and E_2 are the Euclidean distances of a given /u/ token to the same speaker's /ɑ/ and /i/ centroids, respectively. The parameter d_u in the following:

$$d_u = \log(E_1/E_2) = \log(E_1) - \log(E_2), \quad (2)$$

is a quantification of the relative proximity of the /u/-token to these two centroids: When d_u is zero, then the token is equidistant between /i/ and /ɑ/; when it is positive, then it is closer to /i/ than to /ɑ/; and when it is negative, it is closer to /ɑ/ than to /i/. We calculated d_u over all /u/-tokens in this way separately for each speaker and using the speaker-specific /i/ and /u/ centroids as illustrated in Fig. 1 (but in a three-dimensional space). The hypothesis to be tested, then, is that if /u/ is phonetically fronted for younger speakers, then d_u should be smaller, reflecting its relatively closer Euclidean proximity to /i/ than to /ɑ/, compared with d_u for older speakers.

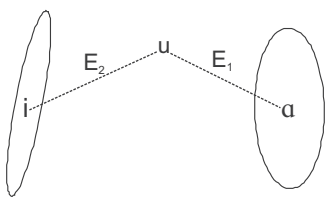

FIG. 1. E_1 and E_2 are the Euclidean distances in an arbitrary two-dimensional space from a single /u/ token to the same speaker's /ɑ/ and /i/ centroids, respectively.

Finally, for the purposes of comparing the influence of C-on-/u/ coarticulation with perceptual responses, we measured the Euclidean distances again separately for each speaker but this time between *used* and *swoop* in the same three-parameter DCT space described earlier. The more that the consonants exert a coarticulatory influence on /u/, then the further apart *used* and *swoop* should be in the parametrized F2 space. Where m_{sw} is the (speaker specific) mean (centroid) of *swoop* in the DCT space, we calculated the Euclidean distances from all tokens of *used* to the same speaker's m_{sw}; and where m_{ju} is the mean of *used* in the same DCT space, we calculated the Euclidean distances from all tokens of *swoop* to the same speaker's m_{ju}. If, for the reasons described in Sec. I, the coarticulatory influences of the initial consonant on /u/ are greater for the older speakers, then they should show greater values on this Euclidean metric (commensurate with a greater F2-trajectory divergence between *used* and *swoop*) compared with younger speakers.

B. Results

We begin by presenting some graphical analyses which were then quantified using the metrics described in Sec. II A 2.

Figure 2 shows the average position in the Bark-scaled F1 × F2 plane of formant values extracted at the temporal

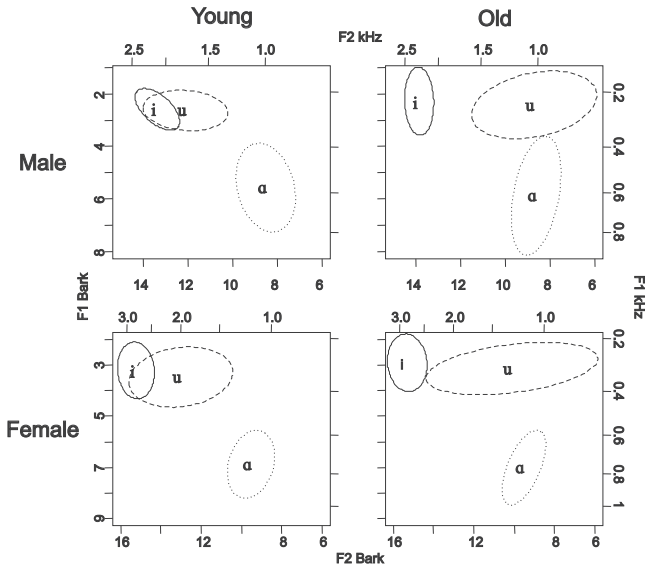

FIG. 2. 95% confidence ellipses for /iuɑ/ in a Bark-scaled formant plane shown separately for the age and gender groups in formant data extracted at the vowels' temporal midpoints.

midpoint of /i, u, ɑ/ separately for the gender and age groups. It is evident that F2 of /u/ is higher for young speakers, which is consistent with the various findings discussed in Sec. I that it is also phonetically fronter. The ellipses for /u/ are also somewhat larger for old speakers which would suggest that consonantal context had a more marked coarticulatory effect on /u/ than for young speakers.

