Abstract Gastrointestinal and pancreatic endocrine tumors are neoplasms of which the pathogenesis is not completely understood and of which the clinical behavior is difficult to predict. Originally, Masson suggested that the cell of origin was an endocrine cell derived from the gastrointestinal epithelium. However, Pearse showed that the endocrine cells throughout the body shared various features, among others the amine precursor uptake and decarboxylation (APUD) capacity, and postulated the neural crest as the common origin for all APUD cells, a hypothesis that received support from the scientific community for many years. Now, biologists start to elucidate the various transcription factors that drive gastrointestinal development, and it has become evident that Masson was presumably right. Transcription factors relevant for development may also operate during tumorigenesis, and their expression may determine tumor biology. With other genetic factors, they may play a role in the pathogenesis of gastrointestinal and pancreatic endocrine tumors, and perhaps, their expression will turn out to be of prognostic or therapeutic value. In this review, current knowledge on the development of endocrine cells, hypotheses on the origin of endocrine tumors, genetic alterations, and prognostic factors are discussed. It is suggested that the increasing understanding of the normal development of gastrointestinal and pancreatic endocrine cells, the accumulating data on genetic alterations in endocrine tumors and the reappraisal of the hypotheses on their pathogenesis formulated in the past may help in elucidating their pathogenesis and in more accurately predicting prognosis.

History

When the French-born Canadian pathologist Pierre Masson retired 50 years ago, he left an impressive oeuvre containing interesting concepts on the origin of gastrointestinal endocrine cells and the pathogenesis of gastrointestinal and especially appendiceal carcinoids.

The term carcinoid had been introduced by Oberndorfer ('Karzinoide' meaning 'carcinoma-like'), who recognized this neoplasm as a separate entity, behaving less aggressively than conventional adenocarcinomas [45]. Masson demonstrated the argentaffin-staining properties of these tumors using a silver impregnation technique and proposed an origin from gastrointestinal endocrine cells. He was convinced that the gastrointestinal endocrine cells derive from the gastrointestinal epithelium itself and do not, as proposed by others, migrate from a neural plexus towards the mucosa. Moreover, he thought that appendiceal carcinoids originate from undifferentiated cells at the base of the crypts, which bud off the epithelium, form complexes with the subepithelial neural plexus, and subsequently acquire their endocrine granules, which, in a way, might be regarded as a sort of stem cell concept. Concerning carcinoids elsewhere in the gastrointestinal tract, he also described a subepithelial intraneural argentaffin cell as the cell of origin [42–44].

In the same period, Feyrter [20, 21] recognized that the endocrine cells scattered in the epithelium of various organs, including the gastrointestinal tract, might be regarded as part of a diffuse endocrine/paracrine system, and Masson's ideas were forgotten when Pearse showed that these cells share important ultrastructural and biochemical characteristics, especially the amine precursor uptake and decarboxylation (APUD) capacity. These observations were consistent with a common origin of the APUD cells, for which the neural crest appeared the only possible candidate [52].

However, experiments by Fontaine and Le Douarin [22] in quail-chick chimeras provided strong evidence against a neural crest origin of most endocrine cells, except thyroid C cells, ganglia, and paraganglia. Although their results

could not completely rule out an ectodermal origin of gastrointestinal endocrine cells, they pointed more towards an endodermal origin, thereby supporting Masson's view and forming a base for the stem cell concept used today [13].

Developmental biology

Illustrative of this concept is the current knowledge on the development of the endocrine cells in the intestine and pancreas at both the cellular and molecular level, to which data from animal models have contributed significantly.

The intestinal epithelium, which is of endodermal origin, contains four main cell types: enterocytes, goblet cells, Paneth cells, and endocrine cells. These are thought to arise from omnipotent stem cells at the base of the crypts of Lieberkühn. Experimental mouse models suggest that the omnipotent stem cells give rise to enterocyte precursors and to (common) precursors of goblet cells, Paneth cells, and endocrine cells, sometimes designated as secretory stem cells [28, 72]. This happens under the influence of transcription factors. A transcription factor encoded by a caudal-related homeobox gene and involved in early intestinal development and differentiation is Cdx2. Cdx2 expression is maintained in the adult intestinal epithelium, although expression in Paneth cells is weak [6, 63]. Differentiation into a secretory stem cell and its descendants is thought to be directed by transcription factors encoded by genes of the basic helix-loop helix (bHLH) family, of which Math1 is (one of) the first in the pathway [72]. As shown in Fig. 1, subsequent differentiation towards an endocrine cell is regulated by the transcription factor neurogenin 3 (ngn3) [28]. Its downstream target NeuroD/BETA2 is especially required for the development of secretin and cholecystokinin producing intestinal endocrine cells [48]. Endocrine differentiation is repressed by Notch signaling. Notch is a transmembrane receptor that exerts its function via lateral inhibition. Hes1 is an important transcriptional repressor of this pathway [29, 64]. Although an obvious role for ngn3 in the differentiation of goblet cells and Paneth cells has not been

established, recently published data suggest its transient expression in a subset of their precursors [59].

The development of the pancreatic endocrine cells, organized in the islets of Langerhans, shows differences from, but also striking similarities to, intestinal endocrine development. The pancreas arises from the duodenal region of the embryonic foregut, where expression of the pancreas duodenum homeodomain protein 1 (Pdx1) is required for the formation of the ventral and dorsal primordia, which, in a later stage, fuse to form the adult organ. At the cellular level, the pancreatic primordia contain Pdx1 positive epithelium, which forms primitive ducts from which the endocrine cells arise [1, 53]. As in the intestine, animal models indicate that ngn3 and neuroD/BETA2 play a role in this process [23, 48, 61], whereas Notch inhibits endocrine differentiation. For Notch, a role has been suggested in modulating the development of the exocrine pancreas [2] and, more recently, in keeping the undifferentiated state of pancreas precursor cells [24]. Math1, required in the intestine for differentiation towards a secretory stem cell phenotype, does not seem to play a role in pancreatic development [60]. Other transcription factors downstream of ngn3 and NeuroD/BETA2, involved in endocrine differentiation of the pancreas, are Pax4, Nkx2.2, Nkx6.1, Pax6, and Isl1 [62]. In the adult pancreas, Pdx1 is almost exclusively expressed in the insulin producing β cells, in which it plays a role in transcriptional activation of the insulin gene, together with NeuroD/BETA2 [41]. Although most endocrine cells are organized in the islets of Langerhans, scattered endocrine cells are found in the exocrine ducts. In a pancreatic duct ligation model in rats, expression of the putative stem cell markers c-kit and nestin and upregulation of the transcription factors Pdx1 and Nkx2.2 have been described, suggesting that in the pancreatic remodeling and neoformation process, similar mechanisms are involved as in embryonic development [54].

Developmental biology related to tumorigenesis

The increasing knowledge on embryonic development influences the ideas on tumor pathogenesis and may also be important in endocrine tumor pathology. A tumor is regarded as a clonal expansion that, in theory, originates from a genetically unstable and deregulated, terminally differentiated cell, from an unstable, deregulated, terminally precursor cell already committed to a certain line of differentiation, or from a deregulated, undifferentiated, omnipotent stem cell. Although an origin from a terminally differentiated cell cannot be ruled out, it has been suggested that pancreatic endocrine tumors have a precursor cell origin [30, 37, 69]. In part, this idea is based on the occurrence of mixed pancreatic tumors, consisting of an endocrine part combined with ductal or acinar features. The concept of derivation from a precursor cell or omnipotent stem cell is especially attractive for these mixed tumors, in which more than one cell type is present because it provides an overt explanation for their histological features. Another exam-

Fig. 1 This diagram shows transcription factors involved in the development of different intestinal epithelial cell types [28, 60, 72]

ple of a mixed tumor is a goblet cell carcinoid, in which the malignant counterparts of goblet cells, endocrine cells and Paneth cells can be found, which is suggestive of an origin from an intestinal secretory stem cell, which is thought to be the precursor of precisely these cell types. In contrast, scattered, supposedly nonneoplastic endocrine cells have been found in ductal adenocarcinomas of the pancreas that were not considered as an intrinsic part of the tumor [49].

In light of the presumed precursor cell origin of certain tumors, including tumors consisting of one cell type, an important consideration is that the transcription factors playing a role in embryonic development may drive tumorigenesis as well. The expression of *Math1* in Merkel cell carcinoma (an endocrine tumor of the skin) [34] and its recently reported repression in colonic adenocarcinoma [36] are in support of this. Other examples of transcription factors expressed in tumors are *CDX2* in intestinal tumors, including carcinoids, and thyroid transcription factor 1 (involved in thyroidal and pulmonary development) in tumors of the thyroid and lung [67, 71].

Knowledge on the role of transcription factors in (endocrine) tumors may help in elucidating their pathogenesis and may even, in the far future, provide a target for therapeutic options, such as specific intervention of the pathways governed by these molecules, and thereby inhibit or stimulate cellular activities of, for example, proliferation or differentiation. However, at this moment, data on the role of the transcription factors mentioned above in gastrointestinal and pancreatic endocrine tumors are limited to reports on the expression of *CDX2* [3, 33].

Genetic alterations

More is known about generalized and also some specific molecular genetic abnormalities underlying gastrointestinal and pancreatic endocrine tumors. One of the genetic changes reported repeatedly in gastrointestinal endocrine tumors, especially in midgut carcinoids (carcinoids of jejunum, ileum, ascending colon, and appendix) and less frequently in pancreatic endocrine tumors, is loss on chromosomal arm 18q. Because, in most cases, no apparent alterations have been found in the tumor suppressor genes *DPC4* and *DCC*, which are located in the affected region, it has been suggested that a currently unknown gene on chromosome 18q is important in the pathogenesis of (especially midgut) endocrine tumors [7, 27, 32, 40, 55, 68, 73]. Because in some midgut carcinoids loss of chromosome 16q21 and gain of chromosome 4p14 have been found in metastases but not in the primary tumor, genes in this region may play a role in tumor progression [32]. Only in a minority of midgut carcinoids allelic loss on chromosomal arm 11q has been described [17, 32, 73], whereas deletions on chromosome 11q have been found more frequently in foregut carcinoids [17, 73]. The different genetic alterations found in foregut and midgut carcinoids suggest that these tumors develop and progress via different molecular pathways [17, 35, 56]. This may at least, in part, explain the clinical, histological,

and immunohistochemical heterogeneity of these tumors, which is addressed in recent reviews on gastrointestinal endocrine tumors [46, 70].

Chromosome 11q13 harbors the tumor suppressor gene responsible for the hereditary syndrome multiple endocrine neoplasia type 1 (*MEN1*), which is associated with pancreatic endocrine tumors. Pancreatic, gastric, and duodenal endocrine tumors of *MEN1* patients and a subset of their sporadic counterparts show loss of heterozygosity of the *MEN1* gene. Because allelic losses distal to this gene have been found, it has been suggested that chromosome 11q contains other tumor suppressor genes that may play a role in pathogenesis as well [11, 16–18, 27, 66]. Another hereditary syndrome associated with pancreatic endocrine tumors is Von Hippel–Lindau (*VHL*) disease, linked to a tumor suppressor gene on chromosome 3p25–26 [38]. Although pancreatic endocrine tumors frequently show loss in this region, mutations in the *VHL* gene have not been found in sporadic cases. It is likely that another tumor suppressor gene near the *VHL* gene plays a role in the pathogenesis of sporadic pancreatic endocrine tumors, and there are indications that allelic losses of chromosome 3p are involved in tumor progression [4, 15]. A role in tumor progression has also been suggested for putative tumor suppressor loci at chromosome 6q [5]. Moreover, allelic losses on the X chromosome were found in pancreatic endocrine tumors and correlated with aggressive tumor behavior [12, 56]. *C-myc* is an oncogene that may be involved in the pathogenesis of pancreatic endocrine tumors [37, 51], and genes with a tumor suppressor function on chromosome 9p, e.g., *Ink4A/Arf* encoding p16, may be of importance in both gastrointestinal and pancreatic endocrine tumors [37, 39, 47].

Alterations in tumor suppressor genes and oncogenes commonly involved in human cancer, like *TP53*, *Rb*, and *KRAS*, have been described in gastrointestinal and pancreatic endocrine tumors, especially in poorly differentiated endocrine carcinomas, but they do not seem to play a major role in pathogenesis [14, 50, 51, 57, 58].

Prognostic features

Some of the genetic alterations mentioned above, such as loss of heterozygosity on chromosome 3p, 6q, and X, may be involved in tumor progression and may turn out to be of prognostic value in the near future, but currently, there are no consistent genetic changes in endocrine tumors that can be used to predict tumor behavior in an individual patient. Also, based on histological criteria, it is difficult to predict prognosis. Generally, it is not a problem to recognize poorly differentiated endocrine carcinomas, which have histological features of small cell carcinoma. However, poorly differentiated endocrine carcinomas of large cell type are underdiagnosed because their endocrine nature is not always recognized and because the WHO classification does not provide clear diagnostic criteria.

In the group of better differentiated tumors, metastasis is the only reliable indicator of malignancy. Other prognostic

factors for pancreatic endocrine tumors have been described by Capella et al. [10], and assessment of malignancy in gastrointestinal endocrine tumors has also been comprehensively reviewed by Bordi et al. [8]. Despite the lack of unequivocal histological criteria for malignancy of a primary tumor, the WHO classification of endocrine tumors published in 2000 distinguishes benign tumors, tumors of uncertain behavior, and low-grade malignant and high-grade malignant carcinomas of the gastrointestinal tract [65] and pancreas [31], based on parameters for which prognostic value has been described [for gastrointestinal endocrine tumors, site, size, depth of invasion, and vaso-invasive growth, and for pancreatic endocrine tumors, also proliferative activity and functionality (i.e., causing a clinical syndrome by hormone secretion)]. In the WHO classification of tumors of the digestive system also published in 2000 [25], the same prognostic parameters are mentioned for gastrointestinal endocrine tumors, for some sites extended with proliferative activity, although a similar grading system is not explicitly presented. Also, the new WHO classification for pancreatic endocrine tumors (2004) [26] does not contain significant differences compared to the old version [31]. The classification system still contains the category of tumors of uncertain behavior, reflecting the lack of clear prognostic features in endocrine tumors.

A recent observation in pancreatic endocrine tumors is the correlation between immunohistochemical expression of cytokeratin 19 (Ck19) and aggressive behavior [19]. During embryonic development, Ck19 is transiently expressed in all pancreatic cells, including endocrine cells, but after 16 weeks of gestation, Ck19 gradually disappears from most cells in the islets of Langerhans, whereas its expression remains strong in the ducts [9]. In view of the presumed precursor cell origin of pancreatic endocrine tumors, it is tempting to speculate that more aggressive pancreatic endocrine tumors arise from an early precursor cell, which has not yet lost its Ck19 expression, or that they arise from a precursor cell that tends to differentiate towards a ductal phenotype not yet visible histologically, but already evident at the immunohistochemical level. The clinical value of Ck19 as a prognostic marker in pancreatic endocrine tumors remains to be evaluated.

Conclusion

The difficulties described above in accurately predicting prognosis of gastrointestinal and pancreatic endocrine tumors bring us back to the observations of Masson. He already described the unpredictable clinical behavior of gastrointestinal endocrine tumors and noticed the higher metastatic capability of ileal carcinoids compared to those of the appendix [43]. Although we probably would not agree with his explanation that this is due to the difference in intestinal motility between the ileum and appendix, it

might be worthwhile to reconsider his ideas, in particular, on the origin of appendiceal carcinoids, and compare and test them with the knowledge and possibilities of today. Especially, evaluation of the role of transcription factors involved in differentiation and of genomic alterations in endocrine tumors may help in elucidating their pathogenesis and in establishing reliable prognostic parameters. It is predicted that especially Masson's concepts on origin and pathogenesis will appear much more valid than when these were considered over the past 50 years, once the molecular developmental biology of the endocrine cell population in the digestive tract has clarified their tumorigenesis 50 years from now. Would there then be better proof of Masson's vision than the century it took us to validate his concept?

Detecting cell-free circulating hTERT mRNA in the plasma may identify a subset of nonsmall cell lung cancer patients

Received: 29 June 2005 / Accepted: 31 August 2005 / Published online: 29 September 2005

Abstract Human telomerase reverse transcriptase (hTERT), the catalytic subunit of telomerase, a marker of cell immortalization, is upregulated in most tumors, including nonsmall cell lung cancer (NSCLC). However, little is known about the role of assessing cell-free plasma circulating hTERT mRNA for tracing these tumors. We investigated by RT-polymerase chain reaction (PCR) and real-time quantitative PCR the prevalence and functional implications of hTERT mRNA in both tumor tissue and paired plasma samples in 34 (27 males and 7 females) stages I–IIIb NSCLC patients (21 adenocarcinomas and 13 squamous-cell carcinomas) by using intron- and exon-spanning primers. Plasma samples of ten

healthy volunteers and normal lung tissue were used as negative controls. We detected hTERT mRNA in the plasma of 4 out of 34 (12%) tumor patients, but none was detected in the ten plasma samples of healthy volunteers. Normal lung tissue was completely devoid of hTERT mRNA. No association was found between hTERT plasma mRNA and clinicopathologic variables of the patients' population. We conclude that cell-free circulating hTERT mRNA is detectable in a subset of patients, whereas it is consistently absent in healthy volunteers. It can be added to the panel of multiple genetic tracers to detect lung cancer in the plasma of patients, although, per se, it is not specific for this tumor.

Introduction

Lung cancer is one of the leading causes of morbidity and death worldwide, with more than 1,200,000 new cases per year, accounting for about 12–15% of all cancers diagnosed in both genders [60]. Unfortunately, most lung carcinomas are discovered in an advanced stage, when the chances of definitive cure are dramatically reduced [13]. Only 10–20% of them are diagnosed when the disease is still limited to the lung without regional lymph node involvement (stage I, pT1–2 N0 M0). These patients may be successfully treated, and they have the highest likelihood of prolonged survival [8, 40]. The occurrence of local or systemic clinical symptoms is a late event that is usually associated with ominous prognosis [47]. Therefore, any effort is warranted to anticipate lung cancer diagnosis as much as possible, especially in high-risk populations of current or former heavy smokers [22, 48], to improve both the detection rate of lung cancer and patients' survival.

The use of molecular markers in body fluids, such as sputum, bronchial brush and lavage, and plasma or serum, has been proposed as a potentially useful diagnostic tool in both lung cancer patients and clinically negative high-risk

chronic smokers [23]. This approach is based on the detection of genetic/epigenetic changes shared by primary tumors [1, 2, 11, 37, 54, 59] or on the quantitative assays of cell-free total circulating DNA [57, 58]. More recent and exciting, however, is the discovery that many different types of cell-free circulating mRNA molecules may be detected in the bloodstream of patients with a variety of malignancies such as melanomas [10, 20, 29, 45], follicular lymphomas [9], and breast [3, 15, 28, 45, 55], large-bowel [9, 35, 56, 72], liver [38, 39, 44], esophagus [10], nasopharynx [36], thyroid [34, 45], prostate [5], and lung [12, 28] carcinomas, in hepatic cirrhosis and chronic hepatitis [38, 39], in patients with trauma [51] or diabetic retinopathy [18, 19], or in women during pregnancy for

either fetal [43, 50, 62, 66, 67] or maternal [42] mRNA. The occurrence of detectable cell-free and stable RNA in the blood of such patients [63] challenges the long-lasting belief that extracellular mRNA is rapidly degraded by blood ribonuclease [52], opening novel options for non-invasive cancer diagnosis (reviewed in Wong and Lo [70]).

Human telomerase reverse transcriptase (hTERT), the catalytic subunit of telomerase, a marker of cell immortalization [6, 7, 25, 27, 64], is upregulated in up to 80–90% of all tumors, including most nonsmall cell lung cancer (NSCLC) [25, 31, 32, 46]. The hTERT subunit has been used as a plasma tracer in patients with malignant melanoma [45], follicular lymphoma [9], and breast [3, 45], large-bowel [9, 35], thyroid [45] and liver [38, 39] carcino-

ma, but little is currently known on the possible implications of cell-free plasma circulating hTERT mRNA in NSCLC patients.

Using real-time quantitative PCR, we document that cell-free circulating hTERT mRNA can be detected in a subset of NSCLC patients, independent of tumor clinicopathologic features, and may become a potentially useful diagnostic tool for these patients.

Materials and methods

Patients and controls

We evaluated plasma samples from 34 (27 men and 7 women) consecutive patients with newly diagnosed and previously untreated stages I–IIIB NSCLC at the European Institute of Oncology in 2004. Clinicopathologic characteristics of the patients are detailed in Table 1. All the patients had been studied preoperatively with clinical history, physical examination, respiratory function tests, total body CT and PET scans, and routine laboratory profile, and all underwent radical surgery inclusive of extended mediastinal lymph node dissection (median value 16.5 excised lymph nodes) to ensure a very accurate pathological staging.

Patients' ages ranged from 40 to 83 years for males (mean±SD 66±10; median 65) and from 51 to 82 years for females (mean±SD 69±10; median 71). According to the current World Health Organization (WHO) classification of lung tumors [61], there were 21 (62%) adenocarcinomas and 13 (38%) squamous-cell carcinomas. Tumor size ranged from 1.3 to 6 cm (mean±SD 3.4±1.3; median 3.2) in the former, and from 1.6 to 9 cm (mean±SD 4.5±2.5; median 3.4) in the latter. Among adenocarcinoma patients, four had *p*-stage IA, eight had *p*-stage IB, three had *p*-stage IIB, five had *p*-stage IIIA, and one had *p*-stage IIIB; among squamous-cell carcinoma patients, two had *p*-stage IA, four had *p*-stage IB, four had *p*-stage IIB, and three had *p*-stage IIIA (*p*=NS). Five (15%) carcinomas were well differentiated (four adenocarcinomas and one squamous-cell carcinoma), 16 (47%) were moderately differentiated (ten adenocarcinomas and six squamous-cell carcinomas), and 13 (38%) were poorly differentiated (seven adenocarcinomas and six squamous-cell carcinomas). All patients were smokers, and detailed smoking habit information was available for most of them.

Plasma samples of ten healthy health care, nonsmoker workers who volunteered to participate in the study were used as negative control. All patients and volunteers gave informed consent to be enrolled into the study that had been approved by the Institutional Review Board (IRB). Proliferative activity of primary tumors was assessed by Ki-67 immunostaining as previously reported [49]. Vascular invasion was considered as being absent or present, whereas tumor necrosis and lymphocytic infiltration were assessed as described elsewhere [57].

Plasma and tumor sample collection

Peripheral venous blood samples were collected from cancer patients before surgery and from healthy volunteers in two EDTA-treated, 7.5-ml blood collection tubes, processed within 30 min to avoid RNA degradation, by double centrifugation at 3,000×*g* for 10 min and then at 4,000×*g* for 20 min, at 4°C, to eliminate blood cell and fragments. One-milliliter plasma aliquots were then stored at −140°C and thawed only once before use. Tumor tissue and paired normal lung parenchyma specimens were immediately removed at the time of surgery and were partly snap-frozen in liquid nitrogen for RNA extraction or fixed in formalin and embedded in paraffin for routine histopathologic examination.

Ribonucleic acid extraction and reverse transcriptase–polymerase chain reaction

Plasma Two-phase experiments tested the effectiveness of different extraction procedures on the yield of detectable circulating mRNA in the plasma of NSCLC patients. First, five plasma samples of NSCLC patients were assayed for the presence of β-actin mRNA by using five commercially available extraction kits according to manufactures' instructions [QIAamp Viral RNA Mini Kit (Qiagen, Milan, Italy), RNeasy Mini Kit (Qiagen), RNeasy Micro Kit (Qiagen), a standard method based on Trizol LS Reagent (Invitrogen Corporation, Leek, The Netherlands), and a combination of Trizol LS Reagent with RNeasy Mini or Micro Kit]. As Trizol was the most flexible method and the most commonly used for RNA extraction from both tissues and body fluids [4, 65, 71, 72], we optimized the experimental procedure by testing different starting volumes of plasma (Fig. 1).

On the basis of these preliminary findings, in the second phase, the Trizol LS Reagent based method was used for the extraction of plasma mRNA in the whole series of 34 patients and ten controls with 3 ml of starting volume, which resulted in the highest yield of recovery. Briefly, 7.5 ml of Trizol LS Reagent was added to 3 ml of plasma in 15-ml tubes that were shaken for 15 min at room temperature, and then 2.4 ml of chloroform was added. Each sample was then incubated for 5 min at room temperature and centrifuged at 12,000×*g* for 15 min at 4°C to achieve separation into three phases. The upper aqueous phase containing RNA was transferred into new tubes and incubated with an equal volume of isopropyl alcohol and glycogen at −30°C for 2 h to ensure RNA precipitation. The mixture was centrifuged at 12,000×*g* for 10 min at 4°C, the supernatant was removed, and the pellet was washed by centrifugation (7,500×*g* for 5 min at 4°C) in cold 70% ethanol, allowed to dry for 5 min at room temperature, dissolved in 20 μl of RNase-free water, and stored at −140°C until use. DNase digestion and total RNA spectrophotometric quantitation were avoided to prevent RNA degradation or loss, and the specificity of the assay was ensured by the use of intron-spanning primers

Fig. 1 Flowchart of the different extraction methods used in the study; the Trizol LS Reagent with 3 ml of plasma was then optimized for both patients and healthy controls

(see below). For RT-PCR analysis, 19 µl of the RNA solution was used.

Tissue Twenty 10-µm-thick frozen sections were cut from each tissue sample, either tumoral (containing at least 80% of neoplastic cells) or normal, added to 1 ml of Trizol Reagent, and processed according to manufacturer's instructions. The yield of extracted RNA was measured spectrophotometrically, and 3 µl of a solution containing 300 ng/µl RNA was used for RT-PCR analysis.

Reverse transcriptase–polymerase chain reaction Reverse transcription using Moloney Murine Leukemia Virus Reverse Transcriptase (M-MLV Reverse Transcriptase, Invitrogen) for tissue samples and GeneAmp RNA PCR Kit (Applied Biosystem, Foster City, CA) for plasma samples were used to generate cDNA for β-actin and hTERT analysis according to the manufacturers' instructions. RT conditions included a 10-min primer incubation step at 25°C, followed by a 42°C extension for 30 min, and a 99°C denaturation for 5 min (in case of tissue, the extension temperature was 37°C for 60 min).

β-actin and hTERT mRNA amplification was achieved using 2 µl of cDNA and AmpliTaq DNA polymerase (Applied Biosystem) for both plasma and tissue samples and specific intron-spanning primers (Table 2). In particular, pseudogene-free primers [30] were applied for β-actin mRNA amplification (annealing temperature 60°C, amplification product 172 bp) to minimize DNA contamination, and primers for an exon 3- to 4-spanning hTERT sequence [39] were chosen (annealing temperature 61°C, amplification product 145 bp). This sequence encodes for telomerase-specific T and I domains essential for the enzymatic function [68] that are not affected by alternative splicing in human cancers [14, 24, 41]. PCR conditions were an initial denaturation step at 94°C for 5 min, followed by 20 (plasma samples) or 35 (tissue samples) cycles of 94 (for 30 s), 60 (for 30 s), and 72°C (for 30 s),

with a final elongation step at 72°C for 7 min (in case of hTERT, the melting temperature was 61°C for 40 s). The specificity of PCR reactions for both plasma and tissue analysis was checked by positive (A549 nonsmall cell lung cancer cell line) and negative (omitting cDNA and enzyme) controls.

Real-time polymerase chain reaction assay

Real-time PCR assay of plasma samples was performed for both β-actin and hTERT mRNAs in a final reaction volume of 20 µl using the TaqMan Universal PCR Master Mix (Applied Biosystem) containing 1 µl of preamplified cDNA according to the standard protocol of the ABI Prism 7700 Sequence Detector (Applied Biosystem). hTERT amplifi-

cation by nested PCR was performed using a mixture of customer-designed internal primers and probe specifically optimized, both purchased from Applied Biosystem, whereas primers for β -actin had been previously validated for quantitative assay [30]. Real-time PCR assay conditions were an initial denaturation step at 95°C for 10 min to activate the TaqMan followed by 40 cycles at 95 (for 15 s) and 60°C (for 1 min), and a final elongation step at 60°C for 1 min. Standard curves for both β -actin and hTERT mRNA

Fig. 3 Amplification plots of the real-time quantitative polymerase chain reaction for hTERT (a, b) and β -actin (c, d) in plasma mRNA from nonsmall cell lung cancer patients (a, c) and healthy volunteers (b, d). Plasma hTERT mRNA is detectable in a subset of patients only (a), but plasma hTERT mRNA is not detectable in the ten healthy volunteers (b), whereas plasma β -actin plasma mRNA is shared by both patients (c) and normal controls (d)

quantification were prepared by amplifying serial dilutions of mRNA extracted from the A549 nonsmall cell lung cancer cell line from 625 to 19.5 pg/ μ l. The relative “input amount” values of each sample for the relevant transcripts were calculated plotting each Ct value on the corresponding standard curve. Each run of amplification included RNA of the same nonsmall cell lung cancer cell line used as a positive control and a negative control without cDNA. Duplicate tests were performed, and the mean value was calculated for each sample.

Statistics

Qualitative data were presented as frequencies and/or percentages and compared using the chi-square or Fisher exact test. All analyses were carried out using the SAS statistical software (SAS Institute, Inc., Cary, NC). All p values (significant if ≤ 0.05) were based on two-sided testing.

Results

Exon 3–4 hTERT mRNA was detected in 33 of 34 (97%) NSCLC samples, whereas normal lung tissue was completely devoid of any transcript. β -actin mRNA was found in 34 of 34 (100%) primary tumors and in all paired normal lung parenchyma samples (Fig. 2).

Exon 3–4 hTERT mRNA was detected in the plasma of 4 out of 33 (12%) hTERT-positive tumor patients, with normalized hTERT threshold ratios being 12.62 (case 60),

11.03 (case 95), 1.76 (case 58), and 6.92 (case 192), respectively. None of the ten plasma samples of nonsmoker healthy volunteers, as well as the single patient whose tumor was devoid of hTERT mRNA (Table 1, case 91), presented any detectable hTERT mRNA level in the plasma (Fig. 3a,b).

On the contrary, 23 of 34 (68%) NSCLC samples showed detectable levels of cell-free circulating β -actin mRNA, as did 6 of 10 (60%) nonsmoker healthy volunteers (Fig. 3c,d).

No significant relationship was found between the occurrence of hTERT mRNA in the plasma and clinicopathologic variables of the patients. In particular, the four patients (three males and one female) with detectable hTERT mRNA in the plasma harbored two adenocarcinomas (cases 60 and 95) and two squamous-cell carcinomas (cases 58 and 192), the ages ranged from 63 to 77 years, tumor size ranged from 3 to 4 cm, tumor grade ranged from G1 to G2, and tumor stage ranged from IB to IIB. Moreover, no relationship was found with the extent of tumor necrosis, the occurrence of vascular invasion, the lymphocytic infiltration, and the proliferative fraction.

Likewise, no significant correlation was found between the presence of β -actin mRNA in the plasma and any clinicopathologic variable of the NSCLC patients' population under evaluation.

Discussion

The main results of the current study are (a) cell-free circulating hTERT mRNA is detectable in a minority of NSCLC patients, but it is likely to be tumor-related because it is undetectable in healthy subjects and in patients with hTERT-negative tumors; (b) most patients and healthy individuals share cell-free circulating plasma mRNA of β -actin; and (c) plasma hTERT mRNA does not undergo complete degradation, and it remains detectable (although at very low levels).

A growing body of evidence supports that many different types of cell-free circulating mRNAs (housekeeping genes such as β -actin, 18S, β -GUS, or glyceraldehydephosphate dehydrogenase (GAPDH) [3, 9, 10, 35, 44, 45, 56, 72], various types of cytokeratins [10, 12, 55, 56], Her-2 [12], heterogeneous nuclear ribonucleoprotein (hnRNP) [12], thyroglobulin [34], tyrosinase [20, 29, 45], 5T4 [28], mammaglobin [15, 55], carcinoembryonic antigen (CEA) [56], protein gene product (PGP) 9.5 [12], prostate-specific membrane antigen [5], Epstein-Barr virus [36], and β -catenin [72]) may be detected in patients with a variety of malignancies, including breast [3, 15, 28, 45, 55], colon-rectum [9, 35, 56, 72], liver [39, 44], nasopharynx [36], esophagus [10], thyroid [34, 45], prostate [5] and lung [12, 28] carcinoma, malignant melanoma [10, 20, 29, 45], and follicular lymphoma [9]. Although hTERT mRNA has been already considered as a potential marker for malignant melanoma [45], follicular lymphoma [9], and breast [3, 45], colon-rectum [9, 35] and liver [38, 39] carcinoma, to the best of our knowledge, this is the first investigation on its detectability in the plasma of NSCLC patients. Highly

sensitive real-time PCR assays have previously been used to identify hTERT mRNA in lymphoma, colorectal cancer, and hepatocellular carcinoma patients [9, 35, 38], β -catenin mRNA in colorectal cancer and adenoma patients [72], cytokeratins 19 and 20 mRNAs in esophageal carcinoma [10], thyroglobulin mRNA in thyroid carcinoma [34], prostate-specific membrane antigen mRNA in prostate carcinoma [5], and glyceraldehyde-3-phosphate dehydrogenase (GADPH) mRNA in hepatocellular carcinoma [44]. In NSCLC patients, however, this assay has not been used thus far.

We document that plasma β -actin plasma mRNA may be detected in most (67%) patients and healthy nonsmoker individuals (60%) in keeping with previous data reporting the detection of other plasma mRNAs such as GAPDH or 18S in both patients and controls [10, 44, 45]. Cell-free hTERT plasma mRNA was detectable in only 12% of NSCLC patients, at variance with a much higher prevalence (59%) in patients with malignant melanoma [45], follicular lymphoma (100%) [9], and breast (25–48%) [3, 45], thyroid (100%) [45], liver (90%) [38, 39], and colon-rectum carcinoma (82%) [35]. El-Hefnawy et al. [10], however, failed to reproducibly detect several types of cancer-related plasma mRNAs in patients with advanced malignant melanoma or esophageal carcinoma. The detection rate of hTERT mRNA in the plasma might depend on the tumor type, the methods used, or the levels of telomerase activity in tumor cells. In fact, a lower capacity of NSCLC cells to shed mRNA into the bloodstream or a selective degradation of hTERT mRNA to avoid telomerase reactivation by horizontal transfer to permissive cells—as suggested for DNA-containing apoptotic bodies [16, 26]—might be potential mechanisms accounting for these discrepancies. Assessing telomerase activity by Telomerase Repeat Amplification Protocol (TRAP) assay by means of the “*TeloTAGGGG*-Telomerase PCR Elisa^{PLUS} kit” (Roche Diagnostic, Mannheim, Germany) according to manufacturer's instructions, we found that only two (60 and 58) of the four patients with cell-free circulating hTERT mRNA were TRAP-positive, without any correlation between enzymatic activity in primary tumors and the corresponding normalized hTERT threshold ratio for circulating mRNA (data not shown). Moreover, there is no relationship between plasma levels of hTERT mRNA and tumor characteristics such as stage, grade, size, intratumoral necrosis, lympho-vascular invasion, lymphocytic infiltration, and proliferative fraction in a similar manner as for cell-free circulating DNA [57] in the same type of tumor.

RNA protection in the blood may be provided by inclusion into lipoproteic complexes or phospholipids [10, 44, 63], either actively secreted by tumor cells *in vivo*, as the shedding of viral particles [53, 69], or released during programmed cell death possibly as apoptotic bodies [10, 17, 21]. The disappearance of mRNA in positive plasma samples after passing them through 0.2 μ m-, but not 0.4- μ m, filters (data not shown) supports that circulating RNA is likely to be particle-associated and partially protected in NSCLC as in other tumor types [10, 44].

Use of plasma instead of serum samples helps to avoid nucleic acid contamination by leukocytes [33] or platelets [10] during clotting. Moreover, to obtain reproducible results, we assayed 3 ml of plasma and set up a 20-cycle preamplification as previously advised by others [10] because either single-round RT-PCR or real-time PCR alone did not allow a consistent detection of plasma hTERT mRNA. Another critical point of PCR assay for circulating mRNA is the proper design of primers spanning exon junctions [10, 30] to improve specificity also in the phase of RT-PCR-based preamplification in keeping with others [10]. Conversely, other authors have chosen intraexon primers for plasma hTERT detection and added a DNase I treatment to assure specificity [9, 35]. This, however, does not eliminate completely the risk of cDNA amplification when considering the very high sensitivity of real-time PCR. Moreover, in keeping with other studies [3, 10], the spectrophotometric measurement of RNA was not feasible in our tumor series due to the low yield of extracted nucleic acids, raising some concerns on the findings obtained in other tumoral settings [9, 35].

We expressed our quantitative results of plasma hTERT mRNA by means of the normalized ratio between the input amount value of hTERT and that of β -actin within each case, although our final result could be in part affected by the inherent efficiency of the RT-PCR-based preamplification protocols (practically, lower than 100%). The numerical thresholds obtained in the four patients positive for plasma hTERT mRNA, however, documented the excess of this mRNA in tumor samples in comparison with a population of healthy volunteers.

Our results show that tumor-related hTERT mRNA can be detected in a subset of NSCLC patients, and it may be added to the panel of genetic plasma markers for lung cancer detection [1, 57–59], although it should be pointed out that this is only a tumor-related marker and not specific for lung cancer. Further studies addressing the entire profile of plasmatic mRNA molecules and case-control studies, including the analysis of high-risk heavy smokers, are clearly warranted to evaluate the potential of assaying cell-free circulating mRNA for early diagnosis or follow-up.

Relationship and prognostic significance of phospho-(serine 166)-murine double minute 2 and Akt activation in node-negative breast cancer with regard to p53 expression

Received: 10 May 2005 / Accepted: 1 September 2005 / Published online: 6 October 2005
© Springer-Verlag 2005

Abstract The Akt signalling pathway plays a central role in tumorigenesis. Activation of Akt is related to a more aggressive phenotype in various human cancers, including breast cancer. Its activation contributes to cancer progression via pleiotropic effects, including suppression of apoptosis and modulation of cell cycle regulation. Murine double minute 2 (MDM2) is an oncoprotein that inhibits the function of p53 tumour suppressor protein. Cell culture studies show that Akt-related phosphorylation of MDM2 at serine 166 allows MDM2 to gain nuclear entry and fulfil its p53 regulating function. This study was designed to analyse the relationship of phospho-MDM2 (pMDM2) expression with Akt activation to determine a possible prognostic relevance of pMDM2 in node-negative breast cancer with respect to Akt activation and p53 status. pMDM2, phospho-Akt (pAkt) and p53 protein expression status were analysed immunohistochemically in 121 paraffin-embedded breast cancer cases. Expression of pMDM2 cor-

related with Akt activation ($P < 0.001$). Univariate analysis identified pMDM2 as a prognostic factor ($P = 0.0458$) in node-negative breast cancers. The unfavourable prognostic significance was even more pronounced in tumours with a pMDM2⁺/pAkt⁺ immunophenotype ($P = 0.0205$). Stratification into a p53-negative subgroup further strengthened the adverse prognostic influence. These data confirm that MDM2 phosphorylation at serine 166 is mediated by Akt kinase. Besides the prognostic impact of pMDM2, our findings suggest that Akt-mediated modulation of the MDM2/p53 complex contributes to increased tumour aggressiveness especially in p53-negative breast cancers. However, due to the relatively small number of patients in this cohort, the results obtained need to be confirmed by larger cohorts.

Introduction

The murine double minute 2 (*MDM2*) gene was originally identified in a transformed tumorigenic 3T3 fibroblast cell line [3]. *MDM2* gene amplification and overexpression of its product have been described in several types of malignancies in humans [5, 16, 18]. P53 and MDM2 participate in a complex autoregulatory feedback loop, in which p53 stimulates *MDM2* expression, and MDM2 protein inhibits the activity of p53 by blocking p53 transcription [20]. Moreover, recent data show that the MDM2 oncoprotein forms a tight complex with wild-type p53 tumour suppressor gene protein, thereby conferring both its degradation and inactivation [11, 14]. Due to its inhibitory effect on p53, MDM2 protein overexpression was shown to be associated with uncontrolled cell proliferation [15].

Growth-factor-mediated activation of the PI3K/PKB (Akt) pathway is a key element of cellular survival and proliferation. Activation of Akt signalling is thought to stabilise MDM2 protein, thereby inhibiting p53-dependent apoptosis [9, 10, 19, 24, 30]. The Akt kinase and its significance in human malignomas, including breast can-

cer, has been the topic of recent research activities. A few studies have examined the potential prognostic value of the Akt kinase in breast cancer with varying results [22, 23]. We recently observed that activation of the Akt kinase is significantly associated with a reduced overall disease-specific survival [26]. Downstream signalling of activated Akt kinase contributes to tumour aggressiveness via several mechanisms, including regulation of apoptosis [4, 6], cell growth [2] and cell cycle control [27, 31]. Besides the well-known consequences of Akt activation, other effectors such as the oncoprotein MDM2 and the p53 tumour suppressor protein have been implicated in Akt-induced tumour survival [10].

Thus, the aim of the present study was to analyse a possible cross talk between pAkt, pMDM2 and p53 in node-negative breast cancer and to determine the prognostic value of phosphorylated MDM2 expression. In an immunohistochemical approach with phospho-specific antibodies, the MDM2 (serine 166) and Akt (serine 473) protein expressions were examined in 121 surgically resected node-negative breast cancer specimens. These results were compared with a broad range of clinicopathological parameters as well as the immunohistochemically determined p53 status of the present series with a mean follow up period of 7.7 years.

Material and methods

Patients

This study comprised 121 female breast cancer patients (mean age 61 years) operated at the Clinic of Gynaecology (University of Essen-Duisburg, Germany) between 1989 and 1996 who underwent surgery and further adjuvant therapy. Clinical records and follow-up information (overall survival) were available in all cases. Only patients without lymph node metastasis were included in the study. The negative lymph node status was confirmed histologically after standard axillary dissection. All surgical material was fixed in 4% formalin and routinely processed. The tumours were classified according to the pathological tumor-node-metastasis (pTNM) system (6th edition) and graded according to Elston and Ellis [8]. During follow-up, 21 out of 121 patients died. Eighteen patients died from breast cancer; the three remaining patients died from either benign (two patients) or concurrent cancer disease (one patient) and were thus excluded from survival analysis. Statistical analysis was based on a mean follow-up period of 7.7 years.

Immunohistochemistry

In the present study, polyclonal rabbit-anti-human phospho-MDM2 (serine 166) antibodies (Cell Signalling Technology, Beverly, MA, USA; 1:25), monoclonal anti-

human-p53 antibodies (directed against both wild-type and mutated-type p53 protein, Biogenex, San Ramon, CA, USA; clone D07, ready-to-use antibody), monoclonal anti-human-p53 antibodies (directed against mutant-type p53 protein, DakoCytomation, Carpinteria, CA, USA; clone PAb240, 1:25) and polyclonal rabbit-anti-human phospho-Akt (serine 473) antibodies (Santa Cruz Biotechnology, CA, USA; 1:2,000) were used. The mutant-type p53 antibodies (clone PAb240) react with the PAb240 epitope, which is inaccessible to binding by PAb240 in its wild-type or native configuration but is exposed on mutant forms of p53 with altered protein conformation [28]. The alkaline phosphatase anti-alkaline phosphatase (APAAP) method was used for antibody demonstration on 5- μ m-thick paraffin sections. Following a high-temperature antigen unmasking technique, pAkt and pMDM2 were incubated overnight in a humidified chamber at 4°C. Immunostaining of p53 (clone D07) was performed after high-temperature antigen retrieval. Slides were incubated with the primary antibody for 45 min at 37°C. The ready-to-use PowerVision Kit (Immunologic, Duiven, The Netherlands) was used for antibody demonstration. Immunostaining of p53 (clone PAb240) was carried out with an automated staining device (DAKO Autostainer). After antigen retrieval the primary antibody was incubated for 30 min at 1:25 dilution; antibody demonstration was achieved using a commercially available anti-mouse immunoglobulin (Ig)G detection kit (EnVision, DakoCytomation). Positive controls were included in each staining series. Mouse Ig, replacing the primary antibody, was used as negative controls.

For the demonstration of a possible colocalization of pMDM2 and pAkt, immunofluorescence double labelling was performed. After antigen retrieval the slides were first incubated with the antibodies directed against pAkt (1:100). Antibody detection was performed with a fluorescein-isothiocyanate (FITC)-conjugated antibody [donkey-anti-rabbit (anti-Fab) antibody, Dianova, Hamburg, Germany; 1:50]. Due to the utilization of two primary rabbit-anti-human antibodies, the remaining epitopes of the host species of the primary polyclonal pAkt-antibody were covered by unconjugated anti-Fab antibodies. Afterwards, the slides were incubated with the pMDM2-antibody for 1 h at room temperature. Subsequently, a secondary biotinylated anti-F(ab')₂ antibody (donkey-anti-rabbit, Dianova; 1:4,000) was applied, and detection was achieved with the fluorescent streptavidin-indocarbocyanin (Cy3) complex. Finally, the sections were counterstained with 4c6-diamidino-2-phenylindole-2HCl (DAPI) solution (Sigma, Taufkirchen, Germany; 1:50,000). Mouse Ig, replacing the primary antibody, was used as negative controls. Fluorescence microscopy was carried out with an Axioplan microscope (Zeiss, Germany) by using the appropriate filter system. Photographs were digitally processed with the AxioVision Software (Zeiss).

The oestrogen receptor (ER) status was determined using an anti-human ER alpha antibody (clone 1D5, DAKO, Glostrup, Denmark) as described earlier [26].

Mitotic count

Mitotic count (MC) was carried out taking into consideration the actual area of ten high-power fields (HPFs) of the Nikon Eclipse E600 microscope. MC results were grouped as 0–8, 9–17 and more than 17 mitotic figures per HPF (field diameter 0.55 mm) [7].

Statistical analysis

Phospho-MDM2 and phospho-Akt immunostainings were assessed by two of the authors (K.J.S. and F.G.) in a blind-trial fashion without knowledge of the clinical outcome. The mean percentage of both counts was used for statistical analysis. All data were converted to a PC and statistically analysed using SPSS version 12 for Windows (SPSS Inc., Chicago, IL, USA). Relationships between ordinal parameters were investigated using two-tailed χ^2 analysis. Differences between the mean values of pMDM2 and pAkt percentages of the various tumour types were compared with the one-way analysis of variance (ANOVA) test. Overall survival (OS) curves were estimated using the Kaplan–Meier method, and any differences in the survival curves were compared by the log-rank test. For multivariate analysis, the Cox regression model was used. Overall, 95% confidence intervals were used throughout.

Results

Immunohistochemical analysis of phospho-MDM2 (serine 166)

In tumour cells phospho-MDM2 immunostaining was exclusively located to nuclei without any detectable cytoplasmic staining. Normal breast tissue showed scattered, mostly weak to moderately positive nuclei. The percentage of pMDM2-positive tumour cell nuclei ranged from 4 to 88%, with a mean value of 62%. Tumours with percentage values lower than the mean value were classified as “low pMDM2 staining status”, and the remainder were classified as “high pMDM2 staining status”. χ^2 analysis revealed significant differences of pMDM2 staining status among the various tumour types investigated ($P=0.019$), with invasive ductal carcinomas showing significantly higher amounts of positive stained nuclei than invasive lobular ($P=0.042$) and mucinous carcinomas ($P<0.001$). In comparison to all other tumour types, mucinous carcinomas revealed lower amounts of positive stained tumour cells ($P<0.005$). Tumours with higher amounts of pMDM2-positive cells exhibited significantly higher mitotic rates ($P=0.046$). χ^2 analysis revealed no statistically significant differences among cases with different histological grading. The results are summarised in Table 1. Representative immunohistochemical stainings are shown in Fig. 1.

Table 1 Clinico-pathological data and phospho-MDM2 (serine 166) expression of 121 node-negative breast cancers

	Phospho-MDM2 (serine 166) expression status ($N=121$)		<i>P</i> value*
	Low, <i>n</i> (%)	High, <i>n</i> (%)	
Total adenocarcinoma	50 (41.3)	71 (58.7)	
Tumour type			$P=0.019$
Invasive ductal	29 (33)	59 (67)	
Invasive lobular	14 (66.7)	7 (33.3)	
Mucinous	4 (80)	1 (20)	
Tubulo/tubulo-lobular	1 (50)	1 (50)	
Others	2 (40)	3 (60)	
Mitotic count			$P=0.046$

**P* value of χ^2 analysis

Immunohistochemical analysis of phospho-Akt

Immunostaining for pAkt was predominantly localized to tumour nuclei. A faint cytoplasmic, but specific, pAkt staining was only occasionally noticed but was disregarded for the calculation of immunohistochemical scores. The number of positive immunoreactive tumour nuclei was counted within 300 cells in the invasive tumour front, as tumour aggressiveness is considered to be highest here. The result was expressed as percentage. The percentage of pAkt-positive tumour cell nuclei ranged from 5 to 83% (mean 61.8%). In accordance with our previous study [25], tumours were separated into two groups, with 45% as the cut-off value for pAkt overexpression. Phospho-pAkt-positive tumours showed a statistically very highly significant association with a high pMDM2 staining status ($P=0.003$; χ^2 analysis) but not with the MC, p53 or ER status. In comparison to all other tumour types, mucinous carcinomas revealed lower amounts of positive stained tumour cells ($P<0.05$).

Immunohistochemical analysis of p53 protein expression

p53 immunostaining for both antibodies was restricted to tumour nuclei. Tumour-adjacent normal breast tissue com-

Fig. 1 Representative immunohistochemical stainings of serial sections of two tumours for phospho-Akt and phospho-MDM2. Tumours with few phospho-MDM2 stained tumour cells (A1) revealed more frequently a scattered nuclear phospho-Akt staining (B1), whereas tumours showing abundant phospho-Akt stained tumour cells exhibited in many cases a high percentage of strongly nuclear phospho-MDM2 stained tumour nuclei. Original magnification, $\times 400$

pletely lacked p53 immunoreactivity. In invasive carcinoma p53 staining was scored as follows: no immunoreactivity or positive staining in less than 10% of tumour cells (-) and positive staining in more than 10% of tumour cells (+). Of all the tumours, 18.2% were classified as p53-positive using the p53 clone D07 antibody, and 6.9% were classified using the clone PAb240 antibody.

Six out of seven cases classified as p53-positive with the mutated-type antibody (clone PAb240) have also been classified as positive with the p53 antibody D07. Tumours classified as p53-positive (clone D07) showed a statistically significant association, with a lower differentiation grade and higher MC ($P < 0.001$). No further relationship

Fig. 2 Double immunofluorescence staining for phospho-Akt (serine 473) (green signal) and phospho-MDM2 (serine 166) (red signal) in a randomly chosen node-negative breast carcinoma. **A** Immunolabelling for phospho-Akt exhibits several stained tumour nuclei (green signal). **B** Immunolabelling for phospho-MDM2 (serine 166) shows scattered strongly stained tumour nuclei (red signal). Notice several tumour nuclei stained for both phospho-Akt and phospho-MDM2 (asterisk). **C** Counterstaining with DAPI so-

lution marks all cell nuclei irrespective of immunolabelling. **D** The digital overlay of phospho-Akt and phospho-MDM2 fluorescence indicates colocalization in several yellow stained tumour nuclei. Other tumour nuclei lack both phospho-Akt and phospho-MDM2 immunostaining. The colocalization of phospho-MDM2 and phospho-Akt in the same tumour cell supports our hypothesis that activation of the Akt signalling pathway is associated with increased MDM2 phosphorylation ($\times 1,000$)

between p53 immunophenotype and pathological parameters was observed.

Correlations among pMDM2 expression, pAkt expression, p53 protein accumulation and ER status

Statistical analysis (regression analysis) revealed a significant direct correlation of the pMDM2 and pAkt staining scores ($P < 0.001$). No correlation was observed between pMDM2 status, ER status or p53 immunophenotype—p53 protein expression lacked correlation with both pAkt and the ER status.

Double immunofluorescence

Double immunofluorescence staining of randomly selected tumour samples with markers for pAkt (green signal) and pMDM2 (red signal) showed a colocalization of both phosphorylated proteins in tumour-cell nuclei (Fig. 2).

Prognosis

Only four out of 50 (8%) patients with a tumour showing low pMDM2 staining status died from breast cancer. However, 14 out of 68 (20.6%) patients classified as high pMDM2 staining status died from breast cancer. Overall survival was inversely associated with a low pMDM2 staining. To explore in more detail the relative prognostic

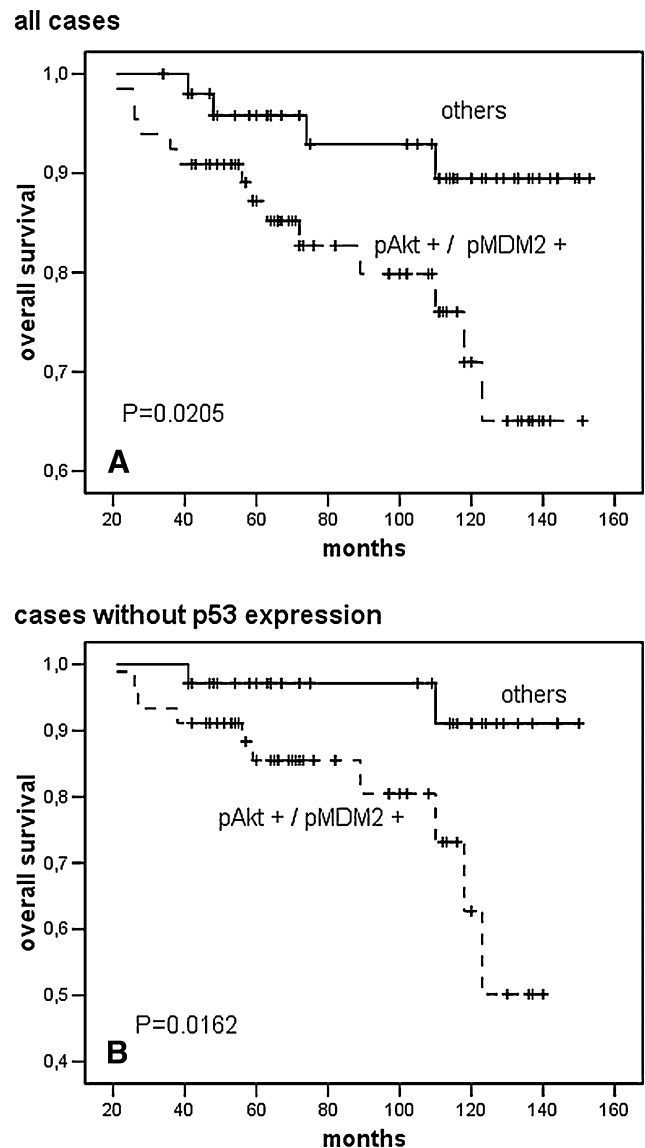

Fig. 4 Kaplan–Meier survival curves for disease-specific overall survival with respect to combined pMDM2/pAkt immunophenotype in the subgroups of **A** all cases and **B** cases without p53 expression of both p53 antibodies

Table 2 Results of multivariate analysis (Cox regression) to determine the independent prognostic value of different variables in relation to overall survival

Covariate	Relative risk (e^{β})	95% CI	<i>P</i> value
pAkt/pMDM2 (+/+ vs +/-, -/+, -/-)	2.362	0.758–7.359	0.138
Histological grade (1, 2, 3)	3.665	1.197–11.215	0.023 ^a
Oestrogen receptor status, negative vs positive	0.572	0.187–1.751	0.328
Mitotic count, 0–8 vs 9–21 vs >16	0.676	0.286–1.601	0.374

^aStatistically significant

contribution of pAkt, we divided the cases into the following categories: (1) pMDM2 low (–) vs high (+) staining and (2) combined pMDM2/pAkt immunophenotype. Using p53 negativity for both antibodies as stratification parameter in the Kaplan–Meier analysis, a high pMDM2 staining status (concerning the complete series) was statistically significantly associated with a reduced disease-specific OS ($P=0.0458$; Fig. 3A). The unfavourable prognostic effect of tumours with a high pMDM2 staining status increased in the p53-negative subgroup ($P=0.0276$; Fig. 3B).

The combined pMDM2/pAkt immunophenotype revealed an additional significant influence on disease-specific OS ($P=0.0205$; Fig. 4A) showing the worst clinical outcome for pMDM2⁺/pAkt⁺ tumours. The unfavourable prognostic effect of pMDM2⁺/pAkt⁺ tumours again increased in the p53-negative subgroup ($P=0.0162$; Fig. 4B).

Parallel analysis reveal that histological grading ($P=0.0010$), MC ($P=0.0464$) and a negative ER status ($P=0.0179$) were significantly related to a decreased OS, whereas p53 protein expression was not associated with prognosis. Disease-specific OS and the relevant clinicopathological parameters (histological grading, ER status, MC and pAkt/pMDM2 combined phenotype) were subject to multivariate analysis; only histological grading was statistically associated with disease-specific OS (Cox regression analysis, $P=0.023$) (Table 2).

Discussion

Particularly in patients with node-negative breast cancer, novel markers defining node-negative high-risk patients, who would benefit from adjuvant therapy, would be desirable. This study was designed to investigate the cross talk of phospho-MDM2, phospho-Akt and p53 in node-negative breast cancer. In addition the prognostic relevance of the post-translational modified MDM2 (phosphorylation at serine 166) as well as its combination with pAkt was assessed.

MDM2 is an oncoprotein inhibiting the function of p53 tumour suppressor protein. Its accumulation in neoplastic

cells is due to gene amplification, enhanced transcription/translation or post-translational modification, but apparently, only the latter two mechanisms seem to be of relevance in breast cancer [21]. Recent in vitro data suggest that Akt-dependent phosphorylation of MDM2 at serine 166 leads to an increase in MDM2 stability by protecting it from proteasome-dependent degradation, with the consequence of p53 down-regulation [9, 10].

Our results indicate a significant direct correlation between pMDM2 expression and Akt activation, supporting the concept that activation of the Akt signalling pathway is associated with increased MDM2 phosphorylation. The demonstration of pAkt and pMDM2 colocalization in double immunofluorescence staining argues in favour for this hypothesis. Furthermore, our data are in accordance with recently published observations describing a coincidence of low MDM2 expression and decreased Akt activation in human non-small-cell lung cancers [29].

To the best of our knowledge there are only three MDM2 studies in breast cancer published in the literature; however, these studies arrived at contradictory data concerning the prognostic relevance of MDM2 protein expression [1, 12, 13]. These conflicting results could be due to the complex autoregulatory feedback loop between these two proteins that interact both on the protein level and on the level of gene transcription [21]. Interpretation of MDM2 protein expression in tumours is limited by several parameters, e.g. complexity of the underlying p53–MDM2 interaction, multiplicity of protein isoforms and modifications, the absence of a standard expression definition for overexpression and lack of distinction between cytoplasmic and nuclear staining.

The present study is the first to examine the prognostic value of the phosphorylated MDM2 protein in node-negative breast cancer. Since previous studies using antibodies against the non-phosphorylated MDM2 reveal contradictory results, the investigation of the phosphorylated MDM2 oncoprotein may help to clarify the role of MDM2. Additionally, the utilized phospho-specific antibody detects phosphorylation at serine 166 via Akt kinase and, thus, offers the chance to semi-quantify the modified MDM2 oncoprotein in its presumed p53 regulating status. In contrast to both cytoplasmic and nuclear staining of the non-phosphorylated MDM2 immunohistochemistry observed in other studies [21], the phospho-specific antibody used in our present study was shown to exclusively stain tumour cell nuclei, enabling a simple and reproducible interpretation of pMDM2 staining results. The finding of a constant nuclear pMDM2 staining is in accordance with recent data describing an Akt-promoted nuclear translocation of MDM2 from the cytoplasm to the nucleus [17].

Concerning survival, univariate analysis showed a significant correlation of pMDM2 overexpression with an unfavourable prognosis. The adverse prognostic effect increased in tumours with a combined pMDM2⁺/pAkt⁺ immunophenotype. However, multivariate analysis failed to prove its independent prognostic value. Since Akt-mediated phosphorylation of MDM2 promotes degradation and inactivation of p53, particularly wild-type p53, an additional survival analysis with a restriction to cases

lacking p53 expression was performed. It is interesting to see that the level of significance in both the pMDM2-positive and the combined pAkt⁺/pMDM2⁺ subgroups increased, suggesting that the functional inactivation of p53 via Akt-related MDM2 phosphorylation might be more effective in breast cancer lacking a p53 overexpression or mutation. We are, of course, aware that an immunohistochemical approach is ultimately not the gold standard to identify tumours with wild-type p53, but the determination of the p53 genotype was beyond the scope of this study.

In conclusion, this study demonstrates that phosphorylation of MDM2 at serine 166 seems to be induced by the Akt(PKB) kinase not only (as recent data suggested) *in vitro* but also *in vivo*. The findings put additional emphasis on the role of Akt-mediated MDM2 phosphorylation as a negative regulator of p53-dependent growth control and illuminates the diversity of biological effects of activated Akt/PKB signalling in breast cancer. Besides the well-known relevance of this serine–threonine kinase in inhibiting cell death via modification of proapoptotic proteins such as Bad, Forkhead transcription factor and caspase 9 [4, 6], the Akt kinase may promote cell survival by influencing the p53–MDM2 loop. This could at least partly explain the poor clinical outcome of breast cancer patients with Akt activation as previously described in a paper [26]. Since Akt-induced MDM2 phosphorylation results in the functional inactivation of primarily wild-type p53, it is tempting to speculate that this mechanism represents one of the various signalling events leading to increased tumour aggressiveness in breast cancers lacking p53 mutations but exhibiting Akt activation. The statistical power of this study is, unfortunately, reduced due to the relatively small number of participating patients and heterogeneity of tumours. Therefore, it is necessary to confirm these promising results in larger cohorts.

Renal artery changes in patients with primary renal cell carcinoma

Received: 26 February 2005 / Accepted: 1 September 2005 / Published online: 28 September 2005
© Springer-Verlag 2005

Abstract Arterial fibromuscular dysplasia (FMD) is a noninflammatory, nonatherosclerotic, occlusive condition of the systemic arteries, most frequently affecting renal arteries. Renal cell carcinoma (RCC) might be associated with arterial hypertension; however, there are no data in the literature regarding the relationship between RCC and associated renal artery changes. We analyzed a consecutive series of 57 (35 male and 22 female) patients aging from 35 to 79 years (mean 58.9 years) who underwent nephrectomy due to RCC in the year 2003. The patients had RCC measuring from 2 to 16 cm (mean 7.1 cm). Specimens were routinely fixed, embedded in paraffin, cut, and stained with hematoxylin and eosin, Mallory trichrome method, and orcein. Renal arteries of 26 patients (20 male, 6 female) showed no changes. In these patients, RCC measured 2.5–11 cm in largest diameter (mean 6.6 cm). In 24 patients (10 male, 14 female), renal arteries showed FMD. RCCs in these patients measured between 2 and 16 cm (mean 8.0 cm). Seven patients had atherosclerotic changes in renal arteries. In this series, FMD was found in a significant

proportion of patients with RCC, mainly in women. The cause of such changes and their relationship with RCC and systemic hypertension should be further analyzed.

Keywords Fibromuscular dysplasia · Renal cell carcinoma · Renal arteries

Introduction

The renal arteries arise from the abdominal aorta at the level of L2, and the right renal artery is longer than the left one. Different lesions may involve main renal artery including atherosclerosis, fibromuscular dysplasia, and some other conditions, such as Takayasu arteritis, radiation injury, and congenital malformations [11].

Arterial fibromuscular dysplasia (FMD) is a noninflammatory, nonatherosclerotic, occlusive condition of systemic arteries, the renal arteries being most frequently affected. Major clinical conditions associated with FMD are hypertension, stroke, claudication, and intestinal ischemia [7]. FMD of renal arteries is bilateral in nearly half of patients, more commonly on the right side (3:1), is usually diagnosed in the fourth decade, with female predominance, and most frequently involving the distal two thirds of the renal artery and its branches [11, 12]. Incidence of the FMD found at autopsy study is about 1% [4, 8].

There are three principal pathologic types of FMD: intimal, medial, and adventitial fibromuscular dysplasia. Primary intimal fibroplasia (type I) is a rare condition that occurs in children and young adults, comprising about 2 to 5% of all FMD lesions [3, 9, 14, 15], and sometimes it can be difficult to distinguish this type of FMD from nonspecific fibrosis as seen in atherosclerosis [9]. This type can be connected with progressive renal artery obstruction and ischemic atrophy of the kidney [3]. Medial fibromuscular dysplasia (type II) can be further subdivided into three subtypes: medial “muscular” hyperplasia (type IIa), medial fibroplasia with aneurysms (type IIb), and perimedial fibroplasias (type IIc), of which medial fibroplasia is the most common type of FMD (about 70%). The lesion

usually affects women aging 25 to 50 years, with bilateral involvement in about 60% [3, 9]. Adventitial fibroplasia (type III) is very rare and represents less than 1% of all FMDs [3].

Atherosclerosis is a generalized progressive arterial disease associated with localized arterial occlusions and aneurysms [11]. It accounts for 90% of the cases of renal artery stenosis and usually involves the ostium and proximal third of the main renal artery and perirenal aorta [12].

Renal cell carcinoma (RCC) represents 2% of all human malignancies and over 90% of all malignancies of the kidney. It is two to three times more common in men than in women, and the average age at diagnosis is 55 to 60 years [2, 11]. History of blood hypertension, obesity, and tobacco smoking increases the risk of RCC [1, 11].

The aim of this study was to analyze renal artery changes in patients with renal cell carcinoma.

Materials and methods

A consecutive series of 74 patients aging from 35 to 79 years with RCC who underwent nephrectomy in the year 2003 (44 male and 30 female) was analyzed. Seventeen patients (nine male and eight female) were excluded from the study because five of them had only partial nephrectomy; two were sent for consultation from other hospitals (without renal arteries); in four cases, renal arteries were tangentially cut; and in six specimens, renal arteries were not sampled. Finally, the study group consisted of 57 patients. All relevant patients' data including age, sex,

tumor grade and size, the extent of tumor necrosis, blood pressure, and vena cava status were analyzed. There were 35 male and 22 female patients with RCC ranging in age from 35 to 79 years (mean 58.9 years). The size of RCC was from 2 to 16 cm (mean 7.1 cm). Renal artery and vein as well as ureter margin were routinely analyzed. Specimens were routinely fixed in 10% buffered formaldehyde, embedded in paraffin, cut, and stained with hematoxylin and eosin, Mallory trichrome method, and orcein, and examined by light microscopy. Immunohistochemistry was performed by Microwave Streptavidine Immunoperoxidase protocol (MSIP) in DAKO TechMate Horizon automated immunostainer. We used primary antibodies to smooth muscle actin (SMA) that were purchased from DAKO, Copenhagen, Denmark. Dilution of the antibody was "ready to use." Nuclear grade of RCC was determined according to Fuhrmann et al. [4].

Statistical analysis used in this study included *F* test, *T* test/Cochran–Cox method, and χ^2 test. Level of significance was set at $p < 0.05$.

The classification of FMD included pathologic processes of intimal, medial, and adventitial fibroplasia [3, 9, 15].

Results

Renal arteries of 26 patients (20 male and 6 female) ranging in age from 38 to 74 years (mean 58.6 years) showed no changes. RCC in these patients measured 2.5–11 cm in largest diameter (mean 6.6 cm). In 24 patients (10 male, 14 female) aging from 35 to 79 years (mean 60.0 years), renal

Table 1 Clinicopathologic features of 57 patients with renal cell carcinoma with regard to renal artery status

	Group I	Group II	Group III
Male	20	10	5
Female	6	14	2
Age	38–74 years (mean 58.6)	35–79 years (mean 60.0)	60–69 years (mean 62.0)
Tumor size	2.5–11 cm (mean 6.6)	2–16 cm (mean 8)	2.5–14 cm (mean 6.4)
Tumor necrosis	Less than 50%, 21 More than 50%, 5	Less than 50%, 19 More than 50%, 5	Less than 50%, 6 More than 50%, 1
Blood pressure	110/70–160/100 mmHg (mean 125/84.5)	110/80–200/100 mmHg (mean 138.5/86)	115/70–145/85 mmHg (mean 134/79)
Cell type of RCC	Clear cell, 10; chromophilic eosinophilic, 5; mixed (clear and eosinophilic), 7; mixed with sarcomatoid component, 3; chromophobe, 1	Clear cell, 8; chromophilic eosinophilic, 3; mixed (clear and eosinophilic), 8; mixed with sarcomatoid component, 5	Clear cell, 5; chromophilic eosinophilic, 1; mixed with sarcomatoid component, 1
Nuclear grade	G1, 3 G2, 7 G3, 10 G4, 6	G1, 0 G2, 8 G3, 9 G4, 7	G1, 1 G2, 6 G3, 0 G4, 0

Group I, without artery changes; group II, FMD; Group III, atherosclerosis

arteries showed FMD (Fig. 1), and RCC in these patients were between 2 and 16 cm (mean 8 cm), while 7 patients (5 male and 2 female) aging 60–69 years (mean 62.0 years) had atherosclerotic changes in renal arteries. Tumor size in this group was 2.5–14 cm (mean 6.4 cm). In the first group (cases without renal artery changes), there were three patients with tumorous infiltration of the renal vein. The same number of cases with renal vein infiltration was found in the second group (fibromuscular changes of renal arteries), while only one patient from the third group who had atherosclerotic changes of renal arteries had tumorous infiltration of renal vein. Blood pressure in patients from the first group was from 100/70 to 160/100 mmHg (mean 125/84.5 mmHg), in the second group 110/80 to 200/100 mmHg (mean 138.5/86 mmHg), and in the third group

115/70 to 145/85 mmHg (mean 134/79 mmHg). There were no data about the blood pressure for 14 (24.6%) patients. Four patients with no renal artery changes and five patients from the second group (FMD) were receiving antihypertensive therapy. Necrosis was observed in 45 of 57 tumors (78.9%). There was no statistically significant correlation between the presence ($p=0.750$) and type ($p=0.052$) of FMD and the extent of the necrosis in RCCs. Tumors with type I of FMD 3/7 (42.9%) showed more than 50% necrosis, while only 1/15 (6.7%) tumors with FMD type IIb had the same extent of necrosis. One of two cases with FMD type IIa showed necrosis in more than 50% of tumor mass.

Clinicopathologic features of patients with renal cell carcinoma are shown in Tables 1 and 2.

Table 2 Clinicopathologic features of 57 patients with RCC regarding three different types of FMD

	Type I	Type IIa	Type IIb
Male	3	0	7
Female	4	2	8
Age	52–74 years (mean 62)	35–66 years (mean 50)	36–79 years (mean 60.5)
Tumor size	2–14 cm (mean 7.4)	6–12 cm (mean 9.0)	3–16 cm (mean 8.0)
Blood pressure	120/70–200/100 mmHg (mean 150/90)	120/80–140/95 mmHg (mean 130/87.5)	110/80–175/95 mmHg (mean 136.3/84.2)
Nuclear grade	Predominantly G3	Predominantly G2	Equally G2, 3, and 4
Cell type of RCC	Clear cell, 2; chromophilic eosinophilic, 1; mixed (clear and eosinophilic), 3; mixed with sarcomatoid component, 1	Chromophilic eosinophilic, 2	Clear cell, 6; chromophilic eosinophilic, 1; mixed (clear and eosinophilic), 3; mixed with sarcomatoid component, 5
Tumor necrosis	Less than 50%, 4 More than 50%, 3	Less than 50%, 1 More than 50%, 1	Less than 50%, 14 More than 50%, 1

Type I, intimal; type IIa, medial muscular; type IIb, medial fibromuscular

Statistical analysis showed no significant difference in the age ($p=0.486$), tumor size ($p=0.112$), and mean systolic ($p=0.918$) and diastolic ($p=0.448$) blood pressure between the first and the second group of patients. However, FMD was found significantly more often in female patients ($p=0.009$). Furthermore, there was no statistically significant difference in the age, tumor size, and blood pressure between the first and third group and second and third group of patients. In the group of patients with atherosclerosis and without significant pathomorphologic changes of renal arteries, men were more frequent ($p=0.028$).

Discussion

The incidence of RCC is significantly higher in people with a history of blood hypertension that is not dependent on obesity and tobacco smoking. One of the causes of hypertension is renal artery stenosis due to atherosclerosis in 90% of cases [12].

Fibromuscular dysplasia accounts for less than 10% of cases of renal artery stenosis, the medial type representing about 90% of cases [8, 14].

Atherosclerotic renal artery stenosis is a common and progressive disease; however, it is probable that many atherosclerotic stenoses are never detected because refractory hypertension or renal failure does not develop [12]. In the hypertensive population, high blood pressure may be attributed to renovascular FMD in less than 2% of patients [15]. In patients with renovascular hypertension, FMD is the underlying cause in 20–50% of cases [8]. The etiology of FMD is unknown, although many theories have been advanced, including those involving a genetic predisposition, smoking, hormonal factors, and disorders of vasa vasorum as risk factors [8, 14].

The patients with FMD may be asymptomatic, and the natural history of the disease is relatively benign with progression occurring in only the minority of patients [8].

In our previous study, fibromuscular dysplasia of renal arteries was found in a significant proportion of patients with RCC, mainly in females [7]. These changes might be primary, but also could be the result of some other factors or the effect of the tumor itself.

Hypertension has been implicated as a risk factor for the development of RCC, but quantitative data concerning the levels of blood pressure are limited [1]. A small case-control study based on medical records found that the risk of RCC was higher with higher blood pressure within 5 to 10 years before the diagnosis of RCC. In the study with long-term follow-up, Chow et al. [1] showed that blood pressure was positively related to the risk of RCC. The risk of RCC in men with diastolic pressure of 90 mmHg or more was more than double the risk in men with diastolic pressure below 70 mmHg. Similar data were reported on the relationship and risk for systolic pressure [1, 13].

In our study, renal artery changes were observed in 31 out of 57 patients with RCC. There was no correlation between blood pressure and the presence of FMD.

There are few studies on the relation between RCC and blood pressure that were based on relatively small number of subjects except for the study of Chow et al. [1] on 363,992 Swedish men in whom 759 RCC developed during the 25 years period of follow-up.

Grossly, RCC usually shows large areas of necrosis. Such changes are usually attributed to some abnormalities in tumor vascularization. The data in the literature pointed out to the relationship between the presence and extent of tumor necrosis in RCC and different features including tumor size, cell type, nuclear grade as well as microvessel density and the expression of different markers [6]. However, there are no data about the relationship between fibromuscular dysplasia-like changes and renal cell carcinoma. Onishi et al. [10] reported histological features of hypovascular and avascular RCC; however, the cause of vascular changes was not further analyzed. We observed tumor necrosis in 78.9% of tumors, but there was no statistically significant correlation between the presence and type of FMD and the extent of the necrosis of RCC. However, it seems that a larger study is needed to confirm the relationship between FMD type and tumor necrosis.

On the basis of our results, we may conclude that fibromuscular dysplasia of renal artery occurs in a significant proportion of female patients with renal cell carcinoma, while male patients more frequently had atherosclerosis or no pathomorphologic renal artery changes. However, further studies are needed to elucidate these changes and to determine whether these are primary or represent a consequence of the tumor.

Polymorphous adenocarcinoma of the breast. Report of three cases

Received: 24 May 2005 / Accepted: 28 August 2005 / Published online: 12 October 2005
© Springer-Verlag 2005

Abstract We report three cases of polymorphous adenocarcinoma (PLA) of the breast in 37-, 55- and 74-year-old women, respectively. The patients have no evidence of previous malignancy. The tumours consist of monotonous cells showing a wide spectrum of growth patterns: solid nests, trabeculae, tubules, cribriform structures, strands and fascicles reminiscent of polymorphous low-grade adenocarcinoma of salivary glands. To our knowledge, PLA has never been reported in the breast; therefore, this tumour should be added to the list of neoplastic lesions of the breasts that have the same features as those of the salivary glands.

Introduction

Polymorphous low-grade adenocarcinoma (PLGA) of minor salivary glands is a term given by Evans and Batsakis [8] to a clinicopathological entity of an intraoral malignant tumour, which is also named as terminal duct carcinoma of the oral cavity [13] or as lobular carcinoma of intraoral minor salivary gland origin [12]. These latter authors emphasized similarities between tumours they have described and invasive lobular carcinomas (ILCs) of the breast.

PLGA is virtually exclusive of minor salivary glands of the oral cavity [1, 3]; in rare occasions, it has been reported in the parotid [19] and, in even rarer occasions, in other sites such as the lung [17], skin [24], vulva and vagina [27] and lacrimal glands [22]. The purpose of the present paper is to describe three cases of tumours in the breast with morphology similar to that of PLGA of the salivary glands. To the best of our knowledge, tumours with these features and in such site have not been reported in the literature.

Case report

Patient 1

In 1994, a 37-year-old woman presented with a mass that measured 1.5 cm and was located in the left breast.

The patient had no evidence of previous oropharyngeal primary tumour. She underwent quadrantectomy with axillary lymph node dissection (13 lymph nodes) followed by radiotherapy. On gross examination, the nodule was surrounded by fibrofatty tissue, appeared tan and firm and displayed indistinct borders.

The patient developed liver metastases in early 1997 and died with widespread metastases later in the same year.

Patient 2

A 55-year-old woman presented with a 3.5-cm-diameter firm nodule located in the internal superior quadrant of the

right breast, which was found to be mammographically positive for carcinoma in November 2004. Fine-needle biopsy showed atypical epithelial cells without myoepithelial cell layers that were considered suspicious of carcinoma. The patient underwent quadrantectomy with axillary lymph node dissection (20 lymph nodes) followed by radiotherapy.

When last contacted, the patient was well 6 months after surgery.

Patient 3

In April 2005, a 74-year-old patient presented with a firm nodule in the upper internal quadrant of the left breast. Fine-needle aspiration led to a positive smear for carcinoma. The patient was treated with simple mastectomy together with axillary dissection (11 lymph nodes). The nodule measured 4 cm in its greatest axis, was hard and grey white and had infiltrative margins. There has been no significant follow-up to date.

Fig. 1 *Case 1*: The tumour shows a central core composed of solid nests, while at the periphery, neoplastic cells invade in an Indian-file pattern

Materials and methods

Two cases were retrieved from V.E.'s consult files. Case 3 was encountered among routine cases.

Tissues were fixed in buffered formalin and routinely processed with paraffin. Slides were stained with haematoxylin–eosin; for immunohistochemistry, the ABC method was employed. Source, dilution and antigen retrieval of the antibodies used are listed in Table 1.

Fig. 2 **a** *Case 1*: Solid nests as observed in the centre of the tumour. Neoplastic cells show round, monotonous nuclei. **b** *Case 2*: Solid nests also characterize the tumour centre of this case

Fig. 3 Case 1: **a** Neoplastic cells showing typical “Indian-file” pattern. Round, monotonous nuclei are displayed by neoplastic cells. **b** Cells of a nest showing round, monotonous nuclei

Histology and immunohistochemistry

Patients are described together because their histology and immunohistochemistry are very similar. Microscopically, neoplasms are nonencapsulated and exhibit cells that invade surrounding breast tissues (Fig. 1).

Neoplastic cells show a wide spectrum of growth patterns consisting of solid nests and large areas that are mostly located in the centre of the tumours (Fig. 2a and b), while at periphery trabeculae, occasional tubules and alveolar structures are mostly represented. In some areas, the neoplastic cells show the single-file pattern typical of ILCs (Fig. 3a). Combinations and transitions among all these patterns are frequent. Occasionally entrapped pre-existing ducts, mostly located at the periphery of the tumour, are evident in case 2.

Tumour cells are composed of elements showing moderately variable round to ovoid nuclei with dispersed vesicular chromatin, inconspicuous to small nucleoli and prominent nuclear membrane (Fig. 3b). Mitoses average 10/10, 10/10 and 12/10 high-power fields (HPF; $\times 400$). No tumour necrosis is seen. The stroma within the tumours is collagenous; in case 3, abundant basal lamina is present among the neoplastic cells (Fig. 4). Cytology (i.e. vesicular nuclei) shows the same features as those of the invasive counterpart. All cases are scored as grade 2 [5]. Neither vascular nor nerve invasion is present. No metastases are found in regional lymph nodes in all cases. In situ duct

Fig. 4 Case 3: **a** Solid nests and sheets as seen at low power. **b** Basal lamina-like material is observed among neoplastic cells

carcinoma of intermediate differentiation [15] is observed at the edge of the invasive lesion in case 3.

The three tumours show similar immunohistochemical features, with minor variations. Keratin 7 strongly and diffusely stains several areas of both lesions, while it appears absent mostly at the periphery of both neoplasms, where resemblance with ILC is more evident (Fig. 5). Keratin 14 is absent in cases 1 and 3, while it occasionally stains cells of case 2. Smooth muscle actin is consistently absent in all cases, as is P63 in cases 1 and 3. The same

antibody stains the nuclei of several neoplastic cellular nests, while it is absent in other areas in case 2 (Fig. 6). E-cadherin stains most of the cells from all cases. The stain does not outline the cell membrane, as is usually seen in duct carcinoma, but shows interruption of staining, here named as “fragmented” E-cadherin stain (Fig. 7). Epithelial membrane antigen (EMA) is negative in the three tumours, as are estrogen receptor (ER) and progesterone receptor (PR). Androgen receptors, c-kit and chromogranin are consistently negative in the two cases stained (cases 2 and 3). On the contrary, Bcl-2 strongly stains the two cases tested (cases 2 and 3) (Fig. 8). Glial fibrillary acidic protein (GFAP) stains only small areas in case 3 (Table 2).

Discussion

We describe three cases of breast carcinoma with features of polymorphous adenocarcinoma (PLA) similar to those referred to as PLGA of the salivary glands. In recent years, most of the tumours seen in salivary glands have also been reported in the breast [11]. These include, in addition to the well-delineated adenoid cystic carcinoma (ACC) [16], mucoepidermoid [4], acinic cell [2] and syringoid [11, 25] carcinomas. Lesions also shared by the two organs are duct carcinoma [11, 13], mixed salivary gland tumours [18] (including carcinoma ex-pleomorphic adenoma) [14] and adenomyoepithelioma [6] (not to mention pure myoepithelial cell carcinomas) [10]. All these tumours of the breast are morphologically similar to those of the salivary glands, although clinical behaviour can differ, being more aggressive in the salivary gland as a general rule [11].

The three present cases displayed a very polymorphous structure consisting of central areas showing solid nests, surrounded at the periphery by alveolar and cribriform structures as well as trabeculae and Indian-file-arranged cells. Neoplastic elements had moderate variability of nuclei that appeared round to ovoid, with sparse vesicular

chromatin. Mitoses ranged from 10 to 12 per 10 HPF, and necrotic areas were absent. Bcl-2 was strongly positive in the two cases tested, and GFAP showed areas of positive elements in one case. All these features were consistent with the features of PLGA as described in minor salivary glands [1, 8].

The present tumours in the salivary glands have to be distinguished from ACCs. The fact that they show only one type of cell and are devoid of actin-positive elements in both cases, as well as of c-kit in cases 2 and 3, renders these tumours different from ACC, which, on the contrary and by definition, shows two types of cells and actin-positive elements [16].

ILC was simulated in the present cases by the Indian-file pattern shown in some peripheral areas. The neoplastic cells from the three cases were E-cadherin-positive, and EMA, ER and PR were, on the contrary, distinctly negative, with all features being different from those seen in ILC [7, 26]. Androgen receptors were consistently negative in the two cases stained (cases 2 and 3)—a finding that was not common in ILCs, which were positive in nearly 90% of the cases [21].

No evidence of neuroendocrine differentiation was present both at structural and immunohistochemical levels [20].

Admittedly, cases 2 and 3 are recent patients, but case 1 had a very aggressive clinical course, with the patient dying of widespread disease 3 years after diagnosis. All three cases were scored as grade 2, were of large sizes and had invasive margins at the moment of diagnosis. No ER and PR were present. Therefore, it seems that, in view of the present data, the biological behaviour and morphological features of the three tumours are more in consonance with those of high-grade carcinomas. In this respect, it seems that the term *low grade*, as used for the PLGA of the salivary glands, is not appropriate for the present breast tumours.

In the salivary glands, no fewer than 13 of 40 PLGA cases reported by Evans and Luna [9] had local recurrences; six cases presented with lymph node metastases and three cases had distant metastases. These data are in consonance with other reports of PLGA [23] in which it appears that, even in salivary glands, it remains an aggressive lesion and, consequently, the term *low grade* does not seem appropriate anymore. In the skin, three of six cases of adenocarcinoma with features very similar to those of the PLGA of the salivary glands recurred (two cases) or metastasized (one case) [24]. Aggressive clinical behaviour led these same authors [24] to name their lesion as polymorphous carcinoma of the sweat glands—a name that can also be adopted in carcinoma of the breast for the same reason. At variance with the present cases, the PLGA of the salivary glands frequently shows neurotropism [1]. This might be due to the limited number of the present cases or due to different anatomic sites of origin, as the same phenomenon is seen in ACCs occurring in the breast [16].

In conclusion, the purpose of the present paper was to report on three cases of PLA of the breast, the last of salivary-gland-like tumours that has not yet been reported

in this site. We propose that the three cases presented in this report fill this gap.

Acknowledgements The work was financed by grant no. 2002064975 (Cofin 2002) of the Ministry of University and Research and by the University of Bologna (60%). Dr. G. Collina is thanked for providing us access to case 3.

Elevated hepatocyte paraffin 1 and neprilysin expression in hepatocellular carcinoma are correlated with longer survival

Received: 14 April 2005 / Accepted: 25 August 2005 / Published online: 12 October 2005
© Springer-Verlag 2005

Abstract Hepatocyte paraffin 1 (Hep Par 1) and neprilysin (CD10) are well-known markers of hepatocellular carcinoma (HCC). To assess their potential prognostic role, we conducted a retrospective analysis of 97 formalin-fixed and paraffin-embedded HCC from patients treated by surgery with curative intent, using standard immunohistochemical procedures and semiquantitative analysis. Strong Hep Par 1 expression and canalicular CD10 staining pattern were significantly correlated with smaller tumor size ($p=0.007$ and 0.04 , respectively). On univariate analysis, longer overall survival was observed in patients with strong Hep Par 1 expression ($p=0.0005$) and in patients with a CD10can staining pattern ($p=0.02$). On multivariate analysis, the combined immunohistochemical score (CIS) obtained by addition of Hep Par 1 and CD10can scores and subtraction of cytoplasmic CD10 score was retained as the single most important prognostic factor ($p=0.001$). Patients with a CIS <4 had a 3.5-fold increased risk of death, as compared to those with a CIS ≥ 4 . In conclusion, strong Hep Par 1 expression, presence of CD10can labeling, and absence of CD10cyt staining are favorable prognostic factors in HCC, which can be easily combined into a single immunohistochemical score for routine clinical use.

Keywords Carcinoma · Hepatocellular · Immunohistochemistry · Antibodies · Monoclonal · Prognosis

Introduction

Prognosis of hepatocellular carcinoma (HCC) after hepatic resection with curative intent remains very poor despite improved surgical techniques [17, 23, 26]. In addition, in low endemic areas like Switzerland, HCC is often discovered in elderly patients with a long-standing alcoholic cirrhosis and at high operative risk. Therefore, adequate prognostic stratification of the patients to guide the clinician in treatment choice is essential. The most important histopathologic prognostic factors are tumor size, vascular invasion, tumor multifocality, and tumor grade [1, 24, 29, 30]. Combined scores based on histological features or image analysis have also been proposed [23]. In addition, the prognostic significance of a variety of gene products related to the cell cycle or to cell adhesion has been described in the literature, such as the tumor-suppressor gene p53, the cell cycle inhibitors p21, p27, and cyclin D, and the cell adhesion molecule beta-catenin [18, 20, 31]. However, none of these markers have found their way into routine clinical use.

Hepatocyte paraffin 1 (Hep Par 1) [2, 21, 27, 38] and neprilysin (CD10 or CALLA) [5, 40] are well-established markers of HCC, and their use as diagnostic aid is well documented in the literature. Hep Par 1 has been obtained by immunizing mice with a crude antigen extracted from human liver tissue [38]. It reacts with a hepatocyte-specific epitope of the mitochondrial membrane [21, 22, 38], resulting in a granular cytoplasmic staining pattern. This marker has been shown to be highly specific for normal and neoplastic liver tissue. CD10 is a zinc-dependant cell membrane metalloproteinase, which participates in the postsecretory processing of neuropeptides and peptide hormones [37]. In the past, it has been widely used as a marker of lymphoblasts in acute lymphoblastic leukemia [4]. More recently, it has also been shown that CD10 is expressed on the canalicular domain of the cell membrane in normal and neoplastic liver tissue [7, 11, 12].

Specificity of these two markers has been well established in the literature, allowing the distinction of HCC

from cholangiocarcinomas and carcinoma metastases to the liver [25, 27, 28]. Surprisingly, to our knowledge, despite several studies on the diagnostic value of these markers and their association with tumor grade and growth pattern, the possible association of their expression with survival has never been examined in detail. In reviewing our pilot series of HCC, the extent of Hep Par 1 and canalicular CD10 (CD10can) expression seemed to be related to the degree of differentiation. In contrast, cytoplasmic CD10 (CD10cyt) expression seemed to be restricted to cases with low Hep Par 1 and CD10can expression. We therefore decided to systematically evaluate the prognostic value of these three parameters. In the current retrospective study, we analyze the immunohistochemical expression of Hep Par 1 and CD10 in formalin-fixed and paraffin-embedded HCC tissue from patients who underwent either partial hepatectomy with curative intent or total hepatectomy followed by liver transplantation to assess their prognostic value.

Patients and methods

Patients and tissue samples

All patients ($n=122$) who underwent either partial hepatectomy with curative intent or total hepatectomy with liver transplantation because of primary HCC and who were diagnosed at the Institute of Pathology in Lausanne, Switzerland, between January 1992 and May 2001 were selected for this retrospective study. Excluded were patients with mixed hepato-cholangiocarcinoma ($n=8$), fibrolamellar carcinoma ($n=1$), inadequate follow-up ($n=11$), missing material for immunohistochemistry ($n=2$), and patients who died within 30 days after diagnosis ($n=3$). The ethics committee of our institution approved the study protocol.

The remaining 97 patients consisted of typical Western European patients whose clinical characteristics were similar to those of several other published series [9, 26, 32]. Treatment was partial liver resection in 72 patients (74%) and total hepatectomy followed by liver transplantation in 25 patients (26%). Most patients (78%) were men. The median age was 63 years (range 14 to 89 years) and was similar for male and female patients. Cirrhosis was found in 67 patients (69%). Serology was positive for hepatitis B virus surface antigen in 10 patients (10%) and hepatitis C virus antigen in 18 patients (19%). Preoperative aspartate aminotransferase, alanine aminotransferase, gamma glutamyl transferase, and alpha-fetoprotein (AFP) levels were also recorded. Overall survival time was calculated from date of diagnosis to date of death or date of last follow-up until closure of the study which was chosen at 30 August 2002. Intermediate outcomes were not considered. Median follow-up time computed according the Kaplan–Meier estimate of potential follow-up was 47 months. Overall median survival time was 28 months in the whole cohort and 23 months in the subgroup of patients treated with partial hepatectomy.

All specimens were fixed in 10% buffered formalin and embedded in paraffin according to standard histological

practice. All available hematoxylin/eosin-stained sections (mean 3, range 1 to 12) were reviewed by two experienced pathologists (D.M. and C.F.), and a representative paraffin block containing both carcinoma and nontumorous tissue was selected for immunohistochemistry. Tumor stage was determined using the International Union against Cancer's tumor–nodes–metastasis (TNM) classification of malignant tumors [34]. Because of small sample size, stages pT1 and pT2 were grouped together. Tumors were divided into grades 1, 2, 3, and 4 according to Edmondson and Steiner [13]. In the case of a heterogeneous tumor, the highest grade was retained for the database. Classification of tumor architecture into trabecular, acinar, compact, and scirrhous growth pattern was performed according to the World Health Organization's criteria [16]. Because of relatively low numbers of tumors in the various non-trabecular categories, they were grouped together for statistical analysis. Tumor size, tumor multifocality (solitary nodules/multiple nodules), and microvascular invasion (MVI) were also recorded. Hepatocellular Prognostic Index (HPI) was computed according to Lauwers et al. [23], using the following formula: $HPI = (MVI \text{ status} \times 0.459) + (\text{nuclear grade} \times 0.287)$. Two prognostic groups were derived from this index: HPI-low ($HPI \leq 0.746$), corresponding to patients with rather good prognosis according to Lauwers et al. [23], and HPI-high ($HPI > 0.746$), corresponding to patients with poor prognosis.

With regard to tumor stage, 33 patients (34%) had stages I and II disease, 29 (30%) had stage III, and 35 had (36%) stage IV. Most HCC were less than 5 cm in size ($n=58$, 60%), solitary ($n=54$, 56%), and with a trabecular architecture ($n=75$, 77%). The tumor differentiation was grade 1 in 15 HCC (15%), grade 2 in 47 (48%), grade 3 in 27 (28%), and grade 4 in 8 (8%). MVI was present in 35 HCC (36%). HPI was high in 51 tumors (53%).

Immunohistochemistry

Immunohistochemistry was performed with mouse monoclonal antibodies directed against Hep Par 1 (clone OCH1E5, DAKO) and CD10 (clone 56C6, Novocastra) using the streptavidin biotin complex (ABC) method. In brief, 3–4 μ tissue sections were mounted on aminopropylmethoxysilane-coated slides, deparaffinized in xylene, and rehydrated in a graded alcohol series. Endogenous peroxidase was blocked with 1% H_2O_2 in methanol for 30 min at room temperature. Antigen retrieval was performed by boiling the sections (microwave) in 10 mM citrate buffer pH 6.0 for 15 min (Hep Par 1) or 1 mM in EDTA pH 7.5 for 15 min (CD10). After conditioning with normal horse serum at a 1:30 dilution for 5 min, the sections were incubated either with anti-Hep Par 1 at a 1:10 dilution for 1 h or with anti-CD10 at a 1:20 dilution overnight. Detection was performed using biotinylated anti-mouse IgG at a 1:200 dilution and peroxidase-conjugated ABC complex (both from Vector Laboratories) according to the manufacturer's specifications. Between all steps, sections were washed in Tris-buffered saline. Peroxidase activity was revealed with

3,3-diaminobenzidine-tetrahydrochloride as chromogen, and sections were counterstained with Mayer's hematoxylin.

Primary antibodies were omitted as a negative control. Nontumorous liver tissue adjacent to HCC and present on the same slide was used as positive control.

The immunohistochemical Hep Par 1 and CD10 staining of all slides was evaluated independently by two observers (D.M. and W.K.F.S) in a blinded manner. Divergent scorings were discussed until a consensus was reached. To assess reproducibility, a subset of slides was analyzed by a third pathologist (F.T.B.), who had not done the initial evaluation based on the information contained in this manuscript without additional training. Individual tumor cells were considered to be positive for Hep Par 1 when their cytoplasmic staining intensity was similar or stronger than that of the adjacent nontumorous hepatocytes. CD10cyt staining was considered to be positive in tumor cells when the cytoplasm showed unambiguous labeling in contrast to the preexisting hepatocytes which were negative. Positive CD10can staining was defined as crisp focal labeling of the canalicular aspects of the tumor cell membrane when its intensity was similar or stronger than that of the nontumorous canaliculi.

Based on the percentage of positive cells, Hep Par 1, CD10can, and CD10cyt immunolabelings were semiquantitatively classified into four groups, based on a priori determined cutoff points. In the first group, less than 5% of the tumor cells were positive (score 0); in the second group, 5 to 30% of the tumor was positive (score 1); in the third group, 30 to 90% of the tumor cells were positive (score 2); and in the last group, more than 90% of the tumor was positive (score 3).

A combined immunohistochemical score (CIS) was computed as follows: CIS = Hep Par 1 score + CD10can score - CD10cyt score.

Statistical analysis

Correlation tests between immunohistochemical and clinicopathological parameters were performed using either Kruskal-Wallis tests (for continuous or ordered variables such as age, HPI, or tumor grade) or Chi-squared tests (for categorical variables), unless there was concern regarding an inadequate number of observations, in which case, a Fisher's exact test was used [3].

Overall interobserver agreement was compared using kappa statistics. According to common usage, kappa values of ≤ 0.5 were considered "poor", 0.51-0.6 "moderate", 0.61-0.8 "good", and > 0.8 "excellent".

For Fisher's exact tests and survival analysis, clinicopathological and immunohistochemical variables were dichotomized into groups of similar size as follows: age < 65 vs. ≥ 65 years, tumor size ≤ 5 vs. > 5 cm, HPI ≤ 0.746 (low) vs. > 0.746 (high), Hep Par 1 < 3 vs. $= 3$, CD10can < 2 vs. ≥ 2 , CD10cyt < 1 vs. ≥ 1 , and CIS < 4 vs. ≥ 4 .

Survival percentages over time were calculated by the Kaplan-Meier method [19], and their corresponding

standard errors were determined using the formula of Greenwood [15]. Univariate associations between the potential prognostic factors and overall survival were tested using the log-rank test.

Prognostic variables which had been at least marginally significant in univariate analysis (log-rank test < 0.1) were further analyzed in various Cox regression models using backward selection with $p < 0.05$ as the exit criterion.

Given the relatively small number of outcome events, several distinct Cox regression models with a limited number of covariates had to be evaluated [6].

Estimated hazard ratios of death, with respect to the indicated reference group, their 95% confidence intervals (CI), and p values were calculated with appropriate binary variables to identify each group of interest [10]. Values of hazard ratios greater than unity indicated increased rates of death with respect to the chosen reference category.

To evaluate the impact of type of surgery, univariate and multivariate analysis were done on the whole study population as well as on the subgroup of patients with partial liver resection.

Statistical analyses were carried out by means of the software packages Stata, S-plus 2000, and SPSS.

All probability values were evaluated by two-sided tests, and differences were considered to be significant if the p value was less than 0.05.

Results

Correlation of Hep Par 1 and CD10 immunolabeling with clinicopathological features

Hep Par 1 resulted in a diffuse labeling of the cytoplasm of nontumorous hepatocytes, which served as internal positive control, with a distinctive granular pattern. It was independent of the underlying liver pathology, and there was no staining difference between cirrhotic and non-cirrhotic liver tissue. Most HCC showed a similar cytoplasmic labeling, albeit at a highly variable intensity (Fig. 1a-c). Hep Par 1 expression, evaluated semiquantitatively as outlined in "Patients and methods", was extensive (score 3) in 54 (55%) HCC, partial (score 2) in 31 (32%) HCC, and focal or absent (score 1 or 0) in 13 (13%) HCC.

CD10 labeled in nontumorous liver exclusively the luminal portion of bile canaliculi of the hepatocytes as well as the luminal surface of the bile duct epithelium. There was no staining difference between cirrhotic and non-cirrhotic liver. In HCC, a similar canalicular staining pattern was seen forming sharp branching lines which were typically located between cells and not within them (Fig. 1d-f). CD10can labeling was widespread (score 3) in 20 (21%) HCC, partial (score 2) in 38 (39%) HCC, focal (score 1) in 11 (11%) HCC, and completely absent in 28 (29%) HCC. In addition, some HCC displayed a CD10cyt labeling (Fig. 1g,h), and very few tumors exhibited a diffuse cell membrane staining. This type of staining was not seen in nontumorous hepatocytes. CD10cyt staining

Fig. 1 Representative examples of immunohistochemical staining in HCC for Hep Par 1 (a–c) and CD10 (d–h): individual tumor cells (*tu*) are considered positive for Hep Par 1 when their cytoplasmic immunolabeling is similar to that of adjacent nontumorous hepatocytes (*n*). CD10 labeling is considered to be canalicular (d–f) when there is a crisp linear staining between adjacent tumor cells (*inset*, d). CD10cyt staining is considered significant if individual tumor cells show an unambiguous cytoplasmic staining in contrast to surrounding nontumorous liver tissue which is negative (g–h). Scoring is based on the percentage of positive tumor cells: score 3, more than 90% labeled tumor cells (a, d, and g); score 2, between 30 and 90% (b, e, and h); and score 1, less than 30% positive tumor cells (c and f). Scale bars 100 μ m

was extensive (score 3) in 5 (5%) HCC, partial (score 2) in 23 (24%) HCC, focal (score 1) in 18 (19%) HCC, and absent in 51 (52%) HCC.

Correlations between immunohistochemical features and histopathologic parameters are reported in detail in Table 1. High levels of Hep Par 1 expression (score=3) were significantly correlated with small tumor size ($p=0.007$), absence of MVI ($p=0.03$), and low HPI ($p=0.04$). In addition, Hep Par 1 expression decreased with increasing tumor grade in a significant manner ($p=0.01$; Fig. 2a). All other parameters, including International Union Against Cancer tumor stage and tumor pattern, lacked any significant correlation with Hep Par 1 score. Extensive CD10can labeling (score \geq 2) was more frequent in small HCC ($p=0.04$) and male patients ($p=0.01$). Like Hep Par 1, CD10can expression was reduced in poorly differentiated tumors ($p=0.03$; Fig. 2b). CD10cyt staining was not correlated with any clinicopathological feature. A high CIS (\geq 4) showed a

highly significant correlation with reduced tumor size ($p=0.05$), and it was also more frequently observed in male patients ($p=0.04$). Furthermore, CIS decreased with decreasing tumor differentiation ($p=0.05$; Fig. 2c).

To assess reproducibility, a subset of immunolabelings was reviewed by another pathologist without particular training. The interobserver agreement was excellent for Hep Par 1 and CD10can labeling ($\kappa=0.87$) and moderate for CD10cyt labeling ($\kappa=0.53$).

Correlation of Hep Par 1 and CD10 expression with survival by univariate analysis

To determine the prognostic value of Hep Par 1 and CD10 labeling, the immunohistochemical scores were analyzed as categorical variables using cutoff points that were chosen in a manner to split the study population in two

Table 1 Relationship between expression of Hep Par 1 or CD10 and pathological factors

groups of similar size. To detect a possible bias resulting from the type of surgery, univariate and multivariate survival analyses were done not only on the whole study population but also on the subgroup of patients with partial liver resection. On univariate analysis (Table 2) of the whole cohort, Hep Par 1 expression and CD10can labeling were significantly associated with overall survival ($p=0.0005$ and 0.02 , respectively). Indeed, median survival time of patients with tumors showing a strong Hep Par 1 staining (score=3) was more than 100 months in contrast to patients

with a score of <3 who survived only 15 months (Fig. 3a). Similarly, survival of patients with an at least moderate CD10can staining (score ≥ 2) was 54 months in contrast to 17 months for the other patients (Fig. 3b). Similar results were found in the subgroup of patients with partial liver resection, who showed also a significant association of strong Hep Par 1 staining with longer median overall survival (33 vs. 14 months, $p=0.03$). There was a trend toward better overall survival among patients with a CD10can score of ≥ 2 (28 vs. 16 months, $p=0.09$). In contrast,

Fig. 2 Correlation between Edmondson and Steiner's tumor grade and immunohistochemical scores: Hep Par 1 expression is significantly decreased in grades 3 and 4 carcinomas (a). CD10can expression is highly decreased in grade 4 tumors (b). Combined immunohistochemical score (CIS=Hep Par 1 score + CD10can score - CD10cyt score) shows a progressive decrease with increasing tumor grade (c). *p* values were determined using Kruskal-Wallis tests

^bCIS (score Hep Par 1 staining + score CD10 canalicular staining – score CD10 cytoplasmic staining)

there was only a weak association between CD10cyt labeling and overall survival in the whole cohort ($p=0.2$) and in the subgroup of patients with partial resection ($p=0.3$). Patients

with CD10cyt positive tumors tended to have a reduced overall survival as compared to patients with CD10cyt negative tumors.

Fig. 3 Overall survival curves of all 97 patients who underwent either partial hepatectomy with curative intent or total hepatectomy with liver transplantation according to Hep Par 1 score (a), CD10can score (b), combined immunohistochemical score (CIS=Hep Par 1 score + CD10can score – CD10cyt score) (c). Overall survival curves of the subgroup of 72 patients who underwent partial hepatectomy with curative intent according to combined immunohistochemical score (d). *p* values were determined using the log-rank test

To be able to use these immunohistochemical parameters in a routine clinical setting, they were combined into a simple score according to the following formula: CIS = Hep Par 1 score + CD10can score - CD10cyt score. On univariate analysis, there was a highly significant correlation between CIS and overall survival in both the whole cohort ($p=0.0004$) and the patients with partial liver resection ($p=0.01$). In the whole study population, patients with a CIS ≥ 4 survived more than 80 months whereas the median overall survival of the others was only 17 months (Fig. 3c). Similar median overall survival times were found in the subgroup of partially resected patients (80 vs. 16 months; Fig. 3d).

Multivariate survival analysis

Multivariate analysis was performed using several Cox regression models with a limited number of covariates, because the number of outcome events did not allow the evaluation of all pertinent parameters at once. Prognostic variables which had been at least marginally significant (log-rank test <0.1) in univariate analysis (tumor size,

stage, multifocality, and grade as well as MVI, HPI, and surgical margins; Table 3) were further analyzed in various Cox regression models using backward selection with $p<0.05$ as the exit criterion. Following clinicopathological parameters had no impact on survival in univariate analysis and were not further assessed in multivariate models: preoperative transaminase levels and cholestatic parameters, viral hepatitis B and C, alcohol-related liver disease, cigarette smoking, sex, age, and tumor growth pattern. Although not statistically significant on univariate analysis in our series, concomitant liver cirrhosis and preoperative AFP levels were included in a multivariate model because they are well-known prognostic markers.

In the models including only clinicopathological parameters, the retained prognostic factors were tumor multifocality and size in the whole cohort and tumor multifocality and grade in the subgroup of patients with liver resection (model 1 from Table 4).

In the model including Hep Par 1, CD10can, and CD10cyt, all three immunohistochemical parameters were retained, and the regression coefficients (whole cohort) were 0.72, 0.77, and 0.78 for Hep Par 1, CD10can, and CD10cyt, respectively (model 2 from Table 4). Taken

^aModel 1 includes only clinicopathological parameters. Model 2 includes only immunohistochemical parameters. Models 3 and 4 include clinicopathological parameters together with one immunohistochemical parameter. Models 5 and 6 include CIS in addition to clinicopathological parameters; both models retain the same final variables

^bSignificance of the Wald test, variables with $p > 0.05$ were discarded from the model

^cFor dichotomous variables (size, multifocality and CIS), the relative risk is such a change for a patient within the specified category as compared to the other one. For grade, the relative risk is such a change for a patient within the specified category as compared to the reference category (grade 1)

^dHPI computed according to Lauwers et al. [23]

^eCorrelation coefficients for Hep Par 1 =3, CD10can ≥2, and CD10cyt ≥1 are 0.721, 0.772, and 0.775, respectively

^fCorrelation coefficients for CD10can ≥2 and CD10cyt ≥1 are 0.897 and 0.748, respectively

^gCIS (score Hep Par 1 staining + score CD10 canalicular staining - score CD10 cytoplasmic staining)

^hPreoperative AFP levels

together with the selected clinicopathological parameters, Hep Par 1 and CD10can were retained in the models (models 3 and 4 from Table 4, respectively). However, *p* values and relative risk were lower for Hep Par 1 and CD10can alone as compared to CIS (see below).

All models testing CIS in conjunction with different clinicopathological parameters resulted in the retention of the same final variables. Models 5 and 6 from Table 4 are representative examples. CIS was the most significant prognostic factor in both the complete cohort ($p=0.001$) and the subgroup of liver-resected patients ($p=0.004$). Patients with a CIS <4 , as compared to those with a CIS ≥ 4 , had a 3.5-fold (95% CI 1.7–7.3) and a 3.7-fold (95% CI 1.5–8.9) increased risk of death in the whole cohort and the subgroup of patients with liver resection, respectively. In the model of the whole cohort, tumor multifocality was the only additional prognostic factor ($p=0.005$): patients with multifocal HCC had a 2.4-fold (95% CI 1.3 to 4.3) increased risk of death as compared to those with solitary tumors. In the model of patients with liver resection only, tumor multifocality ($p=0.02$) and Edmondson and Steiner's grade ($p=0.04$) were retained in addition to CIS.

Discussion

Hepatocellular carcinoma is one of the most common malignant tumors worldwide that has typically poor prognosis regardless of the treatment, and its incidence and mortality are on the rise in Western nations [14]. Clinicians need prognostic indicators to inform their patients and to stratify them for eventual additional therapy. The present study of Hep Par 1 and CD10 expression in HCC by immunohistochemistry was undertaken to identify new prognostic markers for patients treated with curative intent by partial or total hepatectomy, the latter with liver transplantation.

In our study population, strong cytoplasmic Hep Par 1 and CD10can expression, as well as absent CD10cyt labeling, were correlated with longer overall survival. To obtain a practical algorithm for clinical use, these three immunohistochemical parameters were combined into a single immunohistochemical score, which showed a highly significant correlation with overall survival. Multivariate analysis proved CIS to be the most important independent prognostic factor, followed by tumor multifocality and Edmondson and Steiner's grade. Furthermore, CIS is superior to Hep Par 1 or CD10 scores alone with regard to risk assessment. To our knowledge, this is the first study to demonstrate the prognostic value of these markers, although their use is well documented in establishing the diagnosis of HCC [5, 7, 8, 38]. CIS was also the most significant prognostic indicator in the subgroup of patients treated by partial hepatectomy, which excludes the possibility of a bias due to the type of surgery. Unfortunately, the limited number of patients treated by total hepatectomy and the limited duration of follow-up precluded analysis of this subgroup.

A future study is planned to examine in detail the prognostic value of Hep Par 1 and CD10 in this group of patients.

Prognostic indices are usually derived from the final Cox regression model by using the regression coefficients as weights for the corresponding scores [6]. However, we preferred a more simple prognostic index based on a weight of +1 for Hep Par 1 and CD10can and a weight of -1 for CD10cyt scores for two reasons. First, its determination is simple enough to be applicable in a routine setting. Second, as shown by the Cox model, including these three parameters, the absolute value of their regression coefficients is roughly the same (about 0.7), which justifies a posteriori such a score. Interestingly, several parameters, such as TNM stage, tumor size, MVI, HPI, and surgical resection margins, which are known in the literature to be of prognostic significance, were not retained in our Cox regression models. This can be explained by correlation of the immunohistochemical variables with these clinicopathological parameters, as shown in Table 1 for tumor size and grade, MVI and HPI. Second, tumor multifocality, which remains significant in our multivariate models, contains partly the same prognostic information as TNM stage, which is based on the former.

The precise biological mechanisms underlying the impact of Hep Par 1 and CD10 expression on prognosis have yet to be identified. It might be linked to the fact that Hep Par 1 and CD10can expressions are indicators of a high degree of differentiation. Indeed, in our series, there was a correlation between the expression of these markers and histological grade. These findings are in line with several reports in the literature [5, 8, 21, 39]. Another argument in favor of this hypothesis is the fact that poorly differentiated HCC are known to be devoid of bile canaliculi [5, 7]. Therefore, these tumors are frequently unreactive with antibodies directed against CD10 which is a neutral endopeptidase located at the luminal aspects of bile canaliculi. To explain the intriguing feature of CD10cyt labeling in the less differentiated and more aggressive tumors, one might also speculate that redistribution of CD10 from the cell surface to the cytoplasm is an indirect sign of lost cell polarity, which is one of the hallmarks of cancer [35]. This redistribution might be the consequence of aberrant glycosylation, alternative splicing, or a truncating mutation of the CD10 gene [33, 36].

In conclusion, our study identifies Hep Par 1 and CD10 expression as the most informative predictors of overall survival in HCC patients treated by partial liver resection with curative intent. Introduction of these parameters in clinical decision making, however, requires confirmation of these preliminary findings in another population of HCC patients. Whether these findings apply also to patients treated with total hepatectomy and liver transplantation as suggested by the present work will require further studies. Future prospective studies are also necessary to determine whether or not the CIS can be helpful for the choice of additional treatment and prediction of prognosis in patients who are beyond curative surgery.

Expression of protease-activated receptors and tissue factor in human liver

Received: 12 May 2005 / Accepted: 22 August 2005 / Published online: 29 September 2005
© Springer-Verlag 2005

Abstract Thrombin, acting via protease-activated receptors (PARs), and tissue factor (TF) are involved in inflammation, tissue repair and tumorigenesis. Hepatocellular carcinomas (HCCs) usually complicate chronic liver diseases characterised by inflammation and fibrosis. The aim of this study was to describe the expression of PARs and TF in normal liver, cirrhosis and HCCs. We performed an immunohistochemical detection of PAR-1, PAR-3, PAR-4 and human TF in human tissue samples from 19 subnormal livers, 33 cirrhosis and 30 HCCs. PAR-1 was found on endothelial cells of sinusoids and larger vessels. In cirrhosis, spindle-shaped cells within septa and T lymphocytes were PAR-1 positive. A few PAR-1-positive tumour cells were found in 10% of HCCs. PAR-4 expression was restricted to macrophages, B lymphocytes and nerves. PAR-3 expression was rare. Unexpectedly, TF was expressed in 95% of normal livers and in 94% of cirrhosis but only in 50% of HCCs ($p < 0.001$). Staining was

mostly hepatocellular. No association existed between TF labelling and clinicopathological characteristics of HCCs. In conclusion, the pattern of expression of PARs is compatible with its role in chronic liver disease by promoting inflammation via immune cells and neurogenic stimulation. However, our data do not support a role for PARs or TF in HCC progression.

Keywords Thrombin receptor · Tissue factor · Human liver · Immunohistochemistry · Liver neoplasm

Introduction

Thrombin is a multifunctional serine protease. Besides its key role in haemostasis, thrombin is also involved in inflammation and tissue repair processes. Indeed, it has long been known that thrombin is chemotactic for monocytes [2] and participates in lymphocyte activation [24]. More recently, thrombin was shown to stimulate the synthesis of connective tissue proteins by fibroblasts [7, 8]. Thrombin also increases the metastatic potential of tumour cells notably by promoting tumour cell adhesion to the endothelium and extracellular matrix [21, 41].

Thrombin is generated via a cascade of reactions whose physiological initiator is tissue factor (TF). TF is a 47-kDa transmembrane glycoprotein that is expressed physiologically in vascular endothelial cells, macrophages and blood monocytes [23]. TF does not normally come in contact with the circulation, but during tissue injury, it is locally expressed and binds to factor VII, thereby activating the extrinsic coagulation system. In inflammatory lesions, TF is expressed by endothelial cells and monocytes/macrophages [35]. TF is also expressed by most epithelial tumour cell types [6]. A correlation between elevated TF expression and advanced stages of malignancy has been confirmed in many human cancers, like colorectal carcinomas, gliomas, prostatic cancers, non-small-cell lung cancers, melanomas, and laryngeal and pancreatic carcinomas [1, 4, 19, 25, 34, 42, 43]. Whereas the extracellular domain of

TF is required as a coagulation activator, its cytoplasmic tail is also involved in cell signalisation events that could lead to inflammation, tumour cell survival, tumour angiogenesis, and cancer progression and metastasis [27].

Thrombin acts via activation of protease-activated receptors (PARs) that belong to a large family of G-protein-coupled seven transmembrane domain receptors. Thrombin cleaves the extracellular amino-terminal peptide of the receptor. The new N-terminal peptide, as a tethered ligand, binds to the body of the receptor itself, resulting in its activation. Three out of four PARs, PAR-1, PAR-3 and PAR-4, are activated by thrombin, whereas PAR-2 is activated by trypsin and mastocyte tryptase [9]. PAR-1, the first-described thrombin receptor, is expressed in smooth muscle and endothelial cells, fibroblasts and blood cells. In the liver, only one study reported in situ expression of PAR-1 in human samples from normal liver, chronic hepatitis, cirrhosis and fulminant hepatitis [22]. Recently, several publications strongly suggest that thrombin and PAR-1 are important for tumorigenesis and metastasis [3, 5, 15, 16, 33].

Hepatocellular carcinoma (HCC) is the main type of primary liver cancer. In Western countries, it occurs mainly as a complication of a pre-existing cirrhosis, most often secondary to chronic viral hepatitis C or B, or alcoholic liver disease. Whereas there is now accumulated evidence that thrombin and its receptors are involved in liver fibrogenesis [13, 17, 22], the role of the haemostatic cascade has been slightly addressed in HCC. Specifically, there are no published data on TF expression in HCC, while those on PAR expression are scarce [10].

Thus, the aim of this work was to study the distribution and localisation of thrombin receptors PAR-1, PAR-3 and PAR-4 and of TF in normal human liver, cirrhosis and HCC.

Materials and methods

Tissue samples

Eighty-two samples obtained during surgery were analysed. Sixteen histologically normal liver tissue samples were taken at a distance from benign liver tumours (focal nodular hyperplasia, $n=2$; hydatid cyst, $n=1$), and colorectal ($n=12$) and mammary ($n=1$) cancer metastasis. Six cirrhosis samples without associated HCC were also tested. Thirty HCC and surrounding liver tissue samples were studied in the same tissue section. Surrounding liver was cirrhotic in most cases, due to chronic hepatitis C or alcohol consumption ($n=27$), and was rarely subnormal ($n=3$). Twenty-six of the 30 HCCs were diagnosed in men with a mean age of 61 years. Half of the HCCs were multiple (16/30) with partial or complete tumour capsule (17/30). The mean tumour size was 4 cm (1–18.5 cm). HCCs were usually (26/30) classified as grade II or III according to Edmondson's grade. Features of vascular invasion were present in 15 out of 30 tumours and capsular invasion in only nine cases.

Methods

All samples were fixed in 10% formalin and embedded in paraffin. Serial tissue sections (4 μm thick) were cut, mounted on glass slides and dried at 56°C before dewaxing in xylene and rehydration in alcohols according to standard histological procedures. Antibodies against PARs were bought from Santa Cruz Biotechnology Inc. (Santa Cruz, CA): PAR-1 (monoclonal, clone ATAP2, dilution 1:1,000), PAR-3 (goat polyclonal, C-20, dilution 1:750), PAR-4 (goat polyclonal, C-20, dilution 1:3,500). All sections were subjected to heat-induced epitope retrieval using a vegetable steam cooker in citrate buffer pH 6 for 5 min, followed by inhibition of endogenous peroxidase (H_2O_2 0.3% in methanol, 30 min). Incubation of primary antibodies was done at room temperature for 45 min. After washing in phosphate-buffered saline, sections for PAR-3 and PAR-4 labelling were incubated with a rabbit anti-goat antibody (Dako, Glostrup, Denmark) at room temperature for 45 min before incubation with EnVision TM+ anti-rabbit polymer dextran (Dako). For PAR-1, sections were directly incubated with EnVision TM+ anti-mouse polymer dextran (Dako).

Tissue factor immunostaining was done in an automated immunostainer (Autostainer Plus, Dako) with a previously described anti-TF polyclonal antibody raised in rabbit [1]. After heat-induced antigenic retrieval in citrate buffer pH 6 for 10 min, endogenous peroxidase activity was inhibited. Non-specific binding was reduced by incubating the sections with 60% human serum with bovine serum albumin. Sections were incubated with anti-TF antibody (dilution 1:2,000) for 1 h. The staining was amplified by an EnVision TM+ anti-rabbit polymer dextran. TF immunostaining was also performed in frozen tissue from selected cases.

All stainings were revealed with a diaminobenzidine substrate source. Sections were counterstained with hemalum, dehydrated and mounted in Eukitt.

Tissue factor expression was evaluated semi-quantitatively as the percentage of positive cells [1] and was scored as 0 (no positive cells), 1 ($\leq 10\%$ positive cells), 2 (10 to 30% positive cells) or 3 ($> 30\%$ positive cells).

Complementary immunohistochemical labelling using commercially antibodies to CD3 (Dako), CD20 (clone L26, Dako), alpha smooth muscle actin (clone 1A4, Dako) and CD68 (clone KP1, Dako) was also performed in selected cases on serial sections using an automated immunostainer (ES 320 Ventana, Tucson, AZ, USA) and an LSAB procedure (Ventana). Double immunostaining was also done using the DakoCytomation EnVision doublestain system (Dako), with PAR-1 (EnVision-Peroxidase, DAB substrate buffer) and alpha smooth muscle actin (EnVision-Alkaline phosphatase, Fast red substrate buffer), PAR-1 and CD31 (EnVision-Alkaline phosphatase, Fast red substrate buffer), and PAR-4 (EnVision-Peroxidase, DAB substrate buffer) and CD68 (EnVision-Alkaline phosphatase, Fast red substrate buffer).

Negative controls were systematically obtained by omitting the primary antibody. Lymphocytes were used as positive controls for PAR-1 and PAR-4, whereas prostatic carcinomas ($n=3$) were used for TF.

Statistical analysis

The chi-square test and Yates' derived Fisher's exact test were used for comparisons as appropriate. For patients with HCC, clinical data such as local and distant recurrences as well as follow-up were obtained from the Department of Liver Surgery and Transplantation. Five-year overall and disease-free survival data were determined by the actuarial Kaplan–Meier method. The impact of TF immunostaining on survival was evaluated by univariate analysis using the log-rank test. Statistical significance was set at $p < 0.05$.

Results

Thrombin receptors

Protease-activated receptor-1

Endothelial cells from sinusoids and vessels were diffusely labelled in every sample whether normal or diseased without differences in intensity (Fig. 1a,e). In cirrhotic tissue, an immunostaining was observed in fibrous septa with an intensification around areas of ductular reaction; this staining appeared located to the cytoplasm of spindle-shaped cells resembling fibroblasts or myofibroblasts and co-expressing alpha smooth muscle actin (Fig. 1a,f). No staining of fibroblasts was observed in portal tracts of normal liver samples. Mononuclear inflammatory cells that look like lymphocytes were also labelled; they were located either in the lumen of sinusoids, in the mesenchyme

of portal tracts or in fibrous septa. The lymphoid origin of these cells was confirmed in cases of viral hepatitis C where prominent lymphoid follicles. Indeed, PAR-1-positive cells were located at the periphery of the follicle and co-expressed the CD3 antigen, indicating that they were T lymphocytes (Fig. 1b,c). Normal hepatocytes and biliary epithelial cells were always negative.

In HCC, an immunostaining identical to that observed in cirrhotic septa was also observed in fibrotic bands inside the tumour and in the capsule, when present. In 3 out of 30 HCCs, clusters of tumour cells showed a delicate membranous staining (Fig. 1d).

Protease-activated receptor-3

PAR-3 immunolabelling was confined to scarce polymorphonuclear neutrophils within sinusoids in only one out of all specimens tested.

Protease-activated receptor-4

Whatever the type of tissue (normal, cirrhotic livers or HCC), three compartments of staining were noted: (1) B lymphocytes (CD20 positive) located at the centre of lymphoid follicles or dispersed in the lumen of sinusoids, portal tracts, fibrous septa and bands (Fig. 2b,c); (2) macrophagic cells (CD68 positive) such as Kupffer cells in sinusoids (Fig. 2a,e), histiocytes and giant cells found in portal tracts and occasionally in a few inflammatory HCCs; and (3) in nerves (Fig. 2d).

Fig. 1 Patterns of PAR-1 immunostaining: **a** endothelial cells from sinusoids and vessels as well as spindle-shaped cells in fibrous septa in cirrhotic tissue express PAR-1; **b** T lymphocytes express both PAR-1 and **c** CD3 antibody in follicles of post-hepatitis C cirrhosis in serial sections of the same case; **d** tumour cells in a grade III HCC

showed a delicate membranous staining with PAR-1; **e** co-expression of CD31 (red) and PAR-1 (brown) in endothelial cells of sinusoids; **f** co-expression of alpha smooth muscle actin (red) and PAR-1 (brown) in spindle-shaped cells in fibrous septa

Tissue factor

Tissue factor was expressed in 18/19 normal livers (95%) and 31/33 cirrhotic samples (94%; Table 1). The staining was mainly found in the cytoplasm of hepatocytes, sometimes with a polarised disposition at the sinusoidal pole (Fig. 3). In normal liver, the distribution of the hepatocellular staining was mainly centrolobular and enhanced in hepatocytes located under the Glisson's capsule. In cirrhosis, hepatocellular staining was diffuse in half of the cases, involving more than 30% of hepatocytes. Endothelial cells from neovessels and/or spindle-shaped cells within cirrhotic septa were sometimes stained.

On the other hand, TF labelling was observed in only 50% of the 30 HCCs tested. When present, the staining was found mainly in the cytoplasm of tumour cells and rarely in neovessels. Less than 10% of tumour cells were positive in 10 out of 15 cases and more than 30% in only a single case (Table 1). In each case, the percentage of positive cells in HCC was lower than in the surrounding tissue, either cirrhotic or not. In selected cases, a similar staining pattern for TF was found when using cryosections, indicating that the results were not secondary to a fixation artefact (data

not shown). No staining was observed when omitting primary antibodies.

The percentage of TF-positive cells was significantly lower in HCC than in cirrhosis ($p < 0.001$) (Table 1). There was no association between the positivity of TF immunostaining and known histoprognostic factors of HCC, i.e. tumour size, tumour number, Edmondson's grade, tumour capsule, capsular invasion and vascular invasion (data not shown). There was no association either between TF ex-

pression in HCC and overall or disease-free survival with a median follow-up of patients of 11 months (range 1–41).

Discussion

In this report, we describe for the first time the distribution of the three thrombin receptors, PAR-1, PAR-3 and PAR-4, and of TF in a series of subnormal, cirrhotic and carcinomatous liver samples.

A single study previously reported *in situ* expression of PAR-1 in normal human liver, chronic hepatitis, cirrhosis and fulminant hepatitis [22]. Like in this publication, we found PAR-1 expression all along sinusoids, as well as in the endothelium of blood vessels and inflammatory cells in normal liver and chronic hepatitis. In cirrhosis, we also found PAR-1-positive cells in fibrous septa, within newly formed blood vessels and in spindle-shaped cells corresponding to fibroblasts or myofibroblasts (Fig. 1f). Many inflammatory cells also expressed PAR-1 as previously described [22]. In a few samples from HCV-infected patients with many lymphoid follicles, we were able to demonstrate that PAR-1-positive cells located at the periphery of the lymphoid nodules co-expressed the T-cell marker CD3 (Fig. 1). This finding is in keeping with other studies demonstrating that thrombin is a potent regulator of T lymphocytes *in vitro* and that thrombin receptors are available at the surface of human T and NK lymphocytes [12, 20, 30]. In contrast, PAR expression on B lymphocytes was reported as negative [18, 37]. However, these studies were performed before the description of PAR-4. When we labelled liver sections with a PAR-4 antibody, we found that lymphocytes in the centre of lymphoid follicles that expressed the B lineage marker CD20 also expressed PAR-4 (Fig. 2). Thus, within lymphoid follicles, PAR-1 labelling and PAR-4 labelling are mutually exclusive, resulting in a mirror image. This selectivity likely results in specific responses to various agonists. Firstly, it is known that thrombin action on PAR-1 or PAR-4 evokes distinct signalling pathways [32, 36, 40]. Secondly, besides being receptors for thrombin, both PAR-1 and PAR-4 also bind other molecules. This has been clearly shown for PAR-1 that is also stimulated by factor Xa [28] and activated protein C [29], while PAR-4 is also suggested to be a receptor for plasmin [26] and cathepsin G [31]. Finally, PAR-3 staining was an incidental finding since we found only a single case where a few polymorphonuclear cells were labelled. Altogether, our results in cirrhotic samples are in agreement with the proposed role for PARs in inflammatory processes. More specifically, they suggest that PARs could be involved in the regulation of the immune response, acting via T lymphocytes/PAR-1 for cellular immunity and B lymphocytes/PAR-4 for the humoral response. This is in agreement with one recent study that demonstrated the key role of PAR-1 in chronic inflammatory bowel disease [39]. Finally, as previously reported in other organs [11, 40], we found an expression of PAR-4 in nerve sections. This is in accordance with recent observations showing that several PARs are

expressed in the nervous system and are likely involved in the regulation of neurogenic inflammation [38].

In HCC, thrombin receptors were essentially expressed within the same compartments as in the cirrhotic liver with no obvious differences in staining intensity. Only in three cases did we see a membrane staining of PAR-1 in a few clusters of tumour cells (Fig. 1). As observed by D'Andrea et al. [10], we showed that HCC-associated fibroblasts expressed PAR-1, whereas portal fibroblast from normal liver did not. However, in cirrhosis, which can be considered a preneoplastic step in the course of chronic liver disease, fibroblasts were also PAR-1 positive.

We also studied TF expression in the liver. To our knowledge, there are no previous data of such sort reported in human liver. TF expression was recently reported in a transgenic murine model of HCC where it was observed in endothelial cells and macrophages [14]. In contrast, in human liver, we found a predominant hepatocytic expression of TF. TF was expressed in the majority of non-tumour samples, either normal or cirrhotic. Normal livers sampled in the periphery of metastasis or of benign liver tumours were all positive, indicating that it is unlikely to have a bias due to the vicinity of a cancer. In light of the previous publications about other cancers [1, 34, 43], the lack of TF labelling in half of the HCCs was unexpected. This was unlikely a methodological problem due to the antibody used since prostatic carcinomas used as positive controls [25] were labelled as expected (data not shown). In addition, when positive for TF, HCCs were always less stained than the surrounding liver tissue. TF-positive HCCs were not different from TF-negative HCCs in terms of size, histological grade, local signs of invasiveness (vascular invasion, tumour capsule invasion) or outcome.

In conclusion, the pattern of expression of PARs in the course of chronic liver disease is compatible with the role proposed for these receptors in chronic inflammation. On the other hand and unlike in other organs, our data do not support a significant role for either PARs or TF in liver cancer progression.

Claudins 1, 3, 4 and 5 in gastric carcinoma, loss of claudin expression associates with the diffuse subtype

Received: 31 March 2005 / Accepted: 17 May 2005 / Published online: 12 October 2005
© Springer-Verlag 2005

Abstract In this study expression of claudins 1, 3, 4 and 5 were studied in 118 cases of gastric carcinoma and compared with proliferation, apoptosis and E-cadherin expression. Expression of all these claudins could be seen in gastric carcinoma, most prominently for claudin 4, and least expression was found for claudin 5. All claudins showed significantly more expression in gastric carcinomas of intestinal type. Their expression was significantly associated with each other. Expression of claudins 4 and 5 was associated with E-cadherin. Strong expression of claudin 5 was associated with higher cell proliferation and apoptosis. Claudin 3 expression had an association with a better prognosis of the patients, especially in the intestinal type. The results show that expression of claudins 1, 3, 4 and 5 is lower in diffuse-type gastric carcinomas. Possibly they play a role in determining the diffuse phenotype and loose cohesion of cells in diffuse type of gastric carcinoma in a similar manner as E-cadherin. The loss of their expression does not clearly associate with poorer prognosis of the patients, except for claudin 3, where strong expression was associated with a better outcome of the patients, a feature especially related to intestinal-type tumours.

Introduction

Claudins are tight junctional proteins which are present at epithelial and endothelial cell membranes [22, 23]. Tight junctions are structures which regulate the flow of water, ions and various macromolecules through paracellular spaces, and claudins are crucial for this barrier function [22–24]. In addition to claudins, tight junctions contain occludin and tight junctional proteins zonula occludens ZO-1, ZO-2 and ZO-3, which show close association. ZO-2 associates with occludin and claudins at the cell membrane and also with ZO-1 and ZO-3 and the actin cytoskeleton [14]. At present, at least 23 different claudins are known in humans, and their expression may vary in different cells and tissues of the body [24]. Claudin 2, for example, is found in murine liver and kidney, but not in lung tissue [14]. On the other hand, claudin 4 is found in murine lung and kidney, but not in liver [14]. Claudin expression may also be different in some tissues like those in mouse and rabbit kidney, where variable expression is found in different tubular segments of the nephron [5, 16]. Claudin expression varies also in gastrointestinal tissues. In rat liver, claudin 4 was absent and claudin 5 was only present in endothelial cells, whereas claudin 3 was uniformly expressed and claudin 2 was more strongly expressed in periportal hepatocytes [15]. In rat pancreas, claudin 2 was expressed in junctional epithelia ductal cells, whereas claudin 5 was present in acinar cells and claudins 3 and 4 in both [15]. Site-specific differences in claudin expression can also be found in the gastrointestinal tract [15]. In rat gut, differences in claudin expression were also seen in mucosa between the surface and basal epithelia [15].

In human tissues and in tumours in general, expression of different claudins has not been extensively studied. Elevated claudin 3 expression compared to normal tissues has been shown in rat prostate carcinoma [9]. Similarly, overexpression of claudins 3 and 4 has been shown in breast and ovarian carcinoma [4, 6, 7]. On the other hand, loss of claudin 7 appears to be associated with a more aggressive behaviour of breast carcinoma [6]. In pancreatic adenocarcinoma and its precursor lesions, claudin 4 overexpression

has been found to be present [12, 20]. In soft tissue lesions, claudin 1 can be used as a marker for perineurinoma [1]. Interestingly also, claudins may have potential in treatment of cancer. In claudin-4-expressing pancreatic cancers, administration of clostridium perfringens enterotoxin results in tumour cell necrosis due to the fact that claudin 4 binds and serves as a receptor for this enterotoxin [13]. Similar results with claudins 3 and 4 have been obtained in breast carcinoma [7].

Distribution of claudin in gastric neoplastic or non-neoplastic tissues has not been studied so far. Our aim was to study the expression of claudins 1, 3, 4 and 5 in a set of gastric carcinomas. The results were associated with tumour proliferation and apoptosis as determined by Ki67 immunostaining and TUNEL assay. We also evaluated expression of claudins 1, 3, 4 and 5 as a prognostic marker by investigating their association with patient survival and tumour stage.

Materials and methods

Study material

There were 118 cases of gastric carcinoma collected from the files of the Central University Hospital of Tampere. Additionally, eight cases of non-neoplastic mucosa were included. All the materials had been fixed in 10% buffered formalin and embedded in paraffin. The array blocks were constructed with a custom-built instrument (Beecher Instruments, Silver Spring, MD, USA). The sample diameter of the tissue core in the array block was 600 μm . Because of the small size of the punch biopsy, at least three biopsies were obtained from the same case, and all samples were analysed. The histological diagnosis of the tumours was based on the criteria of Lauren et al. [3, 8]. The cases consisted of 50 intestinal-, 56 diffuse- and 12 mixed-type tumours. There were 24 stage-I, 26 stage-II, 43 stage-III and 25 stage-IV tumours [18]. In 50 cases, samples from local regional or distal lymph node or peritoneal metastases were available. Survival of patients and other relevant clinical data were obtained from patient journals.

Immunohistochemistry of claudins and E-cadherin

The primary antibodies used in the immunostaining were all purchased from Zymed Laboratories (South San Francisco, CA, USA) designed to be used in formalin-fixed, paraffin-embedded tissues. They were polyclonal rabbit anti-claudin 1 (clone JAY.8), polyclonal rabbit anti-claudin 3 (clone Z23.JM), monoclonal mouse anti-claudin 4 (clone 3E2C1), monoclonal mouse anti-claudin 5 (clone 4C3C2) and monoclonal mouse anti-E-cadherin (clone HECD-1) [17, 21]. Before application of the primary antibodies, the sections were heated in a microwave oven in 10 mmol/l citrate buffer, pH 6.0, for 10 min. For E-cadherin, pH 9.0 was used, and heating was done for 15 min. After 60 min

incubation with the primary antibody (dilution 1:50 for anti-claudins 1, 3, 4, and 5, and 1:200 for E-cadherin), a biotinylated secondary antibody and Histostain-SP kit (Zymed Laboratories) was used. For all the immunostainings, the colour was developed by diaminobenzidine, after which, the sections were lightly counterstained with hematoxylin and mounted with Eukitt (Kindler, Freiburg, Germany).

Negative control stainings were carried out by substituting non-immune rabbit or mouse serum and PBS for the primary antibodies. As positive controls, non-neoplastic kidney, breast, skin and liver samples were used.

The immunostaining was assessed as follows:

- =no immunostaining present
- + =less than 25% of cells positive
- ++=25–50% of cells positive
- +++ =50–75% of cells positive
- ++++=75–100% of cells positive

In the evaluation, membrane-bound positivity was considered significant. Inasmuch as several biopsies of same tumour were simultaneously present, all samples were evaluated separately, and the average value was used to represent the whole immunoreactivity in tumours.

Ki67 immunohistochemistry

The determination of cell proliferation activity in 5- μm tissue sections was based on the assessment of Ki67^{MIB-1} immunoreactive cells. The antigen retrieval by microwave oven processing (in citrate buffer, twice at 850 W for 5 min) was followed by immunostaining with a mouse monoclonal antibody (IgG, Immunotech S.A. Marseilles, France) at 1:40 dilution. The bound antibodies were visualised with a streptavidin–biotin immunoperoxidase technique (Zymed Laboratories) using diaminobenzidine (0.5 mg/ml) as a chromogen. The sections were counterstained with ethyl green. The sections were analysed with a CAS image analyser giving the percentage of positively labelled tumour cell nuclei in 20 separate high-power fields for each tumour.

Assessment of apoptosis

Paraffin sections (3 μm) were cut on SuperFrost Plus objective slides (Menzel-Gläser, Germany). The sections were de-waxed in xylene and dehydrated through a graded series of ethanol to PBS. After proteinase K digestion (Sigma Chemical Co., St. Louis, MO, USA) for 15 min, apoptotic cells were demonstrated using an ApoTag in situ apoptosis detection kit (Oncor, Gaithersburg, MD, USA) according to the manufacturer's instructions. In the terminal deoxynucleotidyl transferase (TdT) nick end labelling method, the recommended TdT concentration was, however, reduced eightfold. Direct immunoperoxidase detection of digoxigenin-labelled dUTP was followed by counterstaining in 0.02% methyl green in 0.1 mol/l acetate buffer (pH 5.2) for 15 min.

Table 1 Claudins 1, 3, 4 and 5 expression in primary lesions of gastric carcinoma

	Claudin			
	1	3	4	5
–	19 (17.0%)	35 (30.7%)	14 (12.7%)	57 (50.4%)
+	8 (7.2%)	13 (11.4%)	5 (4.5%)	12 (10.6%)
++	25 (22.3%)	18 (15.8%)	22 (20%)	16 (14.1%)
+++	29 (25.9%)	11 (9.7%)	19 (17.2%)	15 (13.3%)
++++	31 (27.7%)	37 (32.4%)	50 (45.4%)	13 (11.5%)
Total	112	114	110	113

Statistical analysis

SPSS for Windows (Chicago, IL, USA) was used for statistical analysis. The significance of associations was determined using Fisher's exact probability test, correlation analysis and two-tailed *t* test. Survival was analysed with the Kaplan–Meier curve, and significance of associations was analysed with log rank, Breslow and Tarone–Ware tests. Cox regression multivariate model (stepwise for-

ward) was used in multivariate analysis. Probability values ≤ 0.05 were considered significant.

Results

In non-neoplastic mucosa, strong claudin 1 expression was seen in corpus and antral epithelia and glands. Areas with intestinal metaplasia also showed expression. With claudin

Fig. 1 Immunostaining of claudins 1 and 3 in gastric carcinoma. Histology of an example of an intestinal (a) and a diffuse (b) gastric carcinoma. Strong membranous expression for claudin 1 (c) and claudin 3 (d) is seen in an intestinal-type tumour, whereas the diffuse type is negative for claudin 1 (e) and claudin 3 (f)

Fig. 2 Immunostaining of claudins 4 and 5 in gastric carcinoma. A histology of an example of another case of an intestinal (a) and a diffuse (b) gastric carcinoma. Strong membranous expression for claudin 4 (c) and claudin 5 (d) is seen in an intestinal-type tumour, whereas the diffuse type is negative for claudin 4 (e) and claudin 5 (f)

3, corpus-type mucosa showed strong expression, whereas expression was weaker in antral mucosa and in areas of intestinal metaplasia. Claudin 4 was weak in antral mucosa; only some basal glands showed staining. Staining in corpus mucosa was stronger, but weaker than with claudins 3 or 1. Areas with intestinal metaplasia, however, showed strong claudin 4 expression. Expression of claudin 5 was also seen

in corpus-type mucosa and in intestinal metaplasia; antral mucosa again showed very weak expression.

The frequency of claudins 1, 3, 4 and 5 expression is shown in Table 1. As can be seen from the table, claudin 1 expression was observed in 83%, claudin 3 in 69%, claudin 4 in 87% and claudin 5 in 49% of the cases (Figs. 1 and 2). Strongest expression was seen for claudins 4 and 3, with

Table 2 Claudins 1, 3, 4 and 5 and E-cadherin expression in different histological types of gastric carcinomas (primary tumours)

	Diffuse	Mixed	Intestinal	Total	Apoptosis (%)	Proliferation (%)	Sum

* $p=0.02$

** $p=0.01$

*** $p=0.024$

claudin 5 showing the least number of strongly positive cases. Inasmuch as the median point for expression of claudins 1, 3 and 4 was ++ and for claudin 5 about +, these were used as breaking points in analysing the data.

The frequency of claudin expression in gastric carcinomas of different histological types can be seen in Table 2. According to the histological diagnosis, diffuse-type tumours showed less claudin 1 ($p=0.006$), claudin 3 ($p=0.004$), claudin 4 ($p=0.004$) and claudin 5 ($p=0.0001$) positivity than intestinal types. No difference was observed between diffuse type and mixed type. There was, however, a significant difference in claudin expression between mixed and intestinal types in claudin 3 ($p=0.03$), claudin 4 ($p=0.02$) and claudin 5 ($p=0.03$) expression, with the latter tumours showing cases with more reactivity.

When compared to each other, significant associations were found between all claudins. There was a significant association between claudin 1 and claudin 3 ($p<0.001$), claudin 4 ($p=0.002$) and claudin 5 ($p=0.002$) expression. Claudin 3 associated with claudin 4 ($p=0.001$) and claudin 5 ($p<0.001$), and claudin 4 associated with claudin 5 ($p<0.001$) expression.

E-cadherin expression was also studied in the samples. Low expression was found in 42% and high expression in 57% of the cases. The distribution of immunoreactivity in different subtypes is shown in Table 2. In diffuse- and mixed-type carcinomas, 45 and 38%, respectively, showed strong positivity for E-cadherin, whereas 72% of intestinal-type carcinomas were strongly positive. There was a strong association between claudin 4 and claudin 5 and E-cadherin expression ($p=0.002$ and $p=0.001$, respectively) but not with claudin 1 ($p=0.475$) or claudin 3 ($p=0.175$). Diffuse carcinomas expressed claudin less frequently than the intestinal type ($p=0.007$). In addition, mixed-type tumours showed less reactivity than the intestinal types ($p=0.03$).

The mean apoptotic index in gastric carcinoma was $0.91\pm 1.67\%$. No difference in apoptosis was found between different histological tumour types. There was no difference in the extent of apoptosis between claudins 1, 3 or 4 expression; tumours with stronger claudin 5 expression had, however, significantly more apoptosis (1.37 ± 2.20 vs $0.66\pm 1.28\%$, $p=0.02$). Apoptosis did not associate with survival of the patients ($p=0.37$), nor was it associated with tumour stage ($p=0.35$).

The mean proliferation index in gastric carcinomas was $31.16\pm 15.36\%$. Diffuse gastric tumours had a significantly higher proliferation index ($34.62\pm 12.88\%$) than tumours of the intestinal type ($25.37\pm 18.13\%$, $p=0.001$). No difference was observed between stage-I–II and stage-III–IV tumours, and proliferation ($p=0.72$) (Table 3). Metastatic lesions had a slightly lower MIB index ($25.64\pm 14.21\%$) than primary lesions ($30.32\pm 15.04\%$), but the association did not reach statistical significance ($p=0.058$). As with apoptosis, tumours expressing stronger claudin 5 had a significantly higher proliferation index (34.1 ± 12.7 vs $28.8\pm 16.4\%$, $p=0.024$). Similar phenomenon was seen with claudin 3 (34.4 ± 15.1 vs $28.4\pm 14.8\%$, $p=0.010$).

There was no significant difference in survival between the different histological types of tumours ($p=0.37$, log

Table 3 Claudins 1, 3, 4 and 5 expression in relation to tumour stage and apoptosis and proliferation in tumours of different stages

	Stages I–II		Stages III–IV
Claudin 1	0	21	24
	1	23	29
Claudin 3	0	21	35
	1	23	19
Claudin 4	0	19	19
	1	24	34
Claudin 5	0	29	32
	1	16	23
Apoptosis	0.75±1.61%		0.83±1.12%
Proliferation	29.5±14.4%		30.4±16.1%

For claudins 1, 3 and 4: 0 Negative or + or ++, 1 +++ or more
For claudin 5: 0 Negative or +, 1 ++ or more

Fig. 3 Kaplan–Meyer curve for claudin 3 in the whole material (a) and separately in intestinal-type tumours (b). Patients with tumours expressing claudin 3 show a better survival than negative ones

rank). There was, however, a significant difference in survival between stage-I–II and stage-III–IV tumours ($p < 0.0001$, log rank), but not between stage-I and stage-II tumours ($p = 0.36$, log rank) or between stage-III and stage-IV tumours ($p = 0.38$). In stage-I–II tumours, survival did not associate with proliferation ($p = 0.90$). Similarly, in stage-III–IV tumours, survival did not associate with proliferation ($p = 0.64$). Claudin expression was not associated with the stage of the tumours, nor was there any significant difference in claudin expression between primary and metastatic lesions. Expression of claudin 3 tended, however, to be stronger in lower stage tumours, but the association did not reach statistical significance ($p = 0.067$). Claudin 1 ($p = 0.40$), claudin 4 ($p = 0.39$) or claudin 5 ($p = 0.29$) did not associate with survival of the patients. With claudin 3, however, the association tested with log rank was near significant ($p = 0.08$), and with Breslow ($p = 0.035$) and Tarone–Ware ($p = 0.049$), it was significant, with cases showing stronger claudin 3 having a better outcome (Fig. 3). If tumours of intestinal types were analysed separately, the association with claudin 3 expression was even stronger ($p = 0.0113$, log rank; $p = 0.0011$, Breslow; $p = 0.0029$, Tarone–Ware), whereas no other claudin showed any significant association if diffuse and intestinal types were analysed separately. According to Cox’s multivariate model, claudin 3 or any other claudins did not have independent prognostic value. In this respect, tumour stage was the only significant factor ($p = 0.0094$).

Discussion

In this study, expression of claudins 1, 3, 4 and 5 was studied in 118 cases of gastric carcinoma. To evaluate changes of expression associated with tumour progression, samples from metastatic sites were also included. Some samples of non-neoplastic mucosa were also included.

The results show variable and heterogenous expression of claudins 1, 3, 4 and 5 in gastric carcinoma. The most prominent expression of claudins was seen for claudins 1 and 4, where about 80% of cases showed positivity, whereas expression was weaker for claudin 3, which showed 69% of cases positive, and for claudin 5, which showed 50% of cases positive.

Comparison of claudins in different epithelial types of tumours showed that diffuse-type carcinomas showed overall lower expression of claudins compared with intestinal types. Thus, loss of claudin expression may be one phenotypic feature distinguishing these two tumour types in analogy with E-cadherin, the expression of which is also lost in diffuse-type carcinoma [10, 11]. In accordance with this, we also observed lower E-cadherin expression in diffuse carcinomas. It might also be that loss of claudin and E-cadherin expression is somehow interrelated inasmuch as E-cadherin has been shown to influence the formation of tight junctions and desmosomes although it mainly mediates the assembly of adherens junctions [2, 25]. In line with this, there was an association between expression

of claudins 4 and 5 and E-cadherin. At present, little data are, however, available on the functional association between E-cadherin and claudins.

E-cadherin expression has been associated with a poorer prognosis of the patients [10, 11]. In general, such an association could not be seen with claudins, except for claudin 3, where its lowered expression was associated with a marginally poorer prognosis. This feature appeared to be associated especially with intestinal types of tumours because when separately analysed, diffuse carcinomas did not show any significant association. According to Cox’s multivariate model, the association with survival did not, however, have independent prognostic value. The only parameter showing independent prognostic value in this material was tumour stage. Stage was not, however, associated with claudin expression, neither did we find any differences in claudin expression between primary tumours and tumours from metastatic sites. Thus it appears that claudin expression has no significance during tumour progression. In intestinal metaplasia, which is a risk factor for gastric carcinoma [3], expression of claudins 1, 3, 4 and 5 seemed to differ at least from antral mucosa cells inasmuch as in the former, expression for claudin 1, 4 and 5 appeared to be more strongly present. It would be interesting in this respect to test their expression in early dysplastic lesions of gastric mucosa and other sites.

Claudin 5 has been associated with endothelial cells, and in some studies, it is suggested to be present only in endothelial cell junctions [22, 23]. In our previous studies, we, however, observed claudin 5 in carcinomas such as breast carcinoma [19]. In addition, in this study, claudin 5 expression was seen in a proportion of gastric carcinomas. Interestingly, claudin 5 expression seemed to be positively associated with biological markers associated with tumour growth, such as proliferation and apoptosis. The reason for this is obscure because there are no known mechanisms to link claudin 5 expression to them. Because claudin 5 is also present in endothelial cells, tumours showing claudin 5 expression could have some additional affinity for blood vessels. However, claudin 5 expression was not clearly different in metastatic lesions compared to primary tumours, indirectly speaking for the fact that its expression does not increase vascular invasion. On the other hand, some other claudins such as claudin 3 are also present on endothelial cells, and interactions based on claudin expression between endothelial and epithelial cells could thus be complex.

In conclusion, tight junctional proteins claudins 1, 3, 4 and 5 show variable expression in gastric carcinoma, and their expression seems to be lower in diffuse-type carcinomas. In this respect, they resemble E-cadherin and, together with this molecule, might contribute to the loose cohesion and histological appearance of diffuse carcinomas. Of the claudins studied here, claudin 3 expression appeared to be associated with a marginally better outcome for patients, a feature that was especially related to the intestinal type.

Objective, planimetry-based assessment of megakaryocyte histological pictures in Philadelphia-chromosome-negative chronic myeloproliferative disorders: a perspective for a valuable adjunct diagnostic tool

Received: 14 June 2005 / Accepted: 19 August 2005 / Published online: 12 October 2005
© Springer-Verlag 2005

Abstract Philadelphia-chromosome-negative chronic myeloproliferative disorders (Ph⁻ CMPDs)—essential thrombocythemia (ET), chronic idiopathic myelofibrosis (CIMF), and polycythemia vera (PV)—may show clinical and morphological similarities, particularly at the early stages. The differential diagnosis of Ph⁻ CMPDs is important due to their different treatment and prognosis. Cytological features of megakaryocytes are considered valuable in this differentiation. To establish an objective measure of megakaryocyte dysplasia in Ph⁻ CMPDs, we performed computer-assisted morphometry of more than 4,000 cells from 20 cases of ET, 10 of CIMF, 10 of PV, and 10 controls. Megakaryocyte sets from three Ph⁻ CMPDs differed significantly in respect to many planimetric parameters, but not a single shape or size parameter could have been used as a discriminative tool between the entities. However, the discriminant function analysis with the simultaneous assessment of 12 planimetric variables allowed for a proper classification of 20 of 20 ET, 10 of 10 PV, and 9 of 10 CIMF cases based solely on the morphometric features of megakaryocytes. Additionally, we identified certain new patterns of megakaryocytes specific for ET, PV, and CIMF, which, although not dominating in one Ph⁻ CMPD, are unlikely to occur in two others. Objective measurements of megakaryocyte sizes and shapes may assist the diagnosis of Ph⁻ CMPDs.

Keywords Megakaryocytes · Chronic myeloproliferative disorders · Essential thrombocythemia · Polycythemia vera · Chronic idiopathic myelofibrosis

Introduction

Chronic myeloproliferative disorders (CMPDs) lacking the Philadelphia chromosome and/or its molecular equivalent—the BCR/ABL translocation (Ph⁻)—encompass a group of hematopoietic neoplasms usually characterized by an indolent but progressive course. Ph⁻ CMPDs manifest with effective hemopoiesis, cellular bone marrow showing inconsistent tendency for fibrosis, and a variably increased risk of transformation into acute leukemia [10]. The most frequent Ph⁻ CMPDs—essential thrombocythemia (ET), chronic idiopathic myelofibrosis (CIMF), and polycythemia vera (PV)—demonstrate both similarities and profound differences, with the worse prognosis attributed to CIMF, the intermediate to PV, and the most favorable to ET [2, 19]. The different biology of Ph⁻ CMPD is reflected in the contemporary therapeutic approach. Some of the patients with CIMF are considered as candidates for an allogeneic bone marrow transplantation [4, 24], whereas many patients with ET require only a “watch and wait” approach or noncytotoxic medications [21]. A recent trend for the detection of Ph⁻ CMPD at an earlier age, combined with the polarization of therapeutic strategies for the three basic entities, increased the demand for an accurate differential diagnosis particularly at the earlier stages, when the clinicopathological pictures of Ph⁻ CMPD may markedly overlap.

The traditional diagnostic approach to Ph⁻ CMPD was exemplified by the sets of criteria developed by the Polycythemia Vera Study Group (PVSG) for PV [1, 18], ET [17], and CIMF [11]. According to PVSG, the diagnostic “center of gravity” was placed within a clinical picture of a disease, whereas the histology of the neoplastic tissue was largely or even completely disregarded. An alternative approach stressing the utility of morphological assessment,

particularly the value of a trephine bone marrow biopsy, was proposed by the groups from Hanover [6, 7] and Cologne [28]. Of particular importance was the description of the very early (“prefibrotic”) CIMF [26]. Most cases of prefibrotic CIMF, when diagnosed according to PVSG, are misclassified as ET or left unclassified [29]. Both approaches, the “clinical” and the “histological,” were combined in the contemporary WHO classification criteria [10], although the impact of the PVSG on the WHO typology seems to be stronger. A recently published comprehensive set of diagnostic criteria based on both PVSG and WHO standards takes into account both the clinics and the pathology of Ph- CMPDs [15].