Figure 3 shows linearly time-normalized trajectories for the second formant frequency over the extent of /ju/ in *used* and /wu/ in *swoop*, averaged separately for the four gender × age combinations. The formant trajectory shapes across gender (left and right panels) are fairly similar, but there are markedly different F2 patterns across the two age groups. In particular, three features characterize the old as opposed to the young group of speakers:

(1) F2 of *used* falls much more steeply and to a lower value (of roughly 1600 Hz in males and 1800 Hz in females) than in the young group for which F2 is more or less level (at around 2000 Hz for the male speakers and just over 2000 Hz for the female speakers).

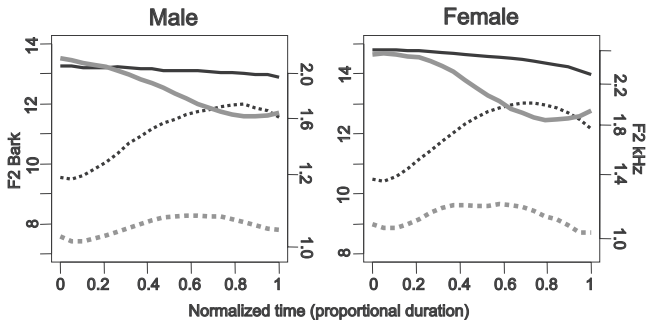

FIG. 3. Bark-scaled F2 trajectories between the onset and offset of /ju/ in *used* (solid) and /wu/ in *swoop* (dotted) that were linearly time-normalized and averaged across the young (black) and old (gray) groups shown separately for male (*left*) and female (*right*) speakers.

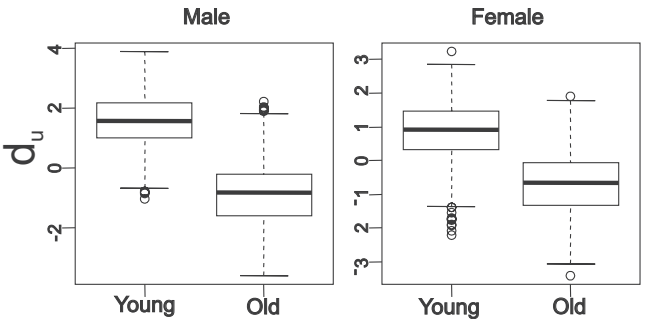

FIG. 4. Boxplots showing the median (thick horizontal bar), interquartile range and outliers (circles) on the parameter d_u, the log Euclidean distance ratio, across the young and old groups separately for male (*left*) and female (*right*) speakers.

(2) F2 of *swoop* rises but to a much lower frequency than for the young group.
(3) There is a considerably greater difference especially at F2 onset but also throughout the entire trajectories between *used* and *swoop* than for the young group. This suggests that the extent of C-on-V coarticulation is somewhat greater in the old group and for two reasons. First, because there is a more substantial deviation for the old group between the F2 onsets and by extension between the F2 loci of /w/ and /j/; and second because there is evidently a greater convergence in F2 toward a common vowel target across these two word contexts in the young group, as shown by the smaller separation between the *used* and *swoop* trajectories in both young male and female speakers.

We quantified the differences in the extent of /u/-fronting between the two age groups by calculating d_u, the log. Euclidean distance ratios in a three-dimensional DCT space, using the formula in Eq. (2) as described in Sec. II A 2. The results of these calculations are shown as boxplots for /u/ and /ju/ words in Fig. 4.