The issue of transition among individual Ph- CMPDs or the existence of borderline cases is highly controversial and not merely academic, taking into account the different consequences of specific diagnoses, particularly when the differentiation between ET and CIMF is considered. Another source of controversy is the very early stages of Ph- CMPD, when the diagnostic criteria usually cannot be fully met and the disease is frequently subclinical. Gradual lowering of the “diagnostic” platelet threshold for ET has gained wider acceptance [8, 13, 22], and the concept of an already mentioned prefibrotic CIMF was almost universally adopted. However, the notion that PV may present with the red blood cell values at the upper norm is still not accepted, although conceptually such a phase in the natural history of this disease has to exist. Both the “borderline” and the early cases of Ph- CMPD are not infrequently eliminated from the research series, but their stubborn existence in the clinical practice makes the differential diagnosis in the CIMF-ET-PV triangle sometimes very challenging and fascinating. The role of a surgical pathologist (hematopathologist) in this process should not be underestimated.

The histological assessment of bone marrow suspected for Ph- CMPD includes all aspects of hematopoietic, stromal, and osseous pathology in the context of complete clinical data, optimally accompanied also by peripheral blood and bone marrow smears. The most important single element of bone marrow histology in this context is the morphology of megakaryocytes, which was stressed by the seminal paper describing the Hanover classification [6] and which was also appreciated by the WHO [10]. According to both sources, the megakaryocytes in Ph- CMPD tend to cluster and show different and characteristic alterations in their morphology. In CIMF, they are pleomorphic, with

balloon-shaped, not deeply lobulated nuclei; in PV, they show only minor shape deviations and are not really pleomorphic, whereas in ET, the typical megakaryocytes are described as enlarged and deeply lobulated [6].

We designed this study to provide a more objective measure of megakaryocyte shapes in Ph- CMPD. We tried to identify such numerical characteristics of their size and shape that could be potentially useful in the diagnostic practice. We stressed that our major goal was not in differentiating the normal megakaryocytes from their CMPD counterparts, as in the diagnostic practice, the histological differentiation between reactive conditions and Ph- CMPDs is usually relatively easy. Instead, we focused on the differences between otherwise typical cases of CIMF, PV, and ET to provide a starting point for classification of more challenging cases.

Materials and methods

The study material encompassed the representative trephine bone marrow biopsies from the files of the Department of Pathomorphology, Collegium Medicum, Jagiellonian University, from the consecutive patients diagnosed with ET, CIMF, and PV starting from the year 2000 and those not treated with cytostatics prior to the biopsy. We selected 10 cases of PV, 10 cases of CIMF, and 20 cases of ET fulfilling the WHO criteria for particular Ph- CMPDs [10]. The cases with suboptimal biopsy quality or those that raised any diagnostic controversies were avoided. Extremely advanced cases of PV (post polycythemic myelofibrosis) and CIMF (presenting with osteomyelosclerosis) were not considered. The basic clinical features of the study group are given in Table 1.

Since completely normal bone marrow tissue samples are practically unobtainable, we constructed a control group of 10 patients with no neoplastic bone marrow disease, mostly the negative pretreatment staging biopsies of patients with lymphoma demonstrating no significant pathology. All the trephines were routinely fixed in formaldehyde, decalcified in a commercial medium (Shandon TBD-1 Decalcifier, Thermo Electronic Corporation), embedded in paraffin, and cut into 3- to 4- μ m sections. The dewaxed sections were stained with hematoxylin and eosin (H & E), periodic acid-Schiff, Giemsa, and Gomori silver. The latter three special stains were used for diagnostic purposes. The megakaryocytes were identified under

Table 1 Clinical features of 40 cases of Ph- CMPD whose megakaryocytes were evaluated in this study

an Olympus BX41 microscope with an Olympus 60× UPlanApo lens. Electronic photographs of 20 consecutive nonoverlapping high-power fields along a serpentine way over the H & E slides were taken. The size of a single picture was 288.2×217 μm (0.062539 mm²), represented by 4,080×3,072 (12,533,760) pixels. Only the areas containing well-preserved hematopoietic tissue were documented. This procedure was aimed at collecting a set of representative and nonbiased high-quality pictures of megakaryocytes for each case. Additionally, the H & E slides were screened with a ×20 lens to identify the most characteristic and diagnostic megakaryocytes for each case. These subjectively selected cells were then photographed using the ×60 lens (10 high-power fields/case) and constituted an accessory set of data.

Collected pictures were subjected to further processing using an application designed by one of us (KO) on the basis of the commercial image analysis system Analysis pro v. 3.2 (Soft Imaging System GmbH, Münster, Germany). This application allowed manual delineation of a selected cell and its nucleus and automatically converted the H & E picture of the cell into a two-color bitmap, performing also the measurements. Only the megakaryocytes with an identifiable nucleus were analyzed. The measurements included the standard parameters of the cell and its nucleus, such as the areas, maximal and minimal diameters, and the perimeters. The application recorded the number of nuclear lobes and allowed further calculation of secondary planimetric characteristics. These included the following:

- The nucleocytoplasmic (NC) ratio based on the quotient of respective areas
- The shape factor (SF), $SF=L^2/4\pi S$, where L represents the perimeter length and S the surface area
- The compactness factor (C), $C=D_{\min}/D_{\max}$, where D_{\min} is the minimum diameter and D_{\max} the maximum diameter

Fractal geometry may provide additional information on the shape complexity of biological structures [3]. To calculate the fractal dimensions of the megakaryocytes and their nuclei, the bitmaps were processed with a set of programs written by RK.

The differences between the groups (both diagnostic categories and individual cases) were explored using ANOVA, multiple ANOVA (MANOVA), and nested MANOVA, as well as nonparametric Kruskal–Wallis ANOVA methods with proper post hoc tests. Discriminant function analysis is used to predict membership in naturally occurring categories [9]. In this method, a variable is added to the model if it allows for a better discrimination of naturally existing groups. For each element (a megakaryocyte) the probabilities of belonging to a given class (like a disease entity) can be obtained [23]. This probability is based on the distance within a multidimensional space between a point representing the element (a megakaryocyte) and a central point (“centroid”) for a whole diagnostic class, encompassing all its elements. Each dimension of the multidimensional space represents one

selected planimetric parameter. Thus, all the megakaryocytes belonging to one diagnostic class (like CIMF or other Ph– CMPDs) form a “cloud” in a multidimensional space, and the location of each cell within this cloud can be specified. The average distance or average probability for all the megakaryocytes belonging to one case (one patient) may be considered as a candidate for a diagnostic parameter whose value takes into account all the relevant planimetric variables. The optimal combination of discriminative parameters included area, perimeter, shape factor, and fractal dimension of both the cytoplasm and the nucleus, and, additionally, the number of completely separated nuclear lobes, area-based NC ratio, maximal diameter of the cytoplasm, and elongation factor of the cytoplasm. All the “cytoplasmic” parameters referred in fact to the whole cellular cross sections, including the nuclear profile. These parameters were calculated for all 4,054 bitmaps (pictures of megakaryocytes). The results were normalized for each parameter, and for each case the means were counted. Mean results were submitted to the Discriminant Analysis module (one of the Multivariate Exploratory Techniques) of the STATISTICA v. 6.1 PL package (StatSoft Inc., Tulsa, OK, USA). The case was grouping variable and all 12 parameters were fixed as an independent variable list. Advanced options (stepwise analysis) were applied with the standard method, with 0.005 as the tolerance value. STATISTICA returned discriminant function analysis results, where a priori classification probabilities were established as the same for all groups, after which a posterior probability table was obtained.

All other statistical calculations were performed with the STATISTICA v. 6.1 PL. The statistical significance level was set at 0.05.

Results

The sets of the randomly selected megakaryocytes subjected to the image analysis encompassed 3,771 cells from Ph– CMPDs. This included 850 cells of CIMF (46–120/case, median 79.5), 1,140 of PV (51–225/case, median 96.5), and 1,781 of ET (36–162/case, median 78.5). As the cell sampling method reflected the differences in megakaryocyte density, these numbers may be easily converted to the density of megakaryocytes per square millimeter of bone marrow, yielding 68.0±17.6/mm² (mean±SD) for CIMF, 91.2±42.1/mm² for PV, and 71.2±29.7/mm² for ET. The control group contained 283 cells (18–51/case, median 27), with the average density of 22.6±8.1/mm². The much higher number of megakaryocytes in Ph– CMPDs compared to the normal or reactive marrow samples reflects their hyperproliferation in this group of diseases, and is a well-known phenomenon [6, 10, 15, 25]. The densities of megakaryocytes differed significantly between the study groups (Kruskal–Wallis ANOVA, $p<0.001$), but in the post hoc analysis, only the difference between control and each other group was significant. Tables 2 and 3 summarize the basic size and shape parameters for the cells and their nuclei, respectively.

The most important results of the megakaryocyte morphometry in Ph⁻ CMPDs may be summarized as follows: Megakaryocytes in Ph⁻ CMPDs, particularly in PV and CIMF, are larger than the normal cells and show markedly greater size variability. The most irregular cell outlines, reflected by low values of the shape factor, characterize the cells in ET, whereas the PV megakaryocytes show very smooth cellular contours, even more regular than those of the normal megakaryocytes. The CIMF megakaryocytes are typically more elongated (low compactness factor) than those in other Ph⁻ CMPDs and normal cells. Again, also in respect to the compactness factor, the PV megakaryocytes are even more regular than the normal cells.

The nuclear size roughly parallels the cytoplasmic size in all groups, but the relatively largest nuclei characterize the ET megakaryocytes. The NC ratio of PV cells is even smaller than that of the normal cells, in contrast to ET and CIMF. The shape and compactness factors of the nuclei of

the PV cells are the highest, reflecting the relatively regular shapes of the megakaryocytic nuclei in this disease. Megakaryocytes in Ph⁻ CMPDs show a marked tendency for the presence of completely separated nuclear lobes. The percentage of cells with two or more completely separated nuclear lobes is significantly higher in the ET megakaryocytes compared to other Ph⁻ CMPDs. The analysis of the planimetric parameters of 2,959 megakaryocytes selected subjectively as the most characteristic for a given case demonstrated very similar tendencies, with a bias for larger cell sizes (data not shown).

Figure 1 illustrates the examples of megakaryocytes identified as specific for the particular Ph⁻ CMPD by the discriminant function analysis. Of note are relatively large and slender megakaryocytes of CIMF and small, very regular cells with tiny nuclear cross sections found in PV. Several types of megakaryocytes were identified as unique for ET—these are long and slender cells smaller than those of CIMF; small, highly irregular firms with very strongly

Fig. 1 Examples of characteristic megakaryocytes identified using discriminant function analysis. The cells of the illustrated types may be rare, but their presence is probably specific for given disorders. **a** Cellular profiles illustrating certain hallmark cells in ET (small slender cells with compact nuclei, highly irregular small cells, large cell with a medusa-like nucleus), CIMF (very large slender cells), and PV (small round cells with tiny regular nuclear cross sections), and CIMF (very large slender cells). Two megakaryocytes from the control sets are given to illustrate the scale: an archetype medium-sized cell and a normal megakaryocyte with the maximal size achieved by the normal megakaryocytes. **b** Some hallmark megakaryocytes in their histological context. Scale bars correspond to 20 μm

segmented nuclei (usually clinging to other megakaryocytes); and relatively large cells with big, medusa-shaped nuclei (Fig. 1). The cells of all these types may be rare and may constitute a minority of megakaryocytes in a given case. However, they can be found in one Ph- CMPD (ET, PV, or CIMF), being unlikely to be found in the others. For instance, the cells specific for CIMF were selected on the basis of their belonging to the CIMF cloud, but outside the area of overlapping with the EP, PV, and normal clouds. The same principle was adopted for other Ph- CMPDs.

Despite the statistically significant differences at the level of sets composed of all the cells belonging to one disease category, the megakaryocyte populations in the individual cases of Ph- CMPDs showed a marked overlap in respect to the individual planimetric parameters. In other words, not a single numerical parameter can be used as a diagnostic “marker” for the differentiation within the

CIMF–PV–ET triangle. The best single (but not perfect) discriminator is a cytoplasm shape factor, demonstrated in Fig. 2a. The PV cases show very characteristic profiles with high mean values and low standard deviation, but the differentiation between ET and CIMF on the basis of this sole parameter cannot be done. The same is true for another strong discriminator at the entity level: the degree of complete nuclear segmentation (Fig. 2b).

However, when numerous planimetric parameters are considered simultaneously using discriminant function analysis, the individual cases (represented by subsets of megakaryocytes) may be assigned to the diagnostic categories with the specified probabilities. The results of the discriminant function analysis are presented in Table 4. Using this approach, we were able to classify properly 9 of 10 cases of CIMF, 10 of 10 cases of PV, and 20 of 20 cases of ET.

Fig. 2 Morphometric parameters constituting the strongest single disease discriminators among 40 cases of Ph- CMPD and 10 control cases. **a** The cytoplasm shape factor (measure of a shape roundness:

I for a circle, 0 for a segment). **b** The degree of complete nuclear segmentation

Discussion

According to contemporary standards, the diagnostics of the Ph- CMPD is a multidisciplinary process including the meticulous analysis of the clinical picture, peripheral blood and bone marrow cytomorphology, bone marrow histology, and chromosomal or molecular exclusion of the BCR/ABL translocation. Despite this complex approach (or perhaps because of it?), the attempts of unequivocal classification fail for some cases, leading to an existence of a CMPD unclassifiable (CMPD-U) category or to long periods of uncertainty in respect to the exact nosological position of the disease in some patients. The CMPD-U group in a summary of 256 Ph- CMPD cases from our institution constitutes 13.4% [20] and, in most other series, 10–20% of all Ph- CMPDs [10]. The percentage of patients in whom a Ph- CMPD is suspected, but not explicitly diagnosed, is really unknown due to the elimination of these “limbo” cases from the research studies. Our knowledge on the pathology of Ph- CMPDs, particularly at the earlier stages, is still very limited, prompting the search for new diagnostic markers of these diseases. A recently published study based on a multidisciplinary, clinicopathological approach explored the heterogeneity within a group of cases fulfilling the PVSG criteria for ET [5]. Surprisingly, upon the reclassification of 142 cases based on the WHO criteria, only 21% fit the WHO ET category, the remaining cases being assigned to the WHO CIMF group or deemed to be unclassifiable (ET/CIMF). Florena et al. [5] also found that the new markers, like the proliferative activity, the percentage of CD34 blasts, and the parameters describing the megakaryocyte clustering, differentiated these Ph- CMPDs. Lundberg et al. found the quantitative and qualitative differences in bone marrow vascular pattern

comparing nine cases of CML, seven cases of PV, and six cases of CIMF [14]. The presence of the numerous so-called “naked nuclei” of megakaryocytes may be a characteristic feature of CIMF [12]. Identification of new and possibly useful markers differentiating Ph- CMPDs in conjunction with the undeniable existence of still unclassifiable cases allows us to suspect that the classification system of Ph- CMPDs may undergo evolution in the nearest future.

Pathologists assessing the trephine bone marrow biopsies suspected for Ph- CMPD assign a great value to the features of megakaryocytes [6, 7, 15, 16, 27]. Increase in their number compared to the age norm, their clustering, and anomalies of the cytological features contribute markedly to the final diagnosis. Megakaryocytes are characterized by extremely complex shapes and significant inter- and intra-individual variability, making simple description of their anomalies very challenging. A planimetry-based approach adopted in this study was aimed at providing some objective data on megakaryocyte anomalies in Ph- CMPDs.

We decided to base our study on the histological material stained with H & E, the most widely used stain in a diagnostic histological practice. Our goal was to examine the megakaryocytes not “as they really are” (i.e., complex three-dimensional structures) but as we see them under the microscope in a situation of establishing an everyday diagnosis. That is why we relied upon routine staining instead of visualizing megakaryocytes with immunomarkers like CD42, CD61, or FVIIR. Although these methods allow for an identification of the higher number of megakaryocytes, particularly the smaller forms [25], they are not necessarily routinely used for the evaluation of a trephine bone marrow biopsy suspected for Ph- CMPD. Besides, at least in our experience, the antigen unmasking procedures

Boldfaced are the cases properly “classified,” i.e., those with probability of the true diagnosis higher than that of the differential diagnoses. Underlined are misclassified cases. The values represent relative probabilities for a case to belong to a given diagnostic category (control, CIMF, PV, or ET), calculated as the average of the probabilities for all the megakaryocytes in this case

adopted to the trephines frequently cause some tissue loss and shape artifacts that could possibly influence the morphometric parameters. The histological slides contain cellular cross sections, whereas the smears visualize the whole cells and apparently could offer a better insight into the megakaryocyte cytomorphology. However, although the cells shown in the smears are not crosscut, they are neither reflecting the “true” picture of a megakaryocyte, as they are inevitably squeezed in the process of the smear preparation. In addition, the intensity of this distortion may be proportional to the object (cell) size. Also, smears are not particularly practical for megakaryocyte assessment in CMPD due to at least two additional factors: much lower number of cells visualized even in a good smear compared to a good trephine (two orders of magnitude more), and a strong influence of fibrosis on the smear contents. Particularly, the megakaryocytes from the areas of an intense local fibrosis could have been underrepresented in the smears in a systematic way. Microscopic examination of human tissue is inevitably based on the assessment of artifacts, and, in fact, histopathology is nothing more than a science of interpretation of the profoundly altered (fixed, cut, and stained) tissue pictures. Adopting this utilitarian perspective, it should not matter whether a characteristic and possibly diagnostic cellular cross section represents a plane corresponding to the maximal cellular diameter or a marginal section, as the valuable diagnostic information may be contained in fact in both pictures. We stress that in the present study we did not attempt to reconstruct the three-dimensional view of the megakaryocytes in CMPDs, but rather to identify some characteristic H & E pictures seen in everyday practice and to link them with the specific clinical context.

Our study, based on the objective analysis of a large set of megakaryocytes, allowed us to propose some more detailed description of “average” megakaryocytes in the three most frequent Ph⁻ CMPDs. They may be summarized as follows:

CIMF: the largest megakaryocytes, but with the NC ratio resembling the normal cells; frequently elongated cellular shapes. The nuclei show irregular outlines but are lobulated to a lesser degree than in ET.

PV: the cells tend to be relatively large (comparable to CIMF) but show very regular and compact (most circle-like) shapes, even more regular than the normal cells. The presence of such megakaryocytes makes PV markedly different from two other Ph⁻ CMPDs. The nuclei often are relatively small (NC ratio even smaller than in the normal cells and other Ph⁻ CMPDs). The degree of nuclear lobulation is comparable to that in CIMF, but the nuclei show less irregular outlines and more compact shapes. Basing on many aspects of their morphology, the typical PV megakaryocytes may be described as large “hypernormal” cells.

ET: the mean cell size is comparable to that of normal cells and smaller than those in CIMF or PV, but the size variability in this group is most pronounced, and, notably, the giant cells not found in a normal marrow are present. The most elaborated cellular surfaces are

reflected by the lowest shape factor. They have the highest NC ratio—nuclei are usually relatively large compared to cell sizes, although cells with very small nuclei are not infrequent (NC ratio is highly variable compared to other Ph⁻ CMPDs and to the normal megakaryocytes). The nuclei show very prominent lobulation, with the highest fractal dimension and more than one third of the cells demonstrating more than two completely separated nuclear lobes. This is significantly higher than in other Ph⁻ CMPDs (~20%) and in the normal cells (~11%).

Of course, the above descriptions pertain to the whole population of cells. The megakaryocytic populations in Ph⁻ CMPDs are strongly diversified in practically all the aspects of their morphology to the extent of surpassing the variability of the normal cells. Occasionally, the presence of a few very atypical cells may provide a clue to the diagnosis, particularly in CIMF. Some rare but possibly “hallmark” types of the cells are illustrated in Fig. 1. They include extremely slender large cells (CIMF), almost perfectly round cells with disproportionally small and round nuclei (PV), and at least three types of atypical megakaryocytes in ET. We stress that these types of cells are not the most frequent for a given diagnostic category and in fact may constitute a small minority of megakaryocytes, being easily overlooked on screening inspection of a slide. For instance, in ET, the cells of this type correspond to approximately 2% of all megakaryocytes, whereas in the other two CMPDs, they may be slightly more numerous (up to 12%). Their presence is, however, very specific for a particular disease, as, for instance, the PV-specific almost-round megakaryocytes with tiny round nuclei are unlikely to be found in ET or CIMF.

The multiparameter planimetric analysis of megakaryocytes with our proposed algorithm based on the discriminant function-generated probabilities may be regarded as a basis for a future, potentially valuable adjunct in the diagnosis of Ph⁻ CMPDs. Of course, we do not imply that this diagnosis could be made solely on the basis of sizes and shapes of the cells belonging to a single hematopoietic lineage, but our preliminary data suggest that the diagnostic strength of this approach may be surprisingly high, with sensitivities and specificities surpassing 90%. One wrongly assigned case (CIMF by WHO and ET by the discriminative planimetric analysis) assessed retrospectively did not pose diagnostic doubts pointing out at typical early CIMF, with anemia, low platelet counts (68,000/ μ L), and slight but clear bone marrow fibrosis (+2). The second misclassified case was a nonneoplastic control, clinically idiopathic thrombotic purpura with the presence of antiplatelet antibody. In the course of this study, this patient was splenectomized, and the histological examination of the spleen did not reveal any features of myeloid metaplasia typical of CIMF.

Our findings prove that the amount of diagnostic information hidden in the shapes and sizes of megakaryocytes may be really impressive and that most cases of otherwise typical Ph⁻ CMPDs may be properly and objec-

tively classified solely basing on these data. We stress that no single planimetric parameter can be used as a categorization tool and that an efficient planimetry-based classification requires a multiparameter approach.

Several words of caution are mandatory. Our study is based on an analysis of a large number of cells but a limited number of cases (40 cases of Ph⁻ CMPDs). The procedure in its current technical implementation is labor-intensive, with the bottleneck step being the manual delineation of megakaryocytes and their nuclei. The more advanced computerization of this procedure is a tempting solution, but as we already realized, it is not easy, mostly due to such factors such as clustering of megakaryocytes (problems in the automated cell delineation), emperipolesis, and very variable nuclear staining contributing to the difficulties in the automated nuclear contour finding. Our study at this step involved only the typical cases of ET, CIMF, and PV in order to establish a starting point for further research on more complicated cases, particularly the early stages and/or borderline pictures. Thus, our preliminary results definitely need validation based on the more extensive research. Nevertheless, we believe that the results are very promising, and the technique, particularly when more extensively semi-automated, may provide a valuable accessory diagnostic tool.

Expression of bFGF/FGFR-1 and vascular proliferation related to clinicopathologic features and tumor progress in localized prostate cancer

Received: 25 April 2005 / Accepted: 20 August 2005 / Published online: 12 October 2005
© Springer-Verlag 2005

Abstract Microvessel density (MVD) has been associated with progression of prostate cancer. Although basic fibroblast growth factor (bFGF) is a known endothelial mitogen, the prognostic role of bFGF and its receptor FGFR-1 in prostate cancer has been controversial. The aim of our study was to examine the tissue distribution and prognostic significance of bFGF, FGFR-1, and microvascular proliferation. Sections from 104 radical prostatectomy specimens were examined by factor VIII/Ki-67 staining for proliferating capillary index (PCI) and MVD, and tissue microarray sections were immunostained for bFGF and FGFR-1. Increased PCI (median 0.49%) was related to strong stromal expression of bFGF ($P=0.003$) but was without prognostic impact. Strong bFGF staining was associated with well-differentiated tumors, no capsular penetration, low serum-prostate-specific antigen (s-PSA), low tumor cell proliferation, and increased time to biochemical failure ($P=0.007$), and was of independent prognostic im-

portance in multivariate survival analysis. bFGF expression in vessels was associated with low MVD ($P=0.0003$). In contrast, strong tumor cell FGFR-1 expression was related to high preoperative s-PSA. Thus, increased stromal and vessel bFGF was associated with less aggressive tumors. Our findings indicate a complex relationship between bFGF/FGFR-1 expression and prognosis of prostate cancer. Vascular proliferation revealed no prognostic impact in this study.

Keywords Prostate cancer · Vessel proliferation · Ki-67 · bFGF · FGFR-1

Introduction

Angiogenesis is essential for the growth and metastatic spread of malignant tumors, and it has been applied as a marker for tumor aggressiveness in several cancers [3, 12, 23]. Microvessel density (MVD), as described by Weidner et al. [49] as an estimate of tumor-associated angiogenesis, is shown to provide strong and independent prognostic information in multiple tumors [23]. In prostate cancer, high MVD has been linked to aggressive behavior [1, 2, 15, 21, 42, 50] and thus correlated with histological grade [1, 42, 50], tumor stage [1, 2, 15, 42], preoperative serum-prostate-specific antigen (s-PSA) [21], and time to recurrence [21]. Also, presence of glomeruloid microvascular proliferation (GMP) has been associated with clinical recurrence in these tumors [41]. However, several limitations of MVD have been pointed out [23], and the identification of additional prognostic markers and regulators of the angiogenic process is of both scientific and clinical interest [23], especially due to the increased use of targeted anti-angiogenic therapy.

A few previous studies on other tumors have focused on vascular proliferation as a candidate angiogenic marker [10]. In prostate and breast cancer, studies on a low number of cases have suggested that vascular proliferation might have no prognostic value [13, 47, 48], but larger studies are needed to be conclusive.

Basic fibroblast growth factor (bFGF or FGF2) is a known mitogen for endothelial cells [6, 16]. The role of bFGF in prostate cancer has been controversial, both in terms of cellular localization and the relationship with clinicopathologic phenotype and prognosis. In some studies, bFGF expression has been found in stromal cells in both benign prostatic hyperplasia (BPH) [7, 19, 39] and prostate cancer [17], using immunohistochemical staining of human tissue. This is in line with findings that bFGF mRNA is localized to stromal cells in prostate tissue [25, 39, 44]. However, others have reported an expression of bFGF in tumor epithelium by immunohistochemistry [4, 9, 43, 44].

FGFR-1 is one of the four known FGF receptors with shared sequence homology, FGFR-1–4, and is known to be required for the development and maintenance of the vascular system [32]. These receptors are coded by four genes with alternative splicing of exons coding for Ig-loop III, which changes their affinity for the different FGF ligands [26, 34, 36]. FGFR-1 is expressed in prostate cancer mainly as the IIIc isoform [31], with affinity for aFGF, bFGF, FGF4, FGF6, FGF8, and FGF9 [34]. A shift from the FGFR-1 IIIb isoform to IIIc in prostate cancer increases its affinity to bFGF to about 50-fold [51]. FGFR-1 has been immunolocalized in benign prostatic basal and stromal cells, whereas luminal cells were negative [17]. In prostate cancer, increased immunoexpression of FGFR-1 in tumor cells was significantly associated with higher Gleason scores [17], but beyond this study, the immunohistochemical expression of FGFR-1 has received little attention in prostate cancer. In cell culture studies, activation of FGFR-1 [14] and transfection of nonfunctioning FGFR-1 [35] have linked the up-regulation of FGFR-1 to increased proliferation and tumor aggressiveness in prostate cancer. In a recent study, FGFR-4, but not FGFR-3, was up-regulated in prostate cancer, and its expression was associated with tumor grade and survival [20].

On this background, the aim of our present study was to examine the immunohistochemical expression and prognostic significance of bFGF and its receptor FGFR-1 in a well-characterized series of prostate cancer patients treated by radical prostatectomy and with long follow-up. We extended our analyses of bFGF/FGFR-1 by including vascular proliferation as estimated by Ki-67/factor VIII staining and MVD. Such angiogenic markers are important to obtain improved prognostication and as candidate markers of predictive value for adjuvant treatment [23].

Materials and methods

Patients

This radical prostatectomy material has been presented previously [21]. Briefly, a series of 104 consecutive hospital-based radical prostatectomy specimens occurring during 1988–1994 were included. None of the patients treated by radical prostatectomy received radiotherapy before biochemical failure or clinical recurrence.

Clinicopathologic variables

The following variables were studied retrospectively: patient age at operation, largest tumor dimension, WHO histological grade, capsular penetration, seminal vesicle invasion, involvement of surgical margins, presence of lymph node metastasis, s-PSA before and after surgical treatment, clinical stage, tumor cell proliferation (Ki-67), microvessel density (MVD) [3, 12, 23], and GMP [41].

Tissue sampling

The entire prostate was cut into 5-mm transverse serial sections and was totally embedded. The upper and lower sections were then cut into parallel sagittal sections. Based on hematoxylin–eosin (HE) stained whole mount slides, the area of highest WHO tumor grade was selected, and corresponding areas were cut out of the paraffin blocks, re-embedded in paraffin, and sectioned for immunohistochemistry.

Tissue microarrays (TMA)

The technique of TMA was introduced in 1998 [30] and validated by independent studies of several tumor markers [24, 33]. For TMA construction, representative tumor areas were identified on HE slides. Tissue cylinders with a diameter of 0.6 mm were punched from the donor block and mounted into a recipient paraffin block using a custom-made precision instrument (Beecher Instruments, Silver Spring, MD). Three parallel tissue cylinders were sampled from each case, as has been suggested [24]. Sections of the resulting TMA blocks (5 μ m) were then made by standard technique and used for bFGF and FGFR-1 immunostaining.

Immunohistochemistry

The immunohistochemical staining was performed on formalin-fixed and paraffin-embedded archival tissue using regular slides (FVIII/Ki-67) and sections from TMA blocks (bFGF/FGFR-1).

Factor VIII/Ki-67 After de-paraffination, the tissue sections were subjected to heat-induced epitope retrieval in TRS, pH 9.9 (DakoCytomation, Copenhagen, Denmark, S3307), using a microwave oven at 500 W for 30 min. After pretreatment with proteinase K (Code S2032) in 10 min, the slides were incubated for 90 min with a monoclonal mouse Ki-67 antibody, clone MIB-1 (M7240, Dako, Copenhagen), diluted 1:50, and rabbit factor VIII (clone A0082, Dako) diluted 1:200, at room temperature. Secondary antibodies were HRP goat anti-rabbit Ig (P0448, Dako) diluted 1:50 and biotinylated goat anti-mouse Ig (E0433) diluted 1:100 with antibody diluent (S2022, Dako) and incubated for 60 min. For Ki-67, antigen localization was achieved by the 3-amino-9-ethylcarbazole-peroxidase (AEC-peroxidase) method, and for factor VIII by strep-

tavidin-biotinylated alkaline phosphatase method and fast blue.

Vessels located between benign glands at some distance from the tumor area served as positive internal controls. Slides in which the primary antibody was omitted served as negative controls.

bFGF and FGFR-1 After de-paraffination, TMA slides were subjected to heat-induced epitope retrieval in citrate buffer (pH=6.0) for 20 min, using a microwave oven at 500 W. The slides were then incubated overnight at room temperature with monoclonal anti-bFGF antibody (GF22, Oncogene, MA) diluted 1:200. For FGFR-1, a polyclonal FGFR-1 antibody (Flg, SC-121, Santa Cruz, CA) was used, diluted 1:150 and incubated for 1 h at room temperature. Staining for bFGF and FGFR-1 was performed on a Dako TechMate 500 slide processing equipment (Dako), using the standard avidin–biotin method. Finally, the antibody was localized by the AEC-peroxidase method with Harris hematoxylin as counterstain.

Evaluation of staining results

Microvessel density In order to quantitate microvessels, the sections were first examined at low and intermediate magnifications ($\times 30$, $\times 125$) to identify the most vascular areas (“hot spots”), and counting was done within this area (entire tumor area), according to Weidner et al. [49], using 10 HPF ($\times 250$). The MVD counts were recorded as the average of all fields examined in each case, as described earlier [21].

Proliferating capillary index (PCI) The PCI was estimated as the fraction (%) of Ki-67 positive vessels, according to an earlier study [10]. Positive vessels were identified as vessels with staining of an endothelial cell nucleus in the vessel wall (Fig. 1a). Inflammatory cells in vessel lumens stained more weakly, and Ki-67 staining tumor cells close to the outside of vessel walls were excluded.

bFGF/FGFR-1 In our study, bFGF stained only stromal elements, including vessels (Fig. 1b), but not tumor cells, and expression in vessels and the stromal compartment was therefore recorded. FGFR-1 stained tumor cells (Fig. 1c) and not stromal elements, and expression in tumor cells was examined. For bFGF and FGFR-1, both staining intensity and positive area were recorded. A staining index (SI, values 0–9) was calculated as a product of staining intensity (0–3) and proportion of positive cells (0%=0, 1–10%=1, 11–50%=2, >50%=3). Strong staining (intensity 3) for bFGF was not found, and due to a great variation in proportion of positive cells in the 11–50% category, an additional cut point was used (11–25%, value 1.5). For vessel bFGF, staining in tumor-associated endothelial cells was recorded as absent or present. For sta-

Fig. 1 Double immunostaining (factor VIII/Ki-67) for vascular proliferation, showing Ki-67 staining in a positive endothelial cell nucleus in prostate cancer (a). bFGF expression by immunohistochemistry is located in stromal cells, but negative in cancer cells (b). Positive FGFR-1 expression in tumor cells (c). Scale bar=25 μ m

tistical purposes, cut-off points for SI categories were based on the distribution of values.

Follow-up

Data concerning s-PSA, loco-regional tumor recurrences, appearance of distant metastases, and patient survival were recorded [21]. Time from surgery until biochemical failure (defined as PSA elevation ≥ 0.5 ng/ml in two consecutive

blood samples) was noted, as well as the recurrence-free survival (time from surgery until the appearance of clinical loco-regional recurrences and/or distant spread). The last time of follow-up was December 2001. The median (mean) follow-up among patients without biochemical failure was 95 (94.6) months. During this period, 67 patients experienced biochemical failures, and 31 patients had clinical recurrences. No patients were lost to follow-up.

Statistics

Associations between variables were assessed by Mann–Whitney *U* test, and Pearson's chi-square test, when appropriate. Univariate survival analysis of time to biochemical failure and time to clinical recurrence was performed by the product-limit method (Kaplan–Meier method) and the log-rank test. The influence of covariates on failure-free survival was analyzed by the proportional hazard method and tested by the likelihood ratio (lratio) test. The level for inclusion of covariates in Cox's multivariate regression analysis was $P=0.10$. The analyses were performed by using the SPSS statistical package (ver 11.0, SPSS Inc., Chicago, IL, USA).

Table 2 Univariate survival analysis (Kaplan–Meier method) by vascular proliferation (PCI), stromal bFGF expression, vascular bFGF expression, and FGFR-1 expression in tumor cells, using time to biochemical failure or clinical recurrence after radical prostatectomy in 104 prostatic cancers

Results

Patient characteristics The median tumor dimension was 28 mm (range 10–45 mm). Of 104 cases, 10 tumors were well differentiated (WHO, histological grade), 66 moderately differentiated, and 28 poorly differentiated. Capsular penetration was demonstrated in 72 of 104 cases (69.2%). Seminal vesicle invasion was found in 35 of 104 cases (33.7%), and positive surgical margins were demonstrated in 55 of 104 cases (52.9%). Pelvic lymph node infiltration was found in 7 patients (6.7%) at the time of radical prostatectomy. Normal s-PSA value is for most practical purposes <4 ng/ml, but varies with age. The median preoperative s-PSA was 11.2 ng/ml (range 1.8–70.0). More details are available in a previous report [21].

Microvessel density The prognostic significance of MVD has previously been determined in this material [21]. Briefly, median MVD was 141 per millimeter squared (mean 151, range 55–324). The associations of MVD with actual parameters in this study are described below.

Proliferating capillary index Median PCI was 0.49% (mean 0.56%, range 0–1.79%). Increased PCI was significantly associated with high expression of stromal bFGF ($P=0.003$, Mann–Whitney *U* test, Table 1). PCI was not related to MVD, clinicopathologic parameters, time to biochemical failure or clinical recurrence. The median Ki-67 tumor cell proliferation index in our series was 6.7% [22].

Stromal expression of bFGF bFGF staining was mainly cytoplasmic, with a perinuclear concentration in stromal cells (Fig. 1b). Weak/absent staining (SI=0–1.5) was noted in 62 cases, and moderate staining (SI=2–8) in 42 cases. Strong stromal bFGF expression showed a significant association with well-differentiated tumors (WHO histological grade, Pearson's test, $P=0.045$), absence of capsular penetration (Pearson's test, $P=0.028$), low preoperative s-PSA (Pearson's test, $P=0.01$), and low tumor cell proliferation (Pearson's test, $P=0.01$).

Vascular expression of bFGF Presence of vessel bFGF expression was associated with low MVD ($P=0.0003$, Mann–Whitney U test, Table 1).

Tumor cell expression of FGFR-1 Staining of FGFR-1 was mainly cytoplasmic in tumor cells, without nuclear staining (Fig. 1c). Weak or absent staining (SI=0–4) was noted in 57 cases, and strong staining (SI=6–9) was observed in 47 cases. Strong tumor cell FGFR-1 expression was associated with preoperative s-PSA above 11.1 ng/ml (median value, Pearson’s test, $P=0.04$), but not with other variables.

Survival analysis In univariate survival analysis of time to biochemical failure, weak expression of stromal bFGF (SI=0–1.5) was associated with shorter time to biochemical failure (log-rank test, $P=0.007$, Table 2 and Fig. 2). Also, a nonsignificant trend between absent bFGF expression in tumor endothelial cells and shorter time to biochemical failure was present (log-rank test, $P=0.09$, Table 2). No significant survival differences were found for PCI and FGFR-1.

In multivariate survival analysis, including standard prognostic variables such as histological grade (by WHO), pathological stage and preoperative s-PSA as covariates, weak bFGF expression independently predicted biochemical failure (HR=1.8, $P=0.03$), along with pathological stage (HR=2.4, $P<0.01$), while histological grade (HR=1.7, $P=0.06$) was of borderline significance. When vessel bFGF was introduced separately into the Cox’s multivariate analysis, with standard prognostic variables as covariates, negative vessel bFGF expression was also an independent

predictor of time to biochemical failure (HR=2.8, $P=0.001$), as was pathological stage (HR=3.1, $P<0.01$), while histological grade (HR=1.7, $P=0.07$) and s-PSA (HR=1.7, $P=0.07$) were of borderline significance.

Discussion

We previously found that microvessel density (MVD) was a significant prognostic factor in this series of prostate cancer patients [21]. Since MVD has limitations as an angiogenic marker [23], it was of interest to focus on other aspects of the angiogenic phenotype. We found that the presence of proliferating vessels within the tumor tissue had no prognostic significance in this radical prostatectomy series. Vascular proliferation was not associated with MVD in accordance with data from a small study of prostate cancer [48]. In the latter study, no significant associations between vessel proliferation and MVD, Gleason score, or tumor proliferation (Ki-67) were found, but survival data were not presented. Our present series is the largest study of vascular proliferation in prostate cancer, and we are the first to report on patient prognosis and to use the method of double staining for Ki-67/factor VIII. This approach is assumed to be sensitive in detecting small and newly formed microvessels. Two studies on breast cancer reported no associations between vessel proliferation and MVD [13, 47], but these studies had no detailed survival data. In prostate cancer, the total amount of microvessels seems to be more important for clinical progress than the subgroup of newly formed vessels as detected by vascular proliferation. Still, increased vessel proliferation (PCI) was significantly associated with strong stromal expression of bFGF, and this finding is in accordance with bFGF as an endothelial cell mitogen [6, 16], thus validating PCI in this study.

Previous studies have differed regarding the anatomical localization of bFGF in prostate tissue. Our own study and four others have located bFGF mainly to stromal cells using immunohistochemistry [7, 17, 19, 39]. Some studies have also found bFGF expression in the tumor epithelium [4, 9, 43, 44], whereas three studies have located bFGF mRNA to stromal cells [25, 39, 44]. One of the latter studies still demonstrated bFGF positivity in the epithelial cells by immunohistochemistry [44]. Some of these differences might depend on the various antibodies used, as no single antibody localized bFGF to stroma and tumor cells simultaneously. bFGF has been shown to stimulate both stromal [19] and cultured epithelial cells [17] from the prostate. In one study, tumor cells were stimulated by autocrine bFGF production, although tumors did not show an increased malignancy in mice [38]. In our study, stromal bFGF expression was significantly associated with less aggressive tumors. The role of stromal bFGF in more aggressive prostate cancers might therefore be minor, and other angiogenic factors may be more important in this tumor subgroup.

Lack of bFGF expression in vessels tended to be associated with increased frequency of biochemical failure,

Fig. 2 Univariate survival analysis (Kaplan–Meier method): weak expression of stromal bFGF was significantly associated with decreased time to biochemical failure in localized prostate cancer. Number of patients in each group shown (events in parenthesis)

and vascular bFGF positivity was significantly associated with lower MVD. Expression of bFGF in vessels might indicate a more mature vasculature being associated with low-grade tumors. Similar observations have been reported for other tumors like melanoma [40], and bFGF has been suggested to promote vascular maturation [29].

In the prostate, other members of the FGF family have been reported, and some of these are locally stimulated by androgen, e.g., FGF-7, FGF-8, and FGF-10 [5]. FGF-9 is the predominant FGF in human prostate, but its role remains to be elucidated [37]. bFGF and FGF-7 might be induced by interleukin (IL)-1 α and IL-8, and they may play a crucial role in the development of prostatic hyperplasia [18, 19]. Different FGF-8 isoforms have been reported to play a key role in prostate carcinogenesis [46], and stronger FGF-8 expression correlated with increasing Gleason score, tumor stage, and reduced survival [8]. Also, FGF-6 is increased in a subset of prostatic cancers [37]. It has been shown that especially aFGF, but also bFGF, FGF-8, and FGF-9, induces expression of metalloproteinases in prostate cancer, contributing to increased malignancy [28, 45].

Increased expression of FGFR-1 protein has been associated with poorly differentiated cancers [17], but immunohistochemical FGFR-1 expression has received little attention. Our finding that FGFR-1 expression in tumor cells was significantly associated with high preoperative s-PSA is in accordance with previous reports, linking up-regulation of this receptor to more aggressive tumor behavior [11, 14, 35]. In cell cultures from murine prostate cancer, activation of FGFR-1 in tumor cells was associated with increased proliferation [14]. Correspondingly, in cells cultured from human prostate cancer, transfection of nonfunctioning FGFR-1 resulted in 99% inhibition of tumor cell proliferation [35] given openings for new therapeutic alternatives targeting fibroblast growth factors. These studies indicate that up-regulation of FGFR-1 in prostate cancer cells is closely linked to increased proliferation and tumor aggressiveness. In contrast to FGFR-1, FGFR-4 has no IIIb splice variant, being expressed only as the IIIc isoform [27]. In a recent study, increased immunohistochemical expression of FGFR-4 was significantly linked to high Gleason scores and reduced disease-specific survival [20].

In summary, our study demonstrates that vascular proliferation does not appear to have any prognostic value in localized prostate cancer, although still significantly related to high expression of stromal bFGF, a known endothelial cell mitogen. Strong stromal expression of bFGF was significantly associated with increased time to recurrent disease, thus indicating a more low-grade tumor phenotype.

Immunohistochemical expression of activated caspase-3 in human myocardial infarction

Received: 23 May 2005 / Accepted: 19 August 2005 / Published online: 5 October 2005
© Springer-Verlag 2005

Abstract There is mounting evidence that apoptosis is important in the pathogenesis of myocardial infarction (MI). One of the key events in the process of apoptosis is activation of caspase-3. Much attention has been recently paid to caspase inhibition as a potential treatment for ischemic cardiac disease. To predict the long-term effect of such treatment, it is essential to understand the significance of caspase-3 in the evolution of MI. Our aim was therefore to analyze immunohistochemical expression of activated caspase-3 in MI. Our study included autopsy samples of infarcted heart tissue from 50 patients with MI. Immunohistochemistry was performed by a sensitive peroxidase–streptavidin method on formalin-fixed, paraffin-embedded tissue, using monoclonal antibodies against activated (cleaved) caspase-3. We found caspase-3-positive myocytes in 18 MI less than 24 h old and in 3 MI that were presumably 48 h old. Their density (number of labeled myocytes/mm²) was greater in patients who received reperfusion treatment (mean 0.160 ± 0.373 vs 0.025 ± 0.037 , $p=0.06$). In MI older than 48 h, positive reaction was observed in neutrophil granulocytes in the interstitium and, in subacute MI, it was observed in mononuclear inflammatory cells, myofibroblasts, and vascular endothelial cells. Our results suggest that apoptosis of myocytes is an important mode of cell death in the early MI, being enhanced in patients who received reperfusion treatment.

After 48 h, apoptosis is an important mechanism of the clearance of neutrophil granulocytes and other inflammatory cells and of scar formation. Treatment with caspase inhibitors therefore will not only affect myocyte loss but will also interfere with the clearance of neutrophils and with the transformation of granulation tissue into a scar.

Introduction

Studies in experimental animals and humans suggest that apoptosis is an important mechanism in the pathogenesis of various cardiac diseases, including myocardial infarction (MI). Despite extensive research, the etiopathogenesis, the distribution, and the significance of apoptosis in the initiation and evolution of MI in humans have not been entirely elucidated [3, 19, 25, 32].

An important controversial issue remains the identification of apoptotic cells. Apoptotic cells can be recognized by characteristic morphological features, such as chromatin condensation, cytoplasm shrinkage, nuclear fragmentation, sarcolemmal invaginations without loss of membrane integrity, and final engulfment of apoptotic bodies by macrophages [11, 18, 26]. However, these features are difficult to observe in the heart [17, 24]. Furthermore, morphology alone does not enable the recognition of cells early in the apoptotic pathway [30].

Several techniques for the detection of apoptotic cells have been developed, the most widely used being the terminal transferase-mediated DNA nick-end labeling (TUNEL) assay that recognizes cells containing DNA strand breaks. DNA strand breaks are not a unique feature of apoptosis, but occur also in necrosis, during repair of reversibly damaged DNA, and postmortem autolysis [13, 18, 32]. The validity of the TUNEL method to detect apoptosis is therefore controversial.

Recently, antibodies that recognize the activated (cleaved) caspase-3 have become commercially available.

The study complies with the current laws of the country in which they were performed.

Studies in various experimental models of apoptosis suggest that this is a reliable indicator of apoptotic rate, with a favorable comparison against the TUNEL assay [6, 8, 13, 30]. Only a few studies on caspase-3 expression in human MI have been reported, which were either based on a very limited number of patients [6] or were focused on the role of apoptosis in postinfarction remodeling [1, 2].

The aim of our study was to analyze the immunohistochemical expression of activated (cleaved) caspase-3 in human MI to evaluate its distribution in myocytes as well as in inflammatory cells and other interstitial cells that contribute to the healing process in MI. Finally, we tried to determine whether or not reperfusion treatment has any impact on caspase-3 expression in human MI.

Materials and methods

Our study included autopsy samples of infarcted heart tissue from 50 patients with MI. MI was diagnosed clinically by symptoms and/or ECG changes and was confirmed by elevated serum levels of markers of cardiac necrosis. In all cases, at least three samples from the infarcted region and border zone were available. Samples of heart tissue from five healthy persons who died in accidents were also included.

Tissue samples obtained at autopsies were fixed in 10% buffered formalin, embedded in paraffin, and cut at 4 μm for H&E slides. For immunohistochemistry, additional sections were cut. Antigen retrieval and staining with a cleaved caspase-3 (Asp175) antibody (Cell Signaling, Massachusetts, USA), diluted 1:40, was performed in an automatic immunostainer (Discovery, Ventana, Tucson, AZ, USA). Sections were treated with biotinylated secondary antibody, followed by incubation with peroxidase conjugated streptavidin. Visualization of the immunoreaction was carried out with 3,3'-diaminobenzidine. Finally, sections were counterstained with hematoxylin.

Tissue sections of colonic adenocarcinoma served as positive control. Sections treated without primary antibodies served as negative controls.

Morphometric analysis was performed by the image analysis system "Cell and Tissue Analysis" (Leica). The density of positive myocytes was expressed as the number of labeled myocytes/ mm^2 .

The duration of MI at the time of death was estimated from histologic changes, and all cases of MI were divided into three groups [35]:

- Group 1 (up to 24 h old): early signs of coagulation necrosis—myocyte hypereosinophilia, pyknosis of nuclei, waviness of fibers at the border, interstitial edema, no neutrophils, or occasional neutrophil in the interstitium.
- Group 2 (more than 1 day and less than 7 days old): signs of total coagulation necrosis—myocytes with shrunken eosinophilic cytoplasm, loss of nuclei, and cross striation, accompanied by edema and neutrophil infiltration of the interstitium.

- Group 3 (more than 7 days and less than 4 weeks old): formation of granulation and fibrous tissue, phagocytosis of dead myocytes.

Statistical analysis

Numerical variables are expressed as mean \pm standard deviation. Differences between groups were tested by the Mann–Whitney *U* test.

Results

Among 50 patients, there were 30 males and 20 females, aged 57–89 years. There were 30 cases of MI less than 24 h old (group 1), 10 cases of MI that were more than 1 day and less than 7 days old (group 2), and 10 cases of MI that were more than 7 days and less than 4 weeks old (group 3). Eighteen patients had received reperfusion treatment (11 patients underwent thrombolysis, and 7 patients underwent percutaneous coronary intervention).

Antibodies against activated caspase-3 stained the cytoplasm of myocytes, which appeared morphologically normal (Figs. 1, 2). No nuclear staining was observed.

In MI less than 24 h old (group 1), caspase-3-positive myocytes were found in 18 of 30 cases. They were located at the border zone and never in the central zone of the MI. In very early MI, in which histologic changes were barely present, the determination of positive myocyte location was speculative. The density of positive myocytes ranged from 0.0111 to 1.2727/ mm^2 . It was greater in patients who received reperfusion treatment than in those who did not

Fig. 1 Immunohistochemical staining for activated caspase-3 in early myocardial infarction: positive reaction in four myocytes. Original magnification $\times 200$

Fig. 2 Immunohistochemical staining for activated caspase-3 in early myocardial infarction: positive cytoplasmic reaction in a myocyte, which appears morphologically normal. Original magnification $\times 400$

Fig. 4 Immunohistochemical staining for activated caspase-3 in subacute myocardial infarction: positive cytoplasmic reaction in mononuclear inflammatory cells, myofibroblasts, and vascular endothelial cells. Original magnification $\times 200$

(mean 0.160 ± 0.373 vs 0.025 ± 0.037 , $p=0.06$, Mann–Whitney U test). No difference was observed between patients with different modes of reperfusion treatment, but the number of patients was too small to draw any conclusions.

In MI more than 1 day and less than 7 days old (group 2), positive reaction for caspase-3 in myocytes was observed in three cases of MI that were presumably 48 h old. In this group, positive reaction was also observed in neutrophil

Fig. 3 Immunohistochemical staining for activated caspase-3 in acute myocardial infarction: positive reaction in numerous neutrophil granulocytes surrounding the necrotic myocytes. Apoptotic bodies are also positive. Original magnification $\times 200$

granulocytes, which infiltrated the interstitium. The reaction was mostly cytoplasmic. Positive reaction was observed in neutrophils that appeared morphologically healthy as well as in apoptotic bodies. In some cases, necrotic myocytes were surrounded by a rim of caspase-3-positive neutrophils, and these were surrounded by caspase-3-negative neutrophils (Fig. 3). In some cases, positive and negative neutrophils were admixed haphazardly.

In MI more than 7 days and less than 4 weeks old (group 3), positive reaction was observed in the cytoplasm of mononuclear inflammatory cells, myofibroblasts, and vascular endothelial cells (Fig. 4). The number of positive cells slowly decreased as granulation tissue was transforming into a fibrous scar.

In heart samples from five healthy persons, who died in accidents, no caspase-3-positive cells were found.

Discussion

One of the key events in the process of apoptosis is the activation of caspases (cleavage of procaspase to active caspase). Among them, caspase-3 is a central effector caspase in many cells, leading to DNase activation, followed by DNA fragmentation [10, 14]. Once cleaved through the activation of the apoptotic cascade, the peptide end of this active caspase represents a novel epitope not present in normal cells. The detection of this novel epitope is believed to be a unique and sensitive indicator of apoptosis. Antibodies to activated (cleaved) caspase-3 have recently become commercially available. Studies in various human tissues and cells have shown that they represent a useful tool to identify apoptotic cells in archival

material expanding the range of disease settings in which apoptosis can be accurately evaluated [13].

We studied the immunohistochemical expression of activated caspase-3 in human MI and found positive myocytes in acute MI during the first 2 days. Similar findings have been demonstrated in experimental MI and human MI [17, 23, 24, 27, 29] using other techniques for detecting apoptotic myocytes, most frequently the TUNEL method. The main difference between most of the previous studies and ours is a lower density of positive myocytes observed in our study. This can be easily explained as it has been shown that TUNEL is not entirely specific for apoptosis but labels also necrotic and autolytic cells, as well as cells during repair of reversibly damaged DNA [13, 32].

The density of caspase-3-positive myocytes was greater in patients who received reperfusion treatment than in those who did not. No difference was observed between patients with different mode of reperfusion treatment, but their number is too small to draw conclusions. Occasionally, positive reaction was observed in myocytes with contraction band necrosis, which is believed to be the hallmark of reperfusion injury [5]. Our findings are consistent with experimental studies that have shown that apoptosis is triggered by ischemia, but it is enhanced after reperfusion [9, 21, 33, 34]. Some experimental studies, on the contrary, have suggested that apoptosis is triggered only by reperfusion and not by ischemia [12, 33].

In contrast to myocytes, little attention has been given to the significance of apoptosis of other cells in the evolution of MI [15, 28]. Takemura et al. [27] have described TUNEL positivity, and Hayakawa et al. [15] have described caspase-3 positivity in infiltrated and proliferated interstitial cells in an experimental model of MI, suggesting that apoptosis might play an important role in the disappearance of these cells after MI. Consistent with these studies, we found positive reaction for caspase-3 in neutrophil granulocytes in the interstitium in acute MI. In subacute MI, characterized histologically by the proliferation of granulation and fibrous tissue, positive reaction was observed in mononuclear inflammatory cells, myofibroblasts, and vascular endothelial cells. The number of positive cells decreased as granulation tissue was transforming into a fibrous scar.

The significance of elimination of noncardiomyocytes by apoptosis in MI has not been fully determined [28, 32]. Leukocytes and macrophages accumulate in the infarcted region to scavenge the necrotic tissue. Necrotic tissue is then replaced by granulation tissue. As repair proceeds, there is a decrease in cellularity, ending with the formation of a fibrotic scar. When the scavenging process is completed, inflammatory cells, which contain cytotoxic factors, must be eliminated promptly so that surviving tissue is not further damaged. The elimination of inflammatory cells by apoptosis appears reasonable, as toxic components are not released in the surrounding tissue [32], and has been confirmed in experimental models of acute inflammation [31]. Similarly, experimental studies have shown that the decrease in cellularity during the transformation of gran-

ulation tissue into a scar is also mediated by apoptosis [7, 27].

Much attention has been recently paid to caspase inhibition as a potential new treatment approach for ischemic cardiac disease [28, 34]. Experimental studies have shown that caspase inhibition reduces myocardial injury induced by ischemia and reperfusion [4, 16, 20–22, 34], but there is little information about the long-term effect of such treatment [15, 28]. To predict the long-term effect of treatment with caspase inhibitors, it is essential to understand the significance of activated caspase-3 in the evolution of MI. According to the results of our study, it may be expected that treatment with caspase inhibitors not only will affect myocyte loss but will also interfere with the clearance of neutrophils and other inflammatory cells and with the transformation of granulation tissue into a scar.

Why is the hyperplastic polyp a marker for the precancerous condition of the gastric mucosa?

Received: 28 February 2005 / Accepted: 16 August 2005 / Published online: 28 September 2005
© Springer-Verlag 2005

Abstract It is well known from the older literature that gastric carcinomas are more likely to develop in a stomach containing hyperplastic polyps. The reason why such a stomach should represent a precancerous condition is, however, largely unexplained. The aim of this study was to determine the disorders of the gastric mucosa in which hyperplastic polyps occur. In 244 patients with hyperplastic polyp, in whom at least two additional biopsies each from the antrum and corpus were available, gastritis was classified on the basis of the updated Sydney System. In none of the 244 patients was the gastric mucosa found to be normal. The most common disorder, at 51.3%, was autoimmune gastritis of the corpus mucosa, while chronic active *Helicobacter pylori* (Hp) gastritis was seen in 37.3% of the patients. Of the patients with Hp gastritis, 56.1% had corpus-dominant Hp gastritis. Other forms were relatively rare: when A-gastritis, corpus-dominant Hp gastritis and any other form of Hp gastritis were lumped together as a precancerous condition, these changes were found in 88.6% of the patients with hyperplastic polyps of the stomach. In the presence of hyperplastic polyps of the gastric mucosa, additional biopsies obtained from the antrum and corpus should always be performed to obtain a basis for deciding whether to apply Hp eradication treatment as potential carcinoma prophylaxis.

Keywords Hyperplastic polyps · Gastritis · Precancerous condition

Introduction

Hyperplastic polyp of the gastric mucosa, the aetiopathogenesis of which still has not been clarified, is itself not considered to be a precancerous condition or lesion because

carcinoma develops within it only in an average of 2.1% (range 0 to 8%) of the cases [4, 26]. From the earlier literature, however, it is known that the detection of such a polyp may be a marker for the risk of gastric carcinoma developing at some other site within the stomach [23]. For this reason, the presence of hyperplastic polyps of the stomach is considered to be a precancerous condition, and appropriate screening examinations are recommended. These older data suggest that the cause of the precancerous condition is to be sought in the status of the gastric mucosa in the antrum and corpus. However, few published reports are available of studies investigating the underlying disorder of the gastric mucosa in patients with hyperplastic polyp, and most of these studies stem from the period prior to the rediscovery of *Helicobacter pylori* (Hp) and before the introduction of the Sydney System of gastritis classification. Based on the results of these older studies, therefore, it can be concluded only indirectly that hyperplastic polyps very probably occur more frequently in atrophic autoimmune gastritis of the corpus mucosa and in Hp-induced gastritis [8, 12, 20].

Against this background, we investigated the antral and corpus mucosa at a distance from the polyps, with the aim of finding answers to the following open questions:

1. In what underlying diseases of the gastric mucosa do hyperplastic polyps develop?
2. Can these underlying diseases explain why hyperplastic polyps of the stomach is a precancerous condition?
3. Can any of these underlying disorders of the gastric mucosa be cured by treatment, with the potential for preventing the development of a gastric carcinoma?

Patients and methods

The status of the gastric mucosa of 244 patients with hyperplastic polyp, from whom at least two biopsies each were obtained concomitantly from the antrum and corpus for histological diagnosis, was retrospectively analysed. The diagnosis of hyperplastic polyp was established in the endoscopic polypectomy specimens of 25% of the patients and

in the surgical polypectomy specimen in two patients. In all other patients, the hyperplastic polyps were diagnosed in forceps biopsies obtained from the polyps. Table 1 shows the age distribution of the patients, Table 2 the distribution of the location of the hyperplastic polyps within the stomach, and Table 3 the number of hyperplastic polyps per patient.

Histological methodology

The biopsy or polypectomy specimens were fixed in 10% formalin solution, dehydrated in the usual manner, and embedded in paraffin. After deparaffination, histological sections (4 µm thick, at least eight sections per tissue sample) were stained with haematoxylin and eosin and, if necessary, with the Warthin–Starry silver stain. The classification and grading of gastritis in the antrum and corpus were based on the updated Sydney System [6]. Corpus-dominant Hp gastritis was diagnosed whenever the grade and activity of the Hp gastritis in the corpus were at least medium grade and at least equally as pronounced as in the antrum. A not-yet atrophic autoimmune gastritis of the corpus mucosa was diagnosed on the basis of the criteria we previously published elsewhere and which have been confirmed by other authors [25, 28].

Results

In none of the patients with hyperplastic polyps was a normal gastric mucosa observed. Most commonly (51.3%),

Table 2 Location of the hyperplastic gastric polyps

autoimmune gastritis of the corpus mucosa, mostly in the atrophic stage, was diagnosed (see Table 4).

In 37.3% of the patients, chronic active Hp gastritis was the most common underlying disease of the stomach in patients with hyperplastic polyps. More than half (56.1%) of these patients presented with corpus-dominant Hp gastritis.

Ex-Hp gastritis was diagnosed in 8.6%, lymphocytic gastritis in 0.8%, and Hp gastritis with additional lymphocytic gastritis in 0.8% of the patients. In 1.2% of the patients, it was not possible to classify the gastritis with certainty (see Table 4).

Analysis of the gastritis classification in relation to the location of the hyperplastic polyps in the antrum and corpus revealed no significant differences.

Discussion

On the basis of this retrospective analysis, the questions posed above can be answered as follows:

1. The most common underlying disease of the gastric mucosa in patients with hyperplastic polyp is autoimmune gastritis of the corpus mucosa and Hp gastritis, in particular gastritis of the corpus-dominant form.

Table 4 Classification of gastritis in the corpus in patients with hyperplastic polyp

	Number of patients	Percent
Chronic active Hp gastritis		
Antrum dominant (43.9%)	40	16.4
Corpus dominant (56.1%)	51	20.9
Ex-Hp gastritis	21	8.6
A-gastritis		
Pre-atrophic	2	0.8
Partially atrophic	48	19.7
Atrophic	75	30.8
Non-classifiable gastritis	3	1.2
Special forms		
Lymphocytic gastritis	2	0.8
Mixed lymphocytic and Hp gastritis	2	0.8
Total	244	100.0

2. This explains why the hyperplastic polyp of the gastric mucosa is a marker for a precancerous condition of the stomach.
3. The second most common underlying condition of the gastric mucosa in patients with hyperplastic polyp can be cured by Hp eradication therapy.

That atrophic autoimmune gastritis of the corpus mucosa is one of the possible underlying diseases in hyperplastic polyps can be deduced indirectly from the results of three older publications prior to the rediscovery of *H. pylori* and the introduction of the Sydney System classification of gastritis. As early as 1977, Elsborg et al. [8] described one or several “gastric mucosal polyps” in 25 of 68 patients with pernicious anaemia. In a comparison of 52 patients with hyperplastic polyp and patients with no such polyps, Laxen et al. [12] found atrophy of the corpus mucosa significantly more frequently in the former. Nakano et al. [20] reported corpus mucosal atrophy in 46 patients with hyperplastic polyps.

Our own observation that Hp gastritis is the second most common underlying disease in patients with hyperplastic polyps can be deduced from several studies with small numbers of patients.

In 35 patients with hyperplastic polyps and Hp gastritis, Ohkusa et al. [21] diagnosed chronic active and atrophic gastritis and observed regression of the polyps following Hp eradication in 12 of 17 patients. Ljubicic et al. [14] also reported regression of hyperplastic polyps following Hp eradication treatment in 16 of 21 patients with Hp gastritis. Following Hp eradication, regression of multiple polyps measuring up to 2.6 cm in diameter was noted in a case report [18].

A relevant comprehensive study has been published by Abraham et al. [1]. In 137 out of 160 patients with hyperplastic polyps, biopsies taken from gastric mucosa at some distance from the polyps in the antrum and corpus were examined.

This study is open to criticism on a number of points [27], for example, that the updated Sydney System was not taken into account and there was no subclassification of the Hp gastritis into corpus-dominant gastritis and A-gastritis (in the pre-atrophic stage). Gastritis was reported in 85% of these patients; however, with regard to the forms of gastritis that we consider of importance in hyperplastic polyps, the numbers cited differ considerably from our own. In the group described by Abraham et al. [1], Hp gastritis was found in 25% of the patients (in our case, 37.3%), and the percentage of autoimmune gastritis differed dramatically, with 12% of the patients in that study compared with 51.3% in our patient population. Furthermore, in our patients with hyperplastic polyps, no C-gastritis was found, in contrast to Abraham’s study, in which it was observed in 20% of the patients. In our patients, hyperplastic polyps presented in the corpus/fundus part of the stomach in 53.5% and in the antrum in 24.1%, compared with 29% and 60%, respectively, in Abraham’s study. Since just 50% of Abraham’s patients had polyps measuring less than 5 mm in diameter, it is pos-

sible that they had foveolar hyperplasia. This possibility is supported by the frequent location of the polyps in the antrum and the high percentage of C-gastritis in that study. Furthermore, the age distribution of his patients showed a large range of 22–88 years, although hyperplastic polyps in patients younger than 50 years is very rare—in our own group of patients, only ten cases. All these discrepancies are difficult to explain, maybe, in part, due to genetic/environmental differences or rather because of different histological interpretation [27].

That hyperplastic polyps of the stomach is a precancerous condition was already known from earlier studies. In a follow-up study, Seifert et al. [23] detected gastric carcinoma in 8.5% of patients with hyperplastic polyps—not in the polyps themselves but in the gastric mucosa at some distance away. The development of a gastric carcinoma within a hyperplastic polyp is, in contrast, very rare [4, 22, 26, 31]. Dijkhuizen et al. [4] and Nakano et al. [20] demonstrate by molecular–pathological methods a certain risk for malignancy in hyperplastic polyps.

Our results show that the most common underlying disease in patients with hyperplastic polyps is autoimmune gastritis of the corpus mucosa. Autoimmune gastritis has long been considered to be a precancerous condition, admittedly with a highly variable incidence of gastric carcinoma development in follow-up investigations [30]. When hyperplastic polyps have been demonstrated, a diagnostic work-up of the matrix, with additional removal of two biopsies each from the antrum and corpus, should be carried out. If autoimmune gastritis is diagnosed in the non-atrophic stage [25], Hp eradication can result in a cure [19]. In the case of advanced autoimmune gastritis, there is a need for gastric biopsy screening examinations in addition to appropriate substitution therapy.

Even more important is the diagnosis of the matrix for the detection of the second most common underlying disease of the gastric mucosa, namely, Hp gastritis.

Although, on the basis of WHO criteria, Hp infection was already classified as definitely carcinogenic in humans in 1994 [10], the development of gastric carcinoma in underlying Hp infection is relatively rare, so that, initially, it is not easy to explain why gastric carcinomas develop more frequently in patients with hyperplastic polyps and Hp gastritis. This apparent contradiction can, however, be explained on the basis of our additional topographic grading of Hp gastritis in the antrum and corpus. While corpus-dominant Hp gastritis is relatively rare—accounting for 14–17% of all Hp infections [11, 13, 29]—in our study, it was seen in more than half of the patients with Hp gastritis. In several retrospective studies, we found this corpus-dominant Hp gastritis to be statistically significantly over-represented in patients with advanced gastric carcinoma [17] and early gastric carcinoma [15] and in first-degree relatives of patients with gastric carcinoma [16]. For this reason, this type of gastritis has been characterised as gastritis of the “gastric cancer phenotype” [24]. These retrospective studies were initially confirmed indirectly by the fact that, in comparison with controls with identical Hp prevalence, relatives of patients with gastric carcinoma significantly more frequently

have hypochlorhydria and atrophy of the gastric mucosa [7], both factors considered to represent an increased risk for the development of gastric carcinoma [9]. Furthermore, relatives of patients with gastric carcinoma are found to exhibit polymorphisms of the interleukin-1 gene family, which are responsible for marked production of acid, which can be seen as an explanation for the corpus-dominant Hp gastritis [5]. In their study of a family, Carneiro et al. [2] reported on hyperplastic polyposis and diffuse carcinoma of the stomach; they described the occurrence of hyperplastic changes/polyps in the non-neoplastic mucosa of E-cadherin mutation carriers [3].

The significance of corpus-dominant Hp gastritis for the development of a gastric carcinoma was confirmed by a large prospective Japanese study [29]. In that study, the relative risk of a gastric carcinoma developing in corpus-dominant gastritis was 34.5, while intestinal metaplasia (6.4) and atrophy (4.9) both represented for a much lower risk for gastric carcinoma.

In conclusion, our study shows that hyperplastic polyps of the stomach is a precancerous condition because of the most common underlying diseases in these patients, namely, atrophic autoimmune and Hp gastritis, in particular the corpus-dominant Hp gastritis. Future studies will have to show whether, in patients with hyperplastic polyp and Hp gastritis, gastric carcinoma prophylaxis is possible through Hp eradication.

Recurrent high-grade leiomyosarcoma with heterologous osteosarcomatous differentiation

Received: 19 July 2005 / Accepted: 9 September 2005 / Published online: 14 October 2005
© Springer-Verlag 2005

Abstract Leiomyosarcomas (LM) of the soft tissue comprise approximately 5–10% of all soft tissue sarcomas. Besides the classic LM, several distinctly uncommon features of the cellular and growth patterns of LM have been described. The term “dedifferentiated LM” has rarely been used in the literature to describe soft tissue LM containing areas of undifferentiated, pleomorphic appearance or detectable heterologous differentiation. We report on a case of high-grade LM with almost entire transition to an osteosarcoma, which was classified as recurrent high-grade LM with heterologous osteosarcomatous differentiation. The identification of areas with osteosarcomatous dedifferentiation in soft tissue sarcomas can be of clinical importance because of a possible change in oncologic treatment strategies.

Introduction

Leiomyosarcomas (LM) of the soft tissue are relatively infrequent malignant mesenchymal tumors in adults, which comprise approximately 5–10% of all soft tissue sarcomas. LM occur in the uterus, along the gastrointestinal tract and, to a lesser extent, in the soft tissues of the retroperitoneum, abdominal cavity, or the extremities. On histopathologic investigation, most LM consist of more or less uniform spindle cells that are arranged in bundles or fascicles, reminiscent of being of smooth muscle origin. Typical tumor cells have abundant eosinophilic cytoplasm and cigar-shaped nuclei. Besides this classic LM, several distinctly uncommon features of the cellular and growth patterns of LM have been described. These tumors may have schwannoma-like nuclear palisading, epithelioid changes, abundant pleomorphism, prominent inflammatory infiltrates, myxoid changes [19], or occasionally, the occurrence of CD68-positive osteoclastic giant cells [2, 11, 14].

Osteoclastic giant cells in soft tissue tumors are the hallmark of some benign and malignant so-called fibrohistiocytic tumors, like giant cell tumors of soft tissue (giant cell tumor with low malignant potential) or undifferentiated pleomorphic sarcomas with giant cells (giant cell malignant fibrous histiocytoma; [6]). These tumors occasionally exhibit metaplastic bone formation, which is uncommon for LM. Heterotopic bone formation can also be seen regularly in other entities of soft tissue sarcomas, like synovial sarcoma or malignant peripheral nerve sheath tumor, but the presence of malignant neoplastic osteoid or bone formation in soft tissue tumor should lead to the diagnosis of extraskeletal osteosarcoma [13].

LM as one part of tumors with dual lineage differentiation in combination with liposarcoma [20], rhabdomyosarcoma [18], and osteosarcoma [4] seem to be rare events and have only been reported sporadically.

We report on a case of LM of the soft tissue of the groin with transition to osteosarcoma within local recurrence.

Case report

A 35-year-old woman presented with a 10.8-cm maximum diameter lump of the right groin region. On histopathologic investigation of the specimen, an initial diagnosis of a high-grade LM was made (International Union Against Cancer (UICC), pT2b pNx pMx G3 R0; American Joint Committee on Cancer (AJCC), 4). An adjuvant local radiation treatment was temporarily stopped because of poor wound healing (19.8 Gy, single dose 1.8 Gy). Five and seven months later, the tumor showed local recurrences. After the first recurrence, a reconstruction of the soft tissue defect was achieved by the use of a rectus abdominis flap. Additionally, lung metastases were discovered 6 months after the first surgical intervention. Under chemotherapy with adriamycin and ifosfamide, a good response of the local tumor recurrence as well as of the pulmonary metastases could be seen. One year after the initial diagnosis of LM, the second local recurrence of the tumor was resected and investigated histopathologically.

Pathology

Gross pathology (second recurrence)

A soft tissue specimen measuring 20.8×18.2×10.0 cm, containing skin, subcutaneous tissue, and a musculocutaneous flap (*M. rectus abdominis*), was studied. Within the specimen, two 10.5- and 9.0-cm circumscribed tan-white tumors were detectable (Fig. 2a). Both tumors were cystic and contained a brown-red fluid.

Microscopic pathology

Primary tumor

Specimens of the primary tumor material could be classified as high-grade LM using light microscopy (Fig. 1a). This diagnosis was confirmed by positive immunohistochemical staining with α -smooth muscle actin (Dako, Glostrup, Denmark; dilution 1:1000, clone 1A4; Fig. 1b) and desmin antibodies (Dako; dilution 1:30, clone D33; Fig. 1c).

Recurrent tumor

Microscopically, the recurrent tumor showed high cellularity and was composed of round irregular to pleomorphic cells with considerable mitotic activity and atypical mitotic figures. Neoplastic osteoid was deposited in a lacy, trabecular pattern and was focally mineralized (Fig. 2b). The tumor cells resembled malignant osteoblasts, and osteoclastic giant cells were frequently scattered throughout the tumor (Fig. 2c).

Fig. 1 a Light microscopic findings of the initially resected high-grade leiomyosarcoma (hematoxylin–eosin, H & E, ×200). b Immunohistochemical staining with smooth muscle actin antibody (×400). c Immunohistochemical staining with desmin antibody (×400)

Only minor portions of the tumor exhibited a more fascicular arrangement of tumor cells, with spindle cells and elongated nuclei.

Immunohistochemically, the tumor cells of the osteosarcomatous part of the recurrent tumor stained negatively with antibodies against smooth muscle actin. Osteoclastic giant cells showed a positive reaction with a CD68 antibody (Dako; dilution 1:1200, clone PG-M1; Fig. 2d). More than 50% of the tumor cells of the spindled part of the tumor reacted positively with antibodies against smooth muscle actin.

Discussion

Differentiation is the process whereby cells become specialized to execute specific functions and lose their ability to perform others, which means that these cells lose their so-called cell plasticity. Fully differentiated cells are generally mitotically inactive. In addition, the state of terminal differentiation was thought to be fixed, but it is now clear that differentiated cells may be capable of reentering the cell cycle on appropriate stimuli and that differentiation can be dynamically altered or even be reversed [9]. The cells with the most extensive potential of differentiation (plasticity) are stem cells, including mesenchymal stem cells. During dedifferentiation or retrodifferentiation, the expression of gene products associated with a differentiated phenotype and cell cycle regulation are reversed. The cells lose their special functions but regain cell plasticity. In cancer development, the expression of defects in the cellular control of the differentiation process and in the activation of pathways that initiate unregulated self-renewal is thought to be of etiological significance. In this context, it is noteworthy that stem cells and cancer cells have striking similarities, leading to the assumption that some cancers may arise from tissue stem cells [17], although dedifferentiation to more multipotent progenitor cells may

Fig. 3 Diagram of mesenchymal differentiation, dedifferentiation, and transdifferentiation

explain phenotypical change or transdifferentiation of tumor cells in dedifferentiated sarcomas (Fig. 3).

The concept of dedifferentiation in sarcomas has been best characterized for liposarcomas (and chondrosarcomas). In about 10% of cases, well-differentiated malignant adipocytic neoplasms undergo dedifferentiation. Dedifferentiation in liposarcomas classically means the transition of a well-differentiated liposarcoma to a nonlipogenic sarcoma with a higher grade of malignancy. This classical concept of dedifferentiation can be applied to the rare entity of dedifferentiated LM as well. The areas of dedifferentiation in these sarcomas are most frequently pleomorphic undifferentiated sarcomas (malignant fibrous histiocytomas, MFH) but can also exhibit a heterologous (*trans*-) differentiation [10, 22]. The concept of MFH as an entity on its own remains controversial since MFH lack the ability to express typical phenotypic markers. In recent years, it has been hypothesized that MFH originate from multipotent mesenchymal progenitor cells [7]. These findings may explain the high percentage of dedifferentiated liposarcomas with an MFH-like dedifferentiation as well as the phenomenon of divergent myosarcomatous or osteosarcomatous differentiation (transdifferentiation; [21]).

Tumors that contain two or more lineages of specialized differentiation have sometimes been described as “malignant mesenchymomas” in the past [3, 12, 15, 16]. Since the group of malignant mesenchymomas represents no homogeneous clinicopathological entity, and the majority of tumors considered to be mesenchymomas can be classified in other ways (especially dedifferentiated liposarcomas), this entity seems to be gradually disappearing. Nevertheless, malignant mesenchymoma as an entity on its own is still listed in the latest WHO (2002) classification of tumors of soft tissue and bone [6].

The use of the term “dedifferentiated LM” for soft tissue LM containing areas of nonspecific, poorly differentiated, pleomorphic appearance or detectable heterologous differentiation is uncommon, but according to the WHO classification, this diagnosis can be taken into consideration in those rare cases [6].

In the reported case, the transition from LM to osteosarcoma occurred in the second recurrence of a high-grade LM. This was proven by histopathological investigation of the primary tumor and both recurrent tumor manifestations. Minor portions of the second tumor recurrence still exhibited residual signs of leiomyogenic differentiation.

In our opinion, the diagnosis of a recurrent high-grade LM with heterologous osteosarcomatous differentiation is appropriate for this special case because the tumor gained the osteosarcomatous portion during progression and did not exhibit two lines of differentiation from the beginning, which might have suggested the diagnosis of malignant mesenchymoma. The term dedifferentiated LM may not be used for the reported tumor because this term is, strictly speaking, defined as a biphasic neoplasm composed of areas typical of a low-grade LM with a usually abrupt transition to high-grade sarcoma in which myogenic features are not obvious. This classical definition is mainly based on histomorphological and immunohistochemical criteria and can-

not reflect the entire biological changes of a tumor. Therefore, the strict use of the definition seems to be problematic since heterologous differentiation in sarcomas may represent the consequence of a dedifferentiation process.

However, it is important to detail the different components of a tumor accurately when reporting about sarcomas with dual or multiple differentiations. For this reason, even recurrent soft tissue sarcomas should be extensively investigated in multiple tumor specimens from different tumor locations [5].

Because the described soft tissue tumor showed the morphology of an osteosarcoma in a high proportion (>95%), the case was reported to the clinicians as an extraskeletal osteosarcoma. A standardized therapeutic management of the extraosseous form of osteosarcoma does not exist to date and is discussed controversially in the literature. Ahmad et al. [1] reported on a cohort of 60 patients with extraskeletal osteosarcomas, concluding that extraskeletal osteosarcoma is “clinically and therapeutically distinct from osseous osteosarcoma,” which should be treated similarly to high-risk soft tissue sarcomas. A recent publication showed a more favorable outcome obtained with a more aggressive multiagent chemotherapy like it is used for conventional skeletal osteosarcomas [8].

Expression of CD56 antigen in Langerhans cell histiocytosis associated with T-lymphoblastic lymphoma in a same lymph node

Received: 22 December 2004 / Accepted: 6 February 2005 / Published online: 14 October 2005
© Springer-Verlag 2005

Abstract Association of T-lymphoblastic lymphoma (LBL) and Langerhans cell histiocytosis (LCH) in the same lymph node is very rare. Herein, we report such two cases with expression of CD56 in Langerhans cells. Immunohistochemically, lymphoblasts were positive for anti-polyclonal CD3 antibody, CD34, CD7, CD99, and terminal deoxynucleotidyl transferase. LCH cells were positive for anti-S100 protein, CD1a, CD4, CD56, and CD68. Although those two populations were separated topographically, many histiocytes intermingled with lymphoblasts in the paracortex and a few lymphoblasts were scattered within the intrasinusoidal sheets of histiocytes. Neither admixed eosinophils nor multinucleated giant cells were observed. The pathogenetic mechanism of CD56 expression in LCH associated with LBL is discussed.

Keywords Langerhans cell histiocytosis · T-lymphoblastic lymphoma · CD56

Introduction

The CD56 antigen is a membrane glycoprotein encoded by a single gene located on 11q23-24 and is the most useful marker

currently available for the identification of human natural killer (NK) cells [13]. CD56 also is expressed by a small subset of peripheral blood CD3⁺ T cells and plasmacytoid dendritic cells (DCs) but not expressed on thymocytes, B cells, plasma cells, monocytes, Langerhans cell, or granulocytes. In the neoplasm of hematopoietic cells, CD56 is expressed in non-Hodgkin's lymphoma, of NK or T cell origin, and a subset of acute myelogenous leukemia [6]. Among DC neoplasm, except for recently described "agranular CD4⁺CD56⁺ hematodermic neoplasm" (blastic NK-cell lymphoma), expression of CD56 was not well investigated [1, 11].

Langerhans cell histiocytosis (LCH) may be associated with a wide range of neoplastic disorders, including malignant lymphoma, acute leukemia, melanoma, lung carcinoma, and other solid tumors, either at presentation or during the course of the diseases [3, 4]. The vast majority of malignant lymphoma showing such an association is a classical Hodgkin's lymphoma, and a minority corresponds to follicular lymphoma [3]. Association of T-lymphoblastic lymphoma (LBL) and LCH is rare, and only three such cases have been reported in the literature so far [8, 12].

We report herein two cases of CD56⁺ LCH coexistent with T-LBL in the same lymph node.

Clinical history

Case 1

A 59-year-old woman presented with epigastric pain and weight loss of 7 kg for 3 months. She was a housewife and had been healthy until she felt epigastric discomfort 3 months ago. On physical examination, no abnormal findings were noted except mild epigastric tenderness. There was neither organomegaly nor peripheral lymphadenopathy. Peripheral blood findings were the following: hemoglobin (Hb) 10.9 g/dl, hematocrit (Hct) 32.4%, platelets 567,000/ μ l, white blood cell (WBC) 8,300/ μ l with differentials of neutrophils 65.6%, lymphocytes 23.7%, eosinophils 0.9%, basophils 0.5%, and monocytes 9.3%. Blood chemistry revealed increased liver enzymes, including total bilirubin

1.6 mg/dl, aspartate transaminase 67 U/l, alanine transaminase 93 U/l, and alkaline phosphatase (ALP) 758 U/l.

On abdominal CT scan, an enlargement of multiple retroperitoneal lymph nodes below the renal vein was noted. The liver and spleen were unremarkable. An exploratory laparotomy was performed to obtain diagnostic tissue. On operation, enlarged lymph nodes were noted around the left renal vein, right iliac vessels, aorta, and hepatoduodenal ligament and measured up to 2×2×2.5 cm in dimensions. Biopsy was performed from lymph nodes in para-aortic, hepatoduodenal ligament, and left renal vein region and omentum. The aspiration smear of bone marrow revealed atypical terminal deoxynucleotidyl transferase (TdT)(+) blasts, which were counted up to 5% of all nucleated cells. Chemotherapy with cyclophosphamide, doxorubicin, vincristine, and prednisone regimen of four cycles was performed with complete remission. The disease relapsed and the patient died 2 years after the diagnosis.

Case 2

A 48-year-old man presented with intermittent fever, night sweat, and weight loss of 20 kg for 2 months. On physical examination, he had multiple enlarged lymph nodes, up to 2 cm in the neck, and splenomegaly. Peripheral blood showed anemia and pancytopenia. Hb was 9.0 g/dl, Hct was 26.4%, WBC was 1,400/ μ l with blast 14%, and platelets were 69,000/ μ l. Lactate dehydrogenase was 980 U/l, and ALP was 515 U/l. On CT scan, pulmonary, hilar, mediastinal, and mesenteric lymphadenopathy and splenomegaly were observed. Bone scan showed no significant abnormality. Biopsy from the neck lymph node was performed.

The patient received chemotherapy with methotrexate, dexamethasone, and vincristine, but his condition did not improve. The patient died of sepsis and *Pneumocystis carinii* pneumonia 1 month after diagnosis.

Fig. 1 Histological findings of case 1. **a** Pale sheets of Langerhans cells within sinuses alternating with dark zone of LBL in the paracortex. **b** Large Langerhans cells with abundant cytoplasm. **c** Medium-sized Langerhans cell (*arrow*) with nuclear folding. **d** LBL

Materials and methods

The lymph node was fixed in 10% formalin and then embedded in paraffin. The 4- μ m-thick sections were stained with hematoxylin and eosin. Paraffin sections were subjected to immunohistochemistry using an automated system (Techmate1000, Dakochemate). The antibody panel included CD2, CD3, CD4, CD5, CD7, CD8, CD1a, CD20, CD79a, CD10 (Novocastra), S100 protein, CD68, TdT, CD99, myeloperoxidase, CD34 (Dako), and CD56 (Monosan). All the immunohistochemical stains were performed after microwave antigen retrieval, for which the tissue sections were immersed in Coplin jars containing 0.01 M citrate buffer, pH 6.0, and subjected to heating for 20 min in a 625-W microwave.

For polymerase chain reaction (PCR) amplification of the T-cell antigen receptor- γ (TCR- γ) locus in case 1, DNA was prepared by a standard proteinase K digestion and a phenol/chloroform extraction. A PCR analysis followed by single-strand conformational polymorphism was performed as previously described [15].

Results and discussion

Histological findings

Case 1 Normal architecture of the lymph node was destroyed by infiltration of two different populations (Fig. 1). One was medium to large histiocytes with eosinophilic cytoplasm and irregular nucleus showing nuclear folds. The cytoplasm of histiocytes was scanty to abundant in amount. The majority of histiocytes were aggregated in the marginal and cortical sinus. Neither admixed eosinophils nor multinucleated giant cells were observed. The other was small- to medium-sized lymphoblasts characterized by fine nuclear chromatin and high nuclear cytoplasmic ratio, which replaced paracortex and intimately abutted on the intrasinus-

soidal sheets of histiocytes. The nuclei were round or convoluted, and the cytoplasm was scanty. There was a few follicular remnants surrounded by lymphoblasts. Although those two populations were separated topographically, many histiocytes were scattered among lymphoblasts in the paracortex and a few lymphoblasts were observed within the intrasinusoidal sheets of histiocytes.

Case 2 Overall histological pattern of lymph node was similar to that described in case 1, with minor differences (Fig. 2). Infiltration of histiocytes was more extensive throughout the lymph node. The cells were aggregated in sinusoidal and perifollicular area and intermingled with lymphoblasts. The size of histiocytes was variable, most of them were large with abundant cytoplasm, but others were medium in size with scanty cytoplasm and had folded nuclei.

Immunohistochemical findings

In case 1, the histiocytes were positive for anti-CD4, anti-CD1a, anti-CD68, and anti-S100 protein antibody, and some of histiocytes were weakly positive for CD56. Majority of lymphoblasts were positive for TdT, CD99, and CD7. Several lymphoblasts expressed cytoplasmic CD3. CD34 was positive in many lymphoblasts. CD2, CD5, CD8, CD10, CD20, CD79a, myeloperoxidase, CD4, CD1a, CD68, and S100 protein were negative. CD56 was negative in majority of lymphoblasts but positive in a small number of lymphoblasts (Fig. 3).

In case 2, the immunoprofile of histiocytes was similar to that of case 1, with some differences. The histiocytes showed strong and uniform positive reaction for anti-S100 protein antibody, but expression of CD1a markedly decreased and was observed in a minority of histiocytes. CD56 staining was more intense and uniform, observed in a majority of intra-

sinusoidal and paracortical clusters of histiocytes as well as some lymphoblasts (Fig. 4).

To investigate the expression of CD56 in ordinary LCH, four cases of LCH without coexistent malignancy were stained with CD56 monoclonal antibody. All the cases showed no immunoreactivity on Langerhans cells.

T-cell receptor gene rearrangement

No monoclonality was identified for TCR- γ gene rearrangement.

Association of LCH and T-LBL has been firstly described by Quintanilla-Martinez et al. [12] in 1992. They reported three cases of prethymic adult LBL in the peripheral lymph nodes, two of them being coexistent with LCH. After that, the third case was reported in 2001, in which CD79a was aberrantly expressed in lymphoblastic component [8].

It is interesting that three tumors reported previously as well as two cases presented here belong to prethymic T-cell neoplasm according to the immunophenotype and gene rearrangement analysis. Two cases described by Quintanilla-Martinez et al. [12] showed an immunophenotype of TdT⁺, human leukocyte antigen-DR (HLA-DR)⁺, CD34⁺, CD71⁺, CD38⁺, and CD7⁺. TCR- β and TCR- γ gene rearrangement were germ line [12]. The patients had nodal disease but no peripheral blood involvement. The third case reported by Li et al. [8] also showed an immature T-cell phenotype (TdT⁺, cCD3⁺, HLA-DR⁺, CD34⁺, CD38⁺, and CD7⁺) with aberrant expression of CD79a. Other T- or B-cell markers were negative. T-cell receptor gene rearrangement was not examined. The patient presented with lymphadenopathy with B symptoms. Bone marrow was only partially involved. The phenotype of present cases were CD7⁺, CD34⁺, and TdT⁺,

consistent with prothymocyte. Prothymocytes are the earliest identifiable T-cell precursors to appear in the bone marrow. In addition to TdT, HLA-DR, and CD34, prothymocytes express CD7, generally believed to be the first T-cell lineage-restricted antigen to appear during T-cell ontogeny [7]. In present cases, many lymphoblasts were positive for cCD3 but some lymphoblasts were negative for cCD3. The prothymocytes variably express cCD3. CD3 gene transcription begins during the prothymocyte stage, prior to entrance into the thymus, and cytoplasmic CD3 appears after CD7 but before CD2 [7]. Negative TCR- γ gene rearrangement further supports prethymic stage of differentiation. T-cell LBLs expressing the prothymocyte phenotype may not rearrange any TCR genes or may rearrange only the TCR- δ gene [7].

The reason why prethymic T-LBL is often associated with LCH is unknown.

Coexistence of LCH and malignant lymphoma with close topographic association suggests intimate pathogenetic relation. Magni et al. [9] showed an identical rearrangement of IgH gene in neoplastic Langerhans cell and B lymphocytes in the patient having concurrent nodal follicular lymphoma and cutaneous LCH and claimed that two lesions are derived from common progenitor cell. Because CD34⁺ pleuripotent stem cells can develop into T cells, NK cells, and DCs in an appropriate cytokine environment in vitro [16], it is conceivable that T-LBL and LCH might share common progenitor. On the other hand, in cases reported previously, LCH was regressed when the primary malignancy was treated and had no influence on the treatment outcome of malignant lym-

Fig. 4 Immunohistochemical findings of case 2. **a** S100 protein in the Langerhans cells. **b** CD1a. Weak and focal expression in Langerhans cells. **c** CD56. Langerhans cells showing strong positive immunoreaction. **d** TdT-positive lymphoblasts

phoma [3, 4, 8, 12]. LCH in this situation was thought to be passive accumulation of Langerhans cells by cytokine derived from lymphoma cells or Langerhans-cell-mediated immune response to the lymphoma cells.

Expression of CD56 in LCH is a unique finding that has not been described previously.

LCH is a clonal proliferative disorder of dendritic Langerhans cells, commonly involves the bone and skin, and less frequently other organs. Phenotypically, CD1a, S-100 protein, and peanut lectin agglutinin are the markers most consistently seen in paraffin section immunohistochemical studies, and in frozen section, CD2, cCD3, CD4, CD14, HLA-A, -B, -C, -DR are detected [6]. Expression of CD56 was not well studied in LCH as well as in LCH coexistent with other type of malignancies.

LCH cells share many features of early activated DCs that develop from immature DCs in contact with bacterial products [14]. Plasmacytoid DC, which is a normal counterpart of cutaneous CD4⁺CD56⁺ hematodermic neoplasm, seems to be the only subset expressing CD56 among DCs [1, 11]. It is conceivable that some Langerhans cells can be differentiated from plasmacytoid DCs in suitable cytokine environment. However, there is no direct evidence supporting that Langerhans cell is derived from CD56⁺ plasmacytoid DC. Among DCs in human peripheral blood, Langerhans cell are derived from the CD1a⁺/CD11c⁺ DCs when cultured in the presence of granulocyte macrophage colony-stimulating factor (GM-CSF)⁺IL-4⁺ transforming growth factor beta 1 but not from the CD1a⁻CD11c⁻ DCs resembling plasmacytoid DCs [5].

It is worthy to note that the present two cases showed difference of CD1a and CD56 expression. CD56 expression was more extensive and stronger in case 2 than case 1, while the result of CD1a stain was reverse. Upon receipt of certain stimuli in vitro, LCs undergo a process of activation usually termed LC maturation. This process is characterized by downregulation of antigen uptake moieties, including CD1a and Birbeck granules, and massive upregulation of costimulatory molecules of T-cell activation such as CD40, CD54, CD80, and CD86 [10]. In this context, LCs showing weak CD1a/strong CD56 in case 2 seem to be more activated and mature cells than LCs showing strong CD1a/weak CD56 in case 1. Considering the CD56 negativity in ordinary CD1a/strong LCH as shown in our preliminary study and strong expression of CD56 in CD1a/weak case 2, CD56 in LCH associated with LBL might be upregulated by some cytokines or tumor antigens derived from lymphoma and the intensity depends on the degree of activation.

The clinical implication of CD56 expression in this situation is not known. Usually, CD56-expressing lymphoid malignancies pursue aggressive clinical course [2]. Although the patient in case 2 presented with more advanced disease and shorter survival compared to case 1, clinical observation of sufficient numbers of enrolled patients is required to reach any conclusion on prognostic significance of CD56 upregulation in LCH associated with LBL.

To summarize, we report the expression of CD56 antigen in LCH associated with T-LBL, which expands our understanding on the spectrum of CD56 expressing tumors.

Analysis of chromosomal imbalances in an elderly woman with a giant cell tumour

Received: 17 May 2005 / Accepted: 25 August 2005 / Published online: 12 October 2005
© Springer-Verlag 2005

Abstract Giant cell tumour (GCT) remains one of the most obscure and intensely studied bone tumours. In an effort to resolve questions regarding the genesis and clinical outcome of GCT, advances have been made recently in the identification of chromosomal abnormalities implicated in the tumour. Fusion of telomeres is very frequent in GCT, and this process may be associated with chromosome instability and tumour development. However, little emphasis has been placed on chromosomal imbalances in the molecular characterization of this disease. Here, we report the case of an 83-year-old woman diagnosed with GCT where local recurrence was observed after 11 months of the resection. Cytogenetic studies of the GCT showed a modal number of 46 chromosomes with telomeric associations on 11p and dicentric chromosomes. Moreover, clonal abnormalities, such as del(17p) and losses of chromosomes 4, 13 and 18 and gains on chromosome 7, were also detected. Interestingly, comparative genomic hybridisation (CGH) analysis revealed chromosomal imbalances with gains on chromosomes 1p31-q44, 6q12-q23 and 12q15-q22. Thus, the use of CGH expanded the information obtained by conventional cytogenetics and demonstrated that chromosomal imbalances were associated with the recurrence of the GCT.

Keywords Bone tumour · Giant cell tumour · Cytogenetics · CGH · Chromosomes

Introduction

Giant cell tumour (GCT) represents approximately 4% of all bone tumours and typically occurs in young women, although it has been observed in older subjects [17]. GCT preferentially involves the ends of the long bones and is characterized morphologically by three types of cells: (a) multinucleated giant cells—predominant type, (b) cells with a round morphology resembling monocytes and (c) spindle-shaped, fibroblast-like stromal cells. Recently, it has been suggested that the stromal cells may form a part of the neoplastic component, while the other cell types serve simply as the reactive component [11, 18]. Although 80% of GCTs is benign, local recurrences and metastases can occur, even in cases with a previous benign histology [9, 16]. For this reason, the WHO has classified GCT as an aggressive and potentially malignant lesion [3]. Clearly, histological features are not sufficient to predict the clinical outcome of this tumour, and other parameters are needed for an accurate prognosis.

The most recurrent karyotypic findings in GCT are telomeric associations (tas) that usually affect 11p, 15p, 19q and 21p[17], while numerical alterations are infrequently detected by conventional cytogenetic analysis [10]. This genetic profile differs from other bone tumours in which chromosomal imbalances (e.g. chondrosarcoma, osteosarcoma and chondroma) or recurrent structural rearrangements (e.g. Ewing sarcoma, aneurismal bone cysts and chondroma) are more frequent [10]. In the present study, we have analysed a recurrent GCT by comparative genomic hybridisation (CGH), which permitted us to detect extensive chromosomal imbalances. This novel observation suggests that chromosomal imbalances may predict recurrence of GCT, and thus, our study not only contributes to our basic understanding of this disease but it also reveals a potential new prognostic tool.

Fig. 1 X-ray film shows the stage 3 GCT of the distal radius

Clinical history

An 83-year-old female was evaluated for pain and immobility of her left wrist which developed over the course of 5 months and without previous trauma to the area. Radiographs revealed an osteolytic lesion in the distal epiphysis of the radius, with slightly precise edges and breakage of the cortex (Fig. 1). The local extension of the lesion was studied through computer tomography and magnetic resonance imaging. Marginal block resection was carried out at the distal end of the radius. Reconstruction was performed with wrist arthrodeses using an allograft of fibula and fixation with a plate. Histological examination of the biopsy specimens revealed GCT (Fig. 2). Eleven months following the resection, local recurrence in soft tissue was observed and a marginal resection was performed. Currently, the patient is free of symptoms with no evidence of tumour recurrence during a follow-up of 30 months.

Material and methods

A specimen of the biopsy was minced and disaggregated overnight in a solution of collagenase (400 UI/ml) and

incubated in 3 ml DMEN/F12 (Gibco/BRL, UK) containing 10% fetal calf serum and 5% CO₂ atmosphere. The cytogenetic preparation and G-banding were performed according to routine cytogenetic procedures [12].

CGH analysis was performed as previously described [7]. Briefly, tumour DNA (test DNA) was labelled with biotin-16-deoxyuridine 5-triphosphate (dUTP) (Boehringer Mannheim, Mannheim, Germany), and the reference DNA was labelled with digoxigenin-11-dUTP (Boehringer Mannheim) by a standard nick-translation reaction. Equal amounts (21 µg) of labelled tumour and normal DNAs and 70 µg of unlabelled human Cot-1 DNA (Gibco/BRL, Gaithersburg, MD, USA) were co-hybridised to slides of human metaphase chromosome spread prepared from phytohaemagglutinin-stimulated lymphocytes from normal individuals. After hybridisation for 1 to 2 days in a moist chamber at 37°C, post-hybridisation washes were performed to a stringency of 0.1× saline sodium citrate at 42°C. Tumour and normal DNA were detected by avidin–fluorescein isothiocyanate and rhodamine-conjugated anti-digoxigenin, respectively. These slides were counterstained with 4,6-diamidino-2-phenylindole and mounted with an anti-fade solution. Image acquisition was performed with an epifluorescence microscope (Nikon MDR1000) equipped with a cooled charge-coupled device camera. The images were analysed with Quips CGH software (QUIPS, Vysis, Downers Grove, IL, USA).

The probes used for fluorescence in situ hybridisation (FISH) analyses were LSI p53 (17p13.1) Spectrum Orange and bacterial artificial chromosome (BAC) RP-11 611O2 which contains a DNA sequence specific for the MDM2 gene locus, mapping to 12q12 (RPCI-11 Human Male BAC Library). FISH studies were carried out following well-established methods [8].

Results

A benign tumour typically displays large numbers of evenly distributed multinucleated giant cells on a background of sheets of round to oval mononuclear cells lacking cytologic atypia and atypical mitotic figures (Fig. 2a,b). The neoplastic cells invade locally soft tissue (Fig. 2c).

Chromosomal analysis revealed that most cells were hypodiploidy, varying from 43 to 45 chromosomes, and the description of a representative karyotype was 41-

Fig. 2 Microscopic view a GCT from an 83-year-old woman. **a, b** Biopsy characterized by numerous multinucleated giant cells and oval mononuclear cells. **c** Peripheral areas showing the growth of the lesion with the permeation of the cortex and the extension to the soft tissue

Fig. 3 **a** Representative karyotype showing 44,XX,-2,add(3)(q29),-13,del(17)(p13). **b** 46,XX,del(7)(q36),tas(15;15)(q11;q11),del(17)(p13),add(22)(13). **c** Partial karyotype of telomeric associations (tas) on 11p and 11q and dicentric chromosomes dic(1;?)(p;?) and dic(18;?)(p11;?)

46XX,-2[2],-4[3],+7[3],-13[3],del(17)(p12)[3],-18[4],-22[2] [cp10]/46XX [5]. In addition, no clonal dicentric chromosome (dic) or tas were observed on chromosomes 3p, 11p and 15q (Fig. 3).

Genomic DNA analysis of the tumour specimen by CGH revealed gains on 1p31-q44, 2q24-q34, 3q24-26, 4p15-q34, 5q14-q23, 6q12-q23, 7q31, 8q13-q21, 12q15-q22 and 13q14-q22. The losses were detected on 9q31-q34, 11q23-25, 12q23-q24, 14q31-32, 16, 17, 20q11-q13, 21 and 22 (Fig. 4).

Hybridisation with probe 17p showed that the 30% of cells displayed deletions of TP53 while 15% had three copies of 17p. Regarding the 12q region, all cells analysed contained two signals.

Discussion

Information about the genetic abnormalities underlying GCT has been limited to conventional cytogenetics which can identify tas and dic as the typical aberrations in this type of tumour [14]. These biomarkers, such as tas, have been implicated in chromosomal instability and tumorigenesis and could be responsible for the accumulation of other associated cytogenetic aberrations [1, 19]. However, the precise role of tas in the development of GCT and their molecular consequences are not fully understood. Along with tas, other karyotypic findings, such as clonal, structural and/or numerical changes, have been observed in GCT [3, 15]. Recently, a cytogenetic analysis of a CGT

Fig. 4 Overview of chromosomal regions with gains or losses of genetic material in CGT tumours. CGH profile of case showing gains of 1p31-q44, 2q24-q34, 3q24-26, 4p15-q34, 5q14-q23, 6q12-q23, 7q31, 8q13-q21, 12q15-q22, 13q14-q22 and losses on 9q31-

q34, 11q23-25, 12q23-q24, 14q31-32, 16, 17, 20q11-q13, 21 and 22. Bars to the left (red) and right (green) of each frame indicate losses and gains, respectively

reported a complex karyotype but without tas or dic aberration [11]. In the present study, we have used CGH to confirm and extend observations regarding the genetic changes associated with GCT. Clonal abnormalities were also detected in the current case and confirmed by FISH analysis. Furthermore, single or complex abnormalities could be observed. We noted changes on 17p that suggest the presence of a secondary aneurismal bone cyst component [15]; however, there was neither histological nor radiological evidence in this case of an aneurismal component.

We have found multiple genomic changes by CGH analysis, including gains on 1p32-q44, 6q12-q25 and 12q14-q22 and losses on 17p. Several reports concerning bone/cartilage-forming lesions or benign mesenchymal tumours have demonstrated associations with changes on 6q and 12q [1, 2]. In addition, gains on 1q, 6q and 12q have been associated with a subgroup of malignant bone fibrous histiocytoma of undifferentiated status, suggesting a possible role of these genomic alterations in GCT [4–6]. Recent molecular studies performed by loss of heterozygosity (LOH) revealed the accumulation of genetic abnormalities in primary and recurrent tumours, without any difference between the two groups [13]. LOH of 17p (close to p53 locus) was also observed in primary GCT and their lung metastases. Consistent with this, we have

observed deletion on 17p by both CGH and FISH analysis, suggesting that this genetic abnormality may be associated with the recurrence of the tumour.

For predicting the clinical outcome of GCT, histological classification of the tumour has a limited prognostic value [16]. Recent data suggests that cytogenetic findings could be implicated in the course of the disease [3, 4]. Moreover, chromosomal loss is the most likely molecular event to occur in this disease and may represent a biomarker(s) of tumour progression [13]. Both types of abnormalities were observed in the patient of our study, and therefore, multiple chromosomal changes detected by cytogenetics and CGH could explain the local recurrence of GCT in the soft tissue, which occurred 11 months after removal of the original tumour.

In summary, through the use of the CGH technique, we have described for the first time the presence of chromosomal imbalances in a case of GCT. Further studies will be required to fully evaluate the clinical significance of our findings and to determine the specificity of this genetic profile.

Sudden infant death syndrome (SIDS) shortly after hexavalent vaccination: another pathology in suspected SIDS?

Received: 10 May 2005 / Accepted: 23 August 2005 / Published online: 18 October 2005
© Springer-Verlag 2005

Abstract Experts from panels of the European Agency for the Evaluation of Medical Products have investigated whether there might be a link between hexavalent vaccines and some cases of deaths that occurred. Participants included pathologists with experience in the field of vaccines and sudden infant death syndrome who conducted autopsies. However, to the best of our knowledge, little, if any, attention was paid to examination of the brainstem and the cardiac conduction systems on serial sections, nor was the possibility of a triggering role of the vaccine in these deaths considered. Herein we report the case of a 3-month-old female infant dying suddenly and unexpectedly shortly after being given a hexavalent vaccination. Examination of the brainstem on serial sections revealed bilateral hypoplasia of the arcuate nucleus. The cardiac conduction system presented persistent fetal dispersion and resorptive degeneration. This case offers a unique insight into the possible role of hexavalent vaccine in triggering a lethal outcome in a vulnerable baby. Any case of sudden unexpected death occurring perinatally and in infancy, especially soon after a vaccination, should always undergo a full necropsy study according to our guidelines.

Introduction

The European Agency for the Evaluation of Medical Products (EMA) recently reviewed the safety of centrally authorized hexavalent vaccines. During the April 2003 meeting, it was concluded that there was no change in the benefit/risk profile of these products, and, therefore, no changes in the present conditions of use were recommended [4]. The Committee conducted a detailed review, in particular, of five reports of unexplained deaths in children occurring within 24 h of vaccination with a hexavalent vaccine. These reports were received as part of a routine post-marketing safety monitoring (pharmacovigilance) over a period of 2 1/2 years. During this time an estimated 8.7 million doses of vaccines corresponding to the vaccination of some three million children have been used worldwide [4]. Panels of experts investigated whether there might be a link between the vaccines and the deaths observed. Participants included pathologists with experience in the field of vaccines and sudden infant death syndrome (SIDS) who conducted autopsies. The EMA's conclusions were that the causes of death remained unexplained. SIDS, viral infection, metabolic disorders, allergic reactions or airway obstruction were plausible but were not definitely proven to have been the cause of death [4]. However, to the best of our knowledge, during the mentioned post-mortem investigations, little, if any, attention was paid to examination of the brainstem and the cardiac conduction systems on serial sections, nor was the possibility of a triggering role of the vaccine in the lethal outcome considered.

Case report

A 3-month-old white female infant lost consciousness 1 h after being given a hexavalent vaccination. Emergency help was summoned and arrived quickly. Immediately, resuscitation efforts were attempted by external cardiac massage and assisted ventilation. One hour later the baby reached the hospital, where the resuscitation manoeuvres were

continued, followed by repeated administration of adrenaline and atropine. The baby remained unconscious, with persistent mydriasis, not reacting to light, and was pronounced dead 2 h after arrival at the hospital.

The baby was a firstborn child, born at term in the 42nd week of gestation by Caesarean section, with a birth weight of 3,300 g and an Apgar score of 9–10. The analysis of the placenta after birth was unremarkable. Her parents reported that shortly after birth, the baby had episodes of polypnoea, which was cured spontaneously, and the child continued in apparent good health until the day she received the hexavalent vaccine and then died suddenly. No previous ECG recordings were available. The 35-year-old mother had an unremarkable pregnancy, except for mild hypothyroidism, which required therapy. The baby was bottle-fed. There was no significant family history relevant to the case.

Post-mortem examination was requested with a clinical suspicion of SIDS. The case was analysed at the Institute of Pathology, University of Milan, where more in-depth examinations were performed, including a close study of the cardiac conduction system and the brainstem on serial sections [16, 19–21].

Methods

A complete autopsy was performed according to the autopsy protocol usually followed at our Institute of Pathology in case of sudden death, including careful examination of the cardiac conduction system and of the central and peripheral autonomic nervous structures involved in cardiorespiratory reflexogenesis [16, 19, 21].

The medulla oblongata was divided into three blocks. The first, cranial block, extended from the border between the medulla oblongata and pons up to the upper pole of the olivary nucleus. The second, intermediate block, corresponding to the submedian area of the inferior olivary nucleus, took the obex as the reference point and extended 2–3 mm above and below the obex itself. The third, caudal block, included the lower pole of the inferior olivary nucleus and the lower adjacent area of the medulla oblongata. The first and second blocks were sectioned in a cranial–caudal direction, and the third, in a caudal–cranial direction [13–16]. A fourth block was cut of the brainstem, including the ponto-mesencephalic portion, sectioned in a caudo–rostral direction [14, 16]. From each of these paraffin-embedded blocks, an average of 48 sections were obtained and were alternately stained using haematoxylin–eosin, Bielschowsky, and Klüver-Barrera stains [10, 13]. The pertinent nuclei were outlined, namely, the locus coeruleus, the parabrachial/Kölliker-Fuse complex in the pons; and the arcuate nucleus, the hypoglossus nucleus, the dorsal vagus motor nucleus, the tractus solitarius nucleus, the ambiguus nucleus, the trigeminal tractus and nucleus, and the ventrolateral reticular formation in the medulla oblongata [10, 13–16, 18].

After excluding the presence of gross cardiac malformations, the origin of the coronary arteries was carefully inspected. The heart chambers were regularly examined for

pathologic changes in the atria, septa, ventricles, pericardium, endocardium and coronary arteries. Samples of the myocardium and the major coronary arteries were stained with haematoxylin–eosin and trichromic Heidenhain (Azan).

The cardiac conduction system was removed in two blocks: The first included the sino-atrial node and the crista terminalis, while the second contained the atrioventricular node, from the His bundle down to the bifurcation and bundle branches. These two blocks were serially cut at intervals of 40 μm (levels) and stained alternately with haematoxylin–eosin and Azan [14, 21].

Pathological findings

At autopsy, the baby was described as a well-developed, well-nourished white infant, with a body weight of 5,375 g and body length of 60 cm. Macroscopic examination did not reveal malformations, organ malposition or marks of violence. Results of the gross external and internal examinations were normal for the age and sex.

The study of the brainstem on serial sections revealed bilateral hypoplasia of the arcuate nucleus, as confirmed by two-dimensional morphometric reconstruction (Fig. 1). No abnormalities of the other cardiorespiratory medullary nuclei, namely, the dorsal vagus motor, the tractus solitarius, the ambiguus nucleus, the trigeminal nuclei, the ventrolateral reticular formation, locus coeruleus and the parabrachial/Kölliker-Fuse complex, were observed.

The heart weighed 28 g, and the cardiac diameters were the following: longitudinal 4 cm, transverse 4 cm, antero-posterior 3 cm. Gross cardiac examination revealed multiple dyschromic and brownish areas mainly located in the interventricular septum. Histologically, such areas presented wide myofibrillary injury, characterized by anisoinotriprism and contraction band necrosis typical of acute infarction. Myocardial haemorrhage was also detected. The coronaries were normally patent.

Histological examination of the cardiac conduction system showed islands of conduction tissue in the central

Fig. 1 Bilateral hypoplasia of the arcuate nucleus (ARCn). VMS Ventral medullary surface. Klüver-Barrera stain, $\times 25$

Fig. 2 The atrioventricular node (AVN) presents areas of fetal dispersion and resorptive degeneration. In the central fibrous body (CF), islets of junctional tissue (*) and initial cartilaginous metaplasia (CM) are detectable. Stain, $\times 25$

fibrous body, known as persistent fetal dispersion and areas of resorptive degeneration [7, 21] in the atrioventricular node (Fig. 2).

No other significant pathologic changes were found. The post-mortem gross and microscopic examination corroborated the clinical diagnosis of SIDS.

Discussion

To reduce the number of injections needed to comply with paediatric vaccination requirements, a liquid hexavalent vaccine has been developed for primary booster vaccination of infants against diphtheria, tetanus, pertussis, poliomyelitis, *Haemophilus influenzae* type B and hepatitis B. Seroconversion or seroprotective titres of antibodies against multiple antigens have been achieved in a majority of infants following a primary series of three doses administered at 1- to 2-month intervals from 2 months of age, providing immunity against six important childhood diseases [11].

In the past there was concern that vaccinations might have a causal relationship with SIDS, particularly considering that the peak age for SIDS is 2–4 months, coincidental with the age for vaccinations. Many studies have shown that vaccines are not associated with an increased risk of SIDS [8, 24]. Some studies have even shown a reduced risk of SIDS associated with vaccinations [5]. Despite this, from time to time this controversy is reopened [3].

Recently, Brotherton et al. [2], considering that SIDS peaks at 2 months of age, when vaccination encounters are frequent, estimated the probability of vaccination within the last 24 h for a child who has died of SIDS as 1.3% and as 2.6% in the last 48 h. With the average number of SIDS deaths equal to 130 patients per year in Australia, they estimated that a case of SIDS will occur when vaccination

was given in the last 24 h in 1.7 patients per year and within 48 h in 3.5 patients per year.

In 2003, the EMEA, through its scientific Committee for Proprietary Medicinal Products (CPMP), reviewed the safety of the centrally authorized hexavalent vaccines Hexavac and Infarix Hexa [4]. During the March and April 2003 meeting, the CPMP concluded the following:

1. Vaccination offers benefits to the individual child and to the general population.
2. The causes of death of the five children dead within 24 h of vaccination with a hexavalent vaccine remain unexplained, and it is not possible to establish a cause and effect association with hexavalent vaccines [4].

SIDS or crib death is defined as the sudden death of an infant under 1 year of age that remains unexplained after a thorough case investigation including performance of a complete autopsy, examination of the death scene, and a review of the clinical history [25].

The identification of a possible pathological basis of reflexogenic mechanisms in sudden, unexpected infant death necessarily requires examination of the brainstem nuclei and of the cardiac conduction system on serial sections according to the procedures described in the “Methods” section. The neuropathological and cardiovascular study necessary for the objective identification of the nature and location of each lesion, likely morphological substrata of death, requires examination of a large number of patients according to homogeneous and standardized criteria [15, 16]. It was proposed at the 7th International Conference on SIDS [12] that the current definition of SIDS as “the sudden death of an infant under one year of age which remains unexplained after a thorough case investigation, including the performance of a complete autopsy, examination of the death scene, and review of the clinical history” be modified to include the words “a complete autopsy with an in-depth histopathologic analysis of the cardiorespiratory innervation and specialized myocardium, performed only by an experienced, reliable pathologist”.

More recently, Krous et al. [9] underlined that since the definition of SIDS originally appeared, an enormous amount of additional information has emerged, justifying the additional refinement of the definition of SIDS to incorporate epidemiologic features, risk factors, pathologic features, and ancillary test findings and that the definition of SIDS will be modified in the future to accommodate new understanding of sudden infant death.

Taken together, the abnormalities of the autonomous nervous and cardiac conduction systems described in the present case, as well as the review of the clinical history, represent a plausible basis for the diagnosis of SIDS [6, 13, 15].

Abnormalities in the morphological findings of the brainstem (Fig. 1) and cardiac conduction system (Fig. 2) similar to those detected in this case have already been proposed in infants dying suddenly and unexpectedly as possible morphological substrates for sudden reflexogenic infant death [6, 7, 13, 15, 16, 19, 21].

In this case, histological examination of the brainstem on serial sections revealed bilateral hypoplasia of the arcuate nucleus. In term fetuses, newborns and infants dying suddenly and unexpectedly, we have recently demonstrated a variety of structural defects of the arcuate nucleus, ranging from neuronal immaturity in a well-shaped structure to total agenesis [6, 13, 15, 16].

On one hand, the unexpected death of this vulnerable baby (infant with bilateral hypoplasia of the arcuate nucleus) could have been triggered by the hexavalent vaccination. This case is consistent with the triple-risk model of SIDS, a hypothesis comprising an underlying biological vulnerability to exogenous stressors and some triggering factors in a critical developmental period [6]. On the other hand, this case could be classified as a SIDS “gray zone” or borderline case, defined as a case in which it is difficult to establish whether the pathological findings are sufficiently severe to have caused the death. Recently, our examination of the brainstem of 103 patients of SIDS disclosed five SIDS gray zone cases in which only our further investigations on serial sections successfully identified anatomic-pathological findings likely representing the morphological substrates for a sudden reflexogenic death [20, 23].

Regarding the infarct-like myocardial lesions detected in this patient, two of the present authors have already pointed out, among the disadvantages of external cardiac massage, the not infrequent occurrence of damage to the myocardium and the cardiac conduction system [17, 22]. The compression of the heart between the spine and the sternum exerted by this maneuver causes a direct vertical pressure perpendicular to both the atrial and ventricular septa [17, 22]. In this case, the overinsistent external cardiac massage is responsible for the findings of the wide myofibrillary injury in the interventricular septum, as is typically seen in the contraction band degeneration of hyperacute infarction and as in many examples of myocardial biopsy [1].

In conclusion, the careful examination of the heart, cardiac conduction system and brainstem on serial sections was crucial to classify this case as SIDS and to identify the possible morphological substrates responsible for this lethal reflexogenic sudden death, that is, arcuate nucleus hypoplasia in the brainstem and persistent fetal dispersion and resorptive degeneration in the cardiac conduction system. All cases of sudden unexpected death occurring in infancy and perinatal age, especially soon after a vaccination, should always undergo an investigated necropsy study, according to our guidelines [14].

Acknowledgements The authors wish to express their gratitude to Mrs. Graziella Alfonsi for skillful technical cooperation.

This study was supported by the “Lino Rossi” Research Center for the study and prevention of unexpected perinatal death and sudden infant death syndrome (SIDS) funding (Rectorial Decree no. 225678 of 23/04/04) and by the Ministry of Foreign Affairs (joint project of particular relevance no. 269/P/0085087, “Anatomopathologic and genetic study of the unexplained perinatal death and SIDS”), Italy.

A clear cell malignant gastrinoma of the pancreas with cytoplasmic accumulation of lipid droplets

Received: 1 July 2005 / Accepted: 31 August 2005 / Published online: 28 September 2005
© Springer-Verlag 2005

Sir:

Well-differentiated endocrine tumours of the pancreas are usually diagnosed without difficulty by the presence of small eosinophilic cells with a characteristic disposition in cords, solid nests, tubules and acini separated by a highly vascularised stroma. Clear cell endocrine tumours are rare in the pancreas in the absence of von Hippel–Lindau (VHL) disease, and changes resulting in clear cell appearance are poorly described. We report here the case of a sporadic, malignant clear cell gastrinoma of the pancreas with multiple hepatic metastasis and describe its specific imaging and histological appearances.

A 48-year-old woman with a Zollinger–Ellison syndrome, evidenced by epigastric pain, diarrhea, weight loss and presence of multiple gastroduodenal ulcers on endoscopy, was admitted to Beaujon Hospital. Laboratory tests

revealed elevated levels of circulating chromogranin (5,933 ng/ml; $N < 100$) and gastrin (319 pg/ml; $N < 80$). The patient presented no personal or familial history of VHL disease or multiple endocrine neoplasia type 1 (MEN1). Ultrasound and computer tomography (CT) scan detected a 35-mm caudal mass of the pancreas associated with 18 liver metastases distributed in all lobes, measuring 3 to 25 mm. These lesions were hypoattenuated at CT scan, comprising enhanced CT (Fig. 1a,b). A left pancreatectomy associated with surgical ablation of the eight nodules of the left liver was initially performed, associated with a ligation of the right portal vein. Three months later, a right hepatic lobectomy, which took away ten other nodules, was done.

Grossly, the pancreatic tumour measured 35 mm, was multilobulated and firm. In the liver, the 18 nodules that measured 2 to 23 mm were well delimited. On cross-section, the nodules were yellow-tan. Microscopic examination revealed a lobular disposition of tumour cells presenting a large microvacuolated cytoplasm and well-defined cell borders. The finely vacuolated cytoplasm were not highlighted by Alcian blue and periodic acid Schiff (PAS) stains. The nuclei were round, with moderate atypia, and contained a small nucleoli (Fig. 1c). The stroma was often fibrotic. Mitoses were calculated as two per ten high-power fields; the index of proliferation ki67 (MIB-1 antibody, DAKO) was calculated at 3%. Necrosis and vascular invasion were absent. No lymph node metastasis was detected. Immunohistochemistry confirmed that most tumour cells expressed chromogranin (Fig. 1d), synaptophysin and gastrin (Fig. 1e). An examination of the oil-red-O staining showed that tumour cells contained numerous lipid droplets (Fig. 1f). Five years after the operation, there was no evidence of disease recurrence. The CT scan and levels of circulating chromogranin and gastrin were normal.

The morphological appearance of this endocrine tumour consisting in clear microvacuolated cells is highly distinctive. Endocrine tumour with clear cells has been rarely reported in the thyroid [1], in the adrenocortical gland, in the stomach, in the lung and in the gall bladder. In the pancreas, clear cell endocrine tumours are mostly described

Fig. 1 **a** Unenhanced computer tomography (CT) scan of the liver: two strongly hypoattenuated lesions (*arrows*), the biggest suggesting steatosis component. **b** Enhanced CT scan of the liver at the same level of that in **a**. The two lesions are not enhanced. **c** High-power view of microvacuolated clear cells disposed in lobules. The vacuoles are not stained by periodic acid Schiff (original magnification $\times 400$). **d** Tumour cells strongly express chromogranin (immunoperoxidase; original magnification $\times 200$). **e** Most cells demonstrate reactivity for gastrin (immunoperoxidase; original magnification $\times 200$). **f** The oil-red-O staining confirms the presence of numerous lipid droplets in the cytoplasm of most tumour cells ($\times 300$)

in VHL disease [6]. Only four cases of clear cell endocrine tumour have been described in pancreas without a VHL disease [2–5]. These four tumours were non-functional and were composed of cells containing lipid droplets associated with glycogen in one case [2]. One of these cases was described in a man with a history of MEN1 [5]. The present case is the first clear cell gastrinoma to be reported.

A clear cytoplasm can be the result of accumulation of glycogen, mucin or lipid. It can also be due to the swelling of mitochondria [1]. In our case, there was no evidence of accumulation of glycogen or mucin, as shown by the negativity of the PAS and Alcian blue colorations. However, tumour cells contained numerous lipid droplets highlighted by the oil-red-O staining. Interestingly, the hypoattenuated aspect at CT scan, which is unusual for endocrine tumours, was in accordance with the microscopic findings.

In conclusion, we report the first case of clear cell gastrinoma of the pancreas not associated with VHL disease, due to an accumulation of lipid droplets. Clear cell tumours are a diagnostic challenge for pathologists, and immunohistochemical detection of endocrine markers is essential to confirm the diagnosis. This tumour is important

for the recognition and differentiation of mucinous carcinomas and metastases of renal carcinoma, especially in the liver. A clear cell “sugar” tumour, which can involve the pancreas, should also be eliminated.

ANNOUNCEMENTS

6 May 2006

Problems in Breast Pathology
Malta College of Pathologists
Malta

Course Director
Professor J.G. Azzopardi

Scientific Secretariat
J. De Gaetano and V. Eusebi

9.00 Registration

Chair: J.G. Azzopardi (London/Malta) & Rosemary Millis (London)
9.30–10.00 Ian Ellis (Nottingham) : Prognostic factors: old versus new.

10.00–10.30 Gianni Bussolati (Torino) : The contribution of 3D models to the understanding of breast pathology.

10.30–11.00 Tibor Tot (Falun) : The theory of the sick lobe and the possible consequences.

11.00–11.30 Frederick Koerner (Boston) : The histogenesis of early breast carcinoma.

11.30–12.00 Tanya Tavassoli (New Haven) : To DIN or not to DIN, that is the question.

12.00–12.30 Discussion

Chair: J. Rosai (Milano) & G. Stamp (London)

14.30–15.00: James Connolly (Boston) : Present findings from the benign breast project of the nurses health study.

15.00–15.30: Stuart Schnitt (Boston) : Columnar cell lesions and flat epithelial atypia.

15.30–16.00 Hans Peterse (Amsterdam) : Ring carcinomas: the phenomenon of shift of cell polarization.

16.00–16.30: Thomas Krausz (Chicago) : Breast tumours. Race, loneliness and the pathologist.

16.30–17.00 : Werner Boecker (Muenster): The progenitor cell concept of breast epithelium and how it changes our understanding of proliferative breast disease.

17.00–17.30 : Sunil Lakhani (Brisbane): Myoepithelial cell and breast cancer.

17.30–18.00 : Vincenzo Eusebi (Bologna) : Salivary-like tumours of the breast.

18.00–18.30 : Juan Rosai (Milano) : The vascular lobule. A pitfall on the interpretation of vascular skin lesions following irradiation for breast carcinoma.

S.G. Silveberg (Baltimore) & Jane Dahlstrom
(Camberra) : Conclusive remarks

The congress fee is 30 €, that includes light lunch payable on the spot.

15–16 June 2006

Thyroid Pathology for the Practicing Pathologist
15 rue de l'Ecole de Médecine, Paris, France

A 2-day course will take place in Paris again under the auspices of the French Division of the I.A.P.

This course will be given in English by Prof. M. Sobrinho-Simões (Porto) and Prof. R. Heimann (Brussels).

It will consist of lectures alternating with slide reviews and a slide seminar over a multihead microscope. The cases of this seminar will be sent (on CD) before the meeting.

The audience will be limited to 22 participants.

Course fees: 390 euros (320 euros for members of any I.A.P. division). The fees include registration, hand-out, CD of the slide seminar and coffee breaks.

For further information please contact

Mrs. M. Fontanière
Administrative Secretary
French Division of the I.A.P.
32 Cours Albert Thomas
69008, Lyon, France
Fax: 33 4 78754311

Current practice of Gleason grading of prostate carcinoma

Received: 5 October 2005 / Accepted: 17 October 2005 / Published online: 23 November 2005
© Springer-Verlag 2005

Abstract The Gleason grading system remains one of the most powerful prognostic factors in prostate cancer and is the dominant method around the world in daily practice. It is based solely on the glandular architecture performed at low magnification. The Gleason grading system should be performed in needle core biopsies and radical prostatectomy specimens where it shows a reasonable degree of correlation between both specimens, and most importantly, it remains vital in the treatment decision-making process. This review summarizes the current status of Gleason grading in prostate cancer, incorporating recent proposals for the best contemporary practice of prostate cancer grading.

Keywords Prostate cancer · Gleason grade · Gleason score · Prostate biopsy · Radical prostatectomy

Introduction

The Gleason grading system for prostate cancer, named after Donald F. Gleason, is the predominant grading system

around the world [21–23]. The Gleason grading system is based on glandular architecture which can be divided into five patterns of growth (also known as grades) with decreasing differentiation [10, 21–23]. The primary and secondary pattern or grade, i.e., the most prevalent and the second most prevalent pattern or grade is added to obtain a Gleason score or sum that is to be reported (see [Appendix](#)) [10, 21]. Nuclear atypia or cytoplasmic features are not evaluated. An important issue is that the initial grading of prostate carcinoma should be performed at low magnification using a 4× or 10× lens [16, 18]. Then one may proceed with high-power objectives to look for rare fused glands or a few individual cells. Gleason grading of prostate cancer has changed over the years to adapt to needle biopsies and radical prostatectomy specimens that were unavailable at time when Gleason proposed his system [3, 4, 9, 14, 18, 19, 31, 32, 35, 36, 39, 48]. Issues on the application of the Gleason grading system in prostate cancer have been dealt with in recent consensus conferences organized under the auspices of the Urothology Working Group (European Society of Pathology, ESP), the European Society of Urothology (a full section office member of the European Association of Urology, EAU), and the Italian Society of Urology (SIU; Florence, Italy, June 2003; Palermo, Sicily, June 2005) [9, 39], World Health Organization (Lyon, France, December 2002; and Stockholm, Sweden, September 2004) [3, 14], and International Society of Urologic Pathology (San Antonio, TX, USA, March 2005) [18]. The authors of this review have been involved in the organization and participated in and contributed to these conferences. Important recommendations follow.

Gleason score as prognostic and predictive factor

Gleason grading remains as one of the most significant factors in the clinical decision-making activity both in needle biopsy specimens and after radical prostatectomy is performed; that is, it predicts pathological stage, margin status, biochemical failure, local recurrences, lymph node, disease progression, or distant metastasis after prostatec-

tomy [3, 5–8, 11–13, 31, 32, 35]. Radiation therapy, radical prostatectomy, and other therapies are initially based on the Gleason score; in practice, Gleason scores of 7–10 are associated with worse prognosis, meanwhile Gleason scores of 5–6 are associated with lower progression rates after therapy [17, 19, 20]. In recent years, Gleason score has been included in clinical nomograms which are used with increasing frequency to predict disease progression [25–27, 30, 40, 44–48].

Reporting Gleason scores in prostate needle biopsies

Once carcinoma is detected in the needle biopsy, further descriptive information regarding the tumor type, Gleason score, and amount of cancer is necessary for management of the patient [35, 38]. As a recently indicated, the highest Gleason score was selected by most urologists to determine their treatment plan regardless of the overall involvement (Table 1) [35, 38, 45]. Some issues that need clarification follow.

Gleason scores 2–4

The diagnosis of Gleason scores 2–4 on needle biopsies should be made “rarely, if ever,” and the reasons are compelling [18]: (1) Gleason scores 2–4 cancer is extraordinarily rare in needle biopsies as compared to transurethral resection (TURP) specimens, (2) poor reproducibility among experts [1, 2, 16], (3) the correlation with the prostatectomy score is poor, and (4) “low” Gleason scores of 2–4 may misguide clinicians into believing that there is an indolent tumor [20]. A recent consensus stated that a Gleason score of 1+1=2 is a grade that should not be diagnosed, regardless of the type of specimen with extremely rare exception, since most of these cases in the era of Gleason would today be referred to as adenosis (atypical adenomatous hyperplasia) because of improvement in recognizing basal cells [17, 18, 29]. Cribriform morphology is not allowed within Gleason pattern 2 [5].

Gleason pattern 3

Cribriform pattern 3 applies to round, well-circumscribed glands of the same size of normal glands, but only rare cribriform lesions satisfy these criteria. Therefore, the majority of cribriform patterns should be diagnosed as Gleason pattern 4. “Individual cells” would not be allowed within Gleason pattern 3 [5, 18, 19].

Gleason pattern 4 in Gleason score 7 tumors

The importance of the percentage of Gleason 4 pattern in Gleason score 7 tumors accumulates rapidly [18, 19, 34, 35, 40, 47, 49]. In recently generated nomograms, patients with Gleason score 4+3 vs 3+4 are stratified differently [30]. Whether or not the percentage of pattern 4 tumor should be included in the report remains optional at present time. Small, ill-defined glands with poorly formed glandular lumina also warrant the diagnosis of Gleason pattern 4 as stated by a recent consensus [18].

Gleason pattern 5

Comedonecrosis when seen in solid nests or cribriform masses should be regarded as Gleason pattern 5. However, the definition of comedonecrosis requires intraluminal necrotic cells and/or nuclear debris (karyorrhexis) [18].

Tertiary pattern

Another important change recently incorporated in current practice is the recognition and reporting of the tertiary pattern in needle biopsies [34, 43]. This includes tumors with patterns 3, 4, and 5 in various proportions on a biopsy. Tertiary patterns are uncommon, but when the worst Gleason grade is the tertiary pattern, it should influence the final Gleason score, and therefore, the primary pattern and

Table 1 Diagnostic reporting of Gleason score (see text)

General features

- Perform Gleason grading at low magnification using a 4× or 10× lens.
- Report primary pattern and secondary pattern and assign Gleason score.
- If only one pattern is present, double it to yield Gleason score. A Gleason score is usually assignable even if the cancer is extremely small.
- In a needle biopsy with more than 2 patterns (tertiary pattern), the worst pattern must be reflected in the Gleason score even if it is not the predominant or secondary pattern, use the rule “the most and the worst” (see text).
- In a radical prostatectomy with more than 2 patterns, the primary and secondary patterns must be reflected in the Gleason score. Add tertiary pattern as a note in the report.
- Provide Gleason score for each separately involved core when identified and give overall Gleason score when mixed in one container.
- In general, a diagnosis of Gleason scores 2–4 should not be made.
- Do not report Gleason score after hormonal or radiation therapy except if cancer shows no treatment effect.

Optional features

- Provide percent of tumor with Gleason pattern 4 in Gleason score 7.
- Provide percent of tumor with Gleason patterns 4 and 5 in tumors with Gleason scores 8–10.

the highest grade should be recorded following the rule of “the most and the worst” [18]. For example, a case with primary Gleason pattern 3, secondary pattern 4, and tertiary pattern 5 should be assigned a Gleason score of 8. These tumors should be classified overall as high grade (Gleason scores 8–10) [43, 46].

Needle biopsy with different cores showing different grades

This is related to a case when one or more of the cores shows pure high-grade cancer (i.e. Gleason score 4+4=8), and the other cores show pattern 3 (3+3, 3+4, or 4+3) cancer [18, 24, 27, 35]. If one reports the grades of each core separately, whereby the highest grade tumor (Gleason score 8) would typically be the one selected by the clinician as the grade of the entire case. Others give instead an overall score for the entire case. For example, in a case with Gleason score 4+4=8 on one core with pattern 3 (3+3=6, 3+4=7, 4+3=7), on other cores, the overall score for the entire case would be Gleason score 4+3=7 or 3+4=7, depending on whether pattern 4 or 3 predominated. Likewise, it was demonstrated that when one core is Gleason score 4+4=8 with other cores having pattern 3, the pathological stage at radical prostatectomy is comparable to cases with all needle cores having Gleason score 4+4=8 [3, 6–8, 18, 19]. The use of the highest core grade of the given case in cases where there are multiple cores of different grades advocated in current tables and nomograms gives additional support for giving cores a separate grade rather than an overall score for the entire case. This is the rationale of a recent survey in which 81% of urologists used the highest Gleason score on a positive biopsy, regardless of the overall percentage involvement, to determine treatment [45]. Consequently, it has been recommended to assign individual Gleason scores to separate cores as long as the cores were submitted in separate containers or the cores were in the same container yet specified by the urologist as to their location (i.e., by different color inks). In addition, one has the option to also give an overall score at the end of the case [33, 35].

In cases where a container contains multiple pieces of tissue and one cannot be sure if one is looking at an intact core, it is recommended that one should only give an overall score for that container [18].

Reporting Gleason scores in radical prostatectomies

In these specimens, one should assign the Gleason score based on the primary and secondary patterns with a comment if present on the tertiary pattern (Table 1) [3, 18, 19]. Specific issues follow.

Gleason scores 2–4

Gleason scores 2–4 are rarely seen as the grade of the main tumor in radical prostatectomies performed for stages T1c or T2 disease. These tumors are typically seen in multifocal incidental adenocarcinoma of the prostate found within the transition zone in TURP specimens [17–19]. The situation where Gleason scores 2–4 tumor represents the major tumor at radical prostatectomy performed for tumor incidentally found on TURP (stages T1a and T1b) is uncommon. In one study, Gleason scores 2–4 were the grade of the main tumor in 2% of the radical prostatectomy specimens; this represents a disproportionate number of T1a and T1b tumors, as compared to what would be currently seen in today’s practice. All men with only Gleason scores 2–4 tumor at radical prostatectomy are cured [18, 19].

Gleason scores 5–6

It is important to recognize that the majority of tumors with Gleason scores 5–6 are cured after radical prostatectomy [18, 26].

Gleason score 7

Tumors with a Gleason score of 7 have a significantly worse prognosis than those with a Gleason score of 6. Given the adverse prognosis associated with Gleason pattern 4, one would expect that whether a tumor with Gleason score 3+4 vs 4+3 would influence prognosis [26]. There have been several studies addressing Gleason score 3+4 as compared to Gleason score 4+3 at radical prostatectomy, with somewhat conflicting results. In one study, they reported no significant survival advantage for Gleason pattern 3+4 over 4+3, but other study showed that Gleason score 3+4 vs 4+3 correlated with both stage and progression in men with serum PSA values less than 10 ng/ml and organ-confined disease [30, 47, 48]. Several other investigations have shown that Gleason score 4+3 has a worse prognosis. This is an issue in which much work needs to be done.

Gleason scores 8–10

Gleason scores 8–10 may account for only 7% of the grades seen at radical prostatectomy, but these patients have highly aggressive tumors with advanced stage such that they are not amenable to surgical therapy alone. Overall, patients with Gleason scores 8–10 at radical prostatectomy have a 15% chance of having no evidence of disease at 15 years following surgery [26, 33].

Percent Gleason pattern 4/5

The proportion of high-grade tumor as the preferred method for grading prostate cancer has been proposed, as it is predictive for progression at the extremes (greater than 70% or less than 20% of pattern 4/5) [12, 13]. It has been recently demonstrated that classifying tumors based on the combined percent of pattern 4/5 is more predictive than stratifying patients into Gleason score alone. Therefore, it has been recommended these data be included in the report [13].

Tertiary Gleason pattern

In radical prostatectomy, a higher proportion of cases are found to contain more than two grades, and over 50% of them contain at least three different grades [11, 18]. The progression rate of Gleason scores 5–6 tumor with a tertiary component of Gleason pattern 4 is almost the same as those of pure Gleason score 7 tumors. Gleason score 7 tumors with tertiary pattern 5 experience progression rates following radical prostatectomy approximating pure Gleason score 8 tumors [40, 43]. On the other hand, no such significance could be seen in cases of Gleason (4+4) score 8 with tertiary pattern 5; since Gleason score 8 tumors are already aggressive, the existence of pattern 5 elements adds no difference. These tumors should be graded routinely (primary and secondary patterns) with a comment in the report noting the presence of the tertiary element. In the setting of high-grade cancer (scores 8–10), one should ignore lower-grade patterns if they occupy less than 5% of the area of the tumor [35, 36, 38, 39].

Tumors with one predominant pattern and a small percentage of higher-grade tumor

Some controversy still exist on how to grade tumors, which are over 95% of one pattern, where there is only a very small percentage of higher-grade tumor. For example, a tumor composed of >95% Gleason pattern 3 and <5% pattern 4, some experts would assign a Gleason score 3+3=6, as it has been proposed that one needs over 5% of a pattern to be present for it to be incorporated within the Gleason score. Others might grade the tumor as Gleason score 3+4=7. It seems that the existence of a high-grade component, even if it constitutes less than 5% of the whole tumor, has a significant adverse influence [18, 20].

Radical prostatectomy specimens with separate tumor nodules

Radical prostatectomy specimens should be processed in an organized fashion where one can make some assessment as to whether one is dealing with a dominant nodule or separate tumor nodules and assign a separate grade to each dominant tumor nodule(s). Most often, the dominant nodule

is the largest tumor, which is also the tumor associated with the highest stage and grade [35].

Grading variants and variations of adenocarcinoma of the prostate

A number of architectural or cytologic variations of carcinoma of the prostate have been described [15, 28, 35, 41, 42, 50]. These are descriptive terms used to assist pathologists avoid diagnostic pitfalls. Most of the times, one should grade the tumor solely based on the underlying architecture with some exceptions (Table 2). Variants of prostate cancer include ductal, mucinous (colloid), mucinous signet-ring cell, small cell carcinoma, sarcomatoid carcinoma, and some others (Table 2). The former three are diagnoses tenable only on examination of radical prostatectomy or TURP specimens. If seen in needle biopsy specimens, the diagnostic terminologies used are adenocarcinoma of prostate with ductal features, adenocarcinoma of prostate with signet-ring cell features, and adenocarcinoma of prostate with mucinous (colloid) differentiation. Small cell carcinoma and sarcomatoid carcinoma may be diagnosed on needle biopsies. Ductal adenocarcinoma should be graded as Gleason score 4+4=8 while retaining the diagnostic term of ductal adenocarcinoma to denote their unique clinical and pathological features. There is no

Table 2 Gleason grades in histological variants and variations of prostate cancer (see text)

Variants

- Ductal carcinoma [pattern 4]
- Small cell carcinoma [no grade applies]
- Mucinous (colloid) carcinoma [pattern 4 (some pattern 3) vs grade according to underlying pattern]
- Mucinous signet-ring cell carcinoma [no grade applies]
- Sarcomatoid carcinoma [no grade applies]
- Pleomorphic giant cell [pattern 5]
- Adenosquamous carcinoma [uncertain]
- Lymphoepithelioma-like [no grade applies]
- Basal cell/adenoid cystic carcinoma [no grade applies]
- Urothelial carcinoma (involving prostatic ducts and acini with or without stromal invasion) [no grade applies]
- Squamous cell carcinoma [no grade applies]

Variations

- Atrophic features [underlying glandular pattern]
 - Pseudohyperplastic [pattern 3]
 - Glomeruloid [pattern 3 or pattern 4]
 - Collagenous micronodules (mucinous fibroplasia) [underlying glandular pattern (most pattern 3)]
 - Focal acellular mucin extravasation [ignore mucin and use underlying glandular pattern]
 - Foamy gland carcinoma [underlying glandular pattern (most pattern 3)]
 - Non-mucinous signet-ring cell features (cytoplasmic vacuoles) [underlying glandular pattern (most pattern 4 or 5)]
 - Hypernephroid [pattern 4]
-

consensus on how mucinous (colloid) carcinoma should be scored [18]. Some authors suggest that a Gleason score of 8 is to be assigned, while others recommend ignoring mucin and grading the tumor based on the underlying architectural pattern. Small cell, sarcomatoid, and mucinous signet-ring cell carcinomas should not be assigned a Gleason grade. It has been suggested that the rare pleomorphic giant cell carcinoma of the prostate should be assigned a pattern 5 (Table 2) [18, 28, 37].

Sources of discrepancies between needle biopsy and radical prostatectomy Gleason scores

Several studies have addressed the correlation between Gleason scores in needle biopsies and corresponding radical prostatectomy specimens [35]. In a recent meta-analysis from 18 studies, exact correlation of Gleason scores was found in 43% of cases and correlation plus or minus one Gleason score unit in 77% of cases. Undergrading of carcinoma in needle biopsy is the most common problem occurring in 42% of all reviewed cases, and overgrading is present in up to 15% of cases. In general, adverse findings on needle biopsy accurately predict adverse findings in the radical prostatectomy, whereas favorable findings on the needle biopsy do not necessarily predict favorable findings in the radical prostatectomy [35, 49].

Sampling error

This is related to the small sample of tissue inherent to needle biopsy [35]. The most common type of sampling error occurs when there is a higher-grade component present within the radical prostatectomy, which is not sampled on needle biopsy. This typically occurs when a needle biopsy tumor is graded as Gleason score 3+3=6, and in the prostatectomy exists a Gleason pattern 4 which was not sampled on the biopsy, thus resulting in a prostatectomy Gleason 3+4=7. In some instances, undergrading results from an attempt to grade very tiny areas of carcinoma, so-called minimal or limited adenocarcinoma. Overgrading can result from sampling error in cases where the high-grade pattern is present in needle biopsy, but it may only represent a very minor element in the radical prostatectomy specimen [35].

Borderline cases

There are some cases in the original description of the Gleason grading system that are right at the interface between two different patterns leading to interobserver and possibly intraobserver variability [21, 35].

Pathology error

A common pathology error is seen when pathologists assign a Gleason score of <4 on a needle biopsy which in fact was Gleason score 5–6 or higher. When there is a limited focus of small glands of cancer on needle biopsy, by definition, this is a Gleason pattern 3 or higher [35]. Gleason pattern 3 consists of small glands with an infiltrative pattern. Biopsying truly low-grade adenocarcinoma of the prostate could not result in just a few neoplastic glands but rather would be more extensive, as low-grade adenocarcinoma grows as nodules of closely packed rather than infiltrating glands. Undergrading may result from difficulty in recognizing an infiltrative growth pattern or failing to recognize the presence of small areas of gland fusion [35].

Pathologists' experience

With experience, pathologists recognize grading pitfalls; in particular, the fact that Gleason scores of 4 and lower are almost nonexistent in needle biopsy situation. Furthermore, small areas of fusion in the presence of a predominantly grade 3 background are recognized and will yield a Gleason score of 7 [35, 46].

Intraobserver and interobserver variability

Intraobserver variability of Gleason grade and exact agreement was reported in 43–78% of cases, and agreement within plus or minus one Gleason score unit was reported in 72–87% of cases. Gleason wrote that he duplicated exactly his previous histological scores approximately 50% times. Highly variable levels of interobserver agreement on Gleason scores have also been reported, with ranges of 36–81% for exact agreement and 69–86% within plus or minus one Gleason score unit [45–49].

Conclusions

The Gleason grading system is a powerful tool to predict response to therapy. The needle biopsy Gleason score correlates with virtually all other pathological and clinical parameters after radical prostatectomy. The Gleason score assigned to the tumor at radical prostatectomy is the most powerful predictor of progression and is very useful in stratifying patients for therapy. However, still significant deficiencies in the practice of this grading system exist. An important issue frequently missed by practicing pathologists is that the initial grading of prostate carcinoma should be performed at low magnification using a 4× or 10× lens. Keeping this in mind might help pathologists avoid

overgrade or undergrade prostate cancer in daily practice. Improvements in Gleason grading reproducibility can be achieved by recognizing problematic areas and educating physicians via meetings, courses, website tutorials, and publications.

Appendix

Gleason pattern 1 Nodule of separate, closely packed glands which do not infiltrate into adjacent benign prostatic tissue is very well circumscribed. The glands are of intermediate size and approximately equal in size and shape. The nucleus is typically small, and cytoplasm frequently is abundant and pale-staining. Nuclear and cytoplasm appearances are not taken into account in diagnosis. This pattern is exceedingly rare and usually seen in transition zone cancers (Fig. 1).

Gleason pattern 2 This pattern is characterized with round to oval glands with smooth ends. The glands are more loosely arranged and not quite as uniform in size and

shape as those of Gleason pattern 1. There may be minimal invasion by neoplastic glands into the surrounding non-neoplastic prostatic tissue. The glands are of intermediate size and larger than those in Gleason pattern 1. The variation in glandular size and separation between glands is less than that seen in pattern 3. Although not evaluated in Gleason grading, the cytoplasm of Gleason pattern 2 cancers is abundant and pale-staining (Fig. 1). Gleason pattern 2 is usually seen in transition zone cancers but may occasionally be found in the peripheral zone.

Gleason pattern 3 This pattern is the most common pattern but is morphologically heterogeneous. The glands are infiltrative, and the distance between them is more variable than that in patterns 1 and 2. Malignant glands often infiltrate between adjacent non-neoplastic glands. The glands of pattern 3 vary in size and shape and are often angular (Fig. 1). Small glands are typical for pattern 3, but there may also be large and irregular glands. Each gland has an open lumen and is circumscribed by stroma. Cribriform pattern 3 is rare and difficult to distinguish morphologically from cribriform high-grade prostatic

Fig. 1 Examples of Gleason patterns 1 (a) and 2 (b), Gleason pattern 3 (c–e), Gleason pattern 4 (f–h), and Gleason pattern 5 (i–k). a–k H & E staining

intraepithelial neoplasia (PIN). The latter shows the presence of basal cells. These are lacking in cribriform pattern 3 prostate cancer. This heterogeneous expression of Gleason grade 3 raised an initial subdivision in patterns A, B, and C, respectively.

Gleason pattern 4 Glands appear fused, cribriform, or they may be poorly defined and small. Fused glands are composed of a group of glands that are no longer completely separated by stroma (Fig. 1). The edge of a group of fused glands is scalloped, and there are occasional thin strands of connective tissue within this group. The hypernephroid pattern described by Gleason is a rare variant of fused glands with clear or very pale-staining cytoplasm. Cribriform pattern 4 glands are large or they may be irregular with jagged edges. As opposed to fused glands, there are no strands of stroma within a cribriform gland. Most cribriform invasive cancers should be assigned a pattern 4 rather than pattern 3. Poorly defined glands do not have a lumen that is completely encircled by epithelium.

Gleason pattern 5 This pattern is characterized with an almost complete loss of glandular lumina which are only occasionally present. The epithelium forms solid sheets, solid strands, or single cells invading the stroma; comedonecrosis may be present (Fig. 1). Care must be applied when assigning a Gleason pattern 4 or 5 to limited cancer on needle biopsy to exclude an artifact of tangential sectioning of lower-grade cancer.

Xq25 and Xq26 identify the common minimal deletion region in malignant gastroenteropancreatic endocrine carcinomas

Received: 29 June 2005 / Accepted: 3 August 2005 / Published online: 22 October 2005
© Springer-Verlag 2005

Abstract Loss of heterozygosity (LOH) for markers on X chromosome are associated with malignancy in endocrine tumors of the stomach and pancreas. The aim of this work is to investigate low-grade, well-differentiated endocrine carcinomas (WDEC) vs high-grade, poorly differentiated endocrine carcinomas (PDEC) of the gastroenteropancreatic (GEP) tract for common deletion regions on X chromosome. We performed a comparative allelotyping analysis with 24 highly polymorphic markers for the X chromosome in 12 WDECs and 5 PDECs. Overall, the LOH frequency in all informative loci investigated was 59% in primary and 61% in metastasis, with a significantly higher rate in PDECs than in WDECs ($p < 0.015$ for primary and $p < 0.00005$ for metastasis). In both WDECs and PDECs, the small Xq25 region as defined by DXS8059, DXS8098, and DXS8009 markers showed higher LOH rate as compared to the rest of the chromosome markers ($p < 0.04$). In addition, LOH was very frequently elevated also in DXS294 and in DXS102 loci mapping the chromosomal region Xq26. In no instances differences were found between primary tumors and metastases. Methylation analysis revealed that Xq25 loss preferentially occurred on the inactive X chromosome, a feature in agreement with findings from other human cancers suggesting escape of tumor suppressor genes to X

chromosome inactivation at this region. Overall, our data indicate that the two chromosomal regions, Xq25 and Xq26, may participate to the malignant progression of GEP endocrine carcinomas.

Keywords X chromosome · Gastroenteropancreatic endocrine carcinomas · Loss of heterozygosity · Tumor suppressor genes

Introduction

Molecular and cytogenetic studies indicate that X chromosome is involved in the carcinogenesis and malignant progression of different types of human tumor. An increasing number of genes have been isolated as potentially responsible. Comparative genomic hybridization (CGH) analysis has demonstrated frequent gains on X chromosome that correlated with tumor progression in liver [38], stomach [33], and adrenal gland [32]. Conversely, X chromosome deletions have frequently been associated with the presence of metastases and/or worse prognosis in cancer of the breast [28], the uterine cervix [18], the ovary [6], and in papillary renal cell carcinoma [16]. These deletions are regarded as strong evidence for the occurrence of tumor suppressor genes (TSG) on this chromosome [6, 9, 16, 28, 29].

In our previous studies, allelic losses [loss of heterozygosity (LOH)] for just three microsatellite markers on X chromosome (DXS989 on p arm and DXS1003 and DXS1192 on q arm) were found to be restricted to foregut malignant endocrine tumors [9, 29]. These data were subsequently confirmed by Missiaglia et al. [25] who demonstrated a strong association between X chromosome markers LOH, aggressiveness, and shorter survival rates in 20 nonfunctioning pancreatic endocrine tumors (PETs). More recently, on this line, Chen et al. [4] found that X chromosome LOH frequently occurred in gastrinomas and was significantly associated with aggressive tumor growth and larger tumor size. On this basis, X chromosome LOH has been regarded as a potentially useful prognostic factor for aggressive growth in endocrine tumors of the upper

gastrointestinal tract and pancreas. Conversely, we and others demonstrated that poorly differentiated endocrine carcinomas (PDEC) of the stomach and the colon display similar genetic alterations indicating a site-independent genetic background for undifferentiated endocrine carcinomas at variance with well-differentiated endocrine carcinomas (WDECs) [12, 30].

In this work, we performed a high-resolution comparative allelotyping on X chromosome on WDECs vs PDECs of the gastroenteropancreatic (GEP) tract. Methylation analysis for CpG islands on Xq25 and immunohistochemistry for metalloproteinases 2 (MMP-2) and 9 (MMP-9) regulated by the myeloid elf-1 like factor gene (MEF) located at Xq26 were also performed. Our main aim was to identify minimal common deletion regions, ultimately indicating TSG possibly involved in the mechanism of malignancy in tumors of the GEP endocrine system.

Materials and methods

Patients and tissue specimens

Matched tumor and adjacent normal tissues were obtained from 17 female patients with malignant endocrine tumors of the pancreas and gastrointestinal tract collected in the files of the Department of Anatomic Pathology, University of Parma. According to the World Health Organization (WHO) criteria [36], in 12 patients, the tumors were WDECs (low grade malignant tumors, WHO class 2), and in five patients, the tumors were PDECs (high grade

malignant tumors, WHO class 3). The age range of patients with WDEC was 43–73 years (mean 58.6), and with PDEC, 45–83 years (mean 70).

The main clinicopathological data of patients are summarized in Table 1. In eight cases, metastases were also analyzed (lymph node, cases #1, #2, #4, #6, #13, #14; liver, case #16, and both lymph node and liver, case #17). In two cases (#3 and #12), only liver metastases were available for the study. PDECs were either solitary (#13, #14, #15) or associated with adenocarcinoma (#16) or adenoma (#17). The primary tumor of patient #17 was not available for study, and DNA from liver and lymph node endocrine carcinoma metastases was used. In the two biphenotypic cases, the endocrine and nonendocrine tumor components occurred as separate masses with distinct morphology and were microdissected separately.

All tissue specimens were routinely formalin fixed and paraffin embedded. For 80% tumor cell enrichment, both normal and tumor tissues were microdissected from 5- μ m sections stained with hematoxylin and DNA extracted using the QIAamp Tissue Kit (Qiagen GmbH, Hilden, Germany).

Polymerase chain reaction

DNA samples were microallelotyped for 24 polymorphic microsatellite markers covering the whole X chromosome (Table 2) selected from the Genome databases (<http://www.gdb.org> and <http://www.geneatlas.org>). Moreover, four microsatellite markers (D3S1621, D3S1100, D3S1478,

D3S1481) located on 3p chromosome were analyzed in the study. Forward primers were synthesized with a fluorescent tag (WellRed dyes from Research Genetics, Huntsville, AL, USA). DNA was amplified in a 25- μ l reaction solution containing 2.5 μ l of 10 \times buffer (Promega, Madison, WI, USA), 1 to 2 mM MgCl₂, 0.4 μ mol/l primer pairs, 200 μ M dNTPs, and 1.25 U Taq polymerase (Promega). Amplifications were performed using a 5-min initial denaturation at 95°C, followed by 35 cycles of 30" at 94°C, 30" at 53–64°C, and 1' at 72°C; or by 40 cycles of 1' at 94°C, 1' at 55°C, and 2' at 72°C (Table 2). The fluorescent-labeled polymerase chain reaction (PCR) products underwent electrophoresis on an automated DNA sequencer CEQ 2000XL (Beckman Coulter Inc., Fullerton, CA), and signals were analyzed using CEQ 2000XL analysis software (Beckman Coulter).