For both males and females, it is evident that the log Euclidean distance ratio, d_u, is greater for the younger speakers. Moreover, for the younger speakers, d_u is positive, which suggests that /u/ is closer to /i/ than to /ɑ/ on F2; by contrast, d_u is negative for the older speakers and so for them /u/ is closer on F2 to /ɑ/ than to /i/.

The results of a repeated measures analysis of variance (ANOVA) with dependent variable log Euclidean distance ratio, two between-subjects factors, Age (Young vs Old) and Gender, and a within-subjects factor for Word (9 levels corresponding to the 9 word types shown in Table I with a /u/ or /ju/ nucleus) showed a significant effect for Age [$F(1,13)=117.1$, $p<0.001$]. There was also an (unsurprising) significant effect for Word [$F(1,8)=167.7$, $p<0.001$], which simply means that F2 in the different words in Table I with /u/ or /ju/ nuclei were not all equally close to /i/ as to /ɑ/. There was no significant effect for Gender which may have come about because of the small number of male speakers in the young group.

The only interaction that was significant was Word × Age [$F(1,8)=10.1$, $p<0.001$]. This means that the extent of

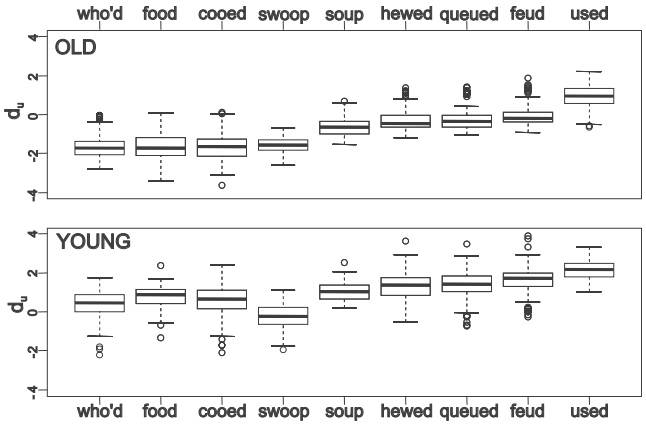

FIG. 5. Boxplots showing the median (thick horizontal bar), interquartile range, and outliers (circles) on the parameter d_u, the log Euclidean distance ratio, for the old (*above*) and young (*below*) groups separately for each word. The boxplots are rank ordered from lowest to highest median d_u in the old group in both cases.

/u/-fronting for the young relative to the old group was not the same in all words. Three findings emerged from a subsequent analysis of the word-specific distributions which are shown separately for the two age groups in Fig. 5. First, as also shown by *post-hoc* Tukey tests, there is a marked and significant ($p<0.001$) difference between the age groups for all words. As Fig. 5 shows, the median log Euclidean distance ratio is greater than zero for all words except *swoop* in the young speakers, which means they are all acoustically closer on (DCT and Bark-transformed) F2 to front /i/ than to back /ɑ/. There is exactly the opposite pattern in the older speakers for which the vowels of all words except *used* are closer to /ɑ/ (since median d_u is negative in these cases). Second, the relative positions and therefore rank order from lowest to highest d_u is very similar for both age groups: The main exception is *swoop* which has a roughly similar median value as the other back variants of /u/ in *cooed*, *who'd*, *food* for the older speakers, but which has a lower value in comparison with the three words in the younger speakers. The third finding falls out from the first two: The differences between the age groups were greatest in words with retracted /u/: that is, the difference between the age groups on the log Euclidean distance ratios was, as Fig. 5 shows, evidently greater for *cooed*, *who'd*, *food* than for *queued*, *hewed*, and *feud*.