Definition of loss of heterozygosity

Allelic loss was defined as the ratio of relative allelic peak height in the tumor DNA to relative allelic peak height in the corresponding normal DNA. The formula employed for the calculation was (T2/T1)/(N2/N1), where T1 and N1 are the height values for the smaller allele, and T2 and N2 are the height values for the larger allele of the tumor (T) and normal (N) samples, respectively. For informative markers, LOH was scored when signal reduction for one allele was of 40% or more [2, 29].

Methylation-specific polymerase chain reaction

The methylation status of a CpG site located at position 225–226 of the DXS8059 microsatellite sequence was determined by methylation-specific PCR (MS-PCR) [28]. Genomic DNA (3 μ g) was modified with sodium bisulfite as originally described by Herman et al. [14]. DNA modification was performed with the CpGenome DNA modification kit according to the manufacturer's instructions (Intergen Company, Oxford, UK). Primers for PCR amplification of the methylated (MA) allele were 59M2CF, 5'-TG TAGTTAGTTTGGTGGTTTGT-3' and 8059MR, 5'-CAAACCAAAAATTCCCTCCG-3', yielding a 97-bp fragment, whereas the primers for amplification of the unmethylated (UMA) allele were 59M2CF, 5'-TG TAGT TAGTTTGGTGGTTTGT-3' and 8059N4R, 5'-AACCA CAAACCAAAAATTCCCTCCA-3', yielding a fragment of 102 bp. Genomic DNA positive controls were unmethylated DNA from normal lymphocytes for UMA allele and CpGenomeUniversal Methylated DNA for the MA allele (Intergen Company). Multiplexed PCR with all four primers was performed in a final volume of 25 μ l in a mixture containing 125 μ M each dNTP, 1.5 mM MgCl₂, 1 μ M each of the primers, 0.05 U/ μ l of Thermo-Start DNA Polymerase (ABgene, Surrey, UK), and 50 ng of the bisulfite-modified DNA. MS-PCR cycling conditions were as follows: 15' at 95°C, for DNA polymerase activation; 35 cycles each consisting of denaturation at 95°C for 30", primer annealing at 54°C for 30", and elongation at 72°C for

30". MS-PCR products were analyzed by 3% metaphore gel electrophoresis. To determine whether the MA or UMA sequence of the DXS8059 marker was lost, normal ad tumoral tissues were compared for the intensity of MS-PCR bands corresponding to the methylated and unmethylated CpG sites using the Gel Doc software (Biorad). The following formula was employed: $(\text{alleleUMA}/\text{alleleMA})_{\text{NORM}}/(\text{alleleUMA}/\text{alleleMA})_{\text{TUM}}$. Values less than 1 were indicative of LOH on MA allele, and values greater than 1 were for LOH on UMA allele.

Immunohistochemistry

The following primary monoclonal antibodies were used: anti-metalloproteinase 2 (MMP-2, clone 1B4, Novocastra, Newcastle, UK; working dilution, 1/50); anti-metalloproteinase 9 (MMP-9, clone 2C3, Novocastra; working dilution, 1/50). Sections were treated with 10 mM citrate, pH 6.0, in a 750-W microwave oven for three 5' cycles for antigen retrieval before immunostaining. Immunostaining was done with the streptavidin-biotin kit (LSAB2, Dako-cytomation, Glostrup, Denmark) according to the manufacturer's specifications. Slides were counterstained with hematoxylin. Colon carcinomas served as positive control for MMP-2 and liver for MMP-9. Negative controls con-

sisted of substituting normal mouse serum for the primary antibodies. The staining was scored as follows: no positive cells (-); <20% of the tumor cells staining positive (+); 20–50% of the tumor cells staining positive (++) ; >50% of the tumor cells staining positive (+++) [37].

Statistics

The data obtained in the primary tumors and metastases were evaluated separately and examined with χ^2 analysis and Fisher's exact test with the SPSS 11.5 statistical software package (SPSS, Inc., Chicago, IL). *P* values less than 0.05 were considered statistically significant, and two-sided *P* values were used.

Results

Microallelotyping analysis on X chromosome

The results of the LOH analysis are summarized in Table 3. In all 17 patients, LOH was detected for at least 1 of the 24 tested polymorphic markers mapping at the whole X chromosome. In one case (#13), LOH was identified with all microsatellites studied. Metastases showed the same

• LOH, ○ retention of heterozygosity, ★ noninformative, *nd* not determined, *T* primary tumor, *M* metastasis, *A* esocrine component

pattern of alterations as the primary tumors except in cases #1 and #4 in which allelic losses were found for additional loci (five in case #1; one in case #3). Overall, the LOH frequency for all informative loci investigated was 59% for primaries and 61% for metastases, with higher rates for PDECs as compared to WDECs primaries (72 vs. 55%, $p < 0.015$) and metastases (81 vs. 48%, $p < 0.00005$). The frequency of LOH at the individual 24 microsatellite loci varied from 39% in DXS996 locus to 82% in DXS8098 locus. The total degree of informativeness for the microsatellite markers used in the study was of 70% (38–93%), without any difference between WDEC (72%) and PDEC (66%).

Two common regions of deletion were identified on the long arm of X chromosome. Overall, the most frequent losses were observed at Xq25 region with a LOH frequency for DXS8059, DXS8098, and DXS8009 loci as high as 73, 67, and 80%, respectively, in primary tumors and 60, 100, and 75%, respectively, in metastases. No statistical significant difference was observed at any level between primary and metastatic tissues.

In particular, the LOH rate for primary carcinomas in the small region (of approximately 4.6 Mbp in length) defined by DXS8059 and DXS8009 was significantly higher than in the rest of the chromosome ($p < 0.04$). No statistically significant differences were observed between WDECs and PDECs both in primary (68 vs. 87%, respectively) and metastatic tissues (64 vs. 83%, respectively). Moreover, DXS8098 was the only locus lost in WDEC case #2, whereas in case #3, its deletion was associated with a loss of only one of the other p-ter markers. Finally, all informative markers in this region were lost in nine cases (#1mt, #4, #5, #6, #10, #13, #14, #16, #17mt).

The overall frequency of LOH was elevated also for DXS294 (primary, 79% vs metastases, 67%) and DXS102 (primary, 60% vs metastases 71%) loci mapping the chro-

somal region Xq26 (of approximately 1 Mbp in length). The rate of losses at these loci was significantly higher in PDEC (primary and metastasis 100%) than in WDEC (primary 62%, metastasis, 49%). For all cases investigated, the degree of markers' informativeness in the chromosomal regions at Xq25 and Xq26 was of 69 and 70% respectively, with no difference between WDECs and PDECs.

Other microsatellite markers with high LOH rate in WDECs and PDECs both in primary and metastatic tissues were DXS989 (62 and 70%), DXS56 (70 and 67%), DXS990 (67 and 100%), and DXS1153 (71 and 100%) located on Xp22.13, Xq13.2–13.3, Xq21.33, and Xq22.1–22.3 respectively. No statistically significant difference was observed in the LOH frequency of these microsatellite markers between WDECs and PDECs.

To evaluate the relation of allelic losses on X chromosome with those on 3p, reported by several studies [8, 15, 27, 31] to be associated with malignant progression, we have investigated four microsatellite markers of 3p (D3S1621, D3S1100, D3S1478, D3S1481). In our case, the overall 3p LOH rate was 48% in primary tumor and 37.5% in metastases with significant difference between primary PDECs (90%) and WDECs (19%) ($p < 0.0003$). When the LOH rates at Xq25 and Xq26 were compared with those at 3p, an inverse correlation was found for WDECs (Xq25, $p < 0.0007$; Xq26, $p < 0.002$). Conversely, no differences were found for PDECs.

The nonendocrine component of the two biphenotypic tumors (#16, #17) consistently showed a lower number of LOH than its endocrine counterpart (Table 3).

Methylation analysis on X chromosome

Methylation analysis of CpG islands in microsatellite loci may provide information concerning chromosome inacti-

Fig. 1 a Results of methylation-specific PCR of a CpG site located at position 225–226 of the DXS8059 marker in malignant gastroenteropancreatic endocrine tumors. Analysis of the intensity of the bands using the Gel Doc software showed LOH of the methylated allele in all samples except the PDEC #14 (*N* normal, *T* tumor tissue, *M* metastatic tissue, *UMA* unmethylated allele, *MA* methylated allele). **b** Intense immunohistochemical expression of MMP-2 in a case of PDEC (#13). **c** Electropherograms of the same tumor showing LOH for DXS294 marker in tumoral tissue

MA Methylated, UMA unmethylated

vation. To determine if the X copy undergoing LOH in our series of GEP carcinomas was active or inactive, we selected DXS8059 marker containing two CpG sites available for methylation analysis (Fig. 1) because the DXS8098 marker, which showed the highest rate of LOH in our series, does not contain any CpG site. The five WDECs (#4, #6, #7, #9, and #10) and the four PDECs (#13, #14, #16, and #17) which exhibited LOH at DXS8059 marker were analyzed (see Table 4). Our results showed that Xq25 LOH occurred in the active (unmethylated) allele of cases #14 and #16 and in the inactive allele of the remaining cases.

Immunohistochemistry

To determine the potential implication of myeloid elf-1 like factor (MEF), a putative tumor suppressor gene located on Xq26, tumor samples from 10 cases were investigated by immunohistochemistry for MMP-2 and MMP-9 that are negatively regulated by MEF. The immunohistochemical results are summarized in Table 4. The expression of MMP-2 was detected in 5/9 (56%) primary tumors, with strong positivity (+++) in two cases and weak and focal positivity (+) in three cases. The expression of MMP-9 was detected in 2/9 (22%) primary tumors, one of these showing moderate positivity (++) , the other weak staining. No relation between MMP-2 or MMP-9 and Xq26 LOH was found (Table 4). It is worth noting, however, that the two cases with strong MMP-2 positivity showed Xq26 LOH (Fig. 1b).

Discussion

Different regions of X chromosome were shown to be deleted in malignant tumors of different organs including breast [28], uterine cervix [18], ovary [6], prostate [19], and kidney [16]. The present work shows high frequency of LOH on X chromosome in a series of malignant GEP

endocrine primaries (59%) and metastases (61%), with a significantly higher LOH rate in PDEC (72% primaries and 81% metastases) than in WDEC (55% and 48%). This latter finding is in accordance with the results of a recent work by Furlan et al. [12] based on a microallelotyping analysis of chromosomes 1, 3, 5q, 6, 11, and 18, showing a significantly higher frequency of chromosomal derangements in PDECs than in WDECs of the GEP tract. Moreover, no recurrent allelic imbalance at specific chromosomal regions was detected in PDECs according to the primary anatomic site. Similar findings were also reported in a previous study from our laboratory [30]. The present results demonstrate that X chromosome is heavily involved in the chromosomal instability of PDECs.

Our study also aimed at assessing common deletion regions on X chromosome in an attempt to focus on potential TSGs implicated in endocrine tumor pathogenesis and malignancy. The existence of such genes is supported by the X chromosome involvement in the establishment of immortality and in the control of cell proliferation in vitro [21, 34].

Frequent X chromosome LOH has been detected in carcinomas of gallbladder [40], breast [28], ovary [6], and in renal oncocytomas [39]. In neuroendocrine tumors, X chromosome deletions have been reported in parathyroid [11], pancreatic, and gastric tumors [9, 25, 29]. Such losses were associated with malignancy in endocrine tumors of the stomach and pancreas, whereas they were virtually absent in benign neoplasms. However, the small number of markers tested in these studies did not allow to identify a common minimal chromosomal region of deletions [9, 29].

The present study of malignant GEP endocrine tumors relied on a panel of 24 polymorphic microsatellite markers on the whole X chromosome and demonstrated that the two chromosomal regions Xq25 and Xq26 were most frequently lost. The highest frequency of LOH (67% in primaries and 100% in metastases) was found for DXS8098 marker mapping on Xq25 between the two

other frequently deleted loci, DXS8059 and DXS8009 (73 and 80% in primaries and 60 and 75% in metastases, respectively). The same LOH pattern with the highest frequency of losses for DXS8098 and high LOH rates for DXS8009 and DXS8059 was reported in breast carcinomas and associated with larger tumor size, higher histological grade, and axillary lymph node metastasis [28].

For the development of neoplasia, complete inactivation of the tumor suppressor function is necessary in autosomal chromosomes requiring the inactivation of both alleles [22]. In the X chromosome, one of the two copies is almost entirely inactivated by DNA methylation during early development [28]. In the present study, we determined which copy, active or inactive, underwent loss of the Xq25 region. Our results showed that the loss occurs preferentially on the inactive X chromosome. Similar prevalence of Xq25 losses of the inactive Xq has been also reported in ovarian and breast carcinomas [5, 6, 28]. The most likely explanation for this phenomenon is that the putative tumor suppressor gene(s) in Xq25 escapes X inactivation and is expressed from both chromosomes or from the inactive X chromosome alone [28]. In addition, this hypothesis implies that if the putative TSG is expressed on the active X chromosome it may be inactivated by point mutations [28].

There are several putative tumor suppressor genes within the Xq25 chromosome region, here identified as frequently deleted. Among them, ODZ1 and SH2D1A appear as good candidates. ODZ1 encodes for Tenascin, an oligomeric glycoprotein of the extracellular matrix involved in morphogenetic movements, tissue patterning, repair, and tumor invasion [17, 24, 26]. SH2D1A was found mutated in the X-linked lymphoproliferative disease [23] and in associated non-Hodgkin lymphomas [3].

Additional X markers were also found frequently deleted in the present study, including DXS294 (79% in primaries and 67% in metastases) and DXS102 (60% in primaries and 71% in metastases), both mapping at Xq26. This chromosomal region appears to be involved in the development of different tumors including ovarian [6] and breast carcinomas [7] and endocrine tumors of the lung [10]. In ovarian carcinomas, Xq25–26.1 LOH has been associated with higher histological grade and advanced tumor stage [6].

Candidate tumor suppressor genes mapping at Xq26 are myeloid elf-1 like factor MEF and Glypican-3 (GPC-3). MEF (ELF4) is an ETS-transcription factor with tumor suppressive activity as demonstrated in cell lines of human nonsmall cell lung carcinoma [35]. MEF may have an important role in tumor differentiation and angiogenesis by suppressing the transcription and promoter activities of the genes encoding for the matrix metalloproteinases, MMP-2 and MMP-9, and interleukin-8 [13, 35]. In our study, the immunohistochemical expression of MMP-2 was intense in two PDECs only, both with Xq26 LOH, whereas MMP-9 was consistently negative with the exception of two cases showing weak positivity (Table 3). These results do not support the involvement of the tumor suppressor gene MEF in most GEP endocrine carcinomas. GPC-3 is a heparan sulfate proteoglycan linked to the cell membrane by a

glycosyl–phosphatidylinositol anchor and is involved in the progression of several types of malignant tumors, including mesotheliomas, ovarian, and lung carcinomas [20].

Finally, several studies pointed out the significant association of 3p LOH with malignancy in GEP endocrine tumors [8, 15, 27, 31]. In the present study, 3p LOH rates were found inversely correlated with those at Xq25–26 in WDECs, indicating an independent involvement of the two chromosome regions in the pathogenesis of well-differentiated malignant endocrine neoplasms. On the contrary, no differences were found in PDECs in keeping with the high chromosomal instability of this type of tumors. In this study, 3p LOH rates in PDECs were higher than those found in previous investigations from our laboratory [30, 31]. The use of a larger number of 3p markers in the present study may justify such difference, indicating that PDECs have more extended allelic losses on 3p. As previously demonstrated, in fact, the extension of 3p LOH increases with tumor aggressiveness [1].

In conclusion, our data suggest that LOH on X chromosome is an important event in the carcinogenesis of GEP endocrine carcinomas and reveal the existence of two common chromosomal deletion regions, mapping at Xq25 and at Xq26 and harboring candidate tumor suppressor genes potentially involved in the progression and malignant behavior of these tumors.

Acknowledgements We wish to thank Mrs. Emilia Corradini for her histological assistance and Dott. Nicoletta Campanini for immunohistochemistry.

Endoglin (CD105) expression in angiogenesis of colon cancer: analysis using tissue microarrays and comparison with other endothelial markers

Received: 11 April 2005 / Accepted: 3 August 2005 / Published online: 22 September 2005
© Springer-Verlag 2005

Abstract Some markers of angiogenic endothelial cells are emerging as targets of cancer therapy. The present study compares the expression of CD105 with that of other endothelial markers in all tissue layers during the development of colon cancer. We immunohistochemically analyzed the expression of the colon adenoma–carcinoma sequence by endothelial cells using a panel of eight endothelial markers. We examined sections from endoscopic mucosal resection and surgical resection of tubular adenoma ($n=31$), carcinoma in adenoma ($n=11$), and adenocarcinoma ($n=34$). Cylindrical cores were punched out from donor paraffin blocks of normal mucosa adjacent to tumors, from tumor lesions of mucosa, submucosa, muscularis propria, subserosa, and serosa, and from lymph node metastases. CD31 (PECAM-1) was universally expressed in the blood vessels of adenoma–carcinoma lesions as well as in normal mucosal vessels (80–95%), with no significant differences. In contrast, cancer-associated blood vessels (up to 80%) and cancer cells themselves expressed high levels of CD105. In normal mucosa, CD105 was weakly expressed in endothelial cells of capillaries ($\leq 21\%$), and significant differences in its expression in endothelial cells between the normal mucosa and adenoma, carcinoma in adenoma, and adenocarcinoma were found. Flt-1, Flk-1, transforming growth factor- $\beta 1$, transforming growth factor- β receptor II, and CD44 were strongly expressed in the cancer cells but were not expressed in the blood vessels. Vascular endothelial growth factor was expressed at $<30\%$ in the blood vessels of adenoma, carcinoma in adenoma, and carcinoma. Moreover, this study provided evidence that CD105 was expressed exclusively in endothelial blood vessels by double immunostaining of

CD105 and D2-40. The present study shows that de novo blood vessels of colon cancer specifically express CD105. These findings provide the basis for novel antiangiogenic cancer therapies.

Introduction

Colon cancer is a widespread human disease that is one of the major causes of morbidity and mortality worldwide [19]. Most colorectal carcinomas are considered to originate from precursor lesions (adenomas) [18]. Adenoma is thought to progress to carcinoma over many years because of multiple accumulated molecular alterations [25].

Angiogenesis is an important step in the process of cancer growth. It promotes metastatic spread by providing the means for cells to detach from the primary tumor and to travel in the bloodstream to distant metastatic sites. Moreover, the most important prognostic factor for colon cancer is the depth of cancer invasion. Cancer is always accompanied by angiogenesis as it grows and invades the surrounding tissues, and angiogenesis is a complex of endothelial cell growth and stem cell differentiation brought about by interactions of growth factors and their ligands.

Vascular endothelial growth factor (VEGF) is a potent mitogen and cytoprotective factor for vascular endothelial cells, and its receptors (VEGFR-1/Flt-1 and VEGFR-2/Flk-1), which are expressed exclusively by endothelial and neoplastic cells, have been documented [6, 11, 26].

CD105 is a receptor for transforming growth factor (TGF)- $\beta 1$ and TGF- $\beta 3$, and it modulates TGF- β signaling by interacting with TGF- β receptor I (TGF- β RI) and/or TGF- β receptor II (TGF- β RII) [22]. CD105 is predominantly expressed on cellular lineages within the vascular system and is overexpressed on proliferating endothelial cells. Several studies indicate that CD105 is involved in the development of blood vessels and that it represents a

powerful marker of neovascularization of various types of tumors, including colon cancer [1, 4, 8, 9, 17, 28]. CD105 is emerging as a prime vascular target of antiangiogenic cancer therapy [10]. We reported that the predominantly CD105-positive microvessel count of polyploid-type early colon cancer is higher than that of nonpolyploid-type early cancer [20]. However, to our knowledge, the expression of CD105 in vessels of lesions invading all the various tissue layers during the colon adenoma–carcinoma sequence (adenoma, carcinoma in adenoma, and adenocarcinoma) has not been compared with that of other endothelial markers.

The use of tissue microarrays in colorectal carcinoma has been validated by analyzing the immunohistochemical expression of some markers [12]. We therefore compared the expression of CD105 in several hundred target spots with that of other endothelial markers in all tissue layers during the development of colon cancer using tissue microarrays and immunohistochemistry. To specifically differentiate the vascular expression of CD105 and CD31 as pan-endothelial markers, we compared them using double immunofluorescence. Additionally, to exclude the idea that the CD105-stained vessels represent lymphatic vessels, we performed a double immunohistochemistry of CD105 and D2-40, which has been reported as a new selective marker for lymphatic endothelial markers [13]. We also compared the vascular expression of the antibody between the normal mucosa adjacent to tumors and the neoplastic lesions.

Materials and methods

Tumor samples

Between 1998 and 2003, 36 consecutive resected colon samples and 40 endoscopic mucosal resection (EMR) samples from 76 patients (42 men, 34 women; age range 39–95 years) with colonic tumors were obtained from the files of the Department of Pathology, Faculty of Medicine, Saga University and its affiliated hospital. The specimens were formalin-fixed and paraffin-embedded, and the tumor was diagnosed from observations of sections stained with hematoxylin and eosin (H&E). Histological subtypes were classified according to the Japanese classification of colorectal carcinoma [29]: 31 tubular adenomas (10 mild, 10 moderate, and 11 severe atypias), 11 carcinomas in adenoma (focally expressed cancer cells in adenoma), and 34 adenocarcinomas (16 well, 16 moderate, and 2 poor differentiations). Table 1 shows the details of the patients and their diseases.

Tissue microarray

To identify the targets of core samples, we examined the microscopic features of each layer of invasion on slide sections and marked the locations to be punched out (Fig. 1).

Table 1 Clinicopathological data

Variable	Number
Number of patient	76
Age (years)	
Range (median)	39–95 (67)
Gender	
Male	42
Female	34
Histopathology	
Tubular adenoma	31
Mild atypia (low-grade dysplasia)	10
Moderate atypia	10
Severe atypia (high-grade dysplasia)	11
Carcinoma in adenoma	11
Adenocarcinoma	34

Moderately differentiated	16
Poorly differentiated	2
Tissue cores	
Normal adjacent tumor	76
Depth of invasion	
Mucosa	76
Submucosa	33
Muscular propria	31
Subserosa	25
Serosa	6
Lymph nodes	11

Under a light microscope, we selected and marked areas of normal mucosa and representative tumor from each layer on H&E slides and corresponding paraffin blocks. The tissue microarrayer (Beecher Instruments, Sun Prairie, WI, USA) was used to prepare cylindrical cores of 1.5 mm in diameter. Cores were punched out from donor blocks and placed in recipient blocks.

Two array blocks of 258 cores were derived from the normal mucosa adjacent to tumors ($n=76$), from tumor lesions from mucosa ($n=76$), submucosa ($n=33$), muscular propria ($n=31$), subserosa ($n=25$), and serosa ($n=6$), and from lymph node metastases ($n=11$). The depth of each core depended on the extent of tumor cell invasion (Table 1). The array blocks were then incubated for 30 min at 37°C to improve adhesion between the cores and the paraffin of the recipient block.

Double immunostaining

For double immunofluorescence, the tissue array slides were deparaffinized and soaked in 0.01 M citrate buffer (pH 6.0) at 90°C for 40 min for antigen retrieval. The samples were treated with 10 mg/ml bovine serum albumin (BSA) to inhibit nonspecific antibody binding and then were incubated with the primary murine monoclonal antibody CD105 for 1 h at 37°C. After washing thrice

Fig. 1 Sources of punctured cores. Cores were punched out from the normal mucosa and neoplastic layer of adenoma at the mucosal level (**a** and **b**), carcinoma in adenoma (**b**), and normal mucosa, as well as in the mucosa, submucosa, muscular propria, subserosa, and serosa levels (**c**) of cancer tissues, and in lymph node metastasis (**d**). The box shows all layers from one advanced cancer in a representative tissue microarray (**e**). *Inset:* A transition area of adenoma (*left half*) and cancer (*right half*) in the right circle of **b**

with PBS (pH 7.2), the samples were incubated with fluorescein-isothiocyanate (FITC)-labeled secondary rabbit polyclonal antibody against murine immunoglobulin G (IgG) for 30 min at 37°C. To inactivate the primary and secondary antibodies, the samples were heated in the citrate buffer at 90°C for 15 min. This treatment made it possible to carry out the second immunoreaction with the monoclonal antibody. For the second immunoreaction, the same procedure was repeated; the samples were treated with 10 mg/ml BSA, incubated with another primary antibody CD31, and then incubated with rhodamine-labeled secondary antibody. After washing with PBS, FITC-labeled and rhodamine-labeled samples were examined using a fluorescence microscope (Olympus BX60, Tokyo, Japan). To detect nonspecific antibody binding, control sections were incubated with either normal murine or rabbit serum or PBS instead of primary antibody. No staining was observed in these control samples.

For double immunohistochemistry, after incubation with the first primary antibody CD105 and then washing with PBS, the alkaline-phosphatase-labeled secondary rabbit polyclonal antibody against murine IgG was reacted for 30 min at 37°C and visualized with the BCIP/NBT substrate system (Dako, USA), which produces a blue purple color. After microwave heating in ethylenediaminetetraacetic acid (EDTA; pH 8) for 5 min, the specimens were incubated with the second primary antibody (D2-40, mouse monoclonal antibody; Nichirei, Japan) for 3 h. The same procedure with the first step was repeated, and the expression of the second antibody was visualized with the

New Fuchsin Substrate Kit (Nichirei), which produces a red color.

Immunohistochemistry

Sections from each array block were cut at a thickness of 4 μ m. Briefly, the slides were placed at 60°C for 15 min, deparaffinized in xylene, and rehydrated in a series of graded alcohols. Thereafter, antigen retrieval was performed by microwave heating in EDTA (pH 8) for 6 min (for CD105, mouse monoclonal clone 4G11), then the slides were autoclaved (121°C) in EDTA (pH 8) for 5 min using the appropriate antibodies (for CD44, mouse monoclonal MH114; VEGF, mouse monoclonal clone C-1; Flt-1, rabbit polyclonal C-17; Flk-1, rabbit polyclonal N-931; TGF- β 1, rabbit polyclonal V; and TGF- β R2, rabbit polyclonal L-21) and with proteinase K (Dako, Japan) for 10 min (for CD31, mouse monoclonal clone JC70A; Table 2). The sections were incubated with primary antibodies overnight at 4°C, washed, and incubated with goat antimouse or goat antirabbit Igs (EnVision Peroxidase; Dako) for 30 min at room temperature.

Histological assessment

Images of an immunostained section ($\times 200$) were captured on a computer (Windows XP, 7000 cl; Fujitsu) with a

Table 2 Used antibody

Antibody	Clone	Pretreatment	Dilution	Company

Nikon ACT-1 software by using a Nikon digital camera (DXm 1200) attached to an operator light microscope (Nikon Eclipse, E600). Assessment was performed on live images from each core. Endothelial staining of at least one blood vessel from each core was considered as a positive expression of the blood vessels. Staining of $\geq 10\%$ of the neoplastic or normal epithelial cells was considered positive in neoplastic or normal epithelial cells. Positive immunoreactivity was graded as weak (+), moderate (++), and intense (+++).

Fig. 2 Double immunofluorescence of CD105 and CD31. Normal mucosa (*upper layer*) and cancer lesion (*lower layer*). CD105 is rarely expressed in the normal mucosa (**a1**) and is intensely expressed in angiogenic small blood vessels and capillaries (**b1**). An intense vascular expression of CD31 is universally noted in all large and small blood vessels and capillaries (**a2** and **b2**). Their characteristics are demonstrated in the merged images (**a3** and **b3**, *arrows*). Original magnification, ×200

Statistical analysis

Differences in the vascular endothelial expression of an antibody between a normal mucosa and neoplastic mucosal adenoma, carcinoma in adenoma, and adenocarcinoma from each layer were analyzed using the *t* test of independent samples. $P < 0.05$ was considered significant.

Results

Double immunofluorescence staining revealed that CD31 (PECAM-1) was universally expressed in small blood vessels and capillaries. On the other hand, CD105 was rarely expressed in normal mucosal vessels; however, in the cancer tissue, CD105 was intensely expressed in newly formed numerous capillaries, which reflect angiogenesis (Fig. 2). After the demonstration that CD105 was specifically expressed in angiogenic blood vessels, the detailed relationship between markers of blood vessels and tumor histology was assessed by immunohistochemistry.

CD31 was universally expressed in the blood vessels of all layers of adenoma, carcinoma in adenoma, and adenocarcinoma lesions (Fig. 3), as well as in those of normal mucosal blood vessels (80–95%) (Fig. 5). Vascular endothelial expression of CD31 in normal and neoplastic

Fig. 3 Expression of CD31 (a1–d1), CD105 (a2–d2), and VEGF (a3–d3). Immunohistochemistry. Original magnification, $\times 200$. Normal mucosa (a1–a3), neoplastic lesion at mucosal level (b1–b3), subserosal level (c1–c3), and lymph node metastasis (d1–d3) from 1.5-mm tissue cores of the same specimen. Intense vascular expression of CD31 (a1); absent expression of CD105 (a2) and VEGF (a3) in normal mucosa. Intense expression of CD31 (b1) in large blood vessels and CD105 (b2) in smaller blood vessels from serial sections. Cancer tissues expressed VEGF but not the blood vessels (b3). In subserosal layer and lymph node metastasis, only CD105 is expressed (c2 and d2). *Inset*: Original magnification $\times 400$

mucosal layers of adenoma, carcinoma in adenoma, and adenocarcinoma from all layers did not significantly differ (Fig. 5). CD105 was intensely expressed in vascular endothelial cells of neoplastic mucosal adenoma, carcinoma in adenoma, and various layers of adenocarcinoma at a level corresponding to the depth of cancer invasion. The CD105 expression was also seen in the cytoplasm of neoplastic epithelial cells (Fig. 3). CD105 was expressed by 30 and 54% of vascular endothelial cells in the neoplastic mucosa of adenoma and carcinoma in adenoma, respectively. Moreover, CD105 was also expressed in endothelial cells of blood vessels in neoplastic mucosa (65%), submucosa (72%), muscular propria (80%), subserosa (68%), serosa (50%) of adenocarcinoma, and lymph node metastasis (45%). In contrast, only 12, 18, and 21% of blood vessels in normal mucosal layers of adenoma, carcinoma in adenoma, and adenocarcinoma, respectively (Fig. 5), weakly expressed CD105, and its expression in normal epithelial cells was not found. Unlike CD31, vascular endothelial expression of CD105 significantly differed between the normal and neoplastic mucosal layers of adenoma, carcinoma in adenoma, adenocarcinoma lesions ($p < 0.05$, $p < 0.05$, and $p < 0.0001$, respectively; Fig. 5). Additionally, by using a double immunostaining of CD105 and D2-40, our results demonstrated that CD105 was

expressed exclusively in the endothelium of newly formed blood vessels within and around tumors from all layers, and no double-positive staining in the same vessels was found (Fig. 4).

VEGF was expressed on vascular endothelial cells ($< 30\%$) and in the cytoplasm of normal and neoplastic cells ($< 50\%$) throughout all layers of adenoma, carcinoma in adenoma, and adenocarcinoma. Vascular expression of VEGF

Fig. 4 Double immunostaining of CD105 (blue purple) and D2-40 (red). No apparent double labeling of CD105 and D2-40 in the vessels. Original magnification, $\times 200$

Fig. 5 Expression of CD31, CD105, and VEGF. Vascular endothelial cells express CD31, CD105, and VEGF throughout all tissue levels of colon adenoma, carcinoma in adenoma, and adenocarcinoma. Only CD105 significantly differs between the normal mucosa and adenoma or cancer (middle three boxes). CD31 (upper boxes) and VEGF (lower boxes) are not different between them. *n* Normal mucosa adjacent to the tumors at the level of tumor/cancer cells, *m* mucosal layers, *sm* sub-mucosa, *mp* muscular propria, *ss* subserosa, *se* serosa. Significantly different: **p*<0.001 and ***p*<0.05. Grade of immunoreaction: (rectangle) weak, (dotted rectangle) moderate, and (filled rectangle) intense

was lost in the serosa of adenocarcinoma and lymph node metastasis. The expression of VEGF in the vascular endothelium did not significantly differ between normal and neoplastic mucosal layers of adenoma, cancer in adenoma, or adenocarcinoma (Fig. 5).

CD44 was not expressed in the vascular endothelium in normal tissues and in all layers of adenoma, carcinoma in adenoma, and adenocarcinoma, and was intensely expressed in the neoplastic cell membrane (Table 3). Flt-1 (cytoplasm and cell membrane), Flk-1 (cytoplasm and nuclei), TGF-β1 (cytoplasm), and TGF-βRII (cytoplasm and nuclei) were intensely expressed in neoplastic cells in all layers of adenoma, cancer in adenoma, and adenocarcinoma, but not in endothelial cells (Table 3).

Table 3 Immunohistochemical results

Markers	Vascular endothelial cells	Tumor cells
CD31	+ ^a	-

TGF-β1	-	+ (cc)
TGF-βRII	-	+ (cc, cn)

cc Cell cytoplasm, cm cell membrane, cn cell nucleus
^aCD31 is mostly positive in preexisting larger blood vessels, whereas CD105 is positive in newly formed small blood vessels

Discussion

Endoglin (CD105), a cell membrane glycoprotein, was obviously upregulated in endothelial cells in de novo blood vessels of various tumors compared with those in normal tissues [3, 15, 16, 22, 27]. As far as we know, no study has compared the endothelial expression of CD105 with a lymphatic endothelium marker to exclude the idea that the CD105-stained vessels represent lymphatic vessels. The present study provides evidence that CD105 was expressed exclusively in the endothelium of newly formed blood vessels compared with D2-40, which was reported as a selective lymphatic endothelial marker [13]. Our results show no double-positive staining of CD105 and D2-40 in the same vessels (Fig. 4). CD105 is expressed in vascular endothelial cells of polypoid-type early colon cancer [20]. To our knowledge, the present study is the first to identify CD105 expression at levels corresponding to the depth of cancer invasion in the colon adenoma–carcinoma sequence (adenoma, carcinoma in adenoma, adenocarcinoma, and lymph node metastasis).

Angiogenesis always accompanies the development of cancer and metastasis, and the depth of tumor invasion of the colon wall determines the stage of cancer, which is a useful prognostic indicator and basis for the selection of appropriate therapy. We therefore considered that the expression of CD105 in each layer of the colon should be defined and compared with that of other angiogenetic markers. In this respect, we showed that CD105 was expressed at high levels in vascular endothelial cells in de novo blood vessels of the adenoma–carcinoma of the colon

and was weakly expressed ($\leq 21\%$) in blood vessels of the normal mucosal layer. CD105 expression significantly differed between the normal mucosa and the corresponding layers of adenoma, carcinoma in adenoma, and adenocarcinoma ($p < 0.05$, $p < 0.05$, and $p < 0.0001$, respectively), whereas CD31 and VEGF expression did not differ among them. This finding supports that of Akagi et al. [1], who showed that the expression of CD105 significantly differed from low-grade to high-grade adenoma and to carcinoma, whereas the MVD for a pan-endothelial marker (CD34) did not differ in the colorectal adenoma–carcinoma sequence. Moreover, when compared with CD31 and VEGF, CD105 was more intensely expressed in de novo microvessels (Fig. 3).

A higher expression of both VEGF and CD105 (MVD) correlates with a deeper invasion and lymph node metastasis in gastrointestinal cancer [30]. Our study also shows that CD105 expression is related to the depth of invasion, but not to VEGF expression (Fig. 3).

Flk-1 is expressed in the colon [24], lung [14], and prostate [2], and Flt-1 is expressed in pancreatic cancer [23, 26]. In contrast, we found that Flk-1 and Flt-1 were not expressed in vascular endothelial cells, whereas Flt-1 was intensely expressed in the cytoplasm and membrane of neoplastic cells and Flk-1 was found in the cytoplasm and nucleus of neoplastic cells.

Several studies have shown that CD31 is expressed in blood vessels in normal tissues, as well as in cancer tissues [1, 5, 7]. We found that 80–95% of the normal mucosa adjacent to the tumor and all layers in adenoma, carcinoma in adenoma, and adenocarcinoma expressed CD31.

One report describes that CD44 is expressed in the vascular endothelium [21]. However, we discovered a weak expression in lymphatic endothelial cells (data not shown) and an intense expression in normal and neoplastic cell membranes, but none in vascular endothelial cells.

The cytoplasm and nucleus of neoplastic cells expressed high levels of TGF- β 1 and its receptor (TGF- β RII), whereas vascular endothelial cells expressed none.

These results confirm that CD105 was specifically expressed in de novo blood vessels of colon cancer.

Spindle cell tumours of the pleura: a clinical, histological and comparative genomic hybridization analysis of 14 cases

Received: 3 June 2005 / Accepted: 3 August 2005 / Published online: 17 September 2005
© Springer-Verlag 2005

Abstract We examined 14 spindle cell tumours of the pleura that were sent to a Mesothelioma Panel for re-evaluation after a primary suspicion of mesothelioma. The clinical, histological, immunohistochemical and CGH findings were investigated. Final diagnoses were eight sarcomatoid mesotheliomas (SM) and six non-mesotheliomas: two pulmonary sarcomatoid carcinomas, an epithelioid hemangioendothelioma, a malignant solitary fibrous tumour, a malignant pleural smooth muscle tumour and an extraskeletal osteosarcoma. Seven of the eight SM and two of the other six tumours presented with unilateral pleural effusion, dyspnoea, and chest pain, which are characteristic clinical findings in malignant mesothelioma. No single antibody used in the immunohistochemistry separated SM from other tumour types. The most frequently observed chromosomal losses in SM were 4q, 4p11-p13/p15, 6q and 13. Losses of 4p11-p13/p15 and 4q occurred in combination in four out of five SM with detectable chromosomal changes, but neither was found in any of the other tumours. Gain or high-level amplification of 5p was also common in SM. According to our results and literature, losses at 4p, 4q and 9p and gain at 5p are the chromosomal changes that best differentiate SM from pleural sarcomas and lung carcinomas. CGH analysis may help distinguish a cyto-keratin-positive SM from a sarcomatoid carcinoma. Sim-

ilarly, in the case of a cyto-keratin-negative tumour, CGH analysis may disclose chromosomal changes characteristic of sarcomas or mesotheliomas.

Keywords Sarcomatoid mesothelioma · Spindle cell tumour of the pleura · CGH · Immunohistochemistry

Introduction

Differentiating sarcomatoid mesotheliomas (SM) from other spindle cell tumours of the pleura, e.g. pleural sarcomas and sarcomatoid carcinomas of the lung with invasion to the pleura, by morphological and immunohistochemical criteria is often difficult. The correct diagnosis also requires additional information from the clinical history, from imaging studies and from macroscopic surgical findings (e.g. diffuse vs localized pleural-based tumour mass).

The sarcomatoid differentiation is common in malignant mesotheliomas (MM) and occurs in pure form in SM as a component of biphasic mesothelioma or in association with a dense, collagen-rich, poorly cellular tumour tissue in desmoplastic MM. MM-associated immunohistochemical markers such as calretinin and cytokeratin 5/6 are useful in the differential diagnosis of epithelioid MM [6, 18]. However, neither calretinin nor cytokeratin 5/6 are uniformly sensitive markers for MM because they refer to the epithelioid component of the tumour and pure SM are often negative for both these antigens [1, 15]. The co-expression of cytokeratin and vimentin has been considered characteristic for all types of MM [4, 6]. However, pleomorphic and sarcomatoid carcinomas of the lung and other organs also express cytokeratin and vimentin. Furthermore, cytokeratin expression tends to decrease in poorly differentiated epithelial tumours, but some sarcomas may express cytokeratin.

Here we describe the clinical, histological, immunohistochemical and comparative genomic hybridization (CGH) findings of 14 primary spindle cell tumours of the pleura that have been sent for the evaluation of the Finnish Mesothelioma Panel. The aim of our study was to investigate

how these findings could be used in the differentiation between spindle cell tumours of the pleura, especially when diagnosing sarcomatoid type of MM.

Materials and methods

Tumour specimens

Fourteen spindle cell tumours of the pleura were drawn from the archives of the Finnish Mesothelioma Panel. They were sent for diagnostic re-evaluation because of a suspicion of pleural MM. The Finnish Mesothelioma Panel has four pathologist members, and it provides consultation services for problem cases but, as opposed to some other European Panels, does not collect all MM in its area. The Ethics Committee for Research in Occupational Health and Safety approved this study, and the National Authority for Medicolegal Affairs gave the permission to use the samples obtained for diagnostic purpose for research.

Immunohistochemistry

All 14 cases were immunostained with Techmate immunostainer for cytokeratin CAM5.2 (Becton Dickinson 349205, trypsin antigen retrieval; undiluted), vimentin (Dako, mouse anti-vimentin 7095; undiluted), calretinin (Zymed, rabbit anti-calretinin; 1:50 dilution, microwave antigen retrieval in citrate buffer, pH 6) and muscle actin (Dako, mouse anti-human muscle actin 7121; 1:10 dilution). In addition, six cases were stained for CD34 (Becton Dickinson 347660; 1:50 dilution, microwave antigen retrieval in citrate buffer, pH 6), S-100 (Dako, rabbit anti-S-100 H0066; undiluted) or cytokeratin 5/6 (Dako, mouse anti-cytokeratin 5/6 M7237; 1:50 dilution, microwave antigen retrieval in citrate buffer, pH 6); five cases for CEA (Dako, anti-human carcinoembryonic antigen H7096; undiluted, microwave antigen retrieval in citrate buffer, pH 6); four cases for CD15 (Becton Dickinson, mouse anti-human CD15 550382; 1:50 dilution, microwave antigen retrieval in citrate buffer, pH 6); three cases for Ber-EP4

(Dako, mouse anti-human epithelial antigen M0804; 1:50 dilution, microwave antigen retrieval in citrate buffer, pH 6) and two cases for EMA (Dako, mouse anti-human epithelial membrane antigen M7097; undiluted), depending on the differential diagnosis.

Diagnoses

Three or four pathologists in the Panel made primary diagnoses in each of the 14 cases independently, and then all the cases were evaluated uniformly. Primarily, the independent diagnoses based on light microscopy and immunohistochemistry were certain or probable MM only in four cases, whereas in ten cases, the diagnoses varied from uncertain to opinions in favour of MM or other diagnoses. The clinical characteristics of the patients are given in Table 1. The symptoms mentioned are the main presenting symptoms at the time of diagnosis. The clinical

and surgical/radiological/autopsy findings were classified either typical or unusual for MM (Table 2). The clinical findings were considered to be typical if the patient had the common clinical presentation of pleural MM including, e.g. unilateral pleural effusion with dyspnoea (known to be present in 80–90% of MM patients) and chest pain (present in 70% of MM patients), and the disease progressed typically for MM. Surgical and autopsy findings were considered typical when multiple pleural nodules or masses, more numerous on the parietal pleura but also involving the visceral pleura, or unilateral pleural effusion with pleural thickening was observed.

CGH analysis

CGH was performed as previously described by El-Rifai et al. [7]. Tumour DNA was labelled with FITC-dCTP and FITC-dUTP (DuPont, Boston, MA) and normal reference

⁴At least 50% of tumour cells positive for cytokeratin (CAM5.2) and vimentin

⁵Focal positive staining for calretinin in epithelial-like tumour cells

DNA with Texas-Red-dCTP and Texas-Red-dUTP (DuPont) in a standard nick-translation reaction. Hybridization mixture consisted of 1 µg of labelled tumour DNA, 1 µg of reference DNA and 20 µg unlabelled Cot-1 DNA, and hybridization was performed onto normal metaphase chromosomes in a moist chamber at 37°C for 48 h. After hybridization, the slides were washed and mounted with anti-fading medium containing a counterstain (Vector Laboratories, Burlingame, CA). CGH images were analysed using the ISIS digital image analysis system (MetaSystems, Altlußheim, Germany). Based on previous studies and control results, chromosomal regions were interpreted as over-represented (gained) when the red-to-green ratio exceeded 1.17 and under-represented (lost) when the ratio was less than 0.85. The region was considered as highly amplified when the ratio exceeded 1.5. Ninety-nine per cent confidence limits with 1% error probability were used to confirm the interpretation.

Results

Clinical findings

The main clinical features of the patients are given in Tables 1 and 2. Final diagnoses reached were eight SM and six non-MM, and they were confirmed by consensus after immunostaining of additional tissue blocks and taking clinical information into account. In this material, six out of 14 (44%) of the primarily proposed MM changed into other diagnoses after thorough diagnostic procedures and re-evaluation by the panel of pathologists. It was noticed that 4/6 non-MM presented with unusual clinical findings, such as absence of pleural effusion, and two had upper arm pain. Three of these six cases had radiological or surgical findings unusual for MM. Only one MM case had an unusual

symptom presentation, having only dyspnoea and weakened general condition, whereas all others had either remarkable unilateral pleural effusion or chest pain or both. Among eight MM, three had autopsy findings unusual for MM, including two cases with widely spread metastases (liver, intestines and suprarenal) and one case with bilateral pleural tumour. These findings were not observed clinically during the patients' diagnostic work-ups. Two patients in the non-MM group and five in the MM group (62%) had a known work-related asbestos exposure (Table 1).

Immunohistochemistry

The results of immunohistochemical stainings are given in Tables 2 and 3. No single antibody used separated SM from other tumour types. The positive staining for calretinin in epithelioid-like tumour cells was seen in 4/8 SM (50%) but in none of the other tumours. Immunostaining for cytokeratin CAM5.2 occurred in 6/8 SM (75%) and in the two sarcomatoid carcinomas. All except one of the SM expressed muscle actin, but positive staining was also seen in the smooth muscle tumour and in one of the two sarcomatoid carcinomas. Co-expression of cytokeratin and vimentin was observed in 4/8 (50%) of the SM and in none of the other tumours (Table 2).

CGH results

DNA copy number changes were detected by conventional CGH in 11 of the 14 specimens as shown in Table 4. No changes were observed in two SM and in a malignant solitary fibrous tumour. There was no predominance of losses or gains in either SM or in the other spindle cell

SM4	1p22-32, 4p11-15, 4q, 9p23-pter	1q21-qter, 8, 9q31-qter	None
SM5	None	5p	5p12-pter
SM6	None	None	None
SM7	4p11-p15, 4q, 6q11-q22, 13, Xp11-pter, Xq11-q22	1p32-p36, 5p, 7, 22	1q21-q24, 5p13-pter, 7p, 8q13-qter, 11, 12q22-qter, 17q22-qter, 22q
SM8	4p11-p15.2, 4q, 6q11-qter, 13, 18q	6p12-pter, 8, 12q24-qter, 17q21-qter	3p23-pter, 8q, 17q23-qter

tumours. In addition, high-level amplifications were observed in both groups.

In SM, losses of DNA sequences were observed in nine chromosomes. The chromosome arms most frequently lost were 4p11-13, 4p11-15, and 4q, which were observed in

combination in 4/8 (50%) cases. The losses of 6q and chromosome 13 were also common in SM (4/8, 50%). In the other spindle cell tumours, losses of chromosome 4 were not observed, whereas losses of 6q and chromosome 13 were observed.

Table 5 Most common chromosomal changes in sarcomatoid mesotheliomas as compared to other relevant tumour types according to the literature

N/Tumour type	Reference	Losses at			Gain at

67/Synovial sarcoma	[24]	0	0	0	0
29/Leiomyosarcoma	[8]	0	10	16	7
Lung cancer ³					
50/NSCLC	[21]	32	60	70	10

¹Percentage of tumours with the chromosomal change

²Sarcomas most commonly detected in the pleural cavity or lung

³Non-small-cell carcinomas (NSCLC) were adenocarcinomas and squamous cell carcinomas of the lung; no CGH data available on pleomorphic carcinoma of the lung

Gain of DNA sequences was detected in 12 different chromosomes in SM and in 8 chromosomes in the other spindle cell tumours. High-level amplifications were common in SM as well as in the other spindle cell tumours. Most commonly, a high-level amplification was observed in 5p in SM (4/8, 50%), whereas, among other tumours, this high-level amplification was only seen in an extraskeletal osteosarcoma.

Discussion

We describe 14 cases of pleural spindle cell tumours, which were diagnostic challenges at the time of primary diagnosis. Clinical presentation of the disease together with the radiological and surgical findings seemed to be an important diagnostic clue. All except one SM presented with unilateral pleural effusion that required pleural drainage often repeatedly. SM patients also had dyspnoea and chest pain due to the tumour. The patients with other spindle cell tumours had more variable presenting symptoms, which included arm pain in two cases and chest pain and dyspnoea without pleural effusion in one case. Radiological and autopsy findings were also unusual for MM in three of the six non-MM spindle cell tumours: epithelioid hemangioendothelioma formed a large, cystic tumour and several smaller tumour nodules; spindle cell carcinoma had metastasized to the contralateral lung and kidney; and malignant smooth muscle tumour presented without pleural effusion. On the other hand, solitary fibrous tumour and extraskeletal osteosarcoma of the pleura had clinical and radiological findings similar to MM, whereas two of the SM had extrathoracic metastases in autopsy, and one of these patients had unusual CO₂ retention as a first disease symptom. The clinical symptom that separated the SM and non-MM group was arm pain that occurred in two patients with sarcomatoid carcinomas spread to the pleura.

The diagnosis of MM often relies on immunohistochemistry. As compared to the efficacy of immunohistochemical markers in confirming the diagnosis of epithelioid MM, their role in SM is not so clear. Calretinin and cytokeratin 5/6 are feasible immunohistochemical markers in discriminating between adenocarcinomas and epithelioid or biphasic MM, being positive in up to 100% of these type of MM and only focally positive in less than 10% of pulmonary adenocarcinomas [19]. In SM, calretinin expression has been demonstrated less often, the positive staining occurring in 20–70% of tumours [1, 11, 15], whereas cytokeratin 5/6 has not stained SM [15]. In the present study, half of the SM demonstrated focal positive staining for calretinin. We considered calretinin positive if the staining was seen in epithelioid-like cells and included both nuclear and cytoplasmic positivity. Lucas et al. [15] reported that calretinin staining reaction was less intense and more diffuse in SM than in the epithelioid MM, although 70% of the SM in their material were positive. We did not observe any calretinin positivity in the non-MM group, but Lucas et al. [15] reported 17% of sarcomas and 60% of sarcomatoid carcinomas to be calretinin-positive.

Calretinin seems to be neither sensitive nor specific marker of SM.

Positive staining for cytokeratins has also been considered important in the diagnosis of MM. However, in two recent studies, the complete absence of cytokeratin staining in 15–23% of SM was reported [1, 15]. In our material, cytokeratin 8 (CAM5.2) stained 6/8 (75%) SM, but in two cases, less than half of the tumour cells were positive. In the non-MM group, spindle cell carcinoma was strongly cytokeratin-positive and pleomorphic carcinoma faintly positive. Altogether, other benign or malignant spindle cell tumours may also express cytokeratins [1, 5, 16], and they may be negative in SM.

Smooth muscle or myofibroblastic differentiation has been demonstrated in MM. Lucas et al. [15] reported that 60% of SM were smooth-muscle-actin-positive, but 58% of sarcomas and 10% of sarcomatoid carcinomas also stained positive in their material. In this study, all except one of the SM, a spindle cell carcinoma and a malignant smooth muscle tumour, were positive for smooth muscle actin. Thus, this further confirms that smooth muscle actin does not have much value in discriminating SM from other spindle cell tumours. In our case with extensive smooth muscle differentiation in a tumour encasing the lung, a diagnosis of malignant smooth muscle tumour of the pleura was made. Whether this type of tumour actually represents one type of SM is controversial [9, 17]. The presence of heterologous bone and cartilage in this tumour as well as asbestos exposure of the patient might favour the diagnosis of SM. However, the smooth muscle tumour of the pleura contained chromosomal losses at 10q and 13q, which are the most common losses described in soft tissue leiomyosarcomas [8], whereas loss at 10q is rare in SM [13].

The knowledge of chromosomal changes detectable by CGH in epithelioid and sarcomatoid MM is accumulating, although CGH so far has not been recommended as a diagnostic tool. In MM, on average, more losses and less gains and high-level amplifications have been reported in the literature as compared to carcinomas and sarcomas [2, 10, 22]. Furthermore, in a recent CGH study of 90 cases of MM, losses of chromosomal material were more common than gains, and SM were reported to have a fourfold higher number of amplifications than other MM subtypes [13]. In our study, gains were as frequent as losses both in the SM as well as in the other spindle cell tumours. High-level amplifications were also detected in both groups.

The most frequently observed losses in these eight SM were 4q, 4p11-p13/p15, 6q and 13, all these occurring in 50% of tumours. Losses of 4p11-p13/p15 and 4q occurred in combination in 4/5 SM with any detectable changes, but neither was found in any of the other tumours. In earlier cytogenetic analyses, losses at chromosomal regions 1p, 4q, 6q, 9p, 13q and 14q have been detected commonly in MM [10, 13, 14]. Among the non-MM spindle cell tumours, the loss of DNA was most often seen in 6q in the present study, but this finding was also common in SM. Losses on chromosome 6 and on 6q have also been reported in benign solitary fibrous tumours of the pleura and in mesodermomas (pleural MM with unusual meso-

dermal features), respectively [11, 12]. Gain or high-level amplification at 5p occurred in 4/6 SM, with detectable chromosomal gains in the present series. The chromosome arm 5p was also the most common site of gain or amplification in SM in the study of Krismann et al. [13]. This gain of chromosomal material has also been detected in about 10% of osteosarcomas and other soft tissue tumours (see references in Table 5), including our case of extraskeletal osteosarcoma of the pleura. Table 5 shows the most common chromosomal changes in SM as compared to other relevant tumour types according to the literature and our results. SM contain chromosomal aberrations characteristic of both epithelial tumours and sarcomas and thus differ from both groups.

In addition to morphological and immunohistochemical examinations, all clinical and radiological/surgical information as well as extensive tumour sampling, when possible, are necessary for the diagnosis of pleural spindle cell tumours. Immunostaining of several tumour blocks for cytokeratins and calretinin may be sufficient for the diagnosis of SM because it increases the likelihood of detecting small epithelioid, calretinin-positive areas, which confirm the diagnosis of MM. CGH analysis may help distinguish a cytokeratin-positive SM from a sarcomatoid carcinoma. Similarly, in the case of a cytokeratin-negative tumour, CGH analysis may disclose chromosomal changes characteristic of sarcomas or MM.

LAT1 expression in normal lung and in atypical adenomatous hyperplasia and adenocarcinoma of the lung

Received: 27 April 2005 / Accepted: 15 August 2005 / Published online: 21 September 2005
© Springer-Verlag 2005

Abstract No previous study has investigated neutral large amino acid transporter type 1 (LAT1) in normal lung cells, or in atypical adenomatous hyperplasia(s) (AAH) and nonmucinous bronchioloalveolar carcinoma(s) (NMBAC) of the lung. The authors examined: (1) the levels of *LAT1* mRNA/*glyceraldehyde-3-phosphate dehydrogenase* (*GAPDH*)

mRNA in 41 normal lung tissues and 34 NMBAC using semiquantitative reverse transcription–polymerase chain reaction; (2) *LAT1* mRNA and protein expressions in 35 normal lung tissues, 34 AAH (11 lesions were interpreted as low-grade AAH and 23 as high-grade AAH), and 43 NMBAC using in situ hybridization and immunohistochemistry; and (2) the association of the incidences of *LAT1* mRNA and protein expressions with cell proliferation in these lesions. The level of *LAT1* mRNA/*GAPDH* mRNA (1) tended to be higher in NMBAC (12.0 ± 8.1) than in normal lung tissues (1.0 ± 0.2), and (2) covered a much wider range (from 0 to 276) in NMBAC than in normal lung tissues (from 0 to 5.8), with six NMBAC having values higher than 7.0, while 5.8 was the highest value detected in normal lung tissues. In peripheral normal lung tissues, *LAT1* mRNA and protein were detected in bronchial surface epithelial cells and alveolar macrophages (but not in nonciliated bronchiolar epithelial cells, or in alveolar type I or type II cells). In bronchial surface epithelial cells, *LAT1* protein appeared to be of a nodular type, which was considered to be a nonfunctional protein pattern. The incidences of positive expressions for *LAT1* mRNA and protein were 54.5 and 27.3% in low-grade AAH, 65.2 and 52.2% in high-grade AAH, and 65.1 and 79.1% in NMBAC, respectively. In the case of *LAT1* protein expression, significant differences could be shown between total (low-grade plus high-grade) AAH and NMBAC, and between low-grade AAH and NMBAC. Thus, in terms of the incidence of *LAT1* protein expression, high-grade AAH appeared intermediate between low-grade AAH and NMBAC. The Ki-67 labeling index (a cell proliferation score) was significantly higher in those AAH and NMBAC that were *LAT1*-protein-positive than in their *LAT1*-protein-negative counterparts. In conclusion, *LAT1* expression may increase with the upregulation of metabolic activity and cell proliferation in high-grade AAH and NMBAC.

Introduction

Nonmucinous bronchioloalveolar carcinoma(s) (NMBAC) of the lung is one of the major histological types of lung adenocarcinoma [24]. In the 1999 *World Health Organization international histologic classification of tumours* [25], it is defined as an adenocarcinoma with a pure bronchioloalveolar growth pattern and with no evidence of stromal, vascular, or pleural invasion. However, its histogenesis is not well-understood. Atypical adenomatous hyperplasia(s) (AAH) of the lung, which is classified among preinvasive lesions in the World Health Organization classification of lung and pleural tumours [25], is a proliferation of alveolar epithelial cells and is usually found incidentally in lungs surgically resected for lung cancer, predominantly in patients with adenocarcinoma.

Facilitated diffusion and active transport are responsible for the transport of substances such as glucose and amino acids. System L-amino acid transport mediates sodium-independent uptake of nonpolar branched-chain or aromatic neutral amino acids and is the major route by which mammalian cells take up nutritionally essential amino acids from extracellular fluids [2, 3, 5, 6]. Indeed, system L-amino acid transport plays a critical role in the absorption of amino acids by the intestine, kidney, and placenta. Recently, genes encoding proteins responsible for system L-amino acid transport have been cloned, and large amino acid transporter type 1 (LAT1) is the first member of the system L-amino acid transporter family to be identified [7, 10]. LAT1 requires covalent association with the heavy chain of 4F2 cell surface antigen (4F2hc) for its functional expression in plasma membrane [22]. Previous studies have shown LAT1 to be highly expressed in proliferating tissues, many tumor cell lines, and primary human tumors, but to be at barely detectable levels in adult tissues (except the brain, testis, and placenta), while 4F2hc is ubiquitous [2, 3, 5, 6, 8, 19–21, 23, 26]. Furthermore, overexpression of LAT1 in hepatocytes has been found to enhance their growth, leading Campbell and Thompson [1] to suggest that LAT1 may play an important role in cell growth. However, no study has yet investigated LAT1 expression in normal lung cells, or in AAH and NMBAC of the lung.

In this study, we took the opportunity to examine the expression of LAT1 mRNA and protein in normal lung cells, as well as in AAH and NMBAC. We investigated: (1) whether distributions of LAT1 mRNA and protein would be revealed in normal lung tissues; (2) whether LAT1 mRNA might be produced in normal lung tissues and NMBAC; (3) whether incidences of LAT1 mRNA and protein expressions might differ among normal lung tissues, precancerous lesions, and peripherally located adenocarcinomas; and (4) whether incidences of LAT1 mRNA and protein expressions would show associations with cell proliferation in these lesions. To those ends, we measured the levels of *LAT1* mRNA/*glyceraldehyde-3-phosphate dehydrogenase* (*GAPDH*) mRNA in 41 normal lung tissues and 34 NMBAC (measuring 30 mm or less in the greatest

diameter) using a real-time reverse transcription–polymerase chain reaction (RT-PCR) approach. Furthermore, we examined the expressions of LAT1 mRNA and protein as well as cell proliferation index in 35 normal lung tissues, 34 AAH, and 43 bronchioloalveolar carcinomas (measuring 20 mm or less in the greatest diameter) using in situ hybridization and immunohistochemical approaches. Our goal was to obtain a better understanding of the relation of LAT1 expression to metabolic activity in normal lung cells, AAH, and NMBAC.

Materials and methods

From 1980 to 2002, the surgical pathology services of the National Defense Medical College Hospital (Tokorozawa, Japan) and the Keio University Hospital (Tokyo, Japan) received fresh frozen tissues of 41 normal lungs (resected from 41 patients with lung cancer) and 34 NMBAC of the lung (resected from 34 patients; measuring 30 mm or less in the greatest diameter), and also paraffin-embedded specimens of 34 AAH of the lung (resected from 19 patients) and 43 NMBAC of the lung (resected from 43 patients; measuring 20 mm or less in the greatest diameter). Of the 34 AAH lesions, 23 were interpreted as high-grade based on the findings of increased cellularity and cytological pleomorphism [14–17].

RT-PCR

Total mRNAs were obtained from the 41 normal lung tissues and 34 NMBAC (measuring 30 mm or less in the greatest diameter) that were available. Total RNA was isolated using acid guanidinium isothiocyanate–phenol–chloroform extraction and ethanol precipitation [4]. RT-PCR was performed using an amplification reagent kit (TaqMan EZRT-PCR kit; Applied Biosystems, Alameda, CA) with *LAT1* or *GAPDH* primers, as previously reported [18]. The *LAT1* and *GAPDH* primers were synthesized by an automated DNA synthesizer. The sense and antisense sequences of the *LAT1* primers were 5'-GTG ACG CTG GTG TAC GTG CT-3' and 5'-GGG TGG ATC ATG GAG AGG AT-3', respectively, while the sequence of the TaqMan probe was 5'-CTC CGT CAA TGG GTC CCT GTT CAC AT-3'. The cDNA amplification product was predicted to be a 251-bp fragment from positions 918 to 1,168 in the cDNA of *LAT1*. Primers were also synthesized to amplify the cDNA encoding *GAPDH*, a constitutively expressed gene, as a control. In the case of *GAPDH*, the sequences of the primers and TaqMan probe used were 5'-GAA GGT GAA GGT CGG AGT C-3' (sense), 5'-GAA GAT GGT GAT GGG ATT TC-3' (antisense), and 5'-CAA GCT TCC CGT TCT CAG CC-3' (TaqMan probe). Both TaqMan probes were labeled at the 5' end with the reporter dye molecule 6-carboxyfluorescein and at the 3' end with the quencher dye 6-carboxytetramethylrhodamine. The re-

action master mix was prepared according to the manufacturer's protocol to give final concentrations of 1× reaction buffer, 300 μM 2'-deoxyadenosine 5'-triphosphate, 300 μM 2'-deoxycytidine 5'-triphosphate, 300 μM 2'-deoxyguanosine 5'-triphosphate, 600 μM 2'-deoxyuridine 5'-triphosphate, 3 mM Mn(OAc)₂, 0.1 U/μl *rTth* DNA polymerase, 0.01 U/μl AmpErase UNG, 200 nM AM primers, and 100 nM TaqMan probe. To perform PCR, the RT reaction was incubated at 60°C for 30 min, followed by incubation at 95°C for 5 min to deactivate AmpErase UNG. The present PCR employed was performed using 40 amplification cycles (using 1,000 ng of RNA for *LATI* mRNA and 50 ng of RNA for *GAPDH* mRNA) at 95°C for 20 s and at 60°C for 1 min. For this, an ABI PRISM 7700 Sequence detector (Applied Biosystems) was used. Total RNA extracts from lung cancer were used as control templates (total RNA: 1,000, 200, 40, and 8 ng for *LATI* mRNA; 200, 40, 8, and 1.6 ng for *GAPDH* mRNA). Increase in fluorescence was proportional to the concentration of the template in the present PCR (Fig. 2a). Threshold cycle was calculated by determining the point at which the fluorescence exceeded a threshold limit (ten times the standard deviation of the baseline). In other words, signals were regarded as positive if the fluorescence intensity exceeded ten times the standard deviation of the baseline fluorescence. A standard curve was obtained using the threshold cycles established separately for four wells for each applied RNA amount (Fig. 2b). PCR products were separated by electrophoresis in a 3% agarose gel then stained with ethidium bromide (Fig. 2c).

In situ hybridization

In situ hybridization was performed essentially as previously described [16]. Briefly, sections of 35 normal lung tissues, 34 AAH, and 43 NMBAC (measuring 20 mm or less in the greatest diameter) were treated with 0.2 N HCl for 20 min, incubated in 2× standard sodium citrate (SSC) for 10 min at 37°C, and incubated in 5 μg/ml proteinase K for 10 min at 37°C. Sections were subsequently post-fixed in 4% paraformaldehyde for 5 min, then incubated in 0.1 M triethanolamine buffer (pH 8.0) containing 0.25% (vol/vol) acetic anhydride for 10 min to prevent nonspecific binding due to oxidation of the tissue. Hybridization was carried out overnight at 42°C in 50% (vol/vol) deionized formamide, 5× Denhardt's solution, 5% (wt/vol) dextran sulfate, 2× SSC, 0.3 mg/ml salmon sperm DNA, 5 mM ethylenediaminetetraacetic acid, and 10 ng/ml biotin-labeled probes. After performing a final stringent wash at 37°C for 20 min, hybridization was detected immunologically. The *LATI* cDNA probe used was a 251-bp fragment (obtained from positions 918 to 1,168 in the cDNA of *LATI*) subcloned into the *EcoRI* site of a pGEM-T Easy Vector (Promega, Madison, WI). Antisense probes and corresponding sense probes were labeled with biotin using SP6 and T7 polymerases, respectively, by means of an RNA labeling kit (Roche Diagnostics, Mannheim, Germany).

Immunohistochemistry

We used polymer peroxidase method (EnVision+/HRP; Dako Cytomation, Denmark) on deparaffinized sections of

Fig. 1 *LATI* mRNA and protein expressions in normal lung tissues viz. bronchial surface epithelial cells in the bronchus (a, d), serous cells of the bronchial glands (b, e), and chondrocytes of the bronchial cartilage (c, f). *LATI* mRNA appeared diffuse in the cytoplasm of positive cells within the normal lung. *LATI* protein was expressed as a single nodular spot in the cytoplasm of bronchial surface epithelial cells (d), while it was detected as a granular spreading pattern within the cytoplasm of lung components (e, f), except the bronchial surface epithelial cells. Scale bar, 100 μm

Table 1 Expressions of LAT1 mRNA and protein in normal lung

Anatomical site	Number of lesions	LAT1 mRNA expression [n (%)]	LAT1 protein expression [n (%)]
Bronchus

Alveolar macrophages	35	35 (100)	35 (100)

35 normal lung tissues, 34 AAH, and 43 NMBAC (measuring 20 mm or less in the greatest diameter), employing mouse monoclonal antibodies against LAT1 (1:20; clone no. 4D9; Transgenic, Kumamoto, Japan) and Ki-67 (1:20; clone no. Ki-55; Dako Cytomation, Tokyo, Japan). The sections received autoclave pretreatment of 0.05 M citrate buffer (pH 6.0) for 20 min before immunohistochemistry against both antibodies. For negative control, incubation step with the primary antibody was omitted. In absorption tests for LAT1, sections were treated with the primary antibody in the presence of LAT1 peptide.

Data analysis

For in situ hybridization and immunoreactivity analyses, staining was scored as: (-) negative reaction of tumor cells; (\pm) <10% of tumor area stained; (+) 11–25% stained; (2+) 26–50% stained; or (3+) \geq 51% stained. The tumors in which stained tumor cells made up more than 25% of the

Fig. 2 Semiquantitative RT-PCR for *LAT1* mRNA. **a** Amplification plot obtained in real time using the semiquantitative RT-PCR method. Total RNA (1,000, 200, 40, and 8 ng) extracted from lung cancer was subjected to RT-PCR. **b** Standard curve for the threshold cycle of RT-PCR. The threshold cycle (obtained in quadruplicate) was plotted for each of the four RNA amounts applied. **c** Detection of PCR products. For instance, five PCR products (in two non-cancerous normal lung tissues and in tumors from three patients with peripherally located NMBAC) were detected at 251 bp. **d** Levels of *LAT1* mRNA/*GAPDH* mRNA in normal lung tissues ($n=41$) and

NMBAC ($n=34$). When the actual "*LAT1* mRNA/*GAPDH* mRNA" value obtained for normal lung tissues in one individual patient was expressed as "1.0" and all other values were expressed in a relative manner, the mean \pm SEM values obtained for the *LAT1* mRNA/*GAPDH* mRNA levels in 34 NMBAC and 41 normal lung tissues were 12.0 ± 8.1 and 1.0 ± 0.2 , respectively. These levels tended to be higher for NMBAC than for normal lung tissues. Furthermore, 9 of 34 NMBAC (26.4%) had values higher than 5.8 (which was the highest value detected in the normal lung tissues)

tumor were graded as positive. For Ki-67 analysis, the percentage of nuclei exhibiting a positive immunoreaction (Ki-67 index) was determined based on immunoreactions in at least 1,000 cells.

Statistical analysis of differences in incidence between two groups was performed using chi-square analysis, while that of differences between two groups in levels of *LAT1* mRNA/*GAPDH* mRNA or the Ki-67 labeling index was performed using unpaired Student's *t* test. A value of $p < 0.05$ was considered significant.

Results

Distributions of *LAT1* mRNA and protein in normal lung

On in situ hybridization analysis, *LAT1* mRNA appeared diffuse in the cytoplasm of positive cells within the normal lung (Fig. 1). Detection of *LAT1* mRNA was as follows: 100% for bronchial surface epithelial cells (35 of 35 cases), 91.7% for chondrocytes of the bronchial cartilage (22 of 24 cases), 65.2% for serous cells of bronchial glands (15 of 23 cases), and 100% for alveolar macrophages (35 of 35 cases), but it was zero for nonciliated bronchiolar epithelial cells (Clara cells), goblet cells of the bronchus, mucinous cells of the bronchial glands, and alveolar type I or type II cells (Table 1, Fig. 1).

On immunohistochemistry analysis, *LAT1* protein appeared granular in the cytoplasm of chondrocytes of the bronchial cartilage, serous cells of the bronchial glands, and alveolar macrophages within the normal lung (Fig. 1).

In the cytoplasm of bronchial surface epithelial cells, however, the expression of *LAT1* protein appeared as a single nodular spot, described as nodular-type staining, which was considered to represent an intracellularly localized nonfunctional protein. In the absorption test for *LAT1* antibody, no *LAT1* protein was detected using immunohistochemistry (data not shown). The following findings for *LAT1* protein were similar to those described above for *LAT1* mRNA. *LAT1* protein detection was as follows: 100% for bronchial surface epithelial cells (35 of 35 cases), 83.3% for chondrocytes of the bronchial cartilage (20 of 24 cases), 73.9% for serous cells of the bronchial glands (17 of 23 cases), and 100% for alveolar macrophages (35 of 35 cases), but it was zero for nonciliated bronchiolar epithelial cells (Clara cells), goblet cells of the bronchus, mucinous cells of the bronchial glands, and alveolar type I or type II cells (Table 1, Fig. 1).

Semiquantitative RT-PCR for *LAT1* mRNA in normal lung tissue and NMBAC

Polymerase chain reaction products were detected at 251 bp in noncancerous normal lung tissues and NMBAC (Fig. 2c). *GAPDH* mRNA levels (obtained using a total RNA of 50 ng for each sample) ranged from 0.72 to 18 ng (as control RNA levels). Therefore, semiquantitative RT-PCR for *LAT1* mRNA was performed using a total RNA of 1,000 ng for each sample. When the actual "*LAT1* mRNA/*GAPDH* mRNA" value obtained for normal lung tissues in one individual patient was expressed as "1.0" and all other values were expressed in a relative manner, the mean \pm

Fig. 3 *LAT1* mRNA and protein expressions in low-grade AAH (positive reaction; a, d), high-grade AAH (positive reaction; b, e), and peripherally located NMBAC (positive reaction; c, f). *LAT1* mRNA was localized to within the cytoplasm of cells in AAH and NMBAC by in situ hybridization, whereas *LAT1* protein was localized in the plasma membrane as well as the cytoplasm of cells in AAH and NMBAC by immunohistochemistry. Scale bar, 100 μ m

Table 2 Expressions of LAT1 mRNA and protein in AAH and NMBAC of the lung

Lung condition	Number of lesions	LAT1 mRNA expression [n (%)]	LAT1 protein expression [n (%)]
AAH			
Total	34	21 (61.8)	15 (44.1)*
Low grade	11	6 (54.5)	3 (27.3)**
High grade	23	15 (65.2)	12 (52.2)

* $p=0.0015$

** $p=0.0010$

standard error of the mean (SEM) values obtained for the *LAT1* mRNA/*GAPDH* mRNA levels in 34 NMBAC and 41 normal lung tissues were 12.0 ± 8.1 and 1.0 ± 0.2 , respectively (Fig. 2d). These levels tended to be higher for NMBAC than for normal lung tissues, although a significant difference between normal lung tissues and NMBAC was not detected ($p=0.13$). The *LAT1* mRNA/*GAPDH* mRNA levels covered a much wider range (from 0 to 276) in NMBAC than in normal lung tissues (from 0 to 5.8). Moreover, six NMBAC had values higher than 7.0, whereas 5.8 was the highest value detected in the normal lung tissues.

Clinicopathological findings of AAH

There were 19 patients with a total of 34 AAH lesions. Nine of these 19 patients were male. Age at diagnosis was within the range 51–77 years, with a median age of 62 years. Among the 19 cases with 34 AAH lesions, 12 cases showed only one AAH lesion. Four of these 12 cases had only AAH lesions, without lung cancer. Among the 15 cases of lung cancer, there were 13 cases of adenocarcinoma, 1 case of squamous cell carcinoma, and 1 case of large cell carcinoma. Each AAH lesion in a patient with carcinoma was completely separated from the carcinoma by macroscopic examination, and in sections on a slide by microscopic examination. The diameter of the AAH lesions was within the range 1–20 mm, with a median diameter of 5 mm. In terms of diameter, there was no significant difference between low-grade AAH lesions (mean \pm SD, 6.1 ± 4.5 mm)

and high-grade AAH lesions (mean \pm SD, 6.1 ± 3.9 mm). Of the 34 AAH lesions, 23 were interpreted as high-grade based on the findings of increased cellularity and cytological pleomorphism.

Expressions of LAT1 mRNA and protein in AAH and NMBAC

Expression of *LAT1* mRNA was confined to the cytoplasm of hyperplastic and neoplastic cells (Fig. 3). A positive *LAT1* mRNA expression was recognized in 61.8% of all AAH (21 of 34 lesions) [54.5% of low-grade AAH (6 of 11 lesions) and 65.2% of high-grade AAH (15 of 23 lesions)] and in 65.1% of NMBAC (28 of 43 lesions). LAT1 protein was detected in the cytoplasm and on the plasma membrane of hyperplastic and neoplastic cells (Fig. 3). The intensity of LAT1 protein staining sometimes varied within a given case. A positive LAT1 protein expression was recognized in 44.1% of all AAH (15 of 34 lesions) [27.3% of low-grade AAH (3 of 11 lesions) and 52.2% of high-grade AAH (12 of 23 lesions)] and in 79.1% of NMBAC (34 of 43 lesions). In the seven cases with multiple AAH (four cases with two AAH, two cases with four AAH, and one case with six AAH), the intensity and immunoreactive area varied among the multiple AAH in each case. The incidence of a positive expression for LAT1 protein was significantly different between total AAH and NMBAC, and between low-grade AAH and NMBAC ($p=0.0015$ and $p=0.0010$, respectively; Table 2).

Relationship between Ki-67 index and incidences of LAT1 mRNA and protein in AAH and NMBAC

The Ki-67 labeling index (taken as a cell proliferation score) increased from low-grade AAH (mean \pm SEM, 1.6 ± 0.3 , ten lesions) to high-grade AAH (3.0 ± 0.6 , nine lesions) to NMBAC (7.4 ± 0.7 , 33 tumors). Significant differences were detected between total AAH and NMBAC, between low-grade AAH and NMBAC, and between high-grade AAH and NMBAC ($p<0.0001$, $p<0.0001$, and $p=0.0062$, respectively). The Ki-67 labeling index was significantly higher in those AAH and NMBAC that were positive for LAT1 protein than their LAT1-protein-negative counterparts ($p=0.037$ and $p=0.034$, respectively; Table 3).

Table 3 Ki-67 labeling index in AAH and NMBAC of the lung

Lung condition	Number of lesions	LAT1 mRNA		LAT1 protein	
		Positive	Negative	Positive	Negative

Discussion

In the present study, we measured the levels of *LAT1* mRNA/*GAPDH* mRNA in normal lung tissues and NMBAC measuring 30 mm or less in the greatest diameter, and then applied in situ hybridization and immunohistochemistry to the normal lung, AAH, and NMBAC measuring less than 20 mm in diameter. Although the levels of *LAT1* mRNA/*GAPDH* mRNA failed to show a significant difference between normal lung tissues and NMBAC using semiquantitative RT-PCR, we observed that the incidence of a positive expression for LAT1 protein increased or tended to increase from low-grade AAH to high-grade AAH to NMBAC (with the incidence in high-grade AAH apparently being intermediate between those in low-grade AAH and NMBAC and tending to be closer to the latter than to the former). Furthermore, the Ki-67 labeling index (a cell proliferation score) was significantly higher in LAT1-protein-positive AAH and NMBAC than in their LAT1-protein-negative counterparts. Hence, our results are consistent with an upregulation of metabolic activity in both high-grade AAH and NMBAC alongside an upregulation of LAT1 protein.

It has previously been reported that LAT1 is expressed in some normal tissues, including the blood-brain barrier, activated lymphocytes, basal layer of the skin, proximal tubules of the kidney, placenta, and testis, and also in a variety of tumor cells such as glioma, breast cancer, bladder cancer, and colon cancer [8, 11, 19, 21, 23, 26]. To our knowledge, however, LAT1 expression has not previously been reported in the normal lung. We observed, using in situ hybridization and immunohistochemistry, that LAT1 mRNA and protein were expressed in a variety of lung components (including bronchial surface epithelial cells, serous cells of the bronchial glands, alveolar macrophages, and chondrocytes of the bronchial cartilage), although they were not detected in nonciliated bronchiolar epithelial cells (Clara cells), type I alveolar epithelial cells, type II alveolar epithelial cells, or mucinous cells of the bronchial glands. It should be noted that LAT1 protein in the bronchial surface epithelial cells was localized only to the cytoplasm, with a nodular pattern appearance that was considered to be nonfunctional (because it was not present on the plasma membrane). By semiquantitative RT-PCR, *LAT1* mRNA/*GAPDH* mRNA levels could be measured in 37 of 41 normal lung tissues, supporting the above results that were obtained using in situ hybridization and immunohistochemistry. Furthermore, the *LAT1* mRNA/*GAPDH* mRNA levels observed in normal lung tissues covered quite a wide range (from 0 to 5.8). This variety of levels may be due to heterogeneity or disproportionality among lung cell components.

In the present study, the *LAT1* mRNA/*GAPDH* mRNA values covered a much wider range (from 0 to 276) in NMBAC than in normal lung tissues (see above). In particular, six NMBAC (17.6%) had values higher than 7.0, and nine NMBAC (26.4%) had values higher than 5.8, which was the highest value obtained for the normal lung. Moreover, the mean NMBAC value tended to be higher than that

obtained for normal lung tissues. Furthermore, *LAT1* mRNA was not detected in Clara cells or in type II alveolar epithelial cells in normal lung specimens using in situ hybridization. Based on these findings, the mean *LAT1* mRNA/*GAPDH* mRNA value may be lower in normal peripheral lung tissues (if we exclude cell components comprising central lung tissues, such as bronchial surface epithelial cells, serous cells of the bronchial glands, and chondrocytes of the bronchial cartilage) than in NMBAC. Furthermore, our immunohistochemical results indicate that bronchial surface epithelial cells in the central bronchi and peripheral bronchioles may produce a nonfunctional LAT1 protein (judging from the nodular-type cytoplasmic staining pattern), whereas the LAT1 protein is detected in the plasma membrane as well as in the cytoplasm in NMBAC. Thus, functional LAT1 protein may be produced at significantly higher levels in NMBAC than in normal lung tissues.

It is generally accepted that NMBAC was derived from nonbronchiolar epithelial cells (Clara cells) or type II alveolar epithelial cells, based on the phenotypic expression of neoplastic cells [9, 12]. In our in situ hybridization and immunohistochemical investigations, *LAT1* mRNA and protein were not detected in Clara cells or in type II alveolar epithelial cells in normal lung specimens. Campbell and Thompson [1], who transiently overexpressed LAT1 and 4F2hc (either alone or together) in nontransformed mouse hepatocytes, demonstrated that overexpression of LAT1 alone was sufficient to significantly increase system L transport activity in these hepatocytes, and that hepatic cells overexpressing LAT1 displayed a growth advantage relative to control cells under conditions involving limited arginine. Therefore, they suggested that LAT1 overexpression was an early event in hepatocarcinogenesis and that it provided neoplastic cells with selective growth or survival advantage, particularly under conditions of nutrient stress. Sang et al. [21] noted that TA1/E16, a partial sequence corresponding to LAT1, was expressed in rat-transformed cell lines and rat fetal liver, but not in adult liver. This led Campbell and Thompson [1] to propose that cells in which LAT1 was not normally expressed, such as hepatocytes, may acquire a growth advantage if LAT1 became constitutively expressed at some stage. This idea would support its involvement in the tumor growth of a lung adenocarcinoma if NMBAC acquired the ability to produce LAT1 during cancer development, although the induction of LAT1 expression may be an effect related to the upregulation of metabolic activity in AAH and NMBAC.

In the results obtained by in situ hybridization, the incidence of *LAT1* mRNA expression was relatively high (between 54.5 and 65.2%) in AAH and NMBAC, and no difference in the incidence of *LAT1* mRNA expression was detected between AAH and NMBAC. In contrast, the incidence of LAT1 protein expression increased or tended to increase from low-grade AAH to high-grade AAH to NMBAC, and a significant difference in its incidence was found between total AAH and NMBAC. The reason for this discrepancy between the incidence of *LAT1* mRNA (already high in low-grade AAH) and that of LAT1 protein

(progressive increase from low-grade AAH to high-grade AAH to NMBAC) is unclear. One possibility is that a rapid increase in *LAT1* mRNA may occur at the very early stage in the development of a lung carcinoma, with the subsequent synthesis of LAT1 protein occurring slowly throughout the development of this carcinoma. Another possibility is that, for reasons as yet unknown, LAT1 protein might be broken down more rapidly in the early stages of this development than in the later stages. Be that as it may, it would appear that *LAT1* mRNA expression may be a useful marker for evaluating early events in the pathogenesis of NMBAC. Furthermore, our results reveal a discrepancy between the incidence of *LAT1* mRNA (65.1%) and that of LAT1 protein (79.1%) in NMBAC. Although the reason for this discrepancy is as yet unclear, one possibility is that the probe used for in situ hybridization may be of lower sensitivity than the antibody used for immunohistochemistry. In addition, we reveal heterogeneities in expressions of LAT1 protein and mRNA among multiple AAH in individual cases, suggesting that AAH may be heterogeneous in terms of metabolic activity, cell growth, and the potential to progress to NMBAC. However, a limitation of this study was that we had only a small number (two cases) of NMBAC materials measuring 20 mm or less in the greatest diameter for RT-PCR, and no AAH. Moreover, the number of low-grade AAH lesions was lower than the number of high-grade AAH and NMBAC lesions. Confirmation of a role for LAT1 in AAH and NMBAC would need evidence from a large-scale study using molecular techniques.

In the present study, the Ki-67 labeling index increased from low-grade AAH to high-grade AAH to NMBAC, indicating a gain in proliferative activity from premalignant cells to malignant cells. These results are similar to findings described previously [9]. Furthermore, the Ki-67 labeling index was significantly higher in LAT1-protein-positive AAH and NMBAC than in their LAT1-protein-negative counterparts. These results suggest that the proliferating cells in AAH and NMBAC underwent an increase in their metabolism, with an associated upregulation of LAT1 protein.

In conclusion, the results of our study on LAT1 are consistent with high-grade AAH being a lesion closely associated with NMBAC of the lung. Furthermore, LAT1 protein overexpression in AAH and NMBAC shows a significant association with the Ki-67 labeling index, indicating an upregulation of metabolic activity. Finally, it is well-known that LAT1 requires 4F2hc for its functional expression. Furthermore, 4F2hc has been reported to induce cell proliferation and to be expressed in numerous tissues [20]. In the present study, we could not investigate the possible link between the functional role of 4F2hc and the overexpression of LAT1 (because a suitable 4F2hc antibody was not available to us). Therefore, further investigations of AAH, on a larger scale, will be necessary to establish whether 4F2hc expression at the plasma membrane correlates with metabolic activity and cell growth in AAH and NMBAC.

Acknowledgements We thank Dr. Robert Timms for correcting the English version of the manuscript. The anti-LAT1 antibody was supplied by Kumamoto Immunochemical Laboratory, Transgenic.

Abstract Mantle cell lymphoma (MCL) is an aggressive lymphoma with accepted risk factors such as proliferation markers. To date, the different follicular dendritic cell (FDC) patterns have never been analyzed in comparison with the overall survival time. Lymph node biopsy specimens from 96 patients were analyzed by conventional morphology and immunohistochemistry with antibodies against cluster differentiation (CD)20, CD5, CD23, cyclin D1, and FDC (Ki-M4P). Two groups can be distinguished with different FDC patterns: a nodular pattern in 79 cases and a diffuse pattern in 17 cases. A Kaplan–Meier analysis revealed significantly better survival for the nodular group ($p=0.0312$). This group was subdivided into a group with a nodular FDC pattern similar to the FDC distribution in primary follicles (PF-nodular in 72 cases) and one with a nodular FDC pattern resembling the colonization of ger-

minal centers (GCs) by tumor cells (GC-nodular in seven cases). A Kaplan–Meier analysis showed that patients with MCL with a PF-nodular FDC pattern had a significantly better clinical outcome than patients with the other two patterns ($p=0.0033$). If only cases with classical cytology ($n=79$) were analyzed (blastoid types excluded), patients with a PF-nodular FDC pattern had a better clinical outcome ($p=0.0008$). The distribution of FDC in MCL is a diagnostic tool for identifying patients with a better clinical prognosis.

Introduction

Mantle cell lymphoma (MCL) has become a well-accepted entity since the diagnostic chromosomal translocation t(11;14) was first described [54]. This entity had been referred to as lymphocytic lymphoma of intermediate differentiation, intermediate lymphocytic lymphoma [52], or mantle-zone lymphoma [50] and was called centrocytic lymphoma in the Kiel classification [22]. The typical antigen constellation of centrocytes in this lymphoma includes the coexpression of cluster differentiation (CD)5 and CD20 and negativity for CD3, CD10, and CD23 [27, 38, 45, 47]. The term mantle cell lymphoma is based on the growth pattern in early stages of the disease. This is characterized by a nodular growth pattern of the lymphoma around residual reactive germinal centers (GCs), a so-called mantle-zone pattern [50]. Other patterns are nodular and diffuse [49, 55]. Corresponding to the growth pattern, dense networks of follicular dendritic cells (FDCs) have also been described in these lymphomas [3, 9, 55].

The function of these cells in the genesis and clinical course of MCL is not yet clear. To our knowledge, no study has been done on different FDC patterns and survival in patients with MCL. For this study, the paraffin-resistant monoclonal antibody Ki-M4P was used, which accurately detects FDC in lymph nodes [31].

We report on the growth pattern, and, for the first time, on the FDC pattern in MCLs in comparison with the clinical outcome of 96 patients enrolled in two multicenter prospective trials [4, 26].

Patients and methods

Patients

Lymph node biopsy specimens from 96 patients enrolled in two multicenter prospective trials (1975 and 1985) were included [4, 26]. The criterion for inclusion was a histopathological diagnosis of MCL verified by a reference pathologist of the European Mantle Cell Lymphoma Study Group (M.T. and R.P.). The diagnosis of MCL was made according to the morphological and immunological criteria specified by the European Lymphoma Task Force (ELTF) [55] and according to the criteria suggested by Banks et al. [3]. Table 1 shows the clinical characteristics of the patients.

Morphology

Histological sections from tissue biopsy specimens were stained with hematoxylin and eosin (H & E), Giemsa, and Gomori silver impregnation and reviewed.

Cytology

The cytology was classified into classical and blastoid subtypes [6, 49].

Growth pattern

The growth pattern of the tumor was divided into two different types (according to Weisenburger et al. [49] with modifications):

- (1) nodular pattern (more than 50% nodular growth pattern) and
- (2) diffuse pattern (more than 50% diffuse growth pattern).

Immunohistochemistry

Four-micrometer-thick sections were mounted on 3-aminopropyltriethoxy-silane (APES)-coated slides and routinely processed. They were dewaxed in xylene and rehydrated in graded ethanol. The following antibodies were used for the immunohistochemical analysis: anti-CD3 (polyclonal rabbit antiserum, DAKO, Hamburg, Germany) [25], anti-CD5 (monoclonal, Novocastra, Newcastle, UK) [20], anti-CD20 (L26, monoclonal, DAKO) [24], anti-CD23 (monoclonal, Novocastra) [11], anticyclin D1 (monoclonal), anti-FDC (Ki-M4P, undiluted cell cul-

topathology, University of Kiel, Germany). Detection of the reactive epitopes in fixed material required previous antigen retrieval. For CD5, CD20, CD23, cyclin D1, and Ki-67, this was achieved by boiling the sections immersed in 0.01 M citric acid, pH 6.0, for 2 min and 30 s in a pressure cooker [2]. The CD3 epitope and the FDC were unmasked by digesting the sections with 0.02% protease XXIV (Sigma, Deisenhofen, Germany), pH 7.5, for 15 min at 37°C. Primary antibodies were then incubated on the sections for 60 min at room temperature. The immunoreactions were enhanced either by means of the avidin–biotin complex (ABC) technique [13] or the alkaline phosphatase antialkaline phosphatase (APAAP) method [8], followed by brief counterstaining with Mayer’s hematoxylin. In the former case, endogenous peroxidase activity was previously blocked for 10 min in 30% hydrogen peroxide in methanol, biotinylated pig antirabbit immunoglobulin G (IgG) (E 353, DAKO) for the polyclonal anti-CD3 antibody, and the reaction was catalyzed by streptavidin-conjugated peroxidase using diaminobenzidine as a chromogen. For APAAP immunostaining, rabbit

antimouse antiserum (Z 259, DAKO) was used as a secondary antibody, and naphthol-AS-biphosphate was used as a chromogen. Immunolabeling was evaluated by investigators blinded to the clinical information.

FDC distribution

Regarding the distribution of FDC, MCL was divided into two groups:

- (1) nodular pattern (more than 50% nodular FDC pattern) (Fig. 1a and b) and
- (2) diffuse pattern (more than 50% diffuse FDC pattern) (Fig. 2).

The nodular FDC pattern was subdivided into two different patterns according to the criteria of Annecy [55]:

- (1) a nodular FDC pattern similar to the FDC distribution in primary follicles (PF-nodular, Fig. 1a) and
- (2) a nodular FDC pattern resembling the colonization of GC by tumor cells (GC-nodular, Fig. 1b).

Controls

Tonsil samples from our routine files were used as positive controls.

Statistics

Statistical tests were computed using SPSS (version 10.0). Overall survival (OS) time was calculated from the date of diagnosis until death. Survival curves were estimated according to the Kaplan–Meier method and were compared by a log-rank test. *p* values of at most 0.05 were considered

Table 2 Results of the analysis of the growth pattern and the FDC pattern in 96 patients with MCL

Characteristics	Pattern	Number	Median (months)	3-year survival (%)	<i>p</i> value

to indicate statistical significance. The clinical parameters were compared by means of a multivariate Cox regression analysis using a stepwise conditional approach. Analysis of different prognostic parameters in comparison to the FDC distribution was done by likelihood quotient for all three FDC types and Fisher’s Exact Test (two-tailed) for the two FDC types PF and GC.

Results

Clinical features

The clinical characteristics of the 96 patients are summarized in Table 1. The mean age at presentation was 63.4 years (range 41–86 years). The majority of patients were male, with a male to female ratio of 3.4:1 (74 males and 22 females). Most patients (89.5%) presented with advanced-stage disease (III or IV).

Histological findings

Cytology

The majority of cases ($n=79$, 82.3%) had a classical cytology with small- to medium-sized indented nuclei, moderately dispersed chromatin, and scanty pale cytoplasm [6, 22, 49]. In 17 cases (17.7%), a blastoid variant was observed [1, 6, 18, 37, 40, 49]. The median OS time of patients with classical MCL was 31.0 months compared to the blastoid group with 22.7 months ($p=0.1226$).

Growth pattern

The growth pattern was classified by conventional microscopy as nodular or diffuse. A nodular pattern was found in 29 patients (30.2%). In no case was the typical so-called mantle-zone pattern seen. A diffuse pattern was seen in 67 patients (69.8%). The Kaplan–Meier analysis did not show any significant differences between the growth pattern types ($p=0.7468$, Table 2). Excluding cases with blastoid cytology from the analysis of the growth pattern, as suggested by Fisher et al. [10], resulted in a smaller group of cases with a diffuse pattern (50 cases). Interestingly, all 17 cases with a blastoid cytology had a diffuse growth pattern. The relationship between OS time and the different patterns in this smaller group (nodular vs diffuse pattern without blastoid subtypes, Table 2, second group) was still not significant ($p=0.4516$).

Table 3 Results of the analysis of the growth pattern in relation to the FDC pattern in 96 patients with MCL

FDC pattern	Growth pattern	
	Nodular ($n=29$)	Diffuse ($n=67$)
PF-nodular ($n=72$)	25	47
GC-nodular ($n=7$)	2	5
Diffuse ($n=17$)	2	15

Immunohistochemistry

All cases fulfilled the immunophenotyping criteria for MCL, with coexpression of CD20 and CD5. Ninety cases (93.8%) were CD23-negative. In six cases (6.3%), the CD23 staining could not be analyzed. Ninety four cases (97.9%) stained positively for cyclin D1. In two cases (2.1%), the cyclin D1 staining could not be evaluated.

FDC distribution

The staining with the monoclonal antibody Ki-M4p clearly revealed the FDC pattern. The cases were first divided into a nodular (Fig. 1a and b) or diffuse (Fig. 2) FDC pattern according to the criteria of Annecy [55]. Patients with MCL and a nodular FDC pattern ($n=79$) had a significantly longer OS time (median 32.0 months, 3-year survival 41.4%) than patients with a diffuse FDC pattern ($n=17$, median 21.2 months, 3-year survival 29.4%, $p=0.0312$). In a second step, we analyzed the FDC pattern of the cases that did not have a blastoid cytology because this subtype normally has an aggressive clinical course. In this analysis, the nodular FDC pattern predicted a better clinical outcome than that of the diffuse group (Fig. 3b, median survival time 33 vs. 17.9 months, $p=0.0021$).

In the group with a nodular FDC pattern, two different types of FDC networks can be identified: (1) A nodular FDC pattern with an FDC distribution similar to PFs in lymphoid tissue (PF-nodular pattern, Fig. 1a). The staining showed faint Ki-M4p positivity with a mostly nodular network. This pattern was observed in 72 patients. (2) A nodular FDC pattern resembling the colonization of GCs by tumor cells, which was identified in seven patients. In these cases, strongly stained FDC, resembling preexisting GC-associated FDC networks, were seen (GC-nodular pattern, Fig. 1b). Patients with a GC-nodular pattern had a median OS time of only 14.4 months, in contrast to the PF-pattern group of 33.0 months. A significant difference in OS was seen between the PF-nodular and the other two patterns (GC-nodular and diffuse, $p=0.0033$). When blastoid subtypes were excluded, the differences became more evident ($p=0.0008$). Table 2 lists the results of the analysis of the growth and FDC patterns.

An analysis of the FDC distribution in relation to the growth pattern (Table 3) revealed a PF-FDC pattern in 25 of 29 cases (86%) with a nodular growth pattern. Forty seven of 72 cases (65%) with a PF-FDC pattern had a diffuse growth pattern, but the majority of cases with a diffuse FDC pattern ($n=15$) also had a diffuse growth pattern (88.2%, Table 3).

Due to the small number of GC-FDC pattern ($n=6$) and diffuse FDC pattern ($n=9$), the analysis of different prognostic factors in relation to the FDC distribution only has a limited statistical power, and the results had to be interpreted with caution. It revealed that only performance status and an International Prognostic Index (IPI) showed significant differences in each subgroup (Table 4). Inter-

estingly, there was no difference in proliferation activity (Ki-67 index) in different FDC subtypes (p indicates not significant).

Complete clinical information of cases with classical cytology was available for multivariate analysis for only 62 out of 79 patients. A univariate analysis of this smaller group revealed that FDC distribution, Ki-67 index, IPI, age, and performance status [World Health Organization (WHO)] to be significant prognostic markers. In the multivariate Cox regression analysis, only FDC distribution (all three types and PF vs diffuse pattern), IPI, and the Ki-67 index were prognostic factors in our MCL patients (Table 5).

Discussion

Mantle cell lymphoma was first described by Lennert, who called this lymphoma centrocytic lymphoma because of its morphology [21, 22]. Weisenburger identified this entity as an intermediate lymphocytic lymphoma [51, 53] and as mantle-zone lymphoma [48, 50]. Since the identification of the typical cytogenetic abnormality, the translocation t(11;14)(q13;32) [44, 46, 54], various cytological variants, e.g., blastoid types with an aggressive clinical course, have been described [6, 19, 29]. For this lymphoma, the typical growth pattern is a mantle-zone pattern, with tumor cells surrounding residual follicle centers. Additionally, a nodular and a diffuse growth pattern exist [6, 21, 52]. The clinical relevance of the different patterns is unclear. The mantle-zone pattern appears to have a significantly better prognosis [23]. Swerdlow et al. [39] described the pathological features in their study of 18 patients with MCL. They did not detect any differences between the different growth patterns that were of clinical relevance. Histologically, there seems to be a progression from a mantle-zone, to a nodular, and to a diffuse pattern [21, 23, 37]. In our study, 89.5% of the patients were in advanced stages (III and IV) of the disease, and the majority of cases (69.8%) had a diffuse growth pattern. Our results are in line with other studies revealing similar stages of the disease and growth patterns [9, 23, 37]. Lardelli et al. [18] investigated a group of 33 patients with MCL. The authors noticed a trend toward a prolonged median survival time for patients with MCL and mantle-zone pattern (77 months), but it did not reach statistical significance. A reason could be that the number of cases was too small.

In our study, we distinguished two types of growth pattern: a nodular and a diffuse pattern. The median survival time in patients with a diffuse growth pattern was 28.0 months, in contrast to patients with a nodular architecture whose median survival time was 32.0 months. Statistically, there was no significant difference in the OS time

($p=0.7468$). These results are comparable to the data of Argatoff et al. [1], who demonstrated in a large study of 80 patients a diffuse growth pattern in 78%, a nodular pattern in 16%, and a mantle-zone pattern in 6% of patients. There was no significant difference in the OS time between these three groups. In accordance with Fisher and coworkers [10], we also analyzed only the group with classical cytology without the clinically aggressive blastoid variants. Excluding these cases did not influence the statistical results. We conclude that the growth pattern of tumor cells in MCL is not a valid diagnostic tool for identifying patients with a poor prognosis.

In some studies on MCL, networks of FDC were mentioned [3, 9, 32, 37]. These FDC networks in MCL were well described by the ELTF [55]. They described the FDC network in combination with the growth pattern and mentioned, in addition to a nodular growth pattern without residual GCs and loosely structured FDC meshwork (PF pattern), cases with tight FDC clusters (GC pattern).

An FDC network is normally found in reactive lymph follicles [32]. The function of these FDCs in reactive lymph nodes is to present antigens to B cells [12, 15, 17, 42]. The FDC trap the antigen–antibody complexes and make immune-complex-coated bodies, the so-called iccosomes [5, 41]. The B cells endocytose these iccosomes, and the antigen is processed [43]. Networks of FDC have been observed not only in reactive lymphoid tissue but also in lymphoma [7, 28, 32, 35]. The interaction of FDC with normal B cells has been demonstrated in vitro [16, 36]. The interaction of FDC with lymphoma tumor cells has also been investigated [33, 34]. It was demonstrated that the FDC can influence the tumor cells in their environment through cytokines and prolong the entrance of these cells into apoptosis. The majority of proliferating lymphocytes was localized close to FDC. We analyzed the Ki-67 index in different FDC subtypes and could not observe significant proliferation differences, but due to the small number

of cases in the GC-FDC pattern and diffuse FDC groups, these results have only limited statistical power (Table 4).

To our knowledge, no study has investigated the FDC pattern in MCL in relation to the clinical outcome of patients. In our patients, we found both nodular and diffuse FDC patterns. Whereas the majority of cases have a diffuse pattern, the FDC pattern was mostly nodular (82.3%). The OS time was statistically longer (median 32.0 vs 21.1 months) than that for patients with MCL with a diffuse pattern ($p=0.0312$). If we exclude the blastoid variants from the analysis of the FDC pattern, the diffuse group only has a median OS time of 17.9 months, and the Kaplan–Meier analysis becomes more significant ($p=0.0021$). This effect is explained by the fact that the 17 cases with blastoid cytology had a longer median survival time of 22.7 months compared with the diffuse FDC group. Eight blastoid cases had a diffuse FDC network.

In the group with the nodular FDC pattern, we identified two different nodular patterns in accordance with the criteria of Annecy [55]. The first group showed a nodular FDC pattern, with an FDC distribution similar to a PF pattern in lymphoid tissue (Fig. 1a). This most frequent pattern was seen in 72 cases (75.0%). MCL patients with this PF-nodular pattern had a medium survival time of 33 months, in contrast to the second nodular FDC pattern, which resembles the colonization of GCs by tumor cells (GC-nodular). The GC-nodular pattern was only identified in seven cases. In these cases, strongly stained FDC resembling the FDC networks associated with preexisting GCs were seen (Fig. 1b). This pattern shows similarity to the follicular colonization first described in low-grade mucosa-associated lymphoid tissue (MALT) lymphomas by Isaacson and Wright [14]. The so-called FDC pattern of colonized GCs (GC-nodular) had the worst prognosis, with a medium survival time of 14.4 months. A significant difference in the OS of patients with MCL and different FDC networks was seen between the PF pattern and the other two (GC and diffuse) patterns in the analysis of all cases ($p=0.0033$, Table 2) and in that of cases without blastoid cytology ($p=0.0008$, Fig. 3c, Table 2). Multivariate analysis of the FDC distribution and other clinical parameters revealed that only FDC distribution, IPI, and the Ki-67 index are independent prognostic factors in our collective (Table 5).

The analysis of the relation between the FDC distribution and the growth pattern shows that the majority of cases (66.7%) with the PF-FDC pattern had a diffuse growth pattern (Table 3). Only 24 cases (33.3%) had a purely nodular architecture. Taking this into consideration, the analysis of the growth pattern has no predictive value about the FDC pattern. Only the immunohistochemical staining and the analysis of the FDC network distinguished between the FDC patterns.

From these results, we conclude that the interaction of FDC, or their distribution pattern, plays an important role in the clinical course of these malignant lymphomas. It is necessary to exclude aggressive cytological variants of

MCL, like the blastoid subtype from the analysis of the FDC pattern, to better predict the clinical outcome of patients with MCL. The analysis of FDC distribution is a new independent prognostic marker in MCL.

T-/H-cadherin (CDH13): a new marker for differentiating podocytes

Received: 31 January 2005 / Accepted: 27 July 2005 / Published online: 17 August 2005
© Springer-Verlag 2005

Abstract Cadherin molecules are known to be involved in various biological processes other than cell adhesion such as morphogenesis, cell–cell communication, cell recognition or cell signalling. While the classical cadherin molecule is characterized by an extracellular moiety, a transmembrane region and a variable cytoplasmic domain, T-/H-cadherin differs from this pattern due to the absence of a transmembrane region and a cytoplasmic domain, respectively. Its extracellular moiety is bound to the apical cell membrane by a glycosyl–phosphatidyl–inositol anchor and localized to lipid raft domains. As its molecular function and expression pattern is still not fully understood, we used a newly generated anti-T-/H-cadherin antiserum to study immunohistochemically the expression of T-/H-cadherin during the differentiation of foetal human glomeruli. At the early capillary loop stage a strong apical signal comes up for visceral epithelial cells of Bowman’s capsule, which begin to differentiate towards podocytes. At the advanced capillary loop stage, when podocytes have become part of the glomerular filtration barrier, the expression pattern, however, becomes more distinct and most likely restricted to the foot processes of the podocytes. We thus postulate a functional role of T-/H-cadherin for the differentiation of the podocytes and the formation of the glomerular capillary network.

Introduction

Morphoregulatory processes, like embryonic development or differentiation of tissues and organs, as well as maintenance of tissue architecture, require, among others, cell–cell- or the cell–extracellular matrix interactions. In these, cell adhesion molecules or their macromolecular structures act as mediators, transforming their extracellular binding properties via an intracellular signal transduction pathway directly into a regulatory signal for the nucleus and its transcription machinery. Thus, adhesive processes influence the timing of cellular events, like differentiation, proliferation or cell migration.

Among the cell adhesion molecules, the still-growing family of cadherins is the most important [1]. Cadherins are Ca²⁺-dependant transmembrane-localized molecules. The so-called “classical,” or type I, cadherin molecules, like E-cadherin, are characterized (a) by a well-defined extracellular region with a conserved HAV cell-adhesion recognition site (CAR) and extracellular Ca²⁺-binding cadherin domains, (b) by a transmembrane domain and (c) by an intracellular or cytoplasmic part, which links these molecules to the cytoskeleton and to various intracellular signalling pathways via binding, e.g. to catenin molecules.

An unusual member of the cadherin family is T-cadherin [6, 9], also known as H-cadherin [10] or CDH13, now referred to as T-/H-cadherin, which is characterized by the lack of several defined classical domains. Not only the transmembrane region and the cytoplasmic tail are absent from the molecule but also the conserved CAR is missing. From these data, cellular properties have been noticed which differ from the classical cadherin molecules: First, T-/H-cadherin shows an apical instead of a baso-lateral localization. Second, the lack of a direct link to the cytoskeleton via catenin molecules excludes the β -catenin-directed signal transduction pathway from transcriptional regulation of T-/H-cadherin. Third, the absence of a func-

tional CAR and the lack of strong links to the cytoskeleton should exclude this molecule from homo- or heterophilic binding to other cadherin molecules in terms of cell–cell adhesion processes. Instead, the C-terminus of T/H-cadherin is bound to a glycosyl–phosphatidyl–inositol (GPI) anchor [6] as part of a post-translational modification. Like other GPI-anchored molecules T/H-cadherin thus localizes on defined domains of the plasma membrane, the so-called lipid rafts. Lipid rafts are of functional importance for the polarisation of epithelial cells, mainly by sorting out apical membrane proteins [8]. This process leads to a kind of compartmentation of the cell and, consequently, to the expression of defined signalling pathways. A specific form of lipid rafts are the caveolae, with their various caveoli proteins as main components. Furthermore, those caveolae, and T/H-cadherin has been postulated to be a part of them, are regarded as organising centres for signal molecules [8]. A link to activation or inhibitory processes, e.g. of the Ras/mitogen-activated protein kinase (Ras/MAPK) pathway, has been shown.

The function of T/H-cadherin, however, is still controversially discussed, as it is supposed to be different in developmental stages, tissues and organs. While some authors [7] suggested a function for cell recognition, others [11] proposed a regulatory function in cellular signal transduction processes. Again, others demonstrated a negative regulation of cellular growth [9] or postulated a tumour suppressor function [10]. Recent data [12] even indicated towards a possible role in neo-vascularisation during tumour development, as T/H-cadherin showed an over-expression in tumour-penetrating blood vessels.

As we are generally interested in the morphoregulatory function of the various members of the cadherin family, we produced an antiserum against a unique fragment from the N-terminal region to test T/H-cadherin expression during foetal development of mice and humans.

Materials and methods

Expression of fusion protein and generation of antisera

A recombinant fragment of 56 amino acids (GSLQDIFK FARTSPVPRQKRSIVVSPILIPENQRQPFPRDVGKVV DSDRPEGSKFR), covering position 119 to 174 of the T/H-protein, was cloned and expressed in the pATH3 expression system [5]. The fusion protein was purified by gel elution and submitted for the commercial immunisation of rabbits (SEQLAB, Göttingen, Germany).

Western blot analysis

For Western blot experiments proteins were extracted from cells, separated on 10% sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis (PAGE) gels and electroblotted onto nitrocellulose membrane (Hybond C; Amersham Pharmacia Biotech) according to standard protocols. The obtained blots were pre-incubated with non-fat

milk (10% w/v) in Tris-buffer saline with Tween (TBST) (50 mM Tris–HCl, pH 7.4; 0.9% NaCl; and 0.05% Tween 20) and subsequently incubated for 1 h at room temperature (RT) with *anti-T/H-cadherin (a-9002)* or *anti-caveolin-1* (Santa Cruz Biotechnology Inc.) antisera in TBST. After washing, membranes were incubated with an alkaline phosphate-labelled anti-rabbit immunoglobulin G (IgG) antibody for 1 h at RT. After washing in TBST signals were detected using the nitroblue tetrazolium (NBT)/5-bromo-4-chloro-3-indolyl phosphate (BCIP) system.

Immunohistochemistry

Briefly, paraffin sections of human foetal kidneys (weeks 20 and 21) were pretreated by the microwave method and subsequently incubated with *anti-T/H-cadherin (a-9002; 1:200)* or *anti-caveolin-1* (Santa Cruz Biotechnology Inc.; 1:200), followed by incubation with a secondary biotinylated goat-anti-rabbit-antiserum (1:400; Sigma). The presence of bound antibodies was detected with the peroxidase-conjugated Avidin–Biotin Complex method (ABC Kit; Vector) using diaminobenzidine tetrahydrochloride (DAB) as a substrate according to standard protocols.

Results

The specificity of the obtained anti-T/H-cadherin antiserum, *a-9002*, can be shown when immunoblots of fusion proteins and various protein extracts, e.g. from human kidney tissue and from the T/H-cadherin expressing human embryonic kidney cell line *HEK 293*, were positively tested for a specific recognition pattern and a signal of predicted molecular weight (Fig. 1). The observed strong signals in human-kidney-derived protein lysates prompted us to analyse its cellular localization in more detail. We thus tested the expression pattern of T/H-cadherin during human kidney development by means of immunohistochemistry.

The development and differentiation of the kidney is a complex process, which is characterized by a high level of gene activity, and thus, of increased regulatory pathways [3]. Different stages of kidney differentiation have been defined, like condensation stage, epithelial stage, tubulus

Fig. 1 a In immunoblot experiments the anti-T/H-cadherin (CDH13) antiserum *a-9002* was positively tested in protein lysates of adult human kidney tissue (a) and of the human embryonic kidney cell line *HEK 293* (d), while samples of human adult lung (b) and testis tissue (c) were negative. b As a control for the specificity an antiserum against the broadly expressed caveolin-1 was run alongside it

differentiation stage or nephron differentiation stage. For our investigation foetal kidney specimens between the 20th and 22nd weeks of gestation, which were obtained for routine histopathological examinations, were selected, as at this stage, a cortex-to-medulla-orientated gradient from early to fully differentiated nephron stages can be found (Fig. 2a–c).

Immunohistochemical experiments showed distinct patterns of T/H-cadherin expression. While there were no signals at all in the very early stages of nephron differentiation, namely, “comma-shape” and “S-shape” stages, a strong signal appears in the early phase of nephron differentiation, just before the glomerular capillary network differentiates, and extends to the final stage of glomerular capillary network differentiation. At the early stage the inner layer, or VEC, of Bowman’s capsule shows a strong

apical staining, with signals extending well into the lumina (Fig. 2d–f). These epithelial cells will differentiate into podocytes, which coat the glomerular capillary tuft.

With the ongoing differentiation of the glomerulus the continuous layer of VECs apparently disperses, and these cells, which begin to differentiate into podocytes with extended foot processes, move towards the endothelial cells of the invading capillaries. This can be shown by the punctate immunoreaction with the anti-T/H-cadherin antiserum, where signals extend towards the capillaries (Fig. 2g–i). However, the overall impression is that the signal intensity should be slightly reduced. At this stage the podocytes have terminally differentiated and line the glomerular capillary network. These podocytes are part of the glomerular filtration barrier, which consists mainly of the capillary endothelial cells facing the circulating

Fig. 3 Immunohistochemical localization of caveolin-1 in early and advanced stages (a–c) of human foetal kidney development using anti-caveolin-1 antiserum. Note as well the broader expression pattern of caveolin-1 as the almost identical pattern compared with anti-

T/H-cadherin antiserum during glomerular capillary network differentiation. In early stages signals are present in the initially continuous, later dispersed, visceral layer of epithelial cells of Bowman's capsule; magnification $\times 630$

blood, the glomerular basement membrane and the podocytes, facing the urinary space.

As the expression pattern obtained in this delicate stage of nephron differentiation is of particular interest for the pathologist working, e.g. on congenital nephrosis, we decided to run another well-defined marker, anti-caveolin-1, alongside it.

Caveolin proteins are the main components of caveolae, a specific organisation of lipid raft domains within the plasma membrane [8]. As the GPI-anchored T/H-cadherin molecule localizes to lipid raft domains of the plasma membrane and potentially to caveolae, and as caveolin-1 has been shown to be expressed by podocytes and to be localized in the foot processes of the terminally differentiated podocytes, we chose the well-established marker caveolin-1 for comparison with the expression pattern of T/H-cadherin.

Not only was the presence of caveolin-1 protein confirmed in immunoblot experiments with the abovementioned samples (Fig. 1) but also the obtained staining pattern of the podocytes were almost the same as for the anti T/H-cadherin antiserum when tested on the same specimen by means of immunohistochemistry (Fig. 3a–c). This finding furthermore supports our observation that T/H-cadherin protein should be localized to the foot processes of podocytes, leaving, however, the question of a possible function unsolved.

In all, we were able to demonstrate for the first time a distinct expression pattern of the T/H-cadherin protein at defined stages of nephron differentiation.

Discussion

It should be noted that a signal for T/H-cadherin protein first comes up in VEC at the early capillary loop stage, while previous stages are negative. The hereby observed high intensity, which is equivalent to a high amount of protein, indicates that it could well be linked to a defined differentiation step on the cellular level. We would like

to speculate that its expression could well monitor the transition from VECs towards podocytes. The function of T/H-cadherin is still unknown, but given that lipid rafts and their components are involved in the sorting of apical membrane proteins and compartmentation of the cell, T/H-cadherin could well contribute to the differentiation of the foot processes, as the corresponding staining patterns of T/H-cadherin and caveolin-1 suggest.

Papers published describe various members of the cadherin family as expressed in a hierarchical order during kidney development [4], similar to what has been previously described for the human epidermis [2]. Besides ubiquitously expressed classical cadherin molecules, like E-cadherin, certain cadherin molecules are expressed in narrow stage-specific limits.

Cadherin-11, for example, has a characteristic expression pattern in the early condensation stage of the kidney and is replaced by cadherin-4 (R-cadherin) and/or cadherin-6 (K-cadherin) during the epithelial stage, while during the tubulus stage, cadherin-16 [kidney-specific (KSP)-cadherin] is transcribed [4]. So far, T/H-cadherin is the only published cadherin molecule with a specific expression pattern during the advanced nephron differentiation stage, and specifically in podocytes.

This is of special interest to the pathologist, as a disturbed differentiation can cause conditions like glomerulocystic kidney disease (OMIM #137920) or affect the volume of amniotic fluid by affecting the filtration rate. Oligo- or anhydramnion are conditions where malformations and malfunctions of the foetal kidney, besides maternal placenta insufficiency or early rupture of the foetal membrane, can cause the intra-uterine death of the foetus. Thus, one diagnostic criterion is the differentiation stage of the kidney, and particularly, of the nephrons. From this point of view the characterization and subsequent application of markers specific for this stage of differentiation should be of great help in histopathological evaluation.

In summary, the described pattern suggests that the epithelial podocytes are the expressing cell type during neph-

ron differentiation and that T/H-cadherin should function as a kind of morphoregulatory molecule. We do not yet know what the specific function on the cellular level might be, but given that published data [12] suggest a possible role for T/H-cadherin in the neo-vascularisation process during tumour growth, we would, like to speculate that it can have a similar role for the formation of the glomerular capillary network. However, this has to be proven experimentally in an animal model.

Abstract The seven signal transducer and activator of transcription (STAT) molecules are effectors of hormonal or cytokine stimulation through receptors. STAT 5a, isolated from prolactin-stimulated mammary cells, contributes to normal proliferation and is essential for mammary gland differentiation. Using a monoclonal antibody, we tested 100 formalin-fixed, paraffin-embedded breast tissues representing everything from simple hyperplasia to invasive carcinoma for the expression of STAT 5a in comparison to normal breast epithelial cells. Immunohistochemical analysis was performed following heat treatment in a pressure cooker. STAT 5a was found in endothelial cells, adipocytes, and leukocytes as well as in the cytoplasm and nucleus of normal epithelial cells, usual ductal hyperplasia, and benign lesions such as fibroadenoma. Myoepithelial cells and stromal fibroblasts failed to demonstrate any STAT 5a in addition to most atypical proliferations including in situ and invasive carcinomas. A few examples of lobular intraepithelial neoplasia and invasive carcinoma demonstrated some reactivity, albeit comparatively re-

duced. The absence of STAT 5a in the abnormal breast epithelial cells may indicate a defect contributory to the abnormal state.

Introduction

The seven signal transducer and activator of transcription (STAT) molecules are effectors of hormonal or cytokine stimulation through receptors. In unstimulated cells, STAT proteins exist largely in the cytoplasm as latent transcription factors. In response to exogenous factors, specific STATs undergo tyrosine phosphorylation, nuclear translocation, and DNA binding resulting in the transcriptional activation of distant target genes. There are many genes regulated by the STAT pathway that are required for cell growth, survival, differentiation, and motility [7].

STAT 5a, also called mammary growth factor, was isolated from prolactin-stimulated mammary cells, and is activated through the binding of prolactin to its receptor [17]. STAT 5a has been shown to be involved in integrin-mediated *c-fos* transcription and integrin-mediated adhesion affects control of cell cycle entry and inhibition of apoptosis [5]. In knockout mice that lack STAT 5a, the mammary gland does not develop properly [1, 14]. STAT 5a-deficient mice develop normally, but lobuloalveolar growth during pregnancy is aberrant [15].

It has been suggested that STAT 5a contributes to normal proliferation, and it has been shown that STAT 5a is essential for mammary gland differentiation in mice [15]. Furthermore, known defects in the Janus Kinase (JAK)/STAT pathway have led to the inhibition of growth restraint [19]. STAT 5a is also involved in adipocyte differentiation, its expression correlating with lipid accumulation, and it can be activated in the stroma by growth hormone and the epidermal growth factor [9, 24]. Recently, STAT 5a activation in breast cancer has been associated with a favorable prognosis [18].

Using a monoclonal antibody, we immunohistochemically tested different examples of breast disease for the expression of STAT 5a in comparison to normal breast ductal and lobular epithelial cells.

Materials and methods

For this study, 100 formalin-fixed, paraffin-embedded tissues representing various lesions of the breast were obtained from the files of the Armed Forces Institute of Pathology. The sections were reviewed for the presence of normal breast ductal and lobular epithelium, low-risk ductal intraepithelial neoplasia (DIN) (usual ductal hyperplasia), DIN 1 (atypical ductal hyperplasia), lobular intraepithelial neoplasia (LIN) (atypical lobular hyperplasia or lobular carcinoma in situ), DIN 1–3 (ductal carcinoma in situ), and invasive carcinoma [27]. Specimens were sectioned at 6 μm and then assayed with an antibody to STAT 5a (clone ST5a-2H2, Zymed Laboratories, South San Francisco, CA). Immunohistochemical analysis was performed as previously described [4]. Briefly, formalin-fixed, paraffin-embedded sections were heated at 70°C for 30 min and placed into a prewarmed pressure cooker in a solution of Reveal (Biocare Medical, Concord, CA) in which deparaffinization and antigen retrieval were performed simultaneously at 20 lb/in.² for 3 min. Following depressurization, sections were placed into a prewarmed fresh solution of Reveal for 30 min before being rinsed in warm water. Endogenous peroxide and oxidative compounds were quenched by incubation in 5% H₂O₂ in methanol. Sections were rehydrated in Tris-buffered saline (TBS Plus, Biocare Medical) with 0.1% Tween 20 (DakoCytomation, Carpinteria, CA) added, prior to antibody application. Primary antibody incubations were performed for 60 min, with the ST5a-2H2 antibody diluted in TBS–Tween at 1:400. Detection reagents (ABC Universal Elite, Vector Laboratories Inc., Burlingame, CA) were applied for 45 min each, and all dilutions and intervening rinses were with TBS–Tween. Diaminobenzidine tetrahydrochloride (Sigma Chemical Co., St. Louis, MO) (0.08%) with 0.025% H₂O₂ added in a solution of TBS–Tween (DAB) served as the chromogenic substrate. Sections were allowed to develop in DAB for 12 min, counterstained with hematoxylin, dehydrated, and coverslipped with Permount (Fisher Chemical Co., Pittsburgh, PA) in xylene.

Assayed sections were examined for accurate interpretation of positive signal on a qualitative intensity scale. Tissues were regarded as positively expressing STAT 5a when qualitative intensity was at least 2 on a 4-point scale, and more than 20% of the cells were reactive. The cell type along with reaction product distribution was noted.

Results

The results are listed in Table 1. In normal mammary gland epithelium, STAT 5a was found to exist in the cytoplasm and the nucleus of about 80% of the luminal breast epi-

Table 1 STAT 5a reactivity in various examples of breast epithelium

Fig. 5 **a** H&E stain of a focus of epithelial cell secretory change (200 \times). **b** Immunohistochemical demonstration of STAT 5a in the cells with secretory changes (200 \times). Note: intensity greater than that seen in neighboring epithelial cells

STAT 5a was detected in the cytoplasm and nucleus of epithelial cells in cases of usual ductal hyperplasia and in benign neoplasms such as fibroadenoma. However, in atypical proliferations, ductal carcinoma in situ (DIN 1–3) and in invasive carcinomas, the STAT 5a protein (with rare exceptions) was either not expressed or greatly reduced (Figs. 2, 3 and 4). It was absent in all cells with apocrine differentiation but was readily detected in cells undergoing secretory or lactational change. The reactivity in the secretory cells was often more intense than that seen in the surrounding normal cells, perhaps signaling a higher concentration of antigen in these cells (Fig. 5). Although most examples of LIN did not express STAT 5a, a few examples demonstrated some reduced reactivity. Also, two tubular carcinomas and three invasive carcinomas with squamoid features and inflammation exhibited focal reactivity (data not shown). This may be secondary to increased background STAT 5a in these cases, since it occurred only when the adjacent normal epithelial and inflammatory cells also showed increased STAT 5a expression as compared to STAT 5a-negative carcinomas. All control sections assayed with a normal mouse IgG in substitution for the STAT 5a antibody were nonreactive.

Fig. 6 **a** H&E stain showing small foci of DIN 1 Flat type (flat type epithelial atypia) and DIN 1 (atypical ductal hyperplasia) (400 \times). **b** Immunohistochemical detection of STAT 5a demonstrating its absence in these abnormal foci (400 \times)

Discussion

A reduction of STAT 5a was observed, associated with abnormal breast epithelial cells. The absence of STAT 5a in the abnormal breast epithelial cells may indicate a defect contributory to the abnormal state. Since STAT 5a is required for the development of breast lobules, repressors of its activation or inappropriate signaling through other mechanisms might alter the function and phenotype of these cells. Because the demonstrated expression was seen specifically in cells known from other studies to contain STAT 5a, it was reasoned that the reaction was specific for STAT 5a or a STAT 5a-like protein. In all of the sections, normal ductal and lobular epithelium reacted strongly in the cytoplasm and nucleus with the antibody to STAT 5a, serving as an internal control for cells with weak or absent staining.

STAT 5a expression may be affected by an abnormal genotype. Certain genomic deletions may affect the STAT 5a gene locus, found on chromosome 17q11, incidentally. However, it is also possible that any number of biochemical events involving STAT 5a may act to provide an atmosphere in which cellular transformation can occur. The absence of STAT 5a could result in aberrant signaling or suboptimal transcription of developmental, regulatory, or growth-restraining proteins contributing to altered (metaplastic or neoplastic) phenotypic differentiation.

Numerous reports implicate the suppression of STAT 5a in normal and disease processes [20, 22, 24]. Suppressors of cytokine signaling (SOCS) and protein inhibitors of activated STATs (PIAS) can suppress signal transduction by inhibiting the STAT pathway [10, 26, 28]. Activated SOCS can also stimulate cell proliferation and increase cell survival through the Ras signaling pathway [6]. Therefore, proliferation can occur through at least one mechanism that would inactivate STAT 5a in the process and, in fact, a recent study demonstrated increased SOCS gene expression in breast cancer [21].

The absence of STAT 5a in most abnormal breast epithelial cells including carcinomas is not something that has been widely noted, however. Because STAT 5a is a transcription factor, one might imagine that an over-expression or constitutive expression of STAT 5a would be seen in the uncontrolled growth of breast carcinomas like the reports of over-expression of STAT 3 in these tumors [3]. This has been reported in one study where 76% of the breast cancers examined showed phosphorylated STAT 5a to be present in the nucleus [8]. It has also been shown that in 65% of induced rat mammary gland tumors, STAT 5a was detected in the nucleus using phosphorylation-specific antibodies [23].

These data may seem, initially, to contradict the present findings. Antibody variability, however, can certainly make a difference in detection. Nevalainen et al. saw a decrease in activated STAT 5a in more aggressive breast cancers using a phosphor-specific antibody, while detection of the STAT 5a protein using another anti-STAT 5a was maintained [18]. In contrast, the report by Shan et al. [23] stated that high STAT 5a nuclear expression closely correlated with higher-grade carcinomas and identified a cytoplasmic location for STAT 5a in the normal rat mammary gland. Because the STAT 5a expression in this present study was seen in the nucleus, it was reasoned that at least some of the identified STAT 5a might be of an activated form. The ST5a-2H2 clone used for this study, while not described as an activation specific clone, demonstrated a lack of detection of STAT 5a in higher-grade lesions corroborating the results of Nevalainen et al. [18].

The ST5a-2H2 antibody is directed against the molecule's carboxy-terminus near where the active phosphorylation site is located. Some functional STAT 5a variants may exist that are not detectable with this antibody, and some naturally occurring splice site variants of STAT 5a have been shown to have the ability to suppress the transcriptional activity of the wild-type STAT 5a [30]. Also, a few early studies have pointed to distinct carboxy-terminal truncated forms of STAT 5a [13, 16]. If truncated forms were present in the tumor cells, they would not be visible with this antibody. Tantalizingly, a report examining the expression of various forms of STAT 5a in transgenic mice demonstrated that a carboxy-terminal truncated form of STAT 5a produced the most undifferentiated carcinomas in the mammary glands of these mice [11].

It was of interest to note that a relative over-expression of STAT 5a was observed in cells undergoing secretory change. This was considered unusual because cells under-

going apocrine differentiation (a secretory cell) were uniformly nonreactive. Perhaps the secretory nature of breast epithelium is dependent on viable STAT 5a, and the functional ability of the cell is lost when defects occur in this pathway leading to abnormal cell behavior. Also, the rare lesions showing some expression were either well-differentiated tubular carcinomas or tumors surrounded by a large amount of STAT 5a-positive inflammatory cells. Examples of LIN (merely an indicator of generalized risk) demonstrated the expression nearest to that of normal or hyperplastic samples, and in the study by Cotarla et al., the STAT 5a-positive tumors correlated with increased levels of differentiation [8]. This may indicate that STAT 5a function is maintained in lesions that are differentiated enough to allow normal processes to occur. These findings support STAT 5a as a marker of good prognosis, and the percentage of positive carcinomas reported by Nevalainen et al. is also similar to the number reported here [18]. In addition, a recent report described STAT 5a as a suppressor of invasion due to its loss associated with metastatic lesions and a relationship between STAT 5a and adhesion [25]. STAT 5a, then, has been alternately reported to be an active factor associated with breast carcinoma or acting almost like a tumor suppressor gene in the breast. The correlation of function and tumor grade with respect to STAT 5a expression as determined by the individual antibody employed will have to be investigated further.

Whether or not STAT 5a has an effect on the maintenance of the normal phenotype as it has an effect on the establishment of the normal phenotype is subject to conjecture. In most instances, abnormal cell growth can be identified by an absence of STAT 5a reactivity (Fig. 6). The St5a-2H2 antibody, therefore, might also have a possible clinical utility in distinguishing atypical ductal hyperplasia or grade one ductal carcinoma in situ (DIN 1) from usual ductal hyperplasia (low-risk DIN). Since STAT 5a is required for the normal development of breast lobules, repressors of its activation or inappropriate signaling through other mechanisms might alter the function and phenotype of breast epithelial cells.

In situ glomerular expression of activated NF- κ B in human lupus nephritis and other non-proliferative proteinuric glomerulopathy

Received: 26 April 2005 / Accepted: 3 August 2005 / Published online: 5 October 2005
© Springer-Verlag 2005

Abstract Nuclear Factor- κ B (NF- κ B) has been suggested to play a role in the cellular and molecular mechanisms underlying glomerular injury. We investigated the potential role of NF- κ B activation in the pathogenesis of glomerular injury in 31 patients with class III–V lupus nephritis (LN), 14 patients with non-proliferative proteinuric glomerulopathy and six normal controls. The expression of NF- κ B subunits p65 and p50, and the NF- κ B regulated proinflammatory mediators tumor necrosis factor- α (TNF- α), interleukin-1 β (IL-1 β), interleukin-6 (IL-6) and intercel-

lular adhesion molecule-1 (ICAM-1) as well as CD68 and synaptopodin was examined by Southwestern histochemistry (SWH) or immunohistochemistry. In contrast to non-proliferative glomerulopathy and normal controls, NF- κ B activation (both p65 and p50) was enhanced in glomerular endothelial, mesangial cells or infiltrating cells in class IV LN, along with upregulation of TNF- α , IL-1 β , IL-6 and ICAM-1 expression. Glomerular endothelial and mesangial activation of NF- κ B and mesangial ICAM-1 expression correlated with disease activity and the level of glomerular macrophage infiltration. Podocyte NF- κ B overactivation (predominantly p65) paralleled podocyte expression of TNF- α and IL-1 β in patients with LN and non-proliferative glomerulopathy. Podocyte staining scores of NF- κ B and p65 were positively correlated with the severity of proteinuria in LN and non-proliferative glomerulopathy. These results suggest a pathogenic role for NF- κ B in glomerular injury by multiple mechanisms.

Introduction

In classic forms of immune-mediated glomerulonephritis such as lupus nephritis (LN), immune complex formation and deposition in the kidney result in intraglomerular inflammation with recruitment of leukocytes, and the activation and proliferation of resident renal cells [7]. Apart from macrophages, intrinsic glomerular cells have been demonstrated to be activated and to participate in the process of glomerular injury by the induction of in-

flammatory mediators, including adhesion molecules and cytokines [6, 31, 33]. However, cellular and molecular mechanisms underlying glomerular cell activation have not been fully elucidated in human glomerulonephritis.

Transcription factor nuclear factor- κ B (NF- κ B) is a pleiotropic transcription factor regulating the gene expression of several adhesion molecules, cytokines and chemotactic proteins involved in inflammation, immune response and cell proliferation [4, 14, 24]. NF- κ B belongs to the Rel family of five members: c-Rel, NF- κ B1 (p50/p105), NF- κ B2 (p52/p100), RelA (p65) and RelB. The DNA-binding nuclear form of NF- κ B is a dimer, usually composed of p65 and p50 subunits. In resting cells, NF- κ B exists in the cytoplasm, bound to its inhibitor I κ B that functions to mask the nuclear localization sequence of NF- κ B. In response to numerous stimuli, such as tumor necrosis factor (TNF- α) and interleukin-1 β (IL-1 β), phosphorylated I κ B is disassociated from NF- κ B and subsequently degraded by the proteasome pathway. Activated NF- κ B, free from I κ B, is then translocated from the cytosol into the nucleus, where it promotes the transcriptional activity of downstream target genes by binding to their promoters [11].

Recent studies suggest that NF- κ B activation plays a pivotal role in the activation of mesangial cells and macrophages through the transcriptional induction of inflammatory mediators of glomerular inflammation and injury [20, 27]. NF- κ B activation has been observed in several experimental and human glomerular diseases [2, 29, 38, 39]. Increased activation of NF- κ B has been reported in rat glomeruli shortly after nephrotoxic serum administration, associated with the increased expression of NF- κ B-regulated inflammatory mediator IL-1 β , monocyte chemoattractant protein 1 and intracellular adhesion molecule-1 (ICAM-1), and the development of proteinuria [39]. In human IgA nephropathy and non-proliferative glomerulopathy such as minimal change disease (MCD) and idiopathic membranous nephropathy (IMN), NF- κ B activation assessed by Southwestern histochemistry (SWH) has been observed in glomeruli, along with upregulated transcriptional activity of their downstream target genes [2, 28]. Although the presence of NF- κ B activation in response to glomerular injury is indirectly mentioned in a study of a lupus-like mouse model [50], to our knowledge no report has documented the activation of NF- κ B in the renal tissue of patients with LN.

Since in situ glomerular expression of NF- κ B-responsive genes such as adhesion molecules and cytokines have been reported in experimental and human glomerulonephritis, including LN [5, 16, 23, 41, 49], we hypothesize that NF- κ B activation may play a proinflammatory role in glomerular injury in LN. In this study, we examined the in situ expression of activated NF- κ B, along with NF- κ B-regulated proinflammatory mediators in the context of their potential role(s) in mediating glomerular injury, in human LN as well as non-proliferative proteinuric glomerulopathy.

Materials and methods

Patients

The Ethics Committee of the National University Hospital of Singapore (NUH) approved the use of human renal biopsy tissue for this study. Thirty-one patients who met the revised ACR criteria for SLE [42] and who had undergone diagnostic renal biopsy during the period from 1997 to 2000 participated in the study. Fourteen patients with non-proliferative proteinuric glomerulopathy (eight with IMN and six with MCD) and six samples of normal kidney tissue obtained from nephrectomies performed for treatment of renal cell carcinoma served as disease controls and normal controls, respectively. Tissue samples were obtained either by percutaneous renal biopsy at NUH, or through referral from local nephrologists to the NUH pathology department for definitive diagnosis. Data on proteinuria, serum creatinine and creatinine clearance at the time of biopsy were available for the majority of the patients. Clinical, demographic and histologic data are summarized in Table 1.

Biopsies containing less than five glomeruli were excluded from the present study. For light microscopy, the tissue samples were fixed in 4% paraformaldehyde, embedded in paraffin, and 2- μ m sections were cut and stained with hematoxylin and eosin, periodic acid-Schiff (PAS) reagent, Masson trichrome-silver impregnation (PAAG-MT). For direct immunofluorescence microscopy, a portion of the biopsy sample was snap-frozen, and 5- μ m cryostat sections were cut and stained with fluorescein-isothiocyanated conjugated anti-IgG, IgA, IgM, C3, C1q and fibrinogen antibodies (Dako) in all cases.

Biopsies diagnosed as LN were classified according to the criteria defined by the International Society of Nephrology/Renal Pathology Society in 2003 [48]. The LN disease group consisted of two subjects with focal LN (class III), 23 with diffuse LN (class IV) and six with membranous LN (class V). The class IV group comprised two subjects with class IV-S (A) (diffuse segmental LN with active lesions), two with class IV-S (A/C) (diffuse segmental LN with active and chronic lesions), 15 with class IV-G (A) (diffuse global LN with active lesions) and four with class IV-G (A/C) (diffuse global LN with active and chronic lesions). The "activity index" and "chronicity index" were determined by the following histologic criteria proposed by Austin et al: mesangial cell proliferation, extracapillary lesions (cellular and fibrous crescents), leukocyte infiltration, karyorrhexis/fibrinous necrosis, hyaline deposits, glomerular sclerosis, interstitial inflammation and fibrosis and tubular atrophy [3]. Histologic classification of IMN was made according to the extent of glomerular membrane alterations revealed by silver staining or electron microscopy. The IMN disease group consisted of one subject with stage I, four subjects with stage I/II or II, and three subjects with stage III disease.

^bData from one patient is unavailable

Immunohistochemistry

The mouse monoclonal antibody anti-human RelA/p65 (Chemicon International), which is directed against an epitope of p65 containing a nuclear localization signal, is specific for the detection of activated NF- κB [18, 28]. Polyclonal goat anti-human p50 (Santa Cruz Biotechnology, Santa Cruz, CA, USA) and monoclonal mouse anti-human synaptopodin (PP-44) (Progen, Heidelberg, Germany) were used in previous studies [28, 30]. Polyclonal rabbit anti-human TNF- α [35] and IL-1 β were purchased from Rockland Immunochemicals (Gilbertsville, PA, USA), polyclonal rabbit anti-human IL-6 [26] was purchased from Endogen (Pierce Biotechnology, Rockford, IL, USA) and mouse anti-human ICAM-1 and CD68 were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA) and Dako. The specificity of the antibodies was confirmed by their reactivity with specific human targets by immunoprecipitation and/or Western Blot analysis, as per manufacturer's description.

For the majority of primary antibodies, immunohistochemistry was conducted on paraformaldehyde-fixed paraffin sections with a two-step EnVision+ System peroxidase kit (Dako, Carpinteria, CA, USA) [37]. Except for CD68, slides were subjected to microwave antigen retrieval with wet heat at 98°C for 10 min under 150 W (Milestone Microwave System, Italy). We used 100 mmol/l pH 6.0 citrate buffer with anti-p65 and anti-p50; 10 mmol/l pH 6.0 citrate buffer was used with antibodies against TNF- α , IL-1 β , IL-6, ICAM-1 and synaptopodin before peroxidase blocking. Slides were predigested with pronase for CD68 immunostaining. Endogenous peroxidase was blocked in 3% H_2O_2 for 30 min and sections were incubated with

primary antibodies overnight at 4°C. After rinsing, horseradish peroxidase enzyme-labeled non-avidin-biotin polymer conjugated to goat anti-mouse or anti-rabbit was applied to the sections for detection of p65, TNF- α , IL-1 β , IL-6, ICAM-1 and synaptopodin. Dako LSAB⁺ Peroxidase Kit was employed to detect p50. Briefly, sections were incubated with 20% normal swine serum (Dako) for 30 min to block non-specific binding of proteins prior to incubation with primary antibodies. After rinsing, sections were incubated with biotinylated anti-goat immunoglobulin and horseradish peroxidase-conjugated streptavidin. 3,3'-Diaminobenzidine tetrahydrochloride (DAB) was used for colorimetric detection, followed by mild counterstaining with PAS reagents and Gill's haematoxylin. The specificity of primary antibodies or secondary antibodies was verified by the replacement of primary antibodies with equal concentrations of non-immune sera or by omitting primary antibodies. The positive control was tonsillitis tissue for detection of transcription factors and cytokines, and normal kidney tissue for detection of synaptopodin.

Southwestern histochemistry

SWH was performed as described previously [15, 28]. Complementary oligonucleotides containing consensus binding sequences for NF- κB were synthesized as follows: (sense) 5'-AGTTGAGGGGACTTCCAGGC-3' and (anti-sense) 3'-TCAACTCCCCTGAAAGGGTCCG-5' (Gibco-BRL, LifeTechnology, Gaithersburg, MD). After annealing (98°C for 10 min), the resulting double-stranded DNA probe was 3'-end labeled with digoxigenin (DIG oligonucleotide 3'-end labeling kit, Roche Diagnostics).

Paraformaldehyde-fixed paraffin kidney sections (4 μ m thick) were dewaxed and rehydrated. The preparations were incubated with levamisole (Sigma, St. Louis, MO, USA) to inhibit endogenous alkaline phosphatase activity and then fixed with 0.2% paraformaldehyde for 30 min at 28°C. Sections were subsequently digested with pepsin A (433 U/mg, Sigma) and washed twice in 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES)-bovine serum albumin. The sections were incubated with 0.1 mg/ml DNase I in HEPES-bovine serum albumin for 30 min at 30°C. The labeled probes diluted to 100 pmol/l in HEPES-bovine serum albumin containing 0.5 μ g/ml poly (dI-dC) (Roche Diagnostics) were applied to each slide overnight at 37°C. After incubation in blocking solution (0.01 \times SSC, 0.01% sodium dodecyl sulfate, 0.03% Tween 20, 0.1 mol/l maleic acid, 0.15 mol/l NaCl, pH 7.5), anti-digoxigenin antibody conjugated with alkaline phosphatase (1:250 in blocking solution, Roche) was added overnight at 4°C. The color reaction was developed using nitro blue tetrazolium (NBT/BCIP, Roche) according to the manufacturer's instructions. Slides were counterstained with mild PAS re-

agent minus haematoxylin. Double staining was performed to co-localize active NF- κ B by SWH with immunostaining of TNF- α in selective cases. Sections were sequentially treated for SWH and IHC as described above.

The following conditions were carried out as negative controls: (1) absence of probe; (2) use of a mutant NF- κ B probe (sense 5'-AGTTGAGGCTCCTTTCCCAGGC-3'; anti-sense 3'-GCAACTCCGAGGAAAGGGTCCG-5'); and (3) competition assays with a 200-fold excess of unlabeled NF- κ B, followed by incubation with labeled probes.

Semi-quantitative histological analysis

Histological evaluation was performed under light microscopy by two independent pathologists (L.Z. and R.S.) who were left unaware of the clinical and demographic characteristics of the patients. The agreed-upon score was adopted for the final data set. In cases of disagreement in the scoring, the process was repeated and the final score was

Fig. 1 Glomerular expression of activated NF- κ B in normal controls and class IV LN. A–C Normal controls. NF- κ B activation was barely detectable in normal glomeruli using Southwestern histochemistry (SWH) (A) and immunostaining of p65 (B) and p50 (C). SWH for NF- κ B (D), p65 (E) and p50 (F) in a glomerulus from a patient with class IV-S (A/C) LN. Activated NF- κ B is readily detected in glomerular endothelial cells (*open arrows*), mesangial cells (*open arrowheads*) and parietal epithelial cells (*small arrows*). G NF- κ B activation in inflammatory infiltrates lying freely in capillary lumina or Bowman's space (*small arrows*), and cellular crescents

(*large arrows*) in the SWH stained section from a patient with class IV-G (A) LN. Immunostaining of p65 (H) and p50 (I) in a glomerulus from a patient with class IV-G (A) LN. Podocytes displayed NF- κ B activation predominantly in the form of p65 (H, *closed arrowheads*); cells in cellular crescents demonstrated immunoreactivity with both p65 and p50 (*arrows*). SWH with mild PAS counterstaining (NBT/BCIP; blue nuclei), p65 and p50 [DAB; brown nuclei; with haematoxylin plus mild periodic acid-Schiff (PAS) counterstaining]. Original magnification: $\times 400$ (H, I); $\times 300$ (E–G); $\times 200$ (A–D)

Fig. 2 Glomerular NF- κ B activation in class V LN and non-proliferative glomerulopathy. (A–C) Glomeruli from a patient with class V LN. Double staining of NF- κ B (SWH) and TNF- α (A) showed that podocyte NF- κ B activation (arrowheads) co-localized with TNF- α immunostaining along glomerular capillary walls; a glomerulus from a patient with class V LN displayed predominant expression of p65 (B) in podocytes (arrowheads) in contrast to the lack of p50 (C) in podocytes. (D–F) Glomeruli from a patient with

IMN. (G–I) Glomeruli from a patient with MCD. NF- κ B activation was primarily observed in podocytes (arrowheads) in addition to endothelial cells in idiopathic membranous nephropathy (IMN) (D) and minimal change disease (MCD) (G). Podocytes demonstrated a predominant expression pattern of p65 (arrowheads), while both p65 and p50 were expressed in endothelial cells in IMN (p65, E; p50, F) and MCD (p65, H; p50, I). Original magnification: $\times 400$ (A–C, E, G–I); $\times 300$ (D, F)

^aISN/RPS classification of LN in 2003 [48]

^bRenal tissue from one patient was insufficient for staining

Fig. 3 Glomerular expression of TNF- α , IL-1 β , IL-6 and ICAM-1 in normal and diseased human kidneys. Normal human kidney demonstrated sparse expression of TNF- α (a), IL-1 β (b) and IL-6 (c), and constitutive expression of ICAM-1 along the inner wall of capillary loops (d). A–C Immunostaining of p65, TNF- α and IL-1 β in a glomerulus from a patient with class IV-G (A). TNF- α (B) and IL-1 β (C) were expressed in podocytes with activated p65 (A) (arrowheads); TNF- α expression was also observed in inflammatory leukocytes lying freely in capillary lumen (B, long arrow). D–G Expression of TNF- α and IL-1 β was predominantly localized to podocytes on the outer aspect of glomerular capillaries (arrows) in class V LN (D for TNF- α , E for IL-1 β) and MCD (F for TNF- α , G for IL-1 β). H–M Abnormal expression of IL-6 (H) and ICAM-1 (I) was mainly located in mesangium from the patients with class IV-G (A) and class IV-G (A/C), respectively; no such abnormality was observed in class V LN (J for IL-6, K for ICAM-1) and MCD (L for IL-6, M for ICAM-1). Original magnification: $\times 400$ (A–C, L, M); $\times 300$ (D, F, H–K); $\times 200$ (E); $\times 100$ (a–d)

determined by consensus of both observers. Only glomeruli that were well preserved for conventional morphology were evaluated thoroughly. Extracapillary immunopositive cells, such as those found in fibrous crescents, or glomeruli with global sclerosis, were excluded from the count. The glomerular structures and cell components were identified morphologically by examination of consecutive sections with PAS and PAAG-MT. Additionally, most sections were mildly counterstained with PAS reagents after SWH or immunohistochemistry to allow for the identification of resident glomerular cell types by their anatomic features. Only cells lying within the mesangium, along the inner walls of glomerular capillaries and Bowman's capsule, were

defined as mesangial, endothelial, and parietal epithelial cells (PEC), respectively. Cells along the outer aspect of glomerular capillary loops were defined as podocytes. Anatomically, cells lying freely either in capillary lumina or Bowman's space were considered as infiltrating leukocytes. The anatomic and morphologic features of inflammatory infiltrates were further confirmed by CD68 immunostaining of serial sections. For transcription factors, only cells stained with distinct blue nuclei (SWH) or brown nuclei (immunohistochemistry) stains were counted. Both the number of individual glomerular cells and the number of complete glomeruli were counted, respectively. The number of positively stained cells of each type was expressed as

Fig. 4 Quantitative analysis of glomerular expression of TNF- α , IL-1 β , IL-6 and ICAM-1 in diseased human kidneys. **A** Podocyte expression of TNF- α and IL-1 β . No statistical difference in podocyte expression of TNF- α and IL-1 β was observed between LN and non-proliferative glomerulopathy or between class IV and class V LN ($P>0.05$). **B** ICAM-1 expression in mesangium. Mesangial expression of IL-6 and ICAM-1 in LN was significantly higher than that in non-proliferative glomerulopathy ($P<0.05$); mesangial ICAM-1 expression in class IV LN significantly differed from that in class V LN ($P<0.05$). *No marker expression is detectable; the value of mesangial expression of ICAM-1 and IL-6 in normal control is zero and not shown in chart

the number of cells per glomerular cross-section (cells/GCS). For semi-quantitative analysis, glomerular endothelial and mesangial cells were counted together. In addition, a seven-point scoring system was employed for the evaluation of podocyte positive signals (NF- κ B, p65, p50, TNF- α and IL-1 β) in glomeruli that took both intensity and extent into account [34, 36]. Podocytes were primarily identified by architectural features revealed on light microscopy by mild PAS counterstaining. Synaptopodin staining of serial sections facilitated the evaluation of the extent of podocyte expression of various markers using SWH and immunohistochemistry. Briefly, the intensity was graded as 0 (no staining), 1+ (mild), 2+ (moderate), or 3+ (marked staining), while the extent of staining was graded as 1+ (1–25%), 2+ (26–50%), 3+ (51–75%), or 4+ (>75% of the glomerular tuft).

Statistical methods

Statistical analyses were performed using SigmaStat 3.1 programs (SPSS Inc.). The results were expressed as the mean \pm SD. Statistical significance was determined by one-way ANOVA, followed by Bonferroni's test for multiple comparisons among various groups. For non-parametric data, one-way ANOVA on ranks followed by Dunn's test was used for multiple comparisons test. Correlation was

determined with Spearman's correlation coefficients. P values less than 0.05 were considered to be significant.

Results

Patients

Of the 31 LN subjects, 90.3% were female, and the average age was 33.1 \pm 12.1 years (range 15–59) at the time of LN diagnosis. The degree of proteinuria at the time of diagnostic renal biopsy, as determined by 24-h urine collection, was documented in 96.8% of LN patients, 100% of IMN patients and 83.3% of MCD patients. Clinical criteria for the diagnosis of nephrotic syndrome were met in 16 patients with LN (45.2%), five with IMN (62.5%) and five patients with MCD (83.3%). Serum creatinine was elevated in ten LN subjects (32.3%); all of the non-lupus glomerulopathy subjects had normal serum creatinine levels at the time of diagnostic renal biopsy.

In situ glomerular activation of NF- κ B in normal and diseased kidneys

Activated NF- κ B and its subunit p65/p50 were barely detectable by SWH in glomeruli of normal kidneys

Fig. 5 Correlation analysis of the activity index with glomerular endothelial and mesangial NF- κ B activation (A), as well as mesangial expression of ICAM-1 (B) in LN patients. r , Spearman's correlation coefficient

(Fig. 1A–C). In contrast, activated NF- κ B was readily detected in all disease groups. Activated NF- κ B was extensively expressed in resident glomerular cells (endothelia, mesangial cells, podocytes and PECs) as well as infiltrating macrophages in class IV LN (Fig. 1D–I). Simultaneous expression of p65 and p50 was readily observed in endothelial, mesangial cells and cellular crescents in a glomerulus from a patient with class IV LN (Fig. 1E,F,H,I), while p65 was the predominant form of NF- κ B in podocytes in class IV LN (Fig. 1H,I). Inflammatory infiltrates lying freely in capillary lumina or Bowman's space were also observed in class IV LN (Fig. 1G). In class V LN and non-proliferative glomerulopathy, NF- κ B activation was primarily noted in podocytes in addition to endothelial cells (Fig. 2A,D,G). In class V LN and non-proliferative glomerulopathy, podocyte NF- κ B activation was predominantly in the form of p65 subunit (Fig. 2B,E,H), whereas p50 was mainly localized in endothelial cells if detectable (Fig. 2C,F,I). Semi-quantitative analysis showed that overwhelmingly high numbers of NF- κ B-positive endothelial and mesangial cells and PECs were found in the class IV group; the number of these cells in LN group exceeded that in the non-proliferative glomerulopathy groups (Table 2). No statistically significant difference in the degree of podocyte NF- κ B activation was detected between the LN and non-proliferative glomerulopathy comparison groups as a whole, nor between the IMN versus class V LN or class IV LN versus class V LN subgroups ($P > 0.05$) (Table 2).

Glomerular expression of NF- κ B-regulated pro-inflammatory mediators (TNF- α , IL-1 β , IL-6 and ICAM-1)

An upregulation of TNF- α and IL-1 β immunoreactivity was readily detected in glomeruli of inflammatory LN as compared to normal controls (Fig. 3a,b). Expression of TNF- α and IL-1 β was detected in podocytes in a glo-

Fig. 6 Clinicopathologic correlation analysis of the magnitude of proteinuria with podocyte staining scores for NF- κ B and p65 in both LN (A, B) and non-proliferative glomerulopathy (C, D). r , Spearman's correlation coefficient

merulus showing podocyte expression of p65, from a patient with class IV LN (Fig. 3A–C). Glomerular expression of TNF- α and IL-1 β was also observed in infiltrating leukocytes, and, to a lesser extent, in other glomerular resident cells in class IV LN (Fig. 3B,C). In contrast to class IV LN, expression of both cytokines was primarily restricted to podocytes in class V LN (Fig. 3D,E) and non-proliferative glomerulopathy (Fig. 3F,G). Overall, no statistically significant difference in podocyte expression of TNF- α and IL-1 β was found between LN and non-proliferative glomerulopathy (Fig. 4A).

Glomeruli of normal kidneys showed scant expression of IL-6 and constitutive ICAM-1 expression along the inner aspect of capillary loops (Fig. 3c,d). Expression of IL-6 and ICAM-1 in class V LN (Fig. 3J,K) and non-proliferative glomerulopathy (Fig. 3L,M) was indistinguishable from that observed in normal controls. Unlike TNF- α and IL-1 β , enhanced expression of ICAM-1 and IL-6 was primarily localized in proliferative mesangial areas in the LN group, most evident in class IV LN (Figs. 3H,I and 4B).

Detection of the macrophage marker CD68 in glomeruli

CD68-positive cells, predominantly localized in capillary lumina and Bowman's space, were dramatically increased

in number in glomeruli of class IV LN (Table 1), whereas fewer macrophages were detected in class V LN and macrophages were rarely seen in non-proliferative glomerulopathy (Table 1).

Clinicopathologic correlation analysis

In LN subjects, the number of endothelial and mesangial cells showing NF- κ B activation by SWH was positively and strongly correlated with the activity index (Table 3 and Fig. 5A), whereas no correlation was found between the podocyte expression scores for NF- κ B, p65 or p50 and the activity or chronicity indices (Table 3). The activity index was positively correlated with mesangial expression of ICAM-1 (Fig. 5B). In addition, the degree of glomerular macrophage infiltration was positively correlated with the number of endothelial and mesangial cells positive for NF- κ B and p50, as well as with mesangial expression of ICAM-1 (Spearman's correlation coefficient $r=0.49$, $P=0.02$; $r=0.50$, $P=0.02$; $r=0.53$, $P=0.03$). Notably, podocyte NF- κ B activation detected by SWH and podocyte p65 staining scores were positively correlated with the severity of proteinuria at the time of diagnostic renal biopsy in both the LN and non-proliferative disease groups (Table 3 and Fig. 6).

Discussion

NF- κ B activation of glomerular cells has been investigated in experimental as well as human glomerulonephritis. Endothelial and mesangial activation of NF- κ B has been previously reported in human IgA nephropathy with mesangial proliferation [2]. Numerous studies have shown that various experimental conditions modulating NF- κ B activation result in a parallel modulation of proinflammatory molecule production in mesangial cells [27] and endothelial cells [8, 51]. Additionally, NF- κ B activation has been reported in podocytes, parietal epithelial cells as well as crescents in experimental and human glomerulonephritis [2, 28, 29, 38]. NF- κ B has also been implicated in the activation of macrophages in glomerulonephritis [31]. In the present study, we demonstrate for the first time that NF- κ B is activated in glomerular resident cells and macrophages in human renal biopsies with LN.

In renal biopsies with LN (especially class IV LN), NF- κ B activation in glomerular endothelial and mesangial cells was more remarkable than non-proliferative glomerulopathy (IMN and MCD), and was correlated with the activity index and the degree of glomerular macrophage infiltration. These observations suggest that NF- κ B activation in multiple types of glomerular intrinsic cells may play a pathogenic role in glomerular inflammation and injury in LN. Furthermore, an upregulation of TNF- α and IL-1 β was readily detected in inflammatory leukocytes and resident cells. IL-6 and ICAM-1 were mainly localized to the mesangium in parallel with NF- κ B activation, in glomeruli of the class IV LN group. Our results are consistent with the findings of other groups [25, 41, 49].

The promoter regions of TNF- α , IL-1 β , ICAM-1 and IL-6 contain at least one NF- κ B consensus site that has been shown to be important for their transcription in monocytes and glomerular cells [6, 13, 43, 46]. Moreover, TNF- α itself can also stimulate NF- κ B activation and subsequently induce downstream inflammatory mediators such as IL-1 β , ICAM-1 and IL-6 in GN and rheumatoid arthritis [14, 43, 44]. Recent studies show that increased ICAM-1 expression by TNF- α activation of mesangial cells is one of the major pathways involved in monocyte adhesion to the mesangium [32], and that TNF- α , immunoglobulin aggregates and immune complex deposition increase NF- κ B activation in mesangial cells [12, 40]. In the present study, we found a correlation between mesangial expression of ICAM-1 and both the activity index and the level of glomerular macrophage infiltration in class IV LN, in which mesangial immune complex deposits are frequently seen. This finding further supports the hypothesis that NF- κ B activation of mesangial cells plays a proinflammatory role in glomerular injury by mediating their interactions with monocytes/macrophages through the induction of inflammatory mediators. Moreover, NF- κ B activation and cytokine expression were observed in macrophages in class IV LN. The macrophage is believed to play an important role in amplifying inflammation through interactions with other renal cells in LN [9]. The results imply that NF- κ B is a central regulator of a complex

interaction network between glomerular resident cells and macrophages, mediated by inflammatory molecules in LN.

Another important finding in the present study is the detection of podocyte NF- κ B overactivation, along with podocyte overexpression of the NF- κ B-regulated proinflammatory cytokines TNF- α and IL-1 β in subjects with LN. Notably, podocyte staining scores for NF- κ B, as well as p65, the predominate subunit of NF- κ B within podocytes, were positively correlated with the severity of proteinuria in LN. Similar findings were found in non-proliferative proteinuric glomerulopathy (IMN and MCD) that are characterized by podocyte injury. Our results suggest that NF- κ B activation may be a generalized cellular response of the podocyte and associated with the development of proteinuria, an index of the severity of podocyte injury [45] in human glomerular diseases. However, evidence suggests that different immunopathogenic mechanisms underlie these associations in different disease groups as discussed below.

In immune-mediated class V LN or IMN, the deposits are located in the subepithelium, directly adjacent to the foot processes of podocytes. In the animal model of passive Heymann nephritis which closely resembles human membranous nephropathy, typical subepithelial immune deposits may trigger complement activation and stimulate adjacent podocytes to release inflammatory mediators associated with the subsequent development of proteinuria [19]. In passive Heymann nephritis, NF- κ B activation and overexpression of downstream NF- κ B-regulated genes is observed predominantly in podocytes at an early stage; inhibition of this pathway was shown to reduce proteinuria [29]. These studies support a contributory role for NF- κ B activation as a downstream response to podocyte injury mediated by immune complex deposition in the pathogenesis of proteinuria as occurs in either idiopathic or secondary membranous nephropathy. By contrast, in class IV LN, immune deposits are largely located in the subendothelial or mesangial area, with little direct evidence that the podocyte is a primary target of the immune-mediated injury. Recent studies suggest that inflammatory cytokines such as TNF- α and/or IL-1 β may induce the upregulation of nephrin expression and reorganization of the actin cytoskeleton, which is suggested to contribute to the development of proteinuria [17, 21, 22]. In this context, our observation of podocyte NF- κ B activation likely results from glomerular inflammation in class IV LN. Additionally, podocyte NF- κ B activation and overexpression of cytokines may be related to abnormally high levels of intraglomerular protein trafficking. Recent studies suggest a causal role of enhanced intraglomerular passage of proteins in the triggering of podocyte gene activation and podocyte architectural alterations [1]. MCD is a reversible condition not typically associated with visible evidence of glomerular inflammation or deposition of immunoglobulin or complement by light microscopy. It remains uncertain whether podocyte NF- κ B activation is a causal mechanism of proteinuria in this disease. Putative circulating permeability factors may cause the loss of the glomerular permselectivity that leads to proteinuria in MCD [10]. Whether

podocyte NF- κ B activation is involved in circulating permeability factors-induced proteinuria in MCD remains unproven.

Although the level of podocyte expression of the cytokines TNF- α and IL-1 β in class IV LN did not differ from non-proliferative glomerulopathy, these cytokines produced by podocytes may play different roles under different disease conditions. In class IV LN, TNF- α and IL-1 β produced by podocytes may have local proinflammatory effects on other glomerular resident cells as described above. Baseline levels of glomerular expression of ICAM-1 and IL-6 observed in MCD excludes the proinflammatory role of TNF- α and IL-1 β by podocytes, although the latter may still play a non-inflammatory role in the pathogenesis of proteinuria, such as interruption of podocyte cell architecture (as suggested above) [17, 21, 22].

Recent studies suggest that different dimeric combinations formed by the NF- κ B/Rel family of transcription factors offer the potential for fine-tuning of gene expression [47]. In the present study, p65 was observed to be the predominant NF- κ B subunit in podocytes in all disease groups, while NF- κ B subunit p65 and p50 were equally distributed in other types of glomerular cells in LN. The differential expression of inflammatory mediators such as ICAM-1 and IL-6 was also cell type-specific, exhibiting overexpression in endothelial or mesangial cells, but not in podocytes. The variable distribution of p65 and p50 subunits among different glomerular cell types suggests that NF- κ B-responsive genes may be differentially regulated in a NF- κ B subunit-specific manner in human glomerulonephritis.

In conclusion, our study illustrates the potential role of transcription factor NF- κ B activation in glomerular injury in human LN and illustrates the possible role of molecular signaling in mediating glomerular injury in LN.

Acknowledgements We wish to acknowledge the support from National University of Singapore. This work was undertaken in the Special Histopathology laboratory in the Department of Pathology. We thank Dr. Koh Dow Rhoun for valuable advice and Dr. Thian Chai Lee (Johor Specialist Center, Malaysia) for his assistance in providing the clinical data on the biopsy cases included in the present study. Right ventricular expression of extracellular matrix proteins, matrix-metalloproteinases, and their inhibitors over a period of 3 years after heart transplantation

Received: 6 April 2005 / Accepted: 15 July 2005 / Published online: 14 September 2005
© Springer-Verlag 2005

Abstract Fibrillar collagens I and III, nonfibrillar collagen IV, and the glycoproteins fibronectin and laminin, are elements of the myocardial extracellular matrix (ECM). Alterations in the normal concentrations and ratios of these elements may reflect remodeling in response to physiologic stress. In the case of patients' post-heart transplantation (HTx), specific patterns of alteration may herald myocardial dysfunction. Right ventricular biopsies were taken from the same 28 HTx patients before implantation and 1 week, 2 weeks, and 1, 2, and 3 years after HTx. The above-noted five ECM proteins, six matrix metalloproteinases (MMPs) and two of their tissue inhibitors (TIMPs) were detected by immunohistochemistry and scored as cells per square millimeter or semiquantitatively. The total connective tissue fibers were detected by connective tissue stain and morphometry. Variations in these ECM components were followed in the same patient cohort over 3 years. In summary, during the first 2 weeks after HTx, a predominant increase in connective tissue occurred. Increases in

MMP-8 and MMP-9 were found. By 3 years after transplantation, there was a decrease of connective tissue fibers and a significant reduction of all ECM components and an increase in MMPs and TIMPs. These findings may reflect a pattern of remodeling specific to the transplanted heart.

Introduction

The myocardial extracellular matrix (ECM), which plays a significant role in maintaining the efficiency of cardiac function, contains numerous elements, including collagens I, III, and IV, and laminin and fibronectin. The ECM is not a static structure. It is a dynamic entity [4, 15, 34]. The myocardial fibrillar collagens such as Collagens I and III ensure structural integrity of the adjoining myocytes, provide the means by which myocyte shortening is translated into overall left ventricular pump function, and are essential for maintaining alignment of the myofibrils within the myocyte through a collagen–integrin–cytoskeletal myofibril relation [6, 17, 30, 34].

The ECM forms a continuum between different cell types within the myocardium and provides a structural supporting network to maintain myocardial geometry during the cardiac cycle [34]. Disruption or discontinuities within the fibrillar ECM network will result in a loss of normal structural support and continuity, resulting in myocyte fascicles being subjected to abnormal stress and strain patterns during the cardiac cycle, which, in turn, will result in changes in myocardial geometry and function. The identification and understanding of the enzyme systems responsible for ECM degradation within the myocardium have particular relevance in appreciating the process of rejection of transplanted hearts [7, 23, 28, 36].

The matrix metalloproteinases (MMPs) are a family of enzymes that degrade a wide variety of ECM components.

Different species of MMPs have been categorized on the basis of substrate specificity, and a body of evidence indicates that the MMPs play an important role in the tissue remodeling process [11, 46].

Interstitial collagenase, also known as MMP-1, degrades collagens I and III. Collagenase 3, which is also called MMP-13, also degrades collagens I and III. Gelatinase B, also known as MMP-9, degrades collagens I and IV. Stromelysin 1, also called MMP-3, degrades fibronectin, laminin, and collagens III and IV. It is also involved in MMP activation. The membrane-type-1-MMP (MT-MMP1), also known as MMP-14, degrades collagens I and III and fibronectin and laminin. It also activates pro-MMP-13. The extracellular activity of these enzymes is controlled at the level of gene expression, proenzyme activation, and interaction with specific tissue inhibitors of MMPs (TIMP-1 and TIMP-2) [34]. MMP-8, which is also called neutrophil collagenase, or collagenase 2, degrades collagen I more than collagen III. It does not degrade collagen IV [25].

It has been demonstrated that TIMP-2 forms a complex with MT-MMPs, and that this complex enhances the activation of pro-MMP-2 [18]. It is assumed that the TIMPs bind directly to MMPs in a 1:1 fashion to inhibit them. It has been proposed that this ratio may change in hearts undergoing continued remodeling as a response to stress, suggesting a dysregulation of the normal compensatory remodeling response may lead to prolonged detrimental remodeling and subsequent myocardial dysfunction [20, 25, 34, 36]. For example, MMPs that are expressed at very low levels in normal myocardium such as MMP-13 and MT-MMP1 are substantially up-regulated in congestive heart failure [19]. Previous studies on hearts taken at the time of human heart transplantation (HTx) and at autopsy have provided evidence of collagenolytic activity in cardiac tissue that is consistent with MMP activity [14].

The purpose of the present study is to delineate the changes in the above-noted ECM protein components in the myocardium of transplanted hearts in a cohort of patients during the first 3 years following cardiac transplantation. For the purpose of helping to link the changes noted to the underlying physiologic process, we also performed an analysis of the changes in amounts of various cell types over this time by detecting and quantifying several cluster differentiation (CD) cell markers, namely, CD3, 4, 8, 15, 20, 57, 68, and 69.

Cluster differentiation 3 is a T cell marker which is important for early T cell differentiation. CD4 is a "T helper" cell marker. CD8 is a "killer T cell" marker. CD15 is present on myelomonocytes, monocytes, macrophages, and activated B and T cells. CD20 is present on B cells and is involved in their activation. CD57 is present on "natural killer" (NK) cells. CD68 is present on macrophages. CD69 is present on T cells, NK cells, monocytes, and platelets, and especially on activated T cells, B cells, and NK cells involved in inflammation.

Materials and methods

Patients

Right ventricular biopsies were taken from a group of 28 patients before implantation and 1 week, 2 weeks, 1, 2, and 3 years after HTx at the University of Heidelberg Medical Center (Departments of Cardiac Surgery, Internal Medicine, and Pediatric Cardiology), Heidelberg, Germany. They were embedded in Tissue Tek (Sakura, Netherlands, Batch #4583000) and stored at -72°C . Cryosections ($4\ \mu\text{m}$) were cut at -20°C with Frigocut (Reichert-Jung Model 2700, Nussloch, Germany) and afterwards fixed in acetone.

The recipients' mean age was 45.3 years, with a standard deviation (SD) of 16.9, ranging from 9 to 63 years; 26 were male, and 3 were female. Sixteen patients had suffered from dilated cardiomyopathy, ten from ischemic cardiomyopathy, one from transposition of the great vessels, one from tetralogy of Fallot, and one from double-outlet right ventricle. The donors' mean age was 31.5 years, with an SD of 14.5, ranging from 10 to 55 years, with 20 being male and 9 being female; the cause of death was head trauma for 15, parenchymal intracranial bleeding for six, basilar arterial thrombosis for two, subarachnoid hemorrhage for one, ischemic stroke for one, gunshot wound to the head for one, status asthmaticus for one, thalamic tumor for one, and carbon monoxide poisoning for one. The intensive care of the donors averaged 3.5 days, with an SD of 3.5, ranging from 1 to 19 days.

All hearts were perfused with 2–4 l of histidine–tryptophan–ketoglutarate (HTK) solution (Custodiol, Dr. F. Koehler Chemie GmbH, Alsbach, Germany). The mean ischemic time period was 182 min, with an SD of 53.

Immunohistochemistry

The frozen sections were washed twice in phosphate-buffered saline (PBS) and then processed for 25 min with a mixture of CAS-Block, albumin, and γ -venin. The sections were then incubated for 1 h with a specific antibody. The following antibodies were used to show the ECM components, the MMPs, and their inhibitors:

- MMP-1 (IHC) (Cat. # 551000, BD Biosciences BD PharMingen, San Diego, CA, USA), monoclonal mouse, 1:100;
- MMP-8 (Ab-1) (Cat. # IM38L, Oncogene Research Products, Boston, MA, USA), monoclonal mouse, 1:20;
- MMP-13 (Ab-5) (Cat. # IM79, Oncogene), monoclonal mouse, 1:20;
- MMP-3 (Ab-5) (Cat. # RB-1589-PO, NeoMarker, Fremont, CA, USA), monoclonal mouse, 1:50;
- MMP-9 (Ab-7) (Cat. # IM61, Oncogene), monoclonal mouse, 1:100;

MMP-14 (Ab-1) (Cat. # RB-1544-PO, NeoMarker), monoclonal mouse, 1:10;
 TIMP-1 (Ab-4) (Cat. # IM63 Oncogene), monoclonal mouse, 1:50;
 TIMP-2 (Ab-4) (Cat. # IM82, Oncogene), monoclonal mouse, 1:100;
 Collagen Type I (Cat. # 9 2150-0020, BioTrend, Köln, Germany), polyclonal rabbit, 1:100;
 Collagen Type III (Ab 167M) (Cat. # MU 167-UC, BioGenex, San Ramon, CA, USA), monoclonal mouse, 1:400;
 Collagen Type IV (Ab 379M) (Cat. # AM MU379-UC, BioGenex), monoclonal mouse, 1:100;

Fibronectin (AO 245) (Code # AO 245, DAKO, Denmark), polyclonal rabbit, 1:800;
 Laminin (Cat. # PU078-UP, BioGenex), polyclonal rabbit, 1:50;
 CD3 (Cat. # MCA1477, Serotec, Kidlington, England), monoclonal rat, 1:100;
 CD4 (Cat. # M0716, DAKO), monoclonal mouse, 1:25;
 CD8 (Cat. # M7103, DAKO), monoclonal mouse, 1:100;
 CD15 (Cat. # M0733, DAKO), monoclonal mouse, 1:50;
 CD20 (Cat. # M0755, DAKO), monoclonal mouse, 1:50;

CD57 (Cat. # 18-0167, Zymed Laboratories Inc, USA), monoclonal mouse, 1:100;
 CD68 (Cat. # M0876, DAKO), monoclonal mouse, 1:100; and
 CD69 (Cat. # sc-18880, Santa Cruz Biotechnology, USA), monoclonal mouse, 1:150.

All antibodies were diluted with common antibody diluent from BioGenex. For rabbit antibodies, as a negative control, rabbit immunoglobulin G (IgG) from DAKO (Code # X0936) was used. As a negative control for mouse, mouse Igs from DAKO (Code # Z0259) were used.

The sections were then washed twice in PBS. Afterwards, the second block (antibody diluent and goat serum) was applied and stayed on the sections for 20 min. The sections were incubated for 30 min with the second antibody.

For rabbit antibodies, IgG biotin–antirabbit (Zymed, 1:400) was used. For mouse antibodies, a goat–antimouse super-sensitive detection kit from BioGenex was used. Thereafter, they were washed twice again in PBS. Then, they were incubated with streptavidin–alkaline–phosphatase from the supersensitive detection kit (BioGenex). Again, they were washed twice in PBS, and then they were dyed with Fast Red, and the contrast staining was done by using Hemalaun. The connective tissue staining was done using Elastica van Gieson (EvG).

The tissue content of collagens I, III, and IV, laminin, and fibronectin were then semiquantitatively scored from 0 (without apparent staining) to 3 (demonstrating vigorous staining) [12]. This was performed by two independent investigators through 10, 20, and 40× objective lens on a

Fig. 2 Volume density of connective tissue fibers and the perimysial amount of collagen I, III, IV, laminin, and fibronectin. Mean±SD, * indicates $p < 0.05$ (significant differences compared with values before implantation)

Zeiss Axioskope (Carl Zeiss AG, Jena, Germany) (Fig. 1). The investigators were blinded to patient identity and time of sample. Each slide was analyzed a total of three times, at least once by each investigator, and the results were averaged.

The cells with positive reaction (MMPs, TIMPs, and CD markers) were counted under the Zeiss microscope with 10× enlargement. The area of the sections, selected randomly and in an attempt to include reasonable myocardium and exclude artifact and large blood vessels, were measured with Optimas 5.2 (MediaCybernetics, Leiden, Netherlands), and the Hi Resolution CCD-IRIS camera (Sony, Tokyo, Japan) [15].

Morphometry

The morphometric analysis of EvG-stained sections was done with “random system sampling” on a grid through a light microscope using the point counting method [15, 43, 44]. This again involved random selection of microscopic fields which contain a high proportion of myocardium and no major vessels or color artifacts.

Statistics

The Wilcoxon signed rank test was applied for the MMPs, TIMPs, CDs, and volume density of connective tissue fibers. The sign test was used for collagen I, III, and IV, laminin, and fibronectin. *p* values of $p \leq 0.05$ were regarded as statistically significant.

Results

Connective tissue quality and morphometry

Collagen I is primarily expressed in the perimysium, as can be seen in Fig. 1B. Collagen III is expressed in the perimysium, and also, to some extent, the endomysium, as can be seen in Fig. 1C. The positively stained fibers in the perimysium and endomysium were counted. Collagen IV frames the myocytes, as can be seen in Fig. 1D.

The volume density of connective tissue fibers increased significantly from before implantation to the first and second week after transplantation. It decreased significantly from before implantation to 1, 2, and 3 years after transplantation (Fig. 2).

Matrix protein, MMP and TIMP, and CD immunohistochemistry

The results of the immunohistochemistry of the perimysial amounts of ECM components are indicated as scored data in Figs. 2 and 3, with the data on the CDs shown in Fig. 4.

The expression of collagen I decreased significantly in the first week after transplantation, as well as at 1, 2, and 3

years. The perimysial expression of Collagen III decreased significantly from before implantation at 1, 2, and 3 years.

The perimysial expression of Collagen IV decreased significantly from before implantation at 1, 2, and 3 years after HTx. The perimysial expression of laminin decreased significantly from before implantation at the second week, second year, and third year. The perimysial expression of fibronectin decreased significantly from before implantation at the second and third year after HTx.

The results of immunohistochemistry of the MMPs and TIMPs are shown in Fig. 3. The quantity of MMP-1-positive cells per square millimeter increased significantly from before implantation to the first, second, and third year after transplantation. MMP-8-positive cells increased significantly from before implantation to the first week, second week, and second year after transplantation. MMP-13-positive cells showed a significant decrease from before implantation to the second week, and then a significant increase to the first year, compared with preimplantation. The distribution of MMP-3 showed no significant changes from before implantation to the first 2 weeks or the first 3 years following transplantation. MMP-9 distribution increased significantly from before implantation to the first week, second week, and first year following HTx. MMP-14 (MT-MMP1) showed a significant increase in positive cells from before implantation to the third year.

The distribution of TIMP-1 showed a significant increase from before implantation to 2 and 3 years following HTx. TIMP-2 showed no significant changes from before implantation to the first 2 weeks or the first 3 years after transplantation.

Cluster differentiation 3+ cells, CD57+ cells, and CD69+ cells demonstrated no significant changes in number throughout the observation period. CD4+ cells registered a significant decrease in number from before implantation to the first week after transplantation. CD8+ cells decreased in number from before implantation to the second year following transplantation. CD15+ cells increased significantly in number at the first week, second week, and first year following transplantation when compared to preimplantation. CD20+ cells showed an increase in number at the second week following implantation. CD68+ cells showed significantly increased numbers at the first week, second week, and third year following implantation.

Rejection

Data on rejection were collected on all patients and graded according to the International Society for Heart and Lung Transplantation working formulation for HTx: grade 0, no rejection or equivocal rejection; grade 1, mild rejection; grade 2, focal moderate rejection; grade 3, multifocal or diffuse moderate rejection; and grade 4, severe rejection. In our patients, 196 (40.75%) achieved grade 0 rejection, 169 (35.14%) scored grade 1 rejection, 82 (17.04%) scored grade 2 rejection, 34 (7.07%) had grade 3 rejection, and 0 (0%) scored grade 4 rejection.

Discussion

This study was designed to explore changes of the ECM components and the MMPs and TIMPs involved in the process of remodeling over a time period of 3 years following HTx, using the sequential biopsies of the same cohort of 28 patients over this time period. Only a few groups have looked at the ECM components and the enzymes involved in the structuring of the ECM after human HTx [7, 23]. To date, we are aware of no studies which have focused on a single cohort over such an extended time period.

The current study indicates increased expression in protein level of several MMPs, including MMP-1 and MMP-9, following HTx. Several studies have investigated changes at the level of ECM components, MMPs, and TIMPs occurring in dilated cardiomyopathy and congestive heart failure [10, 11, 20]. Differences in expression of these components are reported in different disease states [10, 11]. Increased MMP activity has been found within the left ventricle following the development of end-stage chronic heart failure [10, 11]. MMP-1 expression increased in ischemic and dilated cardiomyopathy but decreased in hypertrophic cardiomyopathy. MMP-9 expression increased in ischemic cardiomyopathy but decreased in dilated or hypertrophied cardiomyopathy [42].

We found a significant increase in MMP-13 from before implantation to 2 weeks and 1 year after human HTx. MMP-8 increased significantly in the first 2 weeks, whereas MT-MMP1 increased significantly from before implantation to 3 years after (Fig. 3). These findings are similar to those of a study looking at rodent hearts during induced ischemia, where an increase in MMP-13 predominated in the early postischemic period, while MMP-8 and MMP-14 (MT-MMP1) increased during late remodeling [27].

The observation that all MMP and TIMP species are not uniformly increased in patients with different forms of heart failure suggests that specific patterns of MMPs and TIMPs are expressed in the failing myocardium, depending on the type of stress undergone by the myocardium. The particular pattern observed in the current study may reflect the specific stresses which affect the transplanted heart and induce remodeling therein. We found increases in MMP-1, MMP-8, MMP-9, and MMP-13, a pattern similar to that seen previously specifically related to ischemia [27, 42].

Our study finds significant decreases in the perimysial amounts of laminin and fibronectin at 2 and 3 years posttransplantation [32]. Acute heart rejection has been associated with an early increase in the intermyocyte and endothelial deposition of laminin and fibronectin at the graft site, with their peak at 6 h after transplantation [7, 23].

Fibronectin has been thought of as a signal for graft-infiltrating cells and may play a key role in rejection [7, 23]. Macrophages have been found to likely be the primary source of fibronectin found in allograft rejection, although it has also been noted that a significant portion of fibronectin found in allografts comes from extravasation of plasma fibronectin [8, 9]. Of the cell markers we analyzed, it is known that CD68 and CD69, as well as CD4, are found

on macrophages. We found a significant decrease in the number of CD68+ cells at 3 years posttransplantation and a significant decrease in fibronectin expression at 3 years, which may be related. While statistical significance was not reached, one can appreciate a trend toward similarity in the patterns seen on the respective charts (Figs. 3 and 4) of fibronectin, CD68, and CD69.

None of our patients experienced high-grade rejection. The expression of CD69 in peripheral blood lymphocytes has been directly correlated with the presence of rejection of HTx grafts [31]. In our study, CD69+ cell numbers did not change significantly throughout the study period.

At this point, it might also be helpful to briefly discuss the grade of rejection found on our patients and its relation to our data. Of all patient diagnostic samples, approximately 41% showed grade 0 rejection, 35% grade 1, 17% grade 2, 7% grade 3, and 0% grade 4 rejection. As a rejection grade of less than 3 does not normally prompt clinical intervention, our data are likely more representative of "healthier" postcardiac transplant patients.

Cluster differentiation 15+ cells showed significant increase in the first week following transplantation, subsequently decreasing in number to insignificance by the second year. There is little current literature regarding the role of CD15+ cells such as myelomonocytes in posttransplantation hearts. While none of our patients exhibited high-grade rejection, some did show evidence of lower-grade rejection, and the majority of these occurred within the first year. This might suggest a role of myelomonocytes in early low-grade rejection. Further investigation is warranted.

While significance was reached in decreases of numbers of CD4+ and CD8+ cells at 1 week and 2 years, respectively, their total numbers are low, and it is difficult to draw conclusions with respect to these changes.

These ECM components should be looked at as important and active participants in host immune responses leading to graft rejection. The majority of rejection episodes occur within the first 6 months after HTx [45]. Interstitial fibrosis has been found to rise within the first 2 months after heart transplant, with little additional change over the subsequent 5–6 years [2]. Our patients' follow-up over this time period of 3 years showed no severe complications, and this might be a good indicator for their favorable recovery.

All our patients have been transplanted very recently, and they all received angiotensin-converting enzyme (ACE) inhibitors, which may forestall remodeling and reduce fibrosis in the infarcted ventricle [22, 47]. This may have affected the patterns of ECM component expression found here, which may differ from the natural history of posttransplant myocardium.

Tissue inhibitors of MPs inhibit MMPs in a 1:1 stoichiometric manner [34], but this ratio has been found to be altered in situations of pathologic remodeling. We found that over the time period of 3 years following transplantation, the expression of the majority of MMPs and TIMP-1 increased, but the expression of TIMP-2 showed no significant changes. Other studies have discovered similar

trends in different pathological situations. Several studies found that MMP to TIMP ratios significantly increased in abdominal aortic aneurysms, Sjogren's syndrome, and chronic lung disease [3, 13, 37, 38]. One study found an up-regulation in MMP-9 and a down-regulation in TIMP-1 and TIMP-3, but no change in TIMP-2, in failing human hearts [20]. They noted that TIMP-1 responded to alterations in the ECM, whereas TIMP-2 provides a stable level of anti-MMP activity in tissue. Cardiac tissue of patients with ischemic cardiomyopathy similarly displayed no change in TIMP-2 [39, 40].

We found no significant change for TIMP-2, and only a significant increase from before implantation to 3 years for MMP-14 (Fig. 3). It is being said that TIMP-1 potentially inhibits the activity of most MMPs, with the exception of MMP-14 and MMP-2. TIMP-2 is thought to be a potential inhibitor of all MMPs except MMP-9 [34]. It has been discovered that pro-MMP-2 was gradually enhanced in mammalian fibrosarcoma cells by adding a small amount of exogenous TIMP-2 in a dose-dependent manner, but it was inhibited when an increased amount of TIMP-2 was added [25, 35]. MT-MMP has been shown to activate MMP-2/TIMP-2 complexes [35].

In our study, we found an increase in MMP-9 expression from before implantation to the first 2 weeks and the first year. Collagen IV decreased significantly in the first year (Fig. 2). Similarly, MMP-9, also called type-IV collagenase, showed a reverse correlation between its expression and the expression of type-IV collagen in gastric carcinomas [16]. There has been a reported robust increase in MMP zymographic activity in the failing human myocardium that was accompanied by a reduction in fibrillar collagen cross-link formation [14, 34]. Our study discovered similar trends, although immunohistochemistry was used rather than zymography. A similar increase in MMP has been found in early postinfarcted hearts, the early up-regulation of MMP activity after infarction thought to be strongly suggestive of involvement of MMPs in the repair process of the heart [34]. MMP-1, MMP-9, and to a lesser extent, MMP-3, may play an important role in the remodeling of the basement membrane and the ECM [34]. In nonhealing chronic and healing acute wound tissues, there have been reports of similar MMP-9 (gelatinase B) activity, contradicting former hypotheses that chronic ulcers are caused by excessive MMP-9 activity [24].

We found no significant change in the expression of MMP-3 over a 3-year time period (Fig. 3). MMP-3 has been found to be an activator of several precursors of MMPs such as pro-MMP-1, pro-MMP-3, and pro-MMP-9 [10, 26, 41]. MMPs are considered to be involved in the degradation of matrix components but also modulate collagen synthesis. This might be why some groups report an abundance in MMPs accompanied with increased fibrosis, such as those seen in failing hearts, and decreased MMP activity leading to reduced fibrosis [17, 21, 27]. Others have found that an increase in MMP activity and expression were concurrent with a reduction in total myocardial collagen content [14, 29, 33].

Finally, in our study, the volume density of connective tissue fibers increased over 2 weeks following transplantation and then decreased significantly at 1, 2, and 3 years after transplantation (Fig. 2). This initial increase has been marveled at before, as well as in other disease states such as renal failure and conduction system changes following HTx, and in the case of HTx, has been thought to be due to perioperative ischemia and reperfusion injury [1, 5, 19, 28]. Collagens I, III, and IV, and laminin and fibronectin, decreased significantly from before implantation to the second and third year (Fig. 2). MMP-1, MMP-8, MMP-13, MMP-9, MMP-14 (MT-MMP1), and TIMP-1 increased in the years following HTx, while MMP-3 and TIMP-2 showed no significant changes. Interestingly, in our data, while the total volume density of connective tissue fibers approximately doubles at 2 weeks when compared to preimplantation, the sum of the changes seen in individual components during this time period does not seem grossly proportional. This would suggest that other ECM components which we do not measure are contributing to the total connective tissue volume density increase. Further investigation with respect to the components involved during this time period may be warranted.

Our findings may reflect a pattern of remodeling similar to that observed in other scenarios after cardiac stress. It is thought that in the setting of congestive heart failure, initial remodeling following such stress probably represents a beneficial compensatory response, but that prolonged continued remodeling may be detrimental [7, 19, 22, 28, 34]. The decrease in structural ECM constituents observed here may reflect a decrease in the remodeling process over time, perhaps partly due to ACE inhibitor therapy. Further investigation into the factors contributing to this process of reverse remodeling may prove beneficial in increasing the survival of these posttransplant patients and in improving the outcome in patients with heart failure.

End note

Some limitations in this study should be recognized. Due to the large number of variables considered, the statistical power is decreased. This is, to our knowledge, the first study to follow a single cohort of posttransplantation patients for a long time period, and the goal of the study was to help delineate post-HTx ECM component changes over this time period. Further similar studies, perhaps utilizing zymography, mRNA quantification, etc., should be performed to help define more clearly the patterns of ECM component expression in such patients. Another limitation, difficult to eliminate in such studies, is the presence of medications such as ACE inhibitors, which are known to affect the remodeling process.

It should also be noted that the goal of this study was to provide general data regarding the changes in these ECM components over a long time period in postcardiac-transplantation patients and not necessarily to correlate these changes with the pathologic states (i.e., degree of rejection

or pretransplantation pathology) of the patients' hearts at the times of data collection. The comparisons provided in the [Discussion](#) with different disease states are meant as stimuli for further investigation rather than to suggest actual correlation with respect to our data.

Elastofibroma: clonal fibrous proliferation with predominant CD34-positive cells

Received: 20 June 2005 / Accepted: 22 July 2005 / Published online: 17 August 2005
© Springer-Verlag 2005

Abstract Elastofibroma is a rare fibrous lesion that most commonly occurs in periscapular soft tissues and is characterized by accumulated abnormal elastic fibers. Although the lesion is generally regarded as a reactive process, an unusual fibroblastic pseudotumor, or as a fibroelastic tumor-like lesion, its etiology remains largely unknown. Recent cytogenetic demonstrations of chromosomal instability and some recurrent or clonal chromosomal changes have raised the possibility that the lesion represents a neoplastic process. We analyzed 14 cases of elastofibroma to further explore, morphologically and genetically, the characteristics of its cellular composition. The interspersed spindle or stellate cells showed a fibroblast-like appearance and were almost consistently positive for vimentin and frequently positive for CD34 and lysozyme immunohistochemically. No spindle cells of myofibroblastic phenotype were recognized. To assess the clonality of the lesions in female patients, the X-linked polymorphic human androgen receptor gene assay was performed using formalin-fixed, paraffin-embedded tissues. A nonrandom inactivation of the androgen receptor gene was detected in two informative cases. Thus, these findings suggest that CD34-positive mesenchymal cells are an integral component of elastofibroma, which represents a clonal fibrous proliferation.

Keywords Soft tissue · Immunohistochemistry · Electron microscopy · Molecular genetics

Introduction

Elastofibroma is a benign fibrous proliferation that is characterized by its almost exclusive occurrence in the periscapular region of middle-aged or older individuals and, morphologically, by an admixture of excessive collagen and abnormal elastic fibers displaying a beaded or globular appearance. Although the lesion is generally assumed to be a fibrous pseudotumor or a reactive or degenerative process possibly due to repeated minor trauma or physical irritation [20], the true etiology or pathogenetic mechanism of elastofibroma still remains unknown. Interestingly, a genetic susceptibility to this lesion has been suggested by the facts that approximately one third of patients with the lesions in Okinawa had a family history of elastofibroma and that four members of a family had been recorded to have bilateral subscapular elastofibromas [10, 14].

Recently, Vanni et al. [19] reported the cytogenetic findings of three elastofibromas, in which they described chromosome instability as shown by various nonclonal structural changes frequently involving the short arm of chromosome 1. Subsequently, two other groups independently described clonal chromosomal aberrations, in addition to chromosome instability, and suggested a possible neoplastic origin for elastofibroma [2, 8]. In contrast to its peculiar extracellular matrix, the cellular composition of the lesion has, however, attracted little attention and has not been fully characterized. The interspersed spindle cells have been considered to be fibroblastic or myofibroblastic based largely on electron microscopic features [7, 13, 20].

To address these issues, we investigated the cellular composition of elastofibroma using a wide array of antibodies and assessed its clonality by analyzing X-chromosome inactivation as indicated by the methylation status of the X-chromosome-linked human androgen receptor gene.

Materials and methods

Fourteen cases of elastofibroma dorsi were selected from the files of the Department of Pathology and Oncology,

School of Medicine, University of Occupational and Environmental Health (Kitakyushu, Japan). The patients were seven women and seven men, with ages ranging from 45 to 79 years (mean 62.9 years). The lesions ranged in size from 3 to 11 cm (mean 6 cm). Periscapular soft tissues were obtained from four age-matched autopsy cases as controls.

Tissues were fixed in 10% formalin and embedded in paraffin. Deparaffinized 4- μ m-thick sections of tissues were used for histological and immunohistochemical evaluations. In addition to hematoxylin–eosin and elastic van Gieson stains, immunohistochemical staining was performed using the following primary antibodies, with or without an appropriate antigen retrieval, and was accomplished with a labeled polymeric secondary antibody (the EnVision system; DAKO Cytomation, Kyoto, Japan), anti-vimentin (V9, 1:30; DAKO Cytomation), anti-CD34 (QBEnd-10, 1:100; Immunotech, Marseilles, France), anti-CD1a (O10, prediluted; Immunotech), anti- α -smooth muscle actin (1A4, 1:150; DAKO Cytomation), anti-muscle-specific actin (HHF35, 1:50; Enzo Diagnostics, New York, NY, USA), anti-desmin (D33, 1:100; DAKO Cytomation), anti-calponin (CALP, 1:50; DAKO Cytomation), anti-factor XIIIa (polyclonal, 1:500; Calbiochem, San Diego, CA, USA), anti-CD68 (KP-1, 1:100; DAKO Cytomation), anti-CD10 (56C6, 1:10; Novocastra, Newcastle upon Tyne, UK), anti-CD45RO (UCHL-1, 1:200;

DAKO Cytomation), anti-S-100 protein (polyclonal, 1:500; DAKO Cytomation), anti-tropoelastin (polyclonal, 1:100; Elastin Product, Owensville, MO, USA), and anti-lysozyme (polyclonal, 1:500; DAKO Cytomation). In two cases, small pieces of the tissues were fixed in 4% formaldehyde and 1% glutaraldehyde, postfixed in 2% osmium tetroxide, and processed for transmission electron microscopy.

Genomic deoxyribonucleic acid (DNA) was extracted from the formalin-fixed, paraffin-embedded tissues of seven female patients and two female controls (one periscapular soft tissue and one myxoid liposarcoma) after overnight protein digestion by proteinase K (200 μ g/ml) in a lysis buffer [20 mmol/l Tris–HCl, pH 8.0, 20 mmol/l ethylenediaminetetraacetic acid (EDTA), and 2% sodium dodecyl sulfate] at 55°C. The quality of the extracted DNA was assessed by polymerase chain reaction (PCR) using two sets of primers flanking 249- and 312-bp sequences of the β -actin gene. The primer sequences were as follows: forward (consensus) primer gtaaagcggccttgagtg and reverse primers ccagaggcgtacaggatag and ctctagatgggca cagtg. The cycling conditions were as follows: holding at 95°C for 9 min; 40 cycles of 95°C for 20 s, 57°C for 20 s, 72°C for 30 s; and holding at 72°C for 10 min. The crude DNA extract that was positive for β -actin gene in both PCRs was purified twice by extraction with phenol–chloroform–isoamyl alcohol (25:24:1, pH 6.7) and by eth-

anol precipitation. The precipitated DNA was recovered with TE buffer (10 mmol/l Tris-HCl and 1 mmol/l EDTA, pH 8.0) and further purified using a QIAquick spin column (Qiagen, Tokyo, Japan). Between 100 and 250 ng of DNA was incubated with 50 U of *HhaI* (Toyobo, Osaka, Japan), which cleaves the nonmethylated GCGC restriction site, overnight at 37°C. One microliter of DNA solution, with or without restriction enzyme digestion, was used as a template for PCR in the human androgen receptor gene assay (HUMARA). The primer sequences and cycling conditions of the PCR were described previously [3]. PCR products were size-fractionated by electrophoresis on polyacrylamide gels and visualized by silver staining. Images of the electrophoresis were scanned, and allele intensities were measured by densitometry.

Results

The lesions contained sparsely distributed spindle or stellate cells embedded in an abundant fibrocollagenous matrix with many thick, globular, or beaded elastic fibers, which were highlighted with elastica van Gieson staining and immunohistochemistry for tropoelastin (Fig. 1a,b). The abnormal elastic fibers were absent in periscapular soft tissues of controls. The spindle or stellate cells in elastofibroma were invariably positive for vimentin immunohistochemically (Fig. 1c). Besides, a large number (>50%) of them expressed CD34 in all the cases examined (Fig. 1d). The CD34-positive cells often had elongated or slender cytoplasms and were unevenly but randomly distributed throughout the lesion. Many lysozyme-positive spindle or stellate cells were also identified in all but two cases (Fig. 1e), in which the antigen was expressed in only less than 1% of the cells. A minor fraction (less than 5%) of the cells was positive for CD68 and/or factor XIIIa and showed relatively small, rounded, or stellate morphology, suggesting histiocytic cells. The other markers, including actin, calponin, and desmin, were consistently negative in elastofibroma cells (Fig. 1f). Vimentin- or CD34-positive spindle cells were also identified in periscapular fibroadipose tissues of controls, although most of them lacked the expression of lysozyme.

Ultrastructurally, the spindle or stellate cells scattered among the collagen bundles and large masses of dense granular or filamentous materials corresponding to abnormal elastic fibers often possessed irregularly indented nuclei, elongated cytoplasmic processes, well-developed or variably dilated rough endoplasmic reticula, rounded or fusiform mitochondria, and numerous intracytoplasmic filaments of the predominant intermediate type. The elongated cytoplasmic processes frequently encircled the extracellular granular material or were aligned parallel to the collagen bundles (Fig. 2a). Collagen fibrils occasionally sprouted from the cytoplasm or cell surfaces, reminiscent of collagen secretion (Fig. 2b). Many pinocytotic vesicles or lysosomes were seen in some of the spindle or stellate cells. Myofibroblastic cells with intracytoplasmic parallel filaments showing focal densities or subplasmalemmal attachment plaques or fibronexus were absent.

The extracted DNAs of four female patients were proven by PCR to be informative for β -actin gene and were subjected to HUMARA. In two cases with two distinct alleles loaded on the gel before *HhaI* digestion, the signal intensity of one allele was significantly reduced after enzymatic digestion (the ratios of peaks before and after *HhaI* digestion were 1.9 and 2.1, respectively), indicating the presence of a substantial population with a nonrandom inactivation of the gene (Fig. 3). The other two cases

Fig. 3 HUMARA of elastofibromas (EF1–4) (posi-cont, myxoid liposarcoma). A significantly reduced intensity of one (*asterisk*) of the alleles after *HhaI* digestion is detectable in two elastofibromas (EF2 and 3)

showed a single allele before *HhaI* digestion and were considered uninformative.

Discussion

Despite the well-defined clinicopathological features, elastofibroma is an enigmatic entity of uncertain etiology. Its true nature and pathogenetic mechanism are still controversial. In contrast to the peculiar morphology of the abnormal elastic fibers, the interspersed spindle or stellate cells of the lesion have been poorly focused on probably because of their inconspicuous appearance.

Based primarily on ultrastructural features, the cells of elastofibroma are generally considered to be fibroblastic or myofibroblastic [7, 13, 20]. Abundant rough endoplasmic reticula, intracytoplasmic microfilaments, and pinocytotic vesicles have been described in elastofibroma cells, and such findings were also obtained from our electron microscopic observations. In addition to these features, Ramos et al. [13] reported a case of elastofibroma with cells attached ultrastructurally by a tight junction and suggested that it was a pseudotumor of myofibroblasts. However, essential morphological features of myofibroblasts, including bundles of microfilaments with focal densities (stress fibers) and cell-to-stroma attachment sites (fibroneexus), have not been documented previously and were lacking in the two cases examined [15]. Moreover, consistently negative immunohistochemical reactivity to muscle actin, desmin, or calponin in our cases or those examined by Kayaselcuk et al. [6] could not support the view that elastofibroma is a myofibroblastic lesion.

It is noteworthy that the predominant cellular components of our elastofibromas are CD34-positive mesenchymal cells and that this finding has not been described previously in the English literature. CD34 is expressed in dendritic or fibroblast-like mesenchymal cells that almost ubiquitously distribute in the dermis and fibrocollagenous soft tissues, as well as in a wide variety of pathological conditions. Such CD34-positive mesenchymal cells are considered to act as potential "reserve" cells that are capable of endothelial, myoid, and adipocytic differentiation or myxoid or collagenous morphology [17]. Although biologic functions of CD34 expressed in the dendritic or fibroblast-like mesenchymal cells still remain unclear, CD34-mediated signal pathways or cell-matrix interactions may be involved in the pathogenesis of elastofibroma. Because of the lack of coexpression of CD1a, CD10, or CD45RO in the CD34-positive cells, it is difficult to further classify them into distinct subgroups of CD34-positive mesenchymal cells, such as peripheral blood fibrocytes and periadnexal fibroblasts (periglandular stromal cells) [1, 21].

Contrary to the observation by Kahn and Hanna [5], lysozymes—a group of 1,4-*N*-acetylmuramidases that break down bacterial proteoglycans by hydrolyzing cleavage—were frequently expressed in the spindle or stellate cells of the current elastofibromas. Although lysozymes are distributed in a wide variety of cells, including granulocytes,

macrophages, and serous glands [12], fibroblastic or myofibroblastic mesenchymal cells usually lack their immunohistochemical expression, except for those isolated from human palatine tonsils [4]. Lysozymes have been detected in the abnormal elastic fibers of the skin associated with solar elastosis, aging, and pseudoxanthoma elasticum, as well as those in pulmonary emphysema, suggesting their pathogenetic role in degenerated or damaged elastic fibers [16, 18]. The aberrant expression of lysozymes in elastofibroma cells may be related to the production of abnormal or degenerated elastic fibers. Biologic properties of lysozymes expressed by elastofibroma cells should be further examined to address this point.

Another striking result of our study is that the nonrandom inactivation of X-linked androgen receptor gene was identified in two elastofibromas. This finding is in accordance with the clonal chromosomal aberrations in elastofibromas reported by Batstone et al. [2] and McComb et al. [8], who suggested that elastofibroma may represent a true neoplasm rather than a reactive process. Although the clonality of a given condition does not prove its neoplastic nature, this view may also be reinforced by repeated detection of chromosomal instability and by a gain of DNA copy number in a chromosomal region Xq in elastofibromas [2, 11, 19] because such chromosomal changes are commonly associated with various neoplastic processes. However, extreme lyonization or skewed random inactivation of the gene during embryogenesis may draw a false-positive result in HUMARA, although the phenomenon is rare and found only in a minority of healthy individuals [9]. Additional examples of elastofibroma should be examined to exclude this possibility.

In conclusion, our study demonstrates that vimentin/CD34-positive spindle or stellate mesenchymal cells are the major cellular components of elastofibromas and that myofibroblasts are not an integral component of the lesion. The nonrandom inactivation pattern of X-chromosome demonstrated by HUMARA provides further evidence that the lesion is a clonal or potentially neoplastic process.

Osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcoma of soft parts

Received: 24 May 2005 / Accepted: 22 July 2005 / Published online: 12 October 2005
© Springer-Verlag 2005

Abstract Clear cell sarcoma is a high-grade sarcoma with morphological features resembling those of malignant melanoma. An osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts is very rare. Herein, we report an unusual stomach tumor with microscopic and immunohistochemical characteristics of an osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts. The tumor cells were predominantly oval, admixed with some round and spindle elements arranged in nests and fascicles, and admixed with scattered osteoclast-like multinucleated giant cells. Neoplastic cells were positive for S-100 protein, and osteoclast-like multinucleated giant cells were immunoreactive to CD68. The unusual morphology of the tumor caused significant diagnostic difficulties. The differential diagnosis included gastrointestinal stromal tumor, primary or metastatic melanoma, and epithelioid malignant peripheral nerve sheath tumor. To the best of our knowledge, this is possibly the second description of an osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts.

Keywords Stomach · Clear cell sarcoma · Melanoma · Osteoclast

Introduction

Although gastrointestinal stromal tumors (GISTs) account for most mesenchymal tumors arising from within the gastrointestinal tract, clear cell sarcoma and primary or metastatic melanoma have been reported [1, 3, 5, 6, 8, 10, 13, 15–17]. This report describes a case of an osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts, with prominent clear cells and osteoclast-like multinucleated giant cells simulating clear cell sarcomas of soft parts. An osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts was reported originally as an entity by Zambrano et al. [20] in 2003. The tumor shows very similar microscopic features, which consist of nests of oval cells and osteoclast-like multinucleated giant cells. To the best of our knowledge, only one case of an osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts has been described to date. Our case is similar to that reported by Zambrano et al. In the English literature, this is only the second case to have arisen from the stomach.

Case report

A 40-year-old man presented with abdominal pain of 1 year duration. Radiographic and endoscopic studies revealed a large smooth submucosal mass at the transition of the body and the antrum of lesser curvature. On physical examination, no other lesions were detected, and no other black speck of melanoma was seen. A partial gastrectomy was performed. On laparotomy, a gastric tumor with multiple pathological lymph nodes was found.

Pathological findings

The specimen obtained through partial gastrectomy showed a tumor of size 30×30×20 mm, which extended

transmurally and was adherent to surrounding tissues. The mucosa over the tumor was intact.

The specimen was fixed in a neutral buffered formalin and routinely processed, with tissue sections embedded in paraffin. The sections were cut into 4- μ m-thick slices and stained with hematoxylin and eosin. Representative sections were also stained through the EnVision immunohistochemical technique. Immunohistochemical stains were performed with the antibodies listed in Table 1.

Microscopic examination showed a tumor on the muscularis propria and invading submucosa and serosa. The tumor cells were medium-sized, predominantly oval, and admixed with some round and spindle elements arranged in nests and fascicles (Fig. 1a). The cytoplasm was either clear or densely acidophilic (Fig. 1b). The nuclei were centrally located, of somewhat irregular contours, and either normochromatic or only slightly hyperchromatic. The mitotic index was 2.6/10 high power field (0.79 mm⁻²). Cells with nuclear pseudoinclusions and small focal necrosis were observed. Melanin pigments were not seen. A striking feature in this case was the presence of scattered osteoclast-like multinucleated giant cells (Fig. 2a and b). The nuclei of these cells were bland and different from those of the tumor cells. The cytoplasm of some of these cells was focally foamy.

Immunohistochemistry with antibodies for vimentin, S-100 protein, Melan-A, HMB-45, CD34, CD117, α -SMA, CK7, CK5/6, Syn, CD1a, and CD68 was performed. A strong and diffuse reactivity of the neoplastic cells for vimentin and S-100 protein was observed (Fig. 3a); all other

markers were negative. The osteoclast-like multinucleated giant cells were only positive for CD68 (Fig. 3b) but were negative for all other markers.

Discussion

An osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts was reported originally as an entity by Zambrano et al. [20] in 2003. These authors reported six cases of the lesions, with one case arising from the stomach and five cases arising from the duodenum and ileum. All the tumors showed very similar microscopic features consisting of nests of oval cells and osteoclast-like multinucleated giant cells. The neoplastic cells were positive for vimentin and showed reactivity for S-100 protein. Osteoclast-like multinucleated giant cells were positive for CD68 but negative for S-100 protein. Cytogenetic examination revealed a t(12;22)(q13;q12) chromosomal translocation. To the best of our knowledge, only one case of an osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts in the stomach has been described to date. Our case is similar to that reported by Zambrano et al. In the English literature, it is only the second case to have arisen from the stomach.

Based on morphology and particularly on immunohistochemical study, clear cell sarcoma is considered. Clear cell sarcoma presents as a slowly growing, quite often painful nodule in the distal extremities, especially the ankle

Fig. 1 Tumor cells arranged in nests (a). The cytoplasm is either clear or densely acidophilic (b)

Fig. 2 Medium-sized tumor cells admixed with scattered osteoclast-like multinucleated giant cells (a). Higher-power view of osteoclast-like multinucleated giant cells within tumor cells (b)

and the foot, that is closely associated with fascial or tendoaponeurotic structures [4]. However, very rare examples at visceral locations have been described [5, 6, 13]. Microscopically, the distinguishing features of clear cell sarcoma are a clear cytoplasm, prominent nucleoli, the presence of multinucleated tumor giant cells rather than osteoclast-like multinucleated giant cells, a consistent immunoreactivity for S-100 protein, a common reactivity for HMB-45, and the presence of melanin and/or melanosomes in about half of the cases [20]. Some features of the osteoclast-rich tumor of the gastrointestinal tract resembling those of clear cell sarcomas of soft parts are similar to clear cell sarcoma but are negative for HMB-45 in immunohistochemistry, and no typical melanosomes can be found ultrastructurally. In addition, primary melanoma can arise from gastrointestinal mucosal sites, including the esophagus, anorectum, and small bowel [1, 3, 8, 16, 17]. Rarely, cases of primary melanoma of the stomach have been reported [10, 15]. Useful histological features used to recognize the melanocytic origin of the neoplasm are the presence of a correlation between the gastric mucosa and the tumor, cell pigmentation, and melanosomes found ultrastructurally.

In view of their location in the gastrointestinal tract and their mesenchymal appearance, an obvious consideration is that of GISTs and leiomyosarcomas. GISTs account for most mesenchymal tumors arising from within the gastrointestinal tract [2]. They arise most commonly within the walls of the stomach (65–70%) and the small intestines (30–45%) and are seen far less frequently in the esophagus, colon, and rectum, where myogenic tumors predominate [12]. They generally present in adults, with a peak incidence during the fifth and sixth decades, and are infrequent before the age of 40 years. Microscopically, there are

two principal histological patterns: a spindle cell or epithelial character, or a combination of both in variable proportions. Immunohistochemically, GISTs may be positive for CD117, CD34, SMA, and S-100 protein. However, GISTs do not usually exhibit this high degree of S-100 protein immunoreactivity and are almost universally positive for CD117 [19]. Recently, CD117-negative GISTs have been reported, but cytogenetic analysis shows the loss of chromosome 14 chromatid and 14q [11]. Furthermore, we are aware of only two cases of a CD117-positive GIST containing osteoclast-like multinucleated giant cells [7, 9]. In the English literature, only one case of epithelioid leiomyosarcoma with osteoclast-like multinucleated giant cells in the stomach has been reported [7, 18]. A diffuse strong staining for myogenic markers supports the diagnosis of leiomyosarcoma.

Extraskeletal neoplasms with osteoclast-like multinucleated giant cells are uncommon. They are most frequently reported in malignant epithelial tumors of the breasts and pancreas; quite rarely, they are reported in other sites, including soft tissue tumors. The significance of osteoclast-like multinucleated giant cells in tumors, as well as of their pathogenic mechanism of formation, remains obscure. Recent analyses of bone giant cell tumors reveal that neoplastic spindle cells may secrete a variety of cytokines and differentiation factors, including monocyte chemoattractant protein 1, osteoclast differentiation factor, and macrophage colony-stimulating factor. These molecules are monocyte chemoattractants and are essential for osteoclast differentiation, which suggests that the neoplastic spindle cells stimulate blood monocyte immigration into tumor tissues, enhancing their fusion into osteoclast-like multinucleated giant cells [14, 21].

Fig. 3 The tumor cells are positive for S-100 protein (a). The osteoclast-like multinucleated giant cells within tumor cells are positive for CD68 (b)

Another differential diagnosis is epithelioid malignant peripheral nerve sheath tumor. Although the S-100 protein is usually positive in both, its distribution is diagnostically important: Whereas the osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts is diffusely and strongly positive for S-100 protein, the malignant peripheral nerve sheath tumor is only focally positive for this marker [13].

The histogenetic relationship between clear cell sarcoma and the osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts remains elusive. Morphological characters, an intense immunoreactivity for S-100 protein, and the cytogenetics of the two lesions share some similarities; however, our case and those of Zambrano et al. are both negative for HMB-45, and no typical melanosomes are clearly distinct ultrastructurally. This provides strong evidence that the osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts is indeed a separate and distinct entity that is somehow related to clear cell sarcomas of soft parts.

In conclusion, an osteoclast-rich tumor of the gastrointestinal tract with features resembling those of clear cell sarcomas of soft parts is a distinct type of gastrointestinal neoplasm. This neoplasm shares some features with clear cell sarcoma, but also has some important features that are different from the latter. The neoplasm is immunoreactive to the S-100 protein and is negative for CD117 and CD34, which have been segregated from GISTs.

Adenoid cystic carcinoma of the maxillary sinus with gradual histologic transformation to high-grade adenocarcinoma: a comparative report with dedifferentiated carcinoma

Received: 6 December 2004 / Accepted: 25 July 2005 / Published online: 17 August 2005
© Springer-Verlag 2005

Abstract We report a unique case of adenoid cystic carcinoma (ACC) of the maxillary sinus, with gradual histologic transformation from lower-grade ACC (cribriform and tubular types) to high-grade adenocarcinoma (HGA) showing a sequential histologic spectrum via solid-type ACC. A 74-year-old man presented with swelling and mild pain of the right cheek. CT scan showed a mass measuring approximately 4 cm, with marked bone destruction in the right maxillary sinus. A surgically resected specimen revealed that the tumor was comprised of three different components: HGA and solid-type ACC in the central portion and lower-grade ACC in the periphery. The tumor was discriminated from a dedifferentiated carcinoma or hybrid tumor. Autopsy specimens also demonstrated both solid-type ACC and HGA components in the lung and spleen. Immunohistochemically, positive staining of p53 protein was detected on both solid-type ACC and HGA cells, but cyclin D1 and HER2/neu was only seen in HGA cells. Solid-type ACC cells were immunoreactive for CD117 (c-kit), but lower-grade ACC and HGA cells were negative. This case suggests that the overexpression of CD117, p53 protein, cyclin D1, and HER2/neu might be involved in the progression from lower-grade ACC to solid-type ACC and HGA.

Keywords Adenoid cystic carcinoma · Dedifferentiation · Hybrid tumors · Maxillary sinus · Transformation

Introduction

Adenoid cystic carcinoma (ACC) is a specific type of adenocarcinoma, with a characteristic cribriform appearance that commonly occurs in the major and minor salivary glands. Patey and Thackray first reported that ACC with a solid growth pattern was associated with a worse prognosis than that of the cribriform type [12]. Perzin et al. described a more differentiated type of ACC, the tubular form, which is associated with a favorable prognosis [13]. Accordingly, ACCs are histologically classified into three subtypes: tubular, cribriform, and solid. The grading scheme that categorizes ACCs into three histologic grades is as follows: Grade 1—tubular and cribriform patterns without solid components, Grade 2—pure cribriform pattern or mixed with less than 30% of solid areas, and Grade 3—predominantly a solid pattern, and it is closely correlated with prognosis [15]. Therefore, the tubular- and cribriform-type ACCs are lower-grade, whereas solid-type ACC is higher grade.

Recently, cases have been reported of dedifferentiated ACC of the salivary gland and upper respiratory tract, which are rare variants of ACC [1, 2, 7, 9–11]. Dedifferentiation is defined as clonal evolution of a poorly differentiated or high-grade component arising within a low-grade carcinoma without histologic transition or spectrum from the original carcinoma [18], namely, as an abrupt transformation [11]. In all reported cases of dedifferentiated ACC, the low-grade component was tubular- or cribriform-type ACC, and high-grade areas demonstrated poorly differentiated adenocarcinoma or undifferentiated carcinoma. The two elements are clearly demarcated, although there is a transitional zone in some cases.

Although histologic progression from lower-grade ACC to solid-type ACC has previously been reported [16], there are no reports in the literature of transformation from solid-type ACC to high-grade adenocarcinoma (HGA) or undifferentiated carcinoma. The histologic appearance of solid-type ACC is variably sized solid islands of monomorphous tumor cells, which have small nuclei with fine chromatin and indistinct nucleoli, and scant cytoplasm

Fig. 1 CT scan shows a tumor with bone destruction in the right maxillary sinus

[3]. Immunohistochemical staining for cytokeratin of solid-type ACC demonstrated disproportionate ductal-cell proliferation. The HGA showed a more pleomorphic appearance, large nuclei, and infiltrative growth pattern. We present here a case of ACC with gradual transformation from lower-grade ACC to HGA with a continuous histologic spectrum via solid-type ACC. The immunohistochemical characteristics are also described and reviewed as compared with those of dedifferentiated ACC and hybrid carcinoma.

Clinical history

A 74-year-old man presented with swelling and mild pain of the right cheek, anosmia, and nasal bleeding for 6 months. CT scan demonstrated a mass approximately 4 cm in diameter, with marked bone destruction in the right maxillary sinus (Fig. 1). A needle biopsy specimen was diagnosed as poorly differentiated adenocarcinoma, and the mass was excised. Pulmonary and hepatic metastases

were identified at follow-up 1 year later after the surgery. The patient died within 4 months following the development of metastases without any effect of chemotherapy. Autopsy was then performed.

Materials and methods

The whole surgically resected specimen was cut into 12 tissue blocks 5 mm thick for histologic and immunohistochemical examination. For light microscopic evaluation, all thin sections were stained with hematoxylin and eosin. Immunohistochemistry was performed on the deparaffinized tissue sections using the primary antibodies listed in Table 1 and the avidin-biotin-peroxidase complex method of Hsu and co-workers [6].

Results

The surgically resected specimen, measuring 7.5×5×3 cm, was comprised of the right maxillary tumor mass, the overlying skin, and the subcutaneous tissue. Grossly, the tumor was solid with a white or gray-tan appearance and was approximately 4 cm in diameter, with an indistinct margin and destruction of the maxillary bone wall.

Microscopically, the tumor was comprised of three distinct components. In the central portion of the tumor, HGA and solid-type ACC were the main components. HGA was comprised of highly malignant tumor cells with pleomorphic vesicular nuclei and relatively abundant amphophilic cytoplasm proliferating irregularly with loose solid nests (Fig. 2a) or infiltratively in a small tubular and cord-like pattern (Fig. 2b). Solid ACC was comprised of either solid nests of small duct-like structures with occasional comedo-like necrosis (Fig. 2c) or solid nests of larger tumor cells with vesicular nuclei with some ductular structures. There were transitional areas between HGA and solid-type ACC

ACC Adenoid cystic carcinoma, HGA high-grade adenocarcinoma, F focally

Fig. 2 Histopathological appearance of the tumor using hematoxylin and eosin stain. $\times 200$. **a** and **b** High-grade adenocarcinoma. **c** Solid-type adenoid cystic carcinoma with comedo-like necrosis. **d** Transitional appearance from solid-type adenoid cystic carcinoma to high-grade adenocarcinoma

(Fig. 2d). In the periphery of the tumor, a lower-grade ACC component was identified. Small monomorphous cells were infiltratively proliferated with a cribriform or bicellular tubular pattern. Perineural invasion was frequently observed in the area.

The postmortem examination revealed metastases in the lungs, liver, spleen, bone marrow in the lumbar vertebrae, and right pulmonary hilar lymph nodes. Histopathological findings in the metastatic lesions of the lung and spleen were solid-type ACC and HGA, which were similar to those of the central parts of the primary maxillary lesion.

Table 1 summarizes the immunohistochemical findings of the present case. Immunohistochemically, ductal cells stained positively for cytokeratin (AE1/AE3) in all com-

ponents. All components showed a positive reaction for α -smooth muscle actin, markers of myoepithelial cell differentiation, and S-100 protein. Ductal cells in HGA and solid-type ACC areas expressed positive immunoreactivity for S-100 protein. CD117 (c-kit) immunostaining showed a positive reaction only in solid-type ACC, with no positive staining in lower-grade ACC or HGA (Fig. 3a). The staining for p53 protein was positive in more than 50% of carcinoma cells both in the HGA and solid-type ACC areas, whereas it was negative in the lower-grade ACC portion (Fig. 3b). Cyclin D1 overexpression was demonstrated in approximately 30% of the tumor cells in the HGA component, but was only weakly and focally reactive in the ACC component (Fig. 3c). Membranous

Fig. 3 Immunohistochemical findings of the tumor. $\times 200$. **a** Solid-type adenoid cystic carcinoma cells with membranous expression for CD117 (*left*), which is negative in the high-grade adenocarcinoma cells (*right*). **b** Solid-type adenoid cystic carcinoma cells with nuclear expression for p53 protein (*left*), which is negative in the cribriform-type adenoid cystic carcinoma cells (*right*). **c** High-grade adenocarcinoma cells with nuclear expression for cyclin D1 (*left*), which is negative in the solid-type adenoid cystic carcinoma cells (*right*). **d** High-grade adenocarcinoma cells with membranous expression for HER2/neu (*left*), which is negative in the solid-type adenoid cystic carcinoma cells (*right*)

staining for HER2/neu was detected only in the HGA component (Fig. 3d). The Ki-67 (MIB-1) labeling index in lower-grade ACC, solid-type ACC, and HGA areas was approximately 5, 15, and 30%, respectively.

Discussion

The tumor in this case consisted of three different components: lower-grade (tubular and cribriform types) ACC, solid-type ACC, and HGA. We believe that gradual transformation from lower-grade ACC to HGA with a sequential histologic spectrum via solid-type ACC was involved in the tumor development. Discrimination from dedifferentiated carcinoma and hybrid carcinoma, which are organized with pleural carcinoma elements, is necessary in this unique case.

Dedifferentiation is recognized when a lower-grade malignant neoplasm abruptly transforms to a high-grade [11, 17], in which the high-grade component is juxtaposed to the original lesion or the original line of differentiation is lost [2]. This concept should be distinguished from malignancy arising from a benign tumor such as carcinoma ex pleomorphic adenoma, hybrid tumors, and transformation within a high-grade carcinoma to another high-grade pattern [18]. There are no previously reported cases of dedifferentiated ACC of the salivary glands and upper respiratory tract where a solid-type ACC area was mentioned [1, 2, 7, 9, 10], or accounted for only as a scant portion [11], which is consistent with the definition. The present case is unique in that the histologic features indicated a gradually successive transition from lower-grade to solid-type ACC and HGA. Histologic transformation from solid-type ACC to HGA corresponds to a transition from high-grade carcinoma to another high-grade carcinoma, which should discriminate from dedifferentiation.

Hybrid tumors are composed of two histologically distinct categories of tumor, each of which corresponds to an exactly defined tumor entity and an identical origin [14]. In the present case, the tumor components were lower-grade ACC, solid-type ACC, and HGA. Some of the tumor nests of the HGA component with comedo-like necrosis were superficially analogous to salivary duct carcinoma. However, dystrophic calcification, apocrine-like eosinophilic cytoplasm, coarse chromatin, and distinct single nucleolus, which are characteristic features of salivary duct carcinoma [18], were not observed. Immunoreactivity was not detected for CEA, GCDFP-15, androgen receptor, and prostate-specific antigen, which are frequently expressed in salivary duct carcinoma. Therefore, the HGA component was not assigned to a specific carcinoma entity and should be classified into adenocarcinoma NOS (not otherwise specified). The tumor in the present case could be differentiated from hybrid carcinoma.

Histologic transition from solid-type ACC to HGA is a characteristic finding in this case. Comedo-like necrosis and mitoses have appeared to a variable extent in solid-type ACC [3, 4] and were identified in the present case. In the HGA component, there were distinctive irregularly sized

solid islands of highly pleomorphous tumor cells with vesicular large nuclei. There were transitional features between solid-type ACC and HGA. These morphological findings suggest that the increase in cellular atypism and pleomorphism in solid-type ACC might be involved in the initial stage of histologic transformation to HGA. In the autopsy specimens of the lung and spleen, histopathological findings of metastatic lesions showed the same pattern as the central portion of the surgical samples, i.e., combination of solid-type ACC and HGA, showing that solid-type ACC metastasized and then transformed to HGA. These findings also suggest a gradual successive transformation of tumor cells in this case.

Immunohistochemical studies and genetic analysis have been carried out for oncoprotein in dedifferentiated ACC and solid-type ACC. The Ki-67 labeling index was higher in dedifferentiated ACC than in that of lower-grade ACC [1, 2, 11]. The Ki-67 labeling index of solid-type ACC in the present case was between lower-grade ACC and HGA, demonstrating that proliferation activity increased in proportion to histologic progression from lower-grade ACC to solid-type ACC and HGA. CD117 (c-kit) expression was detected in ACC, which was intense in solid-type ACC [5]. Overexpression of p53 protein was detected by immunohistochemistry in six of nine cases (67%) [1, 2, 7, 9, 11], and that of cyclin D1 was detected in five of seven cases (71%) in previously reported dedifferentiated ACC cases [1, 2, 11]. Nagao et al. and Chau et al. reported dedifferentiated ACC cases with a p53 gene mutation [1, 11]. Immunohistochemical positive staining of HER2/neu has been demonstrated in three of five cases (60%) [1, 8, 10] of dedifferentiated ACC. Immunohistochemical expression of p53 protein [8] and p53 gene alterations [17] were markedly more frequent in solid-type ACC than lower-grade ACC. In our case, positivity for p53 protein was detected in both solid-type ACC and HGA cells, but immunoreactivity for cyclin D1 and HER2/neu were detected only in HGA cells. The molecular mechanisms of malignant transformation of ACC have not been clearly elucidated. Our case suggests that overexpression of CD117 (c-kit), p53 protein, cyclin D1, and HER2/neu are involved in the transformation from lower-grade ACC to solid-type ACC and HGA.

Fatal CNS vasculopathy in a patient with refractory celiac disease and lymph node cavitation

Received: 31 May 2005 / Accepted: 3 August 2005 / Published online: 21 September 2005
© Springer-Verlag 2005

Abstract Celiac disease is an enteropathy occurring in genetically predisposed individuals due to a dietary intolerance to gluten. Patients with celiac disease may develop a neurological disorder of unknown cause, although autoimmune mechanisms are suspected. We report on a 56-year-old man with celiac disease, who became refractory to a gluten-free diet and died of a rapidly progressive encephalopathy. Magnetic resonance imaging indicated focal lesions of the cerebellum and brainstem, and electrodiagnostic studies suggested an axonal neuropathy. Autopsy revealed a flattened small-bowel mucosa with intraepithelial lymphocytosis, a spectrum of degenerative changes of the intra-abdominal and mediastinal lymph nodes, including cavitory degeneration, and splenomegaly. Histologically, the lymph nodes showed pseudocyst formation and lymphocytic vasculitis with fibrinoid necrosis, and sections of the brain exhibited fibrinoid degeneration of small

blood vessels, sparse perivascular lymphocytic infiltrates, and perivascular ischemic lesions. Identical T-cell clones were identified in the duodenum, stomach, lymph nodes, and spleen. This patient had an unusual neurological disorder related to a vasculopathy, probably mediated by a circulating neoplastic clone of activated T cells.

Keywords Celiac disease · Encephalopathy · Vasculopathy · Neuropathy

Introduction

Celiac disease is an immune-mediated, small intestinal enteropathy triggered by ingestion of gluten, the storage protein of wheat and related grains [30]. The disease is occasionally associated with disorders of the nervous system, including cerebellar ataxia, seizures, migraine headaches, and peripheral neuropathy [5, 27]. Little is known about the pathogenesis of these neurological disorders as autopsies are rarely performed in such individuals [4, 11, 13, 17, 22, 26, 28]. We describe an unusual case of fatal subacute encephalopathy due to a small vessel angiopathy in a patient with refractory celiac disease complicated by mediastinal and mesenteric lymph node cavitation (MLNC).

Clinical history

A 56-year-old man presented with a history of diminished appetite, diarrhea, and profound weight loss (70 lbs). He had been diagnosed with celiac disease 2.5 years earlier based on positive endomysial antibodies, a duodenal biopsy that revealed total villous atrophy with intraepithelial lymphocytosis, and response to a gluten-free diet. A strict gluten-free diet led to a diminution of symptoms and weight gain (58 lbs), and he returned to his usual state of health. He did well for more than a year, but became symptomatic again despite strict adherence to a gluten-free diet. On admission to the hospital, he complained of decreased appetite, nausea, diarrhea, weight loss, and mental

confusion. Examination revealed a cachectic man with bi-temporal wasting, hypotension, tachycardia, and a fever of 101.9°F (38.8°C). Routine blood tests, including serum iron, folate, vitamin B12, and vitamin E levels, were normal. He had a low serum sodium level (128 mM/l) and elevations of total bilirubin (3.1 mg/dl), alkaline phosphatase (550 U/l), and serum ferritin (854 ng/ml). Anti-gliadin, anti-endomysial, and antinuclear antibodies were negative as was a serologic test for HIV. Urine, blood, and stool cultures were negative. An upper gastrointestinal series revealed dilatation of the small intestine, while an abdominal ultrasound and computerized tomography (CT) scan were normal. A repeat duodenal biopsy exhibited total villous atrophy and persistent intraepithelial lymphocytosis without morphologic evidence of collagenous sprue, lymphoma, or infection; gastric biopsies demonstrated lymphocytic gastritis. The patient received total parenteral nutrition, intravenous steroids, and azathioprine. Neurological examination showed diffuse muscle wasting and weakness (3/5 in the legs and 4/5 in the arms). He had diminished pain sensation in a glove–stocking distribution and areflexia with evidence of an axonal neuropathy on electrodiagnostic studies. Dysmetria and ataxia were detected. A CT scan of the brain was normal except for an ill-defined lucency in the left medial occipital lobe, attributed to focal atrophy. Lumbar cerebrospinal fluid (CSF) had a glucose level of 59 mg/dl, protein 244 mg/dl and one white blood cell. A venereal disease research laboratory test was nonreactive, and cultures for viruses, fungi, and bacteria were negative as were the results of polymerase chain reaction (PCR) for mycobacteria and herpes simplex virus.

The patient deteriorated neurologically with onset of brainstem dysfunction, progression of the peripheral neuropathy, and seizures. He received intravenous immunoglobulin (30 g daily for 3 days) with minimal improvement. On the 14th hospital day, magnetic resonance (MR) imaging demonstrated an area of T2 hyperintensity involving the right cerebellar hemisphere, pons, midbrain, and thalamus (Fig. 1a). Contrast enhancement was observed along

Fig. 1 Axial brain MR images. **a** T2-weighted image shows increased signal in the right pons, brachium pontis, and cerebellum (arrows). **b** Postcontrast T1-weighted image demonstrates enhancement along the lateral aspect of the signal abnormality (arrows)

the periphery of the lesions (Fig. 1b). Repeat CSF examination showed 15 cells (lymphocytes and monocytes). Despite aggressive treatment, including intravenous antibiotics, intravenous steroids, and infusions of gamma globulin, the disorder progressed, and the patient died 6 weeks after the onset of his neurological disorder.

Materials and methods

Morphologic assessment was performed using hematoxylin and eosin stained, formalin-fixed, paraffin-embedded tissue sections (3 μ). Sections of the brain were also stained with Bielschowsky, Gomori methenamine silver, periodic acid Schiff with and without diastase digestion, Ziehl–Neelsen (acid fast bacteria), Gram, Giemsa, and Warthin–Starry stains. The following primary antibodies were used for immunohistochemical staining: CD2 (dilution 1:100; Novocastra, Burlingame, CA, USA), CD3 (dilution 1:800; Dako, Carpinteria, CA, USA), CD4 (dilution 1:50; Novocastra), CD5 (dilution 1:50; Novocastra), CD7 (dilution 1:200; Novocastra), CD8 (dilution 1:40; Dako), TIA-1 (dilution 1:1000; Dako), granzyme B (dilution 1:20; Chemicon, Temecula, CA, USA), perforin (dilution 1:50; Novocastra), CD30 (dilution 1:50; Dako), and C4d (dilution 1:100; ALPCO, Windham, NH, USA). The Envision plus system (Dako) was used for detection. Immunofluorescent (IF) staining was performed after pronase (*Streptomyces griseus*, 50,000 units; Calbiochem, La Jolla, CA, USA) pretreatment (0.03 g/ml for 10 min in TRIS buffer at 37°C) of paraffin-embedded tissue sections using the following fluorescein isothiocyanate–labeled antibodies: IgM, IgG, IgA, C3, C1q, fibrinogen, and albumin (Dako). PCR for T-cell receptor- γ (TCR- γ) gene rearrangement followed by polyacrylamide gel electrophoresis and heteroduplex analysis was performed according to the method of Bottaro et al. [3].

Results

A premortem right cerebellar hemisphere biopsy (performed on hospital day 15) demonstrated small vessel angiopathy, rare occlusive fibrin thrombi, and confluent areas of perivascular ischemic injury. Fibrinoid material was present in the vessel walls and perivascular areas accompanied by edema and an infiltrate of macrophages. Only sparse perivascular lymphocytes were noted in the neural tissue and leptomeninges. Histochemical stains and electron microscopy did not reveal any microorganisms.

Postmortem examination was significant for cachexia, hepatomegaly (2,750 g), and mild splenomegaly (210 g); no distinct mass lesions were identified in any organ. Sections of the duodenum and jejunum showed total villous atrophy (Fig. 2a) and a moderate intraepithelial lymphocytosis (Fig. 2a, insert). Although the intraepithelial lymphocytes lacked morphological atypia, they had an abnormal phenotype: CD2+, CD3+, CD5–, CD7+, CD4–, CD8–, CD30–, TIA-1+, granzyme B+, and perforin+.

Hematoxylin & eosin, *bar*=50 μ m

Mesenteric, para-aortic, and hilar lymph nodes showed a spectrum of histologic alterations from multifocal paracortical histiocytic aggregates to lymphocyte depletion and chylous pseudocyst formation to fibrosis and atrophy. In addition, numerous lymph nodes showed lymphocytic vasculitis of small-sized vessels with fibrinoid necrosis (Fig. 3a). The lymphocytes surrounding and infiltrating the vessel walls had the same immunophenotype as the intraepithelial lymphocytes, and there was no evidence of immune-complex deposition on staining for the different immunoglobulin heavy chains and complement components C1q, C3, and C4d. The amorphous fluid in the cavitory lymph nodes showed scattered clumps of fibrinogen by IF staining (Fig. 3c) that stained bright red with a trichrome stain (Fig. 3b). Apoptotic paracortical lymphocytes were also seen in the areas infiltrated by the atypical lymphocytes. Sections of the spleen showed marked white pulp depletion and a sparse red pulp infiltrate of small lymphocytes. PCR analysis for TCR- γ gene rearrangement demonstrated clonal T-cell products of similar molecular weight with the V10/11 family primers in the small intestine, stomach, lymph nodes, and spleen (Fig. 4).

Sections of the cerebellum revealed widespread loss of Purkinje cells and neurons of the dentate nucleus and astrocytosis, in addition to the histologic changes observed in the premortem biopsy. Microscopic lesions similar to the premortem cerebellar biopsy were also detected in the right pons (Fig. 2b,c), midbrain, thalamus, and basal ganglia. The spinal cord exhibited mild degeneration of the pyramidal tracts and the posterior columns with loss of mye-

could not be determined reliably, and PCR for TCR- γ gene rearrangement of the brain tissue yielded unamplifiable DNA, possibly due to prolonged formalin fixation (1 week).

Discussion

Our patient had refractory celiac disease, based on an initial response to gluten-free diet with subsequent loss of responsiveness to the diet [29]. He subsequently developed a rapidly evolving fatal encephalopathy caused by an acute small-vessel angiopathy, superimposed on a subacute degeneration of the cerebellum and a peripheral neuropathy. The patient was receiving corticosteroids and antimicrobial treatment when he developed neurological symptoms, but cultures, PCR analysis, histologic exam, and electron microscopy ruled out an opportunistic infection. Autopsy revealed mild splenomegaly and a spectrum of destructive changes of the intra-abdominal and mediastinal lymph nodes, including chylous pseudocyst formation in numerous mesenteric lymph nodes, the latter consistent with MLNC [20, 25]. The small-bowel mucosa was flattened, and a clonal expansion of intraepithelial lymphocytes was observed. These lymphocytes lacked morphologic atypia but had an aberrant phenotype (CD4-CD8-). Generalized gastrointestinal mucosal and extraintestinal spread of clonal T cells to the blood and other organs, in the absence of a morphologically overt lymphoma, has been described in patients with refractory celiac disease [9, 10, 31], and many of these patients are believed to have a cryptic enteropathy-associated T-cell lymphoma (EATL) [8, 9].

The pathogenesis of MLNC is unclear; the two extant theories have proposed lymph node damage either due to chronic immune stimulation [18] or the consequence of complement-mediated endothelial damage due to vascular immune complex deposition [23]. Moreover, none of the reported cases of MLNC have documented extra-abdominal lymph node involvement or the presence of a clonal T-cell population within the lymph nodes. Our findings suggest that vascular damage and lymphocyte depletion of secondary lymphoid organs in our case could have been mediated by circulating activated T cells that originated from the small-bowel epithelial compartment. It remains unclear, however, whether cytokines or a contact-mediated mechanism (or both) were responsible for endothelial damage and bystander killing of lymphocytes.

Numerous neurological disorders have been associated with celiac disease [6, 11, 16], and patients with refractory sprue are at the greatest risk for developing these complications [26]. However, the prevalence of these disorders is not known, and an etiologic link with celiac disease remains controversial. Holmes [19] estimated that 6% of patients with celiac disease have neurological disorders. The most common neurological syndromes include cerebellar ataxia and peripheral neuropathy [17, 27]. Of all patients with ataxia, 50% or more have a coexisting neuropathy, usually caused by axonal degeneration [5, 17]. Both disorders often progress slowly [5, 7, 17], although, occasionally, the encephalopathy is rapid and fatal within a

few weeks of onset as in our patient [24]. The cause of neurologic dysfunction remains unknown, but a link with HLA-DQ2 in a large percent of patients with gluten sensitivity and cerebellar ataxia suggests an underlying genetic predisposition [5, 7]. The presence of anti-ganglioside antibodies in a high proportion of patients who have peripheral neuropathies is also supportive of an autoimmune etiology [1].

A wide spectrum of histologic changes of the central nervous system (CNS) have been reported in patients with celiac-disease-associated neurological disorders [4, 11, 13, 17, 22, 26], but Purkinje cell loss and astrocytosis with or without a coexistent neuropathy are the most common finding. Less frequent pathologic features include perivascular lymphocytic infiltrates and reactive changes in endothelial cells of small vessels. Isolated CNS vasculitis has only been reported in one instance [28]. Our patient showed histologic signs of small blood vessel injury of the brain with marked perivascular edema, exudation of fibrin, and ischemic injury of the neural tissue. These findings are similar to those reported in a minority of patients who die due to a cerebral disorder associated with systemic lupus erythematosus [12, 21]. CNS vasculopathy mediated by a clonal circulating T-cell population has not been reported in any of the 21 published studies of celiac disease, where autopsy data was provided.

There are no standardized treatment regimens for celiac-disease-associated CNS complications or neuropathies, and gluten-free diet, the mainstay therapy, often fails to prevent or ameliorate neurological complications [26, 27]. A beneficial response to early dietary intervention, after the onset of neurological complications, has been reported in some patients with neuropathies [15]. Since the vast majority of patients with neurological symptoms do not have a detectable hypovitaminosis, treatment with vitamins (i.e. vitamin B12, folic acid, or vitamin D) is deemed to be of little value [26, 27]. An improvement in symptoms was reported for a patient with cerebral vasculitis, treated with prednisone and cyclophosphamide [28], and for a patient with a brainstem-cerebellar syndrome, who was treated with prednisone alone [14]. Similar immunosuppressive regimens, however, have failed to halt or revert the neurological manifestations of other patients [2, 24, 26].

In summary, we describe a patient with refractory celiac disease who had a CNS disorder due to a small vessel vasculitis in association with MLNC, both possibly linked to the presence of a circulating clone of activated T cells, conceivably representing a cryptic EATL.

Nephroblastomatosis and loss of *WT1* expression associated with trisomy 13

Received: 1 June 2005 / Accepted: 16 August 2005 / Published online: 22 September 2005
© Springer-Verlag 2005

Abstract Trisomy 13 (Patau's syndrome) is a rare finding in newborns. The life span of babies affected by this chromosome abnormality is severely shortened, and multiple, partly severe malformations occur. In this study, we report on an unborn with trisomy 13 (artificially aborted on the 24th week) which showed, among other typical deformities, bilateral nephrogenic rests (nephroblastomatosis). Using molecular analysis, a loss of Wilms' tumor gene 1 (*WT1*) transcript and a biallelic expression of insulin growth factor 2 (*IGF2*) could be revealed. To our knowledge, this is the first reported case of trisomy 13 which showed this type of anomaly and gene expression findings.

Keywords Trisomy 13 · Nephroblastomatosis · Wilms' tumor · Gene expression

Introduction

Trisomy 13 (Patau's syndrome) was first described by Patau in 1960 as a chromosome abnormality due to an extra copy of the 13th chromosome [9]. It occurs in approximately 1/5,000 to 1/15,000 live births. Infants affected with trisomy 13 tend to be small at birth and have a microcephaly with sloping forehead. A holoprosencephaly is common and a myelo-meningocele is found in almost 50% of cases. Usually the child suffers from severe mental retardation, and seizures are common. Deformities of the eye, including

microphthalmia, coloboma, and retinal dysplasia, frequently occur. Cleft lip, cleft palate, or both are present in most cases. Defects of the heart, like ventricular–septal defect, atrial–septal defect, patent ductus arteriosus, and dextrocardia, are frequently observed. Capillary hemangiomas, especially on the forehead in the midline, may also be present. The genitalia are frequently abnormal in both sexes. A single transverse crease on the palm, polydactyl, and hyperconvex, narrow fingernails are common. Hematologically, there is an increased frequency of nuclear projection in polymorph nuclear leukocytes and a persistence of fetal hemoglobin [5].

Nephrogenic rests are the consequence of residual metanephric tissue in a fully developed kidney. They usually occur along the perimeter of a mature renal lobe (perilobar), within the lobe itself (intralobar), or both (combined). Nephrogenic rests can be grossly obvious or microscopically discrete. Nephroblastomatosis designates nephrogenic rests that are multifocal or diffuse and implies more extensive disease. Universal (panlobar) nephroblastomatosis denotes complete replacement of the renal lobe by nephrogenic tissue. The fate of nephrogenic rests and nephroblastomatosis varies and includes hyperplasia, sclerosis, dormancy, obsolescence, or neoplasia [3]. Evidence strongly suggests that neoplastic transformation of nephrogenic rests results in Wilms' tumor (nephroblastoma). Nephrogenic rests frequently occur in the setting of Wilms' tumor; perilobar rests show a strong association with synchronous bilateral Wilms' tumors, whereas intralobar rests are more strongly associated with metachronous tumors [3]. Genetic studies have shown that nephrogenic rests often share many of the same chromosomal defects as Wilms' tumor, which provides further evidence that they are precursor lesions [1].

Case report

The pregnancy of a 31-year-old white woman (2 G/0 P) had been uneventful. Routine ultrasound scan in the 20th week of pregnancy revealed multiple malformations of the fetus.

An amniocentesis was performed and showed trisomy 13. After a lengthy discussion, the mother decided on an induced abortion on the 24th week of gestation. The family history was free of any noteworthy findings.

Pathologic findings

The male fetus measured 30.3 cm in crown–heel length and 3.8 cm in foot length and weighed 520 g. The head was reduced in size, with a circumference of 18.1 cm. As external anomalies, a unilateral cleft lip and palate as well as a significant hypertelorism and dysplasia of the ears were present. The external genitals were hypoplastic. The brain was very fragile, weighed approximately 70 g, and showed some unspecific dysplasia of the cerebellum and an aberration of the brain stem. The kidneys were enlarged (right 10 g, left 4 g, normal 3.5 ± 0.7 g) and revealed hydronephrosis with hydroureter and showed polycystic dysplasia (Potter IIa). The cutting surface displayed bilateral diffuse peri- and intralobar nephroblastomatosis (histological image, Fig. 2). Further findings were hypoplastic lungs and a Meckel's diverticulum.

A fluorescence in situ hybridization (FISH) analysis of the lung tissue for chromosome 13 was performed to confirm the amniocentesis finding (Fig. 1).

Materials and methods

For histological analysis, 3- μ m paraffin sections of all organs were stained routinely with hematoxylin and eosin. The histological evaluation was carried out using a light microscope (Fig. 2).

FISH was performed as described in detail earlier [16]. In brief, a 5- μ m histological section was deparaffinized and pretreated, and hybridization was carried out with 13q14

Fig. 1 To confirm the diagnosis of trisomy 13, FISH for chromosome 13 in lung tissue was performed. Three signals are clearly visible per cell

Fig. 2 **a** Multiple peri- and intralobar nephrogenic rests which are partly well and partly poorly circumscribed. Hematoxylin and eosin, original magnification 45 \times . **b** High-power magnification of an intralobar nephrogenic rest, consisting of round to oval, slightly pleomorphic cells with scanty cytoplasm. Hematoxylin and eosin, original magnification 400 \times

(RB1, Abbott, Wiesbaden, Germany). Counterstaining was performed with 5 μ l DAPI (Qbiogene, Heidelberg, Germany) and Vectashield antifade (Vector Laboratories, Burlington, USA). Evaluation of signals was carried out with an epifluorescence microscope (Axioskop 2, Zeiss, Oberkochen, Germany).

To assess basic genetic changes in nephrogenic rests, the mRNA expression of the tumors and the surrounding healthy tissue was investigated using the PALM Laser-MicroBeam System (P.A.L.M., Germany), which enables contact-free isolation of defined cell populations. A total of 35 histologically mature respectively forming glomeruli and adjacent tubuli as well as an equal area of nephrogenic rests were microdissected. Total RNA was extracted using phenol–chloroform precipitation and transcribed into complementary DNA. All techniques have been described previously by Lehmann et al. [7] and are well established in our laboratory.

PCR primers for expression of Wilms' tumor gene 1 (*WT1*), adult skeletal muscle gene (*H19*), insulin growth factor 2 (*IGF2*), and β -*Gus* were used (Table 1). The target

Table 1 Primer sequences used in this study

Gene	Sequence (5' to 3')
<i>H19</i>	CAACCACTGCACTACCTGACTCAG GTCTTTGATGTTGGGCTGATGAG
<i>IGF2</i>	GAGTCCCTGAACCAGCAAAGAG CCGTGAGAAGGGAGATGGC
<i>WT1</i>	CAGGCAGCACAGTGTGTGAAC TCCAGGCACACCTGGTAGT
β - <i>Gus</i>	CTCATTTGGAATTTTGCCGATT CCGGAGTGAAGATCCCCTTTT

genes for molecular investigation were chosen because of their supposed roles in Wilms' tumor development: β -*Gus* was used as positive DNA input control.

To screen for known polymorphism in *H19* and *IGF2*, genomic DNA was extracted from lung and normal kidney tissue and analyzed using restriction enzyme digestion described in detail by Tessema et al. [14]. For the imprinting analysis, restriction enzymes *Apa*I (*IGF2*) and *Alu*I (*H19*) were used according to the manufacturer's instructions (Fermentas GmbH, Germany).

Results

For *WT1*, an expression was detected in forming glomeruli and mature ones as well as in surrounding tubuli, but in the nephrogenic rests, no expression was detectable (Fig. 3). Concerning *IGF2* and *H19*, RNA expression was found in all examined tissues. Because it is known that *H19* and *IGF2* are imprinted genes and, thus, normally only one

allele is expressed (*IGF2* paternal, *H19* maternal), restriction enzyme digestion was used to screen for polymorphisms. Heterozygosity for *IGF2* and homozygosity for *H19* were observed in lung and normal kidney tissues. Concerning *IGF2*, monoallelic expression (imprinting) was found in the normal tissue, whereas a biallelic expression was observed in the nephrogenic rests (Fig. 3b).

Discussion

An interesting aspect of the pathogenesis of nephroblastoma is the presence of immature embryonic nephrogenic rests and the genetic relationship between these entities. Nephroblastomas are assumed to develop from nephrogenic rests by accumulating genetic alterations and are considered as subclones of nephrogenic rests. The heterogenous genetic pathogenesis of Wilms' tumors has already been the focus of extensive research [12]. So far, a lower level of *WT1* gene transcripts in tumors has been revealed and a correlation of *WT1* mutations with stromal-predominant histology of nephroblastomas could be demonstrated [1]. The role of *WT1* in renal development and maturation of blastema cells suggests that abnormalities of this gene may be involved in the persistence of blastema and hence have a role in the early pathogenesis of Wilms' tumors [11]. Consistent with such previous results, in the unborn fetus presented in this article, transcripts of *WT1* were not detected in the nephrogenic rests but expression was found in the adjacent tissue.

Other genes, including *H19* and *IGF2* (located at 11p15 downstream of *WT1*) and a putative *WT2* at the same location, are likely to be involved in the pathogenesis of Wilms' tumors. *H19* is a developmentally regulated gene with putative tumor suppressor activity, and loss of *H19* expression may be involved in Wilms' tumorigenesis [4]. Drummond et al. (1992) could demonstrate that the *WT1* gene product binds to multiple sites in the promoter region of *IGF2* and acts as a potent transcription repressor in vivo [2]. In a report from Reeve et al., it is stated that in Wilms' tumors, an overexpression of the *IGF2* protein is found [10]. Others reported a loss of imprinting of *IGF2* in sporadic Wilms' tumors and in a group of patients with Beckwith-Wiedemann syndrome [15]. In the present unborn, we were able to detect biallelic expression of *IGF2*, and *WT1* RNA expression was not measurable with the chosen setup in the nephrogenic rests. These findings support the assumption that a loss of *WT1* causes an *IGF2* overexpression and acts as a repressor for *IGF2* transcription. The data from the literature and our results suggest that the loss of *WT1* and the overexpression of *IGF2* possibly support the development of nephrogenic rest to a nephroblastoma.

Concerning the combination of Wilms' tumor and chromosomal aberration, there is the WAGR syndrome showing aniridia, hemihypertrophy, genitourinary dysplasia, mental retardation and other congenital anomalies, and Wilms' tumor [8]. It is well known that this syndrome is associated

Fig. 3 **a** Expression of *WT1*, *IGF2*, *H19*, and β -*Gus* in different compartments. *FG* Forming glomeruli, *T* tubuli, *NG* nephrogenic rests. The loss of *WT1* expression in *NG* is obvious. **b** Imprinting analysis of *IGF2*. Lanes *a* and *b* show different polymorphism restriction products (control). Lane *c* shows that the two different alleles are present on DNA level (heterozygosity). In lane *d*, expression of *IGF2* mRNA is shown (*NG* tissue). Because two bands are visible, *IGF2* must be biallelically expressed. Controls of normal tissue show only one band (data not shown)

with a deletion of chromosomal segment 11p13 on which also the *WT1* gene is located.

Up to now, only two reports of trisomy 13 and nephroblastomatosis, with respect to Wilms' tumor, are to be found in the literature, but no molecular findings are reported [6, 13]. Thus, the question whether the parallel occurrence of trisomy 13 and nephroblastomatosis is a coincidence or whether there is a link between both abnormalities has to be resolved by further investigations.

Follicular dendritic cell tumor of the mediastinum: expression of fractalkine and SDF-1 α as mast cell chemoattractants

Received: 27 November 2005 / Accepted: 5 December 2005 / Published online: 12 January 2006
© Springer-Verlag 2006

Abstract Follicular dendritic cell tumor (FDCT) is a rare tumor mainly located in laterocervical lymph nodes. We report one case of mediastinal FDCT associated with a history of bullous skin disease and clinically obvious immunosuppression. This tumor was characterized by heavy mast cell infiltration. Mast cells were in close relationship with tumor cells as demonstrated by ultrastructural examination and their presence are probably related with the strong expression of mast cell chemoattractants as fractalkine and stromal cell-derived factor-1 α by tumor cells. The long follow-up period of more than 17 years allowed to us assess the relatively indolent evolution of this tumor characterized by three slowly growing local recurrences without metastasis.

Introduction

Follicular dendritic cell tumor (FDCT) is an uncommon tumor, usually affecting laterocervical lymph nodes. Among the nearly 70 cases reported hitherto in the literature, 11 cases are of mediastinal localization [1, 3, 4, 6, 9, 10, 14].

We report one additional case of mediastinal FDCT occurring in a patient with a long-lasting history of bullous skin disease diagnosed as pemphigus vulgaris and clinically obvious immunosuppression. This case is characterized by the unusual presence of numerous mast cells in close relationship with tumor cells as demonstrated by ultrastructural examination. The tumor had a relatively indolent behavior because the patient is still alive after a 17-year follow-up despite three local recurrences after several years of latency.

Clinical history

The patient, a 45-year-old male Italian was referred to our institution for recurrence of a mediastinal mass. He had a long history of pemphigus vulgaris treated with corticoids since 1985. Complete surgical excision of a mediastinal mass of 10 cm in size from anterior and median mediastinum was performed in Italy in March 1987; the histological diagnosis was diffuse mixed B cell lymphoma. At this time, there was neither abdominal nor peripheral lymphadenopathy and bone marrow biopsy was negative. Chemotherapy was delayed for 4 months because of the occurrence of visceral leishmaniasis. The patient finally received six cures of Cytoxan, hydroxydaunomycin (Adriamycin), vincristine (Oncovin), and prednisone from July 1987 to February 1988. In May 1988, a chest CT scan on follow-up disclosed a residual mediastinal mass of 2 cm large associated with a parenchymal nodule in Nelson's lobe. Both lesions were surgically removed; the histological diagnosis of tuberculosis was confirmed by bacteriological results identifying *Mycobacterium Tuberculosis* from culture. In April 1989, a new chest CT scan showed again a 2.5-cm large mass located in the anterior medias-

tinum. This lesion remained stable at least until 1992. At this time, chronic hepatitis C was diagnosed. Then the patient was followed up for 8 years by chest X-ray.

A chest CT scan performed in November 2000 showed a large polylobated mediastinal tumor of 15 cm rising to the left subclavicular area. Clinical examination was otherwise normal without any sign of compression. There was no cutaneous or mucosal blistering lesion. A surgical biopsy of the subclavicular tumor extension was rapidly performed and the histological diagnosis of FDCT led to the decision to undergo surgical resection, which was performed in January 2001. The tumor was encapsulated and could be totally excised in two parts. The patient recovered uneventfully after the operation.

He came back 2 years later in March 2003 for a left cervical mass of 7 cm in size close to the thyroid. This new lesion was considered to have developed from seeding on the biopsy tract and was surgically removed. A new small and asymptomatic paraesophageal tumor was disclosed on CT scan in December 2003. The patient was followed up for one additional year until the onset of compression symptoms led to a new surgical thoracic procedure successfully performed in December 2004.

Material and methods

All techniques were performed on samples from the mediastinal tumor removed in 2001.

Immunohistochemistry

Immunohistochemical studies were performed on paraffin and frozen sections using a labeled streptavidin biotin technique with the following antibodies (1) on paraffin sections: KL1 (Immunotech), anti-epithelial membrane antigen (EMA), anti-vimentin, anti-smooth-muscle actin, antidesmine, CD20, CD3, CD 68, anti-human leukocyte antigen anti-(HLA)-DR, anti-PS100, anti-neuron-specific enolase (NSE), CD31, CD34, c-kit (CD117), CD1a, anti-lysozyme, anti-latent membrane protein (LMP)1, CD35, CNA42, CD21 (Dakopatts), and anti-epidermal growth factor receptor (EGFr) (31G7—Zymed) and (2) on frozen sections: CD35, anti-HLA-DR, CD23 (Dakopatts), anti-stromal cell-derived factor-1 α (SDF-1 α) [2], and anti-fractalkine (CX3C) (Chemocentrix). Antifractalkine and anti-SDF1 immunostaining was performed on control tissues, i.e., normal lymph node and fetal liver. Antigen retrieval was achieved on paraffin sections by steaming in citrate buffer pH 6.1 prior to incubation with all antibodies except anti-actin, anti-LMP1, anti-PS100, and anti-lysozyme, and by protease digestion for anti-LMP1.

In situ hybridization

Non-isotopic in situ hybridization for Epstein–Barr virus-encoded RNA (EBER) was performed on paraffin sections

using fluorescein isothiocyanate-conjugated PNA probe for EBER and detection kit from Dakopatts.

Electron microscopy

Tissue samples fixed in a 2.5% glutaraldehyde solution were postfixed in osmium tetroxide and embedded in epoxy resin. Ultrathin sections were cut and contrasted with uranyl acetate and lead citrate after the selection of appropriate blocks on semithin sections examination. The ultrathin sections were examined using a JEOL transmission electron microscope JEM 100C.

Results

Gross findings

The resection specimen of the mediastinal mass was composed of two parts weighting 410 and 130 g and measuring 12 \times 9 \times 8 and 9 \times 6 \times 5 cm, respectively. The tumor was well limited by a thin capsule. On the cut section, it was homogeneously whitish and firm without any necrotic or hemorrhagic area. A normal residual thymus of 9 cm in its highest dimension was identified at the right edge of the mass. The recurrent cervical lesion removed in March 2003 was a well-limited mass of 6 cm in size with the same gross aspect. In December 2004, the surgical specimens consisted of a paraesophageal and a cervical tumor measuring 6 \times 5 \times 4.5 and 4 \times 2.5 \times 2.5 cm.

Histological findings

The mediastinal mass and the recurrent lesions showed the same histological pattern. The tumor cells were spindle or ovoid with a moderate amount of lightly eosinophilic cy-

Fig. 1 Spindle cells organized in short fascicles intermingled with thin collagen bundles (HE: original magnification \times 400)

Fig. 2 Giemsa staining highlighting the presence of numerous mast cells in addition to small lymphocytes and plasma cells (Giemsa: original magnification $\times 400$)

toplasm; they were arranged in short fascicles intermingled with numerous bundles of hyaline collagen (Fig. 1). Their nuclei were often irregularly folded with clear nucleoplasm and one or two nucleoli that are small to medium in size. Nuclear atypia were mild. Mitotic count was low, less than 1 mitosis per 10 high-power fields. Frequent binucleated cells and occasional symplasmic elements with abundant eosinophilic cytoplasm were seen. There was no necrotic change.

The entire tumor was sprinkled with a heavy population of small lymphocytes, often cuffing around blood vessels. In addition, numerous mast cells highlighted on Giemsa staining were present (Fig. 2). Plasma cells were rare.

The vasculature was represented by a rich network of small blood vessels, some of them with hyalinized wall. There was no residual lymphoid tissue within the mass. The adjacent thymus was histologically normal.

On review, the histological pattern of the first mediastinal tumor removed in 1987 was exactly similar and the revised diagnosis for this tumor was FDCT.

Fig. 3 Tumor cells showing strong immunoreactivity for CD21 (Immunoperoxidase: original magnification $\times 200$)

Fig. 4 Strong cytoplasmic and membranous staining of tumor cells with anti-fractalkine antibody (Immunoperoxidase: original magnification $\times 400$)

Immunohistochemistry and in situ hybridization

Tumor spindle cells were strongly positive for vimentin and CD68 and negative for cytokeratin, EMA, alpha-actin, desmin, NSE, PS100, CD31, CD34, c-kit, CD1a, and lysozyme. They expressed all known markers of follicular dendritic cells: HLA-DR, CNA42, CD35, CD21 (Fig. 3), and CD23. Anti-EGFr staining was strongly positive on most tumor cells with a membrane pattern. The small lymphocytes were a mixture of CD20-positive B cells and CD3-positive T cells. The background cells also included numerous c-kit positive mast cells. LMP1 immunostaining was negative.

Anti-fractalkine antibody demonstrated a strong cytoplasmic and membranous positivity of tumor cells (Fig. 4) and of endothelial cells. On lymph node control sections, endothelial cells, interdigitating dendritic cells, and follicular dendritic cells were positive for fractalkine.

Fig. 5 Strong cytoplasmic and membranous staining of tumor cells with anti-SDF-1 α antibody (Immunoperoxidase: original magnification $\times 1,000$)

Fig. 6 Electron microscopy showing tumor cells with long and complex interdigitating processes with some desmosome-like junctions (arrow). Mast cell at the top containing granules at different stages of maturation and connected to a tumor cell process by a semijunction (double arrow) 1 cm=0.5 μ

Anti-SDF1 antibody disclosed a membranous and cytoplasmic staining of tumor cells and endothelial cells (Fig. 5). On the fetal liver section, SDF1 was strongly expressed on epithelial ductal cells. Tumor cells were negative for EBER probe.

Ultrastructural findings

The tumor cells had numerous interwoven long villous processes, which were sometimes connected by desmosome-like junctions. The cytoplasm did not contain myofilaments.

The numerous mast cells had granules at different stages of maturation. Some mature granules were close to the cytoplasmic cell membrane. Mast cells were close to the tumor cells and frequently their villous processes were intermingled with those of tumor cells. Few semijunctions of the mast cell membrane were present at the contact with the tumor cells (Fig. 6).

Discussion

FDCT are rare tumors, the majority occurring in latero-cervical lymph nodes. Around 15% of all published cases arose or involved the mediastinum [1, 3, 4, 6, 9, 10, 13]. Four among these cases complicated a Castleman's disease [3, 10]. A special form of pemphigus called paraneoplastic pemphigus was described in association with FDCT arising or not from Castleman's disease [16]. In 1985, at the time when the diagnosis of pemphigus vulgaris was made in our patient, the paraneoplastic pemphigus was not yet described and the autoantibodies specific for this disease were not characterized. No serum contemporary with the skin disease was available for our patient to test retrospectively these autoantibodies. Never-

theless, the lack of parallelism between the evolution of the skin bullous disease and the mediastinal tumor is not in favor of a paraneoplastic process.

The expression of EGFr by tumor cells is in agreement with recently published data, which showed that nearly 90% of FDCT expressed EGFr and could be useful for therapeutic approach [17].

Reactive inflammatory cells in FDCT usually consist of small lymphocytes of T cell phenotype and plasma cells. The presence of numerous mast cells scattered all over the tumor is a previously unreported morphological feature in FDCT. At the ultrastructural level, the mast cells were in very close relationship with tumor cells and appeared in a state of active secretion. This feature prompted us to look for the expression of chemokines acting as mast cell chemoattractants such as fractalkine and SDF-1 α . Fractalkine is a CX3C chemokine constitutively expressed in diverse cell types including follicular dendritic cells within hyperplastic lymph nodes [5]. SDF-1 α mRNA and protein are expressed by FDC-like cells in culture [7]. Both chemokines were strongly and diffusely expressed on tumor cells. Because mast cells express both CX3CR1 receptor for fractalkine and CXCR4 receptor for SDF-1 α [8, 12] and fractalkine was shown to have in vitro chemotactic activity toward mast cells [11], the expression of fractalkine and SDF-1 α is likely to be responsible for the presence of mast cells in close relationship with the tumor cells. Ultrastructural features in our case suggest that mast cells are in a state of active secretion. Mast cell infiltrations of various degrees were described in other types of non-epithelial tumors such as leiomyomas and leiomyosarcomas in the uterus [19], soft-tissue sarcomas [18], and more recently in the myxoid epithelioid variant of gastrointestinal tumor [15]. The presence of mast cells would be associated with better prognosis in some of these tumors [18, 19] and could also be a marker for a more indolent course of FDCT. FDCTs are considered as an intermediate-grade sarcoma associated with recurrence, metastatic, and mortality rates of 43, 24, and 17%, respectively [1]. We have followed up on our patient for an exceptionally long period of 17 years while most reported cases have follow-up data with a time interval inferior to 5 years. After an initial treatment consisting of surgical complete excision and adjuvant chemotherapy that is active against lymphoma, he experienced three slowly growing local recurrences at 13, 16 and 17 years without evidence of metastasis despite the large tumor size at the first recurrence. In the largest retrospective study of FDCT [1], only intraabdominal location and nuclear pleomorphism are significantly associated with a higher rate of recurrence, metastasis, or death. In addition, large sized tumors (>6 cm), the presence of coagulative necrosis, abnormal mitoses, high mitotic activity, and lack of adjuvant therapy are likely to be morphologic predictors of unfavorable events [1, 13]; our patient met only the first of these criteria. Very few data are available concerning specifically the course of mediastinal FDCT but in most reported cases, tumors exhibit histological signs of aggressive growth [6], which is not the case for our patient.

To the best of our knowledge this is the first demonstration of the expression of fractalkine and SDF-1 α on the tumoral counterpart of follicular dendritic cells. Other FDCT have to be tested to determine the accuracy of fractalkine and SDF-1 α as diagnosis markers for this type of tumor, which is often a difficult diagnostic challenge.

Acknowledgements The authors thank Prof. Thierry Molina from the Department of Pathology Hôtel-Dieu AP-HP Paris and Dr Agnès Carlotti from the Department of Pathology Paul Brousse Hospital AP-HP for helpful diagnostic discussions, and Ingrid Durand-Gasselín from Institut Paris-Sud sur les Cytokines Hôpital Antoine Bécélère - Clamart for technical assistance.

Nodular lymphoid lesion of the liver with simultaneous focal nodular hyperplasia and hemangioma: discrimination from primary hepatic MALT-type non-Hodgkin's lymphoma

Received: 28 July 2005 / Revised: 15 September 2005 / Accepted: 21 September 2005 / Published online: 6 December 2005
© Springer-Verlag 2005

Abstract Nodular lymphoid lesion (NLL) of the liver is a rare but unique entity and has also been termed reactive lymphoid hyperplasia of the liver. We describe the histological, immunohistochemical and molecular biologic findings of a case with NLL and two other tumors of the liver. The nodular lymphoid mass found in the liver was composed of heterogeneous small lymphocytes forming reactive follicles. Plasma cells, few immunoblasts, centroblasts, few macrophages, epithelioid cells, and giant cells were seen. The lymphoid infiltrate displaced the adjacent hepatic parenchyma. By immunohistochemistry and molecular studies, the lymphocytes were found to be polyclonal. The diagnosis of NLL was made. In addition to NLL, focal nodular hyperplasia and hemangioma were detected. The discrimination of NLL from primary hepatic malignant non-Hodgkin's lymphoma of mucosa-associated lymphoid tissue-type may pose diagnostic difficulties and may require the use of immunohistochemical and molecular techniques. The simultaneous occurrence of NLL with focal nodular hyperplasia and hemangioma in the liver has not been described before.

Keywords Liver neoplasms · Non-Hodgkin's lymphoma · Pseudolymphoma

Introduction

Nodular lymphoid lesion (NLL) is a rare condition observed in the liver. It is characterized by a nodular mass that displaces the normal parenchyma of the liver and is composed of lymphoid tissue with reactive follicles. NLL is a

benign lesion, which has to be distinguished from malignant non-Hodgkin's lymphoma (NHL). The discrimination from primary hepatic lymphoma of the mucosa-associated lymphoid tissue (MALT) type, as introduced by Isaacson et al. in 1995 [4], is especially crucial and may pose considerable problems relying on conventional histological examination alone.

The case presented here displays three different benign liver tumors. In addition to NLL, focal nodular hyperplasia and hemangioma were detected. To the best of our knowledge, this is the first report of a simultaneous occurrence of these tumors in the liver.

Clinical history

A 36-year-old female patient was referred to the department of surgery with two tumors of the liver involving segments VII and VIII. The liver lesions had been detected by computed tomography, which had been performed as screening because of an ovarian cyst. The abdomen was soft on palpation with no pain on pressure and no palpable tumor. An open excisional biopsy of the two tumors was performed to rule out malignancy and establish a definite diagnosis. NHL could not be definitively ruled out in intraoperative frozen section histology. Therefore, a staging procedure was performed with the excision of representative lymph nodes from the pancreas, hepatoduodenal ligament, and mesentery of the small bowel. The postoperative course was uneventful.

Material and methods

Tissue was fixed in 4% buffered formalin, processed and embedded in paraffin. Five-micron sections were stained with hematoxylin and eosin. In addition, Giemsa and Ziehl–Neelsen staining were performed.

Immunohistochemical staining was performed on an automatic immunostainer (Autostainer 720, LabVision, Fremont, CA) by a labeled streptavidin biotin method

using alkaline phosphatase with fast red as chromogen. The following antibodies were applied: CD3 (PS1, Novocastra, Newcastle upon Tyne, UK), CD20 (L26, DakoCytomation, Glostrup, Denmark), immunoglobulin (Ig) κ and λ light chains (rabbit antihuman, Dako), and pan-cytokeratin (MNF116, Dako). Slides were pretreated by pressure cooking in 1 mM EDTA pH 8.0 for 45 sec for cytokeratin-, CD3-, and CD20-staining and by enzymatic digest with protease for 13 min (Protease XI, concentration 0,125%, Sigma-Aldrich, Munich, Germany) for staining of Ig light chains.

For polymerase chain reaction (PCR)-amplification of Ig-heavy chain (IgH) and T cell receptor γ (TCR- γ) chain gene rearrangements, the BIOMED-2 primer sets were used as recommended [17]. The length distribution of PCR fragments amplified was analyzed on an automated sequencer using the GeneScan software (ABI-prism 3100, Applied Biosystems, Darmstadt, Germany).

Results

A subcapsular specimen of 3.5×2.5×2-cm size was obtained from liver segment VIII. The cut surface displayed a brownish tumor of 1.8-cm diameter beneath the capsule. Upon macroscopic examination, the lesion seemed well-circumscribed, without a capsule or pseudocapsule. Histologically, the entire tumor consisted predominantly of mononuclear cells with formation of some lymph follicles (Fig. 1a,b). Between the follicles were small lymphocytes and plasma cells, few immunoblasts, some epithelioid cells, and giant cells (Fig. 1f). The lymphoid infiltrate displaced the hepatic parenchyma in a serpiginous fashion.

In the immunohistochemical investigation, the follicles contained CD20⁺ centrocytic and some centroblastic B lymphocytes (Fig. 1c). B cells and plasma cells were polyclonal in κ and λ light chain stainings. The interfollicular area showed a mixed population of CD3⁺ T cells (Fig. 1c,d) and

CD20⁺ B lymphocytes. Remnants of lymphoid sinus structures were not apparent. Bile ductules were found near the margin of the lesion within the lymphoid infiltrate, showing focal epithelial cell injury in cytokeratin staining (Fig. 1e). Ziehl-Neelsen staining was negative for mycobacteria.

A second tumor of 0.3-cm diameter was found subcapsular in the adjacent tissue of this specimen. Histologically, it consisted of irregular blood vessels with inconspicuous endothelial cells (Fig. 2b). The diagnosis of hemangioma was made.

The specimen from liver segment VII measured $4 \times 3.5 \times 1.5$ cm and contained a tumor of 1.5-cm diameter. The tumor was brownish and had a central scar. Microscopi-

cally, it displayed nodular hyperplastic hepatic parenchyma. The nodules were separated by fibrous septa that formed a central scar. Numerous bile ductules were present in the connective tissue. At the tumor margins and in the stroma, aggregates of lymphocytes and plasma cells were observed (Fig. 2a). Taken together, the tumor showed the typical morphology of focal nodular hyperplasia (FNH).

In the liver parenchyma surrounding the tumors, the portal fields were infiltrated by few lymphocytes and plasma cells. A punch biopsy obtained from the left lobe of the liver showed normal liver tissue without an increased number of inflammatory cells. Granulomas were absent.

Lymph nodes excised from three different locations in the abdomen (peripancreatic, hepatoduodenal ligament, and

mesentery of the small bowel) displayed a normal lymph node architecture. Sinuses were dilated with features of vascular sinus transformation. Interfollicular zones were prominent. No atypical infiltrate or granuloma was observed.

Fragment length analysis of amplified IgH and TCR- γ fragments was performed to assess clonality of B and T lymphocytes in the liver lesion from segment VIII. A polyclonal pattern of IgH and TCR- γ gene rearrangements was observed (not shown).

Discussion

Many lymphoid tumors formerly called pseudolymphoma have been attributed to NHL of MALT-type in recent years. However, some truly reactive nonneoplastic lesions remain, for which the term NLL seems appropriate. Reports in the literature about such lesions in the liver are rare (Table 1). Sharifi et al. [15] published three cases of NLL in 1999, describing similar features as found in the case presented here. Reactive lymphoid follicles were surrounded by a heterogeneous cellular infiltrate, displacing and invading surrounding hepatic tissue. Few lymphoepithelial lesions were present and in one case Ig-light chain restriction was observed by immunohistochemistry. However, there was no evidence of a monoclonal B cell population by molecular genetic analysis. One case in that series contained some scattered epithelioid cells and giant cells, as did the case presented here. An underlying chronic inflammatory process as a probable cause of the disease, as reported by Sharifi et al. [15], was not apparent in the case presented here (Table 1).

NLL has to be distinguished from B cell NHL of MALT-type. First described in 1983 by Isaacson and Wright [3] in the stomach, lung, thyroid, and salivary gland, MALT-type lymphomas have also been reported in numerous other body sites [19]. They recapitulate the features of the mucosa-associated lymphoid tissue and often occur at sites otherwise devoid of such [2]. In 1995, Isaacson et al. [4] published a series of four low-grade NHL of MALT-type of the liver. Since then, a number of small series and sporadic cases of primary hepatic MALT-type lymphoma have been reported [1, 8, 9, 13, 18, 19]. All of these cases displayed a nodular mass of lymphoid tissue with lymphoid follicles and a proliferation of heterogeneous small B cells. Lymphoepithelial lesions were usually present. Primary biliary cirrhosis or chronic hepatitis preceding and accompanying the lymphoma was reported in a few cases [4, 9, 13, 18]. In most cases of primary hepatic MALT-type lymphoma, evidence of B cell clonality was based on Ig-light chain restriction detected by immunohistochemistry. Only in single cases, clonality of lymphocytes was assessed by a molecular gene rearrangement study [8].

At first glance, the case presented here seems to resemble NHL of MALT-type. However, a mixed infiltrate of B and T cells and no restriction of Ig-light chains was seen by immunohistochemistry. A polyclonal B cell pattern was observed by molecular fragment length analysis of rearranged IgH genes. In a needle biopsy of the liver no

underlying inflammatory process was apparent. Normal histology of abdominal lymph nodes from various sites ruled out systemic disease. Therefore, the diagnosis of NLL of the liver seems justified in this case.

In the case presented here, NLL occurred simultaneously with FNH and hemangioma. FNH with a lymphoma-like presentation has been reported before. Schmitz et al. [14] described a case with a single lesion of the liver displaying typical FNH-like features with a central scar by radiological examination. Histologically, a lymphoma-like infiltrate was found in a biopsy of that tumor. Here, FNH and the lymphoid lesion were found separate from each other and the latter did not display a central scar or other histological features of FNH. Thus, it is unlikely that the lymphoid tumor represents an unusual appearance of FNH. Because FNH and hemangioma are both lesions frequently found in the liver, their simultaneous appearance with NLL is most likely coincidental.

The rareness of both NLL and MALT-type non-Hodgkin's lymphoma of the liver and their similarity in many histological features may pose considerable problems in their distinction. The growth of prominent centrocyte-like B cells in a marginal zone pattern and assessment of clonality by immunohistochemical and molecular genetic investigations may be the best discriminating findings. NLL of the liver is a benign process that is adequately treated by local excision. In cases like this, the erroneous diagnosis of low-grade NHL may only be avoided by a thorough histological examination and the use of immunohistochemical and molecular genetic techniques.

Oncocytic adenocarcinoma of the rectum arising on a villous adenoma with oncocytic features

Received: 6 October 2005 / Accepted: 15 December 2005 / Published online: 1 February 2006
© Springer-Verlag 2006

Abstract Rectal adenocarcinoma with diffuse oncocytic features is a very rare lesion, having been reported only once in the English literature. We describe a case of oncocytic adenocarcinoma of the rectum, associated with a villous adenoma, arising on a 66-year-old man. On histological examination, the adenocarcinoma was composed of neoplastic glands lined by a strongly eosinophilic, granular epithelium that deeply infiltrated the rectal wall. Some basophilic calcifications were present in the gland lumina. Superficially, a villous adenoma with high-grade dysplasia was evident; adenomatous cells showed focal eosinophilic changes, consisting of a large granular cytoplasm, an oval atypical nucleus, and a prominent nucleolus. Immunohistochemically, neoplastic glands reacted strongly with antimitochondria antibody, carcinoembryonic antigen, cytokeratin 20, p53, and CDX2. Molecular alterations observed in oncocytic changes and their significance with regards to neoplastic transformation are briefly discussed.

Keywords Adenocarcinoma · Rectum · Oncocytic tumor · Mitochondria · Immunohistochemistry

Introduction

Adenocarcinomas of the large bowel are very common malignant neoplasias. Many histological subtypes have been described (mucinous, signet-ring cell, small cell, squamous cell, adenosquamous, medullary, and undifferentiated) [21]

and have been included in the World Health Organization histological classification of tumors of the colon and rectum [5]. Nevertheless, an oncocytic variant of colorectal adenocarcinoma has been reported only once [20], and very few cases of oncocytic adenocarcinoma of the stomach have been collected recently [25]. Although oncocytic changes can be present in many gastrointestinal neoplasias [16], from an analysis of pertinent literature, it is clear that pure oncocytic neoplasias are far rarer in the gastrointestinal tract than in other sites.

In the present case, an oncocytic adenocarcinoma arising on a precursor lesion (a villous adenoma) with oncocytic changes is described. Extension of oncocytic modifications may allow to define a new histological subtype among colorectal adenocarcinomas.

Clinical history

A 66-year-old man presented for spontaneous rectal bleeding. He had no previous history of inflammatory bowel disease. During echoendoscopy, a large vegetating neoplasia was found in the rectum, extending from 5 to 13 cm above the pectinate line. On ultrasound examination, it apparently infiltrated the submucosa, with no extension into the tunica muscularis; no regional enlarged lymph nodes were found. Multiple biopsies were taken with superficial sampling. On histological examination, the lesion resulted in a villous adenoma with high-grade dysplasia. The patient underwent an endoscopic resection of the rectum and of regional lymph nodes, with subsequent sigmoidostomy. The patient was disease-free after 3 months.

Materials and methods

The specimens were routinely formalin-fixed, paraffin-embedded, and cut overnight. Microscopic slides were stained with hematoxylin-eosin and periodic acid-Schiff. Immunohistochemical stainings were performed using the labeled streptavidin-biotin method in a Lab Vision auto-

stainer (Fremont, CA, USA), with the following antibodies: CDX2 (BioGenex, California, USA), carcinoembryonic antigen (CEA; DakoCytomation, Glostrup, Denmark), chromogranin A (DakoCytomation), cytokeratin 7 (NeoMarkers, California, USA), cytokeratin 20 (NeoMarkers), Ki-67 (DakoCytomation), antimicrotubule antibody (BioGenex), p53 (DakoCytomation), and bcl-2 (NeoMarkers). An appropriate positive control was used.

Results

Macroscopically, a centrally ulcerated tumor (8 cm in the greatest axis) was present (Fig. 1), replacing the whole rectal circumference. On histological examination, the lesion was a moderately differentiated adenocarcinoma, consisting of irregular, branching glands lined by cells

Fig.2 a Infiltrating glands lined by oncocytes and containing some calcifications. **b** High-power view of a neoplastic gland with intraluminal calcifications

Fig.3 Adenomatous glands lined by columnar cells with a finely granular, eosinophilic cytoplasm and with an oval-to-round nucleus (*inset*)

with a finely granular, eosinophilic cytoplasm, a round nucleus, and a prominent nucleolus (Fig. 2a). Many glands contained nuclear debris and microcalcifications (Fig. 2b). The adenocarcinoma invaded through the muscularis propria into nonperitonealized perirectal tissues and reached the radial margins; distal surgical margins were tumor-free. Neither mitoses, nor vascular invasion, nor foci of usual colorectal adenocarcinoma were noted. Around the infiltrating carcinoma, a villous adenoma was found with high-grade dysplasia (Fig. 3); the glands were lined by cells with a large, granular, eosinophilic cytoplasm and an oval-to-round nucleus (Fig. 3). A transition between a classical adenomatous epithelium and these unusual eosinophilic cells was evident. Residual mucosa was unremarkable. Seventeen regional lymph nodes were found, with no evidence of metastasis. According to the American Joint Committee on Cancer, the pathologic tumor stage was pT3N0-R1.

On immunohistochemistry, the adenocarcinomatous component reacted strongly with antimicrotubule antibody (Fig. 4a), cytokeratin 20, and CEA. The adenomatous component was diffusely positive with cytokeratin 20 and CEA, whereas the antimicrotubule antibody reacted focally (Fig. 4b). Ki-67 was positive in 3 and 30% of neoplastic cells in the adenocarcinoma (Fig. 5a) and adenoma, respectively.

Fig.4 The antimicrotubule antibody is diffusely positive either in the adenocarcinoma (a) or in the villous adenoma (b), with a granular cytoplasmic pattern (*inset*)

Fig.5 The Ki-67 rate is very low in infiltrating adenocarcinoma (a). All neoplastic cells display strong immunoreactivity with CDX2 (b) and p53 (c)

Intranuclear immunoreactivity for CDX2 (Fig. 5b) and p53 (Fig. 5c) was noted either in the adenocarcinoma and in the adenoma; in the former, p53 was much stronger than in the latter. Cytokeratin 7 and bcl-2 were unexpressed either in the adenocarcinoma or in the villous adenoma.

Discussion

Oncocytic cellular changes, by definition [6], are morphologically characterized by a finely granular, wide, and eosinophilic cytoplasm and a round nucleus with an evident nucleolus. The “swollen” appearance of oncocytes and their granularity in histological sections are due to the accumulation of mitochondria. Although oncocytic metaplasia is quite common in some epithelia (i.e., intercalated ducts of the salivary glands, or the follicular thyroid epithelium in Hashimoto’s thyroiditis), the terms *oncocytoma* and *oncocytic carcinoma* usually designate tumors that mostly consist of oncocytic cells. How accumulation of mitochondria leads to neoplasia is still an object of debate, but many advances have been achieved in the comprehension of oncocytic tumors in recent years. Most recent review articles on oncocytic neoplasias—some of which offer an exhaustive explanation of biochemical mechanisms underlying mitochondrial accumulation [26]—deal with oncocytic (Hürthle cell) tumors of the thyroid gland [12, 24]. In an oversimplified way, oncocytic transformation is due to an alteration of mitochondrial DNA, probably following oxidative stress, which causes a defective function of organelles and leads to a compensatory increase in cellular mitochondrial content. This degenerative aging process is likely to be the same in all tissues undergoing oncocytic transformation; in fact, it is not possible to morphologically distinguish thyroid oncocytic cells from, for example, renal oncocytic cells. The first case of oncocytic adenocarcinoma of the rectum has been described by Piscitelli et al. [20]. Since then, no other similar cases have been reported in the large bowel, even though oncocytic neoplasias are frequently observed in many sites [3, 15, 17, 22, 28]. Only focal oncocytic changes have been observed in ordinary carcinomas of the gastrointestinal tract [16], and ten cases of gastric oncocytic adenocarcinoma have been extensively discussed recently [25]. Máximo and Sobrinho-Simões [12] suggest that, in the digestive and respiratory tracts, cellular turnover is too high

to allow the accumulation of abnormal mitochondria; this would explain the exceptional occurrence of oncocytic tumors in these areas.

The present case is almost completely superimposable on the first described, as it is an oncocytic, infiltrating adenocarcinoma of the rectum, focally containing small basophilic microcalcifications. Some points of distinction are (1) the complete absence of areas of conventional colorectal adenocarcinoma and (2) the presence of a villous adenoma, which exhibits focal oncocytic changes as well. On immunohistochemistry, neoplastic cells are positive for anti-mitochondria antibody, diffusely in infiltrative glands and focally in the adenoma. They also have a typical colonic phenotype, with immunoreactivity to CDX2, CEA, and cytokeratin 20. Immunohistochemical evaluation of proliferative activity by Ki-67 antibody shows a very low rate in the adenocarcinomatous component, in comparison with that in the villous adenoma. This is not in keeping with the data reported by many papers [2, 7, 8, 23, 27], where the Ki-67 index is higher in carcinomas than in adenomas; it also contrasts with the deep penetration of proliferating cells through the rectal wall.

An alternative explanation for tumor growth (and the high stage of the neoplasia) is blockage of apoptotic cell death. Bcl-2 belongs to a family of genes that regulates cell death [1]; it is expressed in several normal and neoplastic tissues, mostly in developing epithelia [9, 10]. Interestingly, in thyroid carcinomas, bcl-2 expression varies according to the degree of differentiation and results in the absence of anaplastic carcinomas [11, 18, 19] and oncocytic tumors [13, 14]. Since bcl-2 is localized in the outer mitochondrial membrane, it is likely that mitochondrial anomalies cause reduced bcl-2 expression [12]. As mitochondria are also involved in the initiation of apoptosis [4] by a complex biochemical switch, it has been suggested that abnormal mitochondria are unable to start apoptosis itself [12].

In oncocytic thyroid tumors, p53 expression is evident in a high proportion of cases, either adenomas and carcinomas, but its biological significance is still unclear [13]. In the present case, p53 was strongly expressed, but its correlation with oncocytic transformation and low proliferative rate is unknown.

In conclusion, the pathogenesis of oncocytic transformation is still unresolved either in the thyroid gland, where it is

very common, or in the present case. So far, it is not possible to say whether oncocytic changes or intraluminal calcifications have functional implications in colorectal adenocarcinoma. Indeed, even though no prognostic considerations can be performed, oncocytic colorectal adenocarcinoma may constitute more than a morphological curiosity.

Phosphaturic mesenchymal tumor (mixed connective tissue variant): a case report with spectral analysis

Received: 8 December 2005 / Accepted: 19 December 2005 / Published online: 31 January 2006
© Springer-Verlag 2006

Abstract We present a further case of a rare mesenchymal neoplasm termed phosphaturic mesenchymal tumor (mixed connective tissue variant). The patient was a 42-year-old man with a long history of osteomalacia of unknown etiology with pathological bone fracture, abnormality of parathyroid glands, kyphosis, scoliosis, and spondylosis. Laboratory investigation disclosed hypophosphatemia, elevated serum alkaline phosphatase activity, and normal serum calcium level. The patient had a soft tissue mass in the right inguinal area, measuring 11×6×5 cm, which was previously interpreted as a calcified hematoma on sonography. The tumor was surgically removed. Grossly, the tumor was well circumscribed, unencapsulated, and had soft to dense consistency. The cut surface had a variegated appearance due to the presence of large hemorrhagic areas admixed with foci of grey-yellow tissue. Histologically, the tumor was composed of primitive mesenchymal cells, osteoclast-like cells, and cells showing myofibroblastic features without cytologic atypia. There were a well developed vascular network, microcystic areas, and poorly formed cartilaginous foci. Unusual and hitherto unpublished prominent features were flower-like, slate-gray crystals, widespread hemosiderin deposits and large areas of hemorrhages, with the latter comprising approximately 60% of the tumor. A spectral analysis indicated that chemically, the crystals mainly consisted of calcium phosphate and sodium nitrate.

Introduction

Phosphaturic mesenchymal tumor (mixed connective tissue variant) (PMTMCT) is the most frequent variant of a “heterogeneous” group of rare mesenchymal tumors, which often cause osteomalacia or rickets and are accompanied by specific biochemical abnormalities such as hypophosphatemia, hyperphosphaturia, elevated alkaline phosphatase activity, and low or inappropriately normal circulating 1.25 (OH)₂D levels. Classic PMTMCT has unique morphologic features. The tumors are mainly composed of small, bland, spindled cells embedded in a distinctively “grungy”, calcified, myxoid matrix, also often containing fat, microcysts, areas of hemorrhage, osteoclasts, foci of poorly developed cartilage, osteoid, or bone. The vascularity is often prominent, and focally it resembles that seen in hemangiopericytoma. The tumors typically follow a benign clinical course. After neoplasm resection, the serum phosphate concentration usually returns to normal values [1, 3–5, 7–9].

We describe a case of PMTMCT, including the clinico-pathologic features, ultrastructural findings, and results of spectral analysis of the lesional tissue.

Case report

A 42-year-old man presented in 2004 with a soft tissue mass in the right inguinal area that had been detected by somatostatin receptor scintigraphy during a recent hospitalization. His medical history was significant for a pathological fracture of the ulnar bone in 1995, with a protracted unsuccessful healing, requiring an operation in 1997. He was also followed up and treated for hypophosphatemia and osteomalacia of unknown etiology. No abnormality of parathyroid glands was previously found.

Fig. 1 **a** The cut surface of the tumor with extensive areas of hemorrhage. **b** Typical cells of phosphaturic mesenchymal tumor (mixed connective tissue variant). **c** Spindle-cell proliferation, hemosiderin deposits and osteoclast-like giant cells. **d** Numerous crystals and plentiful hemosiderin deposits. **e** Flower-like, slate-gray appearance of the crystals. **f** Prominent hemorrhage and vascular structures

Previous radiological investigations detected various skeletal abnormalities. Radiographic images consistent with osteomalacia were pseudofractures (Looser zone) in the distal diaphysis of the ulnar bone, ventral surface of S1, 12th rib, proximal metaphysis of both femurs, and superior pubic ramus. He had also kyphosis, scoliosis, and spondylosis L5. It is interesting to note that the sonographic investigation performed 6 months before the presentation disclosed a 4×7.8 cm mass in the right inguinal area, which was interpreted as a calcified hematoma.

Laboratory tests revealed a serum phosphate level of 0.55 mmol/l (normal range, 0.7–1.6l). Serum alkaline phosphatase was moderately elevated. Serum calcium was normal.

The patient was administered a long-term phosphate therapy and vitamin D. The soft tissue mass was surgically removed. After the operation, technetium-99 m 2-me-

thoxyisobutyl isonitrile scintigraphy of parathyroid glands revealed a lesion, measuring 1.8×1.0×1.6 cm. Histologically, the parathyroid lesion proved to be an adenoma.

The patient is alive without signs of recurrence of the soft tissue tumor and the parathyroid gland adenoma 15 months after the surgery.

Materials and methods

Tissues were fixed in glutaraldehyde, then in osmium tetroxide and embedded into the Spurr’s resin for ultra-structural study. Specimens were examined with a Philips (Eindhoven, The Netherlands) EM 208S electron microscope. X-ray fluorescence spectrometry was performed at the Institute of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University, Prague,

Czech Republic using the standard hardware (X'Pert Pro) and software (X'Pert HighScore 1.0d) supplied by PANalytical B.V., Almelo, The Netherlands.

Pathological findings

As can be seen, the tumor was a well circumscribed, unencapsulated mass that measured 11×6×5 cm. It had a soft to dense consistency. The cut surface had a variegated appearance due to the presence of large hemorrhagic areas admixed with foci of grey-yellow tissue (Fig. 1a). There was no necrosis.

Histopathologically, the tumor was separated into nodules by septa. The margins of the tumor appeared well delimited from the surrounding muscle, fat, and fibrous tissues. The neoplasm had an appearance of a typical PMTMCT (Fig. 1b). The tumor was composed of small, spindle to oval cells that grew in sheets. There were also clusters of osteoclast-like giant cells, microcystic areas, and poorly formed cartilaginous foci (Fig. 1c). Neither cellular or nuclear pleomorphism nor atypical mitotic figures were found. There were many crystals within the tumorous mass (Fig. 1d). They had a flower-like, slate-gray appearance (Fig. 1e). The vascular network was prominent and consisted of thin-walled capillaries, sinusoids, and lacunae (Fig. 1f). There were also areas of wide-open vascular lumens with a regular endothelial lining stuffed with erythrocytes (Fig. 1f). There were also extensive areas of hemorrhage and hemosiderosis, and these comprised at least 60% of the tumor (Fig. 1c,d,f).

Ultrastructural findings

Electron microscopy had shown osteoclast-like cells, and irregular, primitive-appearing stromal cells with markedly convoluted nuclei, organelle-poor cytoplasm, and occasional stretches of basal lamina. The third type of cells showed myofibroblastic features. These cells disclosed irregular, stellate cellular outlines, partly enveloped by a basal lamina and pinocytotic vesicles. Their cytoplasm contained abundant cisterns of rough endoplasmic reticulum, variable numbers of mitochondria, microfilaments, and dense bodies. The myxoid intercellular matrix was composed of collagen fibers and granules that sometimes formed globular aggregates. There were numerous granules of hemosiderin within the matrix. The blood vessels appear to represent normal capillaries and venules with myxoid walls.

Spectral analysis

Calcium phosphate and sodium nitrate were the dominant substances in the lesional tissue (Fig. 2, Table 1).

Table 1 The results of spectral analysis of the lesional tissue. Calcium phosphate and sodium nitrate were found to be the predominant substances (see also Fig. 2)

01-089-0311	27	2.290	Sodium nitrate	Na(NO ₃)	–

Discussions

Our case is unusual in that the tumor exhibited large areas of hemorrhage, prominent hemosiderosis, and widespread crystals, which altogether often masked the tumor itself. Although prominent vascularity and focal hemorrhages are said to be typical histologic features of PMTMCT, such massive hemorrhages were not found in the English language literature. Coupled with the crystal deposits, which is another hitherto unpublished occurrence, this feature probably explains the diagnostic error of the sonographic examination (misinterpreted as calcified hematoma) in our case, and may also be a potential diagnostic pitfall histologically. Otherwise, the lesion in our patient manifested typical histologic and ultrastructural features.

The coexistence of parathyroid hyperfunction and oncogenic osteomalacia, including osteomalacia caused by PMTMCT, is rare. It has been found in approximately 10% of cases of osteomalacia [6]. All those patients with impaired parathyroid function received anorganic phosphate supplements, which may have stimulated parathyroid hormone secretion and ultimately led to parathyroid autonomy [2, 6]. Microscopic examination showed hyperplasia/adenoma of parathyroid glands [2, 6]. The data from our case are consistent with this hypothesis.

To our knowledge, this is the first report in which a spectral analysis of matrix dystrophic calcification was performed. It demonstrated that the crystals within the tumorous mass were made up of calcium phosphate and sodium nitrate mainly.

In summary, we have described a case of PMTMCT with unusual secondary changes of the lesional tissue such as prominent hemorrhage, hemosiderosis, and formation of crystals. Clinicians and pathologists should be aware of these features because it may prevent a diagnostic pitfall.

Acknowledgement The authors wish to thank Dr. Marek Chvátal from the Institute of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University, Prague, Czech Republic, who performed the spectral analysis.

Salivary hybrid tumour: adenoid cystic carcinoma and basal cell adenocarcinoma

Received: 3 November 2005 / Accepted: 17 November 2005 / Published online: 13 January 2006
© Springer-Verlag 2006

Dear Editor,

Hybrid tumours of the salivary glands are very rare and since their description and definition by Seifert and Donath in 1996 [7], only some 25 cases have been reported [1–10]. A salivary hybrid tumour comprises two different tumour entities, each of which conforms to an exactly defined tumour category, arising within the same topographical area [7]. Most reported cases are carcinomas, either with one or both components being malignant. Benign variants are also described, e.g. combination of basal cell adenoma and canalicular adenoma [7].

We present the fine needle aspirate and histological features of a hybrid tumour arising in the parotid gland of a 68-year-old woman. The tumour is, to the best of our knowledge, a hitherto undescribed variant of salivary hybrid tumour, showing features of both adenoid cystic carcinoma and basal cell adenocarcinoma. The patient presented with a rapidly growing mass in the right parotid gland, and 4 weeks prior to seeking medical advice the mass had become tender and erythematous. When seen in the clinic the mass measured 4×4×3 cm and was located in the body of the parotid anterior to the tragus. The fine needle aspirate was highly cellular with large, branching, basaloid cell clusters and a dispersed population of oval bare nuclei and intact cells with scant cytoplasm (Fig. 1). Most of the cells had small prominent nucleoli. There were

eosinophilic hyaline globules and finger-like structures of basement-membrane-like material associated with some epithelial clusters. The fine-needle aspirate suggested a basaloid neoplasm. There were some features of adenoid cystic carcinoma (spherical globules of basement membrane material surrounded by tumour cells), while other features (cohesive basaloid cells associated with hyaline stromal material and frequent bare nuclei) suggested a basal cell neoplasm (basal cell adenoma/basal cell adenocarcinoma). The patient subsequently underwent total parotidectomy with preservation of the facial nerve and had an uneventful postoperative recovery. Follow-up 3 months later showed no residual disease and she died 5 months later of unrelated causes.

The excised parotid gland contained a whitish, somewhat fleshy tumour measuring 22 mm that microscopically showed two distinct histological components (Fig. 2). The larger part of the tumour, approximately 75%, consisted of an adenoid cystic carcinoma with a mixture of cribriform and tubular growth patterns, with both “punched-out” pseudocysts and some true cysts. However, a solid growth pattern predominated. Here, the flat and spindle-shaped myoepithelial cells with scanty cytoplasm grew in nests and strands with interspersed ductal formations, and the tumour sheets were situated in rather sparse strands of stroma. Mitotic figures were rare (Fig. 3). The other smaller part of the tumour showed features of basal cell adenocarcinoma with invasive lobules composed of basaloid cells with a palisading outer layer. The majority of these cells had basophilic vesicular nuclei and scant cytoplasm. There were also larger cells with paler nuclei towards the centre of the tumour nests. Many of the tumour lobules were surrounded by a thick hyaline membrane with features of the membranous type of basal cell adenocarcinoma (Fig. 4). In yet other areas the trabecular type of basal cell adenocarcinoma was present where basaloid cells formed thin anastomosing cords (two or three cell layers only). There were also more solid areas with virtually no ductal structures. The two tumours shared a similar myoepithelial immunophenotype with variable immunopositivity for S-100, smooth muscle actin, keratins

Fig. 3 Adenoid cystic carcinoma. Cribriform growth pattern with pseudocysts and some true cysts

(pankeratin MNF 116, CK7, CK5D3 and EMA) and myosin heavy chain. The ductal cells of the adenoid cystic carcinoma were strongly positive for MNF 116, CK5D3 and CK7, and positive for EMA. The basal cell adenocarcinoma was EMA negative but showed a more intense MNF 116 expression than did the non-ductal parts of the adenoid cystic carcinoma. The Ki-67 labelling index varied in different areas from 8 to 14% in the adenoid cystic component, whilst being between 4 and 7% in the basal cell adenocarcinoma.

Hybrid salivary gland tumours are rare, accounting for less than 0.1% of all salivary gland tumours [7]. The small number of reported cases makes prognostic assessment and clinical management of these tumours difficult, but management is guided by the most aggressive component. The fine-needle aspirate showed both features of basaloid neoplasm and adenoid cystic carcinoma, underlining its value in the clinical management of salivary gland tumours. The malignant tumour types most frequently found as components of hybrid salivary tumours are adenoid cystic carcinoma, epithelial–myoepithelial carcinoma and salivary duct carcinoma. The most commonly described hybrid is adenoid cystic carcinoma and epithelial–myoepithelial carcinoma [1–10]. As it is not unusual to see varying architectural patterns within individual salivary gland tumours, e.g. cribriform, tubular and solid patterns with adenoid cystic carcinoma, it is important to distinguish this common variation from a true hybrid salivary gland tumour, showing diagnostic criteria for two or more salivary neoplasms.

David B. Weinreb

Re: Detection of JC virus sequences in colorectal cancers in Japan

Received: 18 October 2005 / Accepted: 26 October 2005 / Published online: 20 December 2005
© Springer-Verlag 2005

To the Editors:

We read "Detection of JC virus DNA sequences in colorectal cancers in Japan" by Hori et al. with great excitement. These authors offer convincing evidence that polyoma T antigen may be integrated into the cellular genome of colon carcinoma tissues, although the T-antigen protein is not expressed [4]. We enthusiastically agree with their conclusions and would like to offer additional data to advance this discussion.

First, we have investigated the presence of polyomavirus (PV) T antigen in tumors by immunohistochemistry (IHC), using a primary antibody that reacts with the large T antigen of both the JC and BK viruses [1, 5]. T antigen was not detected in any of 50 cases of colon carcinoma, 18 cases of gastric cancer, or 15 cases of bladder carcinoma.

In addition, we examined by IHC the presence of T antigen in six cases of polyoma virus nephropathy (PVN) in renal transplant patients. In all of these six patients, robust nuclear staining specific for T antigen was observed in scattered tubular cells. The infected tubular cells were characterized by distinct cytopathological features, including anisonucleosis, hyperchromasia with clumped chromatin, and intranuclear inclusions. Such cellular changes represent a "permissive" infection, i.e., a state of viral replication. These histopathological features are absent in our 83 cases of carcinoma.

We agree with these authors that if PV is present in tumors, it is likely to be integrated into the cellular genome, representing a "nonpermissive" infection in which viral replication does not occur.

We conclude that future IHC studies of tumors are likely to be uninformative because we fail to detect viral antigens in nonpermissive infections, which are precisely the category of infections hypothesized to drive oncogenesis. Although recent studies have detected T antigen by IHC in esophageal [2] and colon [3] carcinoma, it remains to be seen whether these data truly represent evidence for a viral etiology in these tumors, or, alternatively, a sequelae of the patient's immunocompromised state.

We look forward to hearing the results of future studies from Dr. Hori's team.

Diagnostic histopathology of breast disease
at Hammersmith Hospital (Imperial College),
London, UK

A week-long course designed for pathologists at Consultant and Senior Trainee level. The course provides a comprehensive coverage of the Histopathology of Breast Disease, with special emphasis on areas that pose diagnostic difficulties. The participants will be given ample time to study histological preparations, followed by illustrated discussion of the cases. There will also be several daily talks dealing with specific topics, given by eminent breast pathologists and followed by discussions. The topics will include update on reporting breast biopsies, immunohistochemistry, hormone receptors and HER2 assessment, Sentinel lymph node biopsy, dealing with the gross specimen, prognostic factors, proliferative lesions/ carcinoma in situ, problems in breast pathology and interpretation of breast core biopsies. The faculty will include Ian Ellis, Christopher Elston, Andrew Hanby, Andrew Lee, Sarah Pinder and Sami Shousha.

15–16 June 2006

Thyroid Pathology for the Practicing Pathologist

15 rue de l'École de Médecine, Paris, France

A 2-day course will take place in Paris again under the auspices of the French Division of the I.A.P.

This course will be given in English by Prof. M. Sobrinho-Simões (Porto) and Prof. R. Heimann (Brussels).

It will consist of lectures alternating with slide reviews and a slide seminar over a multihead microscope. The cases of this seminar will be sent (on CD) before the meeting.

The audience will be limited to 22 participants.

Course fees: 390 euros (320 euros for members of any I.A.P. division). The fees include registration, hand-out, CD of the slide seminar and coffee breaks.

Pathologic examination of the axillary sentinel lymph nodes in patients with early-stage breast carcinoma: current and resolving controversies on the basis of the European Institute of Oncology experience

Received: 17 October 2005 / Accepted: 17 October 2005 / Published online: 24 November 2005
© Springer-Verlag 2005

Abstract Several controversial aspects of sentinel lymph node biopsy (SLNB) for patients with early-stage, node-negative breast carcinoma have been dealt with and resolved in the past decade since its introduction. Unfortunately, however, there is still no consensus on how best to examine sentinel lymph nodes (SLN) histologically. As a consequence, the protocols for SLN examination are remarkably variable in different institutions, leading to a very poor reproducibility of the data stemming from investigations on series of patients whose SLNs have been evaluated according to diverse protocols. Patient outcomes, however, can be optimised only by standardization of the whole procedure of SLNB, with particular reference to the histopathologic scrutiny. Lack of a standardized histopathologic protocol likely derives also from the uncertainties about the clinical implications of minimal lymph node involvement (isolated tumour cells and micrometastases) with regard both to the risk of additional metastases to non-sentinel lymph nodes of the same basin and to the prognostic value for patients' survival. This review aims at highlighting some of the controversial issues of the histopathologic examination of the SLNs, including the number of sections and cutting intervals, the use of immunohistochemistry and the role of molecular biology assays.

Keywords Breast carcinoma · Sentinel node biopsy · Micrometastasis

Introduction

Over the past decade, lymphatic mapping and axillary sentinel lymph node biopsy (SLNB) have been increasingly adopted for staging with minimal morbidity patients with node-negative, early-stage breast carcinoma. Since the procedure was introduced, several problem aspects and controversial issues have been dealt with and resolved, while others still remain open. The studies reported thus far support the validity and safety of SLNB in different clinical scenarios where they were formerly questioned, as for patients with previous surgical biopsy/lumpectomy or with multicentric breast carcinomas [39] and for patients treated with neoadjuvant chemotherapy [27]. The safety of the procedure in pregnant women and the accuracy of a second SLNB for relapsing tumours following conservative surgical treatment inclusive of SLNB remain to be assessed.

Several methodological issues regarding the site of tracer injection, the type of tracer, and the surgical identification and removal of the sentinel lymph node (SLN) have also been clarified, and guidelines or procedures for lymphatic mapping and SLN removal have been agreed upon. It is surprising that, despite its pivotal role in determining the accuracy and hence the clinical utility of SLNB, the histopathologic examination of SLN largely remains an unresolved issue.

To be effective in properly staging with minimal morbidity patients with clinically node-negative breast malignancies, the SLNB must rely upon a very accurate histopathologic examination of the SLNs [7, 42, 45]. It is indeed intuitive that the detection rate of metastatic tumour depends on the accuracy and extent of the histopathologic evaluation, i.e. the number of sections scrutinized. The lack of universally adopted protocols for the examination of SLNs resulted in a wide heterogeneity of the procedures currently used in different institutions, and in several guide-

lines or recommendations issued by scientific organizations at the local or international level. Unfortunately, this led to a very poor reproducibility of the data stemming from investigations on different series of patients whose SLNs have been evaluated according to different protocols. As a result, despite almost a decade of investigations on SLNB and several thousand patients enrolled in clinical studies, a number of questions still remain unanswered. Among these, the most important is whether or not the histopathologic examination of SLNs should aim at detecting even minimal lymph node involvement (isolated tumour cells and micrometastases) using all the available technological resources, from the traditional step sectioning with or without immunohistochemical detection of specific tumour cell markers to more sophisticated assays [e.g. reverse-transcription polymerase chain reactions (RT-PCR)]. This question, however, may only be addressed properly after the clinical implications of minimal lymph node involvement are definitively assessed, with regard both to the risk of additional metastases to non-sentinel lymph nodes of the same basin and to the prognostic value of isolated tumour cells (ITC) and micrometastases for patients' survival [18, 38]. Indeed, due to the lack of a standardized histopathologic examination, the clinical implications of minimal SLN involvement are still debated, with some studies documenting an important risk of additional involvement of higher-echelon lymph nodes and of unfavourable clinical outcome, at variance with the results of other investigations [9, 10, 17, 23–25, 30, 32, 33, 35].

Due to the uncertainty on the clinical implications of minimal SLN involvement, individual institutions have reserved the right to devise their own protocol for SLN examination according to the available resources and the cost/benefit analysis. A recent survey of the protocols used in Europe for the histopathologic examination of axillary SLNs of breast carcinoma patients has unveiled remarkable differences among the 240 laboratories that responded to the questionnaire, with the reporting of 123 somewhat different histological protocols. Almost 12% of the responding laboratories examined only one level per SLN, whereas all the other laboratories performed a multilevel assessment, ranging from the evaluation of 2–5 levels to more than 100 levels separated by 40- μ m cutting intervals. Patient outcomes, however, can be optimised only by standardization of the whole procedure of SLNB, with particular reference to the histopathologic scrutiny [8, 22].

The histopathologic examination of SLN

The very first histopathologic approaches to SLN examination did not differ from the routine assessment of the regional lymph node status, based on the evaluation of a single or very few sections cut from frozen (in case of intraoperative diagnosis) or paraffin-embedded lymph nodes. As expected, however, the high false-negative rate of this traditional approach was soon highlighted by the first reports on the higher accuracy of a more extensive histopathologic examination of SLNs.

Subsequently, a large series of studies aimed at assessing the benefit of a more extensive histopathologic examination of SLNs. Endpoint of the studies was to increase the positive and negative predictive value of the SLNB by using more demanding histopathologic protocols based on sub-serial sectioning of the entire SLNs and the use of ancillary immunohistochemical staining techniques [21] that however had to be cost-effective and not exceeding the workload capacity of the laboratory. It is self-evident that the cost/benefit analyses of an extensive examination of SLNs vary according to several parameters, including the number of patients evaluated, the amount of the reimbursement and the availability of dedicated personnel and instrumentation. As a rule, the detection rate of metastases depends on the number of sections examined from the entire lymph node, so that the prevalence of SLN involvement in a given series of patients depends on the adopted histopathologic protocol. To ensure optimisation of patients' management in different institutions, however, a standardized protocol should be agreed upon [46, 49].

We have devised one of the most demanding protocols for SLN examination of breast carcinoma patients, which requires the histopathologic scrutiny of the entire SLN by step sectioning at very thin cutting intervals. According to this protocol, which is suitable for both frozen and paraffin-embedded lymph nodes, the SLN is bisected along the longest axis or cut into 2- to 3-mm slices if thicker than 5 mm (thinner lymph nodes are processed uncut). In handling the lymph node, special attention should be paid to preserve intact the nodal capsule and the peripheral sinuses, where many metastatic foci may be first seen. Sections are then cut at 50- to 100- μ m intervals until the complete examination of the lymph node by scanning individual sections at 100 \times magnification. Spare sections for immunohistochemistry were formerly cut at each level, but now we perform immunohistochemical reactions on destined sections whenever deemed necessary to confirm the metastatic nature of morphologically atypical cells (approximately 5% of the cases).

The need for a complete examination of the SLN derives from the observation that while larger (macro-)metastases, measuring 2 mm or more, are detected in the vast majority of the cases in the very first sections cut from the middle areas of the nodes, smaller (micro-)metastasis, measuring less than 2 mm, are more randomly distributed throughout the SLN and cannot be reliably detected by the examination of the sections from the central portions of the node. The choice of cutting step sections at 50- to 100- μ m intervals is dictated by the aim of identifying even a minimal lymph node involvement (ITC and micrometastases), which could escape detection by sectioning the node at wider cutting intervals [45, 46].

That such a labour-intensive protocol could not be followed by many other institutions is intuitive, especially when considering that the clinical implications of minimal SLN involvement are still controversial. Thus it is not surprising that recommendations for SLN examination issued by nationwide or international organizations suggest more affordable protocols [8, 22], which re-emphasize the

need for a complete examination of the node, but allow cutting intervals ranging from 0.5 [22] to 1 mm [8]. The rationale for defining these minimal requirements is only to assure the detection of macrometastases and not to search for minimal lymph node involvement by ITC or micrometastases. Accordingly, use of ancillary diagnostic techniques, such as immunohistochemistry or molecular biology assays, is not recommended. Similar conclusions were reached by the panelists of the Consensus Conference held in Philadelphia in 2001 [37]. Whether these recommendations will be maintained or changed depends mainly on the future progresses in unveiling the clinical implications of minimal lymph node involvement.