We quantified these word-specific differences more precisely by measuring in the same Bark-transformed DCT space the Euclidean distances between the age groups separately for each word. More specifically, we calculated for *swoop* the Euclidean distances from all the young speakers' *swoop* tokens to the old group's *swoop* centroid; and the Euclidean distances from all the old speakers' *swoop* tokens to the young group's *swoop* centroid. The more these word-specific distributions of younger and older speakers overlap with each other, then the closer these distances should be to zero. We then carried out the same word-specific Euclidean measure for all word types separately. As Fig. 6 shows, the pattern of the resulting distribution on this measure is very similar to that obtained from the metric used for quantifying

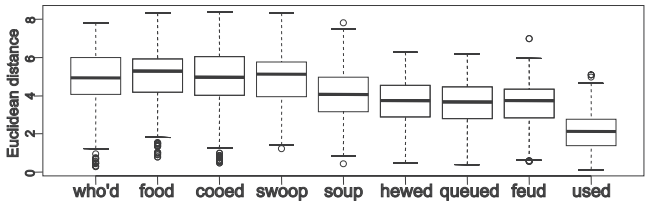

FIG. 6. Boxplots showing the median (thick horizontal bar), interquartile range and outliers (circles) on the inter-Euclidean distances (arbitrary units) between the young and old groups calculated in a Bark-scaled and DCT-transformed F2 space separately for each word. The words are arranged in the same order as in Fig. 5.

the relative position of the old speakers' vowels on a phonetic front–back dimension (Fig. 5). Thus, the greatest difference between the two age groups is for those vowels whose allophones are most retracted in the older speakers. This provides further evidence that the sound change involves a realignment in production of the phonetically back allophones of /u/ toward a phonetically front position (as a result of which, phonetically front variants of /u/ show the least displacement).

As far as the measures of coarticulation described in Sec. II A 2 are concerned, Fig. 7 shows the logarithm of the Euclidean distances from *used* tokens to the *swoop* centroid and from *swoop* tokens to the *used* centroid by age and gender: These distances are clearly greater for the old compared with the young group. A repeated measures ANOVA with dependent variable log Euclidean distances and two between-subjects factors, Age (Young vs Old) and Gender, and a within-subjects factor for Word (*used* and *swoop*) showed a significant effect for Age [$F(1,20)=36.5$, $p<0.001$] but no other significant effects.

III. SPEECH PERCEPTION

A. Method

For the perception experiment, HLsyn (High Level Parameter Speech Synthesis System, version 2.2) was used for creating the synthetic stimuli. With the exception of five subjects from the Old group, of which one participated only in the production experiment and of which four participated

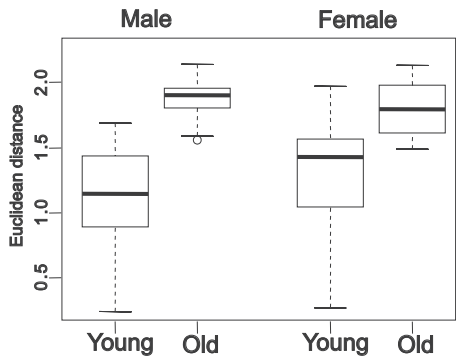

FIG. 7. Boxplots showing the median (thick horizontal bar), interquartile range and outliers (circles) on the logarithm of the inter-Euclidean distances (arbitrary units) calculated in a Bark-scaled and DCT-transformed F2 space between *used* and *sweep* shown separately for age and gender.

only in the perception experiment, listening responses were obtained from the same subjects who had participated in the production experiment (see Sec. II A 1 for further details).

We carried out various pretests with trained L1-English phoneticians to obtain naturalness judgments to a number of continua in the two word-contexts described more fully in the following, both in order to guarantee that our synthesized end points were intelligible as the intended words and to determine the perceptually most natural continuum as far as F2 changes were concerned.

We created two 13-step synthetic continua, one each between two sets of minimal-word pairs: *yeast-used* (/jist/-/just/ and henceforth /jVst/) and *sweep-swoop* (/swip/-/swup/ and henceforth /swVp/). These word pairs were chosen because the anterior /j_s/ context in the former is expected to have a phonetic fronting effect in speech production for which listeners might be expected to compensate perceptually relative to /sw_p/, as described in Sec. I.