Workload for the department of pathology

At first glance, any protocol for a more or less extensive examination of SLNs looks very worrisome for the increased workload for both the histo-technicians and the pathologists. In several institutions, the pathologists' reaction to the implementation of the SLNB for breast carcinoma patients is to declare the unavailability of sufficient human and/or instrumental resources for an extensive examination of the SLNs. This might well be true in rare instances, but in the majority of the cases, the SLN workload should be affordable.

The above-described protocol for SLN examination implemented at the European Institute of Oncology requires that approximately 60 sections are cut from each individual 0.5-cm-thick SLN and examined histologically. This might well seem a painstaking procedure, not affordable in many other centres. The first reaction, however, could be mitigated by considering that in about 70% of the cases, the SLN will be free of metastases, thus preventing any further axillary treatment. In these circumstances, the workload for SLN examination will be counterbalanced by the avoidance of embedding, trimming, cutting and examining sections from each of the 20–30 lymph nodes retrieved by complete axillary clearing.

In approximately 60% of the positive SLNB, the size (>2 mm) of the metastases will allow their detection in the very first sections of the SLN (obtained from the central portion of the nodes, after bisection) or even by touch cytology, and the examination of further sections will be spared. Although these patients will undergo completion axillary dissection, the additional workload for SLN examination may indeed be very limited. In the remaining 40% of the cases, the SLN will be minimally involved by micrometastases or isolated tumour cells whose detection requires a complete examination of the SLN by step sectioning. The diagnosis of minimal SLN involvement will be followed—at least in some institutions—by completion axillary dissection, resulting in a net increase in the workload for the laboratory. It should be noted, however, that this applies to only about 12% of the patients with early-stage breast carcinoma.

From our experience with more than 8,000 SLNB examined in the last 9 years, we have calculated that our

procedure implies an overall additional workload for the laboratory of approximately ten sections per treated patient (considering that almost 75% of the patients undergo SLNB). A slight modification of the protocol (i.e. cutting step sections of the whole SLN at 100- μ m intervals) would be enough to eliminate the need for any additional section. These figures depend on the fact that we routinely scrutinize non-sentinel axillary lymph nodes by examining three to six sections per node. The mean number of SLN per patient is 1.5 (median 1 SLN/patient), the mean number of lymph nodes retrieved by axillary dissection is 27, and the patients with minimal SLN involvement are offered randomisation in a clinical trial comparing axillary dissection with no further treatment. Needless to say, the above conditions vary in different institutions because the mean yield of a completion axillary dissection, the number of sections examined from non-sentinel axillary lymph nodes, the mean number of SLN removed per patients and the mean thickness of the SLNs are highly variable and prevent any general statement to be made. The take-home message, however, is that a truly extensive histopathologic examination of SLNs may well have a lower impact on the global workload of pathology departments than figured and feared at first glance.

False-negative and false-positive SLNB

The assessment of SLN status may be affected by both false-negative and false-positive histopathologic results.

A false-negative SLNB is almost invariably due to a less-than-optimal scrutiny of the SLN, either because of the number of evaluated sections is not high enough to be truly representative of the node status or because metastases escape recognition by the pathologist. The issue of a variable detection rate of metastases according to the more or less extensive examination of the SLNs has been dealt with in the preceding paragraphs. It is quite uncommon for an experienced pathologist to overlook lymph node metastases. There are instances, however, where small and/or morphologically unusual metastases from breast carcinoma may be misinterpreted as non-neoplastic resident cells, most likely nevus cells [34], epithelioid histiocytes of granulomatous lymphadenitis or vessels with high endothelial lining, especially when examining frozen tissue sections. To avoid misdiagnoses, use of ancillary immunohistochemical techniques for specific markers of the epithelial lineage (i.e. cytokeratins) may be extremely useful. These techniques may also be applied to intraoperative frozen section diagnosis, taking advantage of commercially available reagents that allow the reaction to be completed in less than 20 min [5, 41].

Less attention has been paid to the risk of false-positive identification of SLN metastases, although this would imply unwarranted lymph node dissection and improper adjuvant treatments.

Carter et al. [4] first warned of the possible occurrence of passive transport to the axillary lymph node of normal (and neoplastic) breast tissue following diagnostic needle

procedures on the breast. Chiu et al. [6] emphasized inaccurate immunohistochemical procedures as a potential source of false-positive SLNB. Furthermore, the immunoreactivity for low-molecular-weight cytokeratins of fibroblastic reticulum cells invariably present in normal lymph nodes [11, 14] may be responsible for a false identification of metastatic cells. A more subtle cause of false-positive identification of breast metastases is the possible occurrence of benign-appearing breast tissue in the lymph node capsule and/or parenchyma.

The occurrence of ectopic non-neoplastic tissue within lymph nodes is a well-recognized phenomenon, especially for thyroid or salivary structures within latero-cervical lymph nodes or nevus cells in lymph nodes from different basins [13]. Mammary glands are the ectopic epithelial structures most frequently detected within axillary lymph nodes [19], and at variance with most of the aforementioned examples that occur intra-parenchymally, these are commonly seen in capsular or sub-capsular locations or in the peri-nodal fat tissue. Occasionally, the ectopic tissue has been interpreted as metastatic, thus leading to over-staging and, eventually, over-treatment of the patients [13, 19].

We [26] first reported on the occurrence of benign epithelial inclusions of ectopic breast tissue in axillary SLNs of seven breast carcinoma patients, with remarkably different morphological features. Indeed, these benign epithelial inclusions may undergo proliferative changes similar to those encountered in fibrocystic disease (florid duct hyperplasia and sclerosing adenosis), making the differential diagnosis with true metastases very difficult. Again, use of appropriate immunohistochemical reactions for specific markers (e.g. p63, smooth-muscle myosin, calponin) of the myoepithelial cell component, invariably present in benign inclusions and absent in metastatic breast carcinoma, is instrumental in reaching the correct diagnosis, but the examining pathologist should be fully aware of the possible occurrence of such benign inclusions.

Predicting the status of non-sentinel lymph nodes

The extensive examination of SLNs has significantly increased the detection rate of minimal lymph node involvement, and the question has now arisen whether or not micrometastases or ITC only in the SLN predict a risk for additional non-sentinel node metastases high enough to justify completion axillary dissection for these patients. Previous studies had suggested that breast carcinoma patients with minimal SLN involvement could indeed be spared axillary surgery because of an alleged negligible risk of additional metastases, but we and other authors documented a 20–24% risk of involvement of further-echelon lymph nodes in patients with micrometastatic SLNs [40, 49].

More recently, we evaluated a large series of patients with positive SLN biopsy followed by completion axillary dissection, showing that of the 116 patients with ITC only in the SLN, 17 (14.7%) had further axillary involvement, as

did 68 (21.4%) of the 318 patients with SLN micrometastases (0.2–2 mm in size) [47]. The prevalence of additional metastases was not significantly different between these two groups of patients ($P=0.15$), whereas patients with macrometastatic disease in the SLNs showed a significantly higher proportion of non-sentinel lymph node metastases, which were detected in 50.3% (399/794) of the cases ($P<0.0001$). However, when the patients with SLN micrometastases were further stratified according to the size of the micrometastases (up to 1 vs 1–2 mm), those with larger micrometastases showed a significantly higher prevalence of additional metastases (30.2 vs 17.0; $P=0.01$), thus confirming previous data [17, 47]. To summarize, patients with a positive SLN biopsy can be stratified in three groups at significantly different risk for involvement of non-sentinel lymph nodes. Patients with ITC or small (up to 1 mm) micrometastases in the SLN have the lowest risk of additional metastases (16.2%), which increases to 30.2 and 50.3% for patients with 1–2 mm micrometastases or larger metastases, respectively.

In each subgroup of patients with SLN metastases, the identified additional metastases to non-sentinel lymph nodes were mostly of the macrometastatic type, i.e. larger than 2 mm [47], most likely because the non-sentinel nodes were scrutinized with a limited number of sections (3–6) and at least some micrometastases or ITCs were likely missed. Therefore, completion axillary dissection in all the patients with positive axillary SLN biopsy may add clinically meaningful information because in the vast majority of the cases, including those with ITC only or micrometastases in the SLNs, non-sentinel nodes will be shown to harbour metastases larger than 2 mm.

To ascertain whether the identification of minimal SLN involvement (with the associated risk of additional non-sentinel lymph node metastases) is per se informative enough to plan an effective adjuvant treatment without the need for further axillary surgery, the International Breast Cancer Study Group has launched a randomised clinical trial (IBCSG trial 23-01), whereby patients with micrometastatic disease or ITC only in the SLN are randomised to further axillary surgery or follow-up. Primary endpoint of the trial is disease-free survival; secondary endpoints are overall survival and quality of life.

Tumour mRNA markers

The ever-increasing adoption of SLNB for staging patients with minimal morbidity has raised the question of how best to evaluate the SLN to minimize the risk of false-negative results. Owing also to the lack of standardized and widely accepted protocols for a truly extensive histopathological examination of SLN, the relative merits of alternative assays based on the identification of tumour-specific mRNA markers over traditional histological or immunohistochemical methods have been extensively exploited. Initially, qualitative RT-PCR experiments documented that several mRNA markers, either alone or in multimarker assays,

were indeed suitable for a high-sensitivity detection of metastatic breast cancer or melanoma in sentinel or non-sentinel lymph nodes [2, 3, 28, 31].

The specificity of the assays, however, was less satisfactory, with a high prevalence of positive assays in histologically unaffected lymph nodes and also in lymph nodes obtained from patients without malignancies [2]. Because a possible cause of false-positive identification of lymph node metastases by RT-PCR assays might be the illegitimate expression of low levels of target mRNAs by non-neoplastic cells, real-time quantitative RT-PCR (qRT-PCR) assays have been developed to correctly identify lymph node metastases according to a threshold level of mRNA expression [15, 20, 29, 36, 48]. Very recently, dedicated kits and instruments for “rapid” quantitative RT-PCR assays have also become commercially available for the intraoperative detection of SLN metastases from breast carcinoma.

A critical reappraisal of the investigations dealing with the identification of breast carcinoma mRNA markers in axillary sentinel and non-sentinel nodes, however, still challenges the possible application of qRT-PCR assays in the clinical practice. Indeed, in the studies with the largest series of patients evaluated, the overall concordance between qRT-PCR assays for individual or multiple mRNA markers and morphological or immunohistochemical findings ranges from 73.2 [15] to 95.7% [48]. Discrepancies include both false-negative qRT-PCR results, with histologically detected metastases escaping identification by the assays and still positive assays in lymph nodes not harbouring any morphologically identifiable metastasis.

Besides the choice of the molecular assay (qualitative vs quantitative RT-PCR), a most likely cause for the discrepancies between morphological and molecular findings is the sampling procedure, with part (or half) of the lymph node being subjected to molecular biology assays and another part to morphological and immunohistochemical examination. As a consequence, the smallest tumour deposits (micrometastases and ITC) may remain confined exclusively to the sample undergoing one assay, escaping detection by the other.

To minimize the effects of sampling on the final results, we have combined RT-PCR assays with our procedure whereby axillary SLNs of patients with breast carcinoma are snap frozen and examined completely by step sectioning at 50- μ m intervals. While the frozen sections are examined histologically (including immunohistochemical testing), the interval tissue is subjected to RT-PCR assays. Applying this procedure, we have previously examined 146 axillary SLNs from 123 patients for the detection of five different mRNA tumour markers (cytokeratin 19, CEA, mammaglobin 1, MUC-1 and maspin) by qualitative RT-PCR assays [28]. When analysed individually, the general concordance with the histopathologic findings ranged from 78.8 to 83.6%, with none of the different markers attaining a sensitivity higher than 77.8%. Mammaglobin (MGB1) was the mRNA marker most closely correlated with the histopathologic findings, with a sensitivity of 77.8% and a specificity of 86.1%. We have more

recently evaluated the effectiveness of a real-time qRT-PCR assay for MGB1 mRNA in the detection of lymph node metastases in a retrospective series of 81 axillary SLNs from 72 patients, for which the results of the previous qualitative assays were known, and validated the results in a prospective series of 61 SLNs from 61 newly diagnosed breast carcinoma patients.

In our experimental conditions, qRT-PCR assays were indeed more accurate than conventional RT-PCR in assessing the status of axillary SLNs: four of the six false-negative cases in conventional RT-PCR assays turned positive in qRT-PCR experiments, whereas two of the five false-positive cases in conventional RT-PCR assays turned negative in qRT-PCR experiments. Accordingly, qRT-PCR assays were superior to qualitative RT-PCR in terms both of specificity and of sensitivity.

The results were compared with the histopathological findings obtained by a very extensive examination of the same lymph nodes, specifically designed to minimize the possible effects of the sampling procedures on the correlation between morphological and molecular data. The overall concordance with histopathological findings was 93.8 and 93.4% in the retrospective and validation series, respectively, well in line with previous findings from qRT-PCR assays of individual or multiple tumour markers, indicating a concordance ranging from 73.2 [15] to 95.7% [48]. The overall sensitivity of the assay in the two combined series was 88.5% and the specificity 94.8%, with a PPV of 79.3% and an NPV of 97.3%. The false-negative rate of the assay (11.6% or 3/26 histologically positive SLN), and the rate of positive detection of MGB1 mRNA (5.2% or 6/116) in lymph nodes not harbouring any histologically identifiable metastasis, however, question its use in the clinical practice as an alternative to the histopathological examination of the SLN. In the above study, we compared the qRT-PCR findings with a very extensive histopathological evaluation of the SLN, which makes it unlikely that the molecular assay actually identifies true metastases missed at the morphological scrutiny. Whether the molecular assay may be a valuable and cost-effective tool for the identification of breast cancer metastases in axillary SLN that are not subjected to a very extensive histopathologic examination remains to be evaluated.

Epilogue

This review focused on some controversial issues of the histopathologic assessment of SLN status, with special reference to the assumption that the detection of even minimal lymph node involvement may be clinically relevant, both for immediate surgical intervention on further-echelon lymph nodes and for prognostic/predictive evaluations.

The mere occurrence of tumour cells in the regional lymph nodes, however, may not be an invariable predictor of clinical progression of the disease. The results of randomised trials [43, 44, 50] have shown that the observed number of breast carcinoma patients with clinically overt axillary

progression of the disease is much lower than expected based on either the false-negative rate of the sentinel lymph node biopsy or the known prevalence of metastasis to axillary lymph nodes. This suggests that metastatic cells may not progress to clinical disease in all patients and that only some of them have the capability of sustaining tumour progression, consistent with the hypothesis that cancer growth and progression, and hence the clinical outcome of the disease, are dependent on the activation of tumorigenic stem/progenitor breast cancer cells [1, 12].

The stem/progenitor cell theory of carcinogenesis and tumour progression conflicts with the traditional stochastic approach, by which all tumour cells in a given patient share the same potential for progression. According to the stochastic approach, prognosis is dictated by the actual amount of invasive or metastatic tumour cells, and the therapeutic interventions are intended to minimize their number. This leads pathologists to evaluate painstakingly tumour burden and count tumour cells, using all the possible ancillary techniques to identify even individual tumour cells. This attitude may not be truly rewarding. Indeed, the progenitor/stem cell theory predicts that only some (and possibly a minor percentage of) tumour cells are actually responsible for tumour progression and clinical outcome, and that all efforts should be made to target these cells with specific interventions [16]. Thus, what is now needed is to unveil specific markers of the tumorigenic cells that would allow their identification and quantitation in clinical specimens and to re-evaluate the prognosis by alternative means.

Factors to keep in mind when introducing virtual microscopy

Received: 17 June 2005 / Accepted: 4 October 2005 / Published online: 22 November 2005

Abstract Digitization of glass slides and delivery of so-called virtual slides (VS) emulating a real microscope over the Internet have become reality due to recent improvements in technology. We have implemented a virtual microscope for instruction of medical students and for continuing medical education. Up to 30,000 images per slide are captured using a microscope with an automated stage. The images are post-processed and then served by a plain hypertext transfer protocol (http)-server. A virtual slide client (vMic) based on Macromedia's Flash MX, a highly accepted technology available on every modern Web browser, has been developed. All necessary virtual slide parameters are stored in an XML file together with the

image. Evaluation of the courses by questionnaire indicated that most students and many but not all pathologists regard virtual slides as an adequate replacement for traditional slides. All our virtual slides are publicly accessible over the World Wide Web (WWW) at <http://vmic.unibas.ch>. Recently, several commercially available virtual slide acquisition systems (VSAS) have been developed that use various technologies to acquire and distribute virtual slides. These systems differ in speed, image quality, compatibility, viewer functionalities and price. This paper gives an overview of the factors to keep in mind when introducing virtual microscopy.

Introduction

Only recently, advances in computer technology have been made that allow to digitize a complete glass slide. Such virtual slides (VS) can be accessed over the World Wide Web (WWW), making them available to a large audience. Since 1998, several virtual slide systems (VSS) have been developed by different commercial and academic bodies (<http://www.pathmax.com/apiii/exp.html>, <http://141.214.6.12/cyberscope631>) [1–4, 6, 10, 15, 18, 20, 21, 23, 24, 26]. The value of these virtual microscopes varies considerably depending on the technology used for image acquisition, processing, delivery and viewer functionality. Only few sites are publicly available over the Internet (<http://interpath1.uio.no/telemedisin/WebInterPath/interpathindex.htm>, <http://www.bacslabs.com>, <http://virtualmicroscope.osu.edu/virtual.htm>, <http://neuroinformatica.com>, <http://images.scanscope.com>, <http://www.telepathology.dcu.ie/vps02.php3?hits=>, http://www2.primed.helsinki.fi/webmicroscope/atlases/breast/brcatlas_start.asp). An outstanding collection of

more than 900 VS is accessible for public use and education from the University of Iowa (<http://www.path.uiowa.edu/virtualslidebox>).

There is no generally accepted definition of the term “virtual microscopy”. In the past, this term has variably been used for sending single images to a colleague by e-mail, for online atlases containing large single images or for image collections showing various sectors of a slide at different magnifications. Only recently, it became possible to digitize entire slides at high magnification, allowing exploration of the tissue on a computer screen in a manner analogous to a real microscope, thus justifying the designation “virtual microscope”. We advocate the restricted use of the term “virtual slide” for completely digitized slides at full resolution (scanned at 20× or higher), allowing the pathologist to make a clear-cut diagnosis. Similarly, a virtual microscope should provide at least the functionality of a real microscope (scrolling and zooming of the VS) and may offer additional functionalities like Web accessibility, annotations or automated image analysis.

We have developed a VSS called vMic for public WWW access (<http://vmic.unibas.ch>). Emphasis was laid on open standards and maximal image quality still allowing for reasonable download times. In an earlier paper, we discussed the theoretical aspects of virtual microscopy [9]. We now report on the first successful applications of vMic in teaching. The parameters to be considered when planning the implementation/acquisition of a VSS are discussed extensively.

Construction of the virtual slide system

We have built a high-quality/low-cost VSS based on the theoretical requirements described in detail earlier [9]. In short, a typical setup for a VSS consists of a virtual slide acquisition system (VSAS), a server that delivers the VS via Internet/WWW to the user and a viewer—preferably a Web-based version.

The demands for our VSAS were:

- Highest possible image quality
- Use of standard components available on the market
- Least possible effort for custom developments (software)
- Highest possible reusability of the investment

Our VSAS consists of commercially available components (Table 1) and includes: a microscope with a robotic stage, high-quality objectives, and a camera for slide acquisition. An acquisition software moves the stage and acquires the images. Due to limitations of the mechanical precision of components (motorized stage, camera mounting, reproducibility, hysteresis, thermal drift, different z-positions due to autofocus), the creation of a nearly seamless VS is very tedious when using a standard robotic microscope [23]. In order to circumvent time-consuming calibrations, overlaps of about 3–5 μm at 40× magnification at the intersection of two individual images were deliberately chosen for our VSAS. For viewing the digitized slides in a Web browser, a Flash application

Table 1 Components of the vMic slide acquisition system

Microscope	Zeiss Axioskop 2 mot plus
Objectives	Zeiss Plan Apochromat 40×/0.95 for scanning the slides, Zeiss Neofluar 2.5 for overviews
Motorized stage	Maerzhaeuser stage SCAN 75*50
Stage controller	Ludl Controller MAC5000
Camera	Zeiss AxioCam HRc
Software	Zeiss KS400 (includes a macro language enabling to programme a VSAS)
Computers	2 computers with P4/2.4 GHz; one as the capturing system, the second for post-processing

was developed that allows the examination of the slides at different magnifications and to move continuously within a slide, closely emulating the functionality of a real microscope. In addition, the user may directly jump to regions of interest guided by an overview image with a cross and a rectangle indicating the current viewing position (Fig. 1). Annotations describe regions of interest and link to extra information on the Web.

Fig. 1 Virtual slide of the Oral Histology course: The upper part of the vMic viewer shows an overview of a molar tooth. A blue frame plus yellow crosshairs indicate the field of view that is shown at 5× magnification in the lower part

The optical parameters of the VSAS have been chosen to match the limitation of the optical resolution [9]. Maximal image quality was achieved at the cost of low acquisition speed. Each single image was autofocused, and the AxioCam was set to scan mode at 1,300*1,030 pixel, providing full colour information for each pixel.

To reduce capturing time, a mask representing the region of interest was predefined to guide the roboter.

The captured images were post-processed with Java-scripted Adobe Photoshop. This step included correction of colour and gradation as well as applying an unsharp mask. The latter was only applied to the lightness channel in Lab space, generating crisper images without introducing unwanted colour artefacts. Details of post-processing are illustrated at <http://kathrin.unibas.ch/pub/2005-06>. Finally, a multi-resolution stack was produced and transferred to the Web server. The viewer (vMic, <http://vmic.unibas.ch>) and the server have been described in detail previously [9]. Capturing as well as post-processing may last for several hours depending on the slide size and the number of images taken. The components of the described system adhere to open standards and are interchangeable with further developments in the field.

vMIC applications in teaching

After its introduction, vMic (<http://vmic.unibas.ch>) has primarily been used for teaching purposes: as a component of an online histopathology course for medical students (<http://alf3.urz.unibas.ch/hipaku>), in a “virtual histology” laboratory for students in dentistry (<http://oralhisto.unibas.ch>) and in three slide seminars for surgical pathologists (<http://vmic.unibas.ch/patho/seminar>). The slide seminars had all been organized by sections of the International Academy of Pathology.

Histology course for students in dentistry

Students in dentistry have traditionally been taught dental histology by means of introductory lectures and practical hands-on microscopy courses. A professor of anatomy taught histology showing microscopic slides on a microscope projected with a video projector. Every student needed a microscope and a set of glass slides for the laboratory sessions. Many of these valuable glass slides had already been lost, broken, or faded because of prolonged storage and recurrent intensive exposure to the microscopic illumination. Some of the slides used in this course were very old and could not be replaced due to lack of technicians trained in the various technologies required for the preparation of dental tissues. Furthermore, the procedures applied in the production of some of the slides, e.g. grinding of enamel, is very time consuming, and human resources are scarce. In order to avoid further loss of valuable material, a selection of the best slides used during the course was digitized and the course was moved from the microscopy lab to a computer room. Every student now

has identical material of optimal quality to study on a monitor, and the instructor can indicate the coordinates of the area under discussion. Prior to examinations, students may review the slides at home or at one of the numerous public computer workstations offered by the university. Individual use of the course is alleviated by an information sheet provided as a “PDF” file that can be downloaded. The new course (<http://oralhisto.unibas.ch>) was held for the first time during the winter semester 2003/2004. On average, 85% (29/34) of the students in dentistry participated in each virtual microscopy session. Overall, the students were highly satisfied with the new teaching method. The course had been evaluated with an online questionnaire after the last virtual microscope session (Table 2). Remarkably, the students rated image quality of vMic equal (6×) or even superior (7×) to the image quality of their traditional microscopes, whereas no student indicated the reverse. Last but not least, the grades for the histology exams went up from an average of 5.1 to 5.3 (6 being the highest grade). This, however, might be due to various not course-related factors and certainly needs further evaluation.

Histology course for medical students

We have included some of the more than 900 VS of the virtual slidebox of histopathology (<http://www.path.uiowa.edu/virtualslidebox>) and few vMic slides in our Web-based histopathology course for medical students (<http://alf3.urz.unibas.ch/hipaku>).

Traditional slide seminar with additional virtual slides

For the course “Diagnosis of Melanocytic Lesions: Common Problems for the Practicing Pathologist” of the French section of the International Academy of Pathology, VS had been produced in addition to traditional slides. The two courses held in Paris in December 2003 and in November 2004 had been organized by R.L. Barnhill, M.G. Cook, D. J. Ruiter and A. Spatz. The main topic of this annual course is melanocytic lesions that are known for their highly variable appearance in different step sections. Therefore, it was in many cases impossible to provide a set of glass slides for each of the around 80 to 100 participants showing all the diagnostic details of the 12 cases discussed during the 1-day course meeting. In order to circumvent this problem, a representative step section of each course slide was digitized and made available for viewing via the Internet of all the participants prior to the course meeting (<http://vmic.unibas.ch/patho/seminar>).

Traditional slide seminar with virtual slides (without glass slides)

Transplant pathology was the main topic of the 88th annual meeting of the German Society of Pathology in Rostock in June 2004. On this occasion, the German section of the

Some participants of slide seminars did not answer all of the questions. Therefore, the number of respondents for each question varies

International Academy of Pathology organized a slide seminar exclusively with VS. As needle biopsies of the kidney are very small, slide seminars with many participants on this topic were not feasible to date owing to lack of sufficient tissue. The six seminar cases represented various conditions of kidney transplant pathology. The slides were contributed by three specialists in the field—M.J. Mihatsch, H. Regele, and H.-J. Gröne—who discussed their cases on the occasion of the course meeting in Rostock. The slides were published online 1 month prior to the course meeting. The participants could either view the cases at home or at a computer station in Rostock.

The participants of the slide seminars were asked to answer a questionnaire about vMic (Table 2). While most respondents expressed positive opinions about the virtual microscope (“it is the future”), others were more sceptic (“probably useful for slide seminars but not yet good enough for consultation”). The image quality of the VS was rated as either excellent (62%) or good (38%). Nobody had voted for moderate or poor.

All slide seminars are publicly accessible (<http://vmic.unibas.ch/patho/seminar>).

Added value of virtual slides

VS should not simply be regarded as a mere replacement of traditional glass slides. This new technology offers several

advantages and applications to pathology that could not be provided before [3–5, 7, 8, 10, 12, 15, 16, 18–22, 24, 26]. The overview image facilitates orientation within a given section (Fig. 1). Annotations that lead the user to a specific location within the slide are a valuable tool not only in the teaching setting but also for consultations. The one-time digitization of the histological glass slides for teaching purposes is much less time consuming and expensive than the production of a traditional slide set that additionally comprises the replacement of lost, broken or faded sections and delivery. The decision about which cases are to be presented in a course no longer depends on the availability of a large amount of representative tissue but exclusively on didactics. Cytopathology courses [7, 19, 27] or slide seminars in subspecialties traditionally relying on small biopsy samples or needle biopsies such as haematopathology, dermatopathology (<http://vmic.unibas.ch/patho/seminar>, <http://www.pathmax.com/apiiii/exp.html>), hepatopathology or nephropathology (<http://vmic.unibas.ch/patho/seminar>) can now be offered to a large audience. For digitization, a step section representative of the lesion and of best quality is chosen. The fact that the best possible identical step section of a given lesion is allocated to all users is not only desirable for teaching purposes but represents an optimal condition for consensus conferences in research settings [26] or measures of quality control [7, 17]. A group of experts from any part of the world can use the “virtual multi-header microscope” to examine a slide together via the WWW.

Consumer needs

If virtual microscopy is to be widely accepted by pathologists for diagnostic purposes, image quality and functionality should be comparable to that of a traditional microscope. The acceptance of Web-based technology is generally very high in the student population. The improvement of technology should be paralleled by increasing computer competency of the upcoming generation of pathologists [11, 14]. Students have already been shown to rate the quality of images and navigation of a virtual microscope equal to or even better than a real microscope [2, 10, 18]. While real slides need adjustments of focus, lighting and condenser, VS are always ready to use. In contrast, most pathologists found it more difficult to make a diagnosis on vMic slides than with traditional slides. This is probably due in part to unfamiliarity with this new technology and in part to a rather small display and delayed response time when using slow Internet connections.

When we developed vMic, we decided to obtain the highest possible image quality accepting increased time requirements for image acquisition and download. It has to be taken into account that rating of image quality not only depends on the virtual microscope but also on the quality of the computer screen of the user and the quality of the physical microscope vMic is compared to. Due to limited budgets for medical education, microscopes in student labs normally do not feature best-of-breed optics to minimize costs, while VS can be maximized for quality. The latter probably explains why more than half of students in dentistry rated vMic images as superior to a real microscope image.

The overall quality of a VSS will not only be measured by its visual quality and its ability to perfectly emulate a traditional microscope but will also depend on additional functionalities like annotations, automatized slide analysis or discussion tools.

Considerations for acquisition/implementation of a virtual slide system

Nowadays, many companies offer VSAS or even complete VSS (<http://www.soft-imaging.de/rd/english/3412.htm>, <http://www.telepathologycity.com/systems.htm>). They foster different technological approaches, and the price tag varies by a factor of 6 and more. The following discussion of the most relevant parameters in virtual microscopy is intended to help institutions that plan to establish their own VSS.

Acquisition speed

One obvious and central weakness of most existing VSAS is acquisition speed. As long as the system is only planned to serve educational purposes (e.g. vMic, <http://vmic.unibas.ch>), this shortcoming may be acceptable. A single scan may last for hours. However, if VS are to be intro-

duced in routine diagnostics, a very fast and automated system—mostly at a higher price—is mandatory.

Four systems that meet the latter conditions are (incomplete list of available products):

- DMetrix DX-40 scanner (first systems delivered in 2004; <http://www.dmetrix.net>)
- Olympus .Slide (pronounced dot-slide; available since beginning of 2005; <http://www.soft-imaging.de/rd/english/3412.htm>)
- Aperio ScanScope (available since more than 1 year ago; <http://images.scanscope.com>)
- InterScope Xcellerator (<http://www.interscopetech.com>)

The most promising technology is the one used in the DX-40 scanner from DMetrix. This VSAS consists of an array of multiple miniaturized microscopes allowing for ultra-rapid digitization of a whole slide in less than a minute [26].

20× vs 40× objective

In traditional settings, 40× objectives with a numerical aperture (NA) of 0.75 are used for diagnostic purposes. A 40× Plan Apochromat objective (normally used to take images) has up to NA=0.95, providing higher lateral resolution, while depth of sharpness is reduced. A 20× Plan Apochromat objective with NA=0.75 results in the same lateral resolution as a standard 40× objective used for diagnostics.

Some suppliers therefore argue that by using a 20× Plan Apochromat instead of a 40× objective, the scanning time would be reduced by a factor of 4 without cutting on image quality and resolution of the resulting VS. Yet, that claim is only true when comparing two objectives with the same NA. A 40×/NA=0.95 clearly provides higher lateral resolution. Furthermore, the resolution of the camera must be considered as commented on in the next section.

Video camera vs still camera and camera resolution

Video cameras are in general faster than still cameras. They can grab up to 30 images per second, whereas still cameras take up to 1 sec per image. On the other hand, still cameras deliver up to 12 to 20 megapixels per image, whereas video cameras are limited to about 0.3 to 1.3 megapixels per image (640*480 to 1,300*1,030).

Dedicated VS scanners may also use specialized sensors (Aperio, <http://images.scanscope.com>; DMetrix, <http://www.dmetrix.net>).

For optimal colour information, the red, green and blue (RGB) component of light should be collected at each pixel. Many charge coupled device (CCD)-chips use a so-called Bayer mask instead (Fig. 2), which reduces colour information significantly.

Three types of technology are available to gather colour information for every single pixel: (a) three-chip cameras—

grn	red	grn	red
blu	grn	blu	grn
grn	red	grn	red
blu	grn	blu	grn

Fig. 2 Bayer mask. Chequer-board-like filter for RGB (red, green, blue). The intensity of each pixel of the sample is measured at one wavelength (colour) only. Full colour information will then be interpolated, not really measured

the light path is split and RGB components are captured each on a separate chip, (b) scan mode—a sensor is equipped with a Bayer mask and the whole chip is piezoelectrically repositioned four times per image to measure each component separately (e.g. AxioCam HR; image comparison, (<http://alf3.urz.unibas.ch/patho/pub/axiocam.pdf>), (c) three-pass mode—the sensor scans the sample in three successive scans each time using a different illumination for red, green and blue (e.g. DX-40, (<http://www.dmetrix.net>)).

As a rule of thumb, approximately 1 to 1.5 megapixels are needed when taking pictures with a 40× objective and a standard camera to match the optical resolution of a standard microscope [9]. Increasing the resolution of the camera above this value increases image size without yielding more information and should therefore be avoided. When using a 20× Plan Apochromat objective for slide scanning, the camera resolution should be four times higher because the field of view is four times larger than with a 40× objective. Otherwise, image information is lost.

Single/multiple focus planes and z-sharpening

A major drawback of most VS is the lack of multiple focus planes that allow the pathologist and even more so the cytologist to slightly change focus from the main focus plain within the z-axis. Therefore, information contained within a real slide is lost in the VS due to a reduced depth of sharpness. To avoid this drawback, two different approaches have been realized, both scanning the slide at multiple focus planes, but:

- (a) Delivers the additional planes on request to the browser (e.g. Bacus Laboratories WebSlide, (<http://www.bacuslabs.com>)).
- (b) z-sharpening: a software algorithm extracts the sharpest areas from the different focal planes and combines them to a synthesised image with a high depth of sharpness (e.g. Olympus. Slide, <http://www.soft-imag.de/rd/english/3412.htm>; DMetrix, <http://www.dmetrix.net>—announced as a future feature).

Both approaches significantly increase total scanning time. Bacus' WebSlide more closely simulates a real microscope—at the cost of increased download time and a magnitude of storage.

It remains to be evaluated which of the two approaches will lead to more accurate diagnoses with comparative studies of the two methods.

Single large image file vs matrix with thousands of images

Scanning large samples results in dozens of gigabytes of raw data. Advances in computer technology are by and by overcoming the problems arising from handling single large image files. However, only few software tools are able to handle (analysis, post-processing) such huge image files yet. For Web delivery, special server processes are needed for single-file VS, whereas matrices of small files can be served using a standard http demon.

Dynamic downsizing vs pyramidal multi-resolution stack

Two different approaches are used to view VS at different magnifications. Some systems only store the highest resolution on disk. For viewing VS at smaller magnifications, the image is dynamically downsized. This might be appropriate for a single-user system. However, in a multi-user and multi-access system, which is true for most Web applications, dynamical downsizing raises unnecessary high demands to the server [3]. A pyramidal stack stores images at different resolutions [9]. Most VSS use a pyramidal approach. In the case of vMic, this requires less than 12% additional storage space.

Proprietary systems vs open standards

Unfortunately, many suppliers offer VSS that use proprietary image file formats and viewers. Some have adopted Zoomify's technology (<http://www.zoomify.com/customers>). Although this is also a proprietary image file format, a low-cost developer kit enables the development of own viewers optimized for teaching, research or diagnostics. For maximal compatibility, VSAS should be able to export VS as a matrix of single-image files in a standard format.

It would be advantageous if image acquisition was decoupled from image delivery. This would not only foster interchange of VS but also the independent development of value-adding viewer applications for education, research and diagnostics. Open standards in the delivery of VS are the precondition for the construction of a semantic web of pathology (<http://www.w3.org/2001/sw>, <http://www.inf.fu-berlin.de/inst/ag-nbi/research/swpatho/icwe04.pdf>).

Sufficient image quality vs best possible quality

Most VSAS are designed to reach reasonable diagnostic quality allowing the pathologist to make a reliable diagnosis [4, 16, 20, 26]. Depending on the application, this approach is absolutely adequate since it minimizes storage space, scanning time and expenditures for optics. vMic on the other hand aims at maximal quality that is reached when equalling the optophysical limitations of the microscope (40×, NA=0.95). With the advent of improved technologies, maximal quality will sooner or later be standard, although minimal diagnostic quality will still be good enough in the future.

Overlapping images vs seamless images

Producing seamless VS using standard microscope technologies demands tedious alignment procedures [23] or time-consuming software stitching.

Dedicated VSAS (DMetrix, <http://www.dmetrix.net>; Olympus, (<http://www.soft-imaging.de/rd/english/3412.htm>; Aperio, <http://images.scanscope.com>) produce seamless VS. Our user surveys have shown that overlaps are accepted by students and pathologists and are not regarded as a drawback in the use of VS.

Purpose of application

If VS are to be used for educational purposes, a low-cost solution may do since scanning time is not critical and overlaps are accepted by the users. VS in daily diagnostics as introduced at the University of Arizona [26] require a high throughput instrument including many terabyte of disk space.

First test, then buy

Some suppliers do not like customers to test their systems before purchase. Some of the systems we have evaluated would never have been able to deliver a VS. Most of the times, additional implementing work is needed depending on the user preferences. Before investing in an expensive VS equipment, the intended uses should be worked out and the possibility to test the system should be demanded from the supplier.

Outlook

Due to additional functionalities that a physical microscope cannot provide, virtual microscopy is a promising new tool, offering a wide range of new applications in the fields of education, research, diagnosis and quality control (<http://www.baculabs.com>, <http://virtualmicroscope.osu.edu>) [2, 4, 7, 10, 13, 15, 18, 20, 24, 26, 27].

High-speed broadband Internet connections are expected to be available in most laboratories soon, allowing most pathologists and students to profit from publicly accessible sites.

Storing information contained in a single VS (one focal plane only) takes up to ten CD-ROMs or one DVD. Replacing physical slide archives by digital archives is therefore not reasonable at present but will probably be possible within the next decades.

Fast slide-processing time is essential if VS are to be widely used for routine diagnostic pathology including intra-operative frozen sections and second-opinion consultations. The advent of easy-to-handle ultra-rapid slide scanners [25] will ensure a fast propagation of this most recent application in telepathology.

By participating in VS seminars, every pathologist can make a first step towards mastery of this trend-setting technique. The use of vMic (<http://vmic.unibas.ch>) slides is free of charge and does not require registration, allowing everyone to gain first experiences with a new way of looking at histology slides.

Acknowledgements The authors thank Drs. Ray Barnhill, Martin Cook, Dirk Ruitter, Heinz Regele and Hermann-Josef Gröne for the contribution of cases for the VS seminars. This work has been supported by a grant of the University of Basel.

The impact of large sections and 3D technique on the study of lobular in situ and invasive carcinoma of the breast

Received: 5 October 2005 / Accepted: 10 October 2005 / Published online: 3 December 2005
© Springer-Verlag 2005

Abstract The aim of the present study was to investigate the type of intraglandular spread of lobular neoplasia (LN) and its relationship with invasive lobular carcinoma (ILC) through three-dimensional (3D) stereomicroscopy and analyses of large histological sections (histological macrosections, HM). Fifteen cases showing multiple foci of in situ LN and/or ILC (1 pure LN, 12 LN+ILC, and 2 pure ILC) constituted the basis of the present study. Thirteen cases were treated with mastectomy (including the case of pure LN), and two cases were treated with quadrantectomy. In all cases, large parallel 5-mm-thick sections were em-

bedded in paraffin and stained with hematoxylin and eosin (H&E). Selected large paraffin blocks were investigated with stereomicroscopy. The H&E-stained HM were then compared with the corresponding tissues examined using stereomicroscopy. (1) LN was multicentric in nine cases. (2) The average maximum distance among LN foci was 37.9 mm, while the average maximum distance among ILC areas was 58.2 mm. (3) On 3D examination, LN-filled acini and ducts appeared dilated. When “Pagetoid spread” was present, the ducts were lined by a continuous layer of neoplastic epithelium. (4) No anastomoses between lobes were observed in the two cases where glandular trees were visualized. (5) In 12 cases, ILC areas enveloped ducts and acini affected by LN—an association that was more than coincidental. (6) Multicentric ILC areas not associated with LN indicated vascular spread. It is concluded that the information given in LN and ILC, obtained by analyses of large histological sections, is far superior than that obtained by analyses of conventional histological sections, which underestimate multiple distant small foci of invasion. 3D sections are useful in understanding the architecture of specific lesions.

Introduction

Large histological sections (histological macrosections, HM) and three-dimensional (3D) stereomicroscopy allow the visualization of the entire mammary glandular tree. 3D studies were originally applied to mouse breast tissues and gave relevant insights into the development of normal breasts [1, 9].

The site of origin of ductal carcinoma in situ (DCIS)/ductal intraepithelial neoplasia (DIN) is believed to be the terminal ductal lobular unit (TDLU) [21], and the type of intraglandular spread of DCIS/DIN in terms of unifocality or multifocality has been repeatedly shown [7, 11]. Accordingly, well-differentiated DCIS recognizes a multifocal

discontinuous type of growth, with gaps of noninvolved ductal walls located between two neoplastic foci. On the contrary, poorly differentiated DCIS spreads along the ducts in a continuous unifocal fashion without visible gaps [7, 11]. The correlation between mammography and pathology is also enhanced by HM and 3D studies [19]. 3D reconstruction of the breast glandular tree, recently aided by computers, has allowed a better understanding of the normal glandular structure of the breast, which is subdivided into lobes (anatomical structures that are independent of one another) [10, 13]. Lobes vary from 11 to 48 (median, 27) [10] and do not have apparent anastomoses among themselves.

To date, lobular carcinoma, either in situ (lobular neoplasia, LN) or invasive (invasive lobular carcinoma, ILC) [22], has never been studied at the 3D level and, to our surprise, there has only been one study that used HM on ILC, but it did not mention LN [17].

During routine practice, it is common to observe cases containing multiple foci of LN or ILC located far away from one another, but the multifocality (here defined according to Tot [17] as multiple foci in the same lobe) or multicentricity (here defined according to Tot [17] as multiple foci present in different lobes) of LN is a highly controversial issue in the literature. Foote and Stewart [8] stated that LN is always a disease of multiple foci. Subsequent reports have confirmed that multicentric LN is identified in 60–80% of mastectomy specimens [16]. These conflicting results probably are consequent to the fact that, in routine practice, biopsy provides only a limited tissue sample and, thus, the process cannot be visualized in its entire extension.

The purpose of the present study is to investigate the intraglandular spread, size, and multifocality and/or multicentricity of LN and ILC, using HM and 3D stereomicroscopy.

Materials and methods

Fourteen cases that have undergone preoperative diagnostic procedures [either fine needle aspiration cytology or core biopsy (CB)] for palpable nodules, which in turn have led to diagnostic categories of positive (13 cases) or suspicious for malignancy (1 case) [3], were randomly selected for this study from the files of the Section of Anatomic Pathology of the University of Bologna at Bellaria Hospital. Two cases were pure ILC and 12 cases showed LN and ILC simultaneously.

An additional case of pure LN diagnosed by histology of tissues excised for reduction mastoplasty was also included in the study.

On mammography, no calcifications were visible in all cases. The only criterion of selection was the processing of cases using the procedure for macrosections (see below).

The diagnostic criteria of LN (also called lobular in situ neoplasia, LIN) and ILC were in consonance with current histological criteria [22]. Accordingly, E-cadherin immunostaining (monoclonal, clone HECD-1, dilution 1:1,000; Zymed) yielded negative results in all cases. Twelve cases underwent mastectomy, the case of pure LN was treated with bilateral subcutaneous mastectomy, and two cases were treated with quadrantectomy. Axillary dissection was performed in 11 cases.

Specimens were received fresh. In all cases, large parallel 5-mm-thick slices (also called macrosections) were obtained. Care had been taken to slice each section, which included the nipple, perpendicularly to the skin during mastectomy. Slices were then formalin-fixed and paraffin-embedded. From each large block, hematoxylin and eosin (H&E)-stained HM were obtained [9] and used for routine histology.

For 3D stereomicroscopy study, large paraffin blocks were selected with the guidance of a related large H&E

section. Selected blocks were then deparaffinized. Paraffin was melted in a hot bath at 60°C (3–4 h) and subsequently immersed in xylene (four times) for at least 24 h to remove residual paraffin [6]. Tissues were then rehydrated as follows: 50% absolute alcohol and 50% xylene (1 h), absolute alcohol (2 h), and 70% alcohol (2 h). Finally, blocks were washed overnight in distilled water, stained in Harris' hematoxylin for 4–5 min, rinsed in tap water for 10 min, and immersed in four baths of acid alcohol for 8 min each. Then tissues were dehydrated, through a graded series of alcohol to xylene, and finally immersed in methyl salicylate for one night.

3D examination was performed using a stereomicroscope (Nikon, Tokyo, Japan). The H&E-stained large histological slide was used to retrace the lesions to examine corresponding cleared tissues.

In all cases, the number of LN foci (focus is defined here as neoplastic cells located within, at least, a space of one another) and the number of ILC areas (area is defined here as a clump, sheet, or nest of ILC cells), independently of their size, were counted. The distance between foci and areas was assessed microscopically using calibrated lenses on large histological slides.

Results

Clinical data are summarized in Table 1. All patients were female, with age ranging from 41 to 87 years (mean, 62 years). Twelve cases showed LN and ILC at the same time, while one case (case 3) showed only bilateral LN. Pure ILC was present in two cases.

All LN foci showed features of LIN 2, as recently subtyped [22]. ILC was of the classic type in six cases and was of the pleomorphic type [5] in eight cases.

Number of LN foci With the exception of the two ILC cases that did not contain LN foci, all the other cases, as

seen in HM, ranged from a maximum of 77 LN foci randomly distributed throughout the whole section of the right breast in case 3 to a minimum of 2 foci in cases 8 and 11 (mean, 23.9 foci) (Table 2 and Fig. 1). Case 3, the only one that had undergone bilateral mastectomy, had only one focus of LN in the contralateral breast. In no fewer than seven cases was the number of LN foci higher than ten (53.8%).

Distance between LN foci as measured on HM The maximum space between the most distant LN foci ranged from 112 mm in the right breast of case 3 (Fig. 1) to 5 mm in the breast of case 8 (mean, 37.9 mm). The maximum space was greater than 20 mm in not less than nine cases (69%).

Number of ILC areas The number of ILC areas in the 14 cases ranged from 1 (in three cases, 21.4%) to more than 100 (in two cases, 20.7%). The areas were diffusely spread throughout the breast tissues of the various cases and, as general rule, there was a dominant larger-sized area in each case (see Table 2 and Fig. 2a). When multiple ILC areas were present in the same cases, diffuse vascular in-

Fig. 1 Case 3: subcutaneous mastectomy. In this case, 77 foci of LN were observed. The maximum distance between LN foci was 112 mm. In both insets, LN involvement of acini is evident

Fig. 2 Case 2. **a** In this case, LN foci (*lower right inset*), multiple ILC areas (*upper inset*), and ILC intermingled with LN (*lower left inset*) are present. (*) A dominant large area is evident. **b** Neoplastic invasive cells are located in perivascular spaces reminiscent of Hartveit's prelymphatic labyrinth. **c** In the center, neoplastic cells are clearly evident in a small vessel. *Right*: there are cells located in spaces suggestive of Hartveit's channels

vasion or invasion of Hartveit's pseudovascular channels [2] was observed (cases 2, 6, 8, 9, 11, 13, and 15) (Fig. 2b,c).

Distance between ILC areas as measured on HM The maximum distance of uninvolved tissue between the most distant ILC areas ranged from 10 to 130 mm (mean,

Fig. 3 Case 4: LN foci (*arrows*) immersed in ILC cells. On 3D stereomicroscopy, the invasive area shows a "cloudy" appearance with evanescent margins. *Inset*: the corresponding area at HM shows LN (*arrows*) intermingled with ILC

58.2 mm). The size of the largest ILC areas in each case ranged from 10 to 70 mm (mean, 36.7 mm).

Relationship between LN foci and ILC areas In no fewer than ten cases most of the LN foci were located within the largest sized area of ILC, enveloped by and immersed in invasive neoplastic cells (Fig. 3). Nevertheless, in five of such cases (cases 1, 2, 4, 5, and 12), some foci (5–12 foci) of LN were independent of ILC areas. On the contrary, in nine cases, several ILC areas located far from the largest area of ILC did not contain LN foci.

A total of 234 foci of LN were observed in the 12 cases where LN and ILC were present at the same time, and it appeared that 184 LN (78.6%) were located inside ILC areas.

Three-dimensional study On 3D examination, lobular acini of LN were enlarged and globoid, and the related TDLU

Fig. 4 Case 3: the 3D appearance of LN shows the uniform growth of neoplastic cells in acini (as also shown in the *inset* from the same area) as seen with HM

Fig. 5 Case 5: at 3D level, Pagetoid spread manifests as a continuous intramural growth along the duct (arrows). The arrowhead shows serpiginous vessels. Inset: the corresponding histological section as seen with HM

appeared completely filled by neoplastic cells (Fig. 4). No anastomoses between different subsegmental ducts were observed.

LN spread intramurally along larger ducts from acini, presenting the features of “Pagetoid spread” in two cases (cases 3 and 5) (Fig. 5). The spread showed a continuous pattern of growth, and no gaps of noninvolved glandular walls were visible. Duct walls appeared as thickened, bluish structures (Fig. 5). ILC appeared as finely granular, bluish areas that resembled clouds with fading margins. ILC “clouds” (Fig. 6) enveloped ducts and lobules affected by LN (Fig. 3) and also contained numerous vessels.

Fig. 6 Case 10: invasive carcinoma appears on 3D stereomicroscopy as bluish, irregular “clouds.” Inset: the same area as seen in “conventional” histology

Discussion

Since the seminal paper of Foote and Stewart [8] in which it was stated that all LN recognize multiple foci of growth, multicentricity in LN has been shown in as many as 85% of patients [15]. This is in keeping with the present data in which the 13 cases containing LN showed a wide range of multiple foci varying from 2 to 77 (mean, 23.9) in various cases, with no fewer than seven cases (53.8%) having ten or more foci.

Tot [18] has suggested that DCIS usually arises in one “sick” lobe only. This in view of the fact that the maximum distance between different foci of DCIS does not exceed 10 mm in most of the cases [7]—a measurement that probably corresponds to the width of most lobes, although it has been suggested that lobes are of different sizes and can extend from 2 to 23% of the breast volume [10].

The maximum distance between LN foci in the present cases varied from 5 to 112 mm (mean, 37 mm); in addition, in nine cases (69%), the maximum distance was no less than 20 mm. This probably indicates that, in most LN, more than one lobe is affected by the tumor (not to mention case 3 in which virtually all lobes from the same breast were involved).

No anastomoses between lobes were found in the 3D study of the cases in which entire lobes could be visualized—a finding also corroborated by previous works [10]. A continuous type of spread along the breast glandular tree, similar to that observed in poorly differentiated DCIS [7, 11], was seen in the two cases in which Pagetoid spread was found.

Invasive areas, with the exception of three cases that were unifocal (21.4%), were multiple in the same breast. There were as many as more than 100 areas in one case, and these averaged 20.7 in different patients. In cases with multiple involvement, the distance between the farthest-apart areas ranged from 10 to 130 mm. These data are in keeping with the only available study on macrosections of 130 cases of ILC, in which it was found that 39% of cases were unifocal, while the remaining cases were widespread lesions [17].

In the ILC areas of the present cases, the most frequent feature was that of LN immersed in and surrounded by ILC cells in 78.6% of the instances—an association so relevant that it cannot indicate a fortuitous phenomenon [14].

Furthermore, it has been shown in a literature review of 493 cases of pure LN diagnosed with CB that the presence of invasive breast cancer was underestimated in 18% of patients [4]. This further indicates, as shown in the present cases, that LN and LCI are widespread lesions that cannot all be represented in the limited materials obtained by CB. To adequately map a quadrant or a whole breast, numerous conventional histological blocks are required, making routine examination an expensive and time-consuming procedure [9]. Jackson et al. [12] compared two series: one studied with conventional histology and the other studied with HM. With the latter, the size of the invasive carcinoma could be determined for all cases. In contrast, size could be measured for only 63% of the 99 cases studied with

conventional small blocks. The size measured with HM was larger than that measured with conventional blocks; DCIS was also found more frequently, in association with invasive carcinomas, in specimens assessed by HM (80%) than in cases processed using small blocks (63%).

In nine cases in which ILC areas were devoid of LN, neoplastic cells were frequently seen in vessels or in spaces of Hartveit's prelymphatic labyrinth [2], suggesting that multicentric invasive carcinoma without LN is more probably an expression of intramammary metastases.

Admittedly, the number of cases studied here is small, and a selection bias of some sort is present, reflecting the high incidence of pleomorphic ILC observed in eight cases. Six cases were classic ILC, with an average of five ILC areas per case, while the eight pleomorphic cases showed, on average, 32 areas per case. Therefore, it appears that pleomorphic lobular carcinomas are neoplasms different from classic ILC, as shown by the fact they are aggressive tumors, as previously suggested [5, 20] and recently demonstrated by Tot [17].

Nevertheless, in spite of the limited number of cases, the data obtained in the present cases indicate the following:

1. LN equally involves ducts and acini, and Pagetoid spread appears as a thickening of the ductal walls in which the cells spread in a continuous fashion, as shown in 3D stereomicroscopy. No anastomoses between lobes were observed in the two cases in which the glandular trees were visualized.
2. LN observed in the present cases often appeared as a true multicentric lesion, affecting different breast lobes. This finding would probably indicate that there is a near-germline commitment of the breast epithelium to neoplastic transformation [18], although this view has to be further proven.
3. Conventional histological slides clearly would have underestimated ILC areas, as the mean distance between ILC areas was 5.8 cm.
4. ILC contained numerous LN foci (78.6% of LN), suggesting the existence of a direct relation between the two lesions in which LN might be the precursor of ILC.
5. In addition, the presence of multiple areas of pure ILC is probably the result of intramammary metastases in transit, as numerous cells are observed in vessels or Hartveit's spaces.

In conclusion, larger series of LN and ILC, which appear to be more and more necessary to better understand the extent of breast tumors, have to be studied using HM.

Acknowledgement The experiments complied with the laws of the state (Italy) in which they were performed.

Chronic urticaria is associated with mast cell infiltration in the gastroduodenal mucosa

Received: 26 September 2005 / Accepted: 28 September 2005 / Published online: 3 December 2005
© Springer-Verlag 2005

Abstract Chronic urticaria (CU) is characterized by recurrent itching skin eruptions caused by mast cell degranulation. Relapses can be provoked by food intake. The aim of this study was to investigate if the mast cell number in the gastroduodenal mucosa is increased in CU patients, and whether mast cell counting by pathologists is clinically useful. We defined two study groups: 50 disease controls (16 Belgians and 34 Italians) and 43 Belgian CU patients. Mast cells were detected using immunohistochemistry for tryptase and CD117. The mast cell number in the disease controls was 20.2/high-power field (HPF; 133.3/mm²) in the stomach and 32.5/HPF (209.2/mm²) in the duodenum. There was no difference between Belgian and Italian controls, indicating that dietary habits have no influence on the normal gastroduodenal mast cell number. In CU patients, mast cell numbers were significantly higher: 32.4/HPF (186.0/mm²) in the stomach ($P<0.0001$) and 44.8/HPF (246.0/mm²) in the duodenum ($P=0.0002$). CU is thus associated with mast cell infiltration in the gastroduodenal mucosa, even if patients do not have gastrointestinal symptoms. Mast cell counting in gastro-

duodenal biopsies of CU patients can be useful in selecting patients who may respond to a therapy with intestinal mast-cell-stabilizing agents.

Introduction

Urticaria is a very common skin disease characterized by the sudden appearance of smooth, raised, red, pink or white bumps and wheals of varying sizes almost anywhere on the skin (Fig. 1). The lesions usually last for several hours and then disappear without therapy [22]. About 20% of the general population has at least one episode of urticaria during their lifetime. When the disease lasts for more than 6 weeks and the skin eruptions occur at least twice a week, the condition is called chronic urticaria (CU) [15]. The aetiology of CU is unclear in most cases. Epidemiological studies show that it occurs most often in middle-aged women, but it can affect all ages, genders and races. Hidden or overt infections, abdominal disorders, and in some cases, mental strain have been associated with the disease. The skin lesions of CU are caused by vasoactive mediators released through specific or non-specific mast cell degranulation in the skin or elsewhere. CU patients are particularly susceptible to the non-specific histamine-releasing effect of pseudoallergenic substances in various foods and drugs, and the success rate of pseudoallergen-free diets varies between 30 and 50% [5, 27]. It is conceivable that food pseudoallergens induce non-specific mast cell degranulation, rather in the gastrointestinal tract than elsewhere. Activation of many intestinal mast cells may then result in enough histamine release to cause urticaria either directly or indirectly.

Mast cells are involved in numerous inflammatory and immunologic processes. They are part of our innate defence against bacterial and parasitic infections, and they play a role in the induction of the acquired immune response [12]. They store and release various mediators

including histamine, tryptase, fibroblast growth factor-2, vascular endothelial growth factor and nerve growth factor. Histamine causes blood vessels to widen and leak fluid into the surrounding tissue, thereby producing swelling. Histamine also binds on the H1 receptors of neurons, which results in an itching sensation.

Another substance released upon mast cell degranulation is β -tryptase, which is a mast-cell-specific product. In humans, there is a constitutive low-grade release of α -tryptase from mast cells. Therefore, the determination of baseline serum tryptase, which measures both α - and β -tryptase, may be used to estimate the mast cell load. In CU patients, baseline levels of histamine and tryptase are higher than in normals [4, 14]. This may result either from mast cell activation or from a higher number of mast cells in the skin or elsewhere. Haas et al. [13] report an increase in mast cells in lesional and non-lesional skin of CU patients with classical histochemical staining methods. However, recent studies that have used immunohistochemical techniques with specific monoclonal antibodies to mast cell tryptase have not confirmed these findings [6, 21].

In the normal human gastrointestinal tract, mast cells are mainly located in the mucosal lamina propria. In the submucosa, mast cell density is lower, while the muscularis propria and serosa contain only negligible quantities of mast cells. Immunohistochemical data on gastroduodenal mast cell numbers in healthy subjects are however very scarce. The mast cell number in the digestive tract has been studied in mast-cell-related diseases such as systemic mastocytosis, and in other conditions like coeliac disease. Results are contradictory with either the reported increase or decrease [1, 7, 8, 10, 20, 24]. At this moment, little is known about mast cell numbers in the gastroduodenal mucosa in CU. The aim of this study is threefold: (1) to determine by immunohistochemical techniques the mast cell number in the normal gastroduodenal mucosa, (2) to investigate whether different dietary habits influence the mast cell number in normal subjects and (3) to determine whether the number of mast cells is increased in the gastroduodenal mucosa of CU patients because this could be of importance for the therapy for CU.

Materials and methods

Patients

The patient group consisted of 43 Belgian subjects (M/F ratio 15:28, age range 16–77 years, median age 45 years) with CU referred to the Department of Allergy and Clinical Immunology in our hospital. CU was defined as urticarial lesions appearing at least twice a week for more than 6 weeks. In 42 out of 43 patients, the baseline serum tryptase level was determined with the UniCAP-Tryptase fluoro-immunoassay (Pharmacia-Upjohn, Sweden). In 1 patient, tryptase was not measured because of an administrative error. A gastroduodenoscopy was performed prospectively as part of the investigative procedure in all patients, whether gastrointestinal symptoms were present ($n=30$) or not ($n=13$). One patient had been treated for *Helicobacter pylori* (Hp) infection in the months preceding the endoscopy. Biopsies were taken from the gastric corpus, the antrum and/or the duodenum. A urea breath test was included in the diagnostic work up after the start of the study and was performed in 25 out of 43 patients. All patients were questioned for the presence of rhinitis, asthma and food allergic or pseudoallergic symptoms. They were also asked to report on intolerance reactions to food pseudoallergens such as additives, histamine-releasing agents and alcoholic drinks. They were prospectively investigated by skin prick tests (SPT) with a screening panel including pollen of grasses, trees and weeds, with house dust mite, moulds, cat, dog and with food allergens in patients with a positive history. Specific IgE determinations (CAP system, Pharmacia-Upjohn) for respiratory and/or food allergens were performed in patients with a negative SPT. Patients with a positive history and at least one positive SPT or CAP-test were considered as “atopic”, whereas the other patients were designated as “non-atopic”.

Disease controls

A control group of 16 Belgian and 34 Italian (Sardinian) subjects (M/F 17:33, age range 6–72 years, median age 45 years) without urticaria underwent upper endoscopy for abdominal pain, pyrosis, weight loss or anaemia. Biopsies were taken from the gastric corpus, the antrum and/or the duodenum where appropriate. All disease controls were tested for coeliac disease: serology was negative in all cases except for 1 Italian subject having a positive anti-gliadin but negative anti-endomysium Ab test.

Biopsy evaluation

All biopsy specimens were fixed in 10% buffered formalin, routinely processed and embedded in paraffin. Haematoxylin–eosin (HE) stained sections were examined for routine diagnosis using the Sydney system for gastric biopsies [9].

Immunohistochemical detection of tryptase and CD117 (c-kit) was chosen as the preferred method for identification of mast cells. For tryptase detection, a 1:100 diluted monoclonal mouse–antihuman mast cell tryptase antibody solution (DakoCytomation, clone AA1) was applied for 30 min at room temperature after proteolytic enzyme digestion with trypsin. The reaction was completed by adding avidin–biotin–peroxidase complex and 3,3'-diaminobenzidine (DAB) chromogen. CD117 was detected with a 1:250 diluted polyclonal rabbit–antihuman antibody solution (DakoCytomation, code no. A4502). Antigen retrieval was by boiling the dewaxed paraffin sections in 0.01 M Tris–EDTA solution (pH 9) for 30 min. The reaction was completed by addition of peroxidase-labelled anti-rabbit EnVision + Reagent (DakoCytomation) and DAB chromogen. Sections were faintly counterstained with Harris haematoxylin. Mast cells were counted by two pathologists (F.M. and C.W.) on a Zeiss light microscope. Only cells with a visible nucleus and unequivocal cytoplasmic or membranous staining were considered as mast cells. Differential diagnosis with Cajal cells was by cell shape (rounded instead of elongated) and by location. Counting was done only in vertically oriented tissue pieces. Mast cells were counted in five high-power fields (HPF; surface area of 1 HPF at magnification $\times 400 = 0.229 \text{ mm}^2$) and also in 5- μm grids composed of 100 small squares (surface area of 1- μm grid at magnification $\times 400 = 0.090 \text{ mm}^2$), enabling us to express the results as mean mast cell number per millimeter squared. The optical field of the microscope was positioned at the superficial part of the mucosa, so that as much lamina propria as possible was included.

Biopsies were also stained immunohistochemically for Hp in all CU patients and in the disease controls when appropriate. Hp staining was done using a 1:40 diluted polyclonal rabbit–anti-Hp antibody solution (DakoCytomation, code no. B0471) applied for 30 min at room temperature after heat-induced epitope retrieval by boiling the dewaxed paraffin sections in 0.01 M citrate solution (pH 6) for 30 min. The reaction was completed by addition of peroxidase-labelled anti-rabbit EnVision + Reagent (DakoCytomation) and DAB chromogen.

Statistical methods

All statistical analyses were performed using non-parametric tests (Mann–Whitney test and Spearman's rank correlation). *P* values less than 0.05 were considered statistically significant.

Results

Endoscopic findings

Upper endoscopy was normal in all disease controls. In the CU patients, there were no endoscopic abnormalities in 28/43 subjects. Twelve CU patients had signs of reflux oesophagitis, 1 showed gastric mucosal hyperaemia, 1 had a gastric ulcer suspicious for malignancy and 1 had a duodenal ulcer.

Pathological findings

Examination of the HE-stained sections showed normal gastric and duodenal biopsies in all disease controls. Twenty-seven CU patients had stomach and/or duodenal biopsies within normal limits. Otherwise, there were 4 cases of inactive chronic gastritis, 4 cases of active chronic gastritis, 4 cases of reactive gastropathy, 1 with fundic gland polyps, 1 with gastric adenocarcinoma and 2 with benign duodenal ulcers.

Immunohistochemistry for Hp was positive in 3 CU patients, 2 of whom had a positive breath test (no breath test was performed in the third). On the other hand, there were 2 CU patients with a positive breath test but with a negative Hp stain. Thus, there were 5 CU patients with Hp infection (4 of them had active chronic gastritis).

Immunohistochemistry allowed unequivocal identification and counting of mast cells in well-oriented biopsies. The tryptase stain showed granular positivity in the cytoplasm (Fig. 2), while CD117 was present in the cell membrane. Since mast cell numbers obtained by CD117

^bNormal = biopsies histologically normal

stain were comparable to those obtained by tryptase stain (data not shown), all counts were performed on the tryptase stainings. The mean mast cell number for all disease controls together was 20.2/HPF (133.3/mm²) in the stomach and 32.5/HPF (209.2/mm²) in the duodenum (95% confidence intervals for mean mast cell numbers; see Table 1). There was no significant difference between Belgian and Italian controls either in the stomach (Mann–Whitney test, $P=0.49$) or in the duodenum ($P=0.76$).

The mean mast cell number for all CU patients was 32.4/HPF (186.0/mm²) in the stomach and 44.8/HPF (246.0/mm²) in the duodenum. Both in the stomach and in the duodenum, the mean mast cell number was significantly higher in the CU patients than that in the disease controls (Mann–Whitney test, $P<0.0001$ and $P=0.0002$, respectively; Figs. 3 and 4). The difference between CU patients and disease controls was more pronounced in the stomach than in the duodenum (a 61.0% increase in mast cell number in CU patients vs disease controls in the stomach vs a 37.8% increase in the duodenum). The mast cell number in the stomach was not significantly different between

CU patients with (29.4/HPF) and without (32.9/HPF) Hp infection (Mann–Whitney test, $P=0.3574$). When all 20 histologically normal stomach biopsies from CU patients were compared with the control biopsies, the mean mast cell number was still significantly higher in the CU patients (Mann–Whitney test, $P=0.0006$). The same was found when 27 histologically normal duodenum biopsies from CU patients were compared with their corresponding control biopsies ($P=0.0007$).

Relation of mast cell number to atopy, food allergy or pseudoallergy in CU patients

An atopic constitution was demonstrated in 11/43 CU patients. Atopic patients did not differ from non-atopic patients with regard to the gastric or duodenal mast cell numbers ($P=0.8553$ and 0.4126 , respectively).

In 4 of the 11 atopic patients, an IgE-mediated food allergy was detected. In these 4 patients, there was a trend towards higher mast cell numbers in stomach ($P=0.0750$)

Fig. 3 **a** Stomach from control subject (tryptase, original magnification $\times 200$). **b** Stomach from CU patient (tryptase, original magnification $\times 200$)

Fig. 4 **a** Duodenum from control subject (tryptase, original magnification $\times 200$). **b** Duodenum from CU patient (tryptase, original magnification $\times 200$)

than in the non-food allergic patients, but statistical significance was not reached probably because of the low number of food allergic patients.

Fourteen CU patients had a history of food pseudoallergen-induced aggravation of their disease. In these 14 patients, we surprisingly found a lower stomach mast cell number than in those without food pseudoallergy ($P=0.0252$).

Correlation of mast cell number with baseline tryptase levels in CU patients

Baseline tryptase levels were normal ($\leq 11.5 \mu\text{g/l}$) in 38 out of 42 CU patients. The mean value for all patients was $7.2 \mu\text{g/l}$ (range $2.3\text{--}21.9 \mu\text{g/l}$). There was no correlation between the gastric or duodenal mast cell number and the baseline tryptase levels (P values for the Spearman's rank correlation were 0.8998 in the stomach and 0.3982 in the duodenum).

Discussion

In this study, we investigated whether CU, a mast-cell-related disorder which is often aggravated by the intake of pseudoallergen-containing foods, might be associated with mast cell infiltration in the gastrointestinal mucosa. Classically, mast cells have been identified by metachromatic stains such as Giemsa or toluidine blue. We chose to detect them by immunohistochemistry for tryptase and CD117, as these methods are more sensitive and specific [16]. Tryptase is present in the cytoplasmic granules of the mast cells, and CD117 is located in the cell membrane. Positive staining results for tryptase may be more specific for mast cells [25]. Moreover, other authors have found that the results of tryptase and CD117 stains (with antigen retrieval) show a highly significant correlation, so that staining for mast cell tryptase alone apparently is sufficient [20]. Thus, we eventually chose to count mast cells in the tryptase stains. Unfortunately, there are only few authors mentioning normal values obtained by immunohistochemical methods, and their results are variable [7, 20]. We were therefore compelled to determine first the normal values in a disease control group. As there are no data available on the potential effect of different dietary habits on gastroin-

testinal mast cell number, we have included in the disease control group both Belgian and Italian (Sardinian) subjects. Italian dietary habits differ from the Belgian by the use of olive oil "extra vergine", more seafood, more fresh vegetables, more wine, less beer and less food additives.

In the disease control group, we found a mean mast cell number of $20.2/\text{HPF}$ ($133.3/\text{mm}^2$) for the stomach and $32.5/\text{HPF}$ ($209.2/\text{mm}^2$) for the duodenum. Variability was somewhat larger in the duodenal mucosa; 95% confidence intervals were non-overlapping, however. The larger number in the duodenum may have been caused by selection bias: control subjects often had duodenal biopsies taken to rule out coeliac disease, a condition in which mast cell numbers may be increased [23, 26]. However, this cause is not plausible since all controls had normal duodenal histology, and all but one had normal antigliadin and anti-endomysium Ab tests. Our normal value for the duodenum is comparable to the $204.2/\text{mm}^2$ found by Crivellato et al. [7]. In contrast, Siegert et al. [20] found a higher mast cell number in the normal stomach than we did ($331.9/\text{mm}^2$ in the corpus and $251.9/\text{mm}^2$ in the antrum). This may be due to a different positioning of the optical field of the microscope: we chose to count mast cells predominantly in the superficial part of the mucosa, with the aim of including as much lamina propria as possible. Our way of positioning also tends to minimize possible differences between corpus and antrum biopsies.

We found that there was no significant difference between Belgian and Italian controls for mean mast cell numbers either in the stomach or the duodenum. Different dietary habits therefore seem to have no influence on the mast cell number in the gastroduodenal mucosa. This result also allowed us to compare the CU patient group (which is exclusively Belgian) with all disease controls (Italian as well as Belgian).

When compared to the disease control group, our CU patients demonstrated a significantly increased mast cell number in the stomach and the duodenum. Liutu et al. [17] found no significant differences in gastric mucosal mast cell numbers between patients with and without CU. However, they only used the less sensitive toluidine blue staining method. Mast cell numbers in the gastroduodenal mucosa have also been determined in mast-cell-related diseases like systemic mastocytosis and urticaria pigmentosa, again with varying results [8, 10, 20].

Gastrointestinal mast cell infiltration in CU may be primary or secondary to concomitant disorders. An increased number of gastrointestinal mast cells has indeed been described in several infectious or non-infectious types of gastritis, with a correlation between the mast cell number and the density of the polynuclear and mononuclear cell infiltrates [3]. In our study, however, there was no relation between the occurrence of a histological abnormality and mast cell counts. Indeed, even CU patients with histologically normal biopsies showed a significantly higher mast cell number in the stomach and the duodenum than disease controls. Hp infection, which is associated with reactive mucosal mast cell infiltration in the stomach [11, 18], is often reported as a possible cause of CU. In our CU patient group, the prevalence of Hp infection was 8% (3/38) with immunostaining and 24% (6/25) with the urea breath test. CU patients with and without Hp infection did not differ in the degree of mast cell infiltration in the stomach.

An increase in the number of intestinal mast cells has also been described in patients with food allergy by some authors [19] but was not confirmed by others [1]. Some reports even mention an increase in intestinal mast cells in atopic subjects with only inhalant allergy [2]. We were able to exclude that atopy and food allergy were the factors that determined intestinal mast cell infiltration in our CU patients. We may conclude that the observed increase in intestinal mast cell numbers in CU patients is directly connected with the disorder itself rather than being part of an inflammatory cell response.

That food allergens are able to cause local degranulation of mast cells has been proven during segmental mucosal challenges [19]. Likewise, one might expect food pseudoallergens to have a similar local effect on mast cells and to cause urticaria by intestinal mast cell degranulation. We therefore expected a higher mast cell number in CU patients with a history of food pseudoallergy than in those without, but we surprisingly found the opposite. This can be explained in different ways. First, the diagnosis of food pseudoallergy is very difficult and the sensitivity of history-taking is low. Ideally, the results of elimination diets should have been taken into account. Second, it could be that there is indeed no relation between mast cell infiltration and food-induced aggravation of CU. Further studies are needed to clarify this.

Determination of baseline tryptase is currently used to estimate the mast cell load. Clearly, elevated levels were found in only 4 out of 42 (10%) of our CU patients. The mean level of 7.2 µg/l in our study is comparable with the level in Hidvegi et al.'s [14] patients and is significantly higher than that in their control group. We did not find a correlation between baseline tryptase levels and intestinal mast cell numbers, which means that peripheral tryptase levels are probably not affected by local mast cell infiltration but predominantly reflect the total body mast cell load.

In conclusion, we showed that CU is associated with gastroduodenal mast cell infiltration. We strongly suppose that there is a causal relation between both phenomena, but

at this stage, it is impossible to establish the exact relationship. CU could indeed be the consequence as well as the cause of the reactive mast cell infiltration. This has still to be investigated. Further studies are also needed to establish whether it is justified to take endoscopic biopsies for tryptase and CD117 stainings in the absence of clear endoscopic lesions in CU patients without gastrointestinal symptoms. The finding of increased mast cell numbers might on the other hand be helpful in directing therapy towards strategies that could prevent intestinal mast cell degranulation. These patients might, for example, benefit more from pseudoallergen-free elimination diets, from H₂-antihistamines or from mast cell stabilizers as disodium-chromoglycate than CU patients with normal mast cell numbers.

Serious foetal growth restriction is associated with reduced proportions of natural killer cells in decidua basalis

Received: 21 September 2005 / Accepted: 26 October 2005 / Published online: 19 November 2005

Abstract Extravillous trophoblasts are major participants in placental development and remodelling of spiral arteries. Trophoblast invasion is regulated by maternal immune cells, and abnormal leucocyte subpopulation composition has been reported in implantation failure. In pre-eclampsia (PE), with or without foetal growth restriction (FGR), superficial trophoblast invasion and insufficient remodelling of spiral arteries are common findings. In the present study, we have compared spiral artery remodelling and leucocyte composition in decidual tissue from 30 cases (PE=8, FGR=5, PE +

FGR=17) and 31 controls. Six histological remodelling criteria were established, and each pregnancy obtained a remodelling score. Numbers of natural killer (NK) cells (CD56⁺), T cells (CD3⁺) and activated (CD25⁺ or CD69⁺) leucocytes were determined and related to total leucocyte (CD45⁺) numbers in serial sections. Cases demonstrated significantly impaired spiral artery remodelling, inappropriate placental growth and reduced NK cell proportions, as compared to controls ($P=0.02$, $P<0.001$ and $P=0.01$, respectively). Reduced NK cell proportion was primarily found in pregnancies complicated by FGR, with or without PE, and a significant positive correlation was observed between NK cell proportion, trophoblast infiltration and placental growth. Our *in vivo* observations support the hypothesized association between NK cells, impaired placental development and pathogenesis of PE/FGR.

Introduction

A complicated and gestation-related interaction between cells of foetal and maternal origin, hormones, growth factors and matrix components is a prerequisite for successful implantation and subsequent placental development [3, 12, 30]. Effector cells and molecules of the maternal immune system are key participants, and decidual leucocytes may both promote and limit placental development through influencing trophoblast survival, invasion, proliferation and differentiation. Endometrial arteries undergo structural alterations to increase blood flow to the intervillous space [11, 28]. The cellular mechanisms of spiral artery remodelling are unknown, but the role of extravillous trophoblast (EVT) in this process is well recognized [19, 28].

Dramatic changes take place in the composition of uterine leucocyte subpopulations following implantation; natural killer (NK) cells emerge as the most prominent subpopulation [18, 26], constituting 50–70% of total leu-

cocyte numbers in the beginning of pregnancy, with decreasing numbers towards term [18, 26]. The uterine (u)NK cells are highly specialized and regulate trophoblast invasion and spiral artery remodelling by NK receptor recognition of trophoblast-expressed proteins with subsequent cytokine production [12, 18, 26]. Macrophages, T and B cells constitute approximately 15, 10 and 2%, respectively, of uterine leucocyte population, and their proportions remain fairly stable throughout pregnancy [2, 18]. The pregnancy-associated intrauterine immune response also implies reduced leucocyte activation, as assessed by down-regulated expression of the T-cell receptors and activation markers CD69, human leucocyte antigen-DR, CD45DR and CD25 (interleukin-2 receptor α) [10, 27].

Implantation failure and incomplete remodelling of spiral arteries may result in placental hypoperfusion, causing pre-eclampsia (PE) and/or foetal growth restriction (FGR) [8, 28]. Several studies suggest that implantation failure may be ascribed to altered composition and/or function of decidual leucocytes [21, 22, 29, 32], but only two studies have focused on changes associated with PE and/or FGR. One study reported increased NK cell and cytotoxic T-cell numbers among cases [36], whereas the other has found altered uNK phenotype and cytokine profile in the disease group [39].

Decidual leucocytes, and especially NK cells, seem to play an important role in placental development and remodelling of spiral arteries. The aim of the present investigation was to study leucocyte composition in decidual tissues and relate findings to remodelling assessment. Tissues from cases with assumed reduced remodelling of spiral arteries (PE and/or FGR) were compared to normal controls, using immunohistochemical techniques.

Materials and methods

Study groups

Suspected placental disease due to insufficient implantation and remodelling of spiral arteries was the major criterion for inclusion of women into the case group of the study. Thus, women with pregnancies complicated by PE and FGR, alone or in combination, were included. Decidual tissue was collected at delivery by vacuum aspiration of the placental bed, and, for technical reasons, collection of material had to be done during caesarean section (CS) [16, 34]. Thus, only women who delivered by CS were included. In the case group, CS was done on clinical indications, whereas the controls were undergoing CS for various reasons considered irrelevant to the aim of this study. FGR was identified as FGR assessed by prenatal ultrasound measures and birth weight confirmation [24]. A birth weight ≤ 2 standard deviation (SD), corresponding to the 2.5 centile for gestational age, was used as FGR criterion. PE was defined as persistent hypertension (blood pressure of $\geq 140/90$ mmHg) plus proteinuria (≥ 0.3 g/d or $\geq 2+$ according to a dipstick test), developing after 20 weeks of pregnancy [1]. The study was approved by the Regional Committee for Medical Research

Ethics. Specimens were collected at St. Olavs Hospital, the University Hospital of Trondheim from 2002 to 2004. Informed consent was obtained from all participants. Pregnancies with chromosomal aberrations, foetal and placental structural abnormalities or suspected perinatal infections were not included.

Sixty-one women were included in the study (30 cases, 31 controls). Five cases suffered from FGR alone, 17 had PE and FGR in combination and 8 women received the diagnosis PE without FGR (Table 1). Cases and controls differed significantly with respect to several clinical manifestations, among those gestational age at delivery, birth weight and placental weight (Table 1).

Tissue collection and preparation

Decidual tissue was obtained by vacuum suction of the placental bed after the placenta was delivered [16, 34]. The collected tissue was fixed in 10% neutral-buffered formalin, paraffin embedded and cut in sections at 4 μ m on a motorised rotation microtome. One section, stained with haematoxylin, erythrosine and saffron (HES), was used for quality control of the tissue collected. Only specimens containing EVT (decidua basalis) were included for further studies. Three (4.6%) of the 65 collected samples consisted mostly of blood or placental tissue and were rejected at this stage. Placental weight was registered, and the placental weight ratio (PWR; observed placental weight/expected placental weight) was calculated. The expected placental weight was obtained from the placental weight standards given by Benirschke and Kaufmann [4]. All placentas enrolled were examined by a pathologist, in accordance with established routines.

Spiral artery remodelling, visualization and assessment

Remodelling of spiral arteries was examined in two sections from each individual; one HES-stained and a second stained with monoclonal antibodies (mAbs) against trophoblasts [anti-cytokeratin 7 (anti-CK7), clone OV-TL 12/30, diluted 1:300; DakoCytomation, Glostrup, Denmark] and against smooth muscle cells (anti-actin, clone HHF35; Ventana Medical Systems Inc., Tucson, AZ, USA). Double immunostaining was performed in an automated slide stainer (Ventana ES, Ventana Medical Systems Inc.) after deparaffination, rehydration and heat-induced antigen retrieval. The staining procedure was divided in two: anti-CK7 was added in the first step, whereas the second step was initiated with anti-actin. The secondary antibodies in both steps were biotinylated (with a streptavidin–biotin complex), and the binding sites were visualized by a 3c3-diaminobenzidine HCl (DAB) chromogen in the first step (iVIEW DAB Detection Kit, Ventana Medical Systems Inc.) and alkaline phosphatase in the second step (Ventana Enhanced Alkaline Phosphatase RED Detection Kit, Ventana Medical Systems Inc.). All sections were counterstained in haematoxylin.

For arteries to be included for assessment, the presence of a defined lumen and a visible vessel wall was required. The remodelling process of each artery was scored, according to eight criteria (Table 2). Six of the criteria were used primarily to grade the remodelling process [i.e., trophoblast infiltration (Fig. 1a,e), trophoblast replacement of the endothelial layer (Fig. 1c), lumen diameter (defined as the most-narrow-measured lumen in a vessel; Fig. 1b), presence and characteristics of smooth muscle cells in the vessel wall (Fig. 1c)]. The remaining two were included to cover pathological vessel alterations [acute atherosclerosis (Fig. 1f) and endothelial activation/thrombosis (not shown)]. The HES-stained section was used for evaluation of the vessel diameter, amount of fibrinoid in the vessel wall, acute atherosclerosis and endothelial activation/thrombosis (Fig. 1b,d, f), whereas all other criteria were assessed in the CK7/actin-immunostained sections (Fig. 1a,c,e).

The remodelling scores obtained by each artery were added up to a sum-remodelling index for each artery. When arterial cross sections were closely located and considered loops of the same tortuous vessel, the sum-remodelling index of the artery was calculated as the mean of all scores given to its loops. Finally, the mean score for each criterion in each pregnancy was calculated (by including assessment scores from all arteries found in that decidual section), and these scores were used for comparison between cases and controls.

Leucocyte population

Six serial sections were used for immunostaining with mAbs towards leucocyte markers. Sections were cut at 4 µm; that is, the first and the last sections were approximately 20 µm apart. This implies that the lymphocytes (7–15 µm in size)

Table 2 Criteria for assessment of spiral arteries

Criteria	Grade				
	0	1	2	3	4
Remodelling criteria					
Trophoblast infiltration		In decidua, but not adjacent to arteries	Adjacent to vessel wall	In arterial wall	Endothelial cells replaced
Trophoblast replacement ^a	None	<25	25–50	50–75	>75
Lumen diameter (µm)	<25	25–50	50–100	100–200	>200
Fibrinoid in vessel wall ^b	Not present	<25	25–50	50–75	>75
Smooth muscle cells in vessel wall ^c	++++	+++	++	+	Not present
Bundles ^d of muscle cells	Present	Not present			
Pathological alterations					
Acute atherosclerosis ^e	No	<25	25–50	50–75	>75
Endothelial activation/thrombosis ^f	Flat endothelium	Endothelial activation	Signs of thrombosis	Partial thrombosis	Occluding thrombosis

Every cross section was evaluated according to the eight criteria given in Table 1

^aTrophoblast replacement is given as a visually estimated percentage of the endothelial layer of the inner vessel wall

^bFibrinoid replacement is given as a visually estimated percentage of vessel wall area replaced by fibrinoid

^cThe occurrence of smooth muscle cells in vessel wall was quantified; +, ++, +++ and ++++ indicate the spread of muscle cells in vessel wall quadrants

^dA muscle bundle consists of several (>5) smooth muscle cells, closely attached together. The parameter was categorized as present/not present for each vessel

^eAcute atherosclerosis is defined by the presence of lipid-laden cells in the intima layer of the vessel wall, given as a percentage of the lumen circumference

^fEndothelial activation is defined by the presence of prominence, basophilia and vacuolization of endothelial cells of the inner vessel wall

Fig. 1 a–f Remodelling of spiral arteries was assessed in sections double-stained with mAbs against trophoblasts (anti-CK7, brown colour) and against smooth muscle cells (anti-actin, red colour) (a, c, e) and in HES-stained sections (b, d, f). The decidual tissue photographed was collected from two women with PE + FGR (a–b and e–f) and from one control (c–d). Remodelling parameters were given the following scores: trophoblast infiltration—score 2, adjacent to vessel wall ("fx1") (a, e); trophoblast replacement—score 2, 25–50% of the endothelial layer is replaced by trophoblasts ("fx1") (c); lumen diameter 100 μm —score 3 (b); fibrinoid in vessel wall—score 4, more than 75% of vessel wall area is replaced by fibrinoid ("fx2") (d); smooth muscle cells in vessel wall—score 2, present in two quadrants ("fx2") (c); bundles of muscle cells—score 0, more than five smooth muscle cells closely attached together ("fx2") (a). In addition, acute atherosclerosis was scored 4, lipid-laden cells in more than 75% of the intima layer of vessel circumference ("fx2") (f). a–d, $\times 200$; e–f, $\times 100$

found on section no. 1 would not be the same as those observed on section no. 6. The mAb against CD45 (clone F7.2.38, diluted 1:400; DakoCytomation) was used as a common leucocyte marker, and the number of CD45 positive (CD45^+) cells was used as the denominator to calculate the proportion of other markers. Due to this and the distance between section no. 1 and no. 6, mAb against CD45 was added to section no. 3. mAb against CD3, T-cell marker (clone F7.2.38, diluted 1:50; DakoCytomation), was added to section no. 1. NK cells were detected by mAb against CD56 (clone 123C3, diluted 1:20; Monosan, Uden, the Netherlands), and the antibody was added to section no. 2, whereas mAb against CD16 [clone 16CO2(2H7), diluted 1:75; Neo Markers, Fremont, CA, USA] (detects NK cells, macrophages, granulocytes) was used for staining of section no. 4. MAb against the cell activation markers CD25 (clone 4C9, diluted 1:150; Novocastra, Newcastle, UK) (T and B cells) and CD69 (clone CH11, diluted 1:25; Novocastra) (T and B cells, NK cells, granulocytes) were added to section no. 5 and no. 6, respectively.

The leucocyte marker staining was performed in an automated slide stainer (DakoCytomation) after deparaffination, rehydration and heat-induced antigen retrieval. Endogenous peroxidase activity was blocked, and primary antibodies were added. Incubation time for all mAbs was 30 min, with the exception of mAb against CD69 (60-min incubation). Secondly, a peroxidase-conjugated polymer

with antibodies against rabbit/mouse (ChemMate Dako Envision Detection Kit Peroxidase/DAB, DakoCytomation) was used, according to manufacturer's standard procedure. Antibody diluent without antibody was used as a control for non-specific staining. Paraffin-embedded sections of tonsil tissue were used as positive controls for all antibodies. The sections were counterstained in haematoxylin.

Cells stained positively with the different leucocyte markers were counted in identical areas of all serial sections. The area selected was determined on the basis of the following criteria: the area should contain at least 250 CD45^+ cells (to provide cell numbers that were statistically sufficient for comparisons between groups), only small amounts of maternal blood should be present, and the defined area should easily be reproduced from section to section. Areas fulfilling these criteria were demarcated with Indian ink in all sections of each series. Two observers counted positive cells simultaneously, independently and blindly for case/control status, after consensus on inclusion criteria for the different leucocyte populations was reached (Fig. 2). Counting was performed at $400\times$ magnification, using a $13\times 13\text{-mm}$ reticule.

The total cell number used for calculation of the leucocyte subpopulation proportion was obtained by two different approaches: in the first alternative, all CD45^+ cells were counted ($n=\text{CD45}^+$ leucocytes), whereas in the second, only CD45^+ cells with lymphocyte appearance

Fig. 2 a–b Immunostaining with mAbs against CD45 (common leucocyte marker) (a) and against CD56 (NK marker) (b) was performed on formalin-fixed, paraffin-embedded serial sections. Tissue fields containing at least 250 CD45⁺ cells were included in

assessment, and cell proportions were calculated, with the CD45⁺ counts as the denominator. Only positive cells with distinguishable nuclei were counted. The photos demonstrate cells included in ("fx2") and excluded from ("fx1") counting. **a–b**, ×400

were included ($n=CD45^+$ lymphocytes). Ratios between CD3⁺, CD56⁺, CD16⁺, CD25⁺ and CD69⁺ cells and both leucocyte numbers (CD45⁺ leucocytes and CD45⁺ lymphocytes) were calculated for each individual. In addition, the ratios between CD16⁺ and CD56⁺ cells were calculated. The results are given as means±SDs.

Statistical analysis

Results are expressed as the mean of groups±the corresponding SD. The Mann–Whitney test was used for comparison between groups, and Spearman's ranked correlation test was used to examine correlation between spiral artery remodelling and leucocyte subpopulation composition. $P<0.05$ was considered to be significant. SPSS version 12 was used for all statistical analyses.

Results

Spiral artery remodelling

Most sections (89%) contained one or more loops of uteroplacental arteries (remodelled spiral arteries) in decidua basalis. The number of arteries on each section varied from 1 to 15 (4±3), and the number of loops belonging to one spiral artery varied from 1 to 17 (4±3). The number of spiral arteries found in sections did not differ between the case and control groups. In seven sections (PE, 2; FGR + PE, 1; controls, 4), no arteries were found, and accordingly, these pregnancies were excluded from the spiral artery remodelling classification.

The overall case group demonstrated insufficient remodelling of uteroplacental arteries, as expressed by comparison of sum-remodelling indexes of cases (8.8±3.3) and controls (11.1±3.3, $P=0.02$). When the separate remodelling criteria were considered, vessel lumen, trophoblast invasion and endothelial replacement seemed, in order of appearance, to give the best discrimination between cases (2.5±0.5, 1.9±0.6, 0.1±0.2) and controls (2.9±0.4, 2.8±0.7, 0.5±0.5; all $P_s<0.01$). In contrast, fibrinoid replacement and muscle cells (either separate or in bundles) did not differ between study groups (data not shown).

Acute atherosclerosis was observed more frequently among cases (1.0±1.0) compared with controls (0.3±0.5, $P<0.01$), whereas

endothelial activation/thrombosis did not differ significantly between the overall case group and controls (data not shown).

Placental weight and placental histology

The ratio between observed and expected placental weight (PWR) reflects placental growth conditions. The PWR among controls (1.5±0.3) was significantly higher than that found in cases (1.0±0.3, $P<0.001$). Pregnancies with FGR alone and in combination with PE were associated with significantly reduced placental growth as compared to normal pregnancies (both $P_s<0.001$), while in pregnancies with isolated PE, PWR did not differ significantly from controls. Furthermore, a positive association was found between PWR and trophoblast invasion ($P=0.02$) and trophoblast replacement ($P=0.03$).

Morphological alterations in the placenta were more frequent among cases than controls; 13 (43%) cases demonstrated advanced villous maturation, as compared to three (10%) controls. Multiple infarcts (involving more than 15% of the placental volume) were found in four (13%) cases (all of them from the FGR ± PE subgroup) and none in controls. Placental histology was described as normal in five (16%) cases and 17 (55%) controls.

Leucocyte subpopulations and cell activation

The proportion of NK cells (with the CD45⁺ leucocyte numbers as the denominator) was significantly lower in the overall case group (18.5±10.4%), as compared with controls (26.8±13.7%, $P=0.01$; Fig. 3). Pregnancies complicated with FGR had the lowest NK cell ratio as compared with controls ($P=0.01$; Fig. 3). The reduction was less pronounced in pregnancies complicated with PE, and the proportion of NK cells in this group did not differ significantly from controls (Fig. 3). The proportions of CD3 and CD16 positive cells did not differ between cases and controls, neither overall nor in subgroups (Fig. 3). The CD16/CD56 ratios were increased in cases (all cases 0.13±0.10, PE 0.10±0.09, FGR 0.16±0.13, PE + FGR 0.14±0.10) but did not differ significantly from that found in controls (0.11±0.11).

Fig. 3 Proportions (%) of CD56⁺ (NK cells), CD3⁺ (T cells), CD16⁺ (NK cells, macrophages, granulocytes), CD25⁺ and CD69⁺ (leucocyte activation markers) leucocytes, as related to the total number of CD45⁺ (common leucocyte marker) cells, in formalin-fixed, paraffin-embedded serial sections of decidual tissue obtained from

women at delivery. One case group suffered from foetal growth restriction (*FGR*), a second had *FGR* and pre-eclampsia (*PE*) and in the third, *PE* was the only diagnosis. All case groups were compared to controls. Results are displayed as mean values, with the corresponding SD. * $P < 0.05$

When leucocyte proportions were calculated as proportions of CD45⁺ lymphocyte numbers, similar results were obtained. For NK cells, the proportions were 28.0±15.3% among cases and 40.9±18.6% among controls ($P < 0.01$). Both the case group with isolated *FGR* and the *FGR* + *PE* group demonstrated significantly reduced NK cell proportions when NK cell counts were related to CD45⁺ lymphocyte numbers ($P = 0.02$ and 0.03, respectively), whereas in the isolated *PE* group, the reduction was not significant.

Cell activation, as assessed by expression of CD25 and/or CD69, was neither increased in association with *FGR* nor with *PE*. A higher expression of CD25 was found in the group with isolated *FGR* ($P = 0.04$), whereas all other comparisons between study groups and controls demonstrated no significant differences in CD25 and/or CD69 expression (Fig. 3).

NK cell proportion, spiral artery remodelling and placental growth

A positive correlation was observed between NK cell proportion and trophoblast infiltration in pregnancies complicated with *FGR*, i.e., *FGR* ± *PE* ($P = 0.03$). With reference to study groups, this correlation was statistically confirmed by the *FGR* + *PE* group ($P = 0.04$) but not by the group with isolated *FGR* ($P = 1.0$). Furthermore, a positive association was observed between NK cell proportion and PWR in both cases and controls ($P = 0.01$).

Discussion

In this study, we have investigated the leucocyte subpopulation composition in the decidual tissue collected from women at delivery with pregnancies complicated with *PE* and *FGR*, alone or in combination. Tissue was obtained by vacuum suction of the placental bed during CS, a procedure which provides representative material for studies of foeto-maternal interactions in the decidua basalis [16, 34]. Cases demonstrated a reduced proportion of NK cells, as com-

pared to controls. The reduction was primarily found in pregnancies complicated with *FGR*, whereas the association between NK cell proportion and *PE* was less pronounced.

uNK cell numbers decrease from mid-gestation towards term [26]. It is a general problem in research on human reproduction that it is impossible to obtain normal, age-matched controls. As a rule, non-*PE*/*FGR* pregnancies with preterm deliveries are complicated by other pathological conditions that may put influence upon observations. In our study, we found a reduced NK cell proportion in the case group, although their mean gestational age was 6 weeks lower than that of controls, suggesting that differences would have been even more pronounced if comparisons could have been done between gestational age-matched cases and controls.

Several lines of evidence suggest that uNK cells have major roles in implantation and placental development [21, 26]. It is a general assumption that these cells are recruited to decidua from peripheral blood by homing mechanisms [9]. Various signals from decidua (cytokines, chemotactic signals, protease inhibitors) probably coordinate this process [37] and influence the composition of decidual leucocytes which differ significantly from both that in peripheral blood and other tissues [25]. Decidual leucocytes play major roles in implantation and trophoblast invasion [12]. Reduced NK cell numbers have been reported in spontaneous abortion [13, 17, 22, 29, 32, 40], but we know little about the role of NK cells in the implantation failure associated with *PE* and/or *FGR* [36, 39]. Stallmach et al. [36] have studied leucocyte composition in decidual tissue from *PE* and/or *FGR* pregnancies and conclude that NK cell numbers are increased. This contradicts our results, but a comparison between leucocyte subpopulation proportions calculated in the two studies may be difficult; Stallmach et al. [36] used lymphocyte (i.e., CD56⁺ and CD3⁺ cells) numbers as denominator, whereas our results were based on leucocyte (CD45⁺) counts. However, since cases in the present study demonstrated a reduced NK cell proportion, even when we used lymphocyte numbers as denominator, we anticipate that the results in fact are diverging. The size of the areas used for counting of leucocytes in our study was defined by CD45⁺

cell numbers; at least 250 CD45⁺ cells should be present. Both size of areas (7.0±4.0 mm²) and leucocyte densities (120±58/mm²) varied from case to case. Thus, cell proportions seem the most adequate measure for comparisons between groups. However, cases also demonstrated a reduced number of NK cells when absolute numbers were assessed (CD56⁺ cells/mm², 19±12), as compared to that found in controls (30±15, *P*=0.002). These observations differ from the results obtained of Stallmach et al. [36], but comparisons should be done with caution, since both size and localization of selected areas in the two studies differ. A couple of discrepancies between the two studies should be taken into consideration. The study of Stallmach et al. [36] differed from ours with regard to gestational age (cases 33 vs 32 weeks, controls 36 vs 39 weeks), and they used less severe criteria for defining FGR. Since decidual leucocyte composition may vary both by gestational age and with FGR [26], comparisons should be done with caution. Others have reported changes in leucocyte phenotype, cytotoxicity and cytokine production in women with PE ± FGR, both in peripheral blood [14, 15, 23, 31] and decidual tissue [36, 39]. A shift from the CD56⁺CD16⁻ towards the more cytotoxic CD56⁺CD16⁺ NK cell phenotype and increased cytokine production have been reported in decidual lymphocytes in PE [39]. Results were obtained by flow cytometric analysis of lymphocytes isolated from decidual tissue at delivery [39]. Our results may suggest similar changes, but CD16⁺/CD56⁺ proportions were not significantly increased among cases. The increased cytotoxicity and cytokine production previously reported may indicate cell activation in PE [39]. However, we found no convincing cell activation in cases, as assessed by CD25 and CD69 expression. A significant increase in CD25 expression was observed when the group of isolated FGR cases was compared to controls (*P*=0.04), but one should take the small number of cases (*n*=5) in this group into account. In accordance with this, the positive association between increased CD25 expression and FGR was not maintained when all pregnancies complicated by FGR (*n*=23) were included in analysis. Increased numbers of CD25⁺ decidual leucocytes have been reported in women with recurrent abortions [29], but as far as we know, this is the first study to assess CD25 expression in decidual tissues in PE ± FGR. CD69 expression did not differ between cases and controls, in accordance with previous reports [39].

Implantation failure and placental disease may underlie both PE and FGR, and several studies have demonstrated insufficient remodelling [6–8, 20, 28] and reduced placental weight [35] in PE/FGR. Our data support previously published observations; the remodelling scores and PWRs among cases were reduced. The PWR in the control group was higher than expected (1.5). This may be due to the high proportion of large babies in the control group (3673±512), and that large babies have large placentas [5]. In addition, our preparation of placentas before weighing differed from that used to establish expected weight standards [4]; our placentas were weighed together with the umbilical cord and membranes after early umbilical cord clamping, whereas standard placental weight was achieved after trimming off the chorion leave and cutting the cord near the chorionic

plate. The different procedures may explain the elevated PWR in our study but do not influence comparison between cases and controls.

Furthermore, correlation analysis of leucocyte counts, remodelling criteria and clinical data of both cases and controls revealed interesting, and hypothesis-generating, associations; both NK cell proportions and trophoblast invasion were positively linked to placental growth. In pregnancies with FGR, with or without PE, we also detected a significant correlation between NK cell proportion and trophoblast infiltration. Our *in vivo* data support the hypothesized central role of NK cells in regulating trophoblast invasion [33, 36, 38], and the reduced NK cell proportions found among cases, especially in FGR pregnancies, suggest that reduced proportions of NK cells may be part of the impaired placental development and pathogenesis of the disease.

The insufficient implantation underlying PE takes place in the beginning of pregnancy, while the clinical manifestations of the disease appear at mid-gestation or towards term. First trimester decidual leucocyte populations may be examined in specimens collected from abortions, but such material cannot be applied for PE/FGR investigation, since we have no information about possible future development of PE/FGR in the terminated pregnancy. Due to the lack of availability of PE/FGR tissue from early pregnancy, tissue samples collected at birth are probably the best *in vivo* material there is. Since we observed a positive association between impaired spiral artery remodelling and reduced NK cell numbers, it is tempting to suggest that recruitment and composition of decidual leucocytes may have been altered at the early stages of pregnancy. However, due to the time passed between implantation and tissue collection, it is a matter of speculation whether the changes found reflect mechanisms involved in pathogenesis of the disease studied or represent abnormalities occurring as a consequence of the disease. Both possibilities are left open. In future investigations, we plan to transfer the present *in vivo* observations to appropriate *in vitro* settings, examining phenotype and function of decidual leucocytes isolated from normal and PE/FGR pregnancies.

Expression and nuclear localization of Snail, an E-cadherin repressor, in adenocarcinomas of the upper gastrointestinal tract

Received: 18 October 2005 / Accepted: 18 October 2005 / Published online: 17 November 2005
© Springer-Verlag 2005

Abstract Transcriptional E-cadherin down-regulation can be mediated by Snail, a zinc finger transcription factor. To be able to examine nuclear Snail immunoreactivity in archival human cancers, we established a monoclonal antibody against the purified human Snail protein. The specificity of the selected rat antibody Sn9H2 was demonstrated by Western blot analysis using extracts from different cell lines and by immunofluorescence and immunohistochemistry of primary tissues. Subsequently, a series of 340 adenocarcinomas of the upper gastrointestinal tract, including tumours from the oesophagus ($n=154$), cardia ($n=102$) and stomach ($n=84$), arranged in tissue microarrays, were examined for Snail expression and were correlated to E-cadherin expression and clinico-pathological parameters. Nuclear Snail immunoreactivity was seen in 27 tumours (7.9%) and tended to be more frequent in oesophageal adenocarcinomas (11.1%) than in cardiac (6.9%) or gastric (3.6%) carcinomas ($p=0.0428$). In 35% of the Snail-pos-

itive cases, E-cadherin immunoreactivity was lost. No correlation was found for nuclear Snail expression and tumour grade, Lauren's classification, WHO classification, tumour stage and tumour size. The pattern of Snail expression observed with our new hybridoma, Sn9H2, which is currently the only antibody that reacts with endogenous nuclear (active) Snail, suggests only a minor role of Snail in tumours of the upper gastrointestinal tract.

Introduction

The cell adhesion molecule and tumour suppressor gene E-cadherin [online Mendelian Inheritance in Man (OMIM) 192090] is well known to play a crucial role during the progression of human cancer [24]. E-cadherin function is required for the maintenance of normal epithelial tissue architecture and the stabilization of adherens junctions [36]. Its inactivation in carcinomas can disrupt these junctional complexes, resulting in marked phenotypic changes and the acquisition of invasive growth [15, 49]. Immunohistochemical studies have demonstrated that reduced or absent E-cadherin immunoreactivity is common in most cancers, including carcinomas of the oesophagus and stomach [8, 24, 42]. Direct transcriptional repression by zinc finger transcription factors such as Snail [3, 12], Slug [10, 21], Zeb1 (deltaEF1; [20]), Zeb2 (Sip1; [13]) or the basic helix-loop-helix transcription factor E12/E47 [35] is one of the mechanisms that may be responsible for reduced E-cadherin immunoreactivity.

Here, we focus our analysis on the transcription factor Snail, which was first described in *Drosophila* in 1984 [19]. Snail homologues were subsequently found in other species as well, including mouse and human. Snail triggers epithelial-mesenchymal transition (EMT) during embryonic development. Its role during gastrulation and in the delamination of the neural crest from the neural tube has been well established in the mouse (reviewed in [32]).

Since EMT is frequently observed in human tumours [23, 46], Snail has been analysed in carcinoma cells in culture if there is evidence of a functional role during tumour invasion and metastasis. Indeed, it has been shown that Snail directly binds to the E-boxes present in the E-cadherin promoter, resulting in the down-regulation of promoter activity in vitro. Moreover, the transfection of Snail in E-cadherin-positive carcinoma cells induced a full EMT with the down-regulation of E-cadherin and other epithelial marker genes, such as occludin [25], and the up-regulation of mesenchymal markers, including vimentin and fibronectin [3, 12]. Importantly, Snail-expressing cells became invasive after transfection, supporting its role in tumour progression. Snail not only induces invasion but also blocks the cell cycle and confers resistance to cell death [48].

On the mRNA level, Snail is expressed in invasive cells of tumours induced in the mouse skin [12]. In humans, Snail mRNA expression has been detected in biopsies or resected tissue samples from patients with breast cancer [9, 17], gastric cancer [39] and hepatocellular carcinomas [27, 45] and in melanoma cell lines [37]. In colon cancer, Snail mRNA was either found to be expressed [33] or to be absent [40]. Because no Snail-specific antibodies suitable for immunohistochemical analysis of the active, i.e. nuclear localized, molecule have been available so far, evidence for functional Snail protein expression in primary human tumours and tissues is missing. Until now, a direct cellular comparison between E-cadherin down-regulation and endogenous nuclear Snail expression at the protein level in cancer tissues has not been possible.

To analyse nuclear Snail immunoreactivity in human cancers, we established a monoclonal antibody (mAb) in rats against purified human Snail protein. The specificity of the antibody was demonstrated by Western blot, immunofluorescence and immunohistochemistry of cells and primary human tissues. Subsequently, we analysed a series of 340 adenocarcinomas from the upper gastrointestinal tract, i.e. primary carcinomas of the oesophagus, the gastric cardia and the stomach, arranged in tissue microarrays (TMA), for nuclear Snail expression. We compared Snail and a variety of histopathological and clinical parameters and found that Snail expression is significantly more frequent in oesophageal than in cardiac or gastric adenocarcinomas. In 7 out of 20 Snail-positive cases, the expression of Snail in tumour cells was associated with a concomitant loss of E-cadherin expression. No correlation was found between the expression of Snail and tumour grade, tumour stage and histological tumour type according to Lauren's and WHO classification.

Materials and methods

Cell lines

The following cell lines were used: MCF7 (mammary gland, breast epithelium), HTB-135 (stomach carcinoma) and GC2957 (stomach carcinoma). MCF7 and HTB-135 cells

were cultured in Dulbecco's Modified Eagle's Medium (DMEM), 10% foetal calf serum (FCS) and 2.5 ml penicillin/streptomycin (#15140-122, Gibco; 10,000 units/ml penicillin G sodium/10,000 µg/ml streptomycin sulphate). The E-cadherin-positive cell line GC2957 was cultured in RPMI 1640 (#31870-025, Gibco), 20% FCS, 25 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) and 2.5 ml penicillin/streptomycin. MCF7 cells have been reported to express both E-cadherin and Snail [14]. HTB-135 cells are E-cadherin negative and Snail positive (E. Rosivatz, unpublished observation).

Cloning of human Snail cDNA

The cDNA coding for human Snail (SNAI1, OMIM 604238, RefSeq 005985) was amplified by reverse transcription-polymerase chain reaction (RT-PCR) from MDA-MB-435S human mammary carcinoma cells known to express Snail mRNA [3, 12]. Recently, evidence was provided that this cell line is of melanocytic origin [38]. The upstream (5'-CAT ATG CCG CGC TTT CCT CGT CAG G-3') and downstream (5'-AAG CTT TGC GGG GAC ATC CTG AGC AG-3') primers used for the amplification of a 802-bp sequence were designed to contain an *NdeI* site and a *HindIII* site, respectively. After gel purification of the amplification product, the Snail sequence was cloned using the *NdeI* and *HindIII* sites and standard methods into a modified expression vector, pHAT, in-frame with the so-called histidine affinity tag (HAT) sequence (BD Biosciences Clontech, Palo Alto, USA). The original pHAT vector was modified (Jörg Mages, Technical University Munich, Germany, unpublished data) to contain the His tag at the C terminus, instead of the N terminus, of the recombinant protein. The construct was sequenced to exclude sequence alterations that may have occurred during amplification. The recombinant vector, now termed pSnail1HAT, was expressed in bacteria, and the resultant His-tagged protein was purified from inclusion bodies using a talon metal resin (BD Biosciences Clontech) under denaturing conditions using 8 M urea. For the expression of recombinant His-tagged Snail in human tumour cell lines, full-length 6× His-tagged Snail from pSnail1HAT flanked by the *XbaI/KpnI* restriction sites were ligated into the pBK-CMV vector (#212209, Stratagene; GenBank accession no. U37573).

Cell transfection

The day before transfection, 1×10^5 cells per well of a six-well plate were seeded in 2 ml of appropriate growth medium. Cells were grown to 70% confluency for approximately 24 h. For the preparation of solution A, 1 µg plasmid DNA was diluted in 100 µl Optimem (#31985, Invitrogen) for each transfection and mixed gently. For the preparation of solution B, 15 µl Lipofectamine (#18324-012, Invitrogen) reagent was diluted in 100 µl Optimem for each transfection and mixed. Solutions A and B were

combined, mixed gently and incubated at room temperature for 45 min to allow the formation of DNA–liposome complexes. For each transfection, 800 μ l Optimem was added to the DNA–liposome complexes and gently mixed. Growth medium was aspirated from the cells, and the diluted transformation mix was added drop by drop. The cells were incubated with the complexes for 6 h at 37°C in a CO₂ incubator. Following incubation, 1 ml of growth medium (containing twice the normal concentration of serum) was added without removing the transfection mixture.

Twenty-four hours following the start of transfection, the medium was replaced with normal growth medium. An assay for transient gene expression was carried out 48 h after the start of transfection. Alternatively, 72 h after the start of transfection, cells were passaged 1:10 into a selective medium to achieve stable clones.

Quantitative real-time RT-PCR

RNA extraction from the cell lines, RT, quantitative real-time PCR and quantitation of Snail and E-cadherin mRNA expression were done as previously described [39] and were used here without modification. The primers and probes were designed to span an intron to exclude annealing to genomic DNA. Amplicon size was kept below 100 bp. Glyceraldehyde 3-phosphate dehydrogenase (GAPDH) was included as a housekeeping gene control to correct for equal RNA amounts. We then calculated relative amounts of mRNA by the standard curve method in relation to GAPDH levels. The TaqMan runs were done in triplicate and repeated in an independent experiment.

Western blot

For Western blot analysis using hybridoma supernatant Sn9H2 to detect Snail protein, extracts from the MCF7 and GC2957 cells, as well as extracts from fresh, frozen human placenta, were prepared using a 1:1 mixture of 2 \times sodium dodecyl sulfate (SDS) electrophoresis buffer (120 mM Tris pH 6.8, 4% SDS, 16% glycerol, 2% beta-mercaptoethanol) and tissue protein extraction reagent (T-PER, Pierce, Rockford, IL, USA). Twenty micrograms of total protein was used for SDS-polyacrylamide gel electrophoresis (PAGE). Protein detection was performed using a peroxidase-coupled secondary antibody (ECL-Western, Amersham, Germany).

Immunofluorescence analysis of HTB-135 gastric cancer cells

Cells were grown on glass cover slips for 24 h and subsequently rinsed briefly in phosphate-buffered saline (PBS). For cell fixation, cover slips were immersed in freshly prepared 3.7% para-formaldehyde for 30 min, followed by 3 \times washes in PBS. The cover slips were incubated in 0.25% Triton X-100/PBS for 5 min at room temperature for cell permeabilization and then placed cell-side up in a petri

dish and covered with blocking buffer [1% bovine serum albumin (BSA) in PBS] for 30 min. After removing the blocking buffer, primary antibodies [Sn9H2, 1:10 in blocking buffer; anti-His-tag (#70796-3, Novagen), 1:500 in blocking buffer] were distributed on the cover slip and incubated at 4°C for 16 h (Sn9H2) or at room temperature for 2 h (anti-His-tag), followed by 3 \times washes with PBS. Secondary antibodies conjugated to a fluorochrome [anti-rat fluorescein isothiocyanate (FITC), #112-069-044, Jackson laboratories; anti-mouse tetramethyl rhodamine isothiocyanate (TRITC), #115-026-044, Jackson Laboratories] were distributed on the cover slips and incubated for 1 h at room temperature. Cover slips were washed 3 \times with PBS and inverted onto slides containing 10 μ l of mounting medium from Antifade kit (#S-2828, MoBiTec GmbH, Germany). Excess mounting medium was removed, and the edges were sealed and dried before the analysis of immunofluorescence using a Zeiss Axiovert microscope.

Generation of a rat mAb, Sn9H2, against human Snail

Purified His-tagged human Snail protein (50 μ g) was injected both intraperitoneally and subcutaneously into Lou/C rats using CPG2006 (TIB MOLBIOL, Berlin, Germany) as adjuvant. After an 8-week interval, a final boost was given intraperitoneally and subcutaneously 3 days before fusion. The fusion of the myeloma cell line P3X63–Ag8.653 with the rat immune spleen cells was performed essentially as described [28]. Hybridoma supernatants were tested in a solid-phase immunoassay using the His-tagged protein that was used for immunization (10 μ g/ml) adsorbed to polystyrene microtiter plates. An irrelevant His-tagged protein served as a negative control. Bound rat mAbs were detected with a cocktail of biotinylated mouse mAbs against the rat immunoglobulin G (IgG) heavy chains [α -IgG1, α -IgG2a and α -IgG2b (ATCC, Manassas, VA, USA) and α -IgG2c (Ascension, Munich, Germany)]. The biotinylated mAbs were visualized with peroxidase-labelled Avidin (Alexis, Grünberg, Germany) and *o*-phenylenediamine as chromogen in the peroxidase reaction. The clone designated Sn9H2 (rat IgG2) was stably subcloned and used for further analysis.

Immunohistochemical analysis

After standard pressure-cooker-based antigen retrieval with citric acid pretreatment, 2- μ m sections were incubated in goat serum to block nonspecific reactivity. For the detection of Snail-specific immunoreactivity, the specimens were incubated with diluted Sn9H2 hybridoma supernatant (1:20 in 1% BSA in PBS) for 2 h at room temperature. Bound antibodies were detected using the avidin–biotin complex (ABC) peroxidase method (ABC Elite Kit, Vector, Burlingame, CA, USA). Final staining was developed with the Sigma FAST DAB peroxidase substrate kit (Sigma, Deisenhofen, Germany). Haemalaun was used for counterstaining. In addition, E-cadherin immunoreactivity was

detected using the mAbs HECD-1 (Alexis) or clone 34 (#C37020, Transduction Laboratories, Lexington, KT, USA), both of which are known to react with human E-cadherin and to work on archival material. Subsequently, adenocarcinomas from the upper gastrointestinal tract arranged in TMA (see below) were analysed in exactly the same way. For the analysis of cancer samples, non-tumorous epithelium was used as positive control for E-cadherin immunoreactivity. Sections of placenta tissue were used as positive control for Sn9H2.

Immunohistochemical analysis of upper gastrointestinal adenocarcinomas

The analysis was based on 266 patients with adenocarcinomas of the upper gastrointestinal tract who underwent surgical resection without prior radio- and/or chemotherapy between January 1983 and January 2003 at the University of Düsseldorf, Germany. Additionally, 101 patients with oesophageal adenocarcinomas who underwent resection without prior radio- and/or chemotherapy between January 1991 and January 2004 at the Technical University of Munich, Germany, were included. Of the patients, 292 (79.6%) were men. The age of the patients ranged between 29 and 90 years (median 63 years). Together, the series consisted of 158 oesophageal, 108 cardiac and 101 gastric adenocarcinomas. Differentiation between oesophageal and cardiac adenocarcinomas done by a senior pathologist (MS) based on a review of the original macroscopic pathologic descriptions of the operation specimens according to standard criteria [43]. Tumours that had their epicenters in the oesophagus were regarded as oesophageal in origin, and tumours that had their epicenters in the cardia were regarded as cardiac in origin. Staging was performed according to the current tumor, node and metastasis (TNM) classification [44]. Histological typing included Lauren's classification [29] and the current WHO classification for gastric carcinomas [22]. Grading was performed according to the current WHO classification. Signet-ring cell carcinomas and mucinous carcinomas were categorized as G3.

Accordingly, 116 tumours (31.6%) were in stage I, 105 in stage II (28.6%), 110 in stage III (30.0%) and 36 in stage IV (9.8%). According to Lauren's classification, 26 tumours (7.1%) belonged to the diffuse type, 274 (74.7%) to the intestinal type and 67 (18.3%) to the mixed type. According to the WHO classification, this series included 56 signet-ring cell carcinomas (15.3%), 4 papillary adenocarcinomas (1.1%), 7 mucinous adenocarcinomas (1.9%) and 300 tubular adenocarcinomas (81.7%). Twelve tumours were graded as G1 (3.3%), 131 as G2 (35.7%) and 224 as G3 (61.0%). Tumour size (largest diameter) ranged between 5 and 185 mm (median 50).

Construction of TMA

For each of the 367 adenocarcinomas, one paraffin block was selected, and representative, non-necrotic tumour areas

were marked on Haemalaun–Eosin-stained slides from these blocks. Three tissue cylinders with a diameter of 0.6 mm per tumour were punched from these areas and brought into a recipient paraffin block using a tissue arraying instrument (Beecher Instruments, Silver Spring, MD). In the case of signet-ring cell carcinomas, six, instead of three, biopsies were sampled. A sample template designating the sample location by case number was created. Four-micrometer sections from the TMA were used for the subsequent immunohistochemical investigations.

The immunohistological evaluation of Snail expression in TMAs was performed by a senior pathologist (MS). A tumour was considered positive for Snail expression if, in at least one tumour, a sample nuclear expression of Snail was detectable. A positive immunoreactivity was confirmed using whole-tissue sections from the corresponding donor block.

Statistical analysis

The analysis of the expression of Snail and a variety of clinico-pathological parameters, such as tumour stage, nodal status, tumour grade, tumour size, tumour type (according to Lauren and WHO) and location of the primary tumour, was performed according to the chi-square exact test.

Results

To analyse Snail protein expression in human cell lines and tissues, and for the determination of intracellular localization, mAbs were produced in rats against a purified His-tagged human Snail protein. Hybridoma supernatants were tested in a solid-phase immunoassay against the specific protein. Hybridoma Sn9H2 of rat IgG2a subclass was selected for further analysis.

Antibody specificity

Hybridoma supernatant Sn9H2 detected a single protein band at approximately 32 kDa in the *Escherichia coli* inclusion body preparation that was used for protein purification and in the E-cadherin-negative gastric cancer cell line HTB-135 (Fig. 1a). A protein band of very similar molecular weight was seen using a mAb against the tag (anti-His) in the inclusion body preparation that is absent in the HTB-135 cell extract. After the transient transfection of human Snail cDNA fused to the histidine affinity tag sequence in HTB-135 gastric cancer cells, hybridoma supernatant Sn9H2, indirectly detected by an FITC-labelled secondary anti-rat antibody, reacted with a protein that is located in the cytoplasm and strongly in the nucleus (Fig. 1b). Using the anti-His antibody and a rhodamine-labelled secondary antibody, immunofluorescence was exclusively seen in the nucleus, suggesting that exogenously expressed His-tagged Snail is retained within the nucleus while endogenously expressed Snail is localized also in the cytoplasm.

Fig. 1 Analysis of hybridoma supernatant Sn9H2. **a** Western blot. Inclusion body preparation from the transfected *E. coli* strain used to purify Snail protein and a lysate from an E-cadherin-negative gastric cancer cell line, HTB-135, were examined for Snail expression. Protein bands at approximately 32 kDa were observed in both lysates using hybridoma supernatant Sn9H2. An antibody against the His tag, anti-His, detected only a protein band in the *E. coli* lysate. **b** Intracellular localization of endogenously and exogenously expressed Snail. The distribution of Snail in Snail-His-transfected

HTB-135 cells was observed by immunocytochemical staining with hybridoma supernatant Sn9H2 or anti-His antibody, followed by fluorescein isothiocyanate (FITC)-labelled or tetramethyl rhodamine isothiocyanate (TRITC)-labelled secondary antibodies, respectively. Immunofluorescence was visualized and captured with fluorescence microscopy. Endogenously expressed Snail was detected within the nucleus and the cytoplasm; exogenously expressed Snail was seen only in the nucleus

To prove a functional effect of Snail in E-cadherin-positive gastric cancer cells and to provide additional evidence for the specificity of the novel hybridoma supernatant Sn9H2, we analysed GC2957 gastric cancer cells. Using anti-Snail antibody Sn9H2, we were able to

detect a band of about 32 kDa in GC2957 cells, suggesting the expression of low levels of endogenous Snail (Fig. 2a). Using real-time quantitative RT-PCR, we were able to detect only traces of Snail mRNA in GC2957 cells, whereas high levels of Snail mRNA were found in HTB-135

Fig. 2 Hybridoma supernatant Sn9H2 detects a functional Snail protein. E-cadherin-positive gastric cancer cells GC2957 (**a, b**) and MCF7 mammary cells (**c, d**) were transfected with vector as control or with Snail-His. **a** Western blot demonstrating the overexpression of Snail and the reduction of E-cadherin in the Snail-transfected cells. Alpha-tubulin was used as protein loading control. **b** Snail overexpression resulted in cell scattering. **c** Western blot showing the reduction of E-cadherin after Snail overexpression. No change is seen for alpha-tubulin. **d** Quantitative real-time RT-PCR demonstrates the reduction of E-cadherin expression by 95% after 3.7-fold Snail overexpression at the mRNA level. Results are representative of two independent transfection experiments done in triplicates and measured 48 h after transfection. The mRNA levels of vector-transfected cells are set to 100%; the mean \pm standard deviation is shown

gastric cancer cells (data not shown). After the overexpression of Snail in GC2957 cells, the 32-kDa band increased in intensity, and E-cadherin levels were reduced. Alpha-tubulin expression was used to show equal protein loading. Despite low but detectable levels of Snail mRNA and protein, GC2957 cells formed cellular contacts and grew in epithelial-like structures. The overexpression of Snail, however, resulted in cell scattering (Fig. 2b).

After the transfection of another E-cadherin-positive cell line, MCF7 mammary cells, the 32-kDa band detected by hybridoma supernatant Sn9H2 became stronger, less E-cadherin protein was present, and levels for alpha-tubulin did not change significantly (Fig. 2c). Quantitative real-time RT-PCR demonstrated 95% reduced E-cadherin and 3.7-fold increased Snail mRNA levels upon transfection with the Snail cDNA (Fig. 2d).

These results indicate that the overexpression of a functional Snail protein resulting in E-cadherin down-regula-

tion and cell scattering can be visualized using hybridoma supernatant Sn9H2.

Immunohistochemistry using human placenta as test system

After having rigorously demonstrated antibody specificity by Western blot and immunofluorescence, we tested if hybridoma supernatant Sn9H2 may react with formalin-fixed and paraffin-embedded tissues. As a test system, we used human placenta, as this tissue was reported to be Snail-mRNA-positive using Northern blot analysis [34]. Using Western blot analysis, we detected a protein band at about 32 kDa in extracts of human placenta, confirming Snail expression in this tissue on the protein level but without providing information about which cell types are Snail positive (Fig. 3a). In human placenta, two morphologically

Fig. 3 Hybridoma supernatant Sn9H2 detects a nuclear protein in invasive trophoblasts in placenta. **a** Western blot showing Snail expression in placenta; the molecular weight is compared with the purified protein and Snail-transfected GC2957 gastric cancer cells. **b** Diagram of human placenta demonstrating the different cell types, e.g. non-invasive trophoblast stem cells and invasive EVT. **c** Immunoreactivity of Snail and E-cadherin in formalin-fixed and paraffin-embedded placenta. Nuclear Snail immunoreactivity is seen in invasive EVT; E-cadherin is localized at the cell membrane of trophoblast stem cells and reduced or absent in invasive EVT. (The arrow indicates the direction of invasion.)

distinct cell populations that differentiate from cytotrophoblast stem cells can be identified: (a) villous cytotrophoblasts are immotile cells that fuse to form a syncytium overlying the cytotrophoblast stem cells, and (b) extravillous cytotrophoblasts become invasive and invade the endometrium and, eventually, its arterial system. Thus, in placenta, both invasive (extravillous cytotrophoblasts) and non-invasive (cytotrophoblast stem cells) cells are present (Fig. 3b). These different cell types may be optimally suited for the determination of Snail immunoreactivity using formalin-fixed and paraffin-embedded archival material and, consequently, for the demonstration of the usefulness of hybridoma supernatant Sn9H2 for immunohistochemical analysis. As can be seen in Fig. 3c, hybridoma supernatant Sn9H2 exclusively reacts with invasive extravillous trophoblasts (EVT), while trophoblast stem cells are not stained. The immunoreactivity is clearly nuclear, a finding

that is in line with Snail's function as a transcriptional repressor. In contrast, membranous E-cadherin immunoreactivity is seen preferentially in trophoblast stem cells; invasive trophoblasts only show a very faint reaction or they are E-cadherin negative. These very encouraging results enabled us to perform the first analysis for nuclear Snail immunoreactivity of a larger series of primary human carcinomas.

Analysis of nuclear Snail immunoreactivity in primary adenocarcinomas of the upper gastrointestinal tract

According to the immunohistochemical analyses based on TMAs, 27 tumours were considered positive for Snail expression while 313 were considered negative. Immunoreactivity for Snail in the tumour cells was found exclusively

Fig. 4 Snail and E-cadherin immunoreactivity in cancers of the upper gastrointestinal tract. **a** This undifferentiated tumour shows an inverse correlation of Snail and E-cadherin expression. The *rectangles* indicate areas that are shown at higher magnification below the *upper panel*. *Upper panel*, $\times 100$; *lower panel*, $\times 200$. **b** Tumour cells in this tumour show coexpression of Snail and E-cadherin

Table 1 Correlation between the expression of snail in 340 adenocarcinomas of the upper gastrointestinal tract and various clinico-pathologic parameters

	Snail expression		<i>p</i> Value
	Negative (%)	Positive (%)

^aChi square test. Oesophageal carcinomas vs cardiac and gastric carcinomas

nuclear. Twenty-seven cases had to be excluded from further analysis because either only non-cancerous tissue was present in all three punches or all tissue samples had been lost during immunohistochemical staining. Besides cancer cells, immunoreactivity for Snail was found consistently in a small subset of stromal cells (inside and outside of the tumours), i.e. fibroblasts and endothelial cells. This expression tended to be accentuated in areas of mucosal erosion or ulceration.

To validate immunohistochemical analyses based on TMAs, whole-tissue sections from the donor blocks of the 27 Snail-positive carcinomas were immunohistochemically stained for Snail. Analysis of whole-tissue sections confirmed Snail expression in all cases considered to be positive based on TMA analysis. Figure 4 shows examples of some of these cases. Immunohistochemical analysis of whole-tissue sections allowed the semiquantitative assessment of Snail expression. In 14 tumours, 5–25% of the tumour cells were Snail positive; in 4 tumours, 26–50% of the tumour cells were Snail positive; in 1 tumour, the percentage of Snail-positive tumour cells was 51–75%, and in 1 tumour, the percentage was 76–100%.

To analyse the correlation between the expression of Snail and E-cadherin, serial whole-tissue sections of only 20 Snail-positive carcinomas were also immunohistochemically stained for E-cadherin. Of these 20 Snail-positive carcinomas, only 7 showed a loss of E-cadherin

expression in the tumour area where Snail expression was detectable (Fig. 4), indicating no clear correlation between Snail up-regulation and E-cadherin down-regulation.

Correlation of Snail expression and clinico-pathological parameters

The expression of Snail in adenocarcinomas from the upper gastrointestinal tract was not correlated with a variety of clinico-pathological parameters, such as tumour grade, Lauren's classification, WHO classification, tumour stage and tumour size (Table 1). However, the expression of Snail was significantly more frequent in oesophageal adenocarcinomas (11.1%) than in cardiac (6.9%) or in gastric (3.6%) carcinomas (*p*=0.0428).

Discussion

A hallmark in disease progression of epithelial cancers is the functional loss of the homophilic cell adhesion molecule E-cadherin, altering both the physical attachment of cells and the regulatory signals transmitted through cytoplasmic adapter molecules. Reduced or lack of E-cadherin immunoreactivity has been observed in many types of cancers and correlated with histopathological and clinical features, such as tumour dedifferentiation, invasive growth, lymph node metastasis and a worse patient prognosis [24]. The main mechanisms resulting in a loss of E-cadherin function include loss of heterozygosity (LOH) in combination with gene mutations [50], promoter hypermethylation [18, 31], enhanced degradation due to HAKAI, a c-Cbl-like protein [16], down-regulation by the RON tyrosine kinase [2], down-regulation by the transmembrane molecule dysadherin [26] and proteolytic degradation by matrix metalloproteases [30]. While E-cadherin gene mutations are found in diffuse-type gastric cancer [4, 5] and in invasive lobular breast cancer [6], they are rare in other cancers [7] and may not account for the majority of E-cadherin inactivations seen in human cancer tissues.

Recent reports highlighted the significance of EMT regulators that directly repress E-cadherin transcription. Several transcription factors, including the zinc finger transcription factor Snail [3, 12], the Snail-related molecule Slug [10, 21], Zeb2 (Sip1; [13]), Zeb1 [20] and E12/47 [35], may bind to E-box elements present in E-cadherin's promoter, resulting in transcriptional down-regulation. In various types of cancers and cell lines, the increased expression of Snail mRNA has been correlated with the loss of or reduced E-cadherin expression, although in several systems, a coexpression of Snail and E-cadherin was observed [14]. In the current study, we transfected two different cell lines with human Snail and found a concomitant reduction in E-cadherin levels, indicating the expression of a functional Snail molecule.

Most studies analysing Snail expression have been performed at the mRNA level, possibly because only a few commercial antibodies that react with human Snail protein

are available. Using an in-house-made polyclonal antibody against mouse Snail, Dominguez et al. [14] detected a doublet band in Western blot analysis (15% gel) at about 32 kDa in extracts from Snail-transfected HTB-29 and Madin-Darby canine kidney (MDCK) cells (80 µg of a cell extract per lane was used). They postulated a modification of the snail protein (phosphorylation) that may be responsible for the upper band seen in the blot and may regulate nuclear localization. We showed here that in E-cadherin-negative HTB-135 gastric cancer cells, endogenously expressed Snail seems to be localized in the nucleus and in the cytoplasm, whereas exogenously expressed Snail is seen exclusively in the nucleus. When we double our cell lysates from HTB-135 cells (40 µg total protein instead of 20 µg) and extend film exposure time (10 s instead of 5 s), a second smaller band is visible in Western blots (not shown). In extracts from human placenta, however, only one band is seen, migrating at the same position as the purified human protein and most likely corresponding to the “upper” band. In this tissue, Snail immunoreactivity appeared exclusively nuclear (Fig. 3).

When we used commercial anti-Snail antibodies used by others (e.g. [47, 48]), they did not work (data not shown). In addition, none of those could be applied for analysis of Snail nuclear immunoreactivity in archival human tissues so far. Therefore, we generated a rat mAb, termed Sn9H2, against human Snail that works excellently in Western blotting and can be used for immunohistochemical analysis of human tissue samples and, although not yet tested, possibly for immunoprecipitation and chromatin immunoprecipitation studies. The specificity of the antibody was demonstrated by Western blot analysis, immunofluorescence and immunohistochemical analysis of appropriate test systems, such as transfected cells in a culture expressing functional Snail and invasive trophoblasts from human placenta. With our new antibody, a direct correlation between E-cadherin repression and Snail neoexpression can now be analysed in cell lines and tissues, even after formalin fixation. In some cell lines, there is a coexpression of E-cadherin and Snail. A forced overexpression of Snail, however, resulted in the reduction of E-cadherin, suggesting some dosage effect. This may explain the failure to find a concomitant reduction of E-cadherin in every Snail-positive case (see “Results”).

To start with an evaluation of Snail immunoreactivity in human cancers, we chose adenocarcinomas of the upper gastrointestinal tract, i.e. tumours that arise in the oesophagus, in the cardia or in the stomach. Today, it is generally accepted that the majority of carcinomas of the upper gastrointestinal tract develop through an accumulation of somatic genetic and epigenetic changes, such as point mutations and/or LOH in the *p53* gene, promoter methylation of *p16^{ink4A}* and amplification and overexpression of cyclin D1, epidermal growth factor receptor (EGFR) and *c-erbB-2*. In addition, the expressions of E-cadherin and adenomatous polyposis coli (APC) were frequently found to be altered (for review, see [41]). We found Snail immunoreactivity in about 8% of the 340 cases analysed. No statistically significant correlation to the pathological and

clinical data evaluated was seen. However, Snail immunoreactivity was more frequently detected in oesophageal cancers compared with cardia or gastric cancers, although only with marginal statistical significance. From the 154 analysed cases with oesophageal cancers, 17 (11%) were found to express Snail. In the gastric cancers analysed, only 4% Snail-positive tumours were detected. In a previous study, using quantitative real-time RT-PCR, we found Snail mRNA overexpression preferentially in diffuse-type gastric cancers [39]. However, analysing a much larger series of tumours, as was done in the current study, we did not find a statistical correlation between Snail immunoreactivity and Lauren’s classification (diffuse vs intestinal).

Epithelial–mesenchymal transition mediated by Snail is considered to be a local event occurring at certain sites within an invasive tumour; EMT is typically seen at the invasion front [11]. Interestingly, Snail mRNA was not detected in a series of microdissected colon cancers in one study [40] but was reported to be overexpressed in another [33]. As mentioned in the “Results” section, some fibroblasts and endothelial cells showed Snail immunoreactivity. Even after careful tissue microdissection, it cannot be excluded that non-tumourous cells, such as fibroblasts or endothelial cells, are present in the tissue samples and may have contributed to the results of mRNA studies. Hybridoma Sn9H2 can now aid to solve some discrepancies that may have arisen in quantitative real-time RT-PCR analysis of primary tumours.

Using *in situ* hybridisation, Blanco et al. [9] found Snail mRNA expression in scarce fibroblastic cells present in stromal regions of breast cancers. In the same study, 9 out of 21 breast cancers expressed Snail mRNA, inversely correlating with the grade of differentiation of the tumours [9]. The authors concluded that Snail may be a marker of metastatic potential. While estrogen receptor signalling via metastasis associated gene 3 (MTA3) up-regulation was demonstrated to play a role in Snail inhibition in breast cancer [17], the mechanisms for Snail regulation in cancers of the upper gastrointestinal tract are currently unknown. Recently, the human Snail promoter was characterized, demonstrating an induction of Snail transcription by integrin linked kinase (ILK) and the oncogenes Ha-ras and v-Akt [1]. In addition, extracellular signal-regulated kinase (ERK) and NFκB/p65 also stimulated Snail transcription [1]. In an elegant paper, Zhou et al. [51] demonstrated a role for glycogen synthase kinase-3β (GSK-3β) in the regulation of Snail function. The authors found that GSK-3β binds to and phosphorylates Snail at two consensus motifs to regulate both ubiquitination and subcellular localization. Nuclear immunoreactivity, however, indicative of active Snail was apparently not seen in 134 breast cancer samples analysed. Thus, our hybridoma Sn9H2, which, to our knowledge, is currently the only antibody that reacts with endogenous nuclear Snail, may be a valuable tool in determining the percentage of active Snail in archival human cancers. As soon as antibodies for other active E-cadherin repressors suitable for immunohistochemistry of archival human tissues are available, the relative contribution of each of these repressor molecules in

E-cadherin silencing can be analysed in defined sets of human tumours.

In conclusion, we generated a mAb against human Snail and showed nuclear expression in a subset of adenocarcinomas of the upper gastrointestinal tract. Snail's role in these tumours and mechanisms of its regulation, e.g. signalling pathways known to induce EMT, however, have to be established.

Acknowledgements We thank M. Blöchinger and M. Bekesch for excellent technical assistance, J. Mages for providing the modified pHAT vector, and R. Langer for help with some tissues. The E-cadherin-positive gastric cancer cell line GC2957 was kindly provided by R. Seruca, IPATIMUP-Porto. This work is supported by a grant from the Deutsche Krebshilfe (grant no. 10-2012-Be3) to KFB and HH.

Sporadic Cajal cell hyperplasia is common in resection specimens for distal oesophageal carcinoma

A retrospective review of 77 consecutive surgical resection specimens

Received: 11 October 2005 / Accepted: 20 October 2005 / Published online: 25 November 2005
© Springer-Verlag 2005

Abstract Interstitial cell of Cajal (ICC) hyperplasia has been documented in conditions associated with multiple gastrointestinal stromal tumours (GISTs) (familial GIST syndromes, Carney's triad and von Recklinghausen's disease) and rarely in the vicinity of sporadic GISTs. The incidence of sporadic ICC hyperplasia and the so-called seedling leiomyoma (SLM) of the lower oesophagus has not been studied in the KIT era. In a retrospective review of 77 consecutive, routinely processed oesophagogastric resection specimens for distal oesophageal carcinoma, we found foci of ICC hyperplasia in 7 of 77 (9.1%) cases and foci of SLM in 17 of 77 (22%) cases. Two types of ICC hyperplasia were recognized: a non-circumscribed type and a nodular expansile type with peripherally compressed myenteric neural tissues. All cases of ICC hyperplasia were vimentin⁺/CD34⁺/CD117⁺. SLMs were desmin⁺/vimentin⁻/CD34⁻/CD117⁻, similar to smooth muscles of the gut wall. In a prospective study of 32 non-carcinomatous specimens from age-matched patients (mostly autopsy cases), we found SLMs in only one case, but we were unable to detect ICC hyperplasia in any of the cases. We concluded that sporadic KIT-positive spindle-cell hyperplasia and SLMs were unexpectedly common in distal oesophageal specimens harbouring carcinomas. The possible mechanisms leading to the development of these putative precursor lesions will be discussed.

Keywords ICC hyperplasia · GIST precursor · Seedling leiomyoma

Introduction

Gastrointestinal stromal tumours (GISTs) are the most common primary mesenchymal neoplasms of the tubular gastrointestinal (GI) tract [6, 21, 31]. GISTs arise predominantly in the stomach (60–70%), followed by the small intestine (20–25%), the colorectum (10%) [19, 21, 31] and the oesophagus (1–3%) [7, 18, 31]. Extragastrointestinal GISTs are vanishingly rare [26]. At our department, no case of primary oesophageal GIST was found among more than 200 GISTs (unpublished data). GISTs are KIT-signaling-driven neoplasms caused by gain-of-function mutations of *c-kit* or platelet-derived growth factor receptor alpha (*PDGFRA*) oncogenes leading to tumorigenesis through a ligand-independent activation of type III receptor tyrosine kinases [11–14, 17, 33]. Small (measuring less than 1 cm) incidental GISTs were found to harbour *c-kit* mutations [5]. Bland spindle-cell proliferations forming a diffuse band or minute nodules in the region of the myenteric plexus of Auerbach [also called interstitial cell of Cajal (ICC) hyperplasia] have been documented in rare cases of multiple familial GISTs caused by germline mutations of *c-kit* or *PDGFRA* genes [3, 8, 12], in a case of Carney's triad [25], in a case of congenital intestinal neuronal dysplasia [10], in von Recklinghausen's disease [2, 30, 32] and (extremely rare) in the vicinity of sporadic GISTs [15]. Diffuse ICC hyperplasia was found to be polyclonal in nature in one reported case [3]. Precursor lesions for sporadic GISTs have not been well characterized. We recently observed microscopic KIT-positive stromal nodules (ICC hyperplasia) in the vicinity of adenocarcinomas involving the lower oesophagus and the sigmoid colon (one case each) as collision tumours (unpublished data). To our knowledge, the incidence and clinicopathological features of ICC hyperplasia as putative precursor lesions for sporadic GISTs have not been studied in detail before. Seedling leiomyomas (SLMs) are minute (microscopic) lesions of smooth muscle tissues found incidentally in the muscularis propria of the lower oesophagus.

Materials and methods

Seventy-seven non-selected oesophageal/oesophagogastric surgical resection specimens for carcinoma of the distal oesophagus or the oesophagogastric junction were retrieved retrospectively from surgical pathology files at the Institute of Pathology of Nuremberg's Clinic Centre. All hematoxylin and eosin (H&E)-stained slides were systematically reviewed by the first author, looking for the presence of minute spindle-cell lesions in the muscle coat on the oesophageal side of the specimen. At the same time, the presence of minute leiomyomatous nodules in the muscularis propria corresponding to so-called SLMs was recorded. If present, the number, size, location in the outer or inner muscle coat, shape, circumscription, cell type and relationship of the lesion to the myenteric plexus were recorded. Case selection was based on H&E-stained sections only. No serial sectioning or blind immunostaining for enhanced detection was performed. Immunohistochemistry was then performed on fresh-cut sections using the ABC-DAB method and the following primary antibodies:

vimentin (1:50; Linaris), smooth muscle actin (1:200; Dako), desmin (1:250; Dako), h-caldesmon (1:125; Dako), CD117 (1:50; Dako), CD34 (1:200; Zytomed), S-100 (1:2,500; Dako), neurofilament (1:500; Dako), synaptophysin (1:500; Biogenics), bcl-2 (1:200; Dako) and Ki67 (MiB-1) (1:150; Dako). For validation of results, 32 additional specimens from age-matched patients without oesophageal or gastric cancer were collected (autopsy cases) and studied in a manner similar to that performed with six to eight tissue sections taken from the entire oesophagogastric junction.

Results

Four to 19 (mean, 8) H&E-stained sections were available in all cases. The study group included 63 men and 14 women (M:F, 4.5:1) aged 39–81 years (mean age, 62 years). Forty patients (52%) had squamous carcinoma, 35 (45%) had Barrett's carcinoma and 2 (1.3%) had neuroendocrine carcinoma and adenosquamous carcinoma (one each).

SCC Squamous cell carcinoma, BACA Barrett's adenocarcinoma, INT internal muscle layer, IM intermuscular region (plane of the plexus of Auerbach), ♂ male, ♀ female

ICC hyperplasia

Minute spindle-cell lesions with features of ICC hyperplasia at the H&E level were found in seven cases (9.1%). Clinicopathological and immunohistochemical features of the seven cases were summarized in Table 1. There were five men and two women (M:F, 2.5:1) aged 60–75 years (mean, 67 years). Associated cancers were squamous carcinoma in four cases and Barrett's carcinoma in three cases. The size of the lesion varied from 0.4 to 1.0 mm (mean size, 0.7 mm). All lesions were of the spindle-cell type and were located either in the external muscle coat (two cases), the internal layer (two cases) or in the intermuscular region abutting the myenteric plexus (three cases). Two of the lesions showed an expansile (nodular, circumscribed) pattern of growth—with cytomorphology similar to that of usual GISTs (Fig. 1a); with strong reactivity for vimentin, CD117 (not shown) and CD34 (Fig. 1b); but without expression of myogenic (Fig. 1c) or neurogenic markers (Fig. 1d). The remaining five lesions had irregular borders with enclosed muscle fibres between lesional cells (Fig. 2a) and had strong immunoreactivity for CD117 (Fig. 2b), CD34 (Fig. 2c) and S-100 (Fig. 2d). They were negative for synaptophysin, neurofilament, bcl-2, SMA, desmin and h-caldesmon (not shown). No mitoses or cellular atypia were seen in any of the lesions. Ki67 (MiB-1) decorated isolated lesional cells (not shown). Two non-circumscribed lesions with prominent S-100 reactivity were negative for neurofilament and synaptophysin, indicating true S-100 expression in lesional cells. Expansile lesions revealed compressed neural tissues at the periphery of the lesion that were reactive for S-100 (not shown) and synaptophysin (Fig. 1d).

Seedling leiomyomas

Seventeen cases (22%) harboured one or more well-differentiated smooth muscle micronodules with a bright eosinophilic fibrillary cytoplasm typical of smooth muscle cells (Fig. 3a–c). Patients included 14 men and 3 women (M:F, 4.7: 1) aged 39–75 years (mean age, 65 years). Associated cancers were eight cases of squamous carcinoma and nine cases of Barrett's carcinoma. All lesions (except two in the intermuscular region) were located in the inner (circular) muscle layer. In one case, a gastric-side SLM was found (in another case, a submucosal lipoma of the cardia was also found). In three cases, an initial gastric fundic GIST (ICC hyperplasia) was also seen (not shown). More than one SLM (two to six lesions) were found in seven cases (41%). The size of the lesions ranged from 0.1 to 5.0 mm, with one case having, in addition, a 12-mm-large intramural oesophageal leiomyoma that was submitted for frozen section. Immunohistochemically, all SLMs were identical to the gut wall musculature (muscularis mucosae and propria), which was strongly positive for smooth muscle actin, h-caldesmon and desmin (Fig. 3d), but was negative for vimentin, CD117, CD34 and S-100 protein. However, scattered CD117-immunoreactive spindle cells probably representing overrun ICCs were seen in most SLMs and were occasionally prominent (Fig. 3e). In the upper and middle oesophagus, where smooth and striated muscle fibres in the external layer were in close contact, smooth muscle fibres commonly showed a nodular configuration, thus simulating SLM (Fig. 3f).

Control cases

Specimens from 32 patients aged 49–86 years (mean age, 69 years) were extensively examined. All cases were negative for ICC hyperplasia. Only one case revealed five SLMs (<1 mm) in the internal muscle coat. Another case contained a 2-mm sclerosing minute spindle-cell GIST (ICC hyperplasia) on the gastric side of the specimen (fundus), and a third one (HIV-positive) had multiple extramural leiomyomas of the distal oesophagus measuring up to 3.0 cm.

Discussion

The most common primary mesenchymal neoplasms of the tubular GI tract [6, 19, 21, 31] are GISTs, followed by benign polypoid leiomyomas of the muscularis mucosae of the colon and rectum [20]. The vast majority of GISTs occur in the stomach and small intestine [19, 21, 31]. Colorectal GISTs are rare, comprising less than 10% [19, 21, 31]. GISTs primary in the oesophagus are exceptionally rare and are considered to represent less than 1–3% of GISTs [7, 18, 19, 31]. The reason for this striking variability in the incidence of GISTs among the different parts of the GI tract is unknown. Very rare cases of oesophageal GISTs have been reported to occur following irradiation

[23], or in association with HIV infection [24]. GISTs are thought to arise from, or differentiate along, ICCs [9, 15, 27, 29]. ICCs form a network around the myenteric plexus of Auerbach and between muscle fibres of the muscularis propria [28]. Most GISTs show an immunoprofile similar to that of ICCs (vimentin⁺, CD117⁺ and CD34⁺). Abnormalities of the myenteric plexus with focal or diffuse proliferation of KIT-positive spindle cells (ICC hyperplasia) have been demonstrated in conditions known to predispose to multiple GISTs, as in cases of germline mutations of *c-kit* or *PDGFRA* [3, 8, 12], von Recklinghausen's disease [2, 30, 32] and Carney's triad [25]. The finding of ICC hyperplasia explains the development of multiple GISTs in such conditions, possibly because ICC hyperplasia represents a pre-neoplastic lesion. Diffuse ICC hyperplasia was found to be polyclonal in nature [3]. Precursor lesions for sporadic GISTs have not been well defined. The only two available studies dealing with putative mesenchymal precursor lesions in the stomach (so-called gastric microleiomyoma) have preceded the KIT era and therefore contained a mixture of both small GISTs and true microleiomyomas [22, 34]. Grossly recognizable, incidentally found GISTs measuring less than 1 cm were found to harbour *c-kit*-activating mutations and were considered to represent early GISTs [5]. Although diminutive lesions consisting of KIT-positive spindle cells have been rarely recognized in the vicinity of sporadic GISTs [15], there was no report describing in detail the clinicopathological features and the incidence of microscopic sporadic ICC hyperplasia. In the current study, we found ICC hyperplasia in 9.1% of routinely processed oesophageal resection specimens for carcinomas involving the lower third of the oesophagus, which is an unexpectedly high incidence, given that all cases have been routinely processed without extensive or systematic sectioning to enhance detection. No significant association with a specific cancer type (squamous carcinoma vs Barrett's carcinoma) or a previous irradiation was found. Similarly, we found a high incidence (22%) of minute leiomyomatous microlesions, the so-called SLMs, involving the internal muscularis propria of the lower oesophagus. It is well known that the incidence of microleiomyoma varies greatly, depending on the methodology used in a given study [34]. No case of SLM involving the outer muscle coat could be found. With the exception of a few cases of SLMs and two cases of ICC hyperplasia (featuring collision with the associated cancer), ICC hyperplasia and SLMs in this study involved tumour-free lamina muscularis propria surrounding carcinomatous tissues proximally or distally (mostly in sections submitted from the tumour). Given the relatively high incidence of these GIST tumourlets, in contrast to vanishingly rare clinical oesophageal GISTs, it seems very likely that these microscopic lesions mostly represent reactive, self-limiting lesions that probably do not harbour determinant genetic alterations to evolve into true neoplasms. The mechanisms and aetiopathogenetic factors behind the development of these unusual lesions in this peculiar microanatomical region of the GI tract and their association with carcinomas remain unknown. A synchronous occurrence of GISTs and other types of cancer in the GI tract, either at the same site or

involving different parts, is well documented in the literature [1, 16]. Possible explanations for the association of ICC hyperplasia with cancer could be that either: (1) a field effect by a specific carcinogen acts on two different tissue types, initiating histogenetically different neoplasms/lesions (ICC hyperplasia and carcinoma); or (2) the second lesion (ICC hyperplasia) could be induced by growth factors or specific mitogens produced by neighbouring carcinoma and released in the surrounding interstitial microenvironment; and/or (3) a yet unidentified motility-related mechanism caused by the coexisting cancer or its initiating factors may act on and stimulate the proliferative dynamic of ICCs to initiate such reactive (hyperplastic) lesions. The fourth possibility—that ICC hyperplasia represents a mere incidental finding—is disputed by the relatively high incidence in carcinoma specimens and its rarity or virtual absence in our autopsy series, but this must be confirmed in further studies investigating a large number of cases. The significant temporal difference between the two lesions (well-developed carcinoma vs initial mesenchymal proliferation) argues against the first hypothesis (cogenesis), as it is expected that both lesions would be at comparable clinical stages if they had been initiated by the same causal agent or cofactor. If ICC hyperplasia could be induced by locally acting growth factors or mitogens produced by the associated cancer, it is convenient to expect similar lesions in the vicinity of carcinomas in the remainder of the GI tract, especially in the large intestine where carcinomas are more common, but ICC hyperplasia in the large bowel is exceedingly rare (unpublished data). Among hundreds of colonic resection specimens, most of them containing carcinomas, we observed minute GISTs (ICC hyperplasia) in only three cases—all of them in the sigmoid colon and with only one lesion associated with carcinoma (unpublished data). Accordingly, it is likely that ICC hyperplasia is initiated by more than one causal factor; some of them may be site-dependent. Experimental studies have demonstrated that certain carcinogens used to induce gastric carcinoma in rats have also induced gastric leiomyosarcoma, but only after the addition of other specific cofactors such as aspirin and stress [4]. Furthermore, microanatomical peculiarities of the oesophago-gastric junction and its involvement in a specialized motoric function due to the presence of sphincteric structures and the unique presence of the oblique muscle layer in the post-sphincteric region of the gastric fundus may be involved in some way in the very early initiation or promotion of these probably reactive mesenchymal proliferations. Actually, the presence of the oblique muscle layer in the stomach has been suggested as a possible cofactor in the pathogenesis of the so-called microleiomyoma [22, 34].

The relatively high incidence of ICC hyperplasia in the distal oesophagus correlates with an even higher one for gastric fundic ICC hyperplasia (unpublished data). However, in contrast to a high incidence of sporadic gastric ICC hyperplasia that parallels the high incidence of GISTs in the stomach, oesophageal ICC hyperplasia is probably only rarely preneoplastic, given the very rare occurrence of oesophageal GISTs. The striking variance in the incidence of both clinical GISTs and their presumable precursor

lesions (ICC hyperplasia) in different parts of the GI tract may indicate great heterogeneity in the commitment of ICCs and the presence of diverse subpopulations of ICCs possessing greatly varying proliferative and neoplastic potentials. Future studies may contribute to our understanding of the pathogenetic mechanisms involved in the initiation and development of sporadic ICC hyperplasia in this part of the GI tract and their relationship to clinical GISTs.

In our study, considering the mean age of 35 years for patients with clinical oesophageal leiomyomas [18] compared to the mean age of 65 years for those with SLMs, it seems unlikely that SLMs are regular precursor lesions for clinical leiomyomas. In this study, we found only one case with both SLM and clinical leiomyoma at the same site. The exclusive occurrence of SLMs in the internal muscle coat is in accordance with a reactive process that is possibly related to disturbed motility functions and other cofactors. The fate of oesophageal ICC hyperplastic lesions and SLMs is unknown. Rare lesions (ICC hyperplasia) may evolve into true neoplasms through acquisition of additional genetic alterations. Gastric ICC hyperplasia evolves mostly through a course of extensive hyalinization with dystrophic calcification, and only a minority of them may transform into true GISTs, either of the spindle-cell type or the epithelioid-cell type (unpublished data).

The histopathological differential diagnosis of ICC hyperplasia in our study included neuroma-like neural hyperplasia and hypertrophic nerve fibres related to neoadjuvant radiotherapy, focally cellular stromal desmoplasia with prominent myofibroblasts and focal spindling of squamous carcinoma. SLMs are readily recognizable, as they show features of well-differentiated smooth muscle cells similar to normal muscle tissues of the gut wall and they will not be mistaken for ICC hyperplasia if one is familiar with them. However, in the middle and upper oesophagus, where both smooth muscle and striated muscle cells are intimately associated in the outer muscle coat, the smooth muscle component usually takes a somewhat nodular configuration and should be distinguished from SLMs. Furthermore, SLMs are almost exclusive to the internal muscle coat, and their occurrence in the outer layer should be questioned.

In summary, we reported the occurrence of sporadic ICC hyperplasia in 9.1%—and SLMs in 22%—of routinely processed distal oesophageal resection specimens harbouring carcinomas. This high incidence is in favour of a reactive self-limiting process. SLMs are probably unrelated to most clinical leiomyomas of the oesophagus. However, a subset of ICC hyperplasias may represent facultative precursor lesions for sporadic GISTs in a hyperplasia–neoplasia sequence. Further studies are needed to elucidate the molecular–genetic profile (and hence the biological significance) of these microlesions, their initiating mechanisms and their possible role in very early events in tumorigenesis of sporadic GISTs and leiomyomas.