The continua in both cases were created by varying F2 in the following ways. For the /jVst/ continuum, F2 was varied from 1278 Hz (stimulus 1 nearest /u/) to 2428 Hz (stimulus 13 nearest /i/) in equal 0.45 Bark-size steps. The following parameters were fixed for all stimuli in /jVst/: the F2-locus of the preceding /j/ at 2450 Hz; a transition phase of 90 ms in which F2 decreased linearly; a following steady-state vowel of 120 ms in duration; a level F1 and F3 from the periodic onset to the offset at 280 and 2700 Hz, respectively.

For /swVp/, F2 varied between 1014 Hz (stimulus 1) to 2320 Hz (stimulus 13) in 0.35 Bark steps. The /w/ locus was fixed at 600 Hz. There was a transition phase of 45 ms which was followed by a steady vowel of 140 ms with F1 and F3 fixed from the periodic onset to the offset at 280 and 2544 Hz, respectively. The reason why the two continua in /jVst/ and /swVp/ did not have the same formant end points was for reasons of perceived naturalness.

The 26 stimuli were randomized and individual synthetic word tokens were presented from both continua in one session 5 times (5 repetitions × 13 steps × 2 continua=130 randomized stimuli). For the perception experiment, subjects listened to each stimulus separately and carried out a forced-choice identification task in which they responded to each stimulus with one of *used*, *yeast*, *swoop*, or *sweep*.

Since, as described earlier, the two continua were synthesized with different end points, we had to map them onto the same F2-scale for the purposes of comparing the responses between them. The matching was done by aligning in frequency the responses to /jVst/ with those of /swVp/ at the closest F2 correspondences between the stimuli. For example, we compared responses to stimulus 4 from /swVp/ (F2=1260 Hz) with responses to stimulus 1 from /jVst/ with F2=1278 Hz because these were the two stimuli with the smallest F2 difference (Δ_{F2}=1278−1260=18 Hz) between them. As Table II shows, we had to exclude from the analysis responses to stimuli 1–3 from /swVp/ and to stimulus 13 from /jVst/ for which no closest F2 matches from the other continuum were available. We also had to collapse the responses to stimuli 4 and 5, and to 9 and 10 in /jVst/ for the same reason (see Table II for further details). The responses to the continua in Sec. III B are therefore presented for 10 stimuli based on the matched F2 values shown in the right column of Table II.

TABLE II. F2 values on the 13-point synthetic continuum for *sweep-swoop* (column 2), *yeast-used* (column 3), and the derived F2-aligned, 10-point continuum analyzed in this study (far right column).

Stimulus No.	/swVp/ F2 values (Hz)	/jVst/ F2 values (Hz)	Mean F2 value (Hz)

Two types of analyses were carried out on the perceptual responses. First, the results were analyzed with a repeated measures ANOVA with the stimulus number from the synthetic continua as a repeated-measure dependent variable, and with Context (a within-subject factor with two levels, /jVst/ vs /swVp/) and Age (between-subject factor with two levels, Old and Young) as the independent variables. Second, we carried out another repeated measures ANOVA with the same independent variables but with the category boundary obtained separately for each listener (i.e., the F2 frequency for which responses with /i/ or /u/ were 50%) as the dependent variable (Fig. 8). The 50% category boundary was calculated using probit analysis following exactly the same procedure as in, e.g., Lotto *et al.* (1996).