High expression of RELP (Reg IV) in neoplastic goblet cells of appendiceal mucinous cystadenoma and pseudomyxoma peritonei

Received: 9 August 2005 / Accepted: 26 September 2005 / Published online: 2 December 2005
© Springer-Verlag 2005

Abstract The regenerating protein (Reg)-like protein (RELP, also known as Reg IV) is a recently characterized fourth member of the human Reg protein family. The Reg proteins are small, about 20-kD-sized, secretory proteins of C-lectin type. The previously known Reg proteins have been functionally implicated in regeneration, proliferation, and differentiation of the pancreas, liver, and gastrointestinal mucosa. To study the tissue expression of RELP, we raised a monoclonal antibody to RELP. By immunohistochemistry and in situ hybridization, we found a robust de novo expression of RELP in the neoplastic goblet cells of appendiceal mucinous cystadenomas and in the epithelial implants of pseudomyxoma peritonei (PMP). Our findings indicate that RELP serves as a marker for appendiceal mucinous cystadenomas and PMP, and that RELP may contribute to the pathogenesis of these disorders.

Keywords Pseudomyxoma peritonei · RELP (Reg IV) · Reg proteins · CDX2 · Intestinal mucin

Abbreviations RELP: Reg-like protein · Reg: regenerating · PMP: pseudomyxoma peritonei · EIA: enzyme immunoassay

Introduction

Pseudomyxoma peritonei (PMP) is a rare disorder characterized by progressive accumulation of viscous, mucinous ascites in the peritoneal cavity. The gelatinous ascites is produced by disseminated implants of mucinous epithelium on the peritoneal surfaces and omentum. The incidence of PMP is two times as high in women as in men. Therefore, there has been some controversy about the role of ovarian mucinous neoplasms as a potential origin of PMP. Recent immunohistochemical and molecular genetic studies indicate, however, that a dissemination of epithelium from mucinous cystadenomas of the appendix is a common cause of PMP in women. The occurrence of synchronous ovarian mucinous tumors in PMP can, in most instances, be regarded as implants of mucinous epithelium of appendiceal derivation (for review, see: [3, 7]). In rare cases, as recently described by Ronnett and Seidman [13], ovarian teratomas containing elements of mucinous appendiceal epithelium may give rise to PMP. The appendiceal origin is further supported by the high expression of the intestinal mucin MUC2 and the intestinal-specific homeobox gene CDX2 in PMP [10, 16].

The mucinous change in appendix or mucinous cystadenoma, previously called mucocoele, is histologically characterized by extensive mucosal replacement of abundant mucin-producing goblet cells. Despite a usually well-differentiated morphology, cytogenetic studies have revealed monoclonal loss of heterozygosity, indicating the true neoplastic nature of appendiceal mucinous cystadenomas [3, 7].

The regenerating (Reg) proteins belong to a group of calcium-dependent, c-type lectins. The 17 Reg proteins of various mammalian species recognized so far are small (about 20 kD) secreted proteins of four superfamilies, now called Regs I–IV. The Reg proteins have been functionally implicated as growth factors and antiapoptotic “survival

factors" for pancreatic islets and neural cells, as acute phase reactants modifying inflammation, and as regeneration factors stimulating mucosal repair of the gastrointestinal tract.

The genes for the three previously known human Reg proteins (Reg I–III, also called RegIa or Lithostatin A, Lithostatin B, and pancreatitis-associated protein) are clustered in tandem on chromosome 2p12 (reviewed in [18]). Hartupée et al. [2] and Kämäräinen et al. [4] independently identified, cloned, and characterized a fourth member of the human Reg family called Reg IV or Reg-like protein (RELP). The gene for RELP has a different chromosomal location on p12–13, and encodes a secreted protein of 158 amino acids that shows about 45% similarity with the Reg I–III proteins [4].

In situ hybridization revealed a restricted expression of RELP in the neuro-endocrine cells of normal intestinal epithelium. By immunohistochemical staining of RELP with rabbit antibodies, we demonstrated a coexpression of RELP and chromogranin A in selected cells in the crypt epithelium of small intestinal mucosa [4]. A strongly up-regulated expression of RELP was found in the goblet cells in areas of intestinal metaplasia in the gastric mucosa and in Barrett's esophagus [4]. Hartupée et al. [2] reported an accumulation of Reg IV message in colon mucosa from patients with inflammatory bowel diseases. We used immunohistochemistry and found a strong expression of RELP protein in the goblet cells of inflamed intestinal mucosa in Crohn's disease and in ulcerative colitis [4].

In situ hybridization has revealed up-regulated expressions of RELP message in colorectal adenomas and colorectal cancer [15, 19]. Oue et al. [11] recently performed a serial analysis of gene expression on samples from primary gastric cancers and found that RELP was one of the most prominently up-regulated genes in the schirrous type of gastric cancer [11].

Taken together, previous findings indicate that the up-regulated expression of RELP associates with preneoplastic and neoplastic changes in the gastrointestinal mucosa. Given our previous observations on the accumulation of RELP in metaplastic goblet cells in the gastric mucosa, we asked whether RELP is also expressed in the neoplastic goblet cells of appendiceal mucinous cystadenomas and PMP. Here we report the expression of RELP in appendiceal mucinous cystadenomas and in PMP in relation to other intestinal marker proteins.

Materials and methods

Formalin fixed and paraffin-embedded specimens were collected from the archives of the Department of Pathology, Haartman Institute, University of Helsinki. All patients were of Finnish, Caucasian origin. The PMP samples conformed to the classification of Ronnett et al. [12] of disseminated peritoneal adenomucinosis type. Cases representing peritoneal mucinous carcinosis with or without

intermediate/discordant features were not included. The data are summarized in Table 1.

Monoclonal antibodies to RELP

Monoclonal antibodies to RELP have not been reported previously. The RELP coding complementary DNA (cDNA) sequence was amplified by polymerase chain reaction (PCR) and cloned into an expression vector by replacing human immunoglobulin G1 (IgG1) variable region sequence with RELP coding sequence. The human IgG1 heavy chain secretion signal and the N-terminal amino acids of the variable region, glutamine (Gln)-isoleucine (Ile)-glutamine (Gln), are retained on the recombinant protein. Human IgG1 hinge, calponin homology 2 (CH2), and CH3 domains are C-terminal to the RELP coding sequence. SP2/0 myeloma cells were transfected by electroporation with the RELP plasmid, and clonal cell lines that stably secrete the protein were isolated. The recombinant RELP protein was purified by protein A column chromatography.

Mice were immunized with 50 µg of RELP/Fc protein mixed with adjuvant until IgG titers of 1:50,000 were achieved. Three days prior to fusion the mice were injected with 10 mg of RELP in phosphate buffered saline (PBS), administered intravenously. The splenocytes were harvested and fused at a 1:1 ratio with FO murine myeloma cells with a polyethylene glycol 3,000 solution. To assess hybridoma supernatant activity, solid phase enzyme immunoassays (EIA) were performed. RELP/Fc protein or a control Fc construct were coated overnight on to 96-well EIA plates. After washing, the wells were then blocked with 1% bovine serum albumin in PBS. Undiluted supernatants from the growth-positive hybridomas were incubated on both Fc protein coated plates and then probed with horseradish peroxidase (HRP)-labeled goat antimouse IgG Fc-specific antibody. HRP substrate solution was added, and the absorbance was measured at 490 nm by an automated plate spectrophotometer. Only clones specifically reactive to RELP/Fc and not to the negative-control Fc protein were expanded in tissue culture and subcloned. Monoclonal supernatants were purified using protein A.

Mouse monoclonal antibodies to the human mucins-MUC2, mucin 5 subtypes A and C (MUC5AC), and MUC6 were obtained from Novocastra Laboratories Ltd (Newcastle upon Tyne, UK). Monoclonal anti-CDX2 antibody was obtained from BioGenex (San Ramon, CA). Secondary antibody, HRP-conjugated Rabbit antimouse immunoglobulin (IgG), was obtained from Dako (Glostrup, Denmark).

Immunohistochemistry

Four-µm sections from formalin-fixed, paraffin-embedded tissues were mounted on 3-aminopropyl-triethoxysilane-coated slides (Sigma), deparaffinized, and heated twice for 5 min in a microwave oven (650 W) before exposure to the

Appendixes of patient numbers 1 and 2 are normal appendixes. Normal/adenoma (numbers 3–6) are cases where the proximal part of appendix was morphologically normal while the distal portion contained mucinous adenoma. Sections from both parts were mounted and stained on the same slide. Adenoma (numbers 7–12) are appendixes with only mucinous adenoma. PMP (numbers 13–21) are sections of epithelial implants from pseudomyxoma peritonei. Number 14 represents implants from number 8, and number 15 represents implants from number 7 MUC5 MUC5AC

first antibody (monoclonal mouse anti-REL P antibody, dilution 1:500). EliteKit (Vectastain, Vector Laboratories, Burlingame, CA) was used for immunoperoxidase staining, visualized with 3-amino-9-ethylcarbazole (Sigma).

In situ hybridization

We prepared probes by using the TA cloning kit (Invitrogen, San Diego, CA) ligating a polymerase chain reaction-amplified 0.4-kilobase REL P cDNA insert into the pCR-II vector (Invitrogen). The templates for REL P antisense or sense RNA probes were generated by linearizing the appropriate vector construct (3' to 5', or 5' to 3', respectively). The RNA Labeling Kit of Boehringer–Mannheim (Mannheim, Germany) was used according to the manufacturer's instructions to generate digoxigenin-labeled RNA probes by *in vitro* transcription.

Treatment of sections for *in situ* hybridization

Tissue sections were deparaffinized as before and specially prepared for *in situ* hybridization. Prior to hybridization, the sections were treated with 0.3% triton X-100 and then with 10 mg/ml proteinase K for 15 min at 37°C. The sections were then postfixed with 4% paraformaldehyde for 5 min. After acetylation of the section [2×5 min with tri-

ethylamine buffer containing 0.25% acetic anhydride (v/v)], they were incubated with a prehybridization buffer [4× sodium chloride–sodium citrate (SSC) containing 50% deionized formamide] for 15 min at 37°C.

The prehybridization buffer was drained and sections were overlaid with hybridization buffer (Sigma, St. Louis, MI) containing 10 ng of digoxigenin-labeled RNA probe. Sections were covered with plastic coverslips and incubated in a humid chamber at 42°C overnight.

After hybridization, the coverslips were removed and the sections were washed at 37°C twice in 2× SSC for 15 min each then twice with 1× SSC for another 15 min each. Unbound RNA probe was digested with a NaCl–Tris HCl–ethylenediaminetetraacetic acid buffer containing 20 µg/ml of ribonuclease A at 37°C; the sections were washed twice with 0.1× SSC for 30 min each. The labeled probe was detected using the digoxigenin nucleic acid detection kit (Roche, Germany) according to the manufacturer's instructions.

Results

Staining of sections from normal appendix with monoclonal antibody to REL P revealed exclusive expression in scattered cells in the crypt epithelium (Fig. 1b). We have earlier shown that the cells strongly expressing REL P in normal intestinal mucosa codistribute with cells expressing chromogranin A as a marker of neuro-endocrine differen-

Fig. 1 Sections from proximal appendix with normal mucosa (case number 5 in Table 1) (a–f), and from mucinous cystadenoma in the distal end of the same appendix (g–l), stained with van Gieson trichrome stain (a and g) and immunohistochemically with antibodies to RELP (b, arrow heads, and h), CDX2 (c and i), MUC2 (d and j), MUC5AC (e and k), and MUC6 (f and l). Original magnification $\times 100$

tiation [4]. The nuclei of the normal appendiceal epithelium stained strongly for CDX2. Normal goblet cells stained for MUC2 but not for RELP. The MUC2 staining was confined to the perinuclear region and along the cellular membrane (Fig. 1d). A weak staining for MUC5AC was seen locally in a morphologically normal mucosa in one case, while expression of MUC6 was not evident in the sections from normal appendix (Fig. 1e,f).

A strong expression of RELP was seen throughout in the mucin-containing goblet cells of appendiceal mucinous cystadenomas (Fig. 1h). Higher magnifications revealed a slightly granular staining of the goblet content for RELP. The nuclei of the adenomatous mucosa stained for CDX2. MUC2 was also strongly expressed in all cells of the adenomatous epithelium (Fig. 1j). The intracellular staining for MUC2 was mainly seen in the perinuclear, basal, and lateral portions of the goblet cells, and hence, did not fully co-distribute with the staining for RELP.

In contrast to the normal appendiceal mucosa, the adenomatous epithelium stained strongly for MUC5AC. The antibodies to MUC5AC decorated the goblet cells of the upper, luminal portion of the adenomatous mucosa, while the deepest glands did not contain the antibodies to MUC5AC (Fig. 1k). Staining for MUC6 was restricted to the basal, MUC5AC-negative glands in five out of six adenomas that came from women. The epithelium of the basal glands in three appendiceal cystadenomas from male patients did not stain for MUC6 (Fig. 1, Table 1). Immunohistochemical staining of epithelial implants from PMP also revealed a strong expression of RELP in the mucin-producing cells (Fig. 2b). The staining pattern was virtually identical to that seen in the epithelium of appendiceal mucinous cystadenoma. As reported earlier by O'Connell et

al. [10], the epithelial cells of PMP stained throughout for MUC2. As in appendiceal mucinous cystadenomas, the intracellular distribution of MUC2 appeared mainly at the

Fig. 2 Sections of epithelial implants of PMP stained with van Gieson's trichrome stain (a) and immunohistochemically with antibodies to RELP (b), CDX2 (c), MUC2 (d), and MUC5AC (e). Original magnification $\times 100$. In situ hybridization of PMP epithelium with antisense RELP probe (f) and with control, sense probe (g). Original magnification $\times 200$

perinuclear and baso-lateral areas of the goblet cells (Fig. 2c,d). The PMP epithelium also stained for MUC5AC (Fig. 2e), while no staining was seen for MUC6 in the nine cases of PMP investigated in this study (Table 1).

To confirm the local production of RELP in the PMP epithelium, *in situ* hybridization was carried out with anti-sense and sense RNA probes to RELP. As shown in Fig. 2f, a strong signal indicating accumulation of RELP messenger RNA was seen in PMP epithelium, while no signal was obtained from consecutive sections using the sense (control) probe.

Discussion

We have employed a novel monoclonal antibody and *in situ* hybridization to demonstrate a strong expression of RELP in the neoplastic goblet cells of appendiceal cystadenoma and epithelial implants of PMP. However, it appears unlikely that the robust expression of RELP is a consequence of neoplastic transformation because we have previously reported a strong staining for RELP in non-neoplastic, reactive mucosal goblet cells in inflammatory bowel diseases and in metaplastic goblet cells. Goblet cells of normal intact intestinal mucosa did not express RELP at levels discernible by immunohistochemistry or by *in situ* hybridization [4]. RELP and MUC5AC displayed a similar expression profile, albeit with a different intracellular distribution. Therefore, convergent mechanisms appear to regulate the *de novo* acquisition of goblet cell phenotype and activation of expression of the RELP and MUC5AC genes. The molecular details of these events, however, are still poorly understood.

Yamamoto et al. [16] recently provided experimental data to show that the homeodomain protein CDX2 acts as a transcriptional activator to regulate the expression of MUC2 in transfected COS-7 cells. Moreover, Mutoh et al. [8] generated transgenic (TG) mice in which ectopic expression of CDX2 was targeted to the gastric mucosa under the promoter of the noncatalytic subunit of the rat H⁺/K⁺-adenosine triphosphatase gene. They found that the TG mice developed a progressive loss of parietal cells and eventually showed intestinal metaplasia of the entire gastric mucosa. The same authors recently reported a progress from intestinal metaplasia to adenomatous polyps and to invasive gastric cancer in the same TG mice with targeted gastric overexpression of CDX2 [9]. However, it seems unlikely that CDX2 alone regulates the transcription of the RELP gene in appendiceal mucinous adenomas and PMP, because a strong nuclear staining for CDX2 is seen in normal intestinal epithelium, including normal goblet cells, which lack RELP expression.

RELP is abundantly present in normal intestinal neuroendocrine cells. Therefore, we performed immunohistochemistry of appendiceal carcinoid tumors and found

expression of RELP in solid and, in particular, in goblet cell variants of the tumor (manuscript in preparation). Interestingly, appendiceal carcinoid tumors show a similar female preponderance as mucinous adenomas and PMP do [13]. Given the expression of RELP in both tumors, it is tempting to speculate about a common cellular origin of these neoplasms.

Coexpression of MUC5AC and RELP was seen in the goblet cells of PMP. In the appendiceal mucinous cystadenomas, however, RELP homogeneously stained the entire transformed mucosa, while positivity for MUC5AC was seen in its upper, luminal portion, leaving the deepest glands unstained. Adenomatous epithelium in the basal glands stained for MUC6 in five out of six appendiceal mucinous cystadenomas from women, while no reactivity for MUC6 was seen in the adenomas from men. Although the material is too limited to allow any firm conclusions, it is interesting to notice that steroid hormones influence the expression of MUC6 in breast cancer cells [1]. This might have some bearing on the higher female incidence of appendiceal mucinous cystadenomas and PMP.

MUC6 was absent in all ten cases of PMP, while a strong expression of MUC5AC was detected. This might indicate that subclones expressing MUC5AC have a higher propensity for intraperitoneal implantation. The MUC5AC-positive subclones may also be better adjusted for growth and/or survival under poorly oxygenated conditions, like inside the mucous masses of PMP. The MUC5AC-containing goblet cells are also located in the upper portion of the appendiceal adenomatous mucosa, furthest away from the circulation.

The functional significance of the strongly up-regulated expression of RELP in inflammatory, metaplastic, and neoplastic goblet cells remains to be clarified. Because RELP, like other known members of the Reg protein family, is a secreted protein, it may be a ligand for a still unidentified receptor mediating signals in a paracrine or autocrine fashion. A receptor for the homologous Reg I, RegR was cloned by Kobayashi et al. [6]. Reg IR is a 919 amino acid transmembrane protein, which shows homology to the human multiple exostoses-like gene. RegR has been found on beta cells of pancreatic islets and in rat gastric mucosa where it mediates proliferative signals [5]. A corresponding receptor for RELP remains to be identified.

Taken together, we show here a strong *de novo* expression of RELP in the neoplastic goblet cells of appendiceal mucinous cystadenomas and PMP. RELP may serve as a clinical and immunohistochemical marker for these disorders. Our recent observations indicate that RELP displays relative specificity for neoplastic goblet cells of intestinal derivation. Immunohistochemical staining of 73 ovarian tumors with mucinous differentiation revealed some degree of positivity in 15 cases (20%) (unpublished observations). Further studies are in progress to elucidate the pathogenetic role of RELP expression in neoplastic and metaplastic goblet cells in the gastrointestinal tract.

Expression of cell cycle-regulatory proteins, MIB-1, p16, p53, and p63, in squamous cell carcinoma of conjunctiva: not associated with human papillomavirus infection

Received: 26 July 2005 / Accepted: 26 October 2005 / Published online: 3 December 2005
© Springer-Verlag 2005

Abstract Squamous cell carcinoma (SCC), the most common primary malignant tumor of the conjunctiva, has a variable clinical presentation and immunohistochemical profile. Abundant cell cycles exist, including MIB-1 (Ki67 antigen), p16, p53, and p63, within the conjunctiva SCC. This investigation first reports the expressions of cell cycle markers in SCC. A retrospective study was conducted between December 1976 and June 2004, comprising 13 consecutive patients with conjunctiva SCC who were treated with surgical excision. Detailed clinical parameters were also reviewed. Overexpression of MIB-1, p16, p53, and p63 genes were studied by immunohistochemistry. Genechip containing 39 subtypes was used to elucidate human papillomavirus (HPV). The study group contained 13 (100%) men, with a mean age of 68 ± 18 years and follow-up period of 20 ± 17 months. The sample included four (33%) SCC located in the left eye and two (17%) recurrent SCC. Overexpression of the p53 and p63 was considerably higher than that of the p16 ($P < 0.01$). HPV DNA was not detected in any of the 13 cases. This work first examined the immunohistochemical overexpression of cell cycle (MIB-1, p16, p53, and p63) in SCC. This in-

vestigation then showed that the expression of cell cycles in SCC was associated with key tumor clinicopathological features. This approach can help distinguish the potential roles of cell cycle in the development of SCC.

Keywords Cell cycle · Conjunctiva · Human papillomavirus · MIB-1 · p16 · p53 · p63 · Squamous cell carcinoma

Introduction

Squamous cell carcinoma (SCC) is the most common neoplasm of the conjunctiva. SCC also is associated with numerous cell cycle genes [1, 16, 22]. Cell cycle genes vary during cell proliferation and apoptosis [8, 9, 19, 20, 24–26]. The expression of cell cycle genes in SCC previously has never been clarified. To our knowledge, detailed immunohistochemical analysis of the cell cycle genes, the proliferating MIB-1 (Ki67 antigen), and apoptotic p16, p53, and p63 activities of conjunctiva SCC have not been performed.

At least 90% of the basal cells in limbal and peripheral corneal epithelia synchronously progress through the cell cycle. MIB-1 is a marker of actively cycling cells. Actively proliferating cells were identified with anti-Ki67, a marker of the late G1-M phase of the cell cycle [15]. There are two families of cyclin-dependent kinase inhibitors identified. The CIP/KIP family includes p21, p27, and p57, while the INK4 family consists of p16, p15, p18, and p19 [24, 26]. The expression of p16, p53, and p63 are dramatically altered during wound endothelium, suggesting that they may be involved in the changes in cell proliferation observed during carcinogenesis [6]. Moreover, the central role of human papillomavirus (HPV)-16 and HPV-18 in the oncogenesis of conjunctival cancers has been debated for a decade [6, 11–13, 17, 18, 21].

The purpose of the current study was to identify differences in cell cycle protein, MIB-1, p16, p53, and p63 expression in conjunctiva SCC that would express the proliferative and apoptotic capacities. This investigation

then attempted to determine whether the expression of cell cycle in SCC was associated with main clinicopathological features and HPV infection.

Materials and methods

This retrospective study conducted between December 1976 and June 2004 included 13 consecutive patients with SCC who were treated by surgical excision. Detailed clinical parameters were also reviewed [2–4]. The clinical charts displayed data on age, sex, presenting symptoms, and surgical procedures. Follow-up data were gathered from clinical records and standardized telephone interviews. In addition, tumor size and morphologic features were retrieved from the surgical pathology reports. All sections were stained with hematoxylin–eosin and examined for the presence of vascular proliferation, inflammation, cellularity, and fibrosis. The clinical and pathologic features of the SCC were analyzed statistically to identify morphological features related to recurrence and patient age on diagnosis.

Immunohistochemical staining for cell cycle: MIB-1, p16, p53, and p63

Cell cycle markers, including MIB-1, p16, p53, and p63, were studied immunohistochemically in 12 patients of conjunctiva SCC. Formalin-fixed, paraffin-embedded tissues were cut into 4- μ m sections and mounted on glue-coated slides. Slides were deparaffinized in xylene, rehydrated in graded alcohols, and prepared by pressure cooker for 3 min. All slides were treated by tris–EDTA 1 nM pH 9.0 for MIB-1, 1 nM pH 8.0 for p16, 10 nM pH 6.0 for p53, and 1 nM pH 8.0 for p63. The various primary antibodies (MIB-1, 1:100, monoclonal, DakoCytomation; p16, 1:50, monoclonal, Santa Cruz; p53

1:50, DakoCytomation; p63 1:25, DakoCytomation) were applied for immunochemical stains according to the instruction of the manufacturer.

MIB-1 labeling index (%) was determined by counting positive cells per 100 squamous cells. The immunoreactivity was scored semiquantitatively as follows: weak or 0 (<10%) or 1+ (1–20%); moderate or 2+ (21–40%); and strong or 3+ (41–100%) nuclei per 100 nuclei. Stained cells with scale 0 or 1+ were classified as immunonegative, while those with scale 2+ or 3+ were considered immunopositive [16, 19, 22].

Genomic DNA extraction and electrophoresis

Genomic DNA was extracted using proteinase K and the phenol chloroform extraction method [7]. Samples were further purified through the use of a DNAeasy kit (Qiagen Inc., Venlo, The Netherlands). Finally, 1 μ g of DNA solution was eluted, and 1 μ g of the aliquot was used for polymerase chain reaction (PCR) amplification.

HPV genotyping by genechip

The SPF1/GP6+ consensus primers were used to amplify a fragment of approximately 184 bp in L1 open-reading frame first. Next, each PCR experiment was performed with several positive and negative controls [7]. The quality of isolated DNA was checked with glyceraldehyde-3-phosphate dehydrogenase (GAPDH) PCR. The resulting amplicons of 15 μ g were then hybridized with an HPV genechip (Easychip HPV Genotyping Array, King Car Taiwan). Thirty-nine types of HPV ligonucleotide probes of 20- and 30-mer, with an approximately 100–200 poly-T tail, were immobilized on a nylon membrane [7].

Table 1 The basic clinical parameters of the squamous cell carcinoma in conjunctiva

Patient	Age/sex/eye	Main symptoms	Location	Treatment	Outcome
1	20/M/L	Recurrent red eye for 4 years	Limbus	Excision + keratectomy	No recurrence in 24 months
2	76/M/R	Decreased VA	Limbus	Excision + AMT + MMC	No recurrence in 9 months
3	77/M/R	Mass	Limbus	Excision + MMC	No recurrence in 6 months
4	73/M/R	Red eye, blurry	Limbus	Excision + MMC	No recurrence in 26 months
5	60/M/R	Red eye	Bulbar conjunctiva	RT	Persistent of tumor in 12 months, no systemic metastases
6	59/M/R	Recurrent tumor 9 years earlier	Limbus	RT	Persistence of tumor mass 20 months, no systemic metastases
7	70/M/R	Foreign body sensation	Limbus	Excision + cryo	No recurrence in 5 months
8	63/M/R	Red eye	Limbus	Excision + cryo + AMT	No recurrence
9	89/M/R	Mass	Limbus	Excision + cryo exenteration + RT	Recurrence in 1 months, no recurrence after exenteration in 24 months
10	81/M/R	Mass	Limbus	Excision + AMT	No recurrence in 58 months
11	62/M/R	Red eye	Limbus	Excision + AMT	No recurrence 36 months
12	83/M/R	Red eye	Limbus	Excision + AMT + MMC	No recurrence in 24 months
13	62/M/R	Red eye	Limbus	Excision + AMT	No recurrence 36 months

Statistical comparisons were conducted using the Fisher exact test, Student *t* test for unpaired data, and Pearson correlation.

Results

Clinical findings

The patients comprised 13 (100%) men with a mean age of 20.3±16.5 years Table 1. The presentations included seven red eyes (58%), one decreased visual ability (8%), and

Fig. 1 The representative positive staining of MIB-1, p16, p53, and p63 to show the location and staining percentage in conjunctiva SCC (×400)

Fig. 2 Cell percentage of the various cell cycles staining in conjunctiva SCC

three orbital masses (25%). Notably, the sample included four SCC (33%) located in the left eye and two (17%) recurrence. Eight patients were diagnosed first during operative biopsy, and two were current SCC patients. These patients were followed-up for an average of 20.3±16.5 months (median, 32 months).

Expression of MIB-1, p16, p53, and p63 in squamous cell carcinoma

All SCC express immunopositive cell cycle genes, including all MIB-1, p16, p53, and p63 in 13 patients. Most positive MIB-1 staining was limited in the basal layer, but the p16/53/63 showed infiltration in the subepithelial cells (Fig. 1). Stained cell percentage is MIB-1 (41.0+18.6%), p16 (19.1+24.7%), p53 (83+8.1%), and p63 (86.7+8.6%), respectively (Fig. 2).

The percentage of expression of the p53 (80.0%) and p63 (84.6%) had higher expression than p16 (19.8%) (*P*=0.003 and *P*=0.000, respectively). However, p53 and p63 do not differ significantly (*P*=0.339).

Negative detection of HPV in SCC

Detection limit of this assay was determined by serial dilution of plasmid DNA containing the specific segment of L1 open-reading frame, using 39 HPV types and cell lines containing known HPV genotype, such as HeLa and CaSki cells, including between 10 and 100 copies per sample. None of the sample (0%) HPV-type DNA sequences were detected on the genechip.

Discussion

During corneal epithelial wound repair, cells migrating to cover the wound area exhibit a drastic reduction in proliferative activity [25]. In contrast, cells distal to the original wound exhibit a greatly enhanced level of pro-

liferative activity. At least 90% of the basal cells in limbal and peripheral corneal epithelia synchronously progress through the cell cycle. These inhibitors specifically block cells in the G1 phase of the cell cycle [1, 16, 19]. This study aimed to investigate the correlation between MIB-1, cell proliferative activity, and p16, p53, and p63 overexpression in conjunctiva SCC.

Positive staining of MIB-1, indicating cycling cells, was about 41% conjunctiva SCC in our study. Actively proliferating cells were identified with anti-MIB-1, a marker of the late G1-M phase of the cell cycle. It implies that the SCC maintains ability of proliferation well.

The expression of p16-form INK4 family is dramatically altered during wound SCC, suggesting that they may be involved in the changes in cell proliferation observed during carcinogenesis [8, 26]. The staining of p16 was the lowest among apoptotic markers, p16, p53, and p63 in conjunctiva SCC.

The p53 family—p53, p63, and p73—functions as transcription factors that play a major role in regulating the response of mammalian cells to stressors and damage, in part through the transcriptional activation of genes involved in cell cycle control, DNA repair, senescence, angiogenesis, and apoptosis. The strong positive p53 and p63 in this study indicate the malignancy of SCC.

The p53 protein is essential for the regulation of cell proliferation, and its aberrant accumulation is usually seen in malignant tumors [5]. The overexpression of p53 protein is an early event in head and neck carcinogenesis and may represent a biomarker for patients with preinvasive lesions. Mutation of the p53 tumor suppressor gene, often accompanied by overexpression of mutant p53 protein, is the most frequent molecular genetic event described thus far in human cancers. Overexpression of p53 protein (which is either wild type in sequence or mutant) is abnormal.

The p63 transcription factor, a p53 homolog, is essential for regenerative proliferation in epithelial development. Overrepresentation of p63 locus at chromosomal 3q27–29 was a typical finding in SCC. Within the cornea, nuclear p63 is expressed by the basal cells of the limbal epithelium. The identification of p63 as a keratinocyte stem cell marker will be of practical importance for the clinical application of epithelial cultures in cell therapy as well as for studies on epithelial tumorigenesis [23]. In contrast to the tumor suppressive function of p53, overexpression of select p63 splice variants is observed in many squamous carcinomas, suggesting that p63 may act as an oncogene [14, 23].

The results indicate that defects in the p16, p53, and p63 pathways are essential for the malignant transformation of conjunctiva epithelial cells. Molecular footprints at the sites of p53/63 mutations and p16 deletions further indicate that DNA repair activities for G/C to T/A. Transversion and nonhomologous end-joining of double-stranded DNA breaks play important roles in the accumulation of genetic alterations in lung cancer cells [10].

It is well known that HPV, which inactivates p53, is involved in the development of cervical squamous carcinoma,

and the Rb inactivation probably contributes to the high p16^{INK4a} expression in cervical cancer [8, 24]. Although infection of conjunctival epithelium with HPV is thought to be one of the important factors in the development of SCC [11–13, 17, 18], HPV DNA was not detected in any of these 13 cases as compared to some previous studies [17, 18]. Furthermore, HPV subtyping analysis showed that high risk HPV DNA was not present in any of these patients. It is probably associated with geographic regions, lifestyle, or HPV detection multiply methods [11–18]. The above findings strongly support that the SCC of conjunctiva is not associated with HPV infection.

Limitation

We acknowledge two limitations of our study. One is that the number of patients was small, and the other was that the follow-up period was relatively short. We conduct a prospective work to determine the role of cell cycle proteins in conjunctiva SCC.

Conclusion

MIB-1, p16, p53, and p63 may be useful markers of conjunctiva SCC and should be considered in the following up of conjunctiva SCC patients. The expressions of these cell cycles are not related to HPV infection.

Biphasic solitary fibrous tumour: a report of two cases with epithelioid features

Received: 6 May 2005 / Accepted: 19 September 2005 / Published online: 22 October 2005
© Springer-Verlag 2005

Abstract We present two cases of solitary fibrous tumour (SFT) showing biphasic morphology with a spectrum of malignant epithelioid components. Slides prepared from formalin-fixed and paraffin-embedded tissue from both cases were stained with haematoxylin and eosin and by immunohistochemistry. Interphase fluorescent in situ hybridisation studies were performed in both cases using paraffin-embedded tissue to look for the t(X;18) translocation, thereby to exclude synovial sarcoma. Both cases showed biphasic morphology with some areas having typical benign spindle SFT morphology (including CD34 expression) and other areas having a malignant epithelioid appearance. In one of the cases, the epithelioid area, which was well circumscribed and showed packeting of cell groups, demonstrated expression of cytokeratin and epithelial cadherin but not of CD34. In the second case, the immunophenotype of the epithelioid component was similar to that of the benign SFT component. These findings suggest that epithelioid change in SFT shows a range of differentiation at one end, similar to that of a standard SFT, and at the other end, possibly acquiring epithelial characteristics.

Keywords Solitary fibrous tumour · Biphasic · Epithelioid · Epithelial differentiation · Cytokeratin

Introduction

Solitary fibrous tumour (SFT) is an uncommon mesenchymal tumour usually arising from the visceral pleura but also at various extrapleural sites such as the peritoneum, retroperitoneum, mediastinum and orbit. Benign tumours significantly outnumber malignant ones. Epithelioid morphology in SFT has only very occasionally been described [3, 5, 6]. We present two cases of SFT showing distinct biphasic morphology and demonstrating a range of epithelioid differentiation.

Materials and methods

The slides of formalin-fixed and paraffin-embedded tissue were stained with haematoxylin and eosin. The immunohistochemical staining (primary antibodies listed in Table 1) was performed using a Vector Elite avidin–biotin complex method. Fluorescent in situ hybridisation (FISH) studies investigating the presence of a t(X;18) translocation in the tumours were purchased from the Institute of Human Genetics, Newcastle-upon-Tyne Hospitals, UK. The interphase FISH study was carried out by the Institute on 100 nuclei from disaggregated paraffin-embedded tissue using the Vysis SYT probe to investigate the translocation.

Clinical history

Case 1

A 63-year-old woman presented with a non-tender swelling in the posterior part of the right side of her neck. She was otherwise well with no significant past medical history. There was no limitation of cervical spine movement, and she had no neurological deficit in the upper or lower limbs.

An ultrasound scan was performed which confirmed a 40×20-mm mass. A magnetic resonance imaging (MRI) scan showed the presence of a well-defined, multilobulated mass within the substance of the deep transverse spinal muscle, lying deep to splenius capitis and scalene muscles and abutting the vertebral laminae of C3 to C5. No extension into the neural canal was identified. A needle core biopsy from the mass was considered to be suggestive of synovial sarcoma. Tumour excision necessitated peeling the tumour off the laminae of C3 to C5 in a subperiosteal plane. The patient was referred for radiotherapy.

Case 2

A 57-year-old man presented with an approximately 100-mm mass in the left ischio-rectal fossa, which, although present for the last 15 years, had started growing over the previous 6 months. An MRI scan demonstrated a 100×80×60-mm lobulated mass located within the fat of the left ischio-rectal fossa, displacing the rectum to the right and the levator muscles superiorly. These findings suggested a soft tissue sarcoma. No evidence of metastatic malignancy was seen on staging CT scan. An ultrasound-guided core biopsy was performed, which showed a biphasic tumour with spindled and epithelioid elements suggestive of an SFT. The tumour was excised. At operation, the tumour was located in a separate plane from rectum, bladder and prostate and was removed without disturbance of these structures.

Results

Case 1

The resected tumour was ovoid and lobulated, measuring 40×35×20 mm (Fig. 1a). Histologically, a biphasic pattern, with spindled and epithelioid components, was confirmed (Fig. 1b–d). The morphology of the spindle cell component was typical of SFT having variable sclerosis and variable cellularity and showing a haemangiopericytomatous vasculature (Fig. 1b,c). Focal stromal myxoid change was present. There was generally a low mitotic count [2/10 high-power field (HPF)], but in more cellular, non-epithelioid areas, the mitoses rose to 4/10 HPF. Focal microcalcification was also noted within the benign SFT area. The histological appearance of SFT was confirmed by immunohistochemistry, which in spindled areas showed strong and diffuse CD34 expression (Fig. 2a). The spindled tumour cells expressed Bcl-2 and vimentin but not cytokeratin (MNF116 and AE1/AE3) (Fig. 2b), CD99 or epithelial cadherin (E-cadherin). Type IV collagen and laminin were seen, mainly associated with the blood vessels in the spindled area with minor extension of fibres around the tumour cells.

The epithelioid tumour component arose within a distinct, pale yellow nodule approximately 20×15×10 mm in diameter (Fig. 1a). Its large cells had abundant eosinophilic or clear cytoplasm and vesicular pleomorphic nuclei with prominent nucleoli. They were packeted and arranged in sheets (Fig. 1d). Some multinucleate, osteoclast-like giant

Fig. 1 Case 1. Tumour showing a pale yellow nodule (microscopically corresponding to malignant epithelioid component) within firm, pale tissue (a). The spindle cell tumour component shows typical benign SFT with intervening collagen and a haemangiopericytic vasculature (b, c). The malignant epithelioid component shows large cells with clear cytoplasm and a packeted arrangement (d)

cells were present within the nodule. Mitoses were frequent in the epithelioid area (up to 11 mitoses/10 HPF) and were occasionally abnormal. No necrosis was present. Both spindled and malignant epithelioid areas were generally distinct (Fig. 2a,b), but focally, the two tumour patterns merged with an indistinct transition.

The malignant epithelioid cells showed diffuse cytokeratin expression with strong intensity using MNF116 (Fig. 2b) and moderate to strong intensity using AE1/AE3. They showed diffuse E-cadherin (Fig. 2c) and focal CD99; CD34 (Fig. 2a), Bcl-2 and vimentin were negative. The packeted appearance of the epithelioid tumour was accentuated by collagen type IV and laminin expression around the periphery of epithelioid cell groups. Other immunohistochemical stains performed that were negative in both epithelioid and spindle areas were epithelial membrane antigen (EMA), S-100, desmin, smooth muscle actin (SMA),

BerEP-4, calretinin, AUA-1 and CK5/6. In the FISH analysis, there was no evidence of a split signal, a finding consistent with the absence of a t(X;18) translocation.

Case 2

Macroscopically, the excised tumour had well-circumscribed margins and was multilobulated and very vascular. It measured 120×70×65 mm. Microscopically, it showed a biphasic pattern. One component, comprising approximately 50% of total tumour bulk, showed classical benign SFT (Fig. 3a, b) with a haemangiopericytomatous vasculature and hardly any mitoses (0/10 HPF). The other component was very variable, comprising areas with round cell and epithelioid cell morphology. Focally, these comprised

Fig. 2 Case 1. Closely apposed spindled and epithelioid cells are seen, showing strong and diffuse CD34 positivity in the former and none in the latter (a). The epithelioid tumour shows strong

cytokeratin expression (MNF116), whereas the spindled tumour is negative (b). The epithelioid area shows variable E-cadherin positivity (c)

Fig. 3 Case 2. Typical benign SFT areas (a, b). A biphasic area (c) with strands of epithelioid cells intermixed with spindled cells. Sheets of round/epithelioid cells (d). Cytokeratin positivity (AE1/AE3) is

present in epithelioid cells (e). CD34 positivity is present in both epithelioid and spindle cell components (f)

strands of cohesive cells intermixed with the spindle cell components (Fig. 3c). Elsewhere, there were sheets of round/epithelioid cells (Fig. 3d). Given the raised mitotic count (up to 5/10 HPF), extensive infiltration of peripheral fat and the presence of focal moderate nuclear pleomorphism in this component, the tumour was regarded as malignant. No well-marked packeting was identified, and the epithelioid appearance of the sheets of cells was less marked than was seen in case 1. Focal necrosis was identified. Immunohistochemical staining revealed that a proportion of tumour cells in both the epithelioid and spindled areas stained positively with cytokeratin antibodies (AE1/AE3) (Fig. 3e), though cytokeratin detected by MNF116 was restricted to the spindled area. The entire tumour stained strongly with CD34 (Fig. 3f), Bcl-2 and vimentin but was negative for E-Cadherin, S-100 and desmin. EMA was focally positive in benign spindled cells but was negative in epithelioid cells. Focal, weak positivity for CD99 was seen in both components. Laminin and collagen type IV showed vascular staining in both components with extension of fibres around spindle cells, but epithelioid cells were completely negative. The FISH analysis showed no evidence of a split signal, a finding consistent with the absence of the t (X;18) translocation.

Discussion

Two biphasic SFTs with focal epithelioid appearance are described. Epithelioid change in SFT has only very rarely been reported. A cytokeratin-expressing mediastinal tumour arising in a 74-year-old man and an ischioanal fossa lesion arising in a 67-year-old man have been advanced as

examples [5, 6]. In addition, a malignant SFT that did not express cytokeratin has been briefly described as showing 'solid sheets of epithelioid-like cell clusters' [3].

The histological distinction of epithelioid SFT from other epithelioid tumours, such as carcinosarcoma, malignant mesothelioma, synovial sarcoma and thymoma, may be very difficult, the more so if the SFT expresses cytokeratin [2]. Careful histological assessment of epithelioid SFT is required to identify any accompanying typical spindled SFT component, a feature we presently regard as being important in establishing a diagnosis. We note, however, that a spindled SFT area was either absent [6] or was, at most, exceedingly minor [5] in some previous reports of epithelioid SFT. A panel of immunostains appropriate for the differential diagnosis noted above is of use in identifying tumours of non-SFT type or in confirming an SFT-compatible phenotype (CD34-, Bcl-2- and CD99-positive). Occasionally, molecular biologic techniques may be of use as in the demonstration that all eight tumours lacked the t (X;18) translocation, a finding that further helped exclude a diagnosis of synovial sarcoma.

In case 1, there was well-demarcated, focal but extensive epithelioid change associated with malignant transformation, arising in an otherwise histologically typical benign SFT. The epithelioid component was characterised by a modulation of antigen expression with the loss of CD34 and vimentin and acquisition of cytokeratin and E-cadherin. This profound antigen modulation suggests a shift of differentiation pattern. It should be noted that E-cadherin is commonly expressed in soft tissue tumours in two contexts, as true epithelial differentiation such as is seen in synovial sarcoma, epithelioid sarcoma and glandular malignant peripheral nerve sheath tumours (PNSTs) and as a marker

of Schwannian/melanocytic differentiation as is seen, for example, in epithelioid malignant PNST or clear cell sarcoma [4, 7, 8]. SFTs are not of Schwannian/melanocytic derivation and, in keeping with this, are S-100-negative. The expression of E-cadherin in the epithelioid SFT (case 1) described herein therefore supports the presence of epithelial differentiation. Indeed, the epithelioid phenotype, cytokeratin and E-cadherin expression and loss of CD34 and vimentin are all features consistent with epithelial differentiation, though it is recognised that ultrastructural analysis would be required for unequivocal demonstration of epithelial features. In this context, the ultrastructural demonstration of 'primitive desmosomes' in SFTs suggests a restricted degree of epithelial differentiation even in standard SFTs [1]. We suggest that a greater degree of epithelial differentiation may have been present in case 1 of this report. In contrast, in case 2, the lack of E-cadherin and the retention of CD34 suggest that overt epithelial differentiation was not present.

Though the genetic and epigenetic abnormalities underlying epithelioid change in SFT are not known, the expression of E-cadherin in case 1 may have contributed to directing an epithelioid pattern rather than merely reflecting it, the expression of E-cadherin having a recognised role in conferring an epithelioid appearance to tumour cells [7, 9].

In conclusion, we present two cases of epithelioid SFT. Our studies suggest that a variable degree of epithelial differentiation may be present in these tumours.

An adiponectin receptor, T-cadherin, was selectively expressed in intratumoral capillary endothelial cells in hepatocellular carcinoma: possible cross talk between T-cadherin and FGF-2 pathways

Received: 27 May 2005 / Accepted: 14 September 2005 / Published online: 5 November 2005
© Springer-Verlag 2005

Abstract T-cadherin is a unique receptor of adiponectin, which plays a critical role in various angiogenesis. In the present study, T-cadherin expression in tumor vessels of hepatocellular carcinoma (HCC) and, subsequently, the molecular mechanism, which induced T-cadherin expression in sinusoidal endothelial cells were investigated. Sinusoidal endothelium in nontumorous liver, chronic hepatitis, or liver cirrhosis expressed little or no T-cadherin. By contrast, T-cadherin was found in intratumoral capillary endothelial cells of 34 out of 63 HCC specimens. In positive cases, focal T-cadherin expression was found in well-differentiated HCC, whereas diffuse and intense T-cadherin expression was observed in poorly differentiated HCC specimens. T-cadherin was much expressed in intratumoral capillary endothelial cells in a less differentiated HCC region than that in a well-differentiated region in five specimens, in which various differentiated HCC components were coexistent. In a double-cell chamber assay, fibroblast growth factor-2 appeared to have a critical role to induce T-cadherin in cultured liver sinusoidal endothelial cells. The present finding indicated that T-cadherin was selectively expressed in intratumoral capillary endothelial cells of many HCCs, increasingly expressed as tumor progression, and T-cadherin may have a positive role in angiogenesis of HCC. In addition, cross talk between the signal pathways mediated by fibroblast growth factor-2 and adiponectin was suggested.

Keywords T-cadherin · Adiponectin · Hepatocellular carcinoma · Neovascularization

Introduction

Tumor neovascularization is a critical event in various types of malignant tumor growth [3]. Hepatocellular carcinoma (HCC), in particular, is a hypervascular neoplasm, and many approaches that involve the interruption of blood supply have been used for patients with HCC. The intratumoral endothelial cells in HCC have morphological characteristics intermediate between those of ordinary capillary endothelium and the sinusoidal endothelium in normal liver [30]. Sinusoidal endothelium in HCC lost the phenotypes peculiar to liver and acquired the characteristics of capillary endothelial cells with progression of tumor dedifferentiation [22]. A cross talk between hepatic sinusoidal endothelial cells and juxtaposed hepatocytes play a role for the phenotype change and maintenance of sinusoidal endothelial growth and differentiation [6]. Especially, endothelial-cell growth factors, including vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF-2), which is secreted from normal or neoplastic hepatocytes, is believed to regulate the endothelial cell growth by a paracrine manner. Therefore, it is important to unravel the molecules, which are involved in a cross talk between HCC cells and intratumoral capillary endothelial cells, to regulate the tumor neovascularization in HCC.

T-cadherin (also referred to as CDH13 or H-cadherin) is a unique cadherin cell adhesion molecule that is anchored to the cell-surface membrane through a glycosyl phosphatidylinositol (GPI) moiety [26]. The T-cadherin amino acid motif has been well conserved through evolution in vertebrates relative to other classical cadherins [35]. However, T-cadherin lacks the cytoplasmic domain, which is critical for homophilic binding through interaction with submembrane cytoskeletal proteins in classical cadherin molecules [21]. There are also several reports which sug-

gest that T-cadherin plays an important role in signal transduction apart from cell–cell adhesion [9, 15, 34, 43]. In line with this speculation, recently, T-cadherin was identified as a novel receptor for hexameric and high-molecular-weight (HMW) isoforms of adiponectin, which has significant effects on angiogenesis [10]. Interestingly, murine T-cadherin was selectively expressed in transplanted tumor vessels in mice, and murine T-cadherin was believed to be a pivotal molecule for tumor neovascularization [24, 42]. However, there are still few reports that describe T-cadherin expression in intratumoral capillary endothelial cells in human tumors.

We have examined T-cadherin expression in various human malignant tumors, and here, we report that T-cadherin was selectively expressed in intratumoral capillary endothelial cells of HCC but not in sinusoidal endothelial cells in noncancerous liver. We also describe the relationship of T-cadherin expression with FGF-2.

Materials and methods

Antibodies, tissue samples, and immunohistochemical staining

Details of the procedures used to prepare rabbit-specific antibody to human T-cadherin and immunohistochemical staining were described previously [33]. Briefly, rabbits were immunized with human T-cadherin peptide QRQPF PRDVGKVVSDRPERSKFRLTGKGV. Antibody was purified by affinity chromatography using the same peptide. We verified the specificity of the antibody through Western immunoblotting by using various human tissue extracts. Control normal rabbit immunoglobulin (Ig)G was also prepared in our laboratory. Specific antibody to human LYVE-1 and CD34 were purchased from RELIA**Tech** GmbH (Braunschweig, Germany) and Becton Dickinson Immunocytometry Systems (San Jose, CA), respectively.

We examined archival liver tissue specimens that comprised a spectrum of noncancerous liver, liver cirrhosis, and HCC. We examined 63 HCC specimens, which contain a uniform differentiation type. The pathological features of the specimens are summarized in Table 1. All tissue specimens were untreated prior to resection, obtained from pathology files, and classified according to the World Health Organization classification [7]. In the present study, we focused on T-cadherin expression in liver tissues affected with viral infection when we examined HCC specimens. The differentiation in HCC was assessed based on the examination of hematoxylin–eosin (H & E)-stained sections according to Edmonson's grading [5]. Briefly, well-differentiated HCC was composed of tumor cells with minimal atypia and an increased nuclear/cytoplasmic ratio. Tumor cells were arranged in uniformly thin trabeculae. By contrast, in moderately differentiated HCC, tumor cells harboring the abundant eosinophilic cytoplasm and round nuclei were arranged in trabeculae of three or more cells in thickness. Giant tumor cells are more numerous in moderately differentiated HCC. In poorly differentiated HCC,

tumor cells have intense hyperchromatic nuclei and little cytoplasm without demonstrating a trabecular pattern. Pleomorphism and bizarre giant cells were frequently found in poorly differentiated HCC. We also examined five HCC specimens, which composed variously differentiated HCC regions in individual tissue slides. After antigen retrieval by autoclaving with citrate buffer (pH 6.0), the tissues were immunostained with affinity-purified antihuman T-cadherin peptide or control antibody using a streptavidin biotin complex peroxidase kit (DAKO LABS Kit; Dakopatts, Kyoto, Japan). In several experiments, anti-T-cadherin antibody was pre-adsorbed with human T-cadherin peptide, which was used for immunization.

To evaluate the immunostained specimens, the entire tumor section was scanned at low magnification ($\times 40$) to find the areas in which the tumor necrosis is absent. Next, we counted the percentage of endothelial cells positive in ten high-powered fields (HPFs) ($\times 200$). In preliminary experiments, reproducibility was poor in the specimens when less than 10% of the cells were stained in a section. In these cases, intratumoral capillary endothelial cells in other HCC areas sometimes did not exhibit staining with anti-T-

cadherin antibody. Therefore, we considered a specimen to be positive when we observed T-cadherin staining in more than 10% of intratumoral capillary endothelial cells. Finally, two authors reviewed the immunostains independently and drew concordant interpretations.

Assessment of microvessel density

Sections were immunohistochemically stained with anti-human CD34 antibody and examined at low-power magnification ($\times 100$) to identify the areas with the highest density of CD34-positive vessels. In each case, the most vascularized area was selected, and microvessels in five HPFs ($\times 200$) were counted. Finally, the mean microvessel count of the five most vascular areas was taken as the microvessel density, which was expressed as the absolute number of microvessels/HPF.

In situ hybridization

Details of the in situ hybridization procedures were described previously [34]. Antisense digoxigenin-labeled RNA probes to human T-cadherin were generated by promoter-mediated in vitro transcription using a digoxigenin RNA labeling kit (Boehringer Mannheim GmbH, Germany). Two hundred thirty base pairs of human T-cadherin cDNA were amplified by polymerase chain reaction (PCR) and subcloned into a pGEM-T easy vector

(Promega, Madison, WI). We also used sense digoxigenin-labeled RNA probes as a negative control. Digoxigenin-labeled probes were finally visualized using a digoxigenin DNA detection kit (Boehringer). The experimental condition was assessed by using human brain tissues in which T-cadherin mRNA is abundantly expressed.

Double-chamber cell cultures

Human cultured Hep G2 cells were maintained in our laboratory in Dulbecco's medium (Life Technologies, Grand Island, NY) containing 10% heat-inactivated fetal bovine serum (FBS) and 50 $\mu\text{g/ml}$ gentamycin (Life Technologies). Normal human liver sinusoidal microvascular endothelial cells were purchased from the Applied Cell Biology Research Institute (Kirkland, WA) and cultured with cell systems complete (CS-C) medium (Cell Systems, Kirkland, WA). In double-chamber cell cultures using Transwell polycarbonate membrane (Corning Costar Co. Ltd., Cambridge, MA), 1×10^3 Hep G2 and 1×10^4 normal liver sinusoidal endothelial cells were cultured with CS-C medium in upper and lower dishes, respectively, as shown in Fig. 5. Neutralizing goat anti-FGF-1 and goat antihuman VEGF-165 and VEGF-121 antibodies were purchased from Genzyme/Techne (MPLS, Minneapolis, MN). Neutralizing murine monoclonal anti-FGF-2 was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Normal goat IgG and murine monoclonal antibody directed against *Trichosporon beigellii*, which were prepared in our labora-

Fig. 1 Representative immunohistochemical staining of non-cancerous liver and HCC tissues with anti-T-cadherin antibody. Hepatocytes and sinusoidal endothelial cells in noncancerous liver were not stained with anti-T-cadherin antibody (a). T-cadherin expression was not observed in sinusoidal endothelial cells in liver cirrhosis (b). Intratumoral capillary endothelial cells of 9 of 12 well-differentiated HCC specimens did not express a detectable level of T-cadherin (c; arrow indicates well-differentiated HCC region in liver cirrhosis specimen). T-cadherin expression was restricted in the artery or large vessels in Glisson's sheath. T-cadherin expression was observed in intratumoral capillary endothelial cells in moderately to poorly differentiated HCC (d and e). Preadsorption with T-cadherin peptide eliminated staining of endothelium (f). Note that HCC cells were not stained with anti-T-cadherin antibody (c-e). Original magnifications were $\times 100$ (a and c), $\times 200$ (b, d, and f), and $\times 640$ (e)

tories, were also used as control antibodies. Notably, a previous study demonstrated that this murine monoclonal antibody does not react with human tissues, including liver tissues [32]. Antibodies were added to the lower dishes at a final concentration of 10 µg/ml. After culturing for 2 days, liver sinusoidal endothelial cells were harvested. T-cadherin expression was examined by Western immunoblotting as previously described [27]. To exclude the effect of additive in the CS-C medium, the cells were also cultured with Dulbecco's modified Eagle's media (DMEM) and 10% FBS in several experiments.

Several previous studies demonstrated that cultured HCC cells, including Hep-G2-cell-expressed FGF-2 [1]. We also confirmed that cultured Hep G2 cells in our laboratory also secreted FGF-2 by using enzyme-linked immunosorbent assay (ELISA). Briefly, Hep G2 cells were plated in 96-well culture dish plates and allowed to grow at full sheet in DMEM and 10% FBS. After 24 h, the culture medium was changed to DMEM without FBS and further incubated for 2 days. Finally, FGF-2 in culture supernatants were quantified using a standard sandwich ELISA kit (Quantikine FGF basic, R&D Systems Inc, Minneapolis, MN) following the manufacturer's instructions.

Results

T-cadherin was expressed in tumor endothelial cells of HCC

The results of immunohistochemical staining of human HCC are summarized in Table 1, and representative cases are demonstrated in Fig. 1. T-cadherin expression was restricted in the arterial endothelium and not observed in

hepatocytes or in the sinusoidal endothelium of nontumorous liver tissues (Fig. 1a). Neither hepatocytes nor sinusoidal endothelial cells of liver cirrhosis were stained with anti-T-cadherin antibody (Fig. 1b). In contrast, staining with anti-T-cadherin antibody was observed in tumor sinusoidal endothelium of 34 out of 63 specimens, where a specimen is considered T-cadherin-positive when more than 10% of tumor vessels are stained. Notably, T-cadherin expression was not uniform but instead was observed focally (less than 30%) in three positive well-differentiated HCC cases. By contrast, T-cadherin was diffusely (more than 80%) expressed in most moderately positive to poorly differentiated HCC specimens. Preadsorption of antibody with T-cadherin peptide eliminated all staining (Fig. 1f) and verified the specificity of the antibody used in the present study.

Next, we asked whether T-cadherin expression was related to pathological factors of HCC. T-cadherin staining was related to differentiation of HCC. Three of 12 (25%), 15 of 29 (52%), and 16 of 22 (73%) HCC specimens diagnosed as well, moderately, and poorly differentiated types, respectively, were positive for T-cadherin staining (Fig. 1c–e). Significant differences were observed between well- and poorly differentiated HCC ($p=0.007$). However, all other pathological parameters, including the status of nonneoplastic liver tissues adjacent to HCC (cirrhosis or hepatitis) examined, were not significantly related to T-cadherin expression (Table 1).

We further examined five tissue specimens, which contained variously differentiated HCC components. Interestingly, T-cadherin expression was again much found in a less-differentiated region in individual specimens (Fig. 2).

A previous study clearly demonstrated that liver sinusoidal endothelial cells also expressed LYVE-1, whereas

Fig. 2 Representative immunohistochemical staining of HCC tissues, which contained various differentiated cancer foci, with anti-T-cadherin antibody. In this tissue specimen, moderately differentiated HCC, in which pseudoglandular proliferation was observed, was found in the center of a well-differentiated HCC region (a). Note that sinusoidal endothelial cells in noncancerous liver cirrhosis were not stained with anti-T-cadherin antibody (b). In contrast, immunoreactivity was focally found in well-differentiated HCC (c), whereas almost all intratumoral capillary endothelial cells were strongly stained in a moderately differentiated region (d). Original magnifications were $\times 4$ (a), $\times 100$ (d), $\times 200$ (b), and $\times 400$ (c)

Fig. 3 T-cadherin, CD34, and LYVE-1 expression in HCC (a–c) and chronic hepatitis (d–e). In this HCC tissue specimen, both T-cadherin (a) and CD34 (b) immunoreactivity was observed in intratumoral capillary endothelial cells. By contrast, any significant LYVE-1 immunoreactivity was not found in HCC specimen (c). Neither T-cadherin (d) nor CD34 expression was found in chronic hepatitis specimens, whereas LYVE-1 was barely expressed in sinusoidal endothelial cells in chronic hepatitis (f). Original magnifications were $\times 200$

intratumoral capillary endothelial cells expressed little LYVE-1 [20]. In the present study, we examined the correlation of LYVE-1 and T-cadherin expression. As previously reported by Mouta Carreira et al. [20], LYVE-1 was barely expressed in intratumoral endothelial cells in HCC. Any significant overlap expression of T-cadherin and LYVE-1 was not observed in intratumoral capillary endothelial cells in HCC specimens. The median tumor microvascular density of T-cadherin-positive HCC was 56.6, whereas the median tumor microvascular density of T-cadherin-negative HCC was 59.4. Thus, any significant correlation between T-cadherin expression and the microvascular density was observed in the present study. Representative results were demonstrated in Fig. 3.

These findings indicate that T-cadherin molecules were selectively expressed in a tumor surrounding sinusoidal

endothelial cells of HCC, especially in poorly differentiated HCC. Since less differentiated HCC may be developed from a well-differentiated HCC region in an individual patient, T-cadherin expression may be increasingly induced in sinusoidal endothelial cells as the tumor progressed.

mRNA expression in tumor endothelial cells

Our ongoing experiments demonstrated that soluble T-cadherin molecules were present in serum using the sensitive sandwich ELISA assay (unpublished data). Consequently, we examined the possibility that soluble T-cadherin molecules adhered to tumor endothelium using *in situ* hybridization. Positive signals were observed in tumor sinusoidal

Fig. 4 *In situ* hybridization of human HCC (a and c) and liver cirrhosis specimens from the same patient (b). Tumor sinusoid endothelium demonstrated positive signals with the anti-sense T-cadherin probe (a). However, positive signals were not observed in liver cirrhosis specimens except in arterial endothelium (indicated by *) in Glisson's sheath (b). No significant signals were detected with sense probe in HCC specimens (c). Original magnification was $\times 400$ (a–c)

endothelium of HCC specimens with the antisense cRNA probe of T-cadherin (Fig. 4a). Artery endothelial cells, but not sinusoidal endothelium from liver cirrhosis, were stained with the antisense probe (Fig. 4b). No significant reactivity was observed with the control sense cRNA probe (Fig. 4c). These results indicate that tumor endothelial cells express T-cadherin mRNA, and consequently, we excluded the possibility that partially degraded or soluble T-cadherin were adsorbed at the cell surface of tumor endothelial cells. Notably, we did not detect T-cadherin mRNA in nonneoplastic hepatocytes or HCC cells.

Double-chamber cell culture

As described in the "Introduction," VEGF and FGF-2 regulate the endothelial cell growth in HCC by a paracrine manner. We speculated that T-cadherin was also an important molecule, which played a role in the VEGF- or FGF-2-mediated cross talk between neoplastic hepatocytes and sinusoidal endothelial cells. Therefore, we decided to investigate the induction of T-cadherin on sinusoidal endothelial cells by using a double-chamber cell culture.

Cultured nontumorous liver sinusoidal endothelial cells did not express T-cadherin (Fig. 5a). In contrast, sinusoidal endothelial cells in lower compartments of the double-chamber cell culture, in which the upper chamber contained Hep G2 HCC cells, expressed T-cadherin, as shown in Fig. 5b. Therefore, we conclude that humoral factors secreted from Hep G2 HCC cells induced expression of T-cadherin molecules in liver sinusoidal endothelial cells.

Fig. 5 Western immunoblotting of cultured liver sinusoidal endothelial cells. Double-chamber culture was performed as illustrated in the right column with or without Hep G2 cells. No significant band was detected in cultured human liver sinusoidal cells alone by Western immunoblotting by using anti-T-cadherin antibody (a). In contrast, an approximately 100-kDa band was observed in liver sinusoidal cells when they were double-chamber-cultured with Hep G2 human HCC cells (b). An identical 100-kDa band was also observed in sinusoidal endothelial cells in double-chamber culture with neutralizing antibody to VEGF and FGF-1 (c and d, respectively). However, neutralizing antibody to FGF-2 markedly reduced T-cadherin expression in sinusoidal endothelial cells in double-chamber culture (e) even in the presence of Hep G2 in the upper chamber

Neither neutralizing anti-FGF-1 nor VEGF were able to inhibit induction of T-cadherin in sinusoidal endothelial cells (Fig. 5c and d, respectively). In contrast, neutralizing anti-FGF-2 inhibited T-cadherin expression in double-chamber cell cultures, as shown in Fig. 5e. ELISA assay clearly demonstrated that cultured Hep G2 secreted FGF-2. Neither control goat IgG nor murine monoclonal antibody inhibited T-cadherin expression in double-chamber cell cultures. Although we could not exclude the possibility that other humoral factors were also involved in T-cadherin expression, it is likely that FGF-2 plays a critical role in the induction of T-cadherin molecules in sinusoidal endothelial cells.

In addition, there are two major forms of T-cadherin, a mature 100-kDa molecule and a premature partially processed 130-kDa molecule. The present data indicate that mature T-cadherin molecules were induced in cultured sinusoidal endothelial cells in the double-chamber assay and validated again the specificity of the antibody used in this study.

The consistent result was obtained by using DMEM supplemented with 10% FBS instead of CS-C medium.

Discussion

T-cadherin is believed to be a tumor suppressor gene, the promoter region of which is often hypermethylated in a wide variety of malignant tumors (see 35 for a review). T-cadherin is silenced in the tumor cells of the breast, lung, urinary bladder, colon, skin, chronic myeloid leukemia, and pancreas [14, 17, 28, 29, 31, 36, 37, 40, 41]. In contrast, Riou et al. [27] demonstrated that the mRNA expression of the CDH13 gene is higher in HCC than in normal or nontumorous liver tissues using real-time quantitative PCR. Is T-cadherin overexpressed in HCC cells? The answer to this question is currently unknown since, to our knowledge, there is no research available that demonstrates the precise T-cadherin distribution in noncancerous liver and HCC tissues.

The immunohistochemical staining presented here demonstrates that T-cadherin was not expressed in nonneoplastic hepatocytes or HCC cells but selectively expressed in intratumoral capillary endothelial cells. It is likely that highly sensitive PCR can detect T-cadherin mRNA expression in the tumor endothelium of HCC tissues. However, this would not mean that T-cadherin is overexpressed in HCC cells. We suggest that T-cadherin overexpression in tumor endothelium should be considered when examining whether T-cadherin was silenced in malignant tumors. Silencing of T-cadherin expression may be overwhelmed in the presence of T-cadherin expressed in the tumor endothelium. To elucidate these problems, immunohistochemical or in situ hybridization should be performed in parallel.

The present findings indicated that T-cadherin might be increasingly expressed in tumor surrounding sinusoidal endothelial cells as HCC progressed. Therefore, it is likely that T-cadherin may positively mediate tumor angiogenesis in HCC. Recently, T-cadherin appeared to be a receptor for

hexameric and HMW forms of adiponectin [10]. Adiponectin is a kind of adipocytokine, and it is found in the serum in trimer, hexamer, and HMW forms. Regarding the effect of adiponectin on neovascularization, several discordant results have been reported (see 8 for a review). Hexameric and HMW forms of adiponectin activate NF- κ B activity [39] and inhibit apoptosis of endothelial cells [13]. Full-length adiponectin stimulates the differentiation of human-umbilical-vein endothelial cells into a capillary-like structure [25]. Adiponectin can also stimulate new blood vessel growth by promoting cross talk between adenosine monophosphate (AMP)-activated protein kinase and Akt signaling [25]. In contrast, recombinant adiponectin induces apoptosis in endothelial cells and inhibits tumor neovascularization [2]. T-cadherin bound hexameric and HMW adiponectin, but it did not bind to trimetric or bacterial-recombinant adiponectin [10]. Combined together, we speculate that T-cadherin molecules on tumor endothelial cells may bind hexamer and/or HMW adiponectin, activate NF- κ B, and prevent apoptosis of tumor endothelial cells during reorganization and angiogenesis of tumor vessels. However, we cannot discriminate the possibility that T-cadherin in intratumoral capillary endothelial cells play a role in tumor angiogenesis by an unknown mechanism, which is apart from the role of an adiponectin receptor. However, it may be unlikely that T-cadherin in intratumoral endothelial cells directly interacted with other cadherin molecules since each cadherin molecule has a homophilic binding activity. In fact, a previous study demonstrated that no systematic difference in VE-cadherin, another endothelial cell cadherin molecule [38], was found between HCC and nontumorous liver tissues [4].

The present study indicated that FGF-2 might play an important role in the induction of T-cadherin in liver sinusoidal endothelial cells. Several studies have reported that FGF-2 secreted from HCC cells plays an important role in angiogenesis of HCC [16, 18, 23]. Motoo et al. immunohistochemically examined HCC and found that capillarized sinusoids were significantly more numerous in FGF-positive cases than in FGF-negative cases [19]. Notably, plasma levels of FGF-2 were elevated to a greater extent in HCC patients compared to patients with chronic hepatitis and liver cirrhosis [12]. Combined with these previous studies, we suggest that FGF-2 secreted from HCC cells may facilitate T-cadherin (a unique adiponectin receptor) expression in the tumor endothelium by a paracrine manner and attribute the tumor neovascularization to activate the adiponectin-dependent pathway. Notably, Ivanov et al. recently reported that exogenously over-expressed T-cadherin stimulated the proliferation of human umbilical endothelial cells [11].

In conclusion, the current study presents three key results. First, T-cadherin expression was restricted to the arterial endothelium in noncancerous liver tissues and was not expressed in hepatocytes or HCC cells. Second, T-cadherin was selectively expressed in intratumoral capillary endothelial cells in many HCC specimens and may be

increasingly expressed as the tumor progressed. Last, FGF-2 appeared to play a critical role to induce T-cadherin on sinusoidal endothelial cells; thus, a cross talk between adiponectin-T-cadherin and FGF-2 pathways is suggested.

Immunohistochemical expression of p63, p53 and MIB-1 in urinary bladder carcinoma. A tissue microarray study of 158 cases

Received: 9 December 2004 / Accepted: 6 February 2005 / Published online: 8 November 2005
  Springer-Verlag 2005

Abstract P63 is a member of the p53 family, which plays a role in the differentiation of urothelium and is supposed to play a role in urothelial carcinogenesis. P53 and MIB-1 are recognised in many studies as predictive markers of progression, but few studies in the literature have examined p63. The aims of our study were to explore the expression of p63 in bladder carcinomas and to compare this expression to p53 and MIB-1, as well as to stage and grade. Tissue microarrays were performed on 158 urothelial carcinomas (56 pTa, 45 pT1 and 57≥pT2). Immunohistochemical studies were performed with p63, p53 and MIB-1 antibodies. In our study we observed that p63 immunostaining is present in all cell layers in papillary urothelial neoplasm of low malignant potential (PUNLMP), but partially lost in non-invasive papillary urothelial carcinoma low grade (NILGC) and in pT1/≥pT2 bladder cancers. P53 and MIB-1 displayed lower expression in PUNLMP/NILGC vs non-invasive papillary urothelial carcinoma high grade (NIHGC)/pT1, but there was no correlation between the expression of p63, p53 and MIB-1. Our study

demonstrates that p63 expression distinguishes between PUNLMP/NILGC and NIHGC/pT1 ($p=4.10^5$). A statistical difference disserving pTa and pT1/≥pT2 with a statistical significance ($p<10^{-6}$) could also be observed. P63 should be considered as an additional biomarker that might help pathologists to classify their patients.

Introduction

Urothelial carcinomas (UC) are divided into three groups: pTa, pT1 and ≥pT2 disease, regarding the local extension. pTa bladder cancers have a variable recurrence rate and progression [13, 16, 20, 40]. In papillary urothelial neoplasm of low malignant potential (PUNLMP) or non-invasive papillary urothelial carcinoma low grade (NILGC), recurrence varies from 25 to 70%, and few progress towards higher grade or invasive tumors. On the other hand, 15 to 20% of pTa non-invasive papillary urothelial carcinoma high grade (NIHGC) and up to 30% of pT1 tumors develop towards pT2, with muscular invasion and poor clinical outcome [16, 33]. To date, although many investigations have been made, no immunohistochemical marker has proved to be specific to predict clinical outcome in patients with NIHGC or pT1 urothelial carcinomas [32].

p63 is a member of the p53 family located on chromosome 3q27–28. Several studies have shown that p63 seems to play a key role in differentiation of transitional epithelium [44, 48]. Two main isoforms (TAp63 and ΔNp63) with different functions are known. It seems that TAp63 isoform is required for initiation of epithelial stratification and maintains a proliferative potential of basal cell, while ΔNp63 allows cells to respond to signals required for maturation.

In normal bladder, TAp63 has been shown to be expressed in basal cells, whereas ΔNp63 is absent or weakly expressed in these cells [3, 28]. In bladder carcinomas, elevated expression of ΔNp63 and decreased expression of

TAp63 has been observed [28]. These results suggest that Δ Np63 might contribute to progression of bladder carcinomas. Some authors have proposed that p63 could therefore be a prognostic marker. But results of variation in p63 expression and its role in bladder cancer development still remains controversial [17, 19, 28, 44].

As a member of the p53 family, p63 shows strong structural similarities with p53 [8], and biochemical interactions of these two proteins exist [21, 24]. *p53* gene is a well-known tumor suppressor gene that play a key role in cellular damage response and cell-cycle arrest [22]. Loss of p53 function is a frequent finding in all kind of cancers where mutant inactive forms may easily be detectable.

Proliferation index Ki-67 (MIB-1), a marker for cellular proliferation, is a nuclear protein complex expressed in the G1, S, G2 and M phases of the cell cycle of proliferating cells.

Immunohistochemical investigations with p53 and MIB-1 have shown to be predictive markers in the progression of bladder cancer [34, 37, 47]. p53 over-expression has shown to be associated with grade and stage [12, 39] and correlated with recurrence in pTa and T1 cancers as well as tumor progression [12, 22, 37], but its association with overall survival and clinical outcome is still controversial [12, 22]. Studies concerning MIB-1 have underlined the predicting potential of MIB-1 concerning recurrence rates especially in PUNLMP [35, 44]. Increased and diffuse-labelling index of MIB-1 is observed in non-invasive high-grade and invasive high-grade carcinomas [10, 11]. Taken together, p53 and MIB-1 seem to be powerful predictors of tumor recurrence for patients especially with non-muscle invasive transitional cell carcinoma [34].

Using tissue micro arrays (TMA) for immunohistochemical studies has been proven to be a very useful tool in exploration of large series of different tumors of tissues [14, 27, 30].

The aim of our study was to see whether (1) p63 expression varied according to grade and stage of bladder cancer, (2) there was a correlation between p63, p53 and MIB-1 expressions and (3) at least whether there existed a difference in the expression of p63 between the groups PUNLMP/NILGC vs NIHGC/pT1 and \geq pT2.

Materials and methods

This retrospective study concerned 158 patients who underwent either transurethral resection of non-invasive bladder tumors by transurethral resection or cystectomy for invasive bladder cancer between 2001 and 2004 in our establishments. We excluded from our study papillomas and carcinoma in situ as well as reactive atypia and dysplasia, because it is difficult to interpret these lesions with the TMA technique.

All tumor specimen and TMAs with immunohistochemical staining were evaluated by two experimental independent pathologists (E.C. and P.C.). The nuclear grading and the pT stage were adjusted according to the World Health Organization guidelines 2004 [45] into the following

Fig. 1 Nuclear staining of p63 basal cell layers

groups: pTa, (distinguishing PUNLMP, NILGC, NIHGC), pT1 and \geq pT2. The group \geq pT2 concerned pT2 to pT4 bladder cancers. Metastatic progression was not distinguished. The control group composed of 12 cases of non-tumoral bladder specimen from spinal cord-injuries patients were explored.

Different TMAs have been constructed for each pTa, pT1 and \geq pT2. At least three cylindrical score biopsies of 0.6 cm in diameter have been taken from each tumor. Different sites of each tumor were chosen and arrayed in a paraffin tissue bloc. Only scores with at least 200 malignant cells were scored. TMA sections (4 μ m) were de-paraffinized and rehydrated, and immunohistochemistry was performed using the modified streptavidin–biotin–peroxidase method and diaminobenzidine as chromogen; an antigenic retrieval was used if necessary. The panel of antibodies included p63 (monoclonal, clone 4A4; Dako, 1/100), p53 (monoclonal, clone DO-7; Dako, ready to use) and MIB-1 (monoclonal; Dako, 1/50). Positive and negative controls were performed for each antibody. The evaluation of immunoreactivity was procured as follows: 200 cells were counted for each cylindrical score. p63 staining was considered positive if nuclear percentage

Fig. 2 Strong staining of all cell layers in pTa tumor (\times 100)

Table 1 Percentage of p63 in different stages

p63 (%)	pTa, n=56 (%)	pT1, n=45 (%)	pT2, n=57 (%)
0 (<10)	0/56 (0)	6/45 (13)	13/57 (23)
1 (10–80)	4/56 (7)	15/45 (34)	26/57 (46)
2 (>80)	52/56 (93)	24/45 (53)	18/57 (31)
Total	56 (100.0)	45 (100.0)	57 (100.0)

between 0 (stained cells <10%), 1 (>10% stained cells <80%) and 2 (stained cells >80–100%) was assessed. Regarding p53, tumors with nuclear immunoreactivity of more than 10% were considered positive according to other previous studies [26, 27, 47].

For MIB-1, we evaluated the percentage of nuclear staining. MIB-1 staining of more than 10% was considered as positive.

Chi-square test was performed to compare categorical variables with the status of p63, p53 and MIB-1 expression.

Results

The population concerned 41 females and 117 males, mean age 68.5 years (extremes 38–94).

Stage pTa was present in 56 cases (36%) with 22/56 (39%) PUNLMP, 26/56 (47%) NILGC and 8/56 (14%) NIHG. Forty-five cases (28%) were pT1, and 57 (36%) cases were \geq pT2.

p63

p63 expression in control bladder specimen displayed staining only on the basal layer; staining was always nuclear (Fig. 1). No staining was seen on smooth muscle cells, adipocytes or neural cells. Nuclear staining of lymphoid cells was rarely observed. The superficial layer constituted of umbrella cells never showed any immunoexpression.

In the pTa group, expression of p63 was always nuclear; cytoplasmic staining was rare and not considered. In 52/56

Table 2 Percentage of p63 in different grades

p63 (%)	PUNLMP, n=22 (%)	NILGC, n=26 (%)	NIHG, n=8 (%)
<10	0 (0)	0 (0)	0 (0)
10–80	0 (0)	3 (12)	1 (12)
>80	22 (100)	23 (88)	7 (88)
Total	22 (100)	26 (100)	8 (100)

(93%) pTa cases, expression of p63 was homogenous, and intensity was considered as 2. Three NILGC and one NIHG displayed a weaker heterogeneous expression; the percentage of stained cells in these cases was between 10 and 70% (score 1) (Fig. 2). In pT1 urinary bladder cancers, p63 staining was more heterogeneous. Six/fifty-five cases (13%) lost p63 expression, 15/45 (34%) displayed weak staining (score 1) and 24/45 (53%) showed strong homogenous staining (score 2). These results are summarized in Table 1. Usually, loss of expression could be observed predominantly in the upper layers of transitional epithelium and could concern up to six layers, although punctual expression of p63 could be seen. In \geq pT2 cases, no immunostaining was observed in 13/57 (23%) cases, weak staining was seen in 26/57 (46%), and strong staining could be observed in 18/57 (31%) (Fig. 3).

Statistical significant difference was found between PUNLMP/NILGC and NIHG/pT1 groups ($p=4.10^{-5}$). Between pTa, pT1 and \geq pT2, statistical significant difference was also observed. p63 expression in pTa showed more often score 2 than pT1 and pT2 cases together ($p<10^{-6}$), while p63 expression was more often score 1 in pT2 group vs pTa and pT1 ($p=2.10^{-5}$). According to the grade, no significant difference could be observed ($p=1$). Table 2 summarizes p63 expression in different grades of pTa.

p53

No p53 immunoreactivity was found in normal samples. Concerning the pTa group, p53 displayed nuclear expression in 7/22 PUNLMP (32%), in 10/26 NILGC (38%) and in 6/8 NIHG (75%); expression was observed in 20–80% tumor cells. pT1 specimen showed expression in 37/45 (84%) cases and \geq pT2 specimen in 41/57 cases (72%).

Statistical significant difference was seen between pTa, pT1 and \geq pT2 ($p=2.10^{-5}$), with a stronger expression in the pT1 and pT2 groups.

Table 3 p53 and MIB-1 immunostaining

Positive antibody expression, (+/n)	PUNLMP/NIHG, n=48 (%)	NIHG, n=8 (%)	pT1, n=45 (%)	\geq pT2, n=57 (%)
P53	17/48 (35)	6/8 (75)	37/45 (84)	41/57 (72)
MIB-1	2/48 (4)	2/8 (25)	32/45 (71)	45/57 (79)

**Fig. 3** Loss of p63 expression in \geq pT2 tumor ($\times 100$)

Table 4 Comparison between p63 and p53 in global population

	p63<80%	p63>80%	Total (%)
p53<10%	16	40	56 (35)
P53>10%	48	54	102 (65)
Total (%)	64 (40)	94 (60)	158 (100)

No statistical significant difference could be observed between PUNLMP to NILGC/NIHGC ($p=0, 25$). Comparison between PUNLMP/NILGC vs NIHGC/pT1 showed statistical significant difference with 17/48 (35%) cases positive in the first group and 43/53 (83%) cases positive in the second group ($p=10^{-6}$).

MIB-1

No immunoreactivity was found in normal samples for MIB-1.

In bladder tumors, 75/157 (47%) displayed MIB-1 immunoreactivity. In the pTa group, 1/22 (2%) PUNLMP, 1/26 (3%) NILGC and 2/8 NIHGC (25%) displayed increased immunoreactivity with nuclear staining between 10 and 20%. In the pT1 group, two cases (3%) could not be evaluated, because of loss of transitional epithelium in TMA. Eleven/forty-five cases (24%) did not show any MIB-1 expression, and 32/45 (71%) displayed expression in more than 10% of tumor cells. In the \geq pT2 group of bladder cancers, MIB-1 was not expressed in 12/57 (21%) of the cases. Forty-five/fifty-seven (79%) cases showed staining between 10 and 100%.

By comparing pTa, pT1 and \geq pT2, statistical significance could be observed ($p<10^{-4}$) with a stronger expression in pT1 and \leq pT2 groups.

No statistical significant difference could be observed between PUNLMP to NILGC/NIHGC ($p=0, 44$). A statistical significant difference could be observed between PUNLMP/NILGC vs NIHGC/pT1, with a stronger expression in the second group ($p=10^{-8}$).

Table 3 summarizes the distribution of p53/MIB-1 immunostaining in pTa, pT1 and \geq pT2 bladder tumors.

By comparing in pTa, pT1 and \geq pT2 groups, no relation between p63, p53 and Mib-1 expressions could be found (Table 4).

Discussion

At presentation, 70–80% of bladder tumors are non-muscle invasive papillary tumors pTa or pT1. Recurrences are frequent, often during many years. Progression to muscle invasion occurs in about 15–20% of cases [12], taken all different groups of pTa (PUNLMP, NILGC, NIHGC). Especially, NIHGC has a high rate of progression that varies between 23 and 65% in different studies [20, 40]. pT1 tumors progress in up to 30% of cases [16]. Papillary non-invasive and invasive bladder tumors are believed to

have different natural histories, and the proposed pathways concerning papillary tumors is hyperplasia, which develops to urothelial atypia and at least to papillary tumors [16, 33]. The pathway for muscle invasive tumors is proposed as follows by atypia, dysplasia, carcinoma in situ and invasive disease [33]. The debate about choice of treatment, especially for pT1 tumors, is very difficult, as it is not completely clear whether all these tumors display a real aggressive behaviour. It would be important to find reliable markers to predict clinical outcome of urothelial tumors especially in pTa and pT1 groups [16].

p63 is a member of the p53 family, which seems to react by a pathway distinct from p53 [25, 28]. p63 is a protein that is expressed by epithelial cells of stratified epithelia, such as skin oesophagus and exocervix as well as in basal cell layers of different tissues such as breast, prostate and lung [3, 38, 48]. Over-expression of p63 has been observed in squamous cell carcinomas [4, 6, 23]. Recently, Wu et al. [46] reported that p63 can regulate a wide range of downstream gene targets with various cellular functions, including cell cycle control, stress and signal transduction. Some authors reported the potential role on phosphoinositide-3-kinase (PI3K) pathway under the control of epithelial growth factor receptor (EGFR) [1, 2], beta-catenin, uroplakin III [17, 18] and vascular endothelial growth factor (VEGF) [36].

It has been shown that p63 plays a role in urothelial differentiation [44], but seems also to play a role in bladder carcinogenesis. Park et al. [28] have shown an under-expression of one of the major isotypes TAp63, which contains a transactivation domain, while Δ Np63, which lacks the transactivation domain, seems to be over-expressed.

In this study, we have shown that a majority of transitional cell carcinoma [139/158 (88%)] cases express p63 in all cell layers. These results [15, 19, 28, 44, 49] are corresponding to those observed in squamous cell carcinomas of the oesophagus [4, 7] and lung [23].

Moreover, our study confirms a decrease in p63 expression during bladder cancer development from pTa, especially from low-grade to high-grade neoplasms, via pT1 to \geq pT2 ($p=2.10^{-5}$). These results confirm previous observations made in oesophageal squamous cell carcinomas [4] and transitional cell carcinomas [44, 49], but differ from those of Park et al. [28] who failed to determine statistical difference in Δ Np63 expression between pTa, pT1 or \geq pT2.

Our study demonstrates clearly for the first time that p63 expression distinguishes between PUNLMP/NILGC and NIHGC/pT1 ($p=4.10^{-5}$). The loss of p63 expression in NIHGC might be useful to help to differentiate them from NILGC as an additional factor, if morphological criterions are not sufficient. We also observed a statistical difference between pTa and pT1/ \geq pT2 with a statistical significance ($p<10^{-6}$). However, the NIHGC group did not include enough cases to conclude.

Meanwhile, we failed to determine any statistical correlation between survival and p63 expression. Longer follow up may be necessary to assess these results.

On the other hand, we explored the p53 activity in our different samples. As p53 seems to regulate Δ Np63 promoter activity [8, 41] and inversely Δ Np63 inhibits p53 transcription activation [4, 8, 21, 24], we studied the relationship between p53 and p63 expression in bladder cancer.

p53 is over-expressed in numerous malignancies. In transitional carcinomas, p53 expression seems to be able to identify patients with high risk for recurrence in pTa or pT1 tumors [37, 45]. Several studies have documented a sensitive reduction of progression-free interval for p53-positive tumors, with a significant relation of tumor progression [5, 35, 43]. Recent studies concerning tumors of the upper urinary tract [49] and bladder [22, 34] showed that increased p53 expression is significantly associated with advanced tumor stages and poor prognosis. Our results confirm these findings. We have shown p53 expression in PUNLMP and NILGC in 31 and 38%, respectively. In the opposite, NIHGC and pT1 display p53 expression in already 75 and 84% of cases, respectively ($p=10^{-6}$).

Meanwhile, no correlation could be found between p63 and p53 expression in bladder cancer (Table 4), suggesting that p63 and p53 play a role in carcinogenesis by different pathways. These results confirm previous studies concerning bladder carcinoma [44], oesophagus carcinomas [7, 42], lung carcinomas [29], while controversial in breast carcinomas [8, 33].

Proliferation marker MIB-1 has been studied by several trials. Santos et al. [35] have shown that MIB-1-positive tumors have a worse course of disease. Yan et al. [47] observed that MIB-1 could be used to identify patients with high risk for recurrence. Helpap and Köllermann [10] have shown that pattern and intensity of staining for MIB-1 and 34 β E12 might help to distinguish grades. Disturbance of urothelium's stratification and diffuse-labelling pattern by CK34 β E14 and MIB-1 seem to predict higher recurrence rates [11].

The loss of p63 expression in NIHGC might be used to help to differentiate them from NILGC. Our study shows that there exists a relationship between MIB-1 expression and stage. The expression of MIB-1 between the different stages pTa, pT1 and \geq pT2 showed significant differences. pT1 disease displayed MIB-1 expression in 71% of cases and in 79% of \geq pT2 patients, while only 8% of pTa showed increased MIB-1 expression ($p<0,0001$). No correlation could be observed between p63, p53 and MIB-1 staining.

Conclusion

Our study compares p63 expression in pTa (PUNLMP, NILGC, NIHGC), pT1 and \geq pT2. We clearly show for the first time that p63 immunostaining is present in all cell layers in PUNLMP and NILGC, but already partially lost in NIHGC and pT1 bladder cancers. Further studies have to investigate the role of p63 in bladder carcinogenesis and its prognostic value especially by focussing on NIHGC.

Alpha-methylacyl-CoA racemase (AMACR/P504S) protein expression in urothelial carcinoma of the upper urinary tract correlates with tumour progression

Received: 19 September 2005 / Accepted: 27 October 2005 / Published online: 29 November 2005
© Springer-Verlag 2005

Abstract Alpha-methylacyl-CoA racemase (AMACR/P504S) is a useful biomarker of prostate cancer. We evaluated the expression of AMACR in upper urinary tract urothelial carcinomas with respect to associations with tumour stage, grade and metastasis-free survival. A total of 268 tumours were investigated immunohistochemically using a tissue microarray technique. AMACR expression was noted in 127 of 261 (48.7%) evaluated tumours and was associated with high tumour stage [58 of 139 (41.7%) pTa/pT1 vs. 69 of 122 (56.6%) pT2–pT4, $P=0.019$] and high tumour grade [44 of 137 (32.1%) low vs. 83 of 124 (66.9%) high grade, $P<0.001$]. In addition, AMACR expression was associated with the presence of tumour necrosis ($P<0.001$) and marked stromal desmoplasia ($P=0.0026$). This correlation indicates that increased AMACR expression might be related to hypoxia-induced changes in cancer cell metabolism, such as increased dependence on fatty acid oxidation for energy generation. Progressive disease was observed in 73 of 183 (39.9%) patients with solitary invasive carcinomas and was associated with AMACR expression ($P=0.017$). Multivariate analysis, however, proved only pT-stage >1 ($P<0.001$) and high tumour grade ($P<0.001$) to be independent predictors of patient outcome. In conclusion,

AMACR expression correlated with advanced tumour stage and grade and may serve as an additional prognostic indicator in upper urinary tract urothelial cancer.

Keywords Urothelial carcinoma · Transitional cell carcinoma · Upper urinary tract · Alpha-methylacyl-CoA racemase (AMACR) · Prognosis

Introduction

Upper urinary tract urothelial carcinoma (UC) accounts for approximately 5% of all urothelial and for 10% of all renal cancers [1]. TNM-stage and tumour grade are well-known prognostic factors [2]. Assessment of tumour grade, however, may show considerable variation due to inter-observer variability [3, 4]. Therefore, the discovery of new prognostic markers represents an important step for the evaluation of affected patients, not only to predict disease evolution and thus aiding surveillance strategies, but also to identify subgroups that might benefit from adjuvant cancer therapy.

Alpha-methylacyl-CoA racemase (AMACR), formerly known as P504S, is a mitochondrial and peroxisomal enzyme involved in the beta-oxidation of branched fatty acids and bile acid intermediates [5]. Specifically, AMACR catalyses the conversion of (2*R*) alpha-methyl branched chain fatty acyl-CoAs to their (*S*) stereoisomers. Only stereoisomers with the 2-methyl group in the (*S*) position can be metabolised by peroxisomal oxidases, the first enzymes in the beta-oxidation pathway [6, 7]. Immunohistochemically, moderate to strongly positive staining with AMACR has been demonstrated in a wide variety of normal human tissues, including hepatocytes, the epithelium of proximal renal tubules and glomeruli, as well as acinar and ductal cells of major salivary glands. Moreover, strong immunohistochemical staining for AMACR has been demonstrated in most carcinomas arising from these organs [8] and, additionally, in some neoplasms originating from tissue normally lacking AMACR expression, such as prostate [9] and colorectal cancer [10, 11].

With respect to prostate cancer, several groups have shown that AMACR represents a new important biomarker, as it is upregulated in the vast majority of cancer and prostatic intraepithelial neoplasia lesions, which is in sharp contrast to the near-complete lack of expression in both normal and hyperplastic prostate glands [9, 12–15]. Thus, immunohistochemical AMACR staining, alone or in combination with negative staining for a basal cell marker, such as 34betaE12 or p63, has recently been proven useful in the assessment of difficult prostate needle biopsies [16–18].

Recently, AMACR expression has been detected in a subset of UCs [8, 19–21]. However, data systematically correlating AMACR expression with tumour stage and grade as well as patient outcome are currently lacking. Therefore, we evaluated the expression of AMACR in upper urinary tract UCs with special emphasis on associations with tumour stage and grade as well as prognostic significance.

Materials and methods

Case selection

A total of 268 consecutive upper urinary tract UCs (169 pelvic and 99 ureteral tumours) from 239 consecutive patients (108 females, 131 males; ratio 1:1.2) operated between 01/1984 and 12/2004 were retrieved from the archives of our institute. Mean and median age of patients was 69.8 and 70.8 (range 39–89) years, respectively. pT-stages were adjusted according to the UICC 2002 issue of the TNM-system [22]. Grading was performed according to the recently published two-tiered WHO grading system, corresponding to the WHO/ISUP consensus classification [23]. For the correlation of pathological findings with metastasis-free survival, all non-invasive cancers (41 tumours) and all tumours from patients with multiple invasive cancers (37 tumours) were excluded resulting in a group of 190 UCs (134 pelvic and 56 ureteral tumours) from 190 patients (77 females, 113 males; ratio 1:1.5). The patients either underwent nephroureterectomy with bladder-cuff resection ($n=130$), nephrectomy alone ($n=40$), or distal ureteral resection with reimplant ($n=20$) and did not receive adjuvant therapy. Follow-up regimen included abdominal ultrasound and cystoscopy at 3-month intervals for the first 3 years, at 6-month intervals for the subsequent two years and yearly thereafter as well as chest X-ray and computerised tomography at 6-month intervals for the first 3 years and yearly thereafter. Two cases of non-neoplastic pelvic urothelium, two cases of urothelial dysplasia (intraurothelial neoplasia) and two cases of urothelial carcinoma in situ were investigated for comparison. All procedures were in accordance with the ethical standards established by our institution. Informed consent is not required for retrospective analyses dealing with archive material obtained during routine medical treatment.

Immunohistochemistry

For immunohistochemical evaluation, a tissue microarray technique was used. The details of this technique have been described previously [24]. Briefly, tissue microarrays (TMAs) were constructed using a manual tissue arraying instrument (Beecher, Silver Spring, MD). At least three cylindrical core biopsies, 0.6 mm in diameter, were taken from different sites of each tumour and arrayed in a recipient paraffin TMA block. Four micrometer TMA sections were deparaffinised by xylene, rehydrated in graded alcohols, treated for 5 min with 1% H₂O₂, and submitted to microwave epitope retrieval (30 min, 160 W in 0.1 M TRIS–HCl buffer, pH 9.5, containing 5% urea). For the detection of AMACR, sections were incubated for 30 min with the rabbit polyclonal antibody P504S (1:100; Biocare Medical LLC, Walnut Creek, CA, USA) using an automated immunostainer (DAKO-Autostainer, Universal Staining System, DAKO, Glostrup, Denmark). Binding of the primary antibodies was assessed by the DAKO ChemMate detection kit.

Immunohistochemical evaluation and controls

Immunoreactivity was assessed by two investigators (G.R. and C.L.) who were blinded to clinicopathologic data using a semiquantitative scoring system. Discrepancies were resolved by simultaneous reexamination of the slides by both investigators using a double-headed microscope. A distinct granular cytoplasmic staining was considered positive, and immunoreactivity was categorised as “focal” (<10% of tumour cells positive), “moderate” (10–50%), or “extensive” (>50%). Slides of prostate adenocarcinoma known to express AMACR served as positive control. Negative controls included omission of the primary antibody and incubation with DAKO ChemMate Antibody Diluent (Code No. S 2022).

Statistical analysis

Subgroups according to pT-stage and tumour grade were compared with respect to possible differences in immunoreactivity using the Fisher’s exact test. Disease-free survival was assessed using the Kaplan–Meier method and compared by the log-rank test. For multivariate testing, a Cox’s proportional hazards regression model was performed. All reported *P* values were two-sided with significance at $P<0.05$.

Results

Histopathology

Stage pTa was present in 41 (15.3%), pT1 in 102 (38.1%), pT2 in 37 (13.8%), pT3 in 80 (29.9%), and pT4 in eight

Table 1 Upper urinary tract urothelial carcinomas related to tumour stage (pTa–pT4) and tumour grade [low grade (LG) and high grade (HG)]

HG	127	47.4	85	50.3	42	42.4
Total	268	100	169	100	99	100

(3.0%) cases, respectively. There were 141 (52.6%) low- and 127 (47.4%) high-grade cases. Pelvic and ureteral UCs showed a comparable distribution regarding the different categories (Table 1). High tumour grade was associated with high tumour stage [53 of 139 (38.1%) pT1/pT2 vs. 74 of 88 (84.1%) pT3/pT4, $P<0.001$]; no high-grade tumours were detected among non-invasive cancers. Tumour

**Fig. 1** Distinct finely granular cytoplasmic AMACR immunostaining in a high-grade urothelial carcinoma of the upper urinary tract ((a), original $\times 100$). Note focal, though specific, labelling in urothelial carcinoma in situ ((b), original $\times 200$)

necrosis was noted in 113 (42.2%), a marked desmoplastic stromal response in 71 (26.5%) and focal squamous differentiation in 47 of 261 (17.5%) tumours, respectively.

Immunohistochemistry

Cancer tissue allowing a reliable evaluation of AMACR immunoreactivity was present in 261 of 268 (97.4%) cases. Overall, distinct finely granular cytoplasmic AMACR immunoreactivity was noted in 127 of 261 (48.7%) tumours, with 32 (12.3%) cases showing only focal staining, whereas 53 (20.3%) cases showed extensive staining (Fig. 1a). Urothelial carcinoma in situ revealed distinct AMACR positivity of single cancer cells (Fig. 1b), whereas non-neoplastic urothelium and urothelial dysplasia lacked specific labelling.

AMACR expression was associated with high tumour stage [58 of 139 (41.7%) pTa/pT1 vs. 69 of 122 (56.6%) pT2–pT4, $P=0.019$] and high tumour grade [44 of 137 (32.1%) low grade vs. 83 of 124 (66.9%) high grade, $P<0.001$]. Pelvic and ureteral UCs showed comparable staining results regarding the different tumour categories (Table 2).

AMACR expression was associated with the presence of tumour necrosis. Thus, 69 of 111 (62.2%) UCs with necrosis showed AMACR immunoreactivity, compared with 58 of 150 (38.7%) UCs without necrosis ($P<0.001$). In addition, AMACR immunoreactivity was associated with the amount of intratumoural stromal response, as 44 of 69 (63.8%) UCs with marked desmoplastic stromal response showed specific labelling, compared with 83 of 192 (43.2%) UCs lacking marked desmoplasia ($P=0.0026$). Finally, AMACR immunoreactivity was also associated with squamous morphology. Thus, 29 of 46 (63%) UCs with focal squamous differentiation were immunostained, compared with 98 of 215 (45.6%) pure urothelial cancers ($P=0.035$).

Total	127/261	48.7	80/165	48.5	47/96	49

Fig. 2 Metastasis-free survival (months) in patients with upper urinary tract urothelial carcinomas related to the presence of AMACR immunoreactivity ($P=0.017$, log-rank test)

Survival analysis

Follow-up data were available for 183 of 190 (96.3%) patients with solitary invasive UCs. After a mean and median follow-up of 47 and 30 months, respectively, progressive disease was observed in 73 of 183 (39.9%) patients including 57 patients who died from cancer and 16 patients who currently are alive with metastatic disease. The lung was the most common site of metastasis. Mean time to progression was 23 months (median 14, range 0–110). A total of 26 patients died from causes not related to upper urinary tract cancer.

The development of distant metastases was associated with the presence of AMACR immunoreactivity. Thus, 32 of 69 (46.4%) patients with UCs with AMACR expression developed disease progression, compared with 41 of 114 (36%) patients with UCs without AMACR expression ($P=0.017$, log-rank test; Fig. 2).

In a Cox's proportional hazards regression model including patient age, gender, tumour stage, tumour grade and AMACR expression, however, only pT-stage >1 ($P<0.001$, risk ratio [RR]=7.32, 95% confidence interval [CI]=3.32–16.13) and high tumour grade ($P<0.001$, RR=3.64, 95% CI 1.82–7.28) proved to be independent predictors of metastatic disease, whereas AMACR immunoreactivity lacked independent influence on patient outcome.

Discussion

To the best of our knowledge, this is the first study which correlates the expression of AMACR in urothelial cancer with tumour stage, tumour grade and patient outcome. In our series, AMACR is expressed in about 50% of upper urinary tract tumours, with 20% of cases showing extensive

immunostaining. The number of positive cells is higher compared to bladder cancers showing staining in 12–31% [8, 19] and as reported in a single former study regarding pelvic UCs with 12% positivity [20]. These studies, however, only included small numbers of patients and detailed information regarding tumour stage and grade was not given.

In our samples, extensive AMACR expression was detected predominantly in high-stage and high-grade tumours. This is an important finding with respect to differential diagnosis, and pathologists should be aware of AMACR immunoreactivity in poorly differentiated UCs in situations requiring the differentiation from poorly differentiated prostate cancer. In select cases, p63 may serve as an additional biomarker, as it is nearly always expressed in urothelial tumours [25], but constantly absent in prostate cancers.

Comparable results to ours have only been very recently reported for breast cancer. Witkiewicz et al. [26] showed AMACR overexpression in 42 of 160 (26%) invasive breast carcinomas and observed stronger AMACR expression in high-grade compared with low-grade tumours. However, AMACR expression in 25–69% of clear cell and in 100% of papillary renal cell cancers was independent of tumour stage and Fuhrman nuclear grade [20, 27]. Comparable data have been obtained from prostate cancer. Most authors agree that there is no association between AMACR immunoreactivity and established histoprognostic factors, such as Gleason score, pathological stage, or the Ki67 labelling index as a marker of tumour cell proliferation [28]. In contrast, in colorectal cancer, two investigations showed a weaker AMACR expression in high-grade compared with low-grade tumours [21, 29].

The reason why AMACR is predominantly expressed in high-grade UCs as well as high-grade breast cancers is not clear. As AMACR is involved in the beta-oxidation of branched-chain fatty acids, it may be speculated that increased expression might lead to the generation of radical species causing genetic instability and damage of cellular membranes. However, it is not clear whether AMACR is directly involved in cancer initiation and/or progression or if it rather represents an epiphenomenon indicating the use of an alternative pathway for providing energy in neoplastic cells. The latter interpretation may be supported by our finding that tumours showing foci of necrosis and/or marked desmoplastic stromal response revealed strong AMACR immunostaining. Desmoplasia has been shown to correlate with hypoxia of tumour cells in breast cancer [30] and may thus lead to changes in tumour cell metabolism, such as increased dependence on fatty acid oxidation for energy generation.

A systematic review of the literature shows that AMACR expression has so far only been systematically correlated with patient outcome in prostate cancer. Data, however, are contradictory. While Rhodes et al. [31] did not find an association between AMACR expression and recurrence-free survival, Rubin et al. [32] recently observed an association between decreased AMACR ex-

pression and increased rate of biochemical recurrence and cancer-related death. TNM-stage and tumour grade are well-established prognostic indicators of upper urinary tract UCs. According to our study, AMACR may be used as an additional indicator of unfavourable prognosis that, however, lacked independent influence on patient outcome.

Aberrant hypermethylation of *RASSF1A* promoter in ovarian borderline tumors and carcinomas

Received: 19 November 2004 / Accepted: 5 February 2005 / Published online: 29 November 2005
© Springer-Verlag 2005

Abstract The newly identified 3p21.3 tumor suppressor gene *RASSF1A* is inactivated by hypermethylation in variable solid tumors, including those of the lung, breast, prostate, kidney, and ovary. The purpose of this study was to evaluate the methylation status of *RASSF1A* in various types and stages of ovarian epithelial tumors. We analyzed the DNA methylation status of ovarian tumors using methylation-specific polymerase chain reaction in 54 frozen ovarian tumor tissues and in 97 cases of archival ovarian serous epithelial tumors using a microdissection procedure. Hypermethylation statuses were examined vs clinicopathologic findings. *RASSF1A* promoter methylation rates in the various types of fresh ovarian tissues were as follows: serous cystadenoma (1/5), serous tumor of borderline malignancy (2/7), serous adenocarcinoma (4/10), mucinous cystadenoma (0/5), mucinous tumor of borderline malignancy (2/7), mucinous adenocarcinoma (3/6), transitional-cell carcinoma (1/3), clear-cell carcinoma (3/3), and malignant müllerian mixed tumor (3/3). In archived serous tumor tissues, *RASSF1A* promoter hypermethylation

was detected in serous cystadenoma (1/6, 16.6%), serous tumor of borderline malignancy (20/41, 48.8%), and in serous adenocarcinoma (25/50, 50%). The status of *RASSF1A* hypermethylation in borderline tumors was found to correlate statistically with the presence of microinvasion ($p=0.002$), peritoneal implant ($p<0.001$), and bilaterality ($p=0.019$). The *RASSF1A* promoter hypermethylation was frequently found in borderline tumors and carcinomas, suggesting that *RASSF1A* promoter hypermethylation may be a useful molecular marker for the early detection of ovarian tumors.

Introduction

Ovarian carcinoma is the leading cause of death due to female genital malignancy, and more than half of ovarian carcinoma patients are diagnosed with advanced-stage disease [13]. A family history of breast and/or ovarian cancer increases the lifetime risk by 40%, and mutations in the *BRCA1* gene increase the risk by 63% in hereditary forms of the disease [6, 12]. However, most cases of ovarian carcinoma are sporadic. A poor understanding of the biology of sporadic forms of the disease, imperfect screening markers, and few symptoms or warning signs of early-stage disease contribute to early-detection failure.

The debate about the diagnostic features, terminology, and treatment of ovarian borderline tumors continue [16]. Ovarian borderline tumors are subtypes of ovarian-surface epithelial stromal tumors, which are noninvasive and are associated with a much better prognosis than ovarian carcinoma. Microinvasion or invasive implants have been shown to be significant in the mortality of borderline ovarian tumors [2, 3, 5, 17], which are best, although not always effectively, treated by chemotherapy. The sequential progression of serous tumors from serous adenomas through borderline tumor to adenocarcinoma has not been well established, and many investigators are pursuing ac-

tivities to detect and explain these carcinomatous changes. Until now, no well-recognized early molecular events have been reported in borderline tumors.

Epigenetic gene alterations such as aberrant promoter methylation are common and important mechanisms of tumorigenesis and may be mechanistic alternatives to gene mutations for the formation of ovarian tumors. An example is provided by the tumor suppressor gene *RASSF1A* (Ras association domain family 1A gene) and its common homozygous deletion at 3p21.3, which is frequently inactivated in a variety of primary human cancers, including lung cancer (30–80%), breast cancer (49–62%), and renal-cell cancer (23–91%). Among female genital-tract tumors, a high frequency of loss of heterozygosity (LOH) for 3p is found in cervical and ovarian carcinoma [15], and in ovarian tumors, the deletion of the short arm of chromosome 3 is a frequent genetic alteration [7]. Until now, only three reports on the hypermethylation rate of *RASSF1A* have been published in ovarian tumors (Table 1). Yoon et al. analyzed 20 ovarian tumors for *RASSF1A* methylation, and 8 of 20 tumors (40%) were found methylated [21]; similarly, Rathi et al. [14] reported a rate of 41%. In contrast to this, Agathangelou et al. found a methylation rate of only 10% in ovarian cancer [1]. However, in these studies, *RASSF1A* methylation was not examined in benign and borderline tumors and was not compared with clinicopathologic parameters. Consequently, we investigated the methylation status of *RASSF1A* in ovarian tumors at various stages.

Materials and methods

Tissue samples

Fifty-four nonmicrodissected frozen ovarian tumors were collected from patients at the Samsung Medical Center. All samples were stored at -70°C , and formalin-fixed and paraffin-embedded tissue blocks representative of serous carcinoma, borderline tumors, and serous adenoma in 97 cases were obtained from the Department of Pathology. Detailed patient demographic and clinical information was obtained by reviewing medical records. Histologic classifications were established according to the World Health Organization (WHO) criteria, and tumor stage was established according to the Federation of International Gynecological Oncologists of classification. Two cases of normal ovarian tissue were collected from patients without cancer undergoing bilateral salpingo-oophorectomy at the time of surgery for benign gynecological disease. All samples were collected after obtaining appropriate institutional Review Board consent.

Microdissection and DNA extraction

Surgically resected fresh tumor tissues were macroscopically dissected to separate tumorous and nontumorous tissues. DNA from 100 mg (or more) frozen tissue spec-

imens were obtained by overnight digestion with 200 $\mu\text{g}/\text{ml}$ proteinase K at 50°C by following the manufacturer's instructions (Qiagen). Each paraffin-embedded ovarian tissue block was used to prepare a 10- μ tissue section. Sections were stained with hematoxylin to confirm the histological presence of tumor. Tumor areas were carefully microdissected from normal surrounding stromal tissues, placed in an Eppendorf tube, deparaffinized overnight at 63°C in xylene, and then vortexed vigorously. After centrifuging at full speed for 5 min, the supernatant was removed, and ethanol was added to remove residual xylene, and then ethanol was removed by centrifugation. After ethanol evaporation, the obtained tissue pellets were resuspended in lysis buffer (Qiagen), and DNA was isolated according to the manufacturer's instructions (Qiagen).

Methylation analysis

The methylation status of the promoter region was determined by methylation-specific polymerase chain reaction (PCR) (MSP), which distinguishes unmethylated alleles from methylated alleles. Genomic DNA (2 μg) was denatured in NaOH (0.3 M) for 15 min at 37°C . Cytosines were sulfonated in sodium bisulfite (3.12 M; Sigma) and hydroquinone (5 mM; Sigma) in a thermocycler for 30 s at 99°C and for 15 min at 50°C for 20 cycles. The DNA samples were then desalted through a column (Wizard DNA Clean-Up System, Promega), desulfonated in NaOH (0.3 M) and precipitated. We amplified DNA sequences by mixing bisulfite-treated DNA (100 ng) with 50 pmol of primer MU379 (5'-GTTTTGTTAGTTTAATGAGTTTAGTTTTT-3') and 50 pmol primer of ML730 (5'-ACCTCTTCCTCTAACACAATAAACTAACC-3') in a re-

action buffer (100 μ l) containing deoxynucleoside 5'-triphosphates (dNTPs) (200 μ M each) and *Taq* polymerase (Boehringer) at 95°C for 1 min, 55°C for 1 min, and at 74°C for 2 min for 30 cycles. Seminested PCR was performed using DNA (100 ng) of the amplified products and the internal primer ML561 (5'-CCCCACAATCCCTACCCCAAAT-3') and primer MU379 using the PCR conditions described above. Placental-tissue DNA treated in vitro with *SssI* methyltransferase was used as a positive control for amplification of methylated alleles. Water blanks without added DNA were included as negative PCR controls in each assay. PCR products were loaded directly onto 2% agarose gels, stained with ethidium bromide, and visualized under ultraviolet illumination. A portion of the PCR products

were purified using a QIAquick PCR purification kit (Qiagen) and directly sequenced to confirm methylation.

Statistical analysis

Associations between *RASSF1A* methylation and clinicopathologic parameters were analyzed using the Student's *t* test for continuous variables or Fisher's exact test (or the Pearson chi test) for categorical variables. The effects of *RASSF1A* methylation on patient survival were estimated using the Kaplan–Meier method, and differences between the survival curves of the two groups were analyzed using the log-rank test. Quoted *p* values were based on two-sided statistical analysis.

Results

To elucidate the status of *RASSF1A* during ovarian cancer pathogenesis, we analyzed the methylation status of *RASSF1A* promoter in various ovarian tissues. All of the tumors analyzed were of epithelial origin and were classified based on histologic subtype, as shown in Table 2. Initially, the analysis was performed using frozen tissues, and a high frequency (24–100%) of *RASSF1A* promoter hypermethylation was detected. The *RASSF1A* methylation rates in various types of fresh ovarian tissue were serous cystadenoma (1/5), serous tumor of borderline malignancy (2/7), serous adenocarcinoma (4/10), mucinous cystadenoma (0/5), mucinous tumor of borderline malignancy (2/7), mucinous adenocarcinoma (3/6), transitional-cell carcinoma (1/3), clear-cell carcinoma (3/3), and malignant mixed müllerian tumor (3/3) (Table 2). Agarose gel electrophoresis of representative MSP products is shown in Fig. 1. *RASSF1A* methylation was confirmed by direct sequencing of the *RASSF1A* MSP product in seven samples. All samples were methylated at the 12 cytosine–

Fig. 1 Agarose gels showing representative products of MS-PCR analysis in ovarian tumors. *P* is positive control, i.e., artificially methylated DNA, and *N* (water blank) is negative PCR control. The methylated status of the *RASSF1A* CpG island is indicated as methylated (*m*) and unmethylated (*u*). The sizes of the methylation- and unmethylation-specific products were 93 and 105 bp, respectively. *SA*, serous adenoma; *SB*, serous borderline tumor; *SC*, serous carcinoma; *MA*, mucinous adenoma; *MB*, mucinous borderline tumor; and *MC*, mucinous carcinoma. **a** Frozen tissue. **b** Archival tissue

phosphate–guanine (CpG) sites contained in the amplicon (data not shown). The methylated form was composed of 96 base pairs, and the unmethylated form was composed of 106 base pairs; in normal ovarian tissues, hypermethylation was not detected (0/5). We found that one case of serous adenoma and some portions of borderline tumors had an aberrant *RASSF1A* methylation. We then extended the study to include archival tissue. All 97 archived paraffin tissues were evaluated, and *RASSF1A* methylation was detected in serous cystadenoma (1/6, 16.6%), serous tumor of borderline malignancy (20/41, 48.8%), and in serous adenocarcinoma (25/50, 50.0%) (Table 2). The most interesting finding was that borderline tumors and carcinomas have similar methylation rates. Moreover, methylation status was statistically correlated with several clinicopathologic parameters in borderline tumors: ascites at diagnosis ($p=0.027$), surface involvement ($p<0.001$), bilaterality ($p=0.019$), microinvasion ($p=0.027$), and implant ($p=0.001$) (Table 3). When implant cases were divided into two groups of noninvasive and invasive implants, methylation status was significant in only noninvasive implant cases ($p=0.001$). Because the number of cases with invasive implant was so small ($n=4$), the methylation status was inconclusive.

In carcinomas, *RASSF1A* promoter methylation was more frequent in advanced-stage cases, but this was not significant because of the limited number of cases in stages I–II (Table 4). Also, we examined the correlation between

patient survival and *RASSF1A* methylation status, but we found no significant relation.

Discussion

The hypermethylation rate of *RASSF1A* has been extensively studied in variable solid tumors. Whereas we did not study *RASSF1A* gene expression, previous studies have demonstrated that the inactivation of the expression of *RASSF1A* is highly correlated with the methylation of its promoter. Thus, the frequent methylation of the *RASSF1A* gene suggests that it plays a role in ovarian tumorigenesis, especially in the development of epithelial proliferation to form a borderline tumor. Although one [1] report of *RASSF1A* gene in ovarian tumor produced conflicting results, our results are in agreement with the 40 and 41% incidences of hypermethylation in ovarian tumors observed by Yoon et al. [21] and Rathi et al. [14], respectively.

Our findings on *RASSF1A* hypermethylation in ovarian tumors are interesting for several reasons. First, this hypermethylation occurs at an early stage of ovarian tumorigenesis (i.e., in borderline tumors), and this represents the first example of epigenetic inactivation of this tumor suppressor gene at a high prevalence in an early lesion. This contrasts with the genetic inactivation of the major tumor suppressor gene, p53, which generally occurs in late-stage advanced carcinomas. Recently, several reports have demonstrated an early role for *RASSF1A* methylation in the tumorigenesis of thyroid, lung, and breast cancer and suggested its use as a molecular marker of early detection [8, 19, 20]. Ibanez de Caceres et al. [9] also reported the results of *RASSF1A* hypermethylation in serum, plasma, and peritoneal fluid from ovarian cancer patients. They concluded that promoter hypermethylation

was a common and relatively early event in ovarian tumorigenesis that could be detected in the serum DNA from patients with ovary-confined (stage IA or B) tumors in a cytologically negative peritoneal fluid. Results of the present study correspond with the results of earlier studies. Second, the prevalence of *RASSF1A* promoter methylation is similar in borderline tumors and in serous carcinomas. The tumor suppressor role of the *RASSF1A* gene may be involved during the stage of epithelial proliferation rather than during the invasion or metastasis of advanced carcinomas. The progression from a serous borderline tumor to adenocarcinoma remains controversial [16]. However, this *RASSF1A* methylation pattern supports the hypothesis that some proportion of serous carcinomas originate from serous borderline tumors. Third, we observed for the first time that *RASSF1A* methylation occurs more frequently in advanced borderline tumors, i.e., in cases with ascites at diagnosis, surface involvement, bilaterality, microinvasion, and peritoneal implants. There was no significant correlation between *RASSF1A* methylation status and invasive implant, which is a prognostic factor of borderline tumors.

Clinically, it is still controversial whether aberrant *RASSF1A* methylation in human cancer is associated with clinicopathologic features. During breast cancer progression, *RASSF1A* inactivation is common in grade I tumors; *RASSF1A* methylation may thus be an early event [4]. No statistically significant association has been found between *RASSF1A* methylation and age, stage, tumor histology, recurrence/metastasis, or overall survival in patients with bladder cancer or childhood neoplasia [11, 19]. In our study, there was no relationship between *RASSF1A* promoter methylation and stage or survival in carcinomas. It appears that this frequent and ubiquitous epigenetic alteration may potentially be a very early and critical event deregulating apoptosis and cell cycle progression in ovarian epithelial tumors rather than invasiveness or metastasis.

Based on the above, we propose that the epigenetic inactivation of the tumor suppressor gene *RASSF1A*, through aberrant promoter methylation, may play an important role in the formation of borderline tumors and in their progression to adenocarcinoma. Aberrant *RASSF1A* methylation may lead to progressive clonal expansion in borderline tumors, and when the accumulation of such methylation reaches a critical level, or perhaps when an additional genetic/epigenetic alteration occurs, this may subsequently lead to malignant transformation to adenocarcinoma. Although many details of how *RASSF1A* inactivation by hypermethylation contributes to ovarian tumorigenesis remain unknown, its hypermethylation in a subgroup of serous adenocarcinoma suggests that the role of *RASSF1A* methylation may be both critical and indispensable for the formation or progression of this subgroup of ovarian cancers.

Recently, Song et al. [18] found evidence of the tumor suppressor function of *RASSF1A*. He found that *RASSF1A* regulates mitosis by inhibiting the mitogenic APC-Cdc20 complex. *RASSF1A* localized to microtubules during the interphase and to centrosomes and the spindle during mitosis. Cells without *RASSF1A* divided faster than normal

controls, and *RASSF1A* knock-down cells using siRNA showed more abnormal mitotic figures. An in vivo study also revealed larger tumor sizes in *RASSF1A*-negative mice. Thus, we suggest that the loss of *RASSF1A* protein function by hypermethylation increases the speed of the cell cycle, which increases the likelihood of genetic mutation. The most characteristic feature of borderline tumors is the proliferation of epithelium. Therefore, the frequent loss of *RASSF1A* protein in borderline tumors may be self-explanatory. Progression to malignancy results from accumulated damage to both oncogenes and tumor suppressor genes. It would appear that such silencing of a normal tumor suppressor gene is responsible for the proliferation of ovarian epithelial cells.

Initially, we worked with frozen tissues; however, cellular heterogeneity was a common problem that precludes accurate DNA analysis in human tissue samples, i.e., a mixture of neoplastic and nonneoplastic cells such as supporting stromal cells, inflammatory cells, and preexisting original tissue [10]. Moreover, the natures of heterogeneous cells may obscure the results of molecular assays, depending on the ratio of neoplastic to nonneoplastic genomic DNA and the sensitivity of the tests. Although MSP is a highly sensitive technique for the detection of targeted DNA, the relative amounts of competing DNAs present is an important factor. Nonmicrodissected tissue did not represent the homogenous ovarian epithelium or adenoma component even in carcinoma, and thus, results can be distorted by the relatively predominant stromal component. Previous studies have also used nonmicrodissected frozen tissues. Thus, we collected tumor DNA by microdissecting archival tissues and minimized stromal tissue contamination. The rate of methylation in archival tissue was higher than in frozen tissue, which stresses the importance of microdissection when an analysis is performed using PCR, since surrounding stromal tissue may mask tumor-specific changes, especially in borderline cases.

Several conclusions may be drawn from this study. First, the *RASSF1A* hypermethylation rate is infrequent in normal and benign tumors. Moreover, the different hypermethylation frequencies in benign and malignant tumors suggest that in ovarian tumors *RASSF1A* silencing is an epigenetic alteration related to tumor progression. Finally, the frequent hypermethylation rate observed in borderline tumors suggests the possibility that the inactivation of *RASSF1A* may be a relatively early event in ovarian tumorigenesis.

Pathological findings in a patient with Fabry disease who died after 2.5 years of enzyme replacement

Received: 22 June 2005 / Accepted: 31 August 2005 / Published online: 29 November 2005
© Springer-Verlag 2005

Abstract We describe the postmortem findings of a 47-year-old man with Fabry disease, an X-linked glycolipid storage disorder, who was on enzyme replacement therapy with recombinant α -galactosidase A for more than 2 years. The patient had widespread atherosclerotic coronary artery disease that culminated in a massive acute myocardial infarction. Atherosclerotic lesions were seen in the right and left coronary systems, aorta, and the basilar artery. Typical Fabry cardiomyopathy and glomerular nephropathy were found. With the exception of vascular endothelial cells, extensive glycolipid storage deposits were seen in all vascular and nonvascular cells and organ systems. We conclude that, at least in this patient, repeated infusions with α -galactosidase A over a prolonged period did not appreciably clear storage material in cells other than vascular endothelial cells. These findings also illustrate accelerated atherosclerosis in susceptible patients with Fabry disease.

Keywords Fabry disease · Lysosomes · Atherosclerosis · Myocardial infarction · Enzyme replacement therapy · Glycolipids

Introduction

Fabry disease, an X-linked systemic disorder caused by a deficiency of the lysosomal enzyme α -galactosidase A, results in a failure to metabolize α -D-galactosyl moieties [4]. This abnormality leads to the systemic deposition of glycosphingolipids, particularly globotriaosylceramide (Gb₃) [5]. In adulthood, progressive renal failure, strokes, and heart disease develop, leading to death at a median age of 50–55 years. In the past 5 years, enzyme replacement therapy (ERT) with recombinant α -galactosidase A has been added to the standard therapeutic regimen [8, 17, 18, 22]. Targeted primarily to reverse vasculopathy of Fabry disease, ERT has been shown to markedly reduce the cellular storage deposition in vascular endothelial cells [22]. Its long-term clinical effects, however, remain to be fully assessed. No extensive pathological analysis in patients on long-term ERT has been reported thus far. We present in this report the autopsy results of a 47-year-old man who was on ERT for more than 2 years and died suddenly.

Case report

The patient was a 47-year-old man who was diagnosed with Fabry disease at age 19 with α -galactosidase A activity of 1.3% of normal controls. Since 5 years of age, he suffered from episodes of fever and acroparesthesia, hypohidrosis, poor heat and exercise tolerance, diarrhea with abdominal cramps, and bouts of depression. At 35, he developed an acute onset of right-sided weakness and difficulty with word finding. A CT scan revealed a large anterior parietal infarct, and a left carotid angiogram showed marked narrowing of mid-sylvian branches of the left middle cerebral artery (MCA) with an area of avascularity in the left anterior parietal lobe. He was put on oral warfarin therapy with no apparent stroke recurrence. His most recent head MRI scan showed old left encephalomalacia in the left frontal lobe along with white matter

hyperintense lesions on T2 and fluid-attenuated inverse recovery (FLAIR) images on the left.

He had no hypertension. His renal function was normal until age 37 when his serum creatinine was found to be 1.4 mg/dL (normal 0.9–1.4) with a creatinine clearance of 78 mL/min. He had mild-to-moderate proteinuria with variable 24-h protein excretion of up to 1.2 g/24 h. At age 43, his serum creatinine level was 1.5 mg%. His total blood cholesterol at age 20 was 189 mg/dL. At age 36, it was 201 mg/dL, and his HDL and triglyceride levels were 87 mg/dL and 92 mg/dL, respectively. At age 43, total cholesterol was 241 mg/dL, LDL level was 161 mg/dL, and HDL level was 24 mg/dL.

Other abnormalities noted were bilateral pedal edema, mild-to-moderate bilateral high-frequency hearing loss, sinus bradycardia and left ventricular hypertrophy in the electrocardiogram, and mild mitral and tricuspid valve regurgitation.

His therapy included Coumadin and carbamazepine. In addition, he received intravenous α -galactosidase A infusions (agalsidase beta; Genzyme Corporation, Cambridge,

MA) at a dosage of 1 mg/kg every 2 weeks for the last 2.5 years of his life.

He first complained of sharp chest pain at age 40, lasting about 30 s (not precipitated by exertion). He complained mostly of burning chest pain on and off in the years prior to his death. One week prior to his death, he again reported a burning discomfort on his chest, which increased with physical activity. He refused to seek medical attention and shortly thereafter was found dead.

Regarding his family history, his mother, two sisters, and a brother were affected by Fabry disease. Two of his maternal uncles died of the same disease. One died of a cardiac cause at age 39 and another maternal uncle died of stroke at age 47. Another cousin with Fabry disease died of myocardial infarction at age 53.

Pathological findings

The postmortem interval was approximately 32 h before an unrestricted autopsy was performed. Only the pertinent findings will be described.

The heart weighed 520 g with approximately 30–50 mL of pericardial fluid. The right dominant coronary arterial systems showed marked atheromas with calcifications. The left ventricular wall thickness was 1.7 cm (normal 1.0–1.5 cm). Sections of the left coronary arterial system showed significant intimal atheromas with intimal proliferation and calcifications with reduction of the luminal diameter of up to 95% in some regions (Fig. 1a). The right coronary artery also showed significant intimal atheromas and calcification with reduction of the interior diameter of up to 50%. Microscopically, portions of the anterior free wall of the left ventricle showed an inflammatory infiltrate consisting predominately of neutrophils with necrosis of the myocardium (Fig. 1b). Additional sections of the anterior wall distant from the inflammatory infiltrate showed a significant patchy, fibrous scarring of the myocardium. Ultrastructural analysis showed the heart muscle separated by thin strands of fibrosis (Fig. 2). The myocytes showed focal loss of filaments and increased number of mitochondria containing tubulovesicular cristae and dense aggregates. Numerous lamellar inclusions were found in myocytes and fibroblasts. Inclusions were only rarely seen in endothelial cells (Fig. 2d).

The intimal surface of the aorta showed marked atherosclerotic ulcerative plaques. The orifices of major arteries were widely patent.

The lungs were heavy and consolidated with blood-tinged pulmonary edema. Pulmonary hemorrhage was identified in the peripheral hilar region of the right and left lung. Microscopic examination showed significant congestion, with hemorrhage into the bronchioles and spilling into the alveolar spaces with distal necrosis/infarction of the parenchyma. Other sections from the consolidated lung showed areas of frothy, eosinophilic cell-free fluid filling the alveolar spaces and scattered, admixed hemosiderin-laden macrophages.

Fig. 2 Ultrastructure of the heart. **a** Large aggregates of concentric lamellated cytoplasmic inclusions displace cardiac myofibrils to the periphery of the cell. Interstitial fibrosis and increased numbers of mitochondria are secondary features of the cardiomyopathy. **b** Higher magnification of the lamellar inclusions and the accumulated

mitochondria. The latter exhibit tubulovesicular cristae and cell size variation. **c** The myelinoid inclusions sometimes consisted of parallel-stacked lamellae with a zebra-like pattern. **d** Inclusions were only rarely present in endothelial cells of adjacent interstitial capillaries (*arrows*)

The right kidney weighed 140 g and the left one weighed 184 g. The pelvis and calices of both kidneys were markedly dilated with thinning of the renal cortical parenchyma. Microscopically, glomeruli were either normal with occasional mesangial widening or sclerosis (Fig. 3). At the ultrastructural level, numerous lamellar inclusions were present in the glomerular epithelium and tubular epithelial cells. Only an occasional inclusion was seen in endothelial cells of glomerular capillaries (Fig. 4). Glyco-

lipid deposits were not seen in peritubular capillary endothelial cells and only rarely seen in mesangial cells (not shown).

The fixed brain weighed 1,520 g. The left cerebral hemisphere showed a cystic cavity area in the frontoparietal lobes corresponding to an old infarct in the left MCA territory. Microscopically, this area was characterized by abnormal brain parenchyma with abundant reactive astrocytes, few foamy macrophages containing hemosiderin,

and calcification. The basilar artery was atherosclerotic. Luxol fast blue (LFB)-stained deposits were found in blood vessels, mostly in the smooth muscle cells of the media and adventitia and little or none in endothelial cells (Fig. 5). Similar results were obtained by electron microscopy (Fig. 6). Neuronal storage was also observed in various areas including the hypothalamus (Fig. 7a), brainstem, and spinal cord. Sections of the paraspinal ganglia showed prominent neuronal distention with accumulating storage deposits (Fig. 7b).

Discussion

We describe herein the pathological abnormalities of a 47-year-old man with Fabry disease who died of acute myocardial infarction associated with nonhypertensive

atherosclerotic coronary artery disease. Other significant findings at autopsy were the characteristic Fabry cardiomyopathy with increased cardiac mass by both weight and arterial wall thickness, as well as microscopic fibrosis and marked cellular storage. Typical primary and secondary findings of Fabry disease were also found in the kidney, the brain, and the paraspinal sensory ganglia.

A number of autopsy and pathological reports of patients with Fabry disease have been published [6, 7, 10, 20, 21]. The pathological findings in this patient showed an almost complete absence of glycolipid deposits in vascular endothelial cells attributable to the agalsidase beta infusions. Similar findings of predominant clearing of capillary endothelial cells were described in kidney biopsy material in the pivotal trial of agalsidase beta [21]. The presence of marked storage in other cells, including smooth muscle cells and pericytes of the vascular system, as well as in

Fig. 4 Ultrastructure of the kidney. **a** Abundant lamellar inclusions in the glomerular epithelial cells (podocytes) and tubular epithelial cells (not shown). **b** On the other hand, only an occasional inclusion was identified in the glomerular capillary endothelial cells (arrow)

Fig. 6 Ultrastructure of the brain. The smooth muscle cells in the wall of a cerebral vessel shown in a semithin section in **a** (toluidine blue/fuchsin stain) are loaded with lamellar inclusions exhibiting concentric and zebra-like patterns at the ultrastructural level (**b**).

nonvascular cells, after more than 2 years of enzyme infusions suggests that the infused enzyme has limited access to nonvascular endothelial cells. If so, this may constitute a significant limitation of this therapeutic approach. We cannot however exclude the fact that greater storage clearance is achieved in other patients. Efforts to modify recombinant α -galactosidase A or the development of other therapeutic strategies may achieve more complete clearing of storage material. The partial clearance of glycolipid deposits from the vascular tree may explain in part the clinical impression that the incidence of strokes is not reduced in the first few years after α -galactosidase A infusions.

The involvement of the coronary arteries in Fabry disease has been previously recognized [1, 7, 9, 12], although minimized by others [19]. In addition, the possibility of accelerated atherosclerosis in Fabry disease has been previously mentioned [11, 13, 15]. Reported autopsies have shown that these coronary lesions are similar to typical

atherosclerosis except that they are concentric with a white discoloration rather than the eccentric yellowish characteristics of atherosclerotic plaques [1].

The severe atherosclerotic disease seen in this patient that culminated in a fatal coronary event could be coincidental to the Fabry disease process. Nevertheless, we increasingly recognize fixed coronary artery disease among our Fabry disease patient population. For example, five men with Fabry disease from a group of 38 patients who participated in enzyme replacement trials (age range 19–49, not including this patient) were found to have symptomatic fixed coronary artery disease requiring coronary bypass or angioplasty (three patients). In addition, we found that random (not during acute events) blood levels of myeloperoxidase (MPO) in patients with Fabry disease are significantly higher than controls [15]. MPO has been associated with the atherosclerosis process, endothelial dysfunction, and acute coronary events, and it

Fig. 7 **a** Storage in neurons. Hypothalamic nuclei showing neuronal storage. H & E, $\times 40$. **b** Dorsal root ganglia showing swollen storage neurons. H & E, $\times 20$

was recently shown to modify apo A-1 HDL cholesterol to make it more likely to accumulate in macrophages [16]. Evidence for excess production of reactive oxygen species, such as superoxide in Fabry disease, has also accumulated [14, 15]. Recently, another group has shown that aortic atherosclerosis in mice deficient in both apo E and α -galactosidase A is markedly accelerated compared with either of those mouse models alone [3]. Together, this clinical and experimental evidence suggests that the process of atherosclerosis may be accelerated in Fabry disease. It is likely therefore that other factors in combination with α -galactosidase A deficiency render certain patients with Fabry disease susceptible to atherosclerosis. Indeed, we have recently shown that polymorphisms of genes known to be risk factors for stroke modify the likelihood of developing cerebral ischemic lesions in Fabry disease [2]. Therefore, a number of genetic factors may modulate the interaction between the α -D-galactosyl glycolipid accumulation and vascular plaque formation. Additional investigation is necessary to confirm and further characterize this process.

Acknowledgements We thank Dr. Kristen Carr for her participation in the autopsy of this patient. This work was supported by the Intramural program of National Institute of Neurological Disorders and Stroke, NIH.

Intratumour T cells, their activation status and survival in gastric carcinomas characterised for microsatellite instability and Epstein–Barr virus infection

Received: 15 June 2005 / Accepted: 16 August 2005 / Published online: 27 October 2005
© Springer-Verlag 2005

Abstract Gastric carcinomas (GCs) with high microsatellite instability (MSI) or an Epstein–Barr virus (EBV) infection are prevalently poorly differentiated adenocarcinomas with abundant lymphoid infiltration. The aims of the study were to clarify (1) if tumour-infiltrating lymphocytes (TILs) and cytotoxic-activated TILs are associated with a better clinical outcome in patients with GCs characterised for the presence of MSI and EBV; (2) if the nature and the activation status of TILs are involved in tumour cell apoptosis, evaluated using the M30 antibody, directed against a fragment of cytokeratin-18 caspase-cleaved during early steps of epithelial cell apoptosis. The immunophenotype of TILs and the tumour cell apoptosis were analysed with immunohistochemistry in 96 GCs, including 35 MSI GCs, and 61 GCs without MSI [microsatellite stable (MSS)], 17 of which were EBV+. MSI and MSS/EBV+ GCs displayed a significantly higher mean number of cytotoxic-activated TILs and apoptotic tumour cells than MSS/EBV– GCs (CD8+ TILs/HPF, 21.7 and 69.6 vs 6.4; T-cell intracellular antigen (TIA)-1+ TILs/HPF, 16.7 and 32.05 vs 5.2; granzyme B+ TILs/HPF, 7.5 and 8.6 vs 0.8; perforin+ TILs/HPF, 5.9 and 9.2 vs 0.9; and M30 IR

tumour cells, 5.9 and 2.9 vs 2.3%). In addition to the most reliable clinico-pathological parameters (lymph node status, depth of tumour invasion and tumour stage), a univariate analysis showed that the presence of CD3+ TILs higher than 14.9 ($p=0.01$), CD8+ TILs higher than 9.5 ($p<0.05$) and MSI ($p=0.02$) were associated with better overall patient survival. Using a Cox regression model, only a high number of CD3+ TILs ($p=0.02$) and a low tumour stage ($p=0.00001$) were identified as independent prognostic factors. In conclusion, our study demonstrates that a high number of CD3+ and CD8+ TILs is a characteristic of MSI- and EBV-associated GCs and represents a favourable prognostic factor, independently of the pathogenesis of GCs.

Keywords Gastric carcinoma · Microsatellite instability · Epstein–Barr virus · Tumour-infiltrating lymphocytes · Activated cytotoxic T cells · Survival

Introduction

Over the past 10 years, accumulating evidence has indicated that a pronounced intratumour inflammatory reaction plays a crucial role in host response to cancer. Various inflammatory elements (dendritic cells, macrophages, granulocytes and lymphocytes) have been found in the tumour micro-environment, both in supporting stroma and among epithelial cells in tumour nests.

The presence of tumour-infiltrating lymphocytes (TILs) has been shown to correlate with a favourable prognosis in several human malignancies such as melanoma and ovarian, prostatic, renal-cell, breast and colorectal carcinomas [12, 25, 27, 38, 42]. The presence of abundant lymphocytic tumour infiltration is a peculiar histological feature common to gastric carcinomas (GCs), both with Epstein–Barr virus (EBV) infection [4, 28, 37] and with a high level of microsatellite instability (MSI) [4, 34].

The immune response to cancer cells may be mediated by non-specific natural killer (NK) cells [30] or by cancer-specific lymphocytes, which are usually CD8-positive [2, 31].

In GCs, a high level of NK infiltration was significantly associated with a better prognosis of disease [14].

In MSI colorectal carcinomas, the intratumour lymphocytes have been demonstrated to be prevalently cytotoxic-activated T cells [7]. Their presence could be responsible for the increased apoptosis of tumour cells observed in these tumours, although Michael-Robinson et al. [23] demonstrated that TILs and apoptosis are independent characteristics of MSI tumours.

In the present investigation, we studied a series of GCs characterised for MSI status and EBV infection with the

aims of clarifying whether TILs are associated with a better clinical outcome in GC patients and of defining the nature and the activation status of TILs in the different subtypes of GCs.

Materials and methods

Case selection The study included 96 cases of sporadic advanced GCs (Table 1) operated on at the University Hospital of Varese between January 1980 and June 1999.

The majority of the tumours were from a series of 185 cases which had previously been examined for the presence of high MSI, expression of hMSH2 and hMLH1 proteins and EBV infection with in situ hybridisation for EBER-1 [4]. In particular, 35 MSI and 31 microsatellite stable (MSS) GCs were selected for the presence of abundant lymphoid infiltration, while 20 cases, showing a less abundant lymphoid infiltrate, were selected from the remaining consecutive MSS glandular carcinomas. Ten other cases were added to the series because they were known to be EBV-positive. Altogether, 35 cases were MSI, and 61 were MSS carcinomas, 17 of which were positive for EBV.

The tumours were classified, according to the criteria outlined by Carneiro et al. [3], as glandular, solid or mixed types and according to the Lauren criteria [19]. The tumour stage was assessed using the tumour node metastases (TNM) system defined by the International Union Against Cancer [35]. The clinico-pathological data of the GCs, characterised for MSI status and EBV infection, are summarised in Table 1.

All patients were followed-up either until death or for a median period of 150 months (range 42–238 months); information was obtained from the Lombardy Tumour Register and from the record offices of local authorities. The mean overall follow-up was 64.3 months (range 0–238).

Immunohistochemical study The characterisation of TILs was performed on formalin-fixed, paraffin-embedded materials using the avidin–biotin–peroxidase complex (ABC) methods. Briefly, sections were deparaffinised, rehydrated and, for selected antigens, pre-treated with different antigen-retrieval solutions in a domestic 750-kW microwave oven (see Table 2). Endogenous peroxidase activity was quenched in 3% H₂O₂ in water for 10 min.

Primary antibodies (listed in Table 2) were applied overnight at 4°C. Sections were then incubated with biotinylated anti-mouse immunoglobulins and with ABC peroxidase complex, each for 1 h at room temperature.

Immunoreactive intraepithelial lymphocytes were counted at 400× (Leitz, Laborlux K; field area 0.173 mm²) in ten consecutive fields, selecting areas containing the maximal number of neoplastic cells with minimal reactive stroma and necrosis. The mean value of immunoreactive TILs per high-power field was reported. Only the immunoreactive lymphocytes in direct contact with tumour cells were included in the count.

The apoptotic index was expressed as the percentage of M30 immunoreactive cells per 2,000 tumour cells counted in the ten most positive fields at 200×. Areas of intraglandular or superficial necrosis were not considered for the evaluation of the apoptotic index.

Statistical analysis The statistical significance of the results was evaluated using the Wilcoxon rank-sum test for unpaired data, chi-square test and Fisher's Exact Test. The correlation of patient survival with the immunohistochemical and clinico-pathological data was estimated using the Kaplan–Meier product limit method, and statistical differences were tested using the log-rank test. A multivariate analysis was performed with the Cox proportional-hazard regression model.

Results

Clinical and pathological features

The clinico-pathological data of the GCs are summarised in Table 1. There were slightly more males (male to female

Table 2 List of primary antibodies used

Mouse monoclonal antibody	Clone	Specificity	Working dilution	Treatment	Manufacturer
CD3	PS1	ε chain of T-cell receptor	1/100	MW 5 min ×2 EDTA, pH 10	Biogenex (San Ramon, CA, USA)
CD8	4B11	Membrane glycoprotein of CTLs	1/20	MW 5 min ×4 EDTA, pH 8	Novocastra (Newcastle, UK)
Granzyme B	GrB-7	Serine protease of NK cells and CTLs	1/20	MW 5 min ×2 CB, pH 6	Monosan (Uden, Netherlands)

ratio 2.4:1) with MSS/EBV+ cancers compared to MSI and MSS/EBV- cancers (male to female ratios 1.5:1 and 1.2:1, respectively).

Both MSI and MSS/EBV- carcinomas were more frequent in the antrum (77 and 68%, respectively), whereas MSS/EBV+ carcinomas were prevalently located in the gastric fundus (47%) and in the gastric stump (29%) ($p < 0.001$).

Tumour size varied in diameter from 20 to 100 mm. The mean diameters were 58.6, 60.3 and 39.7 mm for MSI, MSS/EBV+ and MSS/EBV- carcinomas, respectively.

Histologically, 64% of all tumours were glandular carcinomas. In particular, 74% of MSI and all the MSS/EBV+ cases were poorly differentiated, whereas 61% of MSS/EBV- were moderately differentiated carcinomas (Fig. 1). According to Lauren's criteria [19], 80% of tumours were intestinal, and only 4% were diffuse GCs; 16% of cases were unclassified.

Fig. 2 Failure time according to MSI and EBV status [log-rank chi-square 6.35 ($p = 0.0417$)]

At diagnosis, MSS/EBV- and MSS/EBV+ carcinomas showed lymph node metastases in 31 of 43 (72%) and 14 of 17 (82%) cases, whereas they were present in only 18 of 35 (51%) MSI carcinomas ($p < 0.05$).

Fifty (52%) patients died of disease after an average time of 32.5 months (range 2–181), including 14 (40%) patients with MSI, 27 (62%) with MSS/EBV- and 9 (53%) with MSS/EBV+ carcinomas.

Thirty (31%) patients died of other causes (mean follow up 46.5 months, range 0–212), and only 16 patients (17%) were still alive at the last follow-up after a mean time of 150 months (range 42–238).

^{S,#,o}Indicators for statistical evaluation

The survival curves (Fig. 2) showed a significantly different prognosis in the three groups (*p*<0.05). In particular, the overall survival was significantly higher for patients with MSI than with MSS/EBV- GCs (*p*=0.01). The mean 5-year survival was 59, 46 and 32% for MSI, MSS/EBV+ and MSS EBV- GCs, respectively.

Characterisation of lymphoid infiltration

Lymphocytes were present both within tumour-cell nests and in peritumoural stroma. CD3+ intraepithelial TILs varied in number from 0 to 254 in a high-power microscopic field (mean value 31.6, median value 14.9).

The mean number of CD3+ TILs was 30.7 (range 1.6–77), 6.6 (range 0–30.4) and 100 (range 43.3–254) in MSI, MSS/EBV- and MSS/EBV+, respectively, and the differences were statistically significant (*p*<0.001; Fig. 3).

The nature and the activation status of TILs were analysed in a subset of GCs, selected because sufficient material was available for study, and the immunohistochemical results are summarised in Table 3. The majority of TILs showed an intense CD8 immunoreactivity. CD8+ TILs varied from 0.3 to 118.7 cells per field, the mean

value being 25.5 and the median value being 14.6. The mean numbers of CD8+ TILs in MSI (21.7; range 2.1–56) and in MSS/EBV+ (69.6; range 26–118.7) GCs were significantly higher (*p*<0.001) than those found in MSS/EBV- cases (6.4; range 0.3–23.7).

A minimal number of TILs was composed of NK cells. The number of CD57+ TILs was significantly higher (*p*<0.01) in MSS/EBV+ (mean value 4.2) than in MSS/EBV- (mean value 0.8) or in MSI (mean value 3.1) GCs.

The presence of cytotoxic cells was confirmed by the expression of T-cell intracellular antigen (TIA-1) in the cytoplasmic granules in a considerable proportion of TILs. The mean number of TIA-1+ TILs was significantly higher in MSS/EBV+ (32.05; range 3–84.6) than that observed in MSS/EBV- (5.2; range 0–29.1; *p*<0.001) and MSI (16.7; range 0.4–59.5; *p*<0.05) GCs.

The activation status of TILs was assessed on the basis of immunoreactivity for granzyme B and perforin. The number of granzyme B+ TILs (Fig. 4) was significantly higher (*p*<0.001) in MSI and in MSS/EBV+ than in MSS/EBV- GCs (mean values 7.5 and 8.6, respectively, vs 0.8). Perforin+ TILs were also significantly more numerous in MSI GCs and in MSS/EBV+ than in MSS/EBV- tumours (mean values 5.9 and 9.2, respectively, vs 0.9; *p*<0.001 and *p*<0.05).

Apoptosis of tumour cells

To assess the apoptotic index of tumour cells, GCs were immunostained with the M30 CytoDEATH antibody that recognises a fragment of cytokeratin-18 cleaved by a caspase at the beginning of the apoptotic process. Tumour cells showed an intense and variable cytoplasmic M30 immunoreactivity in relation to the apoptotic stage of the

cell (Fig. 5). At the beginning of the apoptotic process, in cells which were still histologically normal, the immunoreactivity was distributed throughout the cytoplasm, whereas in damaged cells, the immunoreactivity was localised in granules, which varied in size and number, within the cytoplasm.

The distribution of M30 immunoreactive tumour cells differed among the various tumours; in some cases, M30+

Fig. 6 Failure time according to CD3+ TILs [relative risk 2.03; log-rank chi-square 6.38 ($p=0.0115$)]

cells were dispersed throughout the tumour, while in other cases, they were localised near necrotic areas or within the glandular lumens. The mean percentage of M30+ cells varied from 0.05 to 29.2% (Table 3). M30+ cells were more frequent in MSI and in MSS/EBV+ than in MSS/EBV- GCs (mean percentages 5.9 and 2.9, respectively, vs 2.3; $p<0.01$).

Necrotic areas and intraglandular abscesses, frequently observed in MSS/EBV+ GCs, were always M30-negative.

Correlation with survival

A univariate analysis (Table 4) revealed that the low-tumour stage ($p<0.0001$), the absence of node metastases (pN , $p<0.0001$), the low depth of tumour invasion (pT , $p<0.0003$), the intestinal type ($p=0.04$), the presence of MSI ($p=0.02$) and high numbers of CD3+ TILs and CD8+ TILs correlated with survival. In particular, carcinomas with CD3+ TILs higher than 14.9 (Fig. 6) and CD8+ TILs

higher than 9.5 (Fig. 7) were associated with a significantly improved survival ($p=0.01$ and $p<0.05$, respectively).

The presence of intratumoural CD8+ activated lymphocytes (perforin >1.5 and granzyme B >1.75) was also statistically significant ($p<0.01$).

On the basis of a Cox regression analysis, only a low tumour stage ($p<0.00001$) and a high number of CD3+ TILs ($p=0.02$) were identified as independent prognostic factors (Table 5).

Discussion

Abundant TILs seem to be associated with a more favourable prognosis in various malignancies, including melanomas and breast, renal, colorectal and GCs [12, 25, 27, 38, 42]. Tumour-associated lymphocytes show oligoclonal expansion [13], exhibit tumour-specific cytotoxic activity in vitro [32] and recognise tumour-specific antigens [17, 29, 33].

The prognostic significance of lymphocytic infiltration in gastric cancer was first emphasised by MacCarty and Mahle [21]. In 1976 Watanabe and colleagues [39] ob-

Fig. 7 Failure time according to CD8+ TILs (relative risk 2.09, log-rank chi-square 4.92 ($p=0.0265$)]

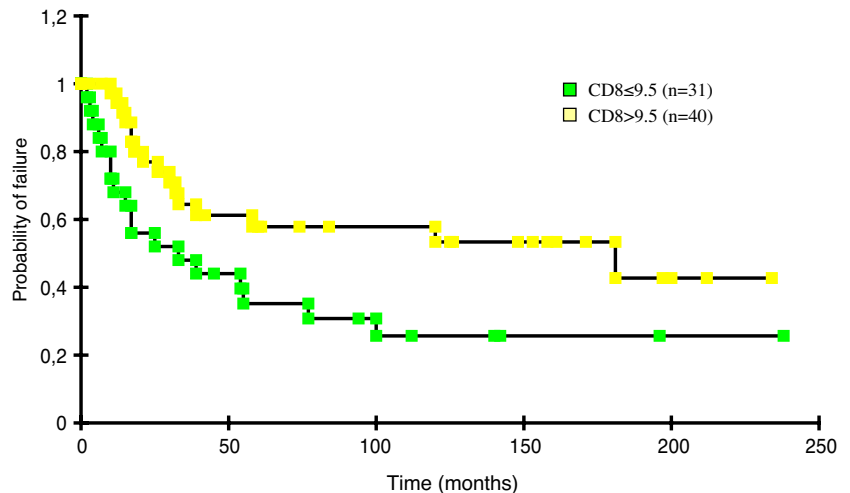

Table 5 Multivariate Cox proportional-hazard analysis of overall survival

Feature	Beta	Standard error	Z value	p value	EXP (beta)	Partial first derivate
Stage	0.7538	0.1544	4.881	0.00001	2.1251	1.53E-05
MSI status	0.2789	0.3454	0.8077	0.2096	1.321	4.77E-06

CD8+ TILs	0.1326	0.4538	0.2923	0.385	1.1418	6.68E-06

served a high survival rate among patients with GCs with lymphoid stroma. With the aim of evaluating the prognostic significance of TILs, we selected, from a series of consecutive GCs, those showing abundant lymphoid infiltration. The MSS/EBV⁻ and MSS/EBV⁺ groups were enriched in number to be better comparable. Our study, with the limit that our cases were partly selected, seems to indicate that the presence of intratumoural T cells correlates with the clinical outcome of advanced gastric cancer after apparently radical surgery. In a series of 96 patients with advanced GCs, cancer-specific survival of patients appeared to be increased by a factor of approximately 2 if more than 14.9 CD3+ TILs or more than 9.5 CD8+ TILs were present per high-power microscopic field. A univariate analysis showed that, in addition to clinico-pathological parameters including stage, lymph node status, depth of tumour invasion, histological type and MSI status, TIL count was significantly correlated with patient survival. A Cox regression analysis confirmed TILs as an independent prognostic factor together with stage.

Two types of GCs are characterised by a large number of TILs: the MSI- and the EBV-associated GCs [16, 28, 34, 37].

Like patients with sporadic MSI colorectal cancers [8, 11, 40], patients with sporadic MSI GCs apparently have a better survival rate than patients with MSS tumours [34, 41]. EBV-positive GCs have sometimes been associated with a survival advantage [5, 16, 36]. However, in 1994, Nakamura et al. [26] observed that, among GCs with lymphoid stroma, there was no significant difference in the 5-year survival rate between cases with EBV-positive and EBV-negative GCs.

The molecular characteristics of tumours that elicit an enhanced immune response are unclear, but the increased production of abnormal peptides seems to be the more probable hypothesis to explain this phenomenon. In patients with MSI colorectal carcinomas with abundant T-cell infiltration, Ishikawa et al. [15] demonstrated the production of specific antibodies against an abnormal fragment of CDX2 protein found in tumour tissue. The aberrant protein is produced by a frameshift mutation in the microsatellite sequence of the CDX2 coding region. This study seems to support the hypothesis that, in MSI tumours, the alteration of the mismatch repair system is responsible for the production, by tumour cells, of abnormal tumour-specific peptides which recruit lymphocytes in the tumour and induce an immune response.

A similar mechanism can operate in EBV-positive tumours, where the recruitment of TILs could be the consequence of the production by a virus, via tumour cells, of abnormal peptides, although this hypothesis has not

been demonstrated yet. As a matter of fact, in their paper, Kuzushima and colleagues [18] observed that CD8-infiltrating lymphocytes did not recognise EBNA-1 and BRAF antigens produced by tumour cells.

The nature and the activation status of TILs in our cases of GCs seem to be similar to that observed by Dolcetti et al. [7] in MSI colorectal carcinomas. In both MSS/EBV⁺ and MSI GCs, the majority of TILs was represented by cytotoxic CD8⁺ cells. A minor component of TILs was represented by NK CD57⁺ cells. Cytotoxic effector CD8⁺ and NK cells are characterised by the presence of TIA-1 immunoreactive granules in their cytoplasm, independently of their activation status. TIA-1 protein is crucial for DNA fragmentation and the apoptotic process [1]. In our study, the mean value was significantly higher in MSS/EBV⁺ and MSI than in MSS/EBV⁻ GCs.

The production and secretion of granzyme B and perforin are indispensable for the activation of cytotoxic and NK lymphocytes. In the presence of Ca⁺⁺, the monomers of perforin are released by the killer lymphocytes and inserted into the membrane of target cells, where they form membrane pores which promote the entry of cytolytic enzymes, in particular, TIA-1 and granzyme B [20]. Granzyme B is a granule-associated serine protease that triggers the apoptotic cascade, probably by activating caspases 10, 3 and 7 [9].

Both perforin⁺ and granzyme B⁺ TILs were significantly more numerous in MSS/EBV⁺ and MSI than in MSS/EBV⁻ GCs, suggesting that the activation of cytotoxic cells is a specific event priming the apoptotic process in MSS/EBV⁺ and MSI GCs.

The M30 monoclonal antibody identifies epithelial apoptotic cells and has been previously used by Michael-Robinson et al. [24] to evaluate the apoptotic index in MSI colorectal carcinomas. This antibody binds to the caspase-cleaved fragment of cytokeratin-18 during the early steps of epithelial cell apoptosis. The demonstration that apoptosis of neoplastic cells was significantly more frequent in MSI (5.87%) and in MSS/EBV⁺ (2.95%) than in MSS/EBV⁻ (2.26%) GCs supports the hypothesis that, in these tumours, TILs play a crucial role in the increased apoptotic cell death of neoplastic cells.

As for the difference between MSI and MSS/EBV⁺ GCs, it is worth noting that, although CD3⁺, CD8⁺ and TIA-1⁺ TILs were significantly higher in MSS/EBV⁺ than in MSI GCs, the percentage of activated TILs, as well as the apoptotic index of tumour cells, were not significantly different between the two subsets of GCs. These data might explain the absence of a significant difference in prognosis between patients with MSS/EBV⁺ and MSI GCs.

In our study, the prognosis of MSS/EBV+ cases appears to be better than that of MSS/EBV- cases, although the difference is not statistically significant. In addition, the prognosis of patients with MSI+ GCs appears to be better than that of patients with MSS/EBV+ GCs. Previous studies examining the correlation between survival and EBV infection in GCs did not consider the MSI status [5, 16, 22] with the exception of that of Grogg et al. [10]. In this context, it is important to underline that in our study, all the MSI GCs are EBV-negative, in agreement with the findings of previous investigations [6, 10]. In addition, our results confirm that MSI GCs are associated with a significantly better prognosis than that of the MSS GCs, and particularly, of MSS/EBV- GCs.

In conclusion, our study demonstrates that the presence of a high number of CD3+ TILs is a favourable prognostic factor, independently of the pathogenesis of GCs. EBV-positive and MSI GCs are two subsets of tumours characterised by a similar intratumour lymphocytic infiltration prevalently composed of activated cytotoxic CD8+ cells. The relatively better prognosis of these subsets of GCs seems to be related to the increased host immune response against abnormal peptides, probably produced by the virus infection or by the presence of an altered mismatch repair system.

Nuclear translocation of H2RSP is impaired in regenerating intestinal epithelial cells of murine colitis model

Received: 25 May 2005 / Accepted: 15 August 2005 / Published online: 28 September 2005
© Springer-Verlag 2005

Abstract Hepatocyte growth factor activator inhibitor type 2-related small peptide (H2RSP) is a recently identified nuclear peptide that is abundantly expressed in the gastrointestinal tract. In this study, we analyzed the expression of H2RSP in normal and injured intestinal mucosa in a murine experimental colitis induced by oral administration of 2.5% dextran sodium sulfate. Results of immunohistochemistry and in situ hybridization showed that H2RSP was expressed predominantly in the epithelium of normal intestine. Whereas H2RSP was localized in the cytoplasm of cells in the crypt, it was translocated into the nuclei of the surface epithelial cells. In injured intestine, H2RSP was detected in the cytoplasm of regenerating epithelial cells, and the nuclear translocation was impaired even in the surface epithelium. However, the mRNA level was not significantly altered in these cells by real-time reverse transcription–polymerase chain reaction using total RNAs obtained from the fractionated mucosal tissue samples prepared by laser-captured microdissection technique. On the other hand, H2RSP mRNA was significantly upregulated in the stromal cells of injured intestinal mucosa compared with those in normal mucosa, which shows cytoplasmic localization of H2RSP. These circumstantial evidences suggest that the nuclear translocation of H2RSP may be related to a signaling involved in the transition from cellular proliferation to differentiation.

Introduction

Hepatocyte growth factor (HGF) activator inhibitor type 2 (HAI-2)-related small peptide (H2RSP) is a small nuclear peptide recently identified during the search for splicing variant forms of human HAI-2 [3]. HAI-2 is a Kunitz-type serine proteinase inhibitor that regulates the activity of HGF activator (HGFA), a serine proteinase responsible for proteolytic processing of immature single-chain HGF into mature two-chain HGF [2, 5, 6]. Chimeric mRNA was transcribed from *HAI-2* and *H2RSP* genes in some human tissues [3], but it was not detected in any mouse tissues even by a sensitive reverse transcription–polymerase chain reaction (RT-PCR) analysis [10]. Thus, it is unlikely that H2RSP is directly involved in the regulation of HGF activation, at least in mice, and so far, biological roles of H2RSP have been poorly understood. H2RSP is identical to immortalization-upregulated protein-1 (IMUP-1), which was identified as one of the mRNAs upregulated in SV40-immortalized fibroblasts compared with senescent fibroblasts [8]. Thus, H2RSP/IMUP-1 may have a role in cellular proliferation.

H2RSP mRNA was detected abundantly in various tissues including the gastrointestinal tissues, and the predicted amino acid sequence contained a potential nuclear localization signal (NLS) in the lysine-rich region of exon 4 [3, 10]. Transfection study and preliminary immunohistochemical analysis revealed that H2RSP was actually translocated into the nucleus in vitro and was detected in the nuclei of the differentiated surface epithelial cells of normal gastrointestinal mucosa [3, 10]. However, little is known regarding the function of H2RSP in the gastrointestinal epithelium. In this study, to obtain a better understanding of the role of H2RSP in the gastrointestinal epithelial cells, we investigated the expression and localization of H2RSP along with mucosal injury and subsequent regeneration phase by using a mouse model of experimental colitis.

Materials and methods

Induction of experimental colitis in mice

C57BL/6 mice were purchased from Charles River Japan (Atsugi, Japan) and kept on standard chow diet ad libitum in a specific pathogen-free condition. Mice matched for age (8–10 weeks), sex, and body weight (20–25 g) were used for all experiments, which were approved by the Animal Care Committee of University of Miyazaki. Experimental colitis was induced by oral administration of 2.5% (w/v) dextran sodium sulfate (DSS; mol. wt.=40 kDa; ICN Biomedicals, Aurora, OH) in drinking water as described previously [1, 4]. To assess the recovery after DSS-induced colitis, mice were treated with 2.5% DSS in drinking water for 7 days, and then drinking water was changed to distilled water without DSS for the following days. Mice were sacrificed by cervical dislocation under ether anesthesia 7, 10, 14, and 21 days after DSS administration.

Preparation of tissue samples

Mouse colorectal tissue was immediately removed after death and divided into two pieces. One piece was fixed in freshly prepared 4% paraformaldehyde in phosphate-buffered saline (PBS) for 16 h and then soaked in 10% sucrose in PBS for 1 h, 15% for 1 h, and 20% for 2 h. Frozen and paraffin sections 3 μ m thick were prepared for in situ hybridization (ISH) and immunohistochemistry, respectively. Another piece was immediately embedded in OCT compound (Sakura Fintek, Inc., Torrance, CA) and snap-frozen with liquid nitrogen. Frozen sections 5 μ m thick were prepared with a clean blade and mounted on glass slides coated with a thermoplastic membrane (Matsumani Glass Ind., Ltd., Osaka, Japan). They were fixed in 70% alcohol, stained briefly with Truidin blue, and processed for the laser-captured microdissection (LCM) of desired tissue elements as described below.

Preparation of anti-H2RSP antibody and immunoblot analysis

Glutathione *S*-transferase (GST)–human H2RSP (hH2RSP) fusion protein was produced using the pGEX expression vector (Amersham Pharmacia Biotech, Buckinghamshire, UK) and full-length hH2RSP cDNA and purified using glutathione Sepharose 4B according to the manufacturer's instructions. The recombinant hH2RSP was generated from GST–hH2RSP by digestion with PreScission protease (Amersham) and purified by the batch method using glutathione Sepharose 4B again. To evaluate the purity of recombinant hH2RSP, the sample obtained in each purification step was subjected to sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) using a 4–12% gradient gel under reducing condition. Anti-hH2RSP rabbit antiserum was raised against the finally purified recombinant hH2RSP, and then its IgG fraction [polyclonal antibody

(pAb)] was affinity purified. To confirm whether anti-hH2RSP also recognized mouse H2RSP (mH2RSP), immunoblot analysis was performed using GST–hH2RSP and GST–mH2RSP fusion proteins, which were prepared as described above. SDS-PAGE was performed under a reducing condition using 4–12% gradient gel. After electrophoresis, the proteins were transferred electrophoretically onto an Immobilon membrane (Millipore, Bedford, MA). After blocking the nonspecific binding sites with 5% nonfat dry milk in 50 mM Tris–HCl (pH 7.5), 150 mM NaCl, and 0.05% Tween 20, the membrane was incubated with anti-hH2RSP pAb diluted in buffer containing 1% bovine serum albumin (BSA) at 4°C overnight, followed by washing in the buffer three times and incubation with peroxidase-conjugated secondary antibody diluted in buffer with 1% BSA for 30 min at room temperature. The labeled proteins were visualized with a chemiluminescence reagent (PerkinElmer Life Sciences).

Immunohistochemical study

In addition to anti-hH2RSP pAb generated in this study, anti-human Ki-67 monoclonal antibody (mAb), namely, MIB-1, which cross-reacts with mouse Ki-67, was purchased from Immunotech Inc. (Westbrook, ME) to detect the proliferating epithelial cells. Deparaffinized and rehydrated serial sections were subjected to antigen retrieval by autoclaving for 5 min in 10 mM citrate buffer (pH 6.0). After treatment with 3% H₂O₂ in PBS for 10 min followed by washing in PBS twice, the sections were incubated with 3% BSA and 10% goat serum (DAKO, Carpinteria, CA) in PBS for 1 h at room temperature to block the nonspecific binding. Subsequently, the sections were incubated with anti-hH2RSP pAb (5 μ g/ml) or anti-Ki-67 monoclonal antibody (\times 50 dilution) in PBS/1% BSA at 4°C overnight. After washing in PBS three times, the sections were incubated with Envision-labeled polymer reagents (DAKO) for 15 min at room temperature. After washing in PBS three times, the sections were visualized with nickel/cobalt-3,3'-diaminobenzidine (ImmunoPure Metal-Enhanced DAB Substrate Kit; Pierce, Rockford, IL) and counterstained with Mayer's hematoxylin.

In situ hybridization

A 525-bp cDNA fragment corresponding to bases 9–533 of mH2RSP cDNA sequence was generated by a polymerase chain reaction (PCR) [10]. The PCR product was subcloned into pBluescript II SK(+) (Stratagene, La Jolla, CA). In vitro transcription was carried out to produce digoxigenin (DIG)-labeled riboprobes, according to the manufacturer's protocols (Roche Diagnostics GmbH, Penzberg, Germany). The sense-strand probe was used as a negative control. In situ hybridization was performed using a fully automated ISH system, Ventana's HX System Discovery, and RiboMap System (Ventana, Yokohama, Japan) according to the manufacturer's instructions. Briefly, after the pretreatment step

(fixation, acid treatment, and conditioning without protease treatment), the sections were applied for hybridization using 1 ng per slide of DIG-labeled probe at 65°C for 6 h. After the hybridization, signals were detected by biotin-labeled anti-DIG antibody. The reaction was detected with BlueMap Kit and counterstained with nuclear fast red.

LCM and following real-time RT-PCR analysis

Sections prepared as above were subjected to LCM using a Leica SVS LMD System (Leica Microsystems, Wetzlar, Germany). Under microscopic guidance, epithelial cells on the mucosal surface, epithelial cells at the crypt base, epithelial cells showing restitution, and interstitial cells were selectively dissected in normal, injured, and regenerating colorectal tissues by focal melting of the membrane through laser activation. Total RNAs were extracted from thickly sliced nonfixed frozen sections (10 $\mu\text{m} \times 5$ slices per tissue sample) by Trizol reagent (Life Technologies Inc., Gaithersburg, MD) according to the manufacturer's instructions. Alternatively, tissue fragments obtained by LCM were dropped by gravity into cap tubes filled with lysis solution of RNAqueous-Micro kit (Ambion Inc., Austin, TX) under microscopic inspection. For RT-PCR, 1 μg each of total RNA was reverse-transcribed by pd(N)₆ and pdT₁₂ mixed primers and SuperScript II reverse transcriptase (Life Technologies Inc.). The resulting cDNA was subjected to real-time PCR on a LightCycler with a master mix of LightCycler DNA master SyberGreen I (Roche Diagnostics, Mannheim, Germany) according to the manufacturer's instructions. The thermal cycle profile was 10 s at 95°C, 15 s at 65°C, and 12 s at 72°C for 40 cycles. Product amplification specificity was determined by melting curve analysis and agarose gel electrophoresis. The amount of mRNA per sample was expressed as percentage of control β -actin mRNA. Primer sequences of mH2RSP and mouse β -actin were as follows: mH2RSP forward primer, 5'-GTCTCTGGCAGCTCCTCCGA-3'; mH2RSP reverse primer, 5'-GGTTTCTTGGCCTTGTCTGA-3'; β -actin forward primer, 5'-AGAGGGAATCGTGCCTGAC-3'; β -actin reverse primer, 5'-CAATAGTGATGACCTGGCCGT-3'.

Statistical analysis

Data were presented as mean \pm SEM. Parametric data were analyzed using Student's *t* test. An associated probability (*p* value) of less than 0.05 was considered significant. All statistical analysis was performed with Statview 5.0 program (Brainpower Inc., Calabasas, CA).

Results

Expression of H2RSP in normal mouse intestine

We first confirmed that anti-hH2RSP pAb generated in this study also recognized mH2RSP by immunoblot analysis

(Fig. 1a). Immunoreacted bands were found in the lanes loading GST-hH2RSP (0.05 $\mu\text{g}/\text{lane}$) and GST-mH2RSP (0.1 $\mu\text{g}/\text{lane}$), whereas no positive band was found in the lane loading 5 μg of GST. Subsequently, immunohistochemical staining using this antibody was performed for mouse intestinal tissues. In normal murine small intestine (Fig. 1b) and colon tissues (Fig. 1c), H2RSP was localized mainly in the cytoplasm of the epithelial cells at the crypt base. These cells were also positive for MIB-1, suggesting proliferating epithelial cells (Fig. 1c, right). On the other hand, in the surface epithelial cells, which were considered as differentiated cells, H2RSP was mainly localized in the

Fig. 1 **a** Immunoblot analysis for confirmation of anti-hH2RSP pAb cross-reactivity to mH2RSP. Immunoreacted bands were found in the lanes loading GST-hH2RSP (lane 2; 0.05 $\mu\text{g}/\text{lane}$) and GST-mH2RSP (lane 3; 0.1 $\mu\text{g}/\text{lane}$), whereas no positive band was found in the lane loading 5 μg of GST (lane 1). SDS-PAGE stained by Coomassie brilliant blue (upper panel) followed by Western blot analysis (lower panel). **b** Immunohistochemical staining of H2RSP for normal mouse small intestine. H2RSP was localized mainly in the cytoplasm of the epithelial cells in the crypt base (arrows) and in the nuclei of the surface epithelium. **c** Immunohistochemistry for normal colon. Similar to small intestine, H2RSP was localized in the cytoplasm of the epithelial cells in the crypt (arrows), which were positive for MIB-1 representing proliferating cells, and in the nucleus of the surface epithelial cells, which were negative for MIB-1 representing mature differentiated cells. **d** In situ hybridization of normal colon. H2RSP mRNA was detected in the epithelial cells of the lower part of the crypt by ISH. Negative control (sense-strand probe) is also shown in the inset

nuclei (Fig. 1b,c). These immunostaining patterns were essentially similar to those observed in human tissues (Uchiyama et al., manuscript in preparation), indicating the cross-reactivity and specificity of the antibody used in this study. In situ hybridization analysis also confirmed the existence of H2RSP mRNA in the epithelial cells, and the signal appeared to be stronger in the cells in the lower part of the crypt (Fig. 1d). These results indicated that H2RSP was expressed by the intestinal epithelial cells, localized in the cytoplasm of the cells in the crypt, and translocated gradually into the nuclei of surface epithelial cells possibly along with the cellular differentiation.

Expression of H2RSP in injured and regenerating intestinal mucosa

To assess the *in vivo* role of H2RSP in the intestinal mucosa, we used a murine experimental model of colitis induced by oral administration of 2.5% DSS for 7 days and examined the patterns of H2RSP expression during the course of the colitis from acute ulcerating phase to regenerating phase. Figure 2 showed representative histological findings of the colonic mucosa 7, 10, 14, and 21 days after the start of oral DSS administration. On day 7 (termination of DSS administration; Fig. 2a), mucosal ulceration and infiltration of various inflammatory cells were seen throughout the colon, although focal epithelial restitution was also noted. Then, the repair of ulcerated mucosa was gradually observed on days 10 and 14 (3 and 7 days after the termination of DSS treatment, respectively). On day 10 (Fig. 2b), epithelial restitution was almost completed, and the mucosal structure was partly repaired. Proliferation of fibroblastic cells and infiltration of inflammatory cells were also seen. On day 14 (Fig. 2c), the mucosa was almost regenerated, although depletion of goblet cells and infiltration of chronic inflammatory cells were still observed in the mucosa. On day 21 (14 days after the termination of DSS treatment; Fig. 2d), the mucosa was completely regenerated, and the histological

feature was not distinguishable from those of normal colonic mucosa, except for mild destruction of the crypts.

Immunohistochemically, accumulation of H2RSP was observed in the cytoplasm (but not in the nucleus) of the regenerating epithelial cells showing restitution on day 10 (Fig. 3a). On day 14, in the late phase of regeneration, the nuclear localization of H2RSP became evident, showing nuclear H2RSP immunoreactivity in two thirds to three fourths of the surface epithelial cells. Some goblet cells were observed, which also showed nuclear localization of H2RSP (Fig. 3b). On day 21, most surface epithelial cells showed nuclear localization of H2RSP (Fig. 3b). Interestingly, interstitial cells of the injured mucosa, which were mainly infiltrating inflammatory cells and proliferated myofibroblastic cells, also showed positive immunoreactivity of H2RSP (Fig. 3a). In these interstitial cells of injured mucosa, H2RSP was localized predominantly in the cytoplasm, whereas only weak nuclear staining was observed in the mononuclear cells in normal mucosa (Fig. 3c). In situ hybridization revealed strong expression of H2RSP mRNA in regenerative epithelial cells on day 10, even on the mucosal surface, as well as in the stromal cells on day 7 (Fig. 3d). These results indicated that H2RSP was upregulated in injured and regenerating mucosa and that the nuclear translocation of H2RSP was impaired in the regenerative epithelial cells and in the proliferating and/or infiltrating stromal cells.

Real-time RT-PCR analysis for H2RSP mRNA expression during DSS-induced mouse colitis

We then performed a quantification analysis of H2RSP mRNA on each designated day along with the course of DSS-induced colitis by real-time RT-PCR (Fig. 4a). Total expression level of H2RSP mRNA was significantly increased on days 7 and 10 ($p < 0.005$, compared with control) when the inflammatory reactions were obvious and subsequent regenerative processes were gradually undergoing in the mucosa. This upregulation of H2RSP was not ob-

Fig. 2 Histology of colonic mucosa 7 (a), 10 (b), 14 (c), and 21 (d) days after the start of oral DSS administration. On day 7 (termination of DSS administration), mucosal ulceration with infiltration of various inflammatory cells was seen throughout the colon, although focal epithelial restitution was also noted. Mucosal ulceration was gradually recovered on days 10 and 14 (3 and 7 days after the termination of DSS treatment, respectively). On day 21 (14 days after the termination of DSS treatment), the mucosa was completely regenerated, and the histological feature was not distinguishable from those of normal colonic mucosa

Fig. 3 Immunohistochemistry (a–c) and ISH (d) of H2RSP in injured and regenerating mucosal tissue after DSS administration. Upregulation and accumulation of H2RSP were observed in the cytoplasm (but not in the nucleus) of the epithelial cells showing restitution and regeneration 3 days after the termination of DSS administration (day 10; a). On day 14 (7 days after the termination of DSS administration), considerable regeneration had occurred, and the nuclear localization of H2RSP became evident. Some goblet cells were observed showing nuclear localization of H2RSP. However, part of the surface epithelial cells still showed the cytoplasmic localization (b). On day 21, most surface epithelial cells showed nuclear localization of H2RSP (b). On day 7 (termination of DSS administration), interstitial cells, mainly infiltrating inflammatory cells and myofibroblastic cells in the injured mucosa, were also positively stained with H2RSP (a). These stromal cells showed cytoplasmic H2RSP localization (c). In situ hybridization revealed strong expression of H2RSP mRNA in regenerative epithelial cells even on the surface and in the stromal cells in injured mucosa (d)

served on day 14, when mucosal regeneration had been almost completed, and the mRNA level of H2RSP was comparable with that of normal control. We next examined

the mRNA levels of H2RSP in fractionated samples of mice with (day 10) and without (control) DSS treatment. By using LCM, epithelial cells on the surface of mucosa, those in the crypt, those showing restitution, and mucosal stromal cells were obtained separately, and total RNA was prepared

Fig. 4 a Real-time RT-PCR analysis of H2RSP mRNA expression during the course of DSS-induced colitis. Total expression level of H2RSP mRNA was significantly increased on days 7 and 10, when the regenerative processes were undergoing and inflammatory reaction was seen in the mucosa. This upregulation of H2RSP disappeared on day 14, when mucosal regeneration was almost complete, and the mRNA level of H2RSP was comparable with that of normal control. * $p=0.004$, ** $p=0.002$, *** $p=0.003$, **** $p=0.003$. b Agarose gel electrophoresis of RT-PCR for H2RSP mRNA expression in fractionated samples obtained by LCM. Note that the band representing mRNAs of the interstitial cells was detectable in the regenerative but not in normal mucosa. S Epithelial cells on the mucosal surface, C epithelial cells in the crypt, I interstitial cells. c Real-time RT-PCR analysis of H2RSP mRNA expression in fractionated samples obtained by LCM. The expression level of mH2RSP mRNA was modestly increased in regenerative epithelial cells, both on the surface and in the crypt, but the differences were not statistically significant. The epithelial cells showing restitution do not show enhanced H2RSP mRNA expression. On the other hand, the H2RSP mRNA level of stromal cells was significantly upregulated in regenerative and inflamed mucosa compared with normal control mucosa. * $p=0.004$

from each fraction. Then the expression level of H2RSP mRNA was analyzed in each sample (Fig. 4b,c). The mRNA levels of H2RSP were modestly increased in regenerated epithelial cells compared with corresponding epithelial cells of normal mucosa; however, the differences were not statistically significant. The epithelial cells showing restitution did not show altered level of H2RSP mRNA compared with the normal surface epithelium. However, the mRNA level in the mucosal stromal cells was significantly upregulated in the regenerating mucosal tissue compared with normal control mucosa ($p < 0.005$). Therefore, a large proportion of increased H2RSP mRNA in the regenerating and inflamed mucosa was derived from the reactive stromal cells.

Discussion

In this study, we analyzed the subcellular localization of H2RSP in normal, injured, and regenerating intestinal tissues using a murine experimental colitis model. Immunohistochemically, H2RSP was localized in the cytoplasm of the proliferating epithelial cells at the crypt base and then translocated into the nuclei of the mature and differentiated epithelial cells at the surface. Of particular interest was the observation that this nuclear translocation was significantly impaired in the regenerating epithelium, showing epithelial restitution as well as cellular proliferation. Therefore, it is intriguing to speculate that the nuclear translocation of H2RSP in the intestinal epithelial cells serves as a signal for the transition from proliferating phase to growth arrest followed by terminal differentiation. In situ hybridization study showed that H2RSP mRNA was strongly detectable in the MIB-1-positive proliferating epithelial cells in the crypt in normal intestine, and the surface-differentiated epithelial cells showed less amounts of H2RSP mRNA. However, real-time RT-PCR analysis revealed that comparable amounts of H2RSP mRNA were also present in the surface-differentiated epithelial cells. We assumed that hybridization of riboprobe to the cellular mRNA may be interfered with in some fashion by mucin produced by the goblet cells of the mucosal surface. Indeed, strong ISH signal was observed in the surface epithelial cells of the regenerating mucosa, in which goblet cells were severely depleted.

In addition to the epithelial cells, the stromal cells of injured mucosa, but not of normal mucosa, also expressed H2RSP abundantly. In DSS-induced colitis, the levels of H2RSP mRNA were significantly increased on days 7 and 10, and most of the increased mRNA in these mucosal tissues appeared to be derived from the stromal cells. Morphologically, these H2RSP-expressing stromal cells were infiltrated inflammatory cells and proliferating fibroblastic (myofibroblastic) cells. In this regard, IMUP-1, an identical peptide with H2RSP, has been identified as one of the mRNAs upregulated in SV40-immortalized fibroblasts compared to senescent WI-38 fibroblasts [8]. This characteristic of IMUP-1 may be consistent with our present observation that H2RSP was upregulated in proliferating fibroblastic cells in response to tissue injury. Notably,

H2RSP was localized in the cytoplasm of these interstitial cells, but not in the nuclei. Therefore, H2RSP might be upregulated in various types of cells showing proliferation and/or active migration accompanying its confined localization in the cytoplasm.

H2RSP is a small peptide containing the effective bipartite basic type NLS in the lysine-rich region of exon 4 [3, 10]. However, no apparent motif of known nuclear proteins interacting with DNA homologous to the predicted amino acid sequence of H2RSP was found in the NCBI database. Thus, it is unlikely that H2RSP directly interacts with nuclear DNA, and the precise function of H2RSP in the nucleus remains unclear at present. H2RSP may interact with ribosomal RNA because H2RSP was especially located in the nucleolus [3, 10], and IMUP-1, a peptide homologous to H2RSP, indeed bound to poly r(G) in vitro [8]. Recently, it has been shown that most of the genes involved in cellular proliferation, RNA splicing and transport, and protein translation are downregulated along with the maturation of colonic epithelial cells by gene expression profiling [9]. H2RSP may be a promising additional candidate for the signaling molecule involved in the transition from proliferation to terminal differentiation and growth arrest in gastrointestinal epithelial cells, acting in the nucleus, having a reciprocal function to the proliferation-initiating molecule such as musashi-1, an RNA-binding protein expressed in stem and early-lineage progenitor cells in mouse intestinal epithelial cells [7, 11, 12].

Fig. 5 Schematic of H2RSP immunolocalization and immunoreactivity in normal and injured mucosal tissues of murine intestine. Localization and intensity of H2RSP immunoreactivity are indicated as a gradation of gray to black shading. In normal intestinal epithelium, H2RSP is translocated into the nucleus along with the differentiation of epithelial cells (*left*). This nuclear translocation is impaired in regenerating epithelial cells showing restitution and proliferation, and the regenerated epithelial cells show increased intensity of H2RSP immunoreactivity (*right*). H2RSP is also upregulated in reactive stromal cells of injured mucosa, which also shows confined cytoplasmic localization in these cells

The summary of H2RSP immunolocalization in normal and injured intestinal mucosa is shown in Fig. 5. In normal intestinal epithelium, H2RSP is present in the nuclei of differentiated surface epithelial cells, whereas its subcellular localization is confined in the cytoplasm in the crypt base. Therefore, H2RSP may be translocated into the nucleus along with the differentiation of epithelial cells. In injured mucosa, the nuclear translocation of H2RSP is impaired in epithelial cells, and these cells undertake subsequent restitution and regeneration. These circumstantial evidences suggest a possible role of nuclear translocation of H2RSP in a signal related to the transition from proliferation to differentiation of intestinal epithelial cells. H2RSP is also upregulated in interstitial cells, such as proliferating fibroblastic cells and infiltrating inflammatory cells, in response to mucosal injury, and H2RSP shows preferred cytoplasmic localization in these reactive stromal cells as observed in the regenerating epithelial cells. To clarify the mechanism underlying the nuclear translocation of H2RSP and its precise function in the nucleus, further detailed experiments are underway in our laboratory.

Marginal zone lymphoma of the lacrimal gland spreading to the lung and the bone marrow 11 years after first symptoms

Received: 5 August 2005 / Accepted: 23 September 2005 / Published online: 17 November 2005
© Springer-Verlag 2005

Abstract We report on the case of a 52-year-old male presenting with an extranodal marginal zone lymphoma of the mucosa-associated tissue (MALT lymphoma) in the lung 11 years after radiotherapy for a MALT lymphoma of the lacrimal gland, which was primarily diagnosed as dacryoadenitis. Both tumors were investigated by immunohistochemistry and molecular techniques demonstrating their clonal genetic relationship. Both harbored the t(14;18)(q32;q21) and a trisomy 3 and showed identical immunoglobulin heavy-chain gene rearrangements. At the time of pulmonary relapse, clonal CD20- and CD43-positive bone marrow B lymphocytes were detected as well. The elaboration of this case emphasizes the importance of the combined use of modern diagnostic methods for establishment of correct diagnosis of MALT lymphomas at late relapses, which is essential for proper patient management.

Keywords MALT lymphoma · Tear gland · Lung · Late relapse · t(14;18)(q32;q21) · Trisomy 3

Introduction

Lymphomas arising in the ocular adnexa, including the conjunctiva, eyelid, lacrimal gland, and orbit, are infrequent and account for approximately 8–12% of all ocular adnexal tumors [3, 7, 8, 10, 18]. They represent the malignant counterpart of a spectrum of ocular adnexal lymphoproliferative lesions [3, 9, 10]. The extranodal marginal zone B-cell lymphoma of mucosa-associated tissue (MALT lymphoma) represents the most common lymphoma subtype at this site and shows a rising incidence in the last decade [1, 3, 13]. Usually, MALT lymphomas have an indolent clinical course but, especially nongastric ones, frequently recur and, occasionally, transform into an aggressive disease [7, 8, 10, 15, 18, 19]. Thus, a closed lifelong follow-up with half-yearly examinations is currently recommended [15]. Late recurrences of MALT lymphoma are mainly documented on a single-case basis, with cases insufficiently studied at the molecular level [2, 4, 12, 19]. Recently, the thus far best-proved follow-up cohort of 86 MALT patients with 37% relapses observed within a median observation period of 47 months was published [15]. Interestingly, these patients did not show evidence for a cytogenetic progression in the recurrent lesions [15].

Here, we report an additional molecularly documented case of MALT lymphoma of the lacrimal gland that recurred after more than 130 months. Recurrence of MALT lymphoma of the lacrimal gland after such a long interval has never been reported before.

Clinical history

In 1994, a 41-year-old male patient was admitted to the ENT unit of our hospital for swelling of the upper eyelid and exophthalmia on the left side. The biopsy performed at

Fig. 1 Computerized imaging of the thorax showing large opacity in the upper left lung lobe and additional smaller lesions in both lungs

that time showed a “lymphoepithelial dacryoadenitis.” An underlying MALT lymphoma was also discussed, but the lymphoid cells did not immunohistochemically show a clear-cut clonal light-chain restriction, so that a reactive process was favored. The patient was successfully treated with steroids, but the symptoms recurred after taking off the treatment. Then, radiotherapy was performed (cumulative dose 20 Gy) leading to complete remission. In 2004, the patient was planned to undergo reconstructive vascular surgery due to peripheral arterial occlusive disease grade II. The patient reported nicotine abuse of 60 pack years and complained about a productive cough for 1 month. A 3×5-cm large opacity in the upper left lung lobe was discovered on a routine chest x-ray. Further evaluation by CT showed additional smaller lesions in both lungs (Fig. 1). Nodal status, laboratory findings, and ^{18}F -fluorodeoxyglucose positron emission tomography (PET) were inconspicuous. Multiple CT-guided percutaneous large-core biopsies of the pulmonary nodule were performed with a 16-gauge

cutting needle with 2.2-cm cutting length inserted into a 15-gauge coaxial needle as described [11]. Pulmonary recurrence of a MALT lymphoma of the lacrimal gland was diagnosed (see “Results”). The patient was given a combined radiochemotherapy with fludarabine and involved-field irradiation. At the time of last control (June 2005), he was in complete remission.

Methods

Immunohistochemistry

Four-meter-thick sections from the formalin-fixed paraffin-embedded tissue samples were immunohistochemically analyzed using an automated immunostainer (Nexes, Ventana, Tucson, AZ, USA). The streptavidin–biotin–peroxidase technique with diaminobenzidine as chromogen was applied. The primary antibodies were diluted in 1% solution of bovine serum albumin in phosphate-buffered saline (pH 7.4) and incubated for 30 min at room temperature. The primary antibodies, their dilutions, and pretreatment conditions are listed in Table 1.

Fluorescent in situ hybridization analysis

Formalin-fixed paraffin-embedded tissue was used for fluorescent in situ hybridization (FISH). For a reliable interpretation of the hybridization signals, we preferred analysis of single-cell suspensions to thin sections [16]. FISH was performed on interphases with the following probe sets: for rearrangements of *BCL10*, BACs RP11-1077C10 and RP11-36L4 (SpectrumGreen) centromeric to *BCL10* and RP11-1080I1 and RP11-40K4 (SpectrumOrange) telomeric to *BCL10*; and for the detection of translocations of *MALT1*, dual-color break-apart rearrangement probes (Vysis, Downer’s Grove, IL, USA). As a result of this probe design, any translocation of *MALT1* should produce separate orange and green signals. For the iden-

tification of the t(14;18)(q32;q21) involving the immunoglobulin heavy-chain *IGH* and *MALT1* genes, P1 artificial chromosome (PAC) 152M5 (SpectrumOrange-labeled) spanning the *MALT1* gene and flanking regions and bacterial artificial chromosome (BAC) 158A2 were used [16]. For the detection of trisomies 3 and 18, we applied centromere-specific probes for the chromosomes 3 (SpectrumOrange) and 18 (SpectrumGreen) (Vysis).

Detection of t(11;18) by reverse transcription-polymerase chain reaction

RNA was isolated from archival formalin-fixed paraffin-embedded lymphoma tissues. Total RNA was extracted from 10- μ m sections. First-strand cDNA synthesis and reverse transcription-polymerase chain reaction (RT-PCR) for the detection of the *API2-MALT1* fusion transcript were performed as described elsewhere [17].

Clonality analysis

DNA extraction from the formalin-fixed paraffin-embedded tissue samples from the lung, bone marrow, and lacrimal gland as well as analysis of *IGH* gene rearrangements was performed as described elsewhere [5].

Results

The core biopsies from the lung lesion showed a diffuse interstitial small lymphocytic infiltrate composed of centrocytoid, centroblastoid, and plasmacytoid cells surrounding the bronchioles and the vessels (Fig. 2). Partial destruction of the alveolar lung parenchyma and accumu-

Fig. 2 Detailed morphological view of the lung biopsy showing a diffuse, predominantly small lymphocytic infiltrate with occasional plasma cells and isolated blasts (e.g., lower left corner) with destruction of the preexisting parenchyma (H & E stain, $\times 400$)

Fig. 3 Immunohistochemical staining for CD20 displaying strong membranous positivity of the lymphoid infiltrate (streptavidin-biotin-peroxidase technique with diaminobenzidine as chromogene, $\times 200$)

lation of foamy macrophages were present as well. Immunohistochemically, the cells stained positively for CD20 (Fig. 3), CD43, IgM, and bcl-2 and remained negative for CD5, CD10, CD23, IgG, bcl-6, and cyclin D1. The plasmacytoid component was CD138 positive and κ -light-chain-restricted. The proliferation fraction (Ki-67) was 5%. The work-up of the primary tumor of the lacrimal gland revealed identical immunohistochemical results.

The biopsy specimens from the lacrimal gland and from the lung were analyzed by FISH for the presence of *MALT1* and *BCL10* rearrangements as well as for trisomies 3 and 18. Three hundred cells per biopsy (lung and ocular adnexa) were investigated. Signals for *BCL10* and centro-

Fig. 4 Fluorescent in situ hybridization with probes for *IGH* (green signals) and *MALT1* (red signals) demonstrating *IGH/MALT1* fusion (···) corresponding to t(14;18) involving *IGH* and *MALT1*. The t(14;18) was detected in the biopsies from the lung (2004) and the ocular adnexa (1994), $\times 1000$

mere 18 were inconspicuous. Centromere 3 probes revealed three signals in 166 out of 300 cells in the lung and 132 out of 300 cells in the ocular adnexa. In the FISH with probes flanking *MALT1*, a split signal indicating a rearrangement of *MALT1* was seen in both biopsies. RT-PCR was negative for the t(11;18) involving *API2* and *MALT1*. In contrast, FISH with probes for *IGH* and *MALT1* demonstrated *IGH/MALT1* fusion signals proving a t(14;18) in each lung (174/300 cells) and ocular adnexal (121/300 cells) biopsies. In conclusion, a t(14;18)(q32;q21) involving *IGH* and *MALT1* (Fig. 4) together with a trisomy 3 was detected in both biopsies of the patient. This constellation pointed to the presence of the same clone (see also next paragraph) in both the primary MALT lymphoma of the lacrimal gland and the lung lesion 11 years after the initial diagnosis.

Interstitial small CD20- and CD43-positive B-cell lymphocytosis in the bone marrow harboring the same *IGH* gene rearrangement as suggested by the identical pattern of PCR products migration in the polynat gel as the pulmonary lesion and the lacrimal gland was detected in the staging trephine biopsy from 2004. The gastric and colic biopsies were inconspicuous.

Discussion

Lymphoid proliferations of the ocular adnexa are categorized in reactive lesions such as reactive lymphoid hyperplasia and atypical lymphoid hyperplasia as well as lymphomas such as MALT lymphoma. They cannot be diagnosed accurately based solely on clinical and imaging criteria [1, 3, 7]. In the past, many of these lesions were considered benign based on their low-grade histological features. However, by the recognition of MALT lymphoma [7] and applying modern molecular techniques, many lymphocytic proliferations formerly classified as benign or atypical lymphoid hyperplasia would now be diagnosed as MALT lymphoma [1]. Immunohistochemistry, flow cytometry, and in situ hybridization for light-chain restriction and PCR analysis of *IGH* rearrangements, as in the present case, proved to be very helpful in achieving a more accurate diagnosis. Meanwhile, distinct recurrent chromosomal aberrations in MALT lymphomas are recognized such as, e.g., t(11;18)(q21;q21) in gastric marginal zone lymphomas [16]. There is a correlation between the presence of a specific translocation and anatomical site of the MALT lymphoma [17]. In gastric and pulmonary lymphomas, t(11;18)(q21;q21) can be predominantly identified, whereas t(14;18)(q32;q21) is most commonly found in lesions of the ocular adnexa, salivary glands, and skin [17]. Concomitantly, t(11;18)(q21;q21) in MALT lymphomas of the ocular adnexa seem to be rare [17]. Numerical aberrations such as trisomies 3 or 18 occur most frequently in MALT lymphomas of the intestine and salivary glands [17] but can be found beside t(14;18)(q32;q21) in ocular MALT lymphomas as well [16]. This distribution of distinct translocations at different anatomical sites is supported by the

findings in our patient. In 2004, he suffered from a MALT lymphoma in/of the lung carrying a t(14;18)(q32;q21) and a trisomy 3, a constellation rather not typical for a primary pulmonary MALT lymphoma. Indeed, 11 years before, he was diagnosed to suffer from steroid-treatment-resistant lymphoepithelial dacryoadenitis, showing on reevaluation the same chromosomal aberrations as the pulmonary lymphoma. Nevertheless, the initial misinterpretation did not prevent a correct clinical management. Since the lacrimal gland lesion recurred after withdrawal of steroids, the patient was given radiotherapy leading to complete remission. Interestingly, at the time of recurrence, a PET was performed but the pulmonary lesions remained silent, a constellation rather typical for marginal zone lymphomas [6], so that the correct diagnosis was established by means of morphological analysis supported by modern molecular techniques. Even more, we identified virtually identical clonal *IGH* rearrangements in the pulmonary and lacrimal lesions and a suspicious interstitial CD20- and CD43-positive small bone marrow lymphocyte population at the time of recurrence. Importantly, this finding was critically considered by the treating physicians when choosing a multimodal systemic (chemotherapy) and local (involved-field irradiation) therapy regimen.

Late recurrences in MALT lymphomas were till recently [15] poorly documented particularly at the molecular level being mainly single-case reports [2, 4, 12, 19]. The median period between first diagnosis and relapse reportedly varies between several months and decades [2, 4, 12, 15, 19]. In the present case, the late pulmonary recurrence of a primary MALT lymphoma of the lacrimal gland was diagnosed after 11 years, with both tumors harboring identical genetic aberrations. Similarly, late recurrences after more than 10 years have been accurately documented in only four cases of MALT lymphomas of the parotid gland as well of the stomach and lung [4, 15]. The reason for this behavior of MALT lymphomas is unclear but underlines their unpredictable course, probably due to higher rates of silent initial multiorgan spread [14]. Though mostly diagnosed at stage IE and often responding to unimodal therapy [12], ocular MALT lymphomas are malignant tumors that can recur even more than a decade after initial diagnosis and/or spread to other MALT organs and to the bone marrow. Our case study emphasizes the feasibility of modern histopathological diagnostic tools for proper diagnosis of MALT lymphomas at late relapses and underscores the importance of extensive staging, paying particular attention to other organs with MALT and bone marrow as well as lifelong follow-up in such patients, which is essential for their appropriate management.

Angiolymphoid hyperplasia with eosinophilia (epithelioid haemangioma) occurring within multiple deep lymph nodes and presenting with weight loss and raised CA-125 levels

Received: 9 October 2005 / Accepted: 11 October 2005 / Published online: 29 November 2005
© Springer-Verlag 2005

Abstract We report a case of angiolymphoid hyperplasia with eosinophilia (epithelioid haemangioma) involving multiple deep mediastinal, abdominal and intramammary lymph nodes in a 52-year-old woman with weight loss and raised CA-125 levels. The unusual clinical presentation with raised CA-125 levels and its occurrence within multiple deep visceral lymph nodes has never been reported in literature.

Keywords Epithelioid haemangioma · Raised CA-125 · Vascular lesion

Introduction

Epithelioid haemangiomas are circumscribed, superficial vascular lesions occurring in the dermis and subcutaneous tissue and clinically presenting as small red pruritic plaques [5]. Occasionally, they are reported in soft tissue, bone and vessels [3]. These lesions show specific histological features and carry a benign clinical behaviour [5].

Clinical history, material and methods and results

A 52-year-old woman presented with weight loss of approximately 6 kg over a period of 3 months. Clinical examination showed no significant findings, in particular,

she was afebrile and had no enlarged peripheral lymph nodes or hepatosplenomegaly. A detailed gynaecological examination showed no abnormality. She was a smoker and smoked ten cigarettes a day. Biochemical investigations showed a raised erythrocyte sedimentation rate of 80 and raised CA-125 levels, which initially measured 158 U/ml and later 190 U/ml (normal less than 35 U/ml). Haematological investigations showed a raised absolute eosinophil count of $4.26 \times 10^9/l$ (normal $0.65 \times 10^9/l$). Chest x-ray showed mediastinal widening. Computerised tomography (CT) scans showed numerous enlarged lymph nodes in the upper central mediastinum, paratracheal, subcarinal and right paracardiac regions (Fig. 1). The largest node measured up to 2.2×1.8 cm. A few smaller abdominal nodes were seen in the coeliac, peripancreatic and para-aortic areas, the largest node measured 1×1.8 cm. No pelvic abnormality was identified. The overall imaging findings suggested a lymphoma. Biopsies from the mediastinal and paratracheal lymph nodes were performed. Multiple tissue pieces measuring 13 and 15 mm in aggregate were received. Both biopsies comprised abundant varying sized proliferating vessels arranged in a fibrotic stroma with numerous incorporated eosinophils and few haemosiderin-containing histiocytes. The endothelial cells lining the vessels showed a striking epithelioid/histiocytoid morphology with large ovoid nuclei, small nucleoli and abundant eosinophilic cytoplasm (Figs. 2 and 3). No Reed–Sternberg cells were seen, and no parasites were identified. One of the biopsies included lymphoid tissue with follicular hyperplasia. On immunohistochemical staining, the epithelioid cells were positive for CD31 (1:20, clone JC70A, Dako, England) (Fig. 4) and CD34 (1:25, QBend10, Novocastra, England) and were negative for Cam 5.2 (1:5, Becton and Dickinson, England). The differential diagnosis was between epithelioid haemangioma (angiolymphoid hyperplasia with eosinophilia) and Kimura's disease. The microscopic features of prominent epithelioid cells lining small blood vessels accompanied by a heavy infiltrate of eosinophils favoured a diagnosis of epithelioid haemangioma; however, the presence of blood eosinophilia was described more commonly in Kimura's disease. an expert referral, the case was diagnosed as an epithelioid haemangioma. Eleven months later, routine mammographic examination showed a shadow in the upper outer

quadrant of her left breast. Ultrasound needle core biopsy which was subsequently performed showed partly effaced lymph node tissue with histological features of an epithelioid haemangioma as described earlier.

A year later, on follow-up, she was clinically stable and asymptomatic. On the CT scan, the nodes appeared stable without any increase in size.

Discussion

Epithelioid haemangioma is a distinct vascular lesion described initially by Wells and Whimster [6] in 1969 as subcutaneous angiolymphoid hyperplasia with eosinophilia. Contrary to our case, these lesions most commonly occur as solitary lesions in the dermal and subcutaneous regions over the head and neck [5]. Less commonly, they are known to occur at multiple superficial sites [2] and occasionally have also been reported in soft tissues, bone and vessels [3]. To the best of our knowledge, epithelioid haemangiomas have not been described in multiple deep mediastinal, abdominal and intramammary locations.

Our case presented with weight loss and, following a detailed investigation, also showed raised CA-125 levels. CA-125 levels are commonly raised in gynaecological malignancies; nevertheless, they can be raised in a few non-gynaecological benign conditions [1]. In our case, there was no evidence of gynaecological disease. Raised CA-125 levels and weight loss have not been described in epithelioid haemangiomas [1]. In this case, the weight loss and the rise in CA-125 levels are unexplained. On the CT scan, the multiple enlarged mediastinal and abdominal nodes, in addition to weight loss and raised CA-125 levels, are features clinically suggestive of a lymphoma or metastatic malignancy. The role of biopsy was crucial since the histological features were diagnostic of epithelioid haemangioma. The unusual site and the distribution of disease combined with the histological features also raised the differential diagnosis of Kimura's disease, Hodgkin lymphoma and parasitic infections. The morphological and

immunohistochemical features excluded Hodgkin lymphoma, and no parasites were identified. Kimura's disease is endemic in the Asian population and is often present in Oriental males as nodules not confined to the head and neck with high incidence of contiguous lymphadenopathy [5]. Presence of blood eosinophilia, although known to occur in both conditions, has been described more commonly in Kimura's disease [5]. Kimura's disease and epithelioid haemangioma both have an eosinophil-rich lymphoid infiltrate [5]. However, a prominent vascular component lined by plump epithelioid endothelial cells is characteristic of epithelioid haemangioma [5]. This feature is classically absent in Kimura's disease, in which the inflammatory infiltrate typically overshadows vessels lined by more attenuated endothelial cells [5]. Kimura's disease and epithelioid haemangiomas were formerly thought to be identical but are now regarded as two entirely unrelated lesions [4, 5]. Our case further blurs the division of these entities with an unusual presentation of epithelioid haemangioma. Another entity that should be excluded on morphological grounds is epithelioid haemangioendothelioma [2]. In our case, the absence of pleomorphism in the endothelial cells excludes the possibility of a haemangioendothelioma.

Our main aim is to report a unique case of angiolymphoid hyperplasia with eosinophilia (epithelioid haemangioma) occurring in multiple deep lymph nodes within the medi-

astinum, abdomen and intramammary locations with an unusual clinical presentation of weight loss and raised CA-125 levels. Both these aspects were never described previously.

Acknowledgement We thank Professor CDM Fletcher (Brigham and Women's Hospital, USA) for his expert histological opinion in this case.

Pulmonary manifestation of a Langerhans cell sarcoma: case report and review of the literature

Received: 4 October 2005 / Accepted: 10 October 2005 / Published online: 22 November 2005
© Springer-Verlag 2005

Abstract In the following, we describe the very rare case of Langerhans cell sarcoma (LCS) in the lung. Throughout the medical literature, only a few cases have been published, and, to the best of our knowledge, this is the first case to be reported in Germany. The patient was an 81-year-old man who showed symptoms such as chronic cough and weight loss. Clinical examination including needle biopsy indicated a high possibility of carcinoma in the right lung and in the mediastinum; however, the final histopathological diagnosis after immunohistochemistry gave evidence of LCS. LCS is a neoplastic proliferation of Langerhans cells with malignant cytological features exhibiting a very aggressive behaviour. LCS can be distinguished from other carcinomas, lymphomas and sarcomas by the typical morphological features of Langerhans cells and the immunophenotype with a consistent expression of S-100 protein and CD1a. In contrast to Langerhans cell histiocytosis, the LCS consists of Langerhans cells with high atypia and a very high mitotic rate.

Keywords Langerhans cell sarcoma · Histiocytosis · S-100 protein · CD1a

Introduction

Neoplasms deriving from dendritic or histiocytic cells occur rarely. These cells are members of the family of immune accessory cells whose primary role is to present antigen to lymphocytes. Although they share a common CD34⁺ stem cell with macrophages, the lineage is separate. Parts of the family are Langerhans cells of the skin, interdigitating cells and veiled cells, which are regarded as different stages of

evolution of the same cell type [10]. Others are the follicular dendritic cells, which are presumably derived from lymph node stromal cells rather than from a haematopoietic precursor cell, although this is still under discussion. In addition, interstitial dendritic cells can be distinguished, which represent the counterpart of Langerhans cells in parenchymal organs [9]. The World Health Organization (WHO) classification of histiocytic and dendritic cell neoplasms differentiates between histiocytic sarcoma, Langerhans cell histiocytosis, Langerhans cell sarcoma, interdigitating dendritic cell sarcoma/tumour, follicular dendritic cell sarcoma (FDCS)/tumour and dendritic cell sarcoma, not otherwise specified [12]. To distinguish the different types, a combination of morphologic and immunophenotypic characterization is necessary. Langerhans cells are positive for CD1a and S-100 protein, negative for CD21, CD35 and CD68, and show Birbeck granules (subdomains of the endosomal-recycling compartment) ultrastructurally. Veiled cells show the same phenotype as Langerhans cells, but have neither Birbeck granules nor complex interdigitating cellular junctions. Interdigitating dendritic cells are positive for S-100 protein and CD68 and negative for CD1a, CD21 and CD35, thus revealing complex interdigitating cellular junctions. The follicular dendritic cells are CD21⁺, CD35⁺, CD1a⁻ and S-100 protein⁺ or ⁻, and they show desmosomes ultrastructurally [12].

Especially neoplasms of the Langerhans cell phenotype occur rarely; hence, only 14 cases of Langerhans cell sarcoma (LCS) have been reported in previous research (see Table 1). Usually LCSs show a multi-organ involvement, including lymph nodes, liver, spleen, lung and bone. This paper reports a case of an LCS arising in the lung of an 81-year-old man and reviews the existing literature concerning these neoplasms.

4 months. Physical examination revealed a pulmonary infiltration, which, on computed tomography (CT) scan (Fig. 1) was identified as a mass lesion occupying the lower lobe of the right lung and mediastinum with radiologic signs of a generalized lymphangitic spread (Fig. 2). Laboratory data on admission were within normal limits except for a leukocytosis with 24 G/l (4–11G/l), an elevated C-reactive protein with 11.4 mg/dl (<0.50 mg/dl) and a hyponatremia of 125 mmol/l (135–145 mmol/l). The patient's lingering smoking habit and the clinical results raised the suspicion of a bronchogenic carcinoma causing a paraneoplastic syndrome of inappropriate anti-diuretic hormone (SIADH) secretion. A bronchoscopy was performed, revealing a tumoural lesion located in the right main bronchus. A biopsy was performed, and the specimen was sent to the Institute of Pathology, University of Munich, for histological examination.

Materials and methods

The paraffin-embedded 13 specimens (diameter together 1 cm) were cut at 2–3 μ m and mounted on SuperFrost/Plus microscopic slides (Menzel, Germany). After deparaffiniza-

Fig. 1 CT scan of the chest showing a mass in the mediastinum and a small pleura effusion of the right lung

Fig. 2 Lymphangitic spread

tion and rehydration, staining for haematoxylin–eosin, giemsa, iron, silver and elastic van Gieson (EVG) as well as immunohistochemical assays for a wide panel of antibodies were performed by standard methods (see Table 2).

For electron microscopy, following deparaffinization, the tissue was buffered in osmium tetroxide, dehydrated in ethanol and embedded in EPON 812 (SERVA Electropho-

resis GmbH, Heidelberg, Germany). To gain a first overall impression, methylene/azur staining of tissue sections with 0.5 μm were performed, then ultrathin sections with 80–100 nm were prepared, stained with uranyl acetate–lead citrate and examined using a transmission electron microscope (EM420; Philips, Eindhoven, the Netherlands).

Pathological findings

Microscopy

The specimens consisted of multiple parts of a highly cellular tumour, which was composed of enlarged round cells arranged primarily in compact, cohesive pattern. The neoplastic cells had lightly eosinophilic and partly vacuolized cytoplasm with ill-defined cell borders. The tumour cell nuclei were large and very variable in size. They ranged between round and oval, grooved and lobulated with delicate membranes, showing chromatin abnormalities and prominent nucleoli (see Fig. 3). The mitotic rate was very high. Partial necrosis surrounded by a granulocytic infiltration was identified. The neoplasm was not encapsulated and extended up to the epithelium. A characteristic feature of the tumour was the presence of small mature lymphocytes, a few plasma cells and very few eosinophils dispersed throughout the process. The remaining lung and the bronchial mucosa were unremarkable.

Immunohistochemistry

The immunohistochemical results are summarized in Table 2. Tumour cells were strongly positive for CD1a and S-100 protein (see Figs. 4 and 5), as well as slightly positive for Vimentin. Focally, there was a very weak expression of CD45, CD68 and CD4. The proliferation marker Ki67 reached 70% (Fig. 6). The tumour cells failed to express Pancytokeratin, thyroid transcription factor (TTF1), HMB-45, Melan A, Aktin, CD3, CD25, CD 30, CD 34 and Chromogranin.

Electron microscopy

Ultrastructural examination showed round tumour cells with regular substructures suitable to Langerhans cells morphol-

Fig. 5 S-100 protein staining, magnification 40× objective

ogy. The cytoplasm of the cells contained non-branching, rough endoplasmic reticulum and small mitochondria.

Birbeck granules could not be identified, possibly due to the fact that the biopsy was previously paraffin embedded and damaged during the fixation process.

Diagnosis

In consideration of histomorphological findings and immunohistochemical staining, a tumour of Langerhans cell origin was diagnosed 1 week after admission to the hospital. The malignant cytologic features and the very high proliferation rate suggested a Langerhans cell sarcoma. The absence of Birbeck granules was explained by the unavailable examination of fresh tissue and the reduced quality of the biopsy.

Treatment

After diagnosis of a Langerhans cell sarcoma (LCS), the existence of other manifestation sites of the LCS besides suspicious lymph nodes para-aortal and cervical (up to 2 cm) was excluded by brain and abdominal CT scans as well as by skeletal scintigraphy. Particularly the skin was normal. Chemotherapy was started using cyclophosphamide, prednisolone, adriamycin and vincristin (CHOP) in a standard dose adapted to the common lymphoma treatment protocols. Due to the tumoural growth, a stenosis of the right middle lobe bronchus had caused a retention pneumonia. Therefore, a second bronchoscopy was performed to accomplish a laser photocoagulation combined with an endotracheal after loading therapy. Following initial recovery, 10 days after the first cycle of CHOP, the patient developed a severe neutropenia with multiple infectious complications, in particular, a fungal infection of the lung. Despite extensive anti-microbial and anti-fungal therapy, the patient's general condition worsened, and he died of severe infectious complications 1 week later. An autopsy was not permitted by his family.

Discussion

Neoplasms of dendritic or histiocytic cells are extremely rare [4]. To the best of our knowledge, Wood et al. [13] published the first case report of a LCS in 1984. His 71-year-old patient showed a diffuse pulmonary infiltration alongside multiple nodules of the skin, each with an infiltration by Langerhans cells in histological specimens [13].

In 1991 Ben-Ezra et al. [1] reported the results of a study of 31 patients with a neoplasm of Langerhans cells. Taking into account characterized morphology and clinical course, they divided the patients into four groups. In this case, immunohistochemical staining for CD1a on paraffin-embedded material was not possible. Hence, the Langerhans

cells had to be identified by finding Birbeck granules. Subsequently, they came to the conclusion that some of the patients suffered under a malignant Histiocytosis X, indicated by highly atypical cytological features and a very aggressive course [1].

Nowadays, antibodies suitable for tissue immunohistochemistry and molecular genetic methods permit the identification of the cell of origin of the different types of histiocytic or dendritic neoplasms.

Malignant disorders of these cell lines derive from immune accessory cells of the peripheral lymphoid tissue. The majority of them involve lymph nodes, with a few cases reported in extranodal sites, like the lung or the skin [9]. The aforementioned neoplasms, in particular histiocytic or Langerhans cell sarcomas, behave in the typical biological way of malignant tumours, i.e. a locally aggressive solitary mass with the ability to recur and metastasize. Among dendritic-cell sarcomas, several subtypes are distinguished: sarcomas deriving from interdigitating reticulum cells and follicular dendritic cells described in several locations, such as lymph nodes, liver, skin and the bowel. Seventy-two cases of FDCCS and interdigitating reticulum cell sarcoma (IDDCS) have been well documented [5]. Sarcomas of histiocytes, as well as sarcomas with Langerhans cell-like differentiation, have been described as bonafide neoplasms with aggressive features and poor response to therapy, occurring in a wide age range, including infants, children and adults. Nevertheless, differentiation between both cell types is possible by morphological, immunohistochemical and ultrastructural methods. Some researchers assume that the distinction is of no great significance, because the clinical behaviour of histiocytic sarcomas and Langerhans cell sarcomas appears similar [7].

In this case report, we are presenting a patient with a pulmonary tumour showing the immunohistochemical features (CD1a+, S-100 protein+ and only very weak CD68+) of a neoplastic proliferation of Langerhans cells. Due to technical reasons, no Birbeck granules could be identified, and, according to the WHO classification of histiocytic and dendritic cell neoplasms, Birbeck granules should theoretically be present in all cases of LCS in which "adequate examination can be carried out" [12], meaning that tumours with the abovementioned features and with no evidence of Birbeck granules should be classified as "dendritic cell sarcoma, not otherwise specified". Although this is probably a non-existent entity if cases are well studied. In our case, the tumour showed overtly malignant cytological features of Langerhans cells and a very high proliferation rate and was therefore classified as a Langerhans cell sarcoma. The absence of Birbeck granules was explained by the unavailable examination of fresh tissue and the reduced quality of the biopsy. The occurrence of Langerhans cells in the setting of other malignancies, as it has been described for cancer of the larynx [14], could be excluded due to the malignant phenotype of the Langerhans cells in this case.

Until the current day, a total of 15 cases considered as LCS, including the present case, have been reported and reviewed in medical literature [2, 3, 6, 8, 9, 11, 13]. In these

few cases, a wide diversity concerning age, site of occurrence, progression and applied treatments has been observed. The age ranges from 10 to 81 years, with a median age of 48 years and a female predominance (1:1.5). In nearly every case, lymph nodes were involved, although cases with extranodular sites were also published [9]. In most cases, chemotherapy was an essential part of the treatment, in particular, the use of drug combinations known for their efficiency in the treatment of lymphatic neoplasms are described. Overall, LCSs impress with their poor outcome. From 13 patients on whom follow-up data were available, eight (61.5%) died of their disease, only three (23%) patients survived in complete remission, one (7.7%) patient reached a partial remission and one (7.7%) patient lived with the disease.

Due to the small number of cases, no organized series of treatments for adults have been published. The diversity of applied treatments reported in medical literature makes it almost impossible to define an optimal strategy. Nevertheless, successful treatment is feasible with a variety of chemotherapy regimens. It is claimed that chemotherapy including steroids may help slow or even stop the progression of LCS.

To the best of our knowledge, only few cases of LCS have been documented in the English literature; however, we were unable to find any comparable case report in Germany. Our patient was an elderly man with an unusual case of LCS initially localized in the lung and mediastinum. Due to the advanced stage of the disease, an intensive therapy with chemotherapeutics and bronchoscopic interventions could not stop the progression of the tumour, and the patient died of respiratory insufficiency and severe infectious complications. Unfortunately the patient's family did not agree to an autopsy. Subsequently, the supposed extension of disease could not be examined.

Misalignment of pulmonary vessels with alveolar capillary dysplasia: association with atrioventricular septal defect and quadricuspid pulmonary valve

Received: 12 October 2005 / Accepted: 25 October 2005 / Published online: 6 December 2005
© Springer-Verlag 2005

Abstract Misalignment of pulmonary vessels (MPV) with alveolar capillary dysplasia (ACD) is a complex congenital vascular abnormality in newborn infants. This condition is often associated with persistent pulmonary hypertension, which leads to severe respiratory distress and finally to the death of the newborn. Here, two cases of MPV with ACD are reported that were associated with atrioventricular septal defects. Both cases showed a combination of a large atrial septal defect and a smaller subvalvular ventricular septal defect. In one newborn, the cardiac malformation was accompanied by a quadricuspid pulmonary valve. These cases emphasize the importance of considering MPV with ACD a possible cause for pulmonary hypertension in the newborn, especially when a concomitant atrioventricular septal defect could represent an alternative explanation for the pulmonary hypertension.

Keywords Alveolar capillary dysplasia · Misalignment of lung vessels · Persistent pulmonary hypertension of the neonate · Atrioventricular septal defects · Quadricuspid pulmonary valve

Introduction

Persistent pulmonary hypertension of the newborn (PPHN) is caused by a variety of diseases including pneumonia, hyaline membrane disease, meconium aspiration, fetal hypoxia or surfactant deficiency. Similarly, congenital heart diseases such as ventricular septal defects, patent ductus arteriosus Botalli or the transposition of great arteries result in high pressure and increased flow in the pulmonary circulation. In rare cases, PPHN is the consequence of a misalignment of pulmonary vessels (MPV) with or without alveolar capillary dysplasia (ACD) [10]. Morphologically, MPV is characterized by pulmonary veins being closely associated with pulmonary arteries and bronchi (for review, see [8]). In contrast, ACD is caused by a loss of alveolar capillaries and dysplasia of alveolar walls leading to a severe impairment of the normal air–blood barrier. In most cases, ACD is associated with MPV [11], but there have also been reports of ACD without MPV [4]. To date, 73 cases of MPV/ACD are reported in the English literature. This congenital disease presents clinically as pulmonary hypertension of the newborn infants, with the cardinal symptom being respiratory failure [7]. Moreover, MPV with ACD is often accompanied by other congenital abnormalities, e.g. of the cardiovascular system or gastrointestinal tract. The present report describes two newborn infants presenting with PPHN caused by MPV with ACD. Both had a concomitant atrioventricular septal defect (AVSD); in one case it was associated with a quadricuspid pulmonary valve.

Clinical history

Case 1 A full-term, 3,130-g baby girl was delivered after a normal pregnancy. One day after delivery, she developed increasing respiratory distress and cyanosis. Echocardiography showed an atrioventricular septal defect with a large atrial and a small ventricular (approximately 3 mm) component. Cardiac catheterization confirmed the diagnosis of atrioventricular septal defect and pulmonary hypertension (pulmonary wedge pressure of 8 mmHg). The respiratory

distress deteriorated, and, because of suspected neonatal sepsis, antibiotic treatment was started. Despite aggressive management of pulmonary hypertension with sedation, analgesia, 100% oxygen, relaxation, hyperventilation, NO inhalation, intravenous prostacyclin and catecholamines, the cardiopulmonary status progressively deteriorated, and the infant expired on the 30th day.

Case 2 A dystrophic newborn girl was delivered in week 38 of the pregnancy. Echocardiography showed an atrioventricular septal defect with a large atrial and a medium-sized ventricular (approximately 5 mm) component and a severe right-to-left shunt. Seven hours after delivery, the newborn showed rapid ventilatory deterioration and a progressive, severe cyanosis. After pulmonary hypertension was diagnosed, 100% oxygen, relaxation, analgesia, sedation, hyperventilation, NO inhalation, intravenous prostacyclin and catecholamines were administered. Genetic testing resulted in the diagnosis of a triple X mosaic constellation (47,XXX). The subsequent course was complicated by oliguria and a capillary leak syndrome, renal vein thrombosis and septicaemia. The newborn died in protracted cardiac failure and due to the capillary leak syndrome on day 23.

Materials and methods

After the autopsy of the newborn infants, several tissue samples from the lungs and other organs were fixed in formalin and embedded in paraffin: case 1 (autopsy limited to thoracic organs): heart, three samples; lungs, eight samples; thymus, one sample; case 2: heart, three samples; lungs, five samples; liver, one sample; spleen, one sample; kidneys, two samples; bone tissue, one sample. Microscopic examination of paraffin-embedded sections (2–3 μm) was performed following standard staining procedures with hematoxylin and eosin, Elastica van Gieson or Masson's trichrome. Immunohistochemical staining was performed using a Techmate 500+ automated immunostainer (Dako-Cytomation, Hamburg, Germany) with an avidin–biotin complex peroxidase-detection system. The antibody specific for human muscle actin (HHF35, dilution 1:2) was obtained from Loxo (Dossenheim, Germany). Negative controls included sections in which the primary antibody was omitted.

Results

In the autopsy, case 1 presented with an atrioventricular septal defect, which was approximately 9 mm in diameter (Fig. 1a). The major defect was found in the atrial septum, whereas a minor cleft-like lesion (approximately 4 mm in diameter) extended to the ventricular septum and disrupted the common atrioventricular valve (arrow). The right atrium and ventricle were dilated, and the right ventricle wall showed a substantial hypertrophy (0.6 cm, right ventricle; 0.4 cm, left ventricle). The weight of the heart

was slightly increased (25 g). The pulmonary valve was quadricuspid without signs of pulmonary stenosis (Fig. 1b). The aortic valve did not show any abnormalities. The lungs showed a marked increase of consistency and weighed 40 g (right) and 50 g (left). The other organs did not exhibit any abnormal findings in the macroscopic examination. Case 2 showed an atrioventricular septal defect very similar to the one described for case 1 except for the slightly bigger size of the ventricular component (diameter, 6 mm). The pulmonary valve was normally tricuspid. However, the intestinal tract exhibited the characteristics of a malrotation type I, with the caecum located in the right upper abdomen.

On histological examination, the lungs of both cases showed very similar morphological alterations. The small pulmonary veins were closely accompanied by muscular arteries and bronchi, partly sharing a common adventitial envelope (Fig. 2a). Even very peripheral pulmonary arterioles showed strong muscularization as demonstrated by immunohistochemical detection of smooth muscle actin (Fig. 2b). The diameter of arteries and arterioles at the level of the terminal and respiratory bronchioli ranged between 100 and 150 and 30 and 60 μm , respectively. There was no evidence of intimal hyperplasia, advanced stages of plexogenic arteriopathy or AV fistula. In contrast, pulmonary venules tended to be wide and thin-walled. The number of

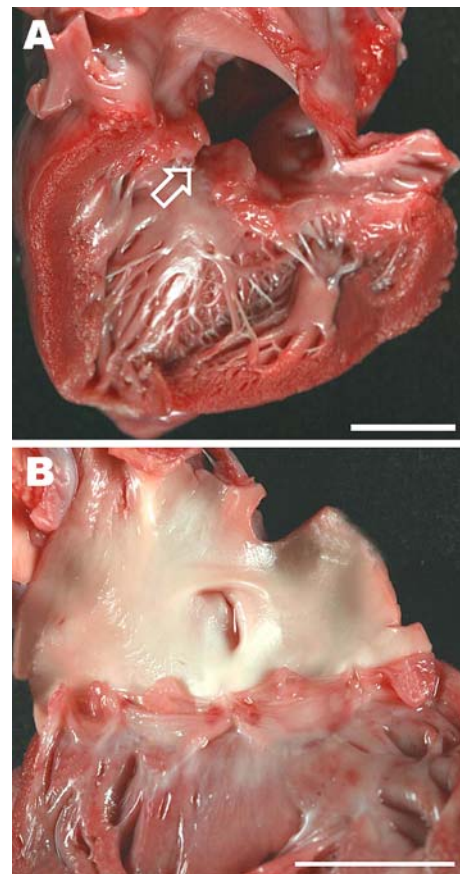

Fig. 1 a Atrioventricular septal defect with a large defect of the atrial septum and a smaller, cleft-like defect in the upper ventricular septum (arrow). b Quadricuspid pulmonary valve. Scale bar=1 cm

Fig. 2 a Lung tissue from the upper right lobe showing misalignment of pulmonary vessels: close apposition of a pulmonary artery and a pulmonary vein with partly common adventitia. The pulmonary vein, normally located within the lung septa, lies between the artery (*left*) and a bronchus (*right*) (Masson's trichrome, $\times 200$). *Inset*: In contrast, lung tissue of a newborn without pulmonary disease demonstrates the normal lung architecture: arteries (**a**) are accompanied by bronchi (**b**), whereas veins run

separately. **b** Immunohistochemical detection of smooth muscle actin demonstrates the anomalous placement of a thin-walled venule lying directly adjacent to an arteriole showing muscularization and medial hypertrophy ($\times 350$). **c, d** Lung tissue exhibiting alveolar capillary dysplasia: thickened alveolar septa with interstitial fibrosis and a reduction of alveolar capillaries. Normal alveoli are replaced by irregular air spaces which are lined by a cuboidal epithelium (**c** H&E, $\times 60$; **d** Masson's trichrome, $\times 200$). Scale bar=100 μm

alveolar capillaries was reduced, and the alveolar septa showed marked thickening, producing irregularly formed air spaces (Fig. 2c). These spaces were lined by a cuboidal epithelium (Fig. 2d). In general, there was diffuse prominent interstitial and periaventricular lung fibrosis. The histological examination of the heart (case 1) showed marked myocyte hypertrophy in the right ventricle wall, partly accompanied by bizarre nuclei of myocytes.

Discussion

ACD and MPV were first described by Janney et al. [7] and Wagenvoort [11], respectively. Both conditions mostly occur together and might represent two different manifestations of the same developmental disease. The precise aetiology of this disease is not known, but alveolar proteinosis due to a mutation in the surfactant protein B gene has been suggested to play an important role [12]. Although most cases of MPV with ACD are sporadic, there are also reports of familial cases that point to the relevance of genetic mutations [1, 3, 6]. The present report describes two newborn infants who clinically presented with PPHN and died of respiratory decompensation shortly after delivery. Both patients had the typical microscopic features of MPV and ACD. Both cases reported here showed very

similar atrioventricular septal defects, and in one case, this defect was accompanied by a quadricuspid pulmonary valve. Many of the reported MPV/ACD cases are associated with other anomalies (for review, see [2]). The cardiac abnormalities in newborns with MPV with ACD include hypoplastic left heart syndrome, bicuspid aortic valve and coarctation of the aorta [4, 9]. To our knowledge, the association of MPV/ACD, AVSD and quadricuspid pulmonary valve has not been reported before. Moreover, the cases described in the present report are of particular clinical interest, since both MPV/ACD and ventricular septal defects are accompanied by pulmonary hypertension. In the case of pulmonary hypertension due to a ventricular septal defect, histological examination shows media hypertrophy of muscular arteries, muscularization of arterioles, and plexiform lesions, but not misalignment of lung vessels or alveolar dysplasia [5]. Moreover, although morphological changes in bronchopulmonary dysplasia in the infant respiratory distress syndrome (IRDS) can resemble those in ACD, the reduction (or even loss) of capillaries is much more prominent in ACD. In cases with pulmonary hypertension and known ventricular septal defects, MPV with ACD has to be considered as an infrequent, but yet important differential diagnosis. A lung biopsy should be performed to histologically confirm MPV with ACD.

Small-cell variant of renal oncocytoma with dominating solid growth pattern: a potential diagnostic pitfall

Received: 22 September 2005 / Accepted: 5 October 2005 / Published online: 16 November 2005
© Springer-Verlag 2005

Keywords Oncocytoma · Small cell variant · Kidney

Dear Editor,

Renal oncocytoma is a distinct benign renal tumour accounting approximately for 4% of all renal tumours. This neoplasm is easily recognizable in its classic form—polygonal cells with abundant granular eosinophilic cytoplasm, arranged in tubuloalveolar cystic pattern—whereas diagnostic difficulties may arise when it exhibits small cells with scant cytoplasm and hyperchromatic nuclei (so-called “oncoblasts”) [2]. Although these small cells are rarely detectable in an otherwise classic renal oncocytoma [1, 3], there is the possibility that they may represent the dominating cell component [2]. One of us (MM), by reviewing a large series of renal oncocytomas, found only 3 out of 134 tumours with a prominent (80% of the entire tumours in two cases and 50% in the other case) small-cell component, and the term “small-cell variant of renal oncocytoma” was proposed for these cases [2]. We

report a rare case of renal oncocytoma with a predominant small-cell component, accounting for about 80% of the entire tumour. The unusual extensive solid growth pattern of the tumour may represent a potential diagnostic pitfall with primary or metastatic malignant small cell tumours.

A 58-year-old woman presented with a vague right-flank pain. Ultrasonography and computerized tomography examination revealed a renal mass, measuring 3.5 cm in greatest dimension and located in the upper pole. A radical nephrectomy with abdominal lymph node dissection was performed. Grossly, a well-circumscribed, nonencapsulated tumour mass, tan in colour, was observed. No central scar or haemorrhagic or necrotic areas were seen. Histologically, the tumour was mainly (about 80% of the entire tumour) composed of small cells with scant pale to slightly eosinophilic cytoplasm and small hyperchromatic round-shaped nuclei, arranged in a solid growth pattern (Fig. 1a,b). Only focally, the tumour cells exhibited a tubular and alveolar growth pattern. After an extensive search, in some tumour areas, we observed that neoplastic small cells gradually merged with larger cells with abundant granular eosinophilic cytoplasm similar to oncocytes as seen in classic oncocytoma (Fig. 1c). In other areas, the transition between the small cells and the classic oncocytes was abrupt (Fig. 1d). Only the small foci of tumour were composed exclusively of typical oncocytes (Fig. 1e). Nuclear pleomorphism was focally observed in classical oncocytes, as well as binucleation. Mitoses, necrosis, and nuclear pleomorphism were absent. Perirenal adipose tissue invasion and lymph node metastasis were not seen. The patient is well, without evidence of tumour after a 2-year follow-up. Immunohistochemical analyses revealed a faint immunoreactivity to antimitochondrial antibody MITO-113 (Biogenex) in the small-cell component (Fig. 1f), whereas a stronger staining was observed in typical oncocytes. All neoplastic cells were positive to epithelial membrane antigen and pancytokeratins. No reactivity was obtained with chromogranin A, synaptophysin, CD56, neuron-specific enolase, leucocyte common antigen, CD34 and CD99. Differential diagnosis mainly revolved around malignant small-cell tumours. Among these, metastatic or primary neuroendocrine carcinomas (small cell

Fig. 1 **a** Low-power magnification showing a small-cell tumour with solid growth pattern. **b** At higher magnification, cells with scant pale to slightly eosinophilic cytoplasm and hyperchromatic nuclei are seen. **c** Tumour area showing small cells intermingling with typical oncocytes as seen in renal oncocytoma. **d** Abrupt transition between small-cell component and typical area of oncocytoma. **e** High magnification of oncocytic tumour component identical to the classic renal oncocytoma. **f** Cytoplasmic immunostaining with the anti-mitochondrial antibody MITO-113 is less strong in the small cells than in the larger ones (typical oncocytes)

carcinoma of renal parenchyma; pelvis urothelial carcinoma with small-cell or neuroendocrine features) and primitive or metastatic neuroectodermal tumour (Ewing's sarcoma) need to be excluded. Unlike these malignant tumours, our case failed to have high mitotic activity, necrosis and immunostaining for neuroendocrine markers and CD99, respectively.

Although the possibility that a renal oncocytoma is composed exclusively of small cells does exist, the present case, along with the three previously reported in the literature [2], suggests that a thorough tissue sampling and careful identification of typical oncocytes, even if as a minor cellular population of the tumour, is the diagnostic key of the small-cell variant of oncocytoma. In addition, the present case, providing evidence that such a rare variant may have a dominating solid growth pattern, widens the morphological spectrum of renal oncocytoma, preventing a potential misdiagnosis of malignancy.

Clinically diagnosed fatal cerebral vasculitis in long-standing juvenile rheumatoid arthritis

Received: 6 September 2005 / Accepted: 26 September 2005 / Published online: 22 November 2005

Cerebral vasculitis · Immunoglobulin therapy

Dear Editor,

Systemic vasculitis is one of the most common extra-articular manifestations of rheumatoid arthritis (RA) [1], although it is less frequent in juvenile RA (JRA).

We report a case of JRA with systemic vasculitis. The patient spent a total of 2 years and 8 months in hospitals over the 39-year course of her disease until she finally died of autoimmune cerebral vasculitis.

The female patient's (born in 1942) polyarthritis and carditis started in 1954 and required several hospitalizations. In 1991, chronic vasculitis was suspected because of cutaneous lesions. In September 1992, she was hospitalized with left side hemiparesis attributed to cerebral arterial thrombosis. In July 1993, she was admitted as an emergency case for partly encrusted pustules of the gluteal region, the posterior thighs and lower arms.

She became withdrawn, lost sphincter control, without localizing neurological signs and symptoms. She was transferred to our Medical Intensive Care Unit (MICU) with the suspected diagnosis of cerebral oedema. Bacteriologic examination of the pharynx revealed *Staphylococcus aureus*. The CT scan showed small multiple foci of decreased density in the cerebral white matter (Fig. 1; Dr. K. Urbanek, Central Institute of Radiology, Budapest). Cerebral vasculitis was diagnosed as part of the basic immunologic disorder. Considering the pustulous skin process and the presence of staphylococcus in the pharynx, we decided against combined immunosuppressive therapy.

In the third week of hospitalization, she gradually became comatose. She was given continuous antibiotic treatment (125 mg Solu-Medrol) combined with intravenous administration of immunoglobulin (6 U Sandoglobulin). The patient became comatose and died. The main clinical and laboratory data of the 39-year case history are summarized in Table 1.

At autopsy, non-specific chronic synovitis was found in small articular deformities and in the synovial membranes of the knees and elbows. These and the fibrous pleural and pericardial adhesions, signs of polyserositis, support the diagnosis of JRA. Histologically, vasculitis was found in the areas of the scattered subcutaneous haemorrhages. Vasculitis was detected in the striated muscles, the ovaries, the perirenal adipose tissue and the brain (Fig. 2). The vasculitis was mainly non-specific, showing acute and also chronic signs of inflammation such as fibrinoid necrosis, perivascular fibrosis and lymphocytic infiltration, and was focally accompanied by thrombosis and haemorrhage. The vasculitis was mainly localized to the arterioles and small arteries of the white matter of all lobes. Corresponding to the vascular lesions, multiple microscopic foci of liquefaction necrosis of various pathological stages corresponded to the hypodense, patchy alterations shown by the CT scan. Further major autopsy findings included mild secondary amyloidosis, above all, in the heart. No gross or microscopic evidence of sepsis was found.

Autopsy confirmed the clinical diagnosis of immune vasculitis in the JRA patient. Cerebral manifestation of immune vasculitis is relatively uncommon in RA. In our case, the

diagnosis of cerebral vasculitis was established on the basis of clinical data and CT findings. The differential diagnosis of infection or septic complication is always a challenge in

immunopathologic diseases. In our case, the pyoderma, positive pharyngeal bacteriology and later pseudomonas positivity represented this diagnostic problem.

In 1990, Schuschke et al. [2] published a case of JRA with fatal cerebral vasculitis, directing our attention to the possibility of such an alteration in JRA. Though in his case all modern imaging techniques were used, the diagnosis was made only at autopsy. In 1989, Moore [3] reported five cases of cerebral immune vasculitis treated successfully with high doses of corticosteroid and cyclophosphamide.

In an autopsy series of 161 RA cases, Bély and Apáthy [4] found 36 cases (22.4%) of systemic vasculitis, 3 of them with cerebral manifestations (8.6 relative percentage).

Referring to the work of Moore [3], in the presence of vasculitis in RA (JRA), higher doses of steroid in combination with immunosuppressive therapy are mandatory. If this treatment is prevented by multifocal bacterial infection, the intravenous administration of highly purified gamma-globulin has to be considered [5].

Our clinical and pathological findings point to the possibility of a rare manifestation of autoimmune cerebral vasculitis related to JRA. The diagnosis may be established in vivo and has a major impact on therapy.

Diagnostic histopathology of breast disease at Hammersmith Hospital (Imperial College), London, UK

A week-long course designed for pathologists at Consultant and Senior Trainee level. The course provides a comprehensive coverage of the Histopathology of Breast Disease, with special emphasis on areas that pose diagnostic difficulties. The participants will be given ample time to study histological preparations, followed by illustrated discussion of the cases. There will also be several daily talks dealing with specific topics, given by eminent breast pathologists and followed by discussions. The topics will include update on reporting breast biopsies, immunohistochemistry, hormone receptors and HER2 assessment, Sentinel lymph node biopsy, dealing with the gross specimen, prognostic factors, proliferative lesions/carcinoma in situ, problems in breast pathology and interpretation of breast core biopsies. The faculty will include Ian Ellis, Christopher Elston, Andrew Hanby, Andrew Lee, Sarah Pinder and Sami Shousha.

15–16 June 2006

Thyroid Pathology for the Practicing Pathologist

15 rue de l'Ecole de Médecine, Paris, France

A 2-day course will take place in Paris again under the auspices of the French Division of the L.A.P.

This course will be given in English by Prof. M. Sobrinho-Simões (Porto) and Prof. R. Heimann (Brussels).

It will consist of lectures alternating with slide reviews and a slide seminar over a multihead microscope. The cases of this seminar will be sent (on CD) before the meeting.

The audience will be limited to 22 participants.

Course fees: 390 euros (320 euros for members of any I.A.P. division).

The fees include registration, hand-out, CD of the slide seminar and coffee breaks.

For further information please contact

How to define follicular thyroid carcinoma?

Received: 23 September 2005 / Accepted: 20 December 2005 / Published online: 28 February 2006
© Springer-Verlag 2006

Abstract The appropriate diagnosis of follicular thyroid carcinoma (FTC) still depends on its histological discrimination from follicular adenoma (including the distinction of benign from malignant oncocytic variants), papillary thyroid carcinoma (particularly from the follicular variants) and poorly differentiated thyroid carcinoma. The use of immunohistochemical markers contributed only marginally to better defining FTC. The introduction of the micro array technique, however, may offer the possibility of getting a better insight into the natural history, as well as predicting the clinical course, of a given thyroid nodule. This review attempts to recapitulate common standards in the diagnosis of FTC, to summarise current molecular data available to distinguish FTC from other benign and malignant tumours and, finally, to outline future perspectives to define FTC on its specific genetic features.

Keywords Follicular thyroid carcinoma · Follicular adenoma · Papillary thyroid carcinoma · Poorly differentiated thyroid carcinoma · Microarray

Introduction

According to the recently published WHO classification of thyroid tumours [89], follicular thyroid carcinoma (FTC) is defined as a “malignant epithelial tumour showing evi-

dence of follicular cell differentiation but lacking the diagnostic features of thyroid papillary carcinoma”. The follicular cell differentiation of FTC can be easily confirmed by thyroglobulin immunohistochemistry; the assessment of the two remaining criteria [proof of malignancy and exclusion of a papillary thyroid carcinoma (PTC)], however, is based on histological features, which still represent the gold standard for the recognition of FTC. Thus, FTC would have to be distinguished both from follicular adenoma (FA) and PTC with a predominantly follicular architecture. Both differential diagnoses may cause severe problems for the surgical pathologist.

To distinguish FA from encapsulated FTC, numerous tissue blocks have to be prepared in a standardised manner [61, 67, 72] and investigated to demonstrate or exclude vascular invasion and/or a capsular breakthrough as the decisive hallmarks of malignancy [20, 34, 65]. FTC with unusual growth patterns may resemble medullary thyroid carcinoma or metastasis to the thyroid, and thus require immunohistochemical stains for the demonstration of its follicular cell differentiation. The lack of appreciation of the diagnostic nuclear features of PTC, particularly in encapsulated tumours, may either lead to the misdiagnosis of an FTC or that of a benign FA. Occasionally, follicular tumours with definite vascular and/or capsular invasion may show nuclear features suggestive of a PTC; for those cases, Williams [91] suggested the term “well differentiated carcinoma not otherwise specified (NOS)”. In contrast to PTC, FTC almost exclusively spreads via the blood stream; due to its usually slow growing rate within the thyroid, the presence of lung or bone metastases may be the first clinical manifestation of FTC.

FTC is traditionally subdivided into two categories with distinctly different biological behaviour [27, 89]. The first type comprises completely encapsulated tumours, grossly resembling thyroid FA, which can only be identified by careful histological examination (*minimally invasive FTC*). The second type comprises diffusely infiltrating non-encapsulated carcinomas or (partly) encapsulated tumours with marked tissue or vascular invasion (*widely invasive FTC*). The differential diagnosis between widely and minimally

invasive FTC is usually straightforward because there is only minimal histological overlap between these two types of FTC. Minimally invasive FTC, however, has to be distinguished from FA by demonstrating vascular and/or capsular invasion (for the details of the histological criteria, see below). It has to be emphasised that both types of FTC are well differentiated thyroid carcinomas; particularly, widely invasive FTC has to be distinguished from poorly differentiated thyroid carcinoma (PDTC [14, 63, 85]), which is nowadays commonly accepted as an independent thyroid cancer entity [89], both clinically and morphologically different from differentiated FTC and PTC.

It still remains unclear whether FTC arises from pre-existing FA or not. Epidemiological and demographic data, showing that the incidence of FTC parallels that of FA in relationship to known environmental factors (particularly the dietary iodine intake) and the fact that FTC occurs in a later age group than FA, suggest that FTC may develop from FA in a sequential progressive manner (“linear tumour progression model”). This concept is also supported by the exceptionally rare occurrence of follicular “microcarcinoma” and the obvious identical cytological appearance of FA and (minimally invasive) FTC. Additionally, as pointed out by Wynford-Thomas [92], there is no supportive evidence for an alternative pathway, i.e., that FTC and FA arise independently from normal thyroid follicular cells. A third model assumes that progression from FA to FTC is only possible within a critical time window, during which an early adenoma may be irreversibly transformed to ultimately become FTC, or after which it is refractory and becomes an end-stage lesion presenting clinically as an adenoma (“time-restricted model” [92]).

Specific markers for the diagnosis of FTC would be most desirable; in the past, a variety of histochemical, immunohistochemical and molecular markers have been proposed to support the diagnosis of FTC. However, the assessment of the specificity of a given marker is hampered by the fact that each marker candidate has to be related to its presence or absence in the respective “nodule”, the diagnosis of which was originally based on the above-outlined *histological* criteria.

The “tumour stages” (i.e., FA or FTC) of the linear tumour progression model (and the time-restricted model) are due to the accumulation of genetic alterations. However, the genetic defect ultimately leading to malignancy has to occur in a certain time period (months? years?) before vascular and/or capsular invasion, as the histological hallmarks for the diagnosis of FTC, are fully developed. Thus, a follicular neoplasm, which, due to its lack of vascular and/or capsular invasion, has to be histologically classified as FA may already exhibit one or several molecular alteration(s) associated with FTC. On the other hand, it cannot be excluded that some follicular neoplasms, despite showing vascular and/or capsular invasion and thus histologically classified as FTC, may represent a subtype of FA never able to metastasise. The exceptionally favourable prognosis, particularly of minimally invasive FTC [63, 68], is highly suggestive that a (substantial) proportion of patients with histologically proven (minimally invasive) FTC may be

unnecessarily treated by thyroidectomy, lymphadenectomy and subsequent radioiodine administration.

The aim of this review is to summarise the histological criteria as the present gold standard in defining FTC and to critically comment on various parameters proposed to distinguish FTC from FA (including the distinction of benign from malignant oncocytic variants), PTC and PDTC.

Differentiating FTC from FA

Due to the favourable prognosis of thyroid cancer, data on its epidemiology depend to a high degree both on clinical screening efforts and the accuracy of the diagnostic methods applied; this is reflected by the broad range of incidence and survival data available from various national thyroid cancer registries. In general, thyroid cancer is rather uncommon, making up only approximately 1% of all human malignancies [76]. Nevertheless, it is the most common endocrine malignancy and its rate of increase is the fastest of all malignancies in women. However, because thyroid nodules are frequently found (up to 50% of the population in areas with iodine deficiency [89]), the assessment of a possible malignant nature of a thyroid nodule represents not only a medical but also an economical problem. In some iodine-deficient endemic goitre areas, FTC constitutes up to 40% of thyroid cancers [28, 32, 64, 90], whereas it occurs distinctly less frequently (5–25%) in non-endemic areas [46]. FTC occurs in an older age group than PTC, with the peak incidence in 60–70-year-old individuals. Just as with PTC, FTC is 2–4 times more frequently found in women than men. FTC seems to be rare in children and young adults. FTC may be exceptionally rarely associated with familial syndromes, these include Cowden’s disease (inherited mutations of the PTEN tumour suppressor gene) and the Carney complex.

At least 50% of FTCs are classified as minimally invasive. This figure represents a shift towards a higher proportion of minimally invasive FTCs amongst all FTCs, most likely reflecting the acceptance of PDTC as an independent clinico-pathological entity leading to a decrease of widely invasive FTC. Two decades ago, minimally invasive FTCs accounted for approximately 40% or less amongst all FTCs [28, 68].

The true incidence of FA is difficult to assess because there are no easily reproducible criteria to distinguish FA from hyperplastic nodules. However, clonality studies [6, 19, 26, 33, 81] have revealed that as many as 60% of thyroid nodules are monoclonal, and thus represent FA. The major task for the surgical pathologist is to meticulously exclude malignancy in each nodule even in multi-nodular goitre.

Grossly FTCs may form a mass ranging from a sharply demarcated nodule of usually more than 1 cm and up to several centimetres in diameter to a diffusely infiltrating tumour replacing a whole thyroid lobe. The latter tumours may macroscopically show extension beyond the thyroid capsule. These two growth patterns usually correspond to the encapsulated and widely invasive types of FTC, respectively.

Microscopically FTCs are composed of follicular, and rarely trabecular, and/or solid growth patterns which cannot be distinguished from the growth patterns seen in FA. The diagnosis of minimally invasive FTC entirely depends on the demonstration of limited vascular invasion and/or localised tumour invasion through its capsule. Widely invasive FTC shows extensive infiltration of the surrounding non-neoplastic tissue(s). Some of the latter may contain remnants of a tumour capsule strongly suggestive that widely invasive FTC most likely develops from encapsulated tumours. When follicular differentiation is poorly developed or even absent, the carcinoma should be preferentially diagnosed as a PDTC [89].

The histological criteria for the diagnosis of minimally invasive FTCs are summarised in Table 1. The controversy of whether capsular breakthrough and vascular invasion are equally associated with metastatic spread is reflected by the fact that some authors apply the term “minimally invasive FTC” only for tumours with capsular invasion, whereas tumours with vascular invasion have been called “encapsulated angioinvasive FTC” [31, 36]. Other features suggesting malignancy, such as high cellularity, an increased mitotic rate, architectural and cellular atypia, foci of necrosis, etc., may be present and should undergo prompt, careful, histological examination; none of these features, however, are sufficient by themselves for the diagnosis of malignancy. In some cases, it may be impossible to ultimately decide whether an encapsulated follicular tumour shows vascular and/or capsular invasion or not; for those cases, Williams suggested the term “follicular tumours of uncertain malignant potential” [91].

Occasionally, FAs without vascular and/or capsular invasion show a pronounced cellular proliferation, less regular cytology, or unusual histologic patterns; these tumours have been referred to as “atypical adenomas” [27]. Several studies have provided unequivocal evidence that atypical adenomas pursue a biologically benign course and do not metastasise or recur [28, 34]. Rosai and co-workers quite correctly stated that the diagnosis of an “atypical adenoma” has become a “wastebasket term for too many pathologists”; they suggested designating these lesions as

“hypercellular adenomas” [61]. According to the WHO classification [89], the “use of the term atypical adenoma is discouraged”. We suggest avoiding the term “atypical adenoma” because it does not indicate a lesion that (even occasionally) behaves biologically “atypically”.

In contrast to the minimally invasive type, widely invasive FTC is easy to distinguish from benign lesions. Widely invasive FTC shows a variable range of solid and trabecular areas intermingled with areas showing a follicular pattern. The tumour may consist of several or multiple nodules of variable size. Between the nodules, broad bands of fibrous tissue may sometimes be present; vascular invasion is usually easy detectable within these bands. Tumour infiltration beyond the thyroid capsule is a regular finding in widely invasive FTC. As noted before, widely invasive FTC, in particular, needs to be distinguished from PDTC [89], although the respective criteria are still far from established (for detailed discussion, see below).

The distinction of FA from FTC may cause considerable histologic problems and cannot be made reliably on cytological specimens [89]. Thus, the identification of genes whose products can be held up as a molecular signature would be a most welcome addition to the diagnostic armamentarium available.

FTCs harbour a number of chromosomal abnormalities and chromosomal imbalances (for an overview, see [89]) which can be detected by comparative genomic hybridisation (CGH). However, CGH is not a practical technique to be performed on large numbers of specimens. Some authors have, however, focussed their efforts on gene mapping in areas of loss of heterozygosity (LOH), for further studies in FTC. Aldred et al. [4] selected genes from chromosomal regions reported to exhibit LOH in FTC. Because of the nature of the question asked, the authors concentrated on down-regulated genes, detecting three genes (caveolin-1, caveolin-2 and GDF10/BMP3b) localised to two chromosomal regions (7q31.1 and 10q11.1), which were found to be coordinately down-regulated. Following the theme of bone morphogenesis signalling and possible interaction with GDF10/BMP3b, they further selected glypican-3 (Xq26.1) and chordin-like (Xq22) for analysis. The expression of each

Table 1 Histological criteria for the diagnosis of minimally invasive FTC

Vascular invasion

Tumour plug or polyp in a sub-endothelial location within a vein (not a capillary; thus, the immunohistochemical demonstration of endothelial cells is not necessary) in or immediately beyond the tumour capsule; vascular invasion within the tumour has no diagnostic or prognostic implication

The tumour cell cluster protruding into is usually, but not necessarily, covered by endothelium

The tumour thrombus does not necessarily have to be attached to the vessel wall; tumour cell clusters without endothelial covering and freely situated in the vessel lumen, however, most likely represent artefacts

Capsular breakthrough

Penetration of the tumour through the whole capsule, deflecting the collagen fibres of the capsule

Contact of the tumour with the surrounding non-neoplastic thyroid tissue

A concomitant vascular invasion is not required even if metastases are already present at the time of diagnosis

Tumour foci within the capsule are not sufficient for the diagnosis of minimally invasive FTC. They represent, most likely, tumour trapping and distortion by fibrosis

Vascular invasion and capsular breakthrough may occasionally occur simultaneously

of these genes was reduced in at least 79% of FTC samples. The fact that a reduced expression of three genes involved in bone morphogenesis signalling was also found in FA and multi-nodular goitre (as well as glycican 3 in PTC) substantially limits the utility of these genes in differentiating FA from FTC. Nevertheless, gene expression analysis of these three genes may be helpful as part of a diagnostic panel to differentiate FA from FTC. Another bone morphogenic factor, BMP7, which is part of the tumour necrosis factor signalling pathway, is decreased in FTC, whereas a negative regulator of that signalling pathway, the BMP and activin membrane-bound inhibitor, was found to be up-regulated in FTC [57, 58]. Rearrangements of the peroxisome proliferator-activated receptor gamma (PPAR γ) are a regular feature of thyroid follicular tumours with a pronounced preponderance for FTC; because these rearrangements may also occur with a lower frequency in FA, they are not specific for FTC [53]. Aldred et al. [3] showed that PPAR γ gene expression was reduced in FTC even in those samples not showing PPAR γ /PAX8 rearrangement; they attributed the reduction in the expression of this gene to changes in one or more regulatory proteins acting upstream from PPAR γ , and which they had not identified. The reduction in expression of PPAR γ was, however, also found to extend to PTC and oncocytic thyroid neoplasms. Marques et al. [39] have recently reported that PPAR γ -negative FTC presented a more aggressive course, and that the follicular variants of PTC (FVPTC) are more likely than classic PTC to be PPAR γ -negative.

Cerutti et al. [16] used serial analysis of gene expression to focus on four genes that correctly categorised benign as opposed to malignant follicular thyroid lesions. Two of these genes have been previously described by Barden et al. [7] to be up-regulated in FTC (DDIT3) and FA (putative *Emu1*), although only the former was found to discriminate between FTC and FA. ARG2, whose expression was reported to be increased in FTC [16], but not in FA, was found to be up-regulated in PTC, too [58, 59]. Whilst AGR2 thus seems to lack specificity to distinguish FTC from PTC, it may be helpful in the context of follicular tumours. Additionally, a specific increase in the expression of aconitase 1 (ACO1) and PCSK2 in FTC was noted; although only the latter has been so far pursued with confirmatory real-time PCR. Takano and co-workers demonstrated that the *decrease* in TFF3 transcript abundance was significantly reduced in FTC, particularly when expressed as a ratio of galectin-3 in the same sample [77, 78].

One of the authors [57] has demonstrated the over-expression of TRIB1, PCSK2, MET, RAP1, GA1, LGALS3 and ACO1 in FTC compared to that in FA. The importance of PCSK2 and ACO1 in differentiating between these two lesions was also recognised in the study by Cerutti et al. [16].

In an exemplary study, Weber et al. [88] honed in on three genes, CyclinD2, PCSK2 and PLAB, that they found to differentiate FTC from FA with 100% sensitivity, 94.7% specificity and 96.7% accuracy. The combination of three genes was less efficient in the identification of FVPTC, and the authors had to include genes specific for PTC to make

the distinction. While this study included many samples and submitted the results to careful unbiased analysis, it does not exclude that some of the other genes identified that were used in combinations cannot be used as diagnostics of FTC.

Differentiating FTC from PTC

PTC is defined as a malignant tumour showing evidence of follicular differentiation and characterised by distinctive nuclear features [89]. PTC regularly shows a broad spectrum of special features concerning its growth patterns, cell types, and stromal reactions. Because papillary structures may be found occasionally in nodular goitres, FA and FTC, the diagnosis of PTC ultimately entirely depends on its nuclear features (ground-glass appearance, irregularity of nuclear contours, grooves, pseudo-inclusions). The appreciation of the nuclear features of PTC is crucially dependent on tissue processing (fixative, duration of fixation, thickness of sections). Finally, the diagnosis of PTC relies on the extent of the nuclear features which should be present in “a significant proportion of the neoplasm” [84, 89]; it must be clearly stated that particularly the diagnosis of encapsulated PTC regularly depends on a considerable subjective judgement.

The majority of tumours representing FVPTC are encapsulated, composed of small- to medium-sized follicles and completely lack papillary structures. FVPTC may be occasionally found with a diffuse or multi-nodular growth pattern. Rarely, FVPTC can be composed predominantly or exclusively of macro-follicles [1]. FVPTC and its variants may cause, if the nuclear features of PTC are insufficiently appreciated, severe problems in the differentiation from FTC, FA or even multi-nodular goitre.

A number of immunohistochemical markers have been proposed to confirm the diagnosis of PTC; these include, amongst others, cytokeratin 19, HBME-1 and galectin-3 [10, 17]. However, neither of these “markers” reliably distinguishes PTC from FTC.

Finley et al. [22] extended their previous experience (compare to Barden et al. [7]) to array RNA from a set of tumours including PTC, FVPTC, FA and hyperplastic nodules. They selected five genes: AM, MET, TROP-2, NRP2 and TFF3. Although they have suggested a high degree of specificity and sensitivity, in both studies, FVPTC frequently clustered with benign adenomas. Among the genes that were found up-regulated in carcinoma but were not further pursued are HVH3, TIMP, HGFR, CPP1, AHR and HLA-DQB, and those in adenomas are CRABP1, THBS4, DPPX, MT1, PDDR, MT2-MMP and RNS1; these genes may be further candidates to select PTC from follicular tumours. Chevillard et al. [18] identified 155 genes that were differentially expressed between normal thyroid and both benign and malignant tumours; 75 genes separated follicular lesions from FVPTC and 43 genes separated FTC from FA. Hierarchical clustering was able to further separate between FVPTC and classic PTC. Platelet-derived growth

factor gene profiling was found to be useful for the identification of PTC [93], which may also be helpful for differentiating FTC from PTC.

The Columbus (Ohio) group [3, 4] has recently put to the test the notion that five genes might distinguish between FTC and PTC: PTC showed increased expression of CITED1, CLDN10 and IGFBP6, but no change in CAV1 or CAV2, whereas FTC showed decreased expression of IGFBP6 and CAV1 and/or CAV2, but no change in CLDN10. These promising results, however, need to be verified in larger samples in a prospective series. As already discussed above, Weber et al. [88] from the same group has extended the notion of selecting a few important genes to separate FTC from FA.

Differentiating the oncocytic variants of FA and FTC from non-oncocytic FTC

Histologically oncocytic or Hürthle cell tumours of the thyroid are predominantly (at least 75%) composed of oncocytic cells (WHO). As recently pointed out by Sobrinho-Simoes et al. [75], there is sufficient clinicopathological evidence to support the concept that every type of thyroid neoplasm (FA, FTC, PTC and poorly differentiated carcinoma) has its oncocytic counterpart; thus, the presence of oncocytic cells should not interfere with the diagnostic criteria of PTC (nuclear characteristics), FA and FTC (vascular and/or capsular invasion).

Macroscopically oncocytic tumours show a distinct mahogany brown appearance; microscopically oncocytic cells are characterised by a hyper-chromatic and pleomorphic nucleus with a generally prominent nucleolus, as well as a granular, brightly eosinophilic cytoplasm containing up to 5,000 mitochondria [41, 50, 74]. The majority of these tumours show a follicular, trabecular and/or solid architecture [35, 61], exhibit a rather uniform oxyphilia throughout the tumour [30] and produce thyroglobulin [29]; they are thus considered to belong to the “follicular family” (FA and FTC) of thyroid tumours [89]. In oncocytic tumours with a predominantly papillary pattern, the diagnosis of an oncocytic papillary carcinoma should only be made if the nuclear features of conventional papillary carcinoma are present [27, 41, 89]; the oncocytic variant of PTC is regarded as a rather uncommon thyroid malignancy [11, 38, 61, 66, 89].

In the 1950s, the American Cancer Society recommended that all oncocytic thyroid tumours should be regarded as malignant; subsequently, it was unequivocally proven that encapsulated oncocytic tumours, as other encapsulated follicular neoplasms, only behave clinically malignant if vascular and/or capsular invasion can be histologically demonstrated [15, 79]. Amongst encapsulated oncocytic tumours, the percentage of tumours showing vascular and/or capsular invasion (thus representing the oncocytic variant of FTC) is considerably higher than the percentage of non-oncocytic FTCs amongst encapsulated non-oncocytic tumours [12, 15, 21, 45, 55, 87]. The rate of metastasis [89], as well as the overall

mortality [15], of patients with oncocytic carcinomas was reported to be higher when compared to conventional FTC [34]; other studies failed to demonstrate a higher malignant potential of oncocytic carcinomas [21, 75, 85]. A less favourable outcome of patients suffering from oncocytic carcinoma is most likely related to a decreased responsiveness of oncocytic carcinomas to radioiodine treatment as a consequence of the decreased iodine uptake and hormone synthesis of oncocytic cells [41, 83].

The knowledge about the mechanism(s) leading to oncocytic thyroid tumours has substantially improved over the past few years (reviewed by Sobrinho-Simoes et al. [75]). The accumulation of mitochondria in oncocytic cells may be due to (1) a primary alteration of the mitochondrial DNA that encodes mitochondrial enzymes [40–42, 48, 79] or (2) somatic or point mutations of nuclear genes encoding for enzymes of the mitochondrial respiratory chain or the Krebs cycle [41]. It has been proposed that if the genetic alterations responsible for the accumulation of abnormal mitochondria occur in already transformed neoplastic cells, the resulting tumour will morphologically, biochemically and clinically correspond to an FTC or PTC; if the mitochondrial alterations occur in a yet non-transformed cell, subsequent further mutations will lead to a “primary” oncocytic neoplasm (showing exclusively Hürthle cell features) [30, 75].

Multiple tumours are found in approximately 20% of patients with oncocytic thyroid neoplasms [30]; those tumours are less frequently malignant than solitary oncocytic tumours. The occurrence of multiple oncocytic thyroid tumours with the same phenotype is strongly suggestive of a germ line alteration [30]. Familial clustering of oncocytic tumours has been reported [55, 69], and consistent cytogenetic alterations have been mapped to chromosome 19p13.2 [13, 25]; however, the exact gene(s) responsible has yet to be identified [43]. The BRAF V600E mutation has been demonstrated in approximately 50% of both conventional PTC and the oncocytic variant of PTC [73, 82]. PTC-specific RET rearrangements have been demonstrated in 4 out of 5 oncocytic PTCs and 7 out of 27 oncocytic carcinomas with a solid/trabecular growth pattern, but not in oncocytic carcinomas exhibiting a follicular architecture [49].

Concerning gene profiling, Baris et al. [8, 9], studying a large number of oncocytic thyroid tumours, were able to identify gene clusters involved in mitochondrial biogenesis and oxidative metabolism, in common with oncocytic tumours of other organs. Genes down-regulated but not further studied include IFIM1, DUP1, TNFSF1, CAV1 and GJA1, which appear to be differentially regulated in FTC. Genes noted to be over-expressed include DDIT3 (see above), CCNG2, BDNF, THBS3, LMO2, DDX24 and CRABP1, which were found to feature in thyroid carcinogenesis. Thomas et al. [80] recently showed that ACO1, PCTAIRE protein kinase and ced homolog reliably distinguish oncocytic tumours from non-oncocytic thyroid tumours. In contrast to the high frequency of retinoblastoma (Rb) protein loss in other malignant thyroid tumours, this crucial regulator of the cell cycle and cell fate is apparently

unaltered in oncocytic tumours [5]. The persistence of wild-type Rb may be essential to the metabolic and proliferative characteristics of oncocytic tumours and may be reminiscent of the mandatory role of wild-type Rb in thyroid cancer with up-regulated CyclinD1 [71].

Differentiating FTC from PDTC

PDTC is defined as a “follicular cell neoplasm that show limited evidence of structural follicular cell differentiation and occupy both morphologically and behaviourally an intermediate position between differentiated (FTC and PTC) and undifferentiated (anaplastic) carcinomas” [62, 89]. Although recognised for more than 20 years as an aggressive type of thyroid carcinoma [14, 63], the diagnosis of PDTC is still not familiar to many surgical pathologists. This may be the most important reason for the observed considerable variations in its different prevalence rates among different geographic regions. The aetiology of PDTC is obscure; pre-existing differentiated tumour areas suggest that some PDTCs have developed from differentiated carcinomas of follicular cell origin (FTC or PTC). Others most likely arise de novo [56]. According to the literature, the morphological appearance of PDTC is highly variable [14, 37, 54, 63, 84, 89].

The major problem in distinguishing FTC from PDTC is caused by rather poorly defined criteria to set the threshold between differentiated carcinoma (both FTC and PTC) and PDTC. The diagnosis of PDTC was based by some authors on growth patterns, whilst others used histologic patterns and/or cytologic features. A variety of immunohistochemical markers, including thyroglobulin, TTF-1, high-molecular-weight cytokeratins, HBME-1 and galectin-3, do not reliably distinguish PDTC from differentiated thyroid carcinoma [60]. As recently reviewed by Albores-Saavedra and Carrick [2], the various growth patterns (insular, trabecular and/or solid) suggested for the diagnosis of PDTC, may also be present in hyperplastic nodules, FA and FTC. The cytologic features of PDTC are regularly found to be similar to or overlapping with those of FTC and PTC; moreover cytologic atypia, mitotic rate and necrosis do not necessarily reflect cell differentiation, particularly in endocrine organs. Thus, Albores-Saavedra and Carrick [2] concluded that the majority of PDTCs represent examples of FTC or PTC with unusual growth patterns; they strongly emphasised that an aggressive clinical course of a given thyroid carcinoma does not justify its inclusion in the category of PDTC.

However, according to the WHO classification [89], PDTC should be treated as a separate entity because of its clinical significance. Volante and co-workers [85] proposed insular characteristics, trabecular and/or solid growth patterns, association with vascular invasion, necrotic areas and/or infiltration of adjacent non-neoplastic tissues, as the main diagnostic features of PDTC. The same group [86] recently showed that patients of ages >45 years, with the presence of necrosis (either focal or extensive) and with mitotic counts >3 per 10 HPF are associated with a more aggressive clinical behaviour of PDTC.

In accordance with others [2], we believe that the morphological diagnosis of PDTC should be based on the above-outlined growth patterns, easily recognisable mitoses and a characteristically focal thyroglobulin immunoreactivity in less than 20% of tumour cells. The occurrence of small foci of PDTC within an otherwise well-differentiated FTC should be reported; it remains to be elucidated whether this finding is associated with a clinical significance.

Because the diagnostic criteria of PDTC are far from being well established, molecular and/or genetic markers would be most welcome [52]. At least 30% of PDTCs show mutations of TP53 [70], approximately 50% show H-, K- or N-RAS mutations. The latter mutations are regularly found in PDTC as multiple activation mutations that are virtually never seen in differentiated thyroid carcinomas [24]. Very rarely, PDTCs express rearranged tyrosine kinase genes such as RET/PTC or NRTK1 [51]. An interesting candidate for a genetic trigger of thyroid tumour dedifferentiation is β -catenin; β -catenin point mutations (in exon 3 of the CTNNB1 gene) block β -catenin's degradation, resulting in a β -catenin accumulation in the nucleus and constitutive activation of target gene expression. CTNNB1 point mutations have so far only been reported in PDTC and anaplastic thyroid carcinomas, but not in FTC and PTC [23, 47]. As the questions of disease stage or disease progression have not been posed in the studies done to date, it is difficult to assign a role to oncogenes or tumour suppressor genes that show gene expression, except that these genes are related to malignant thyroid subtypes. The lack of uniform histologic criteria for PDTC is, of course, limiting the search for genetic mutations, chromosomal abnormalities and gene expression profiling.

Future perspectives for the definition of FTC

The questions asked in gene expression studies done to date were: (1) can gene expression profiling distinguish between benign and malignant thyroid nodules, (2) does this approach ultimately allow distinguishing between FA and FTC and (3) does PTC have a gene expression profile distinct from normal thyroid? The majority of gene expression studies cited in this overview were exploratory

Table 2 Genes whose expressions are useful in the diagnosis of FTC

or “scouting” inquiries. The performance of derivative studies with proper definitions of variables, sufficient numbers of cases included and uniformity of techniques, data acquisition and analysis are largely awaited. To date, the approach of Weber and co-workers [87], as applied to follicular tumours, satisfies most of these criteria.

We feel the time is now ripe to mount concerted collaborative efforts to concentrate on gene products that particularly differentiate between FA and FTC (Table 2). The variation in the expressions of these genes should show a high prevalence in one lesion or the other, and thus offer a high degree of specificity. From a pragmatic viewpoint, it does not matter whether the variation in the expression of these genes spills over to multi-nodular goitre or PTC. The designated genes should be tested either prospectively in a large number of samples from different centres using cDNA array (prepared in one source and distributed to participating laboratories) or with real-time PCR using standardised protocols. Sample preparation, assessment of histological criteria and data capture should follow protocols generally agreed upon, with the raw data being sent to a central coordinating centre. Once a minimum of 5–10 genes have been identified as diagnostics, a prospective study on fine-needle aspiration biopsies of the thyroid should be performed: needle washings would be delivered to an RNA extraction solution and be further processed if the cytology does not show evidence of PTC. Recent progress in real-time PCR technology allows for an economic examination of a large number of genes [44]. One can thus take advantage of the diagnostic concurrence of a larger number of samples.

Multihormonality and entrapment of islets in pancreatic endocrine tumors

Received: 7 December 2005 / Accepted: 8 December 2005 / Published online: 18 January 2006
© Springer-Verlag 2006

Abstract We analyzed pancreatic endocrine tumors (PETs) from 200 patients for the incidence of multihormonality and entrapped islets and correlated the results with clinicopathological features. Our series included 86 cases (43%) of functioning PET and 114 cases (57%) of nonfunctioning PET. Classified according to the WHO classification, there were 32 well-differentiated benign PETs, 85 well-differentiated PETs with uncertain behavior, and 83 well-differentiated malignant PETs. All tumors were immunostained for pancreatic hormones (insulin, glucagon, somatostatin, and pancreatic polypeptide) and for additional hormones such as gastrin, vasoactive intestinal polypeptide, calcitonin, serotonin, and adrenocorticotropic hormone. Multihormonality was found in 34% of all PETs and it was a frequent finding in the tumors of the uncertain behavior (38.8%) group. Islet entrapment was found in 57 tumors (28.5%) and was significantly more frequent in PETs with uncertain and malignant behavior than benign ones ($p=0.01$). In 57 cases, we also investigated whether ductule entrapment accompanied islet entrapment. Of these 57 tumors, 45 (79%) tumors had accompanying ductule entrapment. Ductule entrapment did not show significant correlation with malignancy and was a more frequent finding in nonfunctioning tumors. We conclude that the incidence of multihormonality in PETs is not as high as suggested previously and islet entrapping may reflect aggressive tumor growth and may be a complementary criterion for predicting the biological behavior of PETs.

Introduction

Pancreatic endocrine tumors (PETs) often show a heterogeneous composition. First, they may not only be composed of one cell type producing one hormone but may be multihormonal, i.e., displaying various cell types expressing different hormones [3, 6, 8–12, 18, 21]. Second, they may show ductules, either as a true neoplastic component (mixed ductal–endocrine carcinoma) or as a non-neoplastic component (PETs with entrapped ductules) [1, 4, 13, 16, 20]. Third, they may contain islets, which are thought to be entrapped by the growing tumor [20].

In this paper, we studied the incidence of multihormonality and entrapped islets and ductules in a large series of PETs of differing biology. The results were then correlated with malignancy, as defined by the WHO criteria, and functional properties such as the presence of a hormonal syndrome. This study should enable us to find an answer to the following questions: (1) Can the relatively high figures on multihormonality reported in the literature [3, 11] be confirmed and, if not, could the presence of these entrapped islets have caused the immunohistochemical findings to be misinterpreted with regard to the hormonal/multihormonal profile in PETs? (2) Can the occurrence of multihormonality and/or entrapped islets serve as an additional criterion in the identification of malignant PETs?

Materials and methods

Patients and tissues

We analyzed 200 PETs retrieved from the surgical pathology files and consultation files of the Department of Pathology of the University of Kiel. The tumor material was collected between the years 1972 and 2000. The PETs had been surgically removed from 200 patients. Clinical data (age, sex, and hormonal syndrome) and data on tumor size, metastasis, and gross local invasion at the time of diagnosis were obtained from the patients' records. Detailed pathologic data, including angioinvasion, perineural

invasion, and mitotic index, were obtained by reviewing the slides from the available blocks (mean number 1.5, range 1–5). The tumors were classified according to the WHO classification of tumors of the endocrine pancreas [19]. Tumors confined to the pancreas, smaller than 2 cm in diameter without perineural and angioinvasion, less than two mitosis per ten high power fields (HPF) and <2% Ki-67 were classified as well-differentiated endocrine tumors showing benign behavior. Tumors fulfilling one of the criteria, tumor size ≥ 2 cm diameter, two to ten mitosis per ten HPF, angioinvasion, perineural invasion, and >2% Ki-67, were classified as well-differentiated endocrine tumors with uncertain behavior. A diagnosis of malignancy was based on gross local invasion and/or metastasis.

The tumor tissue had been fixed in either 10% formaldehyde or Bouin's solution and embedded in paraffin. Deparaffinized sections from all available tissue blocks were cut and stained with hematoxylin and eosin and periodic acid–Schiff.

Immunohistochemistry

Three-micrometer sections were cut from one representative block per case for immunostaining for chromogranin A (CGA, monoclonal antibody, Ventana Medical systems, Tucson, AZ, USA, 1:2), synaptophysin (polyclonal antibody, DakoCytomation, Glostrup, Denmark, 1:50), Ki-67

Table 1 Multihormonality in pancreatic endocrine tumors

Tumor type	Number of patients (<i>n</i>)	Multihormonality (%)
Functioning

(monoclonal antibody, DakoCytomation, 1:100), insulin (monoclonal antibody, Biogenex, San Ramon, CA, USA, 1:40), glucagon (polyclonal antibody, Biogenex, 1:60), somatostatin (polyclonal antibody, DakoCytomation, 1:200), pancreatic polypeptide (PP, polyclonal antibody, DakoCytomation, 1:5000), proinsulin (monoclonal, Hy-Test, Turku, Finland, 1:1000), gastrin (polyclonal, Paesel, Frankfurt, Germany, 1:3000), vasoactive intestinal polypeptide (VIP, polyclonal, Zymed, San Francisco, CA, USA, 1:10), serotonin (monoclonal antibody, DakoCytomation, 1:20), calcitonin (polyclonal antibody, DakoCytomation, 1:500), and adrenocorticotrophic hormone (ACTH, monoclonal, DakoCytomation, 1:500). Staining for growth hormone releasing hormone (GRH, polyclonal, Biotrend, Cologne, Germany, 1:100) was performed on only one tumor that was associated with acromegaly. Immunostaining was carried out using the avidin–biotin peroxidase

complex method, as described previously [17]. The slides were subjected to pressure cooker treatment for 3.5 min prior to synaptophysin, VIP, and Ki-67 immunostaining.

Assessment of multihormonality and entrapment of islets and ductules

The percentage of tumor cells positive for each hormone was ascertained by monitoring the tumor tissue and was scored semiquantitatively. Positive immunostaining was recorded if more than 1% of the tumor cells (i.e., more than three to five cells) reacted with one of the hormonal peptide antibodies. Islets entrapped in the tumor were identified by their histopathological features and/or the spatial distribution of immunohistochemically identified islet cell types compatible with the cell composition of a normal islet. Ductule entrapment was defined as the presence of ductular components within the tumor.

Statistical analysis

Statistical analysis was performed using SPSS 11.0 for Windows. Chi square, Fischer's exact test and Student's *T* test and multivariate analysis were used to compare variables where appropriate. Differences with *p* values of less than 0.05 were regarded as significant.

Results

Of the 200 PETs in our series, 32 were well-differentiated PETs with benign behavior, 85 were well-differentiated

PETs with uncertain behavior, and 83 were well-differentiated endocrine carcinomas. There were 111 female (55.5%) and 89 male (44.5%) patients with ages ranging from 3 to 88 years (mean 52.7 years). In 86 cases (43%), the tumors were functioning (i.e., associated with a hormonal syndrome), and in 114 cases (57%), they were nonfunctioning. Among the functioning group, 62 cases were classified as insulinoma (72%), ten cases as gastrinoma (5.8%), five cases as VIPoma (5.8%), five cases as glucagonoma (5.8%), three cases as ACTHoma (3.5%), and one case as GRHoma (1.2%).

Table 1 summarizes the data on multihormonality in PETs. The incidence of multihormonality was 34% for all PETs. In the functioning group, 39.5% of the tumors were multihormonal. In the non-functioning group, the incidence of multihormonality and monohormonal expression was 29.8 and 37.7%, respectively. In the nonfunctioning multihormonal tumors, 19.3% of them expressed two and 9.6% of them expressed three hormone peptides. Among the functioning group, malignant gastrinomas, malignant glucagonomas, and malignant insulinomas had the highest incidence of multihormonality (57, 50 and 50%, respectively). Except for one VIPoma, the hormone causing the syndrome could be localized in all functioning tumors. Somatostatin was the most frequently expressed hormone among the multihormonal tumors, followed by PP and glucagon. Multihormonal expression was observed in 9 of 32 (28%) benign tumors, 33 of 85 (38.8%) tumors of uncertain behavior, and 26 of 83 (31.3%) malignant tumors. There was a random distribution of the various hormone-positive cells in the multihormonal tumors.

Table 2 shows the clinicopathologic features of PETs and the distribution of the tumors with entrapped islets. Fifty-seven tumors (28.5%) had entrapped islets. They

Fig. 1 **a** Malignant PET with an entrapped islet (H.E.). **b–d** Normal distribution of islet cell type hormone antibodies highlight the islet entrapped by neoplastic cells negative for the antibodies (insulin, glucagon, and pancreatic polypeptide, respectively)

were generally found at the tumor periphery and only rarely in the more central portion of the tumors (Fig. 1a). Islet entrapment was a more frequent finding in tumors with uncertain behavior (21 of 85) and malignant tumors (34 of 83) than in benign tumors (2 of 32) ($p=0.01$). The mean size of the tumors with islet entrapment was 3.98 ± 2.86 cm (range 1–15 cm) and that of tumors without islet entrapment was 4.55 ± 3.59 cm (range 0.8–15 cm), which was not statistically significant. On multivariate analysis, islet entrapment was not significant when compared to other parameters such as angioinvasion, perineural invasion, mitotic index, and Ki-67 index.

Multihormonality was detected in 35% of the tumors that had entrapped islets, but there was no association between multihormonality and islet entrapment. Of the tumors with islet entrapment, 70% belonged to the nonfunctioning group, and this was statistically significant ($p=0.017$). In the functioning tumors, islet entrapment was most frequent in ACTHoma, followed by malignant insulinomas. In 57 cases showing entrapped islets, we also investigated the entrapment of ductules. It was found that 45 tumors had both islet and ductule entrapment (79%), demonstrating a close association between entrapped ductules and islets. Entrapped ductules were observed in 14 of 17 (82.4%) functioning and 31 of 40 (77.5%) nonfunctioning tumors. There was no association between ductule entrapment and malignancy.

Discussion

It is well established that PETs can produce more than one immunohistochemically detectable peptide hormone. The incidence rates reported in the literature range from 33 to 69% [3, 9, 10, 12], with a mean value above 50%. In our series, the incidence of multihormonality was 34% for all tumors, both the functioning and nonfunctioning ones. Mukai et al. [12] observed a similar incidence of multihormonality (33%) to that in our study and underlined the importance of islet entrapment in the evaluation of multihormonality. We therefore investigated the incidence of entrapped islets in PETs and found islet entrapment in 28.5% of the cases in our series. As the incidence rate of 34% for multihormonality and of 28.5% for islet entrapment add up to 62.5%, which compares well with the mean incidence rate of 54% that can be extracted from the literature, it is conceivable that entrapped islets with their various cell types may have falsely been considered to be multihormonal tumor cells in some of the early studies. Multihormonality in PETs therefore seems to be somewhat rarer than has previously been thought.

Entrapped islets were most often found at the periphery of the PETs. In some PETs, we recognized entrapped islets already in the hematoxylin- and eosin-stained sections because the islet cells were smaller and more regular in size and shape than the surrounding tumor cells. In most PETs, however, the entrapped islets were only detected in the immunostainings for the four pancreatic hormones, which

clearly revealed the typical cellular composition of islets, depending on the location of the tumor in the pancreas [5]. Difficulties only arose in those tumors in which the outline of an entrapped islet was blurred and indistinct, suggesting the existence of multihormonal tumor cells in its immediate vicinity. We identified such cases as entrapped islets if the adjacent immunostainings revealed that the cells that seemed to have left the islets remained in direct contact with the otherwise typically composed islet core.

Apart from the entrapment of islets, PETs may also entrap ductules. It has always been the question whether these ductules are a neoplastic or nonneoplastic component of the PETs. There is indeed an infrequently encountered group of tumors clearly consisting of both neoplastic ducts and endocrine cells, i.e., mixed exocrine–endocrine carcinomas [14]. In the remaining cases, however, it was often difficult to identify the entrapped ductules as either neoplastic or nonneoplastic. Reid et al. [16] suggested that these ductules should be considered entrapped ducts showing some degree of proliferation, while Deshpande et al. [2] suggested that they should be considered to be neoplastic resulting from transdifferentiation of the endocrine cells. In a recent study, it was confirmed on the basis of clonality and immunohistochemistry that the ductular component is entrapped rather than a neoplastic phenomenon [20]. We think that the significant correlation between islet and ductule entrapment encountered in our series also supports the latter concept. Additionally, in their study, Deshpande et al. [2] reported that ductules were more frequently observed in insulinomas. In our large series of PETs, we found a similar incidence of ductules in both insulinomas and nonfunctioning tumors. Hence, our study did not confirm the association between ductules and insulinomas. It is probably related to the relative frequency of insulinomas in the study in question.

In the WHO classification of well-differentiated PETs, metastasis and gross local invasion were accepted as the definite criteria of malignancy [19]. Angioinvasion, perineural invasion, tumor size, proliferative activity, and mitotic index have also been reported to be associated with aggressive tumor growth [7, 15]. In this paper, we can add islet entrapment as a further criterion suggesting malignancy, as our study showed that islet entrapment was significantly more common in malignant PETs than in their benign counterparts. It may be argued that islet entrapment is correlated with tumor size, as the chance that islets will be entrapped may increase as the tumor grows. However, a comparison of the size of tumors that contained islets with that of tumors that did not failed to reveal any significant correlation. Although islet entrapment is not an independent indicator of malignancy when compared with other parameters such as angioinvasion and perineural invasion, it should alert the observer to the possibility that the tumor may behave aggressively.

In summary, we found a lower incidence of multihormonality in PETs than in earlier studies and conclude that the presence of entrapped islets may have caused the immunohistochemical findings to be misinterpreted with

regard to the hormonal and multihormonal profile of these tumors. Moreover, islet entrapment may be suggestive of malignancy in PETs.

Acknowledgements We would like to thank Maike Pacena and Anja Bredtmann for their excellent technical assistance, Dr. Nadir Arican for help with the statistics, and Kay Dege for editing the manuscript.

Chromogranin A in gastric neuroendocrine tumours: an immunohistochemical and biochemical study with region-specific antibodies

Received: 27 July 2005 / Accepted: 4 October 2005 / Published online: 12 January 2006
© Springer-Verlag 2006

Abstract The aim of the present study was to investigate ECLomas and enterochromaffin-like (ECL) cell hyperplasia in gastric human mucosa regarding the immunohistochemical expression of chromogranin A (CgA) epitopes and to measure the same CgA epitopes in plasma samples. Eight gastric biopsies from ECLomas, seven of type I and one of type III, and biopsies from one patient showing only ECL cell hyperplasia were included in the study. Our results revealed a varying expression of region-specific CgA epitopes in the ECLomas regarding both the frequency of immunoreactive cells and intensity of immunoreactivity. CgA284–301 (pancreastatin) was not revealed in any neoplasm, whereas CgA361–372 (catestatin) was expressed in all ECLomas. However, the number of immunoreactive cells to vesicular monoamine transporter 2 (VMAT 2) or the commercial monoclonal CgA (CgA250–284) antibodies were generally higher. The plasma concentrations of the region-specific CgA radioimmunoassays

differed considerably, with highest concentrations of CgA1–17 and CgA116–130 epitopes and the lowest with the CgA17–37, CgA63–76, CgA238–247 and CgA441–424 epitopes. No relationship was found between tissue expression and plasma concentration of CgA epitopes. In conclusion, this study shows that VMAT 2 and the commercial CgA antibodies seem more useful for histopathological diagnosis of ECLomas than the antibodies to the other CgA regions.

Enterochromaffin-like cells

Introduction

Chromogranin A (CgA) is a glycoprotein consisting of 439 amino acids, which is located in the secretory granules of neuroendocrine (NE) cells and has been widely used as a general NE cell marker in histopathological diagnosis [18]. CgA is released together with hormones and has therefore also been used as a circulating marker for the clinical diagnosis of NE tumours and to evaluate the response to medical treatment in the follow-up of the patients [21].

The primary amino acid sequence of human CgA contains ten potential cleavage sites for specific endogenous proteases [2, 8]. Various CgA-related peptides have been identified biochemically and they are, from the N-terminal to the C-terminal region of the molecule, vasostatins (amino acid sequences 1–17/113) [6, 13], chromostatin (124–143) [10], chromacin (173–194) [35], pancreastatin (250–301) [36], WE-14 (316–329) [5], catestatin (361–372) [19], parastatin (347–419) [9] and GE-25 (367–391) [15]. The immunohistochemical expression of various CgA epitopes has been shown to vary in different human NE cells and tumours and may be of help in the characterization of some neuroendocrine tumours [22–25]. The occurrence of CgA-related peptides in human plasma has also been reported in patients with NE tumours [34].

The enterochromaffin-like (ECL) cells are the predominant NE cell type in the gastric corpus mucosa. This cell

type synthesises histamine, which is localised in the secretory granules together with various proteins, among other CgA. This cell type may give rise to neoplastic lesions ("ECLomas"), which have been divided into three subgroups: types I, II and III [27, 28, 31, 33]. Type I is a mostly benign NE tumour, usually multiple and associated with ECL cell hyperplasia due to hypergastrinaemic chronic atrophic gastritis, with or without pernicious anaemia. Type II shows the same neoplastic–hyperplastic pattern in corpus mucosa as type I and is due to hypergastrinaemia caused by gastrinoma (Zollinger–Ellison syndrome, MEN I syndrome). Evidence has been provided that ECLomas type I and II can develop through a sequence of ECL cell hyperplasia, followed by dysplasia and neoplasia [4, 38]. Type III is a solitary neoplasm, often large and mostly with a malignant behaviour. This tumour is not associated with hypergastrinaemia or any specific gastric pathology, as described for the two other tumour types. Rarely, ECLomas type III induce an atypical carcinoid syndrome, which has been linked to histamine production [29].

The aim of the present investigation was to study the immunohistochemical expression of various CgA epitopes in ECLomas and ECL cell hyperplasia and to measure the same CgA epitopes in plasma samples from the patients included in the study.

Materials and methods

Patients

This study includes gastric biopsies from the oxyntic mucosa of the eight patients with ECLoma and the patient with only ECL cell hyperplasia subsequently observed at the

Section of Anatomic Pathology at Bellaria Hospital during a 7-year period, from 1994 to 2001. At the initial gastroscopy with gastric biopsies, atrophic gastritis was observed in eight of the nine patients, and in seven of these, solitary or multiple polypoid lesions were seen. In one patient (no. 8), a solitary tumour was found without signs of atrophic gastritis. In another patient (no. 3), two polyps were removed initially. Table 1 summarises some features of the tumours in the individual patients, including the presence of ECL cell hyperplasia, pernicious anaemia and other endocrine diseases. None of the patients had signs of atypical carcinoid syndrome. Before gastroscopy, no patients had been receiving medication to decrease or inhibit gastric acid secretion.

Follow-up

A follow-up gastroscopy was performed annually in all the patients except nos. 5 and 6. Patient no. 1 underwent total gastrectomy some months after polypectomy for recurrence of numerous mucosal polyps, ranging from 3 to 8 mm in diameter. The surgical treatment was decided and performed in another hospital. In patient no. 2, the initial gastroscopy was performed in 1997, revealing multiple polyps (diameter ranging from 3 to 10 mm). Endoscopic resection of polyps was performed at yearly intervals during the initial 5 years of follow-up, with the histological diagnosis of carcinoid tumours and ECL cell hyperplasia in the surrounding mucosa. This patient had high concentrations of serum gastrin (maximum 744 pmol/l) during the initial 5 years of follow-up. Somatostatin analogue (lanreotide, 60 mg monthly) was administered from February 2002 up to now due to the

recurrence of carcinoids. Shortly after the treatment was initiated, a marked and persistent decrease in serum gastrin (<100 pmol/l) was observed. The tumour polyps regressed and have not recurred till now. Histologic examination of random biopsy specimens of corpus-fundus mucosa showed ECL cell hyperplasia, but no dysplasia. Patients no. 3 and no. 4 showed persistent ECL cell hyperplasia with dysplasia, but no further tumour polyps have been verified by examination at the subsequent yearly gastroscopies until 2004. Patient no. 5 displayed multiple microcarcinoids of about 0.5 mm in size and ECL cell hyperplasia at the initial gastroscopy in 1996, but this patient refused follow-up and medical treatment. Patient no. 6, an old man, showed at gastroscopy a single gastric polyp with chronic atrophic gastritis, associated with hypergastrinaemia. This patient died in 2003 due to heart failure; therefore, plasma CgA epitopes were not analysed. Patient no. 7 had multiple gastric carcinoids (diameter ranging from 0.6 to 10 mm) and ECL cell hyperplasia in 1997. The polyps were extirpated but recurred in the following year. At follow-up, recurrent microcarcinoids were found at each control and serum gastrin concentrations were elevated; no medical treatment has been given. Patient no. 8 had a large (1.5 cm in diameter) solitary ECLoma of type III according to Solcia classification [33] and normal gastrin plasma concentrations. No signs of recurrences were found in a 9-year follow-up after perendoscopic polypectomy. Patient no. 9 displayed linear and nodular ECL cell hyperplasia and hypergastrinaemia in 1999, but did not develop any visible gastric tumours during a 5-year follow-up. None of the patients alive has revealed signs of lymph node or distant metastasis.

Tissue specimens

The tumour specimens were routinely fixed in 10% buffered formalin for 18–20 h at room temperature and processed to paraffin. Sections (5 µm thick) were cut and attached to poly-L-lysine-coated glass slides. Haematoxylin–eosin was used as a routine staining. Corpus mucosa from surgical specimens of two patients operated for adenocarcinoma were included as non-neoplastic controls. The specimens were taken from macroscopically normal tissue at least 2 to 5 cm from the neoplasm.

Immunohistochemistry

Sections from the tumours were characterised by a monoclonal CgA antibody (LK2H10, Biogenex Laboratories, San Ramon, CA) and a rabbit polyclonal antibody against vesicular monoamine transporter 2 (VMAT 2) (AB1767, Chemicon International, Temecula, CA). All tissue sections were immunostained with the various CgA region-specific antibodies. The production of CgA region-specific antibodies and their dilutions for immunohistochemistry have been described earlier [24]. The streptavidin–biotin

complex (Vectastatin Elite Kit, Vector Laboratories, Burlingame, CA) technique [14] was applied as a single immunostain, with 3-amino-9-ethylcarbazole (Sigma Chemical Co., St. Louis, MO) as chromogen. All the sections were pretreated in a microwave oven three times for 5 min at 750 W, using a citrate buffer (pH 6.0) as a retrieval solution.

Before applying the respective primary antibodies, all the sections were incubated with normal goat serum for 30 min at room temperature, at a dilution of 1:5. Then the sections were incubated with the primary antibodies overnight at 4°C. The region-specific antibodies used have been previously characterized [24].

The sections were incubated with biotinylated anti-rabbit IgG as secondary antibodies (Vector Laboratories) diluted 1:200 for 45 min at room temperature followed by the streptavidin–biotin complex (ABC) for 45 min. Subsequently, the sections were transferred to a solution containing 6 ml of 3-amino-9-ethylcarbazole, 44 ml of acetate buffer and 10 µl of H₂O₂ for about 5 min. After washing with tap water, the sections were counterstained with Mayer's haematoxylin–eosin and mounted with glycerine jelly. Between each staining step, the sections were carefully washed with PBS. The control staining entailed replacement of the first layer of antibodies by pre-immune anti-rabbit antibodies, at a dilution of 1:800.

Plasma samples

About 2–3 weeks before the initial gastroscopy, blood samples were collected from all patients, after overnight fasting, for measurements of gastrin in plasma, performed by a radioimmunoassay as previously described [16].

After an overnight fast, blood for measurements of CgA region-specific epitopes was also collected from seven of the patients. This collection was performed in 2002, i.e. at a varying time after the initial gastroscopy and removal of the tumours. Blood samples were collected in heparin-containing tubes, and plasma samples were divided into aliquots and stored at –20°C until performing the radioimmunoassay. Concentrations of the region-specific CgA epitopes were measured by specific assays as previously described [34].

Ethics

Informed consent to the examinations was obtained from each of the nine patients included in this study after full explanation of the purpose and the nature of all procedures. The study was approved by the local ethical committee.

Results

The examined biopsy sections from eight of the nine patients showed tumours expressing CgA and VMAT 2 immunoreactivity (Fig. 1a,f), i.e. the tumours represented ECLomas.

Fig. 1 **a** Type I ECLoma immunostained with antibodies to VMAT 2, showing a strong immunoreactivity in all ECL cells. Bar=30 μ m **b** The same type I ECLoma as in **(a)**, displaying mainly strong immunoreactivity to fragment CgA100–113. *Top left:* epithelium from normal oxyntic mucosa is seen. Bar=30 μ m **c** The same type I ECLoma as in **(a)** immunostained with antibodies against fragment CgA284–301 (pancreastatin). No immunoreactive cells are visible. *Top left:* a remnant of normal glandular structures. Bar=60 μ m **d** The same type I ECLoma as in **(a)** immunostained with antibodies raised against fragment CgA176–195 (chromacin). More than half of the ECL cells displayed immunoreactivity. Bar=30 μ m **e** Human oxyntic mucosa exhibiting ECL cell linear hyperplasia with antibodies raised against fragment CgA176–195 (chromacin).

Bar=50 μ m **f** Type III ECLoma demonstrating immunoreactivity to VMAT 2, mainly in the periphery of the neoplastic nests. Bar=30 μ m **g** ECLoma type I displaying moderate immunoreactivity to fragment CgA116–130 (chromostatin), mainly in the periphery of the tumour nests. At the top, normal epithelium is seen, and centrally there are two metaplastic intestinal glands containing numerous goblet cells. Bar=30 μ m **h** The same type III ECLoma as in **(f)** showing strong immunoreactivity to fragment CgA361–372 (catestatin), mainly in the periphery of the neoplastic nests. Bar=30 μ m **i** The same type III ECLoma as in **(f)** demonstrating weak immunoreactivity to fragment CgA63–76 (vasostatin). Bar=30 μ m

Seven of these were associated with focal hyperplasia of cells expressing these two proteins; the tumours in these cases represented ECLomas of type I. The ECLomas type I varied in size between 1 and 4 mm and were located in the

mucosa. The biopsies did not permit estimation of the depth of the tumour growth. The pattern varied between solid, trabecular and cell nests; sometimes the tumour revealed more than one growth pattern. The biopsies from the large

solitary tumour (no. 8) did not display ECL cell hyperplasia in the surrounding mucosa, i.e. this tumour represented an ECLoma type III. This ECLoma type III showed a trabecular and solid arrangement and did not invade the submucosa nor the muscularis propria. The biopsies from one patient (no.9) contained only linear and nodular ECL cell hyperplasia without tumour.

The immunoreactivity to the commercial monoclonal CgA and VMAT 2 antibodies in the ECLomas and ECL cell hyperplasia (see Tables 2 and 3) was present in varying frequency, ranging from a moderate number of the cell population to the majority; the intensity of the immunostaining also varied, from weak to strong. The number of immunoreactive cells to these two antibodies was generally higher than that to the region-specific CgA epitopes.

Region-specific CgA epitopes

ECLomas type I The ECLomas expressed between two and nine CgA epitopes. CgA361–372 (Fig. 1h) was expressed in all ECLomas, CgA63–76 (Fig. 1i) in all but one tumour, while CgA284–301 antibody (pancreastatin) (Fig. 1c) was lacking in all cases. The expression of the other epitopes varied. The intensity of the immunostain-

ing reaction with the respective antibody varied remarkably, both between the tumours and within the same tumour (Fig. 1b,d,g) (see Table 2).

ECL cell hyperplasia The expression of CgA epitopes varied in the hyperplastic ECL cells. CgA176–195 (Fig. 1e), 238–247 and 441–424 were expressed in almost all cases, whereas CgA17–38 was not expressed in any case. In general, the immunoreactivity of region-specific CgA antibodies in the hyperplastic ECL cells agreed only partly with that displayed by the ECLomas. Some CgA epitopes were expressed in the tumours but not in the hyperplastic areas (e.g. CgA17–38) and vice-versa (see Table 3).

ECLoma type III Four of the CgA sequences were demonstrated in the ECLoma type III. The frequency of immunoreactive cells varied as well as the staining intensity in different regions of the tumours.

Normal mucosa In the two cases of normal oxyntic mucosa, only four CgA epitopes were expressed (CgA100–113, CgA176–195, CgA324–337 and CgA250–284), mainly with moderate staining intensity. With the other region-specific antibodies, virtually no immunoreactive cells were demonstrated.

Circulating concentrations of gastrin and chromogranin A epitopes

Serum gastrin values were raised in all patients with the exception of the type III ECLoma patient (no. 8) (reference range 11–55 pmol/l). The plasma concentrations of the region-specific CgA radioimmunoassays differed considerably between the 11 different assays. In general, the CgA1–17 and CgA116–130 assays displayed the highest levels. The plasma concentrations of CgA17–37, CgA63–76, CgA238–247 and CgA441–424 were very low compared with the other assays, while the other epitopes were measured in intermediate concentrations (Fig. 2).

Fig. 2 Plasma concentrations of 11 region-specific CgA epitopes in six patients with chronic atrophic gastritis and ECL cell hyperplasia. Values are expressed as mean±SEM

Discussion

The present study is the first investigation of ECLomas regarding the immunohistochemical expression of various region-specific epitopes of the CgA molecule. The study was performed on biopsies removed at the initial gastroscopy. Plasma concentration of these CgA epitopes were performed in samples collected after removal of the tumours.

ECL cells are the main endocrine cell type in the corpus mucosa and display CgA immunoreactivity [32, 37]. However, this immunostain also visualizes other NE cells such as the enterochromaffin (serotonin-containing)

cells. With the introduction of VMAT 2, a more specific characterization of ECL cells can be obtained [7]. The ECLomas type I and type II arise in a hypergastrinaemic condition in a stepwise evolution of hyperplasia (diffuse, linear, nodular) through dysplasia to intramucosal ECLomas, which, later on, may acquire full invasive properties [20, 39]. In type I ECLomas, the absence or marked decrease in gastric acid secretion, caused by chronic atrophic gastritis with or without pernicious anaemia [3, 40], leads to G cell hyperplasia and hypergastrinaemia. In type II ECLomas, the hypergastrinaemia is caused by a gastrinoma (Zollinger–Ellison syndrome, MEN 1 syndrome) [1, 30].

None of our patients with type I ECLoma developed metastasis. One explanation may be that most of them are small and located in the mucosa and submucosa. Type III ECLoma is not related to hypergastrinaemia and has a more malignant behaviour than the other two types [11, 26]. However, our patient with type III ECLoma had no sign of recurrent disease or metastasis during the 9-year follow-up.

In the present investigation, plasma concentration of gastrin and 11 CgA region-specific epitopes were measured in six of the patients. Gastrin concentrations reflect the initial condition and show increased values, which are in line with the patients' condition of chronic atrophic gastritis. The concentration of region-specific epitopes reflects a later stadium of the patients' gastric disease, with various degrees of ECL cell hyperplasia.

All CgA regions except one (CgA284–301; pancreastatin) were identified in one or more tumours, but the frequency and staining intensity varied within, as well as between, the tumours. The antibodies raised against the sequences CgA63–76 (vasostatin) and especially CgA361–372 (catestatin) visualized more neoplastic cells than did the other region-specific antibodies. However, the number of cells expressing either VMAT 2 or the commercial monoclonal CgA (CgA250–284) antibodies were generally higher than when the antibodies to other CgA regions were used. The staining pattern of the hyperplastic ECL cells agreed only partly with that of the ECLomas; some CgA epitopes were expressed in the tumours but not in the hyperplastic areas and vice-versa.

The variation in CgA region-specific expression patterns reflects the available epitopes. The weak or negative immunoreaction with some of the antibodies may indicate that the epitopes in question are masked by other granule-related proteins or that the 3-D molecule structure has hidden some epitopes. Other causes for the various expression of epitopes may be the lack of transcription of some molecule regions or abnormal splicing of the CgA mRNA. Another explanation may be that the pattern is related to specific post-translational processing.

ECL cell function is poorly documented clinically by combined immunohistochemical and RIA studies. Although in our study we were unable to obtain tissue and blood samples at the same period of time, it is of interest to note that molecule regions weakly expressed immunohistochemically were found in higher concentration in the

plasma. On the other hand, CgA epitopes causing intense immunostaining in tissue sections (i.e. CgA63–76, 238–47, 441–424) were detected in low concentration in plasma. It appears likely that these findings may indicate different cleavage sites of the CgA molecule or may reflect, respectively, either a rapid peptide synthesis and release with a too low concentration in the ECL cells or a low release of the molecule fragments with a high concentration in the ECL cells.

In our study, the CgA284–301 sequence, pancreastatin, was the only examined sequence which could not be demonstrated immunohistochemically in either ECL neoplastic or hyperplastic cells. Furthermore, plasma concentrations of CgA284–301 were rather low, which indicate that this part of the molecule is not important in hyperplastic gastric conditions. In rat stomach, however, ECL cells have been shown to be an important source of circulating pancreastatin [12]. This difference can be either a true species difference, with different processing of the CgA molecule, or the effect of antibody specificity.

Of particular interest was that our CgA361–372 (catestatin) antibody was expressed in all ECLomas. Different biological activity has been attributed to catestatin. In addition to inhibiting catecholamine release [19], catestatin has more recently been reported to have a concentration-dependent effect on histamine release [17]. This finding in the present study may be related to the stimulatory role of catestatin on histamine release from the histamine-producing ECL neoplastic cells.

In conclusion, this study shows a variation of the tissue expression and plasma concentrations of different CgA epitopes in ECLomas type I and ECL cell hyperplasia. VMAT 2 and the commercial CgA antibodies stain more tumour cells than the antibodies to the other CgA regions and therefore seem more appropriate for the histopathological diagnosis of ECLomas, especially VMAT 2, which is more specific compared to CgA. Our investigation shows that CgA361–372 (catestatin) is the only CgA region expressed in all ECLomas, but further studies are necessary to clarify if the expression of catestatin may be a helpful complement in the characterization of ECLomas, as our study suggests.

CD56 expression aids in the differential diagnosis of cholangiocarcinomas and benign cholangiocellular lesions

Received: 22 September 2005 / Accepted: 7 December 2005 / Published online: 13 January 2006
© Springer-Verlag 2006

Abstract CD56 (neuronal cell adhesion molecule, N-CAM) has been reported in neuroendocrine tumours and as a marker of reactive biliary epithelial cells. However, up to date, it is not used to distinguish malignant from non-malignant biliary lesions. In this study, we systematically examined CD56 expression on 98 tumours arising from the biliary tree as well as intrahepatic conditions with reactive neoductules. When neuroendocrine carcinomas are excluded, only 4 of 32 (12.5%) cholangiocarcinomas expressed CD56, 2 of which showed clear cell morphology. Reactive bile ductules adjacent to cirrhotic nodules as well as in focal nodular hyperplasia were CD56 positive. Twelve of 17 (70.5%) bile duct adenomas were CD56 positive, whereas von Meyenburg complexes expressed CD56 only very focally in less than 5% of lesional cells. Bile duct cysts were negative for CD56 with the exception of focally interspersed neuroendocrine cells, similar to that seen in segmental bile ducts. Thus, if von Meyenburg complexes are excluded, CD56 can be used to differentiate intrahepatic non-neoplastic from neoplastic proliferations, which is a helpful diagnostic tool in small liver biopsies.

Keywords CD56 · N-CAM · Cholangiocarcinoma · Bile ductules

Introduction

The distinction of cholangiocarcinoma from reactive bile ductules can be a challenge if performed on morphological grounds only. Most often, the clinical picture and macroscopic evaluation of the specimen are helpful, as cholangiocarcinomas present late and as intra- or extrahepatic

mass forming lesions. However, diagnostic challenges exist, such as with periductal infiltrating types [13] or well-differentiated carcinomas in small liver biopsies. In contrast to cholangiocarcinomas, reactive bile ductules are most often found in liver biopsies showing chronic hepatitis or adjacent to cirrhotic nodules. Sometimes, bile ductules are found adjacent to a malignant tumour or in liver biopsies that are non-representative of the tumour to be sampled.

Histologically, invasive growth pattern and cytology of bile duct cells with high nuclear-cytoplasmatic ratio, pleomorphic, irregular and hyperchromatic nuclei, prominent nucleoli or brisk mitotic activity, help to distinguish neoplastic from reactive lesions. However, in some cases, this distinction becomes difficult, especially when small liver biopsies are reviewed or when cytological atypia is minimal. In such cases, the diagnosis perhaps “cannot exclude malignancy”. Thus, to separate benign from malignant biliary epithelium, novel markers are needed. In this study, we describe CD56, previously designated as neuronal cell adhesion molecule (N-CAM), as one such marker. CD56 has also been demonstrated to be expressed on regenerating bile duct epithelium [16], in the setting of alcoholic liver disease [3], congenital and acquired liver disease [9], primary sclerosing cholangitis [16], extrahepatic biliary atresia [15], cholestatic liver disease [12], and during early developmental stages of the ductal plate in fetal livers [5]. However, what has been lacking is a systematic comparison of CD56 on tumours and tumour-like lesions of the cells of the biliary tract and its evaluation as a diagnostic marker.

Methods

Surgical specimens

The study material comprised 98 cases, including 23 intrahepatic cholangiocarcinomas, 9 adenocarcinomas of the extrahepatic bile ducts, 17 bile duct adenomas, 16 von Meyenburg complexes, 8 bile duct cysts and 2 mucinous

cystadenomas. Furthermore, 10 cases of end-stage cirrhosis, 10 cases of focal nodular hyperplasia (FNH) and 11 cases of intrahepatic metastases of colorectal adenocarcinomas were included. Paraffin-embedded tissue that was collected during the period of 1991–2005 was retrieved from the files of the Department of Pathology, University of Bonn. Histologic grade of intrahepatic cholangiocarcinomas and adenocarcinomas of the extrahepatic bile ducts ranged from well (8), over moderately (14) to poorly differentiated (6).

Immunohistochemistry

Tissues were fixed in neutral buffered formalin and embedded in paraffin for histologic processing. Tissue sections were stained with haematoxylin and eosin for conventional histology. Representative paraffin-fixed tissue blocks were cut and processed for immunohistochemical studies using an immunostainer (Techmate 500; DAKO). Sections were stained using anti-CD56/NCAM (1:50 dilution, DAKO), anti-CK7 (1:500, DAKO), anti-HepPar 1 (1:250, DAKO), anti-chromogranin (1:500,

DAKO) and anti-synaptophysin (1:10, DAKO). The antigen–antibody binding was visualized by means of the avidin–binding complex (ABC method), using 3-amino-9-ethylcarbazol (AEC) as a chromogen. Appropriate positive and negative controls were run concurrently. Diagnosis and interpretation of immunohistochemical stains were confirmed by two independent pathologists.

Results

Normal segmental bile ducts express very little CD56. In contrast, reactive neoductules are positive for CD56, as seen in fibrous bands in cirrhosis (Fig. 1a) and in FNH (Fig. 1b).

Most cholangiocarcinomas were CD56 negative (Fig. 2a,b). Only 4 of 32 cases (12.5%) of cholangiocarcinomas were CD56 positive, all of which were negative for the neuroendocrine markers chromogranin and synaptophysin. Of these four CD56-positive tumours, two showed clear cell morphology and immunohistochemical markers consistent with cholangiocellular origin. The remaining two CD56-positive cholangiocarcinomas were both intra-

Fig. 2 CD56 expression in intrahepatic cholangiocarcinoma: These carcinomas are mostly negative for CD56 (a, b) and rarely focally positive for CD56 (c, d) (left: H & E, right: DAB, $\times 200$, scale bar = 100 μm)

Fig. 3 CD56 expression in benign tumours and tumour-like lesions: In bile duct adenoma (a, b), focal expression is also seen in flattened epithelium of mucinous cystadenoma and in ovarian type stroma (c) and in von Meyenburg complexes (d) (left: H & E, right: DAB, $\times 200$, scale bar = 100 μm)

hepatic, moderately differentiated and showed very focal CD56 expression. The first case had tubular and solid architecture (Fig. 2c,d), and the second case had a trabecular growth pattern with intensive desmoplastic stroma.

Eleven intrahepatic metastases of colorectal adenocarcinomas were negative for CD56. Benign tumours and tumour-like lesions showed a somewhat diverse staining pattern with anti-CD56.

In bile duct adenomas, 12 of 17 lesions showed at least partial expression of CD56 (Fig. 3a,b). All eight bile duct cysts examined were either negative or showed very focal staining. Mucinous cystadenomas were negative on most of the epithelium; however, especially in flattened epithelium, CD56 was expressed focally as well as in ovarian type stroma cells (Fig. 3c). The majority of von Meyenburg complexes showed very focal CD56 expression in cells lying in between biliary cells (Fig. 3d), similar as the

staining pattern observed in segmental bile ducts. The summary of the results in Table 1 highlights the observation that CD56 expression is mostly seen in benign cholangiocellular lesions.

Discussion

The distinction of malignant vs benign cholangiocellular proliferations in the liver is of utmost importance since cholangiocarcinomas carry a poor prognosis and high mortality. Lesions that can be mistaken for a cholangiocellular carcinoma are reactive neoductules and bile duct adenomas, also designated as peribiliary gland hamartomas [2, 8]. The pattern of growth does not always distinguish malignant from benign ductular epithelium, as cholangiocarcinoma can be found immediately adjacent to and confluent with adjacent hepatic parenchyma. Also, reactive neoductules occur in direct contact with hepatocytes as seen in cirrhosis (Fig. 1a) and FNH (Fig. 1b), a benign hepatic lesion thought to occur due to aberrant vascular supply. Furthermore, neoductules may show cytological atypia, making the distinction from a malignant glandular proliferation difficult. Especially in small liver biopsies, the architecture may not be of aid in recognizing reactive neoductules.

Cholangiocarcinomas arise from the biliary epithelium anywhere along the biliary ductal system. In this study, we show that reactive neoductules in the liver are CD56 positive, whereas most malignant tumours arising from bile duct epithelium are CD56 negative. Exceptions do exist, however, including cholangiocarcinomas with clear cell differentiation, that are CD56 positive.

Reactive bile ductules can both represent a metaplastic change of hepatocytes and reflect a proliferation of resident bile duct cells or precursor cells thereof. In FNH, evidence

Table 1 CD56 expression in malignant and benign cholangiocellular lesions

	Positive	Negative
Cholangiocarcinoma, intrahepatic	4 ^a	28
Adenocarcinoma of the extrahepatic bile ducts	0	9
Bile duct adenoma	12	5
Bile duct cyst	0	8
Mucinous cystadenoma	0	2
von Meyenburg complex	0	16 ^b
Focal nodular hyperplasia (neoductules)	10	0
Cirrhosis (neoductules)	10	0

Negative: CD56 staining in less than 5% of lesional cells. Positive: CD56 staining in more than 5% of lesional cells

^aTwo of these carcinomas were clear cell cholangiocarcinomas

^bTwelve of 16 cases showed focal CD56 expression in less than 5% of lesional cells

exists for a metaplastic change of resident hepatocytes [6, 7]. We could show in this study that both metaplastic neoductules in FNH, as well as reactive bile duct proliferations, are characterized by expression of CD56. Interestingly, in vitro, mature hepatocytes are able to transdifferentiate into bile duct cells [11]. In cholestatic liver disease, CD56 expression in reactive bile ductules has been correlated with neuroendocrine differentiation of such cells [12].

Bile duct cysts are negative or focally positive for CD56, similar to normal bile ducts. Fortunately, bile duct cysts are easily distinguished from malignant tumours by macroscopic and microscopic findings alone.

In our study, CD56 is partially positive in a substantial number of bile duct adenomas, thus enabling a distinction from malignant counterparts. Bile duct adenomas have also been designated peribiliary gland hamartoma due to the observation that they resemble peribiliary glands rather than bile ducts [2]. Typically, in older lesions, hyalinized stroma develops to compress glands, a feature that must not be mistaken for desmoplastic stroma. Also helpful are the presence of pre-existing portal areas and the absence of cytologic features of malignancy and lymphatic or vascular invasion. In difficult cases, however, CD56 can confirm the diagnosis of a benign lesion.