B. Results

The results of the comparison of the entire continua showed significant effects for Age [$F(1,28)=6.163$; $p<0.05$], and for Context [$F(1,28)=34.3$, $p<0.001$], as well

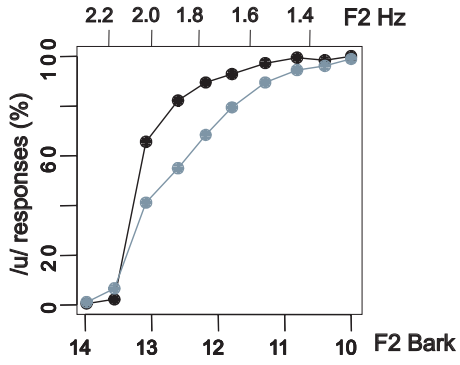

FIG. 8. (Color online) Percentage of /u/ responses as a function of decreasing F2 by young (*black*) and old (*gray*) listeners to synthetic continua pooled across *yeast-used* and *sweep-swoop*.

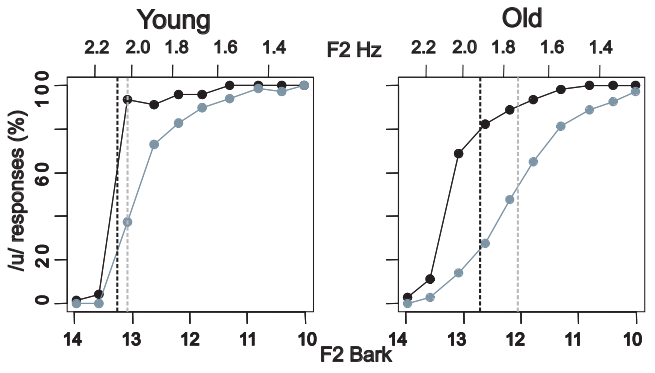

FIG. 9. (Color online) Percentage of /u/ responses as a function of decreasing F2 by young (*left panel*) and old (*right panel*) listeners to *used-yeast* (*black*) and *sweep-swoop* (*gray*). The vertical dotted lines show the mean category boundaries in *yeast-used* (*black*) and *sweep-swoop* (*gray*).

as a significant Context × Age interaction [$F(1,28)=4.3$, $p<0.05$]. The results of the comparison of the category boundaries, whose means for the four Age × Content conditions are superimposed on Fig. 9, were broadly consistent with those obtained from comparing the entire continua. There was a significant effect for Age [$F(1,28)=5.63$; $p<0.05$], for Context [$F(1,28)=39.7$, $p<0.001$], although a not quite significant Context × Age interaction [$F(1,28)=3.67$, $p=0.066$].

The effect across both sets of results for Age shows that, consistent with H3 (Sec. I), the /i-u/ boundary was left-shifted for the Young group: that is younger listeners were more likely to hear the same synthetic token as /u/ compared with older listeners, an effect which is clearly shown in Fig. 8. The effect across both sets of results for Context shows that the /i-u/ boundary was left-shifted in /jVst/: that is, listeners were more likely to hear the same synthetic token as /u/ in *yeast-used* compared with *sweep-swoop* (Fig. 9). This result is a replication of various experiments reviewed in Sec. I showing that listeners compensate perceptually for the effects of coarticulation.

The result of the Context × Age interaction which was significant in comparing the entire continua and not quite significant in comparing category boundaries, together with the data in Fig. 9 showing the responses separately to the two continua by age, is, in general, compatible with Hypothesis 5: Evidently, the young listeners did not compensate as much as the old listeners for coarticulation since the differences in their responses to *yeast-used* versus *sweep-swoop* were less than for older listeners. Thus, *post-hoc* Tukey tests showed that there were no significant differences between *yeast-used* versus *sweep-swoop* for the young listeners, neither in comparing the entire continua nor in comparing category boundaries; but that there were significant differences in older listeners' responses to *yeast-used* versus *sweep-swoop* both in comparing the entire continua ($p<0.001$) and in comparing category boundaries ($p<0.001$).

However, Fig. 9 also shows that the relatively diminished perceptual compensation for coarticulation in younger listeners came about because of differences in responses by the two age groups to /swVp/. More specifically, the results of *post-hoc* Tukey tests showed that there were no significant differences between the two age groups in their responses to /jVst/, either based on comparing the entire continua ($p=0.88$), or based on comparisons between the category boundaries ($p=0.86$). On the other hand, there were significant differences between the age groups in their responses to /swVp/, both in comparing continua ($p<0.01$) and in comparing category boundaries ($p<0.05$). This means that the main reason why there were overall different perceptual responses between the age groups (Fig. 8) was because the /i-u/ boundary on *sweep-swoop* was left-shifted in younger relative to that of the older listeners. We discuss the further implication of this result together with those from the acoustic analysis in Sec. IV.

IV. DISCUSSION

The hypothesis H4, that listeners compensate for the effects of coarticulation, is supported by the results from this experiment. Listeners attribute a certain proportion of vowel fronting on an /i-u/ continuum to the effects of consonantal context and factor this out: Accordingly, there is a greater probability that the same stimulus token will be perceived as /u/ in a fronting context such as /j_s/ than in a backing consonantal context such as /sw_p/. These findings are consistent with various studies showing perceptual compensation for coarticulation (Beddor *et al.*, 2002; Beddor and Krakow, 1999; Kawasaki, 1986; Fujisaki and Kunisaki, 1976; Mann and Repp, 1980), but also more generally with speech perception models (Fowler, 1984; Fowler and Smith, 1986; Ohala, 1993) in which listeners are sensitive to the nature and extent of coarticulatory overlap between segments.

The results of the production study showed unequivocally that younger speakers have a fronter realization of /u/ than older speakers (consistently with H1): this result lends support to other acoustic and auditory studies (Gimson, 1966; Hawkins and Midgley, 2005; Roach and Hartman, 1997) as well as to the longitudinal analysis in Harrington (2007) that /u/ in SSB has fronted in the last 40 years. The present investigation extends these analyses by showing that young listeners not only produce a fronter realization of /u/, but they also have a fronter category boundary in perceiving this vowel. Thus, H3, that young and old listeners respond differently to the same continuum that spans a sound-change in progress, was also supported by these data. In light of these data as well as other recent experimental studies on sound change in progress (e.g., Warren *et al.*, 2007), we have to abandon the notion that there is a uniform relationship between the phonological system and phonetic output for all members of the same speech community. Instead, phonological category boundaries are likely to be specific to different groups of speakers of the same speaking community and above all strongly related to the differences in their own speech production. The model that seems to be best able to account for these differences is an episodic or exemplar-based model of speech perception (Johnson, 1997; Pierrehumbert, 2002, 2003a, b, 2006). In this model, a phonological category is defined by a distribution in a perceptual space that depends on its remembered exemplars. Moreover, speech production involves the selection of one of the

exemplars—typically one that is most probable and nearest the center of the distribution (Pierrehumbert, 2001). Two features from this model are consistent with the results from the present study. First, that the phonological category boundaries can be (and are likely to be) different from one individual to the next, given that the remembered exemplars from which a phonological category is constructed will certainly be different across different individuals, even of the same speaking community. Second that, since in speech production an exemplar is selected from the phonological category that is built out of perceived and remembered exemplars, there is a close link between the category boundaries in speech perception and production: Thus our interpretation of these data within this model is that younger members of the community who place the category boundary closer to /i/ on /i-u/ in perception are also more likely to produce a more fronted /u/ than older members of the same community (because if the category boundary shifts toward /i/, then so does the center of gravity from which tokens are most likely to be selected in speech production).

The most important hypothesis in this paper, H5, was that if, following Ohala (1981, 1993), sound change comes about because listeners fail to undo perceptually the effects of consonant on vowel coarticulation, then the differences in the responses to the two continua should be a good deal less for younger listeners. Before we assess in detail the extent to which this hypothesis was substantiated, we will briefly recap the three main findings from the perception experiments. First, the results showed that, compatible with H5, there was a significantly greater difference in responses to the two continua by the older listeners. Evidently this shows that the older listeners' responses were influenced by consonantal context to a far greater degree than those of the younger listeners. Here there is, once again, compatibility with their speech production because the acoustic influence of consonantal context on the vowel was also greater (H2), as shown by the older speakers' greater divergence between *used* and *swoop* in a (bark and DCT-parametrized) F2 space. Second, the two age groups differed minimally and not significantly in their perceptual responses to *yeast-used*. And third, they differed extensively and significantly in their perceptual responses to *sweep-swoop*.

We now consider in further detail whether these three findings can be reconciled with Ohala's (1981, 1993) model in which a minisound change occurs as a result of a failure to compensate for coarticulation which is then carried over into speech production. Our starting point in this interpretation is the finding that young and old listeners have more or less the same responses to the *yeast-used* continuum. Here we would argue that although both age groups cut up the *yeast-used* continuum in a similar way, the difference is in the classification: Older listeners classify the distinction as /i-u/ as opposed to the younger listeners who classify it as /i-ʉ/. Thus, suppose there is a token midway between the synthesis end points which we denote as [ʉ]. Older listeners compensate for coarticulation and attribute a certain amount of fronting to the consonantal context and classify it perceptually as a back vowel /u/. Younger listeners compensate far less, or minimally, for the effects of consonantal context and classify it perceptually as a central vowel /ʉ/. So, in both cases, the *position* of the category boundary on the *yeast-used* continuum may be roughly the same (left-*shifted* in old speakers because they compensate for coarticulation, but *positioned* to the left and near /i/ in young listeners because /ʉ/, being a central vowel, is characterized in speech production by a mid-high F2) but the *classification* is different. Now consider the results for *sweep-swoop*. Here there is of course no reason to compensate for the fronting effects of coarticulation and so the category boundary for older listeners shifts to the right commensurate with their classification of the low end of the F2 continuum as a back /u/, resulting in a relatively greater proportion of /i/ responses and a marked and significant difference compared with their responses to *yeast-used*. Since younger listeners compensate minimally for coarticulation, their category boundary is not significantly different from their *yeast-used* but it is significantly to the left of the older listeners' *sweep-swoop* boundary (who divide the continuum into /i-u/). Thus all of the findings from the perception experiment and their relationship to those from the production experiment are consistent with the following two ideas. First, older listeners compensate perceptually for the coarticulatory fronting effects of a consonantal context in *yeast-used* but younger listeners do not (or compensate much less). Second, there is a difference of *phonological* category between the two groups: Older listeners make a contrast between /i/ and /u/ whereas for younger listeners of the same speaking community, the contrast is between /i/ and a central vowel /ʉ/. It is because the two age groups cut up the *sweep-swoop* continuum differently and because the young listeners show neither significant evidence of coarticulatory compensation in perception nor of a back vowel allophone in contexts like *swoop* in production that we wish to argue for a difference in phonological category: this is, of course, very different from suggesting that the two age groups have the same /i-u/ contrast and differ because the young speaker-listeners realize /u/ phonetically as [ʉ].

The stages that give rise to the sound change within Ohala's model might then be as follows. The divergence between front and back variants of /u/ 40–50 years ago was very large (and is still considerable in older speakers) necessitating compensation for coarticulation in the front consonantal context to bring about a perceptual realignment of front realizations of /u/ with retracted variants, thereby maintaining the phonetic integrity of the phonological category /u/. With the assumed waning of perceptual compensation for coarticulation, the integrity of the phonological category was preserved by shifting diachronically *in production* the back toward the front variants. This suggests that the extent of this shift was greatest in the phonetically most retracted variants and some evidence to support this has been presented in Figs. 5 and 6 in which, for example, the difference between young and older speakers' production of *food* or *who'd* was greater than for *feud* or *hewed*.

In the above-presented analysis, the failure to compensate perceptually for coarticulation is the trigger for the sound change in which /u/ changes to /ʉ/. However, the data from the present study might be just as compatible with an episodic model of perception and production in which the