In contrast to bile duct adenomas, von Meyenburg complexes show mostly negativity for CD56, with the exception of less than 5% cells that are located in between biliary epithelial cells. von Meyenburg complexes are thought to represent developmental anomalies. Helpful are location and multifocality as well as their size of less than 5 mm. von Meyenburg complexes can be easily distinguished from cholangiocarcinomas, as they frequently lie underneath or in close proximity to the liver capsule. Histologically, they are found parportal and sometimes contain bile, thus distinguishing them from bile duct adenoma. Most often, diagnosis is straightforward on morphologic grounds. However, one needs to take into account negative or only focal expression of CD56 in von Meyenburg complexes when using CD56 as a diagnostic tool.

In contrast to the benign lesions mentioned above, the great majority of cholangiocarcinomas are CD56 negative. Exceptions in this study include the two carcinomas with clear cell differentiation. Clear cell cholangiocarcinomas represent a rare variant that is recognized on morphologic and immunohistochemical grounds [10, 14]. Second, metastases of neuroendocrine carcinomas need to be excluded prior to interpretation of CD56 staining in the evaluation of benign and malignant intrahepatic lesions [4]. Neuroendocrine differentiation can be excluded best by performing a chromogranin or synaptophysin stain. Third, CD56 expression has been observed on cholangiocarcinomas that arise in a background of hepatitis B and C infection [1].

The authors describe that these CD56-positive variants are unlikely to metastasize and more frequently show venous invasion, perineural invasion and intrahepatic metastases. Most of these carcinomas were undifferentiated, thus not posing a problem in misdiagnosis of a benign lesion. In this study, all cholangiocarcinomas examined arose in non-cirrhotic liver tissue and without clinical evidence of hepatitis B or C infection.

In conclusion, CD56 expression, when observed in biliary epithelial cells, is likely reflecting the benign nature of the lesion examined. Clear cell cholangiocellular and neuroendocrine carcinomas should be excluded on morphologic and immunohistochemical grounds. CD56 represents an important diagnostic tool helpful in distinguishing malignant and benign tumours arising from the biliary tree.

Infiltration of CD19⁺ plasma cells with frequent labeling of Ki-67 in corticosteroid-resistant active ulcerative colitis

Received: 3 August 2005 / Accepted: 17 November 2005 / Published online: 25 January 2006
© Springer-Verlag 2006

Abstract Abnormalities in humoral immunity are implicated in the pathogenesis of ulcerative colitis. However, the detailed mechanisms of B-cell activation in the locale remain unaccounted for. We analyzed ulcerative colitis from the standpoint of lymphocytic expansion in the loco. Intestinal specimens obtained at surgery from 30 patients with ulcerative colitis treated with corticosteroids and 15 with Crohn's disease were analyzed by immunohistochemistry and flow cytometry. Ulcerative colitis was characterized by a diffuse distribution of Ki-67⁺ small round cells

particularly in the ulcer base (that were CD19⁺ and CD20⁻), with a significant number of them also CD138⁺. Immunoelectron microscopy for CD19 revealed an abundance of rough endoplasmic reticulum in the cytoplasm. These indicated that they are of immature plasma lineage cells. By contrast, plasma cells in Crohn's disease were negative for CD19, and the labeling for Ki-67 was infrequent, showing mature phenotype. Flow cytometry revealed an occurrence of CD19⁺ and CD20⁻ cells in ulcerative colitis but not in Crohn's disease. The labeling index of Ki-67 among CD19⁺ plasma cells was positively correlated with the clinical activity of ulcerative colitis. High labeling of Ki-67 in CD19⁺ plasma cells is specific for active ulcerative colitis that was resistant to medical treatment by corticosteroids.

Introduction

Ulcerative colitis and Crohn's disease comprise idiopathic inflammatory bowel disease (IBD). Immunologic abnormalities have been implicated in the pathogenesis of IBD, and immunosuppressive therapies are, at least in part, effective for the treatment of IBD. In Crohn's disease, T-helper type 1 (Th1)-shifted overactivation of cellular immunity is closely involved in its pathogenesis together with the abnormality of macrophages [1, 16]. Recent reports indicated that mutation of nucleotide-binding oligomerization domain 2 (NOD2), a key mediator of innate host defense in the intestinal mucosa, is involved in the pathogenesis of Crohn's disease [4, 15]. As for ulcerative colitis, in turn, overactivation of humoral immunity is implicated in its pathogenesis. Halstensen et al. [9] reported accumulation of immunoglobulin G (IgG) and activated complement complex on colonic epithelial cells in ulcerative colitis. Lamina propria lymphocytes contain activated B-cell subsets [24], which are considered to be important sources of increased immunoglobulins, including autoantibodies in ulcerative colitis [5]. Therefore, acute exac-

erbatation of ulcerative colitis is thought to be accompanied by massive, local activation of humoral immune responses. However, little is known about the mechanisms and processes of B-lineage cell activation in the affected intestinal mucosa in ulcerative colitis.

One of the clues to assess the dynamics of lymphocytes in the locale, particularly clonal expansion after possible antigenic stimuli, is to analyze the proliferative activity of lymphocytes by double staining of a lymphoid cell marker and Ki-67, one of the representative cell-proliferation-associated nuclear antigens [8]. This histochemical method was introduced by Saiki et al. in a study on immune responses in Epstein–Barr-virus-associated gastric cancer [18]. In IBD, Ki-67 has been used to assess the proliferative activity of epithelial cells in dysplasia [10, 12]. Fell et al. applied double staining of Ki-67 and lymphoid cell marker to the analysis of lamina propria lymphocytes (LPLs) in IBD without referring to B cells [6].

We already reported the presence of a high labeling index of Ki-67 in CD19⁺ and CD138⁺ cells in inflamed vermiform appendix in patients with ulcerative colitis [11].

However, analyses in the colon were not performed. The present paper performed detailed morphological analyses to report that Ki-67 labeling in lymphoid cells is one of the predominant features of ulcerative colitis, particularly in the ulcer base, and that these proliferating cells were identified as plasma cells. We discuss the possible significance of these novel findings in the pathogenesis of ulcerative colitis.

Materials and methods

Tissue

Tissue specimens were obtained during surgical operations performed on 30 patients with ulcerative colitis and 15 patients with Crohn's disease at Osaka City University Hospital and Tohoku University Hospital. All patients were Japanese. All ulcerative colitis patients had total colitis, which was treated with corticosteroids. The average of total prednisolone dose at the time of operation was 16,731 mg

(420–30,000 mg), and the average dose of recent prednisolone was 41 mg/day (5–60) (Table 1). Patients with Crohn's disease included ten cases with ileocolitis, two with ileitis, and three with colitis. For preoperative treatments, all patients with Crohn's disease were treated with total parenteral nutrition [22], with only one patient receiving corticosteroid therapy. Nonneoplastic, large, and small intestinal tissues were taken from five patients with colon cancer. Tissue samples of ischemic colitis were obtained from three patients during surgical operations.

Fixation

Immediately after surgical resection, fresh tissue samples, 5×5×2 mm in size, were fixed in periodate-lysine-2% paraformaldehyde (PLP) at 4°C for 6 h followed by sequential washing in phosphate-buffered saline (PBS) containing 10, 15, and 20% sucrose for 4 h in each step. The specimens were embedded in an OCT compound (Miles, Elkhart, IN), rapidly frozen in dry ice–acetone, and stored at –80°C until use.

Immunohistochemistry

PLP-prefixed frozen sections were used with the peroxidase-labeled dextran polymer method (Envision staining kit; DAKO, Kyoto, Japan). The chromogen was 3', 3'-diaminobenzidine tetrahydrochloride (DAB) (Dojin, Kumamoto, Japan). Primary antibodies used were mouse monoclonal antibody against CD3 (clone UCTH1, applied at 1:200; Immunotech, Marseille, France), CD19 (clone HD37, 1:200; DakoCytomation, Glostrup, Denmark), CD20 (L26, 1:200; DAKO, California, USA), CD138 (clone MI15, 1:200; DAKO), Ki-67 (clone MIB1, 1:100; DAKO), follicular dendritic cell (FDC, clone CAN.42, 1:500; DAKO) and polyclonal antibodies against IgA (1:2,000; DAKO), IgG (1:2,000; DAKO), and IgM (1:200; DAKO). For Ki-67 staining, the sections were heat-treated in 0.1 M citrate buffer (pH 6.0) at 97°C for 15 min for antigen retrieval. The specificity of immunoreactivity was confirmed by replacing the primary antibodies with isotype-matched control antibodies at the

Fig. 1 Immunostaining of Ki-67. **a** Hematoxylin and eosin stain of ulcer base. Scale bar, 100 μ m. **b** Ulcer base of ulcerative colitis. **c** Normal colonic mucosa. Note the diffuse occurrence of Ki-67⁺ small round cells in ulcer base of ulcerative colitis contrasted by nearly no expression of Ki-67 in inflammatory infiltrate in normal colonic mucosa

same concentration (DAKO), and sections were counterstained with methyl green.

Morphometric analyses of Ki-67⁺ cells

We counted the number of Ki-67⁺ mononuclear cells in a unit area of 0.0625 mm² that corresponded to one microscopic grid area in a $\times 400$ field. Three representative grids were observed in each patient, and the average count was calculated. The labeling of Ki-67 in the epithelial cells was carefully excluded. The counting was done by two independent observers, and the correlation coefficient between the results of both observers was 0.79. The areas we measured were the inflamed mucosa without erosions of ulcerative colitis ($n=25$) and Crohn's disease ($n=15$), the ulcer base (granulation tissue in the bottom area of the open ulcer) of ulcerative colitis ($n=30$), Crohn's disease ($n=15$), ischemic colitis ($n=3$), and the mucosa of normal colon ($n=5$). The differences among these groups were tested by the Kruskal–Wallis test and multiple comparison (SPSS version 11.0, SPSS, Tokyo, Japan).

Counting of the germinal centers

The number of germinal centers was counted by microscopic field ($\times 40$) of H & E-stained inflamed ulcerative colitis and Crohn's disease and non-IBD tissues. The whole length of tissue was searched for the germinal center, calculating the number per unit length (1 mm).

Double staining of Ki-67 and lymphocyte marker (enzyme-linked method)

We performed double immunohistochemistry for CD3, 19, or 20, and Ki-67 with minor modifications from Saiki et al. [18]. First, sections were processed for CD3, 19, or 20 with DAB as a chromogen using an EnVision kit (DAKO). After heat-antigen retrieval of Ki-67 antigen, sections were stained with anti-Ki-67 with True Blue (Kirkegard & Perry Laboratories, Gaithersburg, MD, USA) as a chromogen. The labeling index was defined as the percentage of double-positive cells for Ki67⁺ and each lymphocyte marker among the total numbers of corresponding lymphocytes in a unit area. The method of counting was the same as that of Ki67-positive mononuclear cells.

Fig. 2 Immunostaining of CD19 (**a**) and CD20 (**b**) in ulcer base of ulcerative colitis. Note abundance of CD19⁺ cells contrasted by scantiness of CD20⁺ cells. Counterstained with methyl green. Scale bar, 100 μ m

Double staining of CD19 and CD138

We performed double staining for CD19 and CD138 (plasma cell marker) [23] by both enzyme-linked and immunofluorescent immunohistochemistry. The details of the enzyme-linked method have been described above. For double-labeling immunofluorescent microscopy (performed in four representative cases), fresh frozen sections were fixed in cold acetone for 10 min at 4°C. The sections were sequentially incubated with 10% normal goat serum, mouse monoclonal anti-CD138 antibody (1:8, 11 µg/ml; DAKO), biotinylated goat antimouse immunoglobulin antibody (1:200, 5 µg/ml; Jackson ImmunoResearch, West Grove, PA, USA), and Alexa Fluor 594-conjugated streptavidin (1:100, 10 µg/ml; Molecular Probes Europe, Leiden, the Netherlands) for 15, 30, 20, and 15 min, respectively. After incubation with 10% normal mouse serum, the sections were incubated with fluorescein isothiocyanate (FITC)-conjugated anti-CD19 antibody (1:1; Pharmingen), rabbit anti-FITC antibody (1:40, 10 µg/ml; Molecular Probe), and Alexa Fluor 488-conjugated goat antirabbit immunoglobulin (1:100, 20 µg/ml; Molecular Probe) for 30, 20, and 20 min, respectively. The negative control included replacement of the first- and second-step primary antibodies with isotype-matched control antibodies (IgG1) (DAKO). The specimens were observed with a Nikon Eclipse E800 microscope equipped with band-pass filters for double immunofluorescent microscopy. The fluorescent images were captured with a cooled charge-coupled device (CCD) camera and processed on a personal computer.

Flow cytometry

The procedures for purification of lamina propria mononuclear cells (LPMCs) have been described elsewhere [3, 7, 25]. In brief, mucosal strips were denuded of epithelial cells by ethylenediamine tetraacetate (EDTA) treatment, cut into 5-mm-thick pieces, and digested by collagenase (0.1 mg/ml) (Wako Co. Ltd., Osaka, Japan), for 8 h at 37°C. LPMCs were isolated by means of a Lymphoprep (Nycomed, Oslo, Norway) gradient. The purity (ratio of

Fig. 4 Comparison of labeling index of Ki-67 among CD19⁺, CD20⁺, and CD3⁺ cells in ulcer base of ulcerative colitis analyzed by double-labeling immunohistochemistry

LPMCs) and viability (ratio of trypan-blue-negative, nonprickled cells) were microscopically evaluated, which were consistently greater than 90%. Cell surfaces were stained with FITC- or PE-labeled anti-CD19 and CD20 (Beckton Dickinson). After staining, flow cytometric analysis was carried out on a FACScalibur (Beckton Dickinson).

Immunoelectron microscopy

The preembedding, immunoperoxidase method was applied to PLP-fixed, frozen sections as described previously [18].

Clinical activity of ulcerative colitis

We adopted the activity index of Seo et al., an improved version of the clinical activity of Truelove and Witts, because it is clearly quantitative [19, 21]. The activity index was calculated in 19 cases from which sufficient

Fig. 3 Double staining of lymphocyte marker and Ki-67.

a CD19 (brown) and Ki-67 (blue) in ulcer base of ulcerative colitis. Scale bar, 10 µm. Note most Ki-67 reactivity in the nucleus is expressed in cells immunoreactive for CD19 on the cell surface (arrows). **b** CD3 (brown) and Ki-67 (blue) in ulcer base of ulcerative colitis. **c** CD20 (brown) and Ki-67 (blue) in ulcer base of ulcerative colitis. Note that Ki-67 reactivity is not colocalized with CD3 or CD20

clinical data were obtained (Table 2). The parameters included bloody stool, erythrocyte sedimentation rate, blood hemoglobin, and serum albumin (Table 3). The correlation between this index and the proliferative activity of lymphocytes was tested by the Spearman's test (SPSS).

Results

Distribution of Ki-67⁺ lymphoid cells

The occurrence of Ki-67⁺ small round cells was frequently observed, particularly in granulation tissue in the ulcer base, as a diffuse pattern (Fig. 1a,b). It was notable that this labeling for Ki-67 was not usually associated with a follicular pattern. By contrast, the labeling of Ki-67⁺ in small round cells in Crohn's disease showed mainly a follicular pattern with a sporadic positivity in small round cells in ulcer bases. This clearly indicated that the labeling in Crohn's disease was mostly confined to germinal centers, typical areas of B-cell proliferation. In ischemic colitis, Ki67⁺ small round cells were only sporadically observed. In the normal colonic mucosa, Ki67⁺ small round cells were quite infrequent in the lamina propria except in the areas of lymphoid follicles (Fig. 1c).

Ki-67⁺ round cells were identified as CD19⁺ and CD20⁻ B-lineage cells

To identify the cell types, we first performed immunohistochemistry. The ulcer base of ulcerative colitis abounded of CD19⁺ cells, contrasted by the scarcity of CD20⁺ cells or CD3⁺ cells (Fig. 2). Next, double staining clearly revealed

Fig. 5 a Example of flow cytometry using freshly prepared lamina propria lymphocytes. CD19⁺ and CD20⁻ cells were detected in ulcerative colitis, not in Crohn's disease. **b** Comparison of the ratio of CD19⁺ and CD20⁻ cells among total CD19⁺ cells between ulcerative colitis and Crohn's disease. *UC*, ulcerative colitis; *CrD*, Crohn's disease

Fig. 6 Comparison of the labeling index of Ki-67 among CD19⁺ cells analyzed by double-labeling immunohistochemistry. The percentage of CD19⁺ and Ki-67⁺ cells among total CD19⁺ cells was significantly higher in ulcer base of ulcerative colitis than any other groups by multiple comparison ($P < 0.001$ in all). *ul*, ulcer; *m*, mucosa; *IC*, ulcer base of ischemic colitis; *UC*, ulcerative colitis; *CrD*, Crohn's disease

that it was CD19⁺ cells that showed a higher frequency of Ki-67 positivity in the ulcer base of ulcerative colitis as compared with CD3⁺ and CD20⁺ cells (Figs. 3 and 4). This suggests an active proliferation of B-lineage cells that showed an unusual phenotype of CD19⁺ and CD20⁻ in the ulcer base of ulcerative colitis. This unusual immunophenotype was contrasted by that of B cells in germinal cen-

Fig. 7 Double labeling immunofluorescent microscopy for CD19 (green) and CD138 (red) in ulcer bases of ulcerative colitis and Crohn's disease. Note that most CD138⁺ cells are double-positive for CD19 (orange) in ulcerative colitis (upper panel) but not in Crohn's disease (lower panel). Scale bar, 50 μ m

ters, where CD19⁺ and CD20⁺ B cells of usual phenotype frequently express Ki-67 positivity. Labeling of Ki-67 in CD19⁺ and CD20⁻ B cells was also observed in the inflamed mucosa of ulcerative colitis at a lower rate (vide infra for details).

Flow cytometry was performed to check the occurrence of such CD19⁺ and CD20⁻ cells. Approximately 20% of CD19⁺ cells showed the phenotype of CD19⁺ and CD20⁻ in ulcerative colitis mucosa, contrasted by a predominance of CD19⁺ and CD20⁺ phenotype in Crohn's disease mucosa (Fig. 5a,b). Due to technical difficulty, areas of the ulcer base were not analyzed.

High labeling index of Ki-67 among CD19⁺ cells was specific for ulcerative colitis, particularly the ulcer base

To check the specificity of our findings, we compared the labeling index of Ki-67 in diffusely distributed CD19⁺ cells among different diseases. As shown in Fig. 6, this labeling

Fig. 8 Immunoelectron microscopy for CD19 in ulcer base of ulcerative colitis. Immunoreactivity along the plasma membrane is expressed by black arrows. CD19⁺ cells had eccentrically located nuclei and abundant rough endoplasmic reticula, a feature of plasma cells. Scale bar, 1 μ m

index was significantly higher in the ulcer base of ulcerative colitis (approximately 40% on average) than in the inflamed mucosa of ulcerative colitis, the ulcer base of Crohn's disease, the ulcer base of ischemic colitis, and the inflamed mucosa of Crohn's disease (Fig. 6). In Crohn's disease, no significant difference was noted between the labeling index of Ki-67 in CD19⁺ cells between the small and large intestines. This analysis clearly indicated the specific occurrence of Ki67⁺ and CD19⁺ cells in the ulcer base of ulcerative colitis.

Identification of CD19⁺ and CD20⁻ B-lineage cells as plasma cells

Basal plasmacytosis is one of the most important features of ulcerative colitis [20]. To search for the relationship to plasma cells, we performed double-labeling immunofluorescent microscopy for CD19/CD138 in two representative cases of ulcerative colitis and two cases of Crohn's disease. In the ulcer base of ulcerative colitis, approximately 60% of CD19⁺ cells were double-positive for CD138, a marker of plasma cells (Fig. 7a-c). Nearly identical results were

Fig. 9 Double-labeling enzyme-linked immunohistochemistry for IgG (brown) and Ki-67 (blue) in ulcer base of ulcerative colitis. Arrows, double-positive cells

Fig. 10 Immunostaining of follicular dendritic cell (FDC) marker (clone CAN.42). **a** Ulcer base of UC lacks FDC. **b** Positive control of FDC staining in a germinal center in lymphoid tissue in Crohn's disease. Scale bar, 50 μ m (\times 200)

obtained in the inflamed mucosa of ulcerative colitis. By contrast, CD138⁺ plasma cells in Crohn's disease lacked the reactivity for CD19 (Fig. 7d-f). The same results were obtained by double-labeling enzyme-linked immunohistochemistry for CD19 and CD138 in ten cases of ulcerative colitis and five cases of Crohn's disease (data not shown). Immunoelectron microscopy confirmed that most of the CD19⁺ cells in the ulcer base and inflamed mucosa of ulcerative colitis showed a differentiation toward plasma cells because they had eccentrically located nuclei and abundant rough endoplasmic reticula (Fig. 8). There were a few CD19⁺ cells with typical lymphocytic features. These two observations suggested that CD19⁺ and CD20⁻ B-lineage cells in ulcerative colitis belong to plasma cells. The labeling index of Ki-67 of CD138⁺ cells was lower (30% on average) than that of CD19⁺ cells (45% on average) ($P < 0.01$) in the ulcer base of ulcerative colitis. This suggested that CD138⁺ cells belong to more mature plasma cells than the total CD19⁺ cells do. Collectively, our data clearly showed that one of the most pathognomonic changes for ulcerative colitis is observed in its ulcer base

rather than in the inflamed mucosa, where proliferating CD19⁺ plasma cells were abundant.

Immunoglobulin type

With plasma cell features revealed, we next analyzed the immunoglobulin type. Double staining of immunoglobulins and Ki-67 in six representative cases revealed that Ki-67 positivity appeared in IgG⁺ or IgA⁺ cells but not in IgM⁺ cells in the ulcer base of UC (Fig. 9).

Ulcer base lacks FDCs and germinal centers

To check the microenvironments in the ulcer base in ulcerative colitis, we searched for FDCs that characterize germinal centers. Despite the abundance of plasma cells, the ulcer base of ulcerative colitis lacked FDCs, except sparsely distributed germinal centers (Fig. 10a,b), and

Fig. 11 Results of quantification of germinal centers. *m*, mucosa; *UC*, ulcerative colitis; *CrD*, Crohn's disease. Note that there was no increase in germinal centers in ulcerative colitis

Fig. 12 Positive correlation between the labeling index of Ki-67 among CD19⁺ cells in the ulcer base of ulcerative colitis and the clinical activity of ulcerative colitis

ulcerative colitis tissues showed no increase in germinal centers as compared with normal colonic tissue (Fig. 11).

The labeling index of Ki-67 in CD19⁺ cells is correlated with the clinical activity of ulcerative colitis

We next searched for a possible clinical implication of our findings. There was a significant positive correlation between the labeling index of Ki-67 among CD19⁺ cells in the ulcer base of ulcerative colitis and the clinical activity of ulcerative colitis at the time of operation (Fig. 12). This suggested that active proliferation of CD19⁺ plasma cells that were resistant to medical treatment with corticosteroids takes place in the ulcer base of active ulcerative colitis. In contrast to this, there was no such significant correlation observed as far as plasma cells in the inflamed mucosa were concerned (data not shown), underscoring the importance of these changes in the ulcer base of ulcerative colitis.

Discussion

To the best of our knowledge, the present study documented for the first time the specific occurrence of CD19⁺ plasma cells that showed higher labeling of Ki-67 in the ulcer base of ulcerative colitis. Previous studies on the subsets of lymphocytes in ulcerative colitis dealt with either CD19 or CD20, and no reports compared the distribution changes of the two markers. We compared the two markers to detect the widely spread distribution of CD19⁺ and CD20⁻ cells in ulcerative colitis. A considerable number of them were further positive for CD138. Together with immunoelectron microscopic features, we judged that they belong to plasma cells. Since CD19 is positive in early (or immature) plasma cells [13], CD19⁺ plasma cells in ulcerative colitis included a considerable number of immature plasma cells. The higher labeling of Ki-67 that suggests the proliferative activity in these cells was consistent with this immaturity. These changes were specific for ulcerative colitis because most CD138⁺ plasma cells in Crohn's disease belonged to CD19⁻ and CD138⁺ mature plasma cells that lacked proliferative activity.

The most prominent changes we observed took place in the ulcer base of ulcerative colitis. Caution must be exercised in this explanation because inflammatory reactions occurring in the ulcer base have been generally regarded as secondary changes after the breakdown of the mucosal barrier in ulcerative colitis. Our data here, however, suggest that higher occurrence of Ki-67 in CD19⁺ plasma cells in the ulcer base of ulcerative colitis is not secondary, but at least in part, ulcerative-colitis-specific, since similar findings were not detected in Crohn's disease or ischemic colitis even in the areas of ulceration or actively inflamed mucosa. The positive correlation between the labeling index of Ki-67 of CD19⁺

plasma cells in the ulcer base and the clinical severity of ulcerative colitis further underscores this notion. Collectively, our findings here indicated the importance of abnormalities in the humoral immunity in ulcerative colitis that takes place mainly in the ulcer base and partly in the inflamed mucosa. These reactions by plasma cells would possibly induce an overactivation of humoral immune responses, including autoantibody production.

Next, we considered possible differentiation pathways of plasma cells we observed. To date, three pathways have been proposed for the differentiation of B cells: (a) the pathway via follicles in lymph nodes or gut-associated lymphoid tissue (GALT) (the main pathway) [17], (b) the extrafollicular pathway via splenic marginal zone B-cells-plasmablasts, which shows a high proliferative activity [14], and (c) the B-1 cell pathway that is independent of T cells, which is observed in the peritoneal and pleural cavities [2]. As shown in the results, the proliferation of plasma cells in the present study took place without new formation of the germinal centers. This indicated that these plasma cells are in a distinct maturational pathway from the ordinary one in GALT [17]. The origin of these plasma cells remains to be clarified in future studies.

In conclusion, our study revealed frequent labeling for Ki-67 in CD19⁺ plasma cells (immature plasma cells), which is specific for ulcerative colitis, particularly in the ulcer base. We need further analysis to clarify the mechanisms of plasma-cell responses in ulcerative colitis at various stages with or without medical treatments, which will surely contribute to a better understanding of the pathogenesis of ulcerative colitis.

Peritoneal metastasis inhibition by linoleic acid with activation of PPAR γ in human gastrointestinal cancer cells

Received: 28 September 2005 / Accepted: 29 September 2005 / Published online: 16 December 2005
© Springer-Verlag 2005

Abstract The effect on peritoneal metastasis of linoleic acid (LA) was examined using in vitro treatment of cancer cells and mouse peritoneal metastasis models. Firstly, cell growth of MKN28 human gastric cancer cells and Colo320 human colon cancer cells was suppressed by LA in a dose-dependent manner with increment of apoptosis. LA-induced growth inhibition was recovered by the exposure to antisense *S*-oligodeoxynucleotide for peroxisome proliferator-activated receptor gamma (PPAR γ) or 15-lipoxygenase-1, which converts LA to PPAR γ ligands. LA significantly inhibited invasion into type-IV collagen-coated membrane of MKN28 and Colo320 cells ($p < 0.05$). BALB/c *nu/nu* mice inoculated with MKN28 and Colo320 cells into their peritoneal cavities were administrated with LA intraperitoneally (weekly, four times). The LA treatment significantly diminished the number of metastatic foci of both cells in the peritoneal cavity ($p < 0.05$). Protein production in MKN28 and Colo320 cells treated with LA showed a decrease of epidermal growth factor receptor and an increase of Bax. These findings suggest that LA inhibits invasion and metastasis of human gastric and colon cancer cells by nondietary administration.

Keywords Peritoneal metastasis · Linoleic acid · Peroxisome proliferator-activated receptor gamma · 15-Lipoxygenase-1 · Gastrointestinal cancer

Abbreviations LA: Linoleic acid · ODN: Oligodeoxynucleotide · PPAR: Peroxisome proliferator-activated receptor · LOX: Lipoxygenase · EGFR: Epidermal growth factor receptor · PG: Prostaglandin · HODE: Hydroxyoctadecadienoic acid · OXO: Oxooctadecadienoic acid · CLA: Conjugated linoleic acid · PBS: Phosphate-buffered saline

Introduction

Linoleic acid (LA) is an ω -6 polyunsaturated fatty acid, which is a precursor of prostaglandin (PG) yielding PGE₂ by enzymatic process with cyclooxygenase-2. PGE₂ plays a pivotal role in carcinogenesis due to its properties of proinflammation, proliferation, and immunosuppression [5, 14]. The carcinogenic effect of dietary LA is already evident in rodent colon carcinogenesis models [3, 12, 13, 20]. However, molecular biological direct effects of LA are poorly understood.

Oxidative metabolites of LA by 15-lipoxygenase-1 (LOX 15), in particular 9-hydroxyoctadecadienoic acid (9-HODE), 13-hydroxyoctadecadienoic acid (13-HODE), and 13-oxooctadecadienoic acid (13-OXO), have biological effects as a peroxisome proliferator-activated receptor gamma (PPAR γ) ligand [10]. PPAR γ possesses an anticarcinogenic effect in colon cancer. Synthesized PPAR γ ligands including troglitazon are shown to be effective chemopreventive agents in a rat model of carcinogenesis and in azoxymethane (AOM)-induced colon cancer in mice [11]. Conjugated LA (CLA) is composed of positional tereoisomers of octadecadienoate (18:2), whose chemoprotective properties are studied in experimental cancer models and in vitro examinations [2, 9]. CLA induces apoptosis in cancer cells by activation of PPAR γ as a ligand. A decrease of PPAR γ is associated with metastasis [1, 17]. If LA provides PPAR γ ligands, LA might act as an anticarcinogenic and antimetastatic agent.

Peritoneal metastasis of cancer is a terminal condition of human gastrointestinal cancer, difficult to be treated, and worsens quality of patients' life [15, 16, 18]. Differently from metastasis to solid organs, cancer cells in peritoneal metastasis can be treated with anticancer agents directly delivered by intraperitoneal administration. To elucidate direct effects of LA in cancer cells, we used the peritoneal metastasis models in this study.

Materials and Methods

Cell culture

A human gastric cancer cell line, MKN28, was kindly provided by Dr. W. Yasui (Hiroshima University Graduate School, Hiroshima, Japan). A human colon cancer cell line, Colo320, was provided by American Tissue and Cell Culture. The cells were routinely maintained in RPMI-1640 (Sigma Chemical Co., St. Louis, MO, USA) containing 10% fetal bovine serum (FBS, Sigma Chemical Co.) under the condition of 5% CO₂ in air at 37°C. LA (Calbiochem, Darmstadt, Germany) was dissolved with 70% ethanol (50 µg/µl). For negative control, same amount of 70% ethanol was used.

Cell growth

Cells were harvested from 80% confluent monolayer cultures by a brief trypsinization with 0.1% trypsin and 0.1% EDTA (Sigma Chemical Co.). The cells were seeded at density of 10,000 cells/well of 24-well tissue culture plates and treated under the conditions mentioned in "Results." The cell number was counted by an autocyotometer (Sysmecs, Kobe, Japan) at 24, 48, and 72 h after the treatment. Apoptotic cells were confirmed by the Giemsa staining. One thousand cells were observed to measure apoptotic cell percentage. Each experiment was repeated three times.

Antisense phosphorothioate (S)-oligodeoxynucleotide assay

The 18-mer S-oligodeoxynucleotide (S-ODN) for the antisense sequence from the 1st to the 18th nucleotide of LOX15 and PPAR γ cDNA coding region were synthesized and purified by reverse-phase high-performance liquid chromatography (Sigma Genosys, Ishikari, Japan). The sequence of LOX15 was 5'-CCA TAT AGA TCT GAA T-3' and that of PPAR γ was 5'-CCT GGG GTA AGG TCG G-3'. Each sense sequence 18-mer was for negative control. The cells were pretreated with 3 µM antisense or sense S-ODN for 6 days, with medium exchanges and additions of antisense or sense S-ODN every 2 days. After that, the cells were used for further experiments.

Fig. 1 Effects of linoleic acid (LA) on growth, apoptosis, and invasion in MKN28 and Colo320 cells. **a** Cell growth inhibition by LA. Cell growth inhibition by 200 and 400 µg/ml LA is significantly higher than that by 50 or 100 µg/ml LA in both cell lines ($***p < 0.05$). **b** Percentage of apoptotic cells induced by LA. Apoptotic cells were counted from 1000 cells examined by the Giemsa staining. The apoptotic cells were significantly increased compared with nontreated cells ($***p < 0.05$). **c** In vitro invasion assay of LA-treated cells. Invading cells were significantly decreased compared with nontreated cells ($***p < 0.05$). **a-c** Seventy percent ethanol, 70% EtOH, a solvent for LA, was used as a negative control. Bar, mean of three independent experiment. Error bar, standard deviation

PPAR γ and LOX5 mRNA expression was assessed with reverse transcriptase-polymerase chain reaction (RT-PCR) using 0.5 μ g of total RNA extracted by an RNeasy kit (Qiagen, Hilden, Germany). Primer sets for LOX15 were as follows: upper, 5'-CGC ACG GGG CAA GGA GAC-3'; lower, 5'-TGA CCA CAC CAG AAA ATC-3'. Primer sets for PPAR γ were as follows: upper, 5'-GCC ATC CGC ATC TTT CAG-3'; lower, 5'-CCC CAT CTT TAT TCA TCA-3'. PCR products were electrophoresed in a 2% agarose gel and stained with ethidium bromide. β -Actin mRNA was also amplified for internal control. The experiment was repeated twice.

BALB/c *nu/nu* athymic mice were purchased from Japan SLC Inc. (Shizuoka, Japan). The mice were maintained according to institutional guidelines approved by the Committee for Animal Experimentation of Nara Medical University, in accordance with the current regulations and standards of the Ministry of Health, Labour, and Welfare. The mice were used according to the institutional guidelines when they were 5 weeks old. Cells were briefly trypsinized and washed with PBS, three times. Cells suspended with PBS were injected into the peritoneal cavity by 1×10^7 in each mouse. Ten mice were injected for each group. After the inoculation, LA (100 μ g in 1 ml PBS)

Fig. 2 Effect of antisense *S*-oligodeoxynucleotide (*S*-ODN) for LOX15 or peroxisome proliferator-activated receptor gamma (PPAR γ) growth in MKN28 and Colo320 cells. (a) mRNA expression of LOX15 and PPAR γ in MKN28 and Colo320 cells exposed to sense and antisense *S*-ODNs. β -Actin was detected for internal control. Cell growth inhibition by LA in MKN28 (b) and Colo320 (c) cells exposed to antisense (*AS*) or sense (*S*) *S*-ODN. was weekly injected into the peritoneal cavity four times. Then, those mice were killed to count the number of metastatic foci in the peritoneal cavity.

Immunoblot analysis

Whole-cell lysates were prepared as described previously [6]. Fifty-microgram lysates were subjected to the immunoblot analysis in 12.5% sodium dodecyl sulfate-polyacrylamide gels followed by electrotransfer onto nitrocellulose filters. The filters were incubated with primary antibodies and then with peroxidase-conjugated IgG antibodies (Medical and Biological Laboratories, Nagoya, Japan). An α -tubulin antibody was used to assess the levels of protein loaded per lane (Oncogene Research Products, Cambridge, MA, USA). The immune complex was visualized by the ECL Western blot detection system (Amersham, Aylesbury, UK). Anti-epidermal growth factor receptor (anti-EGFR) and anti-Bax (Santa Cruz Biotechnology, Santa Cruz, CA, USA) were used as the primary antibodies.

Statistical analysis

Statistical significance was examined by the two-tailed Fisher's exact test, the two-tailed chi-square test, and the two-tailed, unpaired Mann-Whitney test using the InStat Software (GraphPad Software, Los Angeles, CA, USA). The statistical significance was defined as a two-sided p value of less than 0.05.

Results

Effect of LA on growth, apoptosis, and invasion in MKN28 and Colo320 cells

We firstly examined the growth inhibitory effect on cancer cells by LA in vitro (Fig. 1a). LA treatment showed growth inhibition in MKN28 and Colo320 cells in a dose-dependent manner. MKN28 cells respectively showed 97 and 98% growth inhibition by treatments with concentrations of 200 and 400 $\mu\text{g/ml}$. Colo320 cells showed 73% inhibition by 400 $\mu\text{g/ml}$ LA. LA induces apoptosis on MKN28 and Colo320 cells (Fig. 1b). Treatment with 100 $\mu\text{g/ml}$ of LA induced apoptosis in MKN28 and Colo320 cells to 22 and 28%, respectively. The induction of apoptosis by LA showed a dose-dependent manner. MKN28 and Colo320 cells were examined invasive for capacity by in vitro invasion assay using culture inserts with type-IV collagen-coated membrane (Fig. 1c). The treatment with 100 $\mu\text{g/ml}$ of LA decreases invading cell number in MKN28 and Colo320 cells to 5 and 17%, respectively, compared with those in nontreated cells. The LA-induced inhibition of invasion showed a dose-dependent manner.

Effect of antisense *S*-ODN for LOX15 or PPAR γ growth inhibition of LA

To test the hypothesis that LA is metabolized by LOX15 to PPAR γ ligands to cause growth inhibitory effect, MKN28 and Colo320 cells were treated with LA under an exposure to sense or antisense *S*-ODNs for LOX15 or PPAR γ (Fig. 2). Constitutive expression of LOX15 and PPAR γ was suppressed by exposure to each specific antisense *S*-ODN (Fig. 2a). The exposure to antisense *S*-ODNs for LOX15 significantly reduced the growth inhibition by LA in MKN28 and Colo320 cells (Fig. 2b). The exposure to antisense *S*-ODNs for PPAR γ also significantly reduced the growth inhibition by LA in MKN28 and Colo320 cells (Fig. 2c).

Effect of LA on peritoneal colonization of MKN28 and Colo320 cells

We next examined the effect of LA on metastasis of MKN28 and Colo320 cells using nude mice models (Fig. 3a). MKN28 and Colo320 cells were inoculated by 1×10^7 in the peritoneal cavity of BALB/c nude mice. After the inoculation, the mice were intraperitoneally administrated with LA (100 μg in 1 ml PBS), weekly, four times. The treatment with

Fig. 3 Effect of LA on peritoneal colonization of MKN28 and Colo320 cells. **a** Experimental design of peritoneal metastasis. Cells (1×10^7) were inoculated into the peritoneal cavity. **b** Number of metastatic foci in the peritoneum. Number of metastatic foci was significantly reduced by LA treatment ($*p < 0.05$). Fig. 4 Effect of LA on production of epidermal growth factor receptor (EGFR) and Bax in MKN28 and Colo320 cells. Protein production of EGFR and Bax was examined by the immunoblotting. Tubulin was detected for internal control. Protein levels are compensated by internal control and standardized by the level in nontreated MKN28 cells, which is set to 1.0. The experiment was repeated twice

LA did not affect body weight of these mice. In 12 weeks after the inoculation, the number of the colonized foci of cancer cells was counted (Fig. 3b). In MKN28 cells, 14 ± 1 per rat of colonized foci were observed in untreated mice, whereas colonizations were decreased to 7 ± 1 foci per rat by the treatment with LA. In Colo320 cells, 21 ± 3 per rat of colonized foci were observed in untreated mice, whereas colonizations were reduced to 13 ± 2 foci per rat by the treatment with LA.

Effect of LA on production of metastasis-related proteins in MKN28 and Colo320 cells

Finally, we examined protein levels in LA-treated MKN28 and Colo320 cells (Fig. 4). In LA-treated MKN28 and Colo320 cells, a decrease of EGFR protein and an increase of Bax were detected. EGFR protein levels in LA-treated MKN28 and Colo320 cells were decreased to 20 and 37%, respectively, compared with those of nontreated cells. In contrast, Bax protein levels in LA-treated MKN28 and Colo320 cells were increased to 154 and 631%, respectively, compared with those of nontreated cells.

Discussion

In the present study, we examined the direct effects of LA on growth, invasion, apoptosis, and metastasis of cancer cells in vitro and in vivo. Our results showed that LA inhibits cell growth and invasion and induces apoptosis with direct exposure to cancer cells. Moreover, LA inhibited cancer cell colonization in the peritoneal cavity. In addition, LA treatment provided the alteration of protein levels of metastasis-related genes. Thus, we can conclude from the data that LA has antimetastatic effect.

We hypothesized that LA is a PPAR γ ligand precursor and that LA metabolites by LOX15, 13-HODE, and 13-OXO have ligand activity for PPAR γ [10]. To confirm this hypothesis, we inactivated PPAR γ by specific antisense S-

ODN. The result showed that the inhibition of growth and invasion and the induction of apoptosis by LA were abrogated by exposure to antisense S-ODN for PPAR γ . Moreover, the decrease of LOX15 expression by exposure to antisense S-ODN for LOX15 suppressed the inhibition of growth and invasion and the induction of apoptosis by LA. These findings support our hypothesis that LA acts as a PPAR γ ligand precursor. We also examined a PPAR γ ligand, CLA, for suppression of peritoneal metastasis of MKN28 and Colo320 cells, which showed same inhibitory effect to LA. However, its efficacy was 10^3 times stronger than LA (data not shown). It suggests that LA metabolites might be weaker agonists of PPAR γ .

PPAR γ is a multifunctional nuclear receptor. Activation of PPAR γ by synthesized PPAR γ ligands provided growth inhibition and apoptosis in cancer cells. Some reports show that down-regulation of EGFR and up-regulation of Bax are associated with antiproliferative and proapoptotic effects [4, 7, 8]. In the present study, we confirmed that LA decreased EGFR expression and increased Bax expression in both MKN28 and Colo320 cells. A recent report shows that PPAR γ is also associated with inhibition of colon cancer metastasis [19]. Metastasis of HT-29 human colon cancer cells is inhibited by thiazolidinedione through induction of terminal differentiation. We examined the alteration of differentiation status of MKN28 and Colo320 cells by LA, testing protein levels of p21waf1; however, no remarkable change was detected (data not shown).

In the present study, we showed the inhibitory effect of PPAR γ on peritoneal metastasis and the activation of PPAR γ by LA. The results suggest that PPAR γ is a key target of metastasis therapeutics. It is necessary to test the suppression of metastasis by dietary LA on animal models.

Differential expression of claudin-2 in normal human tissues and gastrointestinal carcinomas

Received: 3 October 2005 / Accepted: 10 October 2005 / Published online: 17 November 2005
© Springer-Verlag 2005

Abstract Claudins are involved in the formation of tight junctions in epithelial and endothelial cells. Claudins form a family of 24 members displaying organ- and tissue-specific patterns of expression. In the present study, we evaluated the specificity of the claudin-2 expression in various normal human tissues and gastrointestinal cancers by quantitative reverse transcriptase–polymerase chain reaction and immunohistochemistry. In 14 various normal tissues, *claudin-2* mRNA was expressed in the kidney, liver, pancreas, stomach, and small intestine; the highest level of which was detected in the kidney. Colorectal cancers (CRCs) expressed *claudin-2* mRNA at high levels. Immunohistochemical analysis of claudin-2 in 146 gastric cancers (GCs) and 99 CRCs demonstrated claudin-2 expression in 2.1% of GCs and 25.3% of CRCs, respectively. There was no obvious correlation between claudin-2 expression and clinicopathological parameters of CRCs. These results suggest that the expression of claudin-2 may involve organ specificity, and increased expression of claudin-2 may participate in colorectal carcinogenesis.

Keywords Claudin-2 · Gastric · Colorectal cancers

Introduction

Claudin-1 and claudin-2 were the first members of the transmembrane tetraspan family of proteins identified as being involved in tight junction formation with the recruitment of occludin [4] and binding to other tight junction constituents [8]. Claudins form a family of at least 24 members displaying organ- and tissue-specific patterns of expression [9, 17]. Among the claudin family members, expression of claudin-2 is found in the liver, pancreas, and gut in normal rat tissues [17]. Claudin-2 expression is ubiquitous in the epithelial cells at the crypts of the small intestine but restricted to the undifferentiated cell compartment of the colon in rats [17]. Claudin-2 is also known to be expressed in mouse nephron [3, 9]. However, the expression pattern of claudin-2 remains to be elucidated in normal human tissues.

Gastrointestinal cancers including gastric cancer (GC) and colorectal cancer (CRC) are the most common malignancies worldwide. A better knowledge of changes in gene expression during gastrointestinal carcinogenesis may lead to new paradigms and possible improvements in diagnosis, treatment, and prevention. On the other hand, relatively little is known about the expression of claudins in human tumors, and only little information is available on the influence of claudin expression on tumor behavior. It was reported that the expression of claudin-7 was decreased in high-grade breast cancer [10]. Overexpression of claudin-4 has been found in pancreatic adenocarcinoma and its precursor lesions [15, 22], while overexpression of claudin-3 and claudin-4 has been found in prostate and ovarian carcinomas [7, 13]. Concerning the expression of claudin-2 in tumor tissue, it has been reported that claudin-2 expression was detected in 98 (52%) of 188 breast carcinomas [20]. There is one report showing claudin-2 expression in gastrointestinal tumors, but the sample number was small [21].

In the present study, the expression of claudin-2 was investigated in various normal tissues, GCs, and CRCs by

quantitative reverse transcriptase–polymerase chain reaction (RT-PCR) and immunohistochemistry. The aim of this study is to clarify whether claudin-2 expression is specific for cancer by comparing the expression level of claudin-2 in various normal tissues with that in cancer tissues.

Materials and methods

Tissue samples

For quantitative RT-PCR, five GCs and nine CRCs were used. The samples were obtained at the time of surgery at the Hiroshima University Hospital and affiliated hospitals. We confirmed microscopically that the tumor specimens consisted mainly (>50%) of carcinoma tissue. Samples were frozen immediately in liquid nitrogen and stored at -80°C until use. Noncancerous samples of the heart, lung, stomach, small intestine, colon, liver, pancreas, kidney, bone marrow, peripheral leukocytes, spleen, skeletal muscle, brain, and spinal cord were purchased directly from Clontech (Palo Alto, CA, USA).

For immunohistochemical analysis, we used archival formalin-fixed, paraffin-embedded tissues from 245 patients who had undergone surgical excision or removal of the tumor by polypectomy for GC ($n=146$) and CRC ($n=99$). The 146 GCs were either histologically classified ($n=85$) or poorly ($n=61$) differentiated. Ninety-nine CRCs were either histologically classified ($n=47$) or moderately ($n=45$) or poorly ($n=7$) differentiated. Tumor staging was carried out according to the tumor–node–metastasis (TNM) staging system [12]. Because written informed consent was not obtained, for strict privacy protection, identifying information for all samples was removed before analysis; the procedure was in accordance with the Ethical Guidelines for Human Genome/Gene Research enacted by the Japanese Government.

Cell lines

Eight cell lines derived from human GC were used. The TMK-1 cell line was established in our laboratory [16]. Five GC cell lines of the MKN series were kindly provided by Dr. T. Suzuki. KATO-III and HSC-39 cell lines were kindly provided by Dr. M. Sekiguchi and Dr. K. Yanagihara [25], respectively. All cell lines were maintained in RPMI 1640 (Nissui Pharmaceutical Co., Ltd., Tokyo, Japan) containing 10% fetal bovine serum (Whittaker, Walkersville, MA, USA) in a humidified atmosphere of 5% CO_2 and 95% air at 37°C .

Quantitative RT-PCR analysis

Total RNA was extracted with an RNeasy Mini kit (Qiagen, Valencia, CA, USA), and 1 μg of total RNA was converted

to cDNA with a First-Strand cDNA Synthesis kit (Amersham Pharmacia, Little Chalfont, UK). PCR was performed with an SYBR Green PCR Core Reagents kit (Applied Biosystems, Foster City, CA, USA). Real-time detection of the emission intensity of SYBR green bound to double-stranded DNA was performed with an ABI PRISM 7700 Sequence Detection System (Applied Biosystems) as described previously [11]. *Claudin-2* cDNA and internal control cDNAs [β -actin gene (*ACTB*) and glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*)] were PCR-amplified separately. Relative gene expression was determined by the threshold cycles for the *claudin-2* and *ACTB* or *GAPDH* genes. Reference samples (GC cell line, KATO-III) were included on each assay plate to verify plate-to-plate consistency. Plates were normalized to each other by these reference samples. PCR amplification was performed according to the manufacturer's instructions in 96-well optical trays with caps with a 25- μl final reaction mixture. Quantitative RT-PCRs were performed in triplicate for each sample primer set, and the mean of the three experiments was used as the relative quantification value. *Claudin-2* primer sequences are forward primer 5'-TCCCCAAACCC ACTAATCACA-3' and reverse primer 5'-CCAACCTCAG CCAGAGAGAGG-3'. *ACTB* primer sequences were 5'-T CACCGAGCGCGGCT-3' and 5'-TAATGTCACGCAC GATTTCCC-3' [11]. *GAPDH* primer sequences were 5'-GGTGAAGGTCGGAGTCAACG-3' and 5'-AGAGTTAA AAGCAGCCCTGGTG-3'. The units are arbitrary, and we calculated *claudin-2* mRNA expression by standardization to 1.0 μg total RNA from KATO-III as 1.0. We found a similar result in both quantitative RT-PCR analyses of *claudin-2* and *ACTB* or *GAPDH* of 8 GC cell lines, 14 various normal tissues, 5 GC tissues, and 9 CRC tissues. Therefore, throughout this article, we will describe and discuss the results obtained using *ACTB* as an internal control in quantitative RT-PCR analysis.

Western blot analysis

Preparation of whole cell lysates from GC cell lines was made and Western blotting was performed as described previously [26]. Protein concentrations were determined by Bradford protein assay (Bio-Rad, Hercules, CA, USA) with bovine serum albumin used as the standard. Lysates (20 μg) were solubilized in Laemmli's sample buffer by boiling and then subjected to 12% sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) followed by electrotransfer onto a nitrocellulose filter. Anti-claudin-2 polyclonal antibody was purchased from Zymed (South San Francisco, CA, USA), and anti- β -actin mouse monoclonal antibody was purchased from Sigma (USA). Peroxidase-conjugated anti-rabbit IgG and anti-mouse IgG was used in the secondary reaction, respectively. The immunocomplex was visualized with an ECL Western Blot Detection System (Amersham Pharmacia Biotech).

Immunohistochemistry

A Dako LSAB kit (Dako, Carpinteria, CA, USA), which is based on the LSAB method, was used for the immunohistochemical analysis. In brief, microwave pretreatment in citrate buffer was performed for 15 min to retrieve antigenicity. After blocking the peroxidase with 3% H₂O₂-methanol for 10 min, sections were incubated with antibody/rabbit polyclonal anti-claudin-2, 1:100 (Zymed).

Sections were treated consecutively at room temperature with primary antibody for 2 h, followed by sequential 10 min incubation with biotinylated anti-rabbit IgG and peroxidase-labeled streptavidin. Staining was completed after 10 min incubation with the substrate-chromogen solution. The sections were counterstained with 0.1% hematoxylin. The results of staining with each antibody were evaluated with reference to the percentage of stained cancer cells. The results of immunohistochemistry were graded as follows: “-,” 0% to 25% of tumor cells showed immunoreactivity; “+,” 25–50% of tumor cells showed immunoreactivity; “++,” more than 50% of tumor cells showed immunoreactivity. We regarded “++” as positive throughout this report.

Statistical methods

Associations between clinicopathologic parameters and claudin-2 expression were analyzed by Fisher’s exact test. *P* values less than 0.05 were considered statistically significant.

Fig. 1 Quantitative RT-PCR analysis of *claudin-2* in 14 various normal tissues as well as in 5 GC and 5 CRC samples. Among the various normal tissues, the highest level of *claudin-2* expression was found in the kidney; low expression was detected in the stomach, small intestine, liver, and pancreas; and faint expression was seen in the lung and skeletal muscle. In GCs, the expression levels were not so different from that in normal stomach. In CRCs, the expression levels were higher than those in normal colon

Results

Measurement of mRNA expression of *claudin-2* in various normal tissues, GCs, and CRCs by quantitative RT-PCR

To measure the expression levels of *claudin-2* mRNA, we performed quantitative RT-PCR on 5 GCs, 5 CRCs, and 14 normal tissue samples (heart, lung, stomach, small intestine, colon, liver, pancreas, kidney, bone marrow, peripheral leukocytes, spleen, skeletal muscle, brain, and spinal cord). The results are shown in Fig. 1. In general, the expression levels in CRCs were higher than those in GCs and normal tissues. Among the 14 normal tissues mentioned, the highest level of expression was detected in the kidney. Although obvious expression of *claudin-2* was also detected in the liver, pancreas, stomach, and small intestine, it was not as high as compared with the kidney. In the lung and skeletal muscle, a faint expression of *claudin-2* was found. There was no expression in the remaining normal tissues. Expression levels of *claudin-2* were not so different between normal stomach and GCs. While no expression of *claudin-2* was found in normal colon, two of five CRCs expressed *claudin-2* at significantly higher levels (more than 5 arbitrary units).

Expression and localization of claudin-2 in cancer cell lines

To confirm the mRNA expression of *claudin-2* in cancer cells, we performed quantitative RT-PCR in eight GC cell

lines. As shown in Fig. 2a, an obvious expression of *claudin-2* was detected in MKN-45, MKN-74, and KATO-III, whereas only a low level of expression was seen in HSC-39; there was no expression detected in the remaining four GC cell lines. The anti-claudin-2 antibody detected an approximately 22-kDa band on Western blot of cell extracts from MKN-45, MKN-74, and KATO-III (Fig. 2b). We also confirmed these results by immunohistochemical staining in MKN-28 and MKN-45 cell lines. Claudin-2 staining was detected in cell membranes in MKN-45 cells but not in MKN-28 cells (Fig. 2c). Thus, this antibody was considered to be useful in the detection of claudin-2 protein in situ.

Expression and localization of claudin-2 in CRC tissues

To predict the sensitivity of anti-claudin-2 rabbit polyclonal antibody in immunohistochemistry, we examined the mRNA expression and protein expression of claudin-2 in an additional four CRC tissues. Firstly, we performed quantitative RT-PCR to detect *claudin-2* mRNA expression level and found an obvious expression of *claudin-2* (more than 5 arbitrary units) in three of four examined CRC tissue samples (Fig. 3a). The anti-claudin-2 antibody detected an approximately 22-kDa band on Western blot of protein extracts from the three CRC tissues, which showed obvious high expression in quantitative RT-PCR analysis (Fig. 3b). We also confirmed these results by immunohistochemical staining. Claudin-2 staining was detected in cell membranes of the same three CRC tissue samples, which expressed claudin-2 at a significantly higher level in both quantitative RT-PCR and Western blotting analyses (Fig. 4c). Therefore, in these CRC tissue samples, we

Fig. 3 Expression of claudin-2 in CRC tissue samples. Claudin-2 expression was analyzed at the mRNA level by quantitative RT-PCR (a) and at the protein level by Western analysis (b)

found a good correlation between mRNA and protein levels. This result also suggests that in immunohistochemical analysis, our antibody may detect claudin-2 protein expression at levels higher than 5 arbitrary units measured by quantitative RT-PCR analysis.

Fig. 2 Expression and localization of claudin-2 in GC cell lines. Claudin-2 expression was analyzed at the mRNA level by quantitative RT-PCR (a) and at the protein level by Western analysis (b) and immunohistochemistry (c); claudin-2 immunoreactivity was evident in the cell membranes of MKN-45 cells but not MKN-28 cells

Fig. 4 Immunohistochemical analysis of claudin-2 in normal kidney (as a control) as well as in GC and CRC tissues. Staining for claudin-2 was observed in the basal membranes of the proximal tubule of the kidney (a), the cellular membrane of GC cells forming a tubular structure (b), and the cellular membrane of CRC cells forming a papillotubular structure (c). c is case number 1, which expressed *claudin-2* at a high level (more than 5 arbitrary units measured by quantitative RT-PCR), as shown in Fig. 3a,b. Original magnification was $\times 400$

Expression of claudin-2 protein in GCs and CRCs by immunohistochemistry

We then examined the expression of claudin-2 protein in 146 GC and 99 CRC samples by immunohistochemistry. Immunostaining was also performed in normal kidney to serve as a positive control because our real-time RT-PCR revealed a high expression level and a previous report showed claudin-2 expression in mouse nephron. In the kidney, claudin-2 positivity was found strongest in the basal membranes of the proximal tubule, which is consistent with the result of previous reports [3, 9] (Fig. 3a). No obvious staining of claudin-2 was found in normal liver, stomach, and small and large intestines (data

not shown). Of the 146 cases of GC, only 3 (2.1%) were positive for claudin-2. Immunoreactivity of claudin-2 was mainly observed in the cell membranes of GC cells forming a tubular structure (Fig. 3b). In CRCs, 25 (25.3%) of 99 cases were positive for claudin-2. Claudin-2 was mainly localized in the cell membranes of tumor cells forming a papillotubular structure (Fig. 3c).

We analyzed the relation between the expression of claudin-2 and clinicopathologic characteristics of CRC. There was no clear correlation between claudin-2 staining and clinicopathological parameters such as location, T grade, N grade, M grade, stage, and histologic differentiation (Table 1).

Discussion

Cellular tight junctions are structures that help preserve the integrity of cellular layers and regulate their permeability [23, 24]. It may be hypothesized that changes in expression of tight junctional proteins can lead to cellular disorientation and detachment, which are commonly seen in neoplasia. In this study, we demonstrated for the first time the expression of *claudin-2* mRNA in normal human kidney, liver, pancreas, and so on. Among these, the highest level of expression was detected in the kidney. In addition, an obvious expression of *claudin-2* was also detected in the stomach and small intestine. These results are consistent with a previous report in rat and mice; *claudin-2* is expressed in nephron, liver, pancreas, and gut

[3, 17]. We found a basal expression of claudin-2 in kidney tubules, although claudin-2 is not a known basal membrane protein and tight junctions are not known to be in the region of basal membrane. We could not explain well this unusual expression. However, it has been already published by Kiuchi-Saishin et al. [9] that claudin-2, claudin-10, and claudin-11 were clearly concentrated at the tight junction of epithelial cells of the proximal tubules. Among these, only claudin-2 seemed to be distributed along basal plasma membranes in addition to tight junction. This staining is specific for claudin-2 because the kidneys of claudin-2-deficient mice demonstrated no such staining (Furuse et al., unpublished data) [9].

We also investigated claudin-2 expression in 146 GC and 99 CRC cases to evaluate their differential expression of claudin-2 in gastrointestinal cancers. In previous studies, type-specific expression of claudin-1, claudin-2, claudin-3, claudin-4, claudin-5, and claudin-7 has been detected in various types of cancers including carcinomas of breast, pancreas, liver, esophagus, etc. [20, 21]. Soini [21] also analyzed claudin-2 expression in a small number of GCs and CRCs by using the monoclonal anti-claudin-2 antibody and reported that 12 of 13 GCs (92%) and 9 of 11 CRCs (82%) were positive for claudin-2. No method other than immunohistochemistry was utilized. In our study, the frequency of claudin-2 expression in GC and CRC was much lower as compared to the above studies, partly due to the different antibody used. However, our immunohistochemistry must be precise even if it was not so sensitive because we have found a good correlation between levels of *claudin-2* mRNA expression and protein expression by immunostaining and Western analysis of not only GC cell lines but also CRC tissues, as shown in Figs. 2, 3, and 4c. Our antibody may detect claudin-2 expression at levels higher than 5 arbitrary units, as measured by quantitative RT-PCR. In situ hybridization experiments may help detect the expression of claudin-2 with high sensitivity. We will perform it in a future study of claudin-2.

The results of the present study demonstrated that expression of claudin-2 was detected in CRCs, whereas no expression of claudin-2 was detected in normal colon. We did not find any significantly different expression between GC and normal stomach. Therefore, the participation of claudin-2 in tumorigenesis may involve organ specificity. Claudin species have been found to be the major constituents of tight junction strands [2, 5, 9, 19]. The presence of junctional claudin-2 causes the formation of cation-selective channels sufficient to transform a “tight” junction into a “leaky” one [1]. In carcinogenesis of CRC, claudin-2 may contribute to an easier leak of tight junctions in between neoplastic cells. Although we observed claudin-2 staining mainly in the neoplastic cells forming a tubular or papillary structure in both GCs and CRCs, we did not find any significant correlation between claudin-2 protein expression and histological differentiation. Moreover, we could not find any correlation with tumor advancement. Therefore, increased expression of claudin-2 may partici-

pate in the development but not in the progression of CRCs, although the exact mechanism is unknown. It has been shown that human claudin-2 promoter activity is positively regulated by the caudal-related homeobox gene (*CDX2*), as well as by the hepatocyte nuclear factor-1 alpha isoform (*HNF-1 α*) [18]. A published study has shown the presence of functional cross talk between *CDX2* and the Wnt pathway in the positive regulation of claudin-2 expression [14]. These regulations may be the cause of the involvement of claudin-2 in colorectal carcinogenesis. In fact, abnormalities in Wnt signaling, including β -catenin/TCF, have been shown to participate in the pathogenesis of CRC [6]. Further studies are needed to explore the exact mechanism of claudin-2 involvement in gastrointestinal tumor pathology.

Correlation of invasion and metastasis of cancer cells, and expression of the RAD21 gene in oral squamous cell carcinoma

Received: 31 July 2005 / Accepted: 28 October 2005 / Published online: 14 January 2006

Abstract Although RAD21 is involved in the repair of double-strand breaks in DNA and is essential for mitotic growth, its role in cancer has been unclear. In this study, the relevance of RAD21 gene expression to the invasion and metastasis of oral squamous cell carcinoma was clarified using laser microdissection and real-time polymerase chain reaction (PCR). Using two different metastatic potential oral squamous cells [high-metastatic-potential squamous cell carcinoma cells (SAS-Ly) and low-metastatic-potential squamous cell carcinoma cells (SAS)], the relation of RAD21 gene expression to apoptosis, invasion, and metastasis was examined. The results showed that RAD21 gene expression was significantly decreased in oral squamous cell carcinoma when it expressed the $\text{INF}\beta$ and $\text{INF}\gamma$ invasion patterns in comparison with the $\text{INF}\alpha$ invasion pattern ($p < 0.01$). In addition, in comparison with SAS cells, SAS-Ly cells indicated tolerance to cell death induced by an apoptosis induction reagent, while the expression level of the RAD21 gene in SAS cells was increased by the apoptosis induction reagent. However, in SAS-Ly cells, the reagent induced no significant difference. Our findings indicate that the RAD21 gene was closely related to the invasion and metastasis of cancer cells.

Introduction

RAD21 is one of the four subunits of cohesin, the latter of which holds sister chromatids together until anaphase [8, 23]. Cohesin is combined with the chromosome in the G1 phase and holds the sister chromatids until RAD21 is cleaved by separase during the onset of anaphase, with these cleavages allowing chromosomal separation [9, 17, 18, 24, 33]. When RAD21 was knocked out of chicken DT40 cells, it caused premature sister chromatid separation [30]. When RAD21 is mutated at the cleavage site by separase, not only chromosome segregation but also cell division is inhibited [16]. In light of the above fact, RAD21 may play an important role in faithful and stabilized chromosomal separation. Recently, it has been shown that the degradation product formed by the C-terminal cleavage of RAD21 by caspases 3 and 7 becomes a factor which induces apoptosis [13, 26]. In addition, in regard to the association of tumor formation and RAD21, the expression level of the RAD21 gene is suppressed by hypoxia in liver cancer and mammary cancer cells [31], the RAD21 gene is over-expressed in prostate cancer cells [27], and it has been reported that RAD21 gene expression is induced by the BRCA1 gene which is a tumor suppressor gene in breast cancer cells [3]. However, the relation between the RAD21 gene and cancer remains unclear. In the present study, the relevance of the RAD21 gene to the invasion and metastasis of squamous cell carcinoma was investigated in carcinoma tissue samples using laser microdissection and real-time polymerase chain reaction (PCR). RAD21's relevance to cancer cell invasion was investigated using the high (SAS-Ly) and low (SAS) metastatic potentials of the squamous cell carcinoma cell line.

Materials and methods

Cell culture

The SAS cell, a poorly differentiated squamous cell carcinoma cell line, was derived from human tongue primary

lesion [32]. The SAS-Ly cell with high lymph node metastatic potential was established in our department from SAS by repetition of orthotopic implantation to the tongue of the nude mouse [2]. Cells were cultured in Dulbecco's Modified Eagle medium nutrient mixture F-12 ham (SIGMA) supplemented with 10% fetal bovine serum, 50 units/ml penicillin, and 50 µg/ml streptomycin, in a humidified atmosphere, 5% CO₂, at 37°C.

Drug treatment

Actinomycin D and trichostatin A were purchased from Sigma. Actinomycin D was kept as a 1.25-mg/ml solution in ethanol at 4°C, and trichostatin A was an 8.3-mM solution in ethanol at -20°C. SAS and SAS-Ly cells at subconfluent states were treated with these drugs at the desired final concentration and duration. Control cells were treated with the vehicle (ethanol) used to dilute actinomycin D and trichostatin A.

Frozen sample preparation for laser microdissection

Tumor specimens were obtained at surgery from 28 patients with oral squamous cell carcinoma (Table 1). The extracted tissues were embedded in OCT compound and frozen in isopentane cooled in liquid nitrogen. The specimens were then made into frozen blocks, which were sliced using a cryomicrotome (MICROM) at 7-µm thickness for microdissection.

RNA isolation

Total RNA was extracted from the cultured cells by TRIzol reagent (Invitrogen). After phenol/chloroform extraction and ethanol precipitation, RNA was resuspended in diethyl pyrocarbonate (DEPC)-treated water. For total RNA extraction using laser microdissection, the frozen sections were placed at room temperature for 5 min and fixed in 100% methanol for 3 min. After washing with RNase-free water, the sections were stained with 1% toluidine blue. After they were air-dried, the sections were microdissected by means of a PALM Micro Beam (P.A.L.M. Microlaser Technologies). The target areas were the invasive areas in primary lesion and regional lymph node metastasis of squamous cell carcinoma. The invasion pattern of each case was determined in terms of the classification (pattern of infiltration, INF) of the cancer handling convention of Japan [20, 21]. The patterns are regarded as INF α if the cancer nest grows expansively and a clear circumference boundary can be seen between the cancer and the surrounding tissue. INF β is intermediate between INF α and INF γ . INF γ shows an infiltrative growth pattern and the boundary with the circumference tissue is indistinct. From the type of well-differentiated regions that form a cancer pearl, we removed the keratinized area in advance. The number of microdissected cells was esti-

mated to be about 700–2,500 cells for each sample. The total RNA that had been extracted from each population of laser-microdissected cells was independently extracted by means of our previously described method [19]. Extracted total RNA was resuspended in DEPC-treated water.

Real-time quantitative PCR

Using 40–50 ng total RNA of the cells and all RNA extracted from the frozen sections, cDNA was made by reverse transcription with Sensiscript RT (QUIAGEN) and oligo d(T)₁₆ primer (QUIAGEN). The PCR reactions were performed using an ABI PRISM 7000 Sequence Detection System (Applied Biosystems Japan) apparatus employing QuantiTect SYBR Green PCR (QUIAGEN). Each 30-µl reaction mixture contained 15 µl of 2× QuantiTect SYBR Green PCR Master Mix, sense primer (1 µM), antisense primer (1 µM), 2 µl of template cDNA, and RNase-free water. The PCR conditions were as follows: initial denaturation at 95°C for 15 min, 50 cycles at 94°C for

15 s, 57°C for 30 s, and 72°C for 30 s. The primers are described below: RAD21 (GenBank accession no. NM_006265)(5'-TGGGTTGTGTTTGTGTTCTG-3', 5'-TC AAGAGGGTGACCATTGTT-3' and GAPDH (5'-CGAC CACTTGTCAAGCTCA-3', 5'-CAGTTGCCATG TAGA CCCCT-3'). Standard curves were generated using serial dilutions (1–0.0001) of known quantities of tumor cells cDNA. In addition, melting curve analysis was used to ensure the purity of the amplified PCR product. The relative expression of RAD21 was calculated by dividing the value by the GAPDH value of each sample.

Fluorogenic cell viability assay

Cell viability was assessed using a FluoDia T70 OTSTKA ELECTRONICS apparatus employing CellTiter-Blue Cell Viability Assay, Promega according to the manufacturer's directions. The 5×10^4 cells were seeded into each well of a 96-well microtiter plate. After culturing overnight, various

concentrations of drugs, as indicated in the figure, were added to the wells and incubated for 24 h in a humidified atmosphere, 5% CO₂, at 37°C. A blank control, consisting of CellTiter-Blue Reagent and cell culture medium without cells, was used as a measure of background fluorescence associated with the culture system. The control used vehicle-treated cells with CellTiter-Blue Reagent. After incubation, fluorescence was measured and cell viability as a percentage of untreated cells was calculated.

Results

The expression of RAD21 gene in oral squamous cell carcinoma of various invasion patterns and regional lymph node metastasis *in vivo*

Using the laser microdissection method, the cancer cell that corresponds to each invasion pattern is procured from the invasion front in the primary lesion (Fig. 1). The expression

level of the RAD21 gene was examined by means of real-time PCR. As a result, the expression level of the RAD21 gene decreased significantly ($p < 0.01$) in the areas that showed the invasion patterns of $\text{INF}\beta$ and $\text{INF}\gamma$ in comparison with the areas that showed the $\text{INF}\alpha$ invasion pattern (Fig. 2, Table 2).

In regional lymph node metastasis, the expression level of the RAD21 gene also decreased similar to the $\text{INF}\gamma$ invasion pattern (Fig. 2, Table 2).

Invasion pattern of culture cells transplanted in a nude-mouse tongue

It was shown in our previous report that the invasion potential of SAS-Ly cells is higher than that of SAS cells [2]. When both types of cell were transplanted to the lingual edge region of nude mice (BALB/C-nu/nu), the SAS-Ly cell showed an invasive growth pattern to the circumference tissue, and the invasion pattern corresponded to $\text{INF}\gamma$. Meanwhile, the SAS cells showed an expansive growth pattern to the circumference tissue, with the invasion pattern corresponding to $\text{INF}\alpha$ (Fig. 3).

The expression level of the RAD21 gene of high-metastatic-potential squamous cell carcinoma cells (SAS-Ly) and low-metastatic-potential squamous cell carcinoma cells (SAS)

The expression level of RAD21 gene in SAS cells and SAS-Ly cells with the different invasion patterns was analyzed. The RAD21 gene of the SAS-Ly cell significantly decreased in comparison with the SAS cell ($p < 0.05$) (Fig. 4). It was confirmed that the expression levels of the

RAD21 gene in invasion and metastasis in vitro correlated with those in vivo.

Resistance to cell death induced by apoptosis induction reagents in SAS and SAS-Ly

The results of a cell survival test showed that the population of SAS cells decreased to a greater degree than that of SAS-Ly cells by treatments with actinomycin D and trichostatin A. SAS-Ly cells with high metastatic potential showed resistance to apoptosis (Fig. 5).

Effect of apoptosis induction reagents on the expression level of the RAD21 gene in SAS and SAS-Ly

The optimum concentration and time was determined using the SAS cells. After the SAS cells and SAS-Ly cells were treated with 0.5 μ g/ml actinomycin D and 1,000 nM trichostatin A for 24 h, RAD21 gene expression quantity was measured. As a result, though RAD21 gene expression was significantly increased in the SAS cells treated with the apoptosis induction reagent, a change in the expression of the gene was not recognized in the SAS-Ly cells (Fig. 6).

Fig. 5 The cell survivability with the apoptosis induction reagents in SAS and SAS-Ly. SAS and SAS-Ly were used. **a** Dose-related apoptosis in SAS and SAS-Ly treated with increasing concentration of actinomycin D (0.01 to 5 μ g/ml) for 24 h. **b** Treated with trichostatin A (1 to 1,000 nM) for 24 h. The X-axis expresses the concentration of a reagent and the Y-axis expresses the rate of a survival cell to control. The concentration to which resistance to apoptosis induction reagents was shown in SAS-Ly was compared with SAS. Each point represents a mean of triplicates. Bars \pm SD

Discussion

We studied the relation between the invasion pattern of squamous cell carcinoma and the expression level of the RAD21 gene using the laser microdissection method and real-time PCR in surgical material. It became clear that the expression level of the RAD21 gene decreased as the invasion pattern of squamous cell carcinoma changed to $\text{INF}\gamma$ from $\text{INF}\alpha$. It is known that the expression level of the RAD21 gene is down-regulated under hypoxia in many human tumor cells [31]. As well, hypoxia in malignant tumor tissue is more concerned in development of the aggressive character and metastasis of malignant tumor cells [1, 6, 7, 10, 12, 29]. It has been shown that the lowering of oxygen partial pressure in the tumor correlates with prognosis in squamous cell carcinoma of the head and neck [11]. In regard to the biological significance of the invasion pattern, it is known that in oral squamous cell carcinoma, similar to cancer in other organs, an invasive growth pattern such as $\text{INF}\gamma$ indicates high lymph node metastasis frequency and poor prognosis, as compared with

Fig. 6 The expression level of the RAD21 gene in SAS and SAS-Ly treated with apoptosis induction reagents. **a** SAS and **b** SAS-Ly. The SAS cells and the SAS-Ly cells were treated with actinomycin D (0.5 μ g/ml) and trichostatin A (1,000 nM) for 24 h. The relative expression of the RAD21 gene was calculated by dividing the value by the GAPDH value of each sample. The expression level of the RAD21 gene increased significantly ($p < 0.05$) in the SAS cells with apoptosis induction reagents. In SAS-Ly, although the increase was shown, there was no significant difference. Each point represents a mean of triplicates. Bars \pm SD, NS not significant ($*p < 0.05$)

the cancer which shows an expansive growth pattern such as $\text{INF}\alpha$ [4, 22, 25]. Actually, the case of $\text{INF}\gamma$ showed a lot of metastasis in the case we had used (Table 1). Based on the above reports and the results of our study, the RAD21 gene might be related to the development of an invasive pattern. Simultaneously, these results suggest the possibility that the invasion pattern of squamous cell carcinoma reflects the hypoxia in the tumor tissue.

In regional lymph node metastasis, the expression level of the RAD21 gene decreased similarly to the $\text{INF}\gamma$ invasion pattern. This result supports the possibility that cancer cells with high invasion potential cause lymph node metastasis in relation to hypoxic condition.

Further, we analyzed the relation of RAD21 gene expression to invasion and metastasis potential using high (SAS-Ly) and low (SAS) metastatic squamous cell carcinoma cell lines. It became clear that SAS-Ly cells showed an invasive growth pattern similar to $\text{INF}\gamma$ in grafts to the nude mouse, and that SAS cells showed an

expansive growth pattern similar to $\text{INF}\alpha$. This result shows that these cell lines have the phenotype reflecting the invasion pattern *in vivo*, and that the invasion pattern and metastasis are closely related in the cultured cells. In addition, the lower RAD21 gene expression level in SAS-Ly cells than in SAS cells supports the analytical result regarding the quantity of RAD21 gene expression in cancer cells of each invasion pattern of the squamous cell carcinoma tissue. This seems to suggest more firmly that RAD21 is closely related to the potential for invasion and metastasis in oral squamous cell carcinoma.

The RAD21 gene has been identified, by means of the differential display method, as the gene which is down-regulated in the hypoxia [31]. This suggests the possibility that the decrease of the expression level of the RAD21 gene affects various intracellular changes in the hypoxia. In solid tumors, hypoxic condition concerns a selection of the apoptosis-resistant cells, and it has been indicated to be important for progression of tumor cells [15]. As well, hypoxia directly induces the cell's apoptotic resistance [5, 14, 34]. In addition, it has been shown that the angiogenesis of cancer and the apoptosis of cancer cells correlate inversely in squamous cell carcinoma of the head and neck. These are considered to be the results of apoptotic resistance induced by hypoxia in cancer cells [28].

RAD21 is cleaved by caspase 3, and it has become clear that the degradation product in the C-terminal site induces apoptosis, so the RAD21 gene plays an important role in apoptosis [13, 26]. These reports suggest that the apoptotic resistance of the tumor cell and the down-regulation of the RAD21 gene are closely related. Our results supports this: the proportion of cell death due to the apoptosis induction reagent in high-metastatic-potential squamous cell carcinoma cells is lower than in low-metastatic-potential squamous cell carcinoma cells. As well, in SAS cells, the expression level of the RAD21 gene was increased by apoptosis induction, but it lead to no significant change in SAS-Ly cells at the gene expression level. These results indicate the possibility that the decrease of the RAD21 expression level in SAS-Ly cells is a direct cause of apoptotic resistance. Finally, our findings suggest that the RAD21 gene plays an important role in the invasion and metastasis of cancer cells.

Oncocytic modifications in rectal adenocarcinomas after radio and chemotherapy

Received: 17 November 2005 / Revised: 17 November 2005 / Accepted: 18 November 2005 / Published online: 20 December 2005
© Springer-Verlag 2005

Abstract The purpose of the study is to highlight oncocytic modifications in rectal adenocarcinomas and evaluate a possible correlation with preoperative radiochemotherapy (RCT). Twenty-eight cases of advanced rectal carcinoma, treated preoperatively by 5-fluorouracil (200–225 mg/m²) and 44–46 Gy in 22–23 fractions, were studied. All patients underwent biopsy before RCT. Surgery was performed within 6 weeks after RCT. In all cases oncocytic modifications were searched for on hematoxylin and eosin (H&E) and at immunohistochemistry using an antimitochondrial antibody. In addition, in two cases, both pre- and post-RCT tissues were examined at electron microscopy.

All tumors were adenocarcinomas. In pre-RCT biopsies, oncocytic changes were difficult to find on H&E, while the antimitochondrial antibody strongly stained numerous neoplastic cells (mean 48.4%). In post-RCT surgical specimens, oncocytic changes were detected in 24 out of 28 cases on H&E and the antimitochondrial antibody stained most of the residual neoplastic cells (mean 76.7%). Ultrastructural examination revealed large and bizarre mitochondria inside tumor cells both in pre- and post-RCT tissues. In conclusion, the present data suggest that rectal adenocarcinomas are “mitochondrion-rich” tumors. After preoperative RCT, residual neoplastic cells acquire a definite oncocytic phenotype.

Introduction

Since the first definition given by Hamperl in 1894 [12], oncocytes are traditionally described as cells with abundant, granular, and eosinophilic cytoplasm on the basis of optical microscopic appearance at hematoxylin and eosin (H&E). Immunohistochemical and ultrastructural studies revealed that the cytoplasm of these cells is mainly composed of mitochondria [3, 7, 31]. Furthermore, many tumors present focal oncocytic differentiation, however, in oncocytomas or oncocytic tumors (both benign and malignant lesions), at least 75% of the constituent neoplastic cells are oncocytes [40]. Immunohistochemical examination with antimitochondrial monoclonal antibody provides helpful evaluation for diagnosis [26, 41]. Oncocytomas are diffusely distributed in various organs, although the most frequent sites of origin are thyroid, salivary glands, and kidney [39]. To the best of our knowledge, rare carcinomas with oncocytic changes were described in the gastrointestinal tract [25], although only one oncocytoma arising in the rectum was reported [27].

During histological evaluation of tumors from patients treated with preoperative radiochemotherapy (RCT) for

locally advanced rectal carcinoma, we noted a peculiar differentiation toward an oncocytic phenotype. Thus, the aim of the present study is to consider oncocytic differentiation in colorectal adenocarcinoma and to evaluate the possible correlation between oncocytic differentiation and response to preoperative RCT.

Materials and methods

Patients

From January 2000 to February 2005, a total of 28 cases of rectal carcinoma (20 men, eight women) were preoperatively treated with concomitant radiotherapy and chemotherapy at the Department of Oncological Sciences, Bellaria Hospital, University of Bologna (Italy). The clinical assessment and the tumor stage prior to RCT were estimated by physical examination, colonoscopy with rectal biopsy, endorectal ultrasound, abdominopelvic computed tomography (CT) scan, and chest X-ray. Radiotherapy consisted of an external beam irradiation given by means of three orthogonal fields (posterior–anterior, left lateral, right lateral) with a total dose of 44–46 Gy, subdivided in 22–23 fractions, and distributed in the course of about 1 month. Simultaneously (for approximately 32–33 days), patients were treated with 5-fluorouracil (5FU) (200–225 mg/m²) by continuous intravenous infusion. Four to 6 weeks after completion of RCT, patients underwent either an anterior resection (20 patients), or abdominoperineal resection (six patients); an anterior resection with left hemicolectomy and an abdominoperineal resection with radical cystectomy were also performed (one patient each). Surgical specimens were evaluated for residual disease, depth of tumor penetration, and lymph node metastasis according to the tumor-node-metastasis staging [35]. Pathological stage after RCT (tumor classification after neoadjuvant therapy) was then compared with the clinical stage as previously assessed.

Control cases

As controls, 14 surgical specimens of colon adenocarcinoma (four ascending colon, five transverse colon, five sigmoid colon) not treated with preoperative RCT were retrieved from the Anatomic Pathology files of University of Bologna, at Bellaria Hospital, for study and search for oncocytic differentiation.

Histology and immunohistochemistry

All tissues were fixed in 4% buffered formalin and paraffin embedded according to a routine procedure. From each block, sections were stained with H&E and with antimitochochondrial antibody (BioGenex, clone 113-1, dilution 1:500). The processing was carried out using the Ventana BenchMark automated stainer.

On H&E, oncocytic differentiation was diagnosed when cells had intense and granular cytoplasmic eosinophilia and nuclei showed granular chromatin and prominent nucleoli.

Finely granular cytoplasmic immunostaining observed in stromal fibroblasts and in nonneoplastic epithelial cells was considered as internal control. Positive oncocytic counting was performed both on the preoperative small biopsies and in the surgical specimens containing residual cells within fibrous tissues. We decided to count 200 consecutive cells to obtain a quantitative evaluation of the immunohistochemical results.

Ultrastructure

In two cases, ultrastructural investigation was performed, both pretreatment biopsy and posttreatment surgical specimen. Tissues were retrieved from paraffin blocks. Samples were deparaffined; rehydrated; fixed in phosphate-buffered 2.5% glutaraldehyde and 1% osmium tetroxide; dehydrated in alcohol and propylene oxide; and embedded in Epon 812. Thin sections were stained with uranyl acetate and Reynolds' lead citrate and observed in a Phillips CM 10 TEM.

Results

Tumor stage and pathologic response

The total of 28 patients was composed of 20 males and eight females, with a median age at surgery of 66 years.

The pretreatment clinical stage, evaluated by endorectal ultrasound and abdominopelvic CT scan revealed: (1) five stage T2 tumors, 17.9%; (2) 21 stage T3 tumors, 75%; and (3) two stage T4 tumors, 7%. Possible lymph node metastasis was found in 15 (53.6%) cases. All T2 tumors were located very close to the anorectal junction, and preoperative RCT was performed in the attempt to reduce the size, avoiding abdominoperineal resection.

Fig. 1 Case No. 4, pretreatment biopsy, H&E. The lesion is composed of adenocarcinoma; rare cells with modifications reminiscent of oncocytic features are visible (arrows)

Fig. 2 Case No. 4, pretreatment biopsy. Immunohistochemistry with antimitochondrial antibody shows that most of the neoplastic cells are rich in mitochondria. Adjacent normal mucosa, present in the *left corner*, shows a definitely weaker staining

After RCT, pathological examination of surgical specimens detected: (1) one stage T0 tumor, 3.6%; (2) three stage T1 tumors, 10.7%; (3) ten stage T2 tumors, 35.7%; (4) 13 stage T3 tumors, 46.4%; and (5) one stage T4 tumor, 3.6%. Histological staging performed on the surgically resected specimen showed complete regression in one (3.6%) patient and down-staging in 13 (46.4%) patients.

Morphologic analysis before and after treatment

Pretreatment biopsies Twenty-seven patients were diagnosed with invasive, conventional type, adenocarcinoma

Fig. 3 Case No. 21, posttreatment surgical specimen, H&E. Rare neoplastic cells remain among fibrous tissue. Residual cells show clear oncoytic modifications (*upper right inset*), as revealed by antimitochondrial antibody (*lower right inset*)

Fig. 4 Case No. 21, posttreatment surgical specimen. At low power view, antimitochondrial antibody stains residual neoplastic cells

(nine well-differentiated, 15 moderately differentiated, and three poorly differentiated) and one was diagnosed with mucinous adenocarcinoma. On H&E, neoplastic cells with oncoytic differentiation were detectable in 16 cases where they composed 3 to 20% (mean, 5.3%) of the neoplastic population (Fig. 1). Antimitochondrial antiserum strongly stained 5 to 100% (mean, 48.4%) of the neoplastic cells (Fig. 2).

Posttreatment surgical specimens Twenty-four patients were diagnosed with invasive, conventional type adenocarcinoma (15 moderately differentiated, two well-differentiated, five poorly differentiated, and two with scattered

Fig. 5 On ultrastructure, numerous mitochondria are visible in the cytoplasm of the neoplastic cells both in pretreatment (a) and in posttreatment (b) tissues

Fig. 6 Cells positive for anti-mitochondrial antibody at immunohistochemistry (IHC) in pretreatment biopsy and tumor stage reduction (see text)

neoplastic cells only) and three were diagnosed with mucinous adenocarcinoma. In one case, a complete pathologic response was documented. Neoplastic cells with oncocytic differentiation were detectable on H&E in 24 cases where they constituted 10 to 100% (mean, 54.4%) of the residual neoplastic population. Antimitochondrial-positive neoplastic cells varied from 5 to 100% (mean, 76.7%). The two cases with scattered residual neoplastic cells exhibited a definite oncocytic differentiation on H&E and a strong immunoreactivity to antimitochondrial antiserum (Figs. 3 and 4).

Ultrastructure

Ultrastructural examination revealed similar alterations in mitochondrial morphology, both in pretreatment biopsies and in posttreatment surgical specimens. Mitochondria were numerous, closely packed, large, swollen, and bizarre in shape; nucleoli were prominent. The same alterations were more pronounced and appeared more evident in surgical specimens after RCT (Fig. 5).

Control cases

Oncocytic modifications were identifiable on H&E in 14 cases. Oncocytic cells composed 5 to 30% of neoplastic cells (mean 10.7%). Immunoreactivity for antimitochondrial antiserum was present in all cases with the percentage of positive cells varying from 20 to 80% (mean 64.3%).

Additional modifications observed in posttreatment surgical specimens

In surgical specimens of post-RCT rectal carcinomas, eight cases (28.6%) showed mucinous modifications and two cases acquired a definite mucinous phenotype. The case

diagnosed as mucinous adenocarcinoma in pretreatment biopsy did not show features of regression or modifications of histotype after RCT.

Clinical correlations

The percentage of mitochondrial antigen positive neoplastic cells detected in pretreatment biopsies was correlated to the tumor stage reduction induced by RCT. Tumor stage reduction was evaluated by the comparison between pretreatment clinical staging and posttreatment pathological staging. Data collected are illustrated in Fig. 6. Correlation index calculated for the two variable groups was 0.03896. Statistical analysis did not show any statistically significant correlation.

Discussion

In the present study, a series of preoperative RCT led to a stage reduction of the tumor in 13 (46.4%) out of 28 patients. Complete regression was achieved in only one case (3.6%) while 14 (50%) out of 28 patients with rectal adenocarcinoma were not affected by preoperative treatment. These data are consistent with previously published series where a complete response after RCT was observed in only 5 to 10% of the cases [11, 29, 42, 43]. Preoperative RCT can reduce tumor mass in rectal carcinomas and improve surgery efficacy, although the magnitude of this benefit is relatively small. Understanding the reasons for partial response to preoperative RCT is of utmost importance and numerous studies have already addressed this issue [2, 8, 9, 14, 19, 20, 23, 30, 44]. It was shown that radiotherapy may induce changes at the genetic level [21, 22], particularly in those genes regulating proliferation, apoptosis, and tissue repair. This might explain the morphological modifications observed in tissues after RCT.

Regarding the colorectal site, many authors have analyzed morphological features following RCT or radiotherapy alone. Extensive fibrosis, mucous lakes, thickening of the intima, and media layers of blood vessels are well-documented features [4, 45]. Nagtegaal et al. [22] documented mucinous changes in irradiated rectal carcinomas. Increased number of endocrine cells following RCT in rectal cancer were also reported [33, 32]. Similar aspects were also observed in our cases.

To the best of our knowledge, oncocyctic modifications after RCT in colorectal adenocarcinomas were never extensively investigated, although tumor epithelial cells with marked eosinophilic cytoplasm were described [17, 32]. Even after short-term preoperative radiotherapy (25 Gy in 5–7 days), epithelial cells in the crypts displayed an intensive eosinophilic cytoplasm [15]. It is possible to hypothesize that the intense cytoplasmic eosinophilia previously identified is comparable to the oncocyctic modifications observed here.

The present cases show that colorectal adenocarcinomas are characterized by numerous mitochondrion-rich neoplastic cells. These cells, even if not clearly recognizable on H&E, became more evident after immunostaining with antimitochondrial antiserum. In the pretreatment biopsies, a mean of 48.4% of antimitochondrial antibody positive cells was observed. This finding was confirmed in surgical specimens of the 14 untreated colon adenocarcinomas (“control cases”) where a mean of 64.3% cells positive to antimitochondrial antiserum was detected. Thus, colorectal adenocarcinomas may be considered “mitochondrion-rich” tumors [3, 5].

True oncocyctic modifications became evident in surgical specimens of rectal adenocarcinomas after RCT where a mean of 54.4% of neoplastic cells showed the typical features of oncocytes on H&E and a mean of 76.7% of neoplastic cells was strongly positive to antimitochondrial immunostaining. In surgical specimens from two cases that underwent a marked reduction of neoplastic population, the residual neoplastic cells were oncocyctic.

Oncocyctic modifications due to radiotherapy were described in the literature in various organs. Busuttill [1] described similar alterations in 48 specimens of salivary glands after irradiation. In seven irradiated adenomas of a pituitary gland, diffuse fibrosis was found and some irradiated pituitary cells showed cytoplasmic immunoreactivity for mitochondrial protein, mimicking oncocytes [24]. Oncocyte differentiation was also observed after metyrapone therapy in adrenal cortex [38]. Oncocyctic modifications observed and related abundance in mitochondria may represent one of the factors responsible for resistance to RCT.

The mechanism of mitochondriogenesis is a complex phenomenon resulting in the synthesis of membrane phospholipids, DNA replication and expression of the mitochondrial genome and of genes encoding for mitochondrial proteins [46].

Possible mechanisms for oncocyctic cell increase might be: (1) differentiation of epithelial neoplastic cells toward an “oncocyte-appearance” phenotype and (2) selective

proliferation of oncocytes within tumor cells due to their resistance to RCT.

Neoplastic cells may acquire an oncocyctic phenotype after radiation therapy as a response to injury (so-called “secondary oxyphilia”) [36]. It was observed that ionizing radiation and other oxidants increase mitochondrial gene expression and its activity. After irradiation, expression of mitochondrially encoded genes, mitochondrial membrane potential, and ATP production were enhanced in a cell line derived from glioblastoma [10]. Furthermore, the viability of this cell line after exposure to irradiation was high, suggesting a possible protective role against additional oxidative damage. Studies conducted with cationic hexakis (2-methoxyisobutylisonitrile)-technetium-99 m ($^{99m}\text{Tc-MIBI}$), an agent that accumulates in mitochondria of various cells and tissues of high mitochondrial metabolic activity, have shown an increase of mitochondrial membrane potentials and mitochondrial metabolic activity in cancer cell lines after irradiation [6]. Mitochondria may be metabolically activated after RCT and become larger and swollen, determining an oncocyctic appearance on H&E.

On the other hand, oncocyctic differentiation detected in pretreatment biopsies may be responsible for resistance to RCT itself. This was observed in carcinomas of the thyroid exhibiting oncocyctic appearance that are less responsive to radioactive iodine [18]. Homoplasmic mitochondrial DNA (mtDNA) somatic mutations were detected in colorectal cancer [28]. Experimental studies have shown that damage to mtDNA and to the mitochondrial respiratory chain may change the response of tumor cells to anticancer drugs [3, 47]. The antioxidant enzyme manganese superoxide dismutase (MnSOD), located in mitochondria, seemed to be one of the most effective enzymes in protecting cells against ionizing radiation damage [37]. Overexpression of MnSOD improves the survival of cells exposed to gamma radiation [13]. Mitochondrial somatic mutations in the D-loop region—a noncoding sequence of the mitochondrial genome—was described in colorectal cancer not only as potential tumor marker and an independent prognostic factor, but as a factor of resistance to adjuvant chemotherapy with 5FU, suggesting a central role of the mitochondria in drug resistance [16].

In conclusion, we demonstrated that colorectal adenocarcinomas are mitochondrion-rich tumors. Although oncocyctic features were difficult to identify on H&E, immunohistochemical and ultrastructural studies revealed their abundance of mitochondria. After preoperative RCT, residual neoplastic cells of rectal adenocarcinomas exhibited a definite oncocyctic phenotype, as evaluated by both H&E and immunohistochemistry along with ultrastructure. The oncocyctic component and mitochondria enrichment may be considered to be among the factors responsible for the resistance to preoperative RCT.

Rhabdomyosarcoma: molecular diagnostics of patients classified by morphology and immunohistochemistry with emphasis on bone marrow and purged peripheral blood progenitor cells involvement

Received: 8 September 2005 / Accepted: 21 September 2005 / Published online: 20 December 2005
© Springer-Verlag 2005

Abstract Two histologically distinct subtypes of rhabdomyosarcomas (RMS), embryonal and alveolar, are different in many aspects, such as age distribution, primary site, and clinical outcome. We analyzed a group of 30 patients with RMS. The aim was to broaden the spectrum of diagnostic tools in evaluating the primary tumors, their recurrences and/or metastases, and to extend the diagnostic boundary to bone marrow and purged peripheral progenitor blood cell samples. We have performed the RT-PCR assay to analyze RMS for the presence of expression of *MyoD1* gene and for the presence of chimeric transcripts PAX3/FKHR or PAX7/FKHR. *MyoD1* gene expression was found in all 30 patients in samples from primary tumors. The chimeric transcripts PAX/FKHR were identified in 13 of 15 patients with alveolar RMS. Furthermore, the fusion transcript PAX7/FKHR was identified in 2 of 15 patients with RMS classified as embryonal by histology. Bone marrow samples (12) and peripheral blood progenitor cell specimens (13) in ten patients were examined by RT-PCR. We were able to identify 7 patients with bone marrow involvement and/or with contamination of peripheral blood progenitor cells by the tumor cells. We demonstrate that employing molecular diagnostics has an impact on staging, therapy monitoring and recognition of malignant cells at the tumor resection margins.

Keywords Rhabdomyosarcoma · Immunohistochemistry · Molecular diagnosis · RT-PCR · Bone marrow · Peripheral blood progenitor cells

Introduction

Rhabdomyosarcomas (RMS) constitute a heterogeneous spectrum of tumors with respect to clinical behavior and also with respect to tumor morphology [36]. They are frequently composed of primitive cells, which show only a subtle evidence of a lineage-specific differentiation, but they may mature and in some cases may reach a stage close to terminal differentiation resembling myotubes of a developing skeletal muscle. Most RMS in childhood are of two histological subtypes—embryonal (80%) and alveolar (20%), which have distinct clinicopathological features [33]. Alveolar and undifferentiated variants portend an unfavorable prognosis [33, 42]. Because of a broad spectrum of tumor morphology and some overlapping features between the alveolar/undifferentiated and embryonal forms, it may be difficult to classify some of these tumors into an individual category. A standard approach to the diagnosis requires utilization of histology and immunohistochemistry [25, 30, 35], cytogenetical analysis, and molecular techniques [1, 2, 14, 16, 26, 28, 37, 45]. The immunohistochemical profile of RMS is well characterized. The embryonal and alveolar RMS share a similar spectrum of protein expression such as cytoskeletal filaments (vimentin, desmin), muscle-specific cytoplasmic proteins such as myoglobin, contractile filaments (actin, myosin), and regulatory proteins of muscle-specific differentiation (myoD1, myogenin).

The discovery of myogenic determination (*MyoD*) gene family has provided an insight in the regulation of myogenesis and has prompted a search for applicable markers that may assist in the diagnosis of RMS [7, 39]. The *MyoD* gene was first identified by virtue of its ability to convert nonmuscle cells into muscle cells [12]. The genes of the MyoD family represent a nodal point of early myogenesis by up-regulating the expression of other myogenic genes,

such as those coding for desmin, creatine kinase, and myosin [48]. Among the MyoD family genes, the expression of MyoD1 has been found to be the most consistent molecular feature of RMS. MyoD1 protein is a member of a basic helix-loop-helix protein family with nuclear localization and maps on chromosome 11p15. It is a DNA-binding nuclear protein that initiates muscle differentiation in mesenchymal stem cells at the earliest stage of their commitment to the striated muscle phenotype [31]. Although MyoD1 is an excellent molecular marker, there are problems with its immunohistochemical detection in histopathology; another member of myogenic transcriptional regulators, myogenin, is on the protein level consistently detectable in RMS [13].

Most cases of alveolar RMS are characterized by a chromosomal translocation t(2;13)(q35;q14) involving the *PAX3* gene at 2q and the *FKHR* gene at 13q. The *FKHR* gene is coding for a protein of the forkhead family of transcription factors. The FKHR protein contains a central forkhead DNA-binding domain, which is found in a number of different transcription factors including hepatic nuclear factor 3 and interleukin binding factor [17]. The *PAX3* gene is a member of a family of evolutionarily conserved and developmentally regulated genes coding for transcription factors [40]. PAX3 protein contains two discrete DNA-binding domains, a paired box and a paired-type homeodomain, and displays a unique coordinate DNA-binding specificity. This protein is expressed exclusively during embryogenesis, and it is thought to be important in the development of mesenchymal precursors destined to become myoblasts. In muscle progenitor cells, PAX3 is expressed even earlier than myogenic transcription factors, such as MyoD1 and Myf5, and gradually declines during muscle differentiation [5]. The fusion protein PAX3/FKHR exhibits an increased transcriptional potency relative to PAX3 due to swapping of PAX3 and FKHR C-terminal transactivation domains. Cell culture experiments demonstrated that the PAX3/FKHR protein has the capacity to induce phenotypic changes, including cellular transformation and inhibition of myogenic differentiation [10]. Some cases of alveolar RMS have been characterized by a variant translocation t(1;13)(q36;p14), which fuses the *PAX7* gene with FKHR [11, 15, 42]. This chimeric gene transcript is similar in structure and function to that of the PAX3/FKHR. The tumors with the PAX7/FKHR fusion transcript show a predilection for younger patients and appear to have a more favorable prognosis [3, 4].

In this study, we present data on 30 patients with RMS characterized by morphology and by immunohistochemistry. We bring some insights on the specificity of the reverse transcriptase polymerase chain reaction (RT-PCR) assay for the detection of the *MyoD1* gene expression and on the practical diagnostic utilization of molecular events such as the demonstration of the t(2;13)-encoded PAX3/FKHR chimeric transcript and t(1;13)-encoded PAX7/FKHR fusion transcript in primary tumors, bone marrow specimens, and in purged peripheral blood stem cells intended for autologous transplantation.

Material and methods

Seventy-two samples from 30 patients with histological diagnosis of RMS were analyzed (Table 1). All samples from the primary tumors and their recurrences were obtained from fresh tissue, snap frozen and stored at -80°C . All specimens were from the Pediatric Tumor Registry in the Department of Pathology and Molecular Medicine in Prague. Samples of bone marrow or peripheral blood progenitor cells (PBPCs) were collected in ethylenediaminetetraacetate (EDTA) at the time of tumor diagnosis and, in some cases, during chemotherapy. The tumors were diagnosed by light microscopy using hematoxylin and eosin staining complemented by immunohistochemistry. A panel of primary antibodies included vimentin, desmin, sarcomeric actin, MyoD1 protein, myogenin, and anti-CD99 (all obtained from DakoCytomation, Glostrup, Denmark). Super sensitive kit using alkaline phosphatase-antialkaline phosphatase and fast red (BioGenex, San Ramon, CA, USA) was utilized to visualize the results.

RNA extraction

RNA was extracted from $10 \times 5 \mu\text{m}$ thick sections of the frozen tumor tissue or from bone marrow samples using Tri-Reagent (Invitrogen Corporation, Carlsbad, CA) according to the manufacturer's instructions.

Polymerase chain reaction analysis

A total of 1 μg of RNA was reverse-transcribed in a 20 μl reaction volume using 10 pmol of random hexamers as primers and 1 μl of Moloney murine leukemia virus (MMLV) Reverse Transcriptase (Life Technologies, Inc., Gaithersburg, USA) according to the manufacturer's instructions. Reverse transcription included an incubation period of 60 min at 42°C .

Two microliters of cDNA products was then tested for the expression of the regulation gene *MyoD1* (F-MyoD1: 5'AGC ACT ACA GCG GCG ACT, R-MyoD1: 5'GCG ACT CAG AAG GCA CGT C, MyoD1 cDNA probe: 5' GCT ACG AAG GCG CCT ACT ACA ACG AGG CGC) and for the presence of the t(2;13) and t(1;13) translocations using seminested PCR with primers PAX3, PAX7, FKHR-A, and FKHR-B (PAX3: 5' AGC TAT ACA GAC AGC TTT GT, PAX7: 5' GCT TCT CCA GCT ACT CTG AC, FKHR-A: 5' CTC TGG ATT GAG CAT CCA CC, FKHR-B: 5' TCC AGT TCC TTC ATT CTG CA).

Each PCR reaction was carried out with an initial denaturation step at 95°C for 5 min, annealing for 30 s, and extension at 72°C for 30 s, followed by 30 cycles of denaturation at 95°C for 15 s, annealing for 5 s, and extension at 72°C for 5 s. Undiluted PCR product (1 μl) was added to the seminested reaction mix for the second round of 30 cycles. The quality of the isolated RNA was assayed with the A2 and A3 oligonucleotide primers to detect the

ubiquitously expressed cABL kinase (primers A2: 5' TTC AGC GGC CAG TAG CAT CTG ACT T and A3: 5' TGT GAT TAT AGC CTA AGA CCC GGA GCT TTT). Negative controls lacking either RNA or RT were routinely included. Products were identified using 1.5% agarose gel electrophoresis and ethidium bromide staining.

The specificity of the PCR products was confirmed by Southern blot hybridization using AlkPhos Direct Kit (Amersham Biosciences Trading GmbH, Austria) according to the manufacturer's instructions.

Results

Morphology

The embryonal RMS were characterized by a variable cellularity and haphazard cell orientation. Rhabdomyoblastic differentiation was discernible in 12 cases (Fig. 1a). Three cases were characterized as a botryoid subtype. None

of the cases had features of the spindle cell variant [29]. Alveolar RMS had a typical appearance of predominantly round-celled tumors with a characteristic pattern of tumor cell adhesion to the fibrovascular stroma. Two cases had an almost entirely solid morphology, but the alveolar pattern was still focally discernible (Fig 1b). On the basis of the morphological examination of the primary tumors, the original classification was that of embryonal RMS in 15 patients and alveolar RMS also in 15 patients. The distribution of cases with embryonal and alveolar RMS differs from that known from a large series of cases [33] and may be caused, at least partially, by patient distribution in health service referral centers.

Immunohistochemical findings

The results of immunohistochemical staining are summarized in Table 2. Tumor cells stained positively for vimentin and desmin in the majority of cases tested and

Fig. 1 **a** Embryonal RMS showing haphazardly oriented primitive and maturing tumor cells in a loose stroma, original magnification $\times 100$. **b** Alveolar RMS with perivascular palisading of the tumor cells and solid arrangement of the remaining sheets of undifferentiated tumor cells, original magnification $\times 200$

Fig. 2 Immunohistochemical staining demonstrating myogenin. **a** Alveolar RMS is uniformly positive in the tumor cell nuclei, original magnification $\times 200$. Alkaline phosphatase–antialkaline phosphatase, fast red. **b** Undifferentiated tumor cells of embryonal RMS of the urinary bladder show occasional nuclear positivity. The more differentiated tumor cells with abundant cytoplasm are weakly stained or negative, original magnification $\times 200$

less frequently for sarcomeric actin. In addition, rhabdomyoblasts were positive for myogenin in 90% of cases (27/30) and MyoD1 in 60% (18/30). The intensity of myogenin positivity was uniform and strong in alveolar RMS regardless of the degree of differentiation, and even cases with no myoblastic maturation at the hematoxylin–eosin staining level were positive (Fig. 2a). In embryonal RMS, the staining for myogenin varied in individual tumor cells, and they were generally less positive than in the alveolar RMS (Fig. 2b). MyoD1 was positive in a smaller percentage of cases, the pattern of staining was not distinctive when embryonal and alveolar RMS were compared. Moreover, in some cases, the expression of MyoD1 was weak, most likely due to inadequate formalin fixation or other technical problems prior to the immunohistochemical procedure. All tumors were negative for CD99.

Molecular findings

All 30 RMS samples from primary tumors expressed the MyoD1 transcript, which hybridized to the 3' end of the MyoD1 cDNA probe. The absence of MyoD1 expression confirmed by negative RT-PCR and Southern Blot hybridization with non-radioactive-labeled cDNA probe was detected in one patient (case 20) with embryonal RMS after chemotherapy (Fig. 3). This tumor also failed to manifest nuclear immunoreactivity for MyoD1 and myogenin.

The t(2;13) and t(1;13) translocations were identified in cases of RMS having alveolar histology. The fusion transcript PAX3/FKHR indicating the translocation t(2;13) was found in ten patients with the diagnosis of alveolar RMS (Fig. 4), and the fusion transcript PAX7/FKHR indicating the t(1;13) was detected in three histologically diagnosed

alveolar RMS. Furthermore, the fusion transcript PAX7/FKHR, suggesting the diagnosis of alveolar RMS, was found in 2 of 15 patients with RMS classified as embryonal by histology.

One of the latter patients (case 28) had no evidence of alveolar differentiation in the first biopsy, but the morphological features of alveolar RMS were revealed in the second biopsy taken from a residual tumor after chemotherapy (Fig. 5). This tumor was reclassified as mixed RMS; the alveolar component was most probably disclosed by a more extensive tissue sampling, although the possibility that the treatment induced changes in the tumor may have played a role. The other patient (case 23) had the tumor composed of a relatively uniform mixture of undifferentiated short spindle cells and round cells organized in diffuse sheets (Fig. 6). The vasculature and the stroma were inconspicuous. There was a tissue edema diminishing the tumor cell density. The myoblastic differentiation was apparent only at a level detected by immunohistochemistry (variably positive desmin and myogenin). The case was considered to fit the diagnosis of embryonal RMS at the time of diagnosis. After establishing the PAX7/FKHR fusion transcript, we reevaluated the findings, and, admittedly, some features of the tumor may fulfill the criteria of the so-called solid alveolar category [44]. The presence of spindle cells was, however, unusual.

Two cases had alveolar morphology, but there was no evidence of either t(2;13) or t(1;13) fusion transcripts. The first fusion-negative case was a patient with a congenital manifestation of alveolar RMS (case 12). The second was a 2-year-old girl (case 6) with botryoid RMS in the vagina. This

Fig. 4 Detection of the PAX3/FKHR transcript in bone marrow samples and PBPC (case 4, patient with alveolar RMS) using nested RT-PCR (188 bp first round RT-PCR and 158 bp second round RT-PCR). Lines: 1 negative sample of bone marrow after chemotherapy, 2 PAX3/FKHR transcript in the bone marrow sample at the time of the tumor recurrence, 3 PAX3/FKHR transcript in PBPC sample, 4 negative sample of the peripheral blood, 5 PAX3/FKHR transcript in PBPC sample after purging, 6 positive control for the PAX3/FKHR transcript, 7 negative control for reverse transcription, 8 negative control for PCR

patient had no evidence of alveolar differentiation in the first biopsy (from the vagina), but the morphological features of alveolar RMS were revealed in the biopsy taken from a metastatic disease in the inguinal lymph node 14 months after diagnosis and from lung metastasis 5 years later.

Fig. 5 Case 28. The original diagnosis was that of embryonal RMS. The post-therapy excision of the residual tumor showed a hyaline stroma with foci of the tumor having solid alveolar appearance, original magnification $\times 50$. RT-PCR revealed PAXPAH7/FKHR fusion transcript in this patient, confirming the diagnosis of alveolar RMS

Fig. 6 Case 23. The tumor was composed of a mixture of round and spindle cells with a haphazard orientation. The tissue edema present in the tumor separated the cells in a similar fashion as seen in some embryonal RMS. The fibrovascular stroma was inconspicuous, and no features of alveolar morphology were revealed after sampling the entire tumor mass, original magnification $\times 100$. The original morphological interpretation was that of embryonal RMS. RT-PCR revealed PAX/FKHR fusion transcript. The diagnosis was then reevaluated, and the tumor was reclassified as “solid alveolar RMS” with awareness that such tumors may need further analysis in future

In one patient with alveolar RMS (case 13), the presence of the PAX3/FKHR fused gene was detected in the primary tumor and in two subsequent recurrences. We used RT-PCR to identify malignant cells in the resection margin of the tumor at the time of the second recurrence. Two of nine samples taken from the tumor margin, which were shown to be microscopically free of tumor or uncertain whether they contain tumor cells or not on frozen section histology, revealed the fusion transcript PAX3/FKHR of the same size as detected in the primary tumor. In this patient, bone marrow aspirates were also positive for the fusion transcript in the nested RT-PCR.

Although the number of patients with alveolar RMS was small to analyze clinical data such as the differences of the primary tumor sites and the outcome of the patients, we noticed that the age of patients with the PAX7/FKHR fusion was lower than the age of patients with PAX3/FKHR rearrangement. For the former group, it ranged from 1 to 10.5 years (median 6.5 years), while the latter group had the age range from 3.5 to 18 years (median 9.5 years).

Bone marrow samples

Bone marrow samples (12) and PBPC samples (13) in ten patients with alveolar RMS were examined by the RT-PCR technique using the specific primers.

Six of 12 bone marrow samples (from four patients) and 7 of 13 PBPC samples (from five patients) were shown to be positive for the fusion transcript. Four patients had the PAX3/FKHR and two had the PAX7/FKHR fusion product of the same size as detected previously in the primary tumors. One patient with the PAX3/FKHR fusion transcript (case 3) had no detectable fusion transcript in bone marrow samples at the time of diagnosis, but we found the MyoD1 transcript. A relatively weak transcript PAX3/FKHR was repeatedly detected in the primary tumor. Cytogenetic analysis performed in this patient failed to demonstrate $t(2;13)$, probably because $der(2)$ was lost and the small $der(13)$ could not be identified. The cytogenetic analysis of the bone marrow samples showed tetra- and octaploidy. The discrepant findings may be explained by an existence of one clone carrying $t(2;13)$ and by an appearance of secondary clones with different ploidy status and secondary chromosomal changes.

Follow up of patients with bone marrow and PBPC samples tested by RT-PCR is summarized in Table 3. Of the seven patients in whom we were able to identify bone marrow involvement or contamination of PBPCs by the tumor cells, six died of progressive disease, and one lives with a complete remission 3 years after the treatment start. Three patients had no detectable tumor by RT-PCR technique in the bone marrow. Two patients are alive without evidence of the disease. One patient, a boy aged 6 years, had a primary tumor of the paranasal sinuses. His recurrent tumor infiltrated the orbit. The therapy at the time of the tumor recurrence included surgical excision, chemothera-

py, and autologous stem cell transplantation. His bone marrow and peripheral progenitor cells at the time of the recurrent disease showed no evidence of the fusion product PAX7/FKHR. The patient died of a local progression of the tumor 7 months after autologous stem cell transplantation.

Discussion

RMS represent a group of sarcomas challenging investigators for decades to improve their diagnostic approach. Histological classification is well established [33, 34], but in practical diagnostics, there are many causes why the diagnosis is not always straightforward. One of diagnostic caveats in RMS rests in overlapping features between the subsets of RMS, and an incorrect interpretation of histological findings may lead to a choice of inadequate treatment intensity. Current treatment of patients with RMS is based on histopathology subtype, staging, size, and patient's age, those with advanced disease and unfavorable histology (alveolar RMS) require a more aggressive approach.

The immunohistochemical investigations are helpful and are performed routinely virtually in all cases of RMS and related neoplasms. In this study, we may confirm observations showing that there are differences between a strong and uniform pattern of myogenin positivity in alveolar RMS, whereas the pattern in embryonal RMS is more heterogeneous [6, 13, 27]. As has been pointed out, the difference in the intensity of staining cannot be used as a sole criterion discriminating the alveolar from embryonal RMS [6]. The problem with interpreting immunohistochemistry for myogenin, and for MyoD1, also arises in samples showing post-therapy changes. It has been demonstrated that skeletal muscle, especially regenerating or atrophic muscle fibers, may display myogenin positivity [6]. Such a phenomenon may be misleading in the interpretation of the local residual disease when investigated by morphology alone. The most frequent subtypes in children, alveolar and embryonal RMS, are entities associated with different genomic changes. Therefore, molecular analysis helps to define the nature of these tumors more precisely.

All 30 patients with RMS analyzed in this study expressed the MyoD1 transcript in their primary tumors. The absence of MyoD1 expression using RT-PCR and Southern Blot hybridization with a non-radioactive-labeled cDNA probe was detected only in one patient with embryonal RMS after treatment. This residuum of the tumor failed to manifest nuclear immunoreactivity for MyoD1 and myogenin in spite of the presence of well-defined myoblasts in the tissue. The tumor cell differentiation was particularly pronounced in tissues obtained from postchemotherapy patients, and their tumors were often composed of differentiated rhabdomyoblast, a phenomenon recognized by other authors [8, 9]. Downregulation of nuclear regulatory proteins myogenin and MyoD1 in therapy-induced differentiation of rhabdomyoblasts has been noticed by Wang et al. [47].

Data on specificity of MyoD1 expression are contradictory. Frascella et al. [19] considered MyoD1 a sensitive

and specific marker for the molecular diagnosis of RMS. In our study, in accordance with observations published by Gattenloehner et al. [21], we found that the MyoD1 transcript is not entirely specific for RMS. We found weak expression of MyoD1 in normal skeletal muscles. Furthermore, other neoplasms used as a control tissue (teratomas, synovial sarcoma, Ewing tumor/primitive neuroectodermal tumor (PNET), some non-Hodgkin's B cell lymphomas) revealed MyoD1 expression (data not shown). To test the specificity and to minimize the possibility of PCR contamination, we analyzed peripheral bloods and bone marrow aspirates without tumor cell contamination, all of them with negative results of MyoD1 expression. We also analyzed, simultaneously with samples of RMS, other neoplasms (epiteloid sarcoma, aggressive fibromatosis, non-Hodgkin's T cell lymphomas, and carcinomas) which were negative for all tested molecules by RT-PCR. This diminishes the usefulness of MyoD1 investigation in the diagnosis of RMS. Further studies are necessary to address this issue.

Chimeric transcripts and gene fusions can be detected in samples by RT-PCR and are of a great diagnostic significance in RMS. The molecular analysis appears superior to classical cytogenetics, because conventional karyotyping of these tumors is often unyielding [18].

Using RT-PCR, we disclosed PAX/FKHR transcripts in primary RMS in 13 of 15 patients diagnosed as alveolar RMS by histology, which underscores a good correlation between morphological and molecular diagnostics. Two patients with alveolar histology were, however, negative for PAX3/FKHR and PAX7/FKHR transcripts. It is possible that these cases harbored an uncommon variant translocation associated with alveolar RMS such as t(2;11)(q37;q13) [31], t(8;13)(p21;q14) [15], t(2;2)(q35;p23) [46], or had other types of genetic abnormalities that led to the activation of oncogenic pathways as do PAX-FKHR oncoproteins. Two tumors with t(1;13) were diagnosed originally as embryonal RMS by histology. Reexamination of the original material in one patient revealed embryonal type of RMS at presentation with no alveolar features, although multiple samples were taken. After chemotherapy, the residual tumor showed a hyalinized tumor with a focus of a well-defined alveolar RMS, which was underestimated at the time of the residual tumor description. Following the molecular analysis revealing the PAX7/FKHR fusion transcript, the tumor was reclassified as mixed embryonal/alveolar RMS. The second case diagnosed as embryonal RMS retained its morphology as observed in the biopsy of the recurrent tumor, and we were unable to redefine this tumor as a classical alveolar type. The tumor best fitted the category described by Tsokos [44] as a solid alveolar form, although the mixture of undifferentiated round and spindle cells would be rather uncommon for this subtype. Such cases should be possibly classified separately until more detailed data on their molecular profile are gathered.

The potential clinical value of determining minimal (submicroscopic) residual disease in situ by detection of fusion transcripts PAX3/FKHR and PAX7/FKHR by nested RT-PCR was confirmed by our findings, showing

fusion transcripts in microscopically tumor-free resection borders. The tendency to recur locally often observed in RMS may well find its explanation in tumor cells located distant from the main tumor mass and obscured from microscopical identification. This approach also helps to distinguish residual tumor cells with advanced differentiation (post-therapy changes) from atrophic and regenerating muscle cells at the site of the tumor removal.

Fusion transcripts generated through chromosomal translocations have been demonstrated to represent excellent targets for monitoring minimal residual disease in hematological malignancies [20, 32, 43]. Many studies suggest a direct correlation between the numbers of residual tumor cells and the prognosis of the patients. Dissemination of tumor cells in the bone marrow and peripheral blood has been observed also in patients with solid malignancies [22, 49]. The presence of metastases is the most adverse prognostic factor in RMS [38], and the bone marrow is a frequent site of tumor dissemination, particularly in the alveolar subtype [23, 41]. Assessment of bone marrow dissemination by light microscopy has a limited sensitivity. Using the RT-PCR technique, we were able to identify bone marrow involvement in 7 of 12 bone marrow samples and in 7 of 13 PBPC samples. Assessment of a potential tumor cell infiltration of bone marrow grafts or PBPCs destined for stem cell transplantation after myeloablative regimen is important for a selection of tumor cell-free grafts.

The prognostic value of the identification of fusion transcripts in bone marrow aspirates or in PBPC samples has to be proven in further prospective studies. Our results detecting the fusion transcripts typical of alveolar RMS in the bone marrow and PBPC suggest that patients with positive findings are at a high risk of the tumor progression. Similarly, results described by Kelly [23] suggest that RT-PCR assay in alveolar RMS may identify a group of patients who are at a high risk despite having histologically negative bone marrows.

The identification of the translocation variants in alveolar RMS appears to be of prognostic significance [24]. The t(1;13) has been reported to occur in alveolar RMS affecting younger individuals, and the prognosis may be somewhat less unfavorable than that for patients with t(2;13) [24]. Our group of patients is too small to draw conclusions in this respect. However, the age of patients with t(1;13) was lower in the reported series of patients than that in patients with t(2;13). Of patients with t(1;13), one of five presented with metastatic disease at the time of diagnosis, whereas five of ten patients with t(2;13) were diagnosed with a generalized disease. A further follow up of the patients is under way.

In conclusion, the application of RT-PCR techniques in the classification of childhood RMS may help to resolve histological controversies in some cases by the use of criteria based on genetic differences between the alveolar and embryonal RMS. Alveolar histology may be focal within an embryonal tumor and, admittedly, may be missed by an incomplete sampling either by a surgeon or by a

pathologist. From that reason, proper handling of the tumor specimens submitted for histopathological examination remains a high-priority task to avoid misinterpretations. When employing the RT-PCR analysis into the diagnostic support, we may detect fusion gene transcripts, and, therefore, chromosomal translocations specific for the alveolar type of RMS. Beside the histopathological classification, the RT-PCR has a significant impact on specification of diagnosis and on selecting an optimal therapeutic approach. RT-PCR techniques may have a role in staging, in monitoring the effects of therapy, in recognizing malignant cells at the tumor resection margins, in assessing the efficacy of purging protocols for autologous stem cell transplantation, and in post-therapy follow up.

Acknowledgements The study was supported by the Grant FN Motol IG 9746, the Research Project of the Ministry of Education, Youth, and Sports of the Czech Republic No. 0021620813 and by the Research Project of the Ministry of Health No. 00000064203. D2-40 staining in sinonasal-type hemangiopericytoma—further evidence of distinction from conventional hemangiopericytoma and solitary fibrous tumor

Received: 28 October 2005 / Accepted: 2 November 2005 / Published online: 16 December 2005
© Springer-Verlag 2005

Abstract D2-40 is a monoclonal antibody, which reacts with a fixative-resistant epitope of lymphatic endothelium. Sinonasal-type hemangiopericytoma (SHP) and tumors of the (conventional) hemangiopericytoma/solitary fibrous tumor family (HP/SFT) are characterized by prominent vasculature. However, data concerning D2-40 labeling of these tumors are very sparse. In the present study, we investigated D2-40 staining in tissue specimens of 17 patients with SHP (male to female ratio of 2.4:1, median age of 63 years) and compared the immunolabeling with 20 cases of HP/SFT, including three SFT cases from nasal mucosa. D2-40 was detected in vascular channels of all SHP patients examined. By contrast, all cases of HP/SFT did not reveal any vascular channel being positive for D2-40, neither in the nasal cases nor in the remaining patients. This study presented for the first time data on D2-40 labeling in a series of SHP, HP/SFT, and supports the distinction of SHP from HP/SFT.

Keywords D2-40 · Sinonasal-type hemangiopericytoma · Conventional hemangiopericytoma · Solitary fibrous tumor

Introduction

D2-40 is a monoclonal antibody, which is directed against an oncofetal antigen called M2A antigen [6, 14]. This monomeric surface sialoglycoprotein (Mr=40,000) was found first in fetal germ cells and different germ cell neoplasias, mainly in seminoma [14]. Thereafter, it was shown to react with a fixation-resistant epitope on lymphatic endothelium. In several studies, D2-40 could label normal, reactive, and neoplastic lymphatics [6, 9, 10]. Thus, it is now considered

to be the best commercially available antibody for the delineation of normal, reactive, and neoplastic lymphatic endothelial cells [10]. Among the vascular tumors tested for this marker, lymphangioma [6, 8, 9], Kaposi sarcoma [6, 9], kaposiform hemangioendothelioma [3], papillary intralymphatic angioendothelioma (so-called Dabska tumor) [6], hobnail hemangioma [5], and a subset of angiosarcomas were particularly positive [6, 9]. By contrast, hemangiomas, glomus tumors, vessels in angioliomas, and nearly all epithelioid hemangioendotheliomas did not reveal immunoreactivity for this molecule [6, 9].

In the present study, we analyzed sinonasal-type hemangiopericytoma, another tumor type with a prominent vascular component, for D2-40 staining. For comparison, tissue specimens of patients with tumors of the conventional hemangiopericytoma/solitary fibrous tumor family (HP/SFT) were additionally examined.

Materials and methods

The records from the Soft Tissue Tumor Registry of the Institute of Pathology in Jena were searched for cases coded as sinonasal-type hemangiopericytoma (SHP) from 1995 to the present. We found 17 cases of SHP with a male to female ratio of 2.4:1 and a median age of 63 years ranging from 38 to 86 years. All tumors were localized in the nose and the paranasal sinuses, respectively. For comparison of D2-40 labeling, tissue specimens from each of the 20 patients suffering from HP/SFT were retrieved from the case files of the Soft Tissue Registry. SFT was separated from HPC by common histological findings (according to the World Health Organization classification [7]): tumors consistently showing branching vessels with a staghorn configuration and closely packed spindle-shaped to ovoid cells, were designated as HPC. Tumors having patternless architecture and areas of fibrosis were regarded as SFT. HP/SFT patients had a male to female ratio of about 0.9:1 and were 60.3 years old on average (ranging from 8 to 93 years). Nine HP/SFTs were localized in the trunk, six in the head & neck area, including three tumors affecting the nasal and

paranasal mucosa, each one in the orbita, the lung, the lower arm, and the small bowel, while the localization of one tumor was unknown. None of the HP/SFTs examined showed signs of malignancy, and neither recurrences nor metastases have been described for any of these studied cases.

Immunohistochemical staining was performed according to previous protocols [11] using antibodies against α -smooth-muscle actin (ASMA), BCL-2, CD34, and D2-40. The primary antibodies applied for the immunohistochemical analysis are summarized in Table 1. D2-40 labeling was semiquantitatively analyzed and scored as follows: no vessels positive, <20% of vessels positive, >20% and <50% of vessels positive, and >50% of vessels positive.

Results

All of the SHPs studied were localized in the submucosa. They were unencapsulated and revealed a diffuse growth

pattern. The epithelium lining the tumors showed not infrequently squamous metaplasia. Tumor cells were spindle-shaped or ovoid and were arranged in various forms. Most common were fascicular, storiform, and whorled patterns. The nuclei showed blunt edges, cytoplasm was eosinophilic. Signs of atypia such as pleomorphism or significant mitotic rate were not found. Besides thin-walled and variable-sized vessels, hyalinized vascular spaces were occasionally detected (Fig. 1a,b).

Immunohistochemistry demonstrated expression of ASMA in all cases, occurring both in spindle-cells and vessel walls. CD34 was mainly expressed in the vessels, with the exception of four patients revealing faint labeling in the spindle-shaped cells as well. In contrast, BCL-2 was negative in all cases. D2-40 was detected in vascular channels of all SHP patients examined. This molecule revealed a strong membranous and cytoplasmic staining of the endothelial cells, while nuclei were not labeled. D2-40 positive vessels were observed at the periphery and in the center of the SHPs. Centrally located positive vessels were surrounded by numerous sheets of spindle-shaped cells. Semiquantitative analysis revealed eight SHPs with more than 50% of vessels being positive; six SHPs were found with more than 20% and less than 50% of vessels positive; the remaining 3 cases revealed only less than 20% of vessels with D2-40 positivity. D2-40 negative vessels sometimes showed hyalinized perivascular stroma (Fig. 1b). The spindle-shaped cells were completely negative for this antibody. Sometimes, positive staining was observed at the basal lining of epithelial cells in areas of squamous metaplasia (Fig. 1b).

Fig. 1 **a** Overview of SHP shows squamous metaplasia of the nasal mucosa and a mesenchymal tumor with spindle-shaped and ovoid cells, which surround vessels in a concentric fashion (H&E $\times 100$, bar=100 μ m). **b** D2-40 labeling of SHP demonstrates numerous positive vessels (red) at the periphery and in the center of the tumor. Note a vessel with prominent perivascular hyalinization (arrow) being negative for D2-40. A few basal epithelial reveal staining for D2-40 ($\times 100$ bar=100 μ m). **c** Conventional HP reveals numerous, sometimes staghorn-like vessel spaces, which are surrounded by numerous spindle cells. Note complete negativity for D2-40 ($\times 200$, bar=50 μ m). **d** SFT of the nasal mucosa do not obtain D2-40 positive vessels. Note squamous metaplasia of the nasal mucosa with a few epithelia faintly stained for D2-40 (red; $\times 100$; bar=100 μ m)

By contrast, all cases of HP/SFT analyzed did not show any intratumoral vessel or vascular channel being positive for D2-40 (Fig. 1c). In the nasal and paranasal cases, D2-40 was completely absent in tumor areas (Fig. 1d). In the nasal mucosa lining the tumors, squamous metaplasia was also observed, and the basal epithelia showed some D2-40 positivity. D2-40 also stained some residual vessels with localization outside the tumors. On the other hand, all HP/SFT cases revealed a nearly thorough positivity for CD34 and bcl-2 with five cases also focally expressing ASMA.

Discussion

D2-40 is a monoclonal antibody, which has been demonstrated to react with a fixative-resistant epitope of lymphatic endothelium. Several vascular tumors have been tested for this marker [3, 5, 6, 8–10]. Sinonasal-type hemangiopericytoma, also called sinonasal hemangiopericytoma-like tumor, (conventional) hemangiopericytoma, and solitary fibrous tumor are characterized by a prominent vasculature [2, 7, 22]. However, data concerning D2-40 labeling of these tumors are very sparse. Kahn et al. [9] only reported on one case of HP, which did not show D2-40 staining. Therefore, we were prompted to analyze tissue specimens of patients with SHP, HP, and SFT for labeling with D2-40. Because it is now generally accepted that HP and SFT comprise different histological features of a single tumor entity [7], we included cases previously diagnosed as either HP or SFT in one group.

Most interestingly, D2-40 could be exclusively detected in vessels of SHP, while the HP/SFT group revealed a complete negativity. SHP is a rare tumor, which is now generally believed to be different from HP/SFT. SHP shows some differences from HP/SFT concerning the histological architecture and cellularity [20]. Furthermore, it has been shown that SHP can be separated from HP/SFT by means of immunohistochemistry. In contrast to HP/SFT, SHP commonly stains positive for ASMA [12, 17, 20]. While CD34 and BCL-2 are well-known markers for spindle-shaped tumor cells of both HP/SFT, they were only faintly or not detected in previous immunohistochemical studies on SHP [12, 20, 21]. This is in line with our results, which showed only a weak expression of CD34 in the minority of SHP cases and complete negativity for BCL-2.

It should be stressed out that the different immunolabeling of D2-40 in the vessels of SHP, as compared to HP/SFT, further supports the necessary discrimination between the entities. This is of special importance as it is known that SHP has a generally better prognosis than HP with a lower rate of recurrences and metastases [4, 12, 20]. Moreover, cases of HP/SFT family have been reported to occasionally occur in the nasal mucosa [15, 18, 23]. The clinical and macroscopic features may be similar to those of SHP. Thus, nasal HP/SFT represents a relevant differential diagnosis of SHP. One might contradict that D2-40 staining in SFT presented in this study was false negative. However, in the

case of nasal SFT positivity of D2-40 could be observed not only in some residual lymphatics, but also in basal epithelial of the nasal mucosa. The latter finding has been previously described by Kaiserling [10] as well. These data strongly argue against a false negative labeling.

It is known that nasal mucosa typically contains large numbers of lymphatic vessels which play a crucial role in different complaints such as inflammatory diseases [19]. In our study, we found numerous lymphatics labeled by D2-40 in the periphery and in the center of SHP. Particularly in the latter, surrounding spindle-shaped tumor cells were observed. Therefore, it can be considered that D2-40 labeling in SHP is tumor-associated. Several molecules were described as important inductors of lymphangiogenesis and also have been found in lymphatic vascular tumors. Among them, vascular endothelial growth factor (VEGF) C and its receptor, VEGFR-3, seem to play a central role. The two molecules were detected in several lymphatic neoplasms including lymphangioma and hobnail hemangioma [13, 16]. Furthermore, Choi et al. [1] recently reported on significant correlation between VEGFC and D2-40 in breast carcinoma, which possibly could be due to an interaction of the two molecules. However, there is no report so far showing an induction or stimulation of D2-40 by any angiogenic factor. Furthermore, the role of D2-40 in vascular tumors is not known. Thus, conclusions concerning the possible interrelationships and functions of D2-40 in the pathogenesis of these neoplasias (including SHP) remain speculative. Nevertheless, we suggest from our data that the D2-40 positive vessels found in SHP do not represent residual lymphatics only, but might be associated with the tumor development.

In summary, this study presented for the first time data on D2-40 labeling in a series of SHP and HP/SFT, and thus, contributes to the immunohistochemical mapping of D2-40 in (peri-)vascular tumors. Because D2-40 labeling was found exclusively in SHP but not in HP/SFT, including cases from the nasal mucosa, the following conclusions can be drawn: (1) D2-40 further contributes to the differentiation from HP/SFT, and (2) D2-40 stained vessels in SHP do not represent residual lymphatics of the nasal mucosa only, but might have a role in tumor development.

Acknowledgements We wish to thank Mrs. Bergholz, Mrs. Geier, and Mrs. Pelzer (Institute of Pathology, University of Jena) for their excellent technical assistance. We acknowledge the support of Mrs. Gröschel (Tumor Registry, Jena) for providing case data from the consultation files. Special thanks to Dr. Alexander Berndt, (Institute of Pathology, University of Jena) for technical assistance in preparing the figures.

We are very grateful to all pathologists who sent case material and clinical details from patients included in this study.

Natural history of the Nihon (*Bhd* gene mutant) rat, a novel model for human Birt–Hogg–Dubé syndrome

Received: 1 November 2005 / Accepted: 25 November 2005 / Published online: 31 January 2006
© Springer-Verlag 2006

Abstract In the Nihon rat, an established model of hereditary renal cell carcinoma (RCC), the propensity for tumor development, is inherited as an autosomal dominant trait due to a single germline nucleotide insertion mutation in the rat *Bhd* ortholog. The Birt–Hogg–Dubé (BHD) syndrome is a rare autosomal dominant disease characterized by fibrofolliculoma, pulmonary cysts, spontaneous pneumothorax, and renal neoplasm. The renal lesions of the Nihon rat are characterized, and extrarenal lesions are also described in this work. The earliest lesion of the RCC was identified as an altered tubule at as early as 3 weeks of age and rapidly progressed through adenoma to carcinoma with the primary cell type being clear/acidophilic where some similarities were evident to RCCs in BHD syndrome. The Nihon rats demonstrate a heterotopic ossification within RCCs and three extrarenal lesions, clear cell hyperplasia/adenoma of the endometrium, clear cell change of the epithelium of striated portions of salivary glands, and cardiac rhabdomyomatosis. This rat model of hereditary RCC provides a useful tool for analyzing the series of events leading to renal tumorigenesis and for studying *BHD* gene functions.

Keywords Birt–Hogg–Dubé syndrome · Nihon rat · Eker rat · Renal cell carcinoma · Extrarenal lesion

Introduction

In the United States, renal cell carcinoma (RCC) affects more than 35,000 people annually and causes approximately 12,000 cancer-related deaths [14]. There are several histologic variants, but the most common form is the conventional (clear cell) RCC (about 75%) and next in frequency is the papillary RCC (about 10%). Chromophobic RCC and oncocytoma are more rare (about 5%, each) [18, 35]. The vast majority of RCCs are sporadic, but there are several hereditary syndromes associated with RCCs, including Von Hippel–Lindau disease, hereditary papillary renal carcinoma, hereditary leiomyomatosis and renal cell carcinoma (HLRCC), familial renal oncocytoma, tuberous sclerosis, and Birt–Hogg–Dubé (BHD) syndrome, that have been identified [4, 13, 21, 25, 30, 40, 42, 43].

The Eker rat was the first animal model to be established for such hereditary RCCs—featuring an autosomal dominant trait due to a germline defect in the tuberous sclerosis 2 (*Tsc2*) tumor suppressor gene [7, 8, 16]. The animal shows a spectrum from early preneoplastic lesions in the age of 2 months to frank neoplasms in virtually all heterozygotes by the age of 1 year [9–11]. We have established a novel hereditary RCC model from a colony of Sprague–Dawley rats and named it the “Nihon rat” [26]. RCC development is again inherited as an autosomal dominant trait [26]. The heterozygote of the Nihon rat, unlike the Eker rat, begins to manifest preneoplastic lesions for RCC at 3 weeks of age and develops adenomas predominantly consisting of clear cells by the age of 8 weeks [17]. The homozygous mutant condition is lethal at an early stage of fetal life [26]. A germline mutation has been identified in the rat *Bhd* gene where insertion of a single nucleotide results in a frameshift at codon 17 and production of a stop codon 26 amino acids (aa) downstream [12, 27]. A high frequency of loss of heterozygosity (LOH) in primary RCC at the *Bhd* locus and the finding of a point mutation (nonsense) in one LOH-negative case indicate that tumorigenesis is initiated by “Knudson’s two-hit” in the Nihon rat [12, 27].

BHD is a rare autosomal dominant disease characterized by the development of fibrofolliculoma, trichodiscoma, or acrochordon, first described in 1977 [4]. BHD families also have other phenotypic features, including RCC development, pulmonary cysts, and/or spontaneous pneumothorax [4, 25, 29, 41, 44]. Several histopathological variants of RCC, including chromophobe RCC (34%), hybrid of oncocytic neoplasms consisting of chromophobe RCC, and oncocytoma (50%), as well as conventional (clear cell) RCC (9%), have been described in the BHD, whereas RCC in Von Hippel–Lindau disease are always composed of clear cells [21, 29]. The *BHD* gene has been mapped to chromosome 17p11.2, identified, and is known to encode mRNA for a novel protein called folliculin [25]. A canine model for BHD has also been described in German Shepherd dogs where hereditary multifocal renal cystadenocarcinomas, nodular dermatofibrosis, and uterine leiomyoma are naturally occurring [22]. The renal tumors in the dogs are primarily chromophobic and oncocytoma types and histologically similar to RCCs in human BHD cases [22].

In the Nihon rat, the histologic variant of RCC still remains to be investigated, and extrarenal lesions have hitherto not been described. The present work was conducted to characterize RCC and extrarenal lesions of the Nihon rat and to compare the phenotypes with those in the human BHD syndrome.

Materials and methods

Rats

All procedures involving rats were performed in accordance with institutional animal care guidelines established following the Association for Assessment and Accreditation of Laboratory Animal Care International.

Offsprings were obtained by brother–sister mating of male and female heterozygous rats or of male heterozygous and female wild-type rats. Phenotypic expression was determined for these rats by gross or histologic examinations of the kidney since genotypic expression has been assured to be consistent with phenotypic expression when the kidneys were grossly or histologically examined [12]. Among the offsprings, 179 rats (39 and 27 wild-type male and female rats, respectively, and 53 and 60 heterozygous male and female rats, respectively) were used at 55 weeks of age for assessment of histological and biological features of preneoplastic lesions and RCCs of the kidneys and extrarenal lesions (group I). As for cardiac lesions, another 188 offsprings obtained during weeks 9–68 of age (25 and 38 wild-type male and female rats, respectively, and 64 and 61 heterozygous male and female rats, respectively) were subjected for evaluation (group II).

Clinical features

For group I, body weights were measured once in 2 months, and the blood and plasma were evaluated for hematological and biochemical findings, respectively, at necropsy at week 55 using a THMS H.1 (Bayer Medical Ltd.) and a 7170 automatic analyzer (Hitachi, Ltd.), respectively.

Necropsy

All rats in groups I and II were anesthetized with sodium pentobarbital (50 mg/kg body weight, i.p.), exsanguinated, and necropsied. Kidney weights were measured at week 55 of age in group I.

Histopathology

All organs in group I and the hearts in group II were fixed in 10% buffered formalin, and slices were embedded in paraffin. Histological sections were cut at 3 μ m and stained with hematoxylin and eosin (H & E). The periodic acid–Schiff (PAS) reaction, Hale’s colloidal iron, and immunohistochemical stainings were also applied for the kidneys and the PAS reaction and Hale’s colloidal iron staining for the uterus, salivary gland, and heart. Immunohistochemical staining was performed according to standard procedures using mouse monoclonal anti-human cytokeratin (clone: AE1 + AE3, DakoCytomation, Japan) and mouse monoclonal anti-swine vimentin (DakoCytomation) primary antibodies. The renal lesions were grouped into four stages: altered tubule, atypical hyperplasia, adenoma, and carcinoma. The cell types of the renal lesions were classified as clear/acidophilic, acidophilic, basophilic, chromophobic, and oncocytic following the nomenclature of Bannasch [3].

Electron microscopy

Small cubes of the RCCs were fixed in buffered 2.5% glutaraldehyde, postfixed in 1% osmium tetroxide, and embedded in Epon. Ultrathin sections were cut, contrasted with uranyl acetate and lead citrate, and examined using a Hitachi 7600 transmission electron microscope (Hitachi High-Technologies Co.).

Statistical analysis

Data are presented as mean \pm SD, with statistical analysis by the Student’s *t* test at $P < 0.05$ for body weights, hematology, blood chemistry, and kidney weights.

Fig. 1 Body weight curves for normal (rats without RCCs) and heterozygous (rats with RCCs) rats. Mean body weights are expressed as mean±SD as compared to age-matched normal rats (*, P<0.05). Open square (□), solid square (■), open circle (○) and solid circle (●) indicate normal males, heterozygous males, normal females and heterozygous females, respectively

Results

Clinical feature

In group I, 14 of 53 and 10 of 60 heterozygous male and female rats, respectively, were found dead or euthanized in extremis during weeks 42–53 of age. For these rats, primary signs included emaciation, anemia, and hematuria, and body weight gain declined from 8 months of age (Fig. 1). Decreased erythrocyte counts and increased leukocyte and platelet counts (Fig. 2a–c) and elevated urea nitrogen and creatinine (Fig. 2d,e) were the findings of hematology and blood chemistry, respectively.

Gross findings

In both groups I and II, heterozygous rats had bilaterally multiple cysts and white nodules on the surface of kidneys. The normal renal parenchyma was replaced in some heterozygous rats by large nodules or cysts filled with sero-

from normal (open bars) and heterozygous (semi-solid bars) rats, as well as heterozygous rats euthanized in extremis (solid bars) are expressed as mean±SD values (*, P<0.05)

Fig. 3 Gross appearance of kidney in a Nihon rat (rat with RCCs). A 55-week-old heterozygous rat. Multiple large white to tan nodules and cysts filled with blood have replaced the normal kidney parenchyma. Scale bar: 1 cm

sanguinous fluid (Fig. 3). In group I, the kidney weights of the wild-type male and female rats were 3.4 ± 0.4 and 2.3 ± 0.3 g, respectively, and those of the heterozygous male and female rats reached 19.3 ± 16.3 g (3.3 – 59.4 g, $P < 0.05$) and 8.7 ± 7.2 g (2.1 – 35.4 g, $P < 0.05$). Large RCCs occasionally adhered to surrounding organs, but no metastatic lesions were evident in any of the rats.

Histopathology

RCC

In group I, RCCs had developed in 63 of 93 (68%) offsprings derived from mating of male and female heterozygous rats and in 50 of 86 (58%) offsprings derived from mating of male heterozygous rats and wild-type female rats. These incidences were those expected in Nihon rats according to Mendelian inheritance. Altered tubule, atypical hyperplasia, adenoma, and carcinoma, the findings being peculiar to Nihon rats, were observed in the kidneys of heterozygous rats (Fig. 4a–d). These lesions developed at the multiple sites and were scattered throughout the renal cortex and outer medulla in both the kidneys. The growth manners of the adenomas and carcinomas were variable, with tubular, solid, cystic, or cystic–papillary patterns observed.

Altered tubules, considered to be the initial stage of development of RCCs, were defined as a single or clusters of tubules lined by hypertrophic clear or acidophilic epithelium, the former being characterized by unstained cytoplasm and eccentrically located hyperchromatic small nuclei and the latter by centrally located nuclei, distinct cell membranes, and granular and/or vesicular cytoplasm. The altered tubules of clear cell type were often continuous with the collecting duct (Fig. 4a).

Fig. 4 Renal histopathology in Nihon rats (rats with RCCs).

a: An altered tubule composed of clear cells continuous with a collecting duct (H.E.; Scale bar, 20 μ m). **b:** An atypical hyperplasia composed of clear cells and acidophilic cells (H.E.; Scale bar, 50 μ m). **c:** An adenoma showing papillary growth composed of acidophilic cells (H.E.; Scale bar, 200 μ m). **d:** A carcinoma showing a large nodule (H.E.; Scale bar, 400 μ m). **e:** A carcinoma composed of mixed population of clear and acidophilic cells (H.E.; Scale bar, 50 μ m). **f:** High magnification of clear cells with abundant clear cytoplasm and small eccentric nuclei (H.E.; Scale bar, 20 μ m). **g:** High magnification of acidophilic cells with acidophilic granular cytoplasm (H.E.; Scale bar, 20 μ m). **h:** Basophilic cells with basophilic cytoplasm in a papillary lesion. **i:** Oncocytic cells with abundant acidophilic granular cytoplasm (H.E.; Scale bar, 50 μ m). **j:** Heterotopic ossification with mature bone in a clear/acidophilic RCC (H.E.; Scale bar, 50 μ m)

Fig. 5 Special stainings and immunohistochemistry of RCCs in Nihon rats. **a:** Clear cells are partially positive for PAS reaction (Scale bar, 20 μ m). **b:** Acidophilic cells are positive for Hale's colloidal iron staining (Scale bar, 20 μ m). **c:** Clear cells and epithelial cells of a collecting duct are immunoreactive for cytokeratin (Scale bar, 50 μ m). **d:** Neoplastic cells in a RCC are immunoreactive for cytokeratin (Scale bar, 50 μ m)

These tinctorial features of the altered tubules were maintained across the development through RCCs. It appeared, however, in most lesions that monomorphic population of clear or acidophilic cell type found in the altered tubules shifted to mixed population of these cell types along with the development of RCCs. It was often noted that clear cells were arranged along the periphery of the lesions, and acidophilic cells occupied the center of the lesions (Fig. 4e–g). RCCs composed exclusively either of clear or acidophilic cell type were uncommon. There were also lesions consisting of basophilic cells or oncocytic cells at a low incidence. The basophilic cell types were only occasionally noted in focal areas of RCCs in the papillary form (Fig. 4h), and oncocytic cells were few in any form of RCCs (Fig. 4i).

PAS reaction revealed the cytoplasm of clear cells to be partially positive (Fig. 5a) and that of acidophilic cells to be positive for Hale's colloidal iron staining (Fig. 5b). The RCCs were immunoreactive for cytokeratin (Fig. 5c,d), irrespective of cell types or growth manner, whereas they

were uniformly non-immunoreactive for vimentin (data not shown).

In addition to the renal component, heterotopic ossification was evident within 37 of 113 RCCs found at 55 weeks of age. This change was limited to the clear/acidophilic RCCs with a solid form (Fig. 4j) and showed the whole spectrum of osteogenesis, including the presence of osteoblasts, deposition of osteoid, mature bone formation with bone marrow, and remodeling by osteoclasts.

Vascular lesions

Heterozygous rats had vascular lesions in various organs. Although the total incidence reached 21 of 113 heterozygous rats, 14 among these 21 rats were found dead or euthanized in extremis. Primary lesions consisted of thickening of the arteriolar wall in the kidney, mesentery, testis, spleen, and heart, often accompanied by advanced vascular lesions, consistent with periarteritis nodosa in the four former organs (data not shown).

Table 1 Incidence data for extrarenal lesions: uterus and salivary gland

	Male		Female		Total	
	Normal	Heterozygote	Normal	Heterozygote	Normal	Heterozygote
Uterus						
Clear cell hyperplasia/adenoma	NA	NA	0/27 (0%)	18/60 (30%)	0/27 (0%)	18/60 (30%)
Salivary gland						
Clear cell change	0/39 (0%)	3/53 (6%)	0/27 (0%)	12/60 (20%)	0/27 (0%)	15/113 (13%)

Number of rats with the lesion per total number of rats

NA Not applicable

Fig. 6 Histopathology of extrarenal lesions in Nihon rats. **a:** A clear cell adenoma of the endometrium of the uterus (H.E.; Scale bar, 100 μ m). **b:** Clear cell changes of the epithelium of the striated

portion in the salivary gland (H.E.; Scale bar, 50 μ m). **c:** Cardiac rhabdomyomatosis (H.E.; Scale bar, 50 μ m)

Extrarenal lesions

Upon detailed microscopic examinations of all the organs and tissues, three distinctive extrarenal lesions besides RCCs were found in heterozygous rats: (a) clear cell hyperplasia/adenoma of the endometrium; (b) clear cell change of the striated portion of the salivary gland; and (c) cardiac rhabdomyomatosis, all the findings being absent in normal rats.

(a) Clear cell hyperplasia/adenoma of the endometrium of the uterus

The lesion was observed in 18 of 60 heterozygous females (Table 1). Histologically, the initial lesion consisted of the endometrial gland with irregularly arranged clear cells that had PAS-reactive and Hale's colloidal iron staining negative clear cytoplasm and eccentrically located hyperchromatic nuclei, features resembling clear cells in RCCs. These lesions extended across the endometrium to form large nests of clear cells with occasional nodular projections into the glandular and uterine lumen, consistent with adenoma development (Fig. 6a). No mitotic figures were found in any of the lesions.

(b) Clear cell change of the striated portion of the salivary gland

The epithelium of the striated portion of the salivary gland also demonstrated cluster of clear cells with PAS-reactive and Hale's colloidal iron staining negative cytoplasm and eccentrically located hyperchromatic nuclei, at an incidence of 15 of 113 heterozygous rats (Table 1). The lesion was usually multifocal; however, it never became morphologically neoplastic (Fig. 6b).

(c) Cardiac rhabdomyomatosis

Cardiac rhabdomyomatosis was found in 15 of 125 heterozygous rats (Table 2). Young heterozygous rats were more predisposed to the lesions; the incidence for rats in the age ranges of 9–13, 14–26, 27–52, and 53–68 weeks were 9/26, 4/50, 2/15, and 0/34, respectively (Table 2). Lesions were found in the right and left ventricular walls and/or septum and were histologically characterized by multifocal clusters of clear cells with PAS-reactive and Hale's colloidal iron staining negative cytoplasm and eccentrically located hyperchromatic nuclei (Fig. 6c). The spider cells described for human cardiac rhabdomyoma were occasionally present within the lesions. There was no evidence of neoplasia, and no mitotic figures were apparent.

Electron microscopy

Common architectural findings among all the clear, acidophilic, and basophilic cell types of renal lesion included intermediate junctions, interdigitations, and microvilli at the luminal cell surface (Fig. 7c, d). In addition, the cytoplasm of the clear cells was occupied in large part by monoparticulate glycogen that accounted for the clear appearance in paraffin-embedded sections (Fig. 7a). Also noted in the clear cells were a few mitochondria, lysosomes, and lipid droplets in the rim of remaining cytoplasm (Fig. 7a). The acidophilic cells had similar organelles and characteristic lamellar bodies in various proportions, the monoparticulate glycogen being less predominant (Fig. 7b). In the some acidophilic cells, intracytoplasmic lumina with several microvilli were also observed (Fig. 7c). Large

Table 2 Incidence data for cardiac rhabdomyomatosis

Age (weeks)	Male		Female		Total	
	Normal	Heterozygote	Normal	Heterozygote	Normal	Heterozygote
9–13	0/8 (0%)	7/19 (37%)	0/11 (0%)	2/7 (29%)	0/19 (0%)	9/26 (35%)
14–26	0/6 (0%)	2/23 (9%)	0/11 (0%)	2/27 (7%)	0/17 (0%)	4/50 (8%)
27–52	0/2 (0%)	0/7 (0%)	0/6 (0%)	2/8 (25%)	0/8 (0%)	2/15 (13%)

Number of rats with the lesion per total number of rats

Fig. 7 Electronmicroscopy of RCCs in Nihon rats. **a**: Clear cells have abundant monoparticulate glycogen, a few mitochondria, lysosomes and lipid droplet in the cytoplasm. **b** and **c**: Acidophilic cells have various numbers of mitochondria, concentric lamella structures and intracytoplasmic lumen lined with microvilli. The inset in C shows interdigitations. **d**: Basophilic cells have abundant rough endoplasmic reticulum, free and membrane-bound ribosomes, and scattered mitochondria and lysosomes. Microvilli are observed at the surface of the cytoplasm. The inset in D shows a intermediate junction. Scale bars: 5 μ m

amount of rough endoplasmic reticulum and free and membrane-bound ribosomes were features of the basophilic cells (Fig. 7d).

Discussion

In the Nihon rat, the initial stage of RCCs represented by altered tubules was found to appear as early as 3 weeks of age and rapidly progressed to frank neoplasms by 8 weeks of age with high penetrance [17]. The onset of these lesions clearly distinguishes the Nihon from the Eker rat where preneoplastic lesions first occur at 2 months and adenomas at 1 year of age [9–11]. Genotypic analysis also demonstrated a difference between the two rat RCC models. The *Tsc2* tumor suppressor gene has been shown to be responsible for development of RCCs in the Eker rat, whereas the *Bhd* gene is involved in the Nihon rat [16, 27]. These distinct features warrant consideration of this latter animal as a novel model of hereditary RCC.

The Nihon rat model and human BHD exhibit similarities in various aspects, the most notable being the causative gene mutation. The predisposing gene for the human BHD is reported to be located on chromosome 17p11.2 in the germline of patients [25]. The susceptibility gene of the RCC in the Nihon rat has been mapped to distal rat chromosome 10, syntenic with several human chromosome segments including chromosome 17p11.2, and a germline single nucleotide insertion has been identified in the rat *Bhd* ortholog [12, 16, 27].

The second similarity involves phenotypic expression during RCC development. However, there are dissimilarities as well as similarities in the cytologic features between RCCs in human and the Nihon rat. One of the predominant types of RCC in the BHD syndrome is chromophobic, which is further subclassified into granular (type I cells), eosinophilic granular with perinuclear halos (type II cells), and clear cytoplasm (type III cells) [2, 29, 41]. Chromophobic RCCs, unlike conventional RCCs, contain abundant mucopolysaccharides that react positively with Hale's colloidal iron [5, 36, 38]. Although they are immunoreactive for cytokeratin, they are negative for vimentin [5, 6, 15, 20, 23]. Ultrastructurally, the RCCs are characterized by numerous cytoplasmic microvesicles, which are thought to arise from outpouchings of the mitochondria [19, 37, 39]. In the Nihon rat, morphologic findings for RCCs are in many aspects consistent with human counterparts of chromophobic type. They include unstained clear cytoplasm under H & E-stained sections, reactivity to Hale's colloidal iron, immunoreactivity for cytokeratin, and non-immunoreactivity for vimentin. However, at the electron microscope level, intracytoplasmic microvesicles are only present in human RCCs and abundant monoparticulate glycogen only in the Nihon rats.

The cytogenetic origin of RCCs is also most likely to be common in both human and Nihon rat kidneys. One of the characteristic features of RCCs in the Nihon rat is that altered tubules often merge into normal cortical or medullary collecting duct, strongly suggesting an origin from the epithelium of the collecting duct system. This notion is

further strengthened by the fact that RCCs were immunoreactive to cytokeratin and not vimentin, consistent with normal collecting duct. It has also been reported that chromophobic RCCs and oncocytomas common in BHD originate from intercalated cells of renal collecting tubules and distal tubules, respectively [1, 33, 34].

In contrast to these similarities, the skin and lung were within normal limit in the Nihon rat unlike in BHD syndrome where fibrofolliculoma and pulmonary cysts or pneumothorax, respectively, are reported to occur.

It is of interest to note additional distinctive lesions in the Nihon rat. Heterotropic ossification was associated with RCCs at approximately 30%, the finding and incidence being unexpected. Ossification also occurs within RCCs in humans though only at a low incidence [32]. The extrarenal lesions including clear cell hyperplasia/adenoma of the endometrium of the uterus, clear cell change of the epithelium of striated portion in the salivary gland, and cardiac rhabdomyomatosis are of types rarely found as spontaneous change in rats. All three lesions as well as RCCs share the finding of clear cell alteration despite occurring in different organ system. Another phenotypic similarity between Nihon rats and human BHD syndrome is present in the salivary gland where salivary (parotid) oncocytoma of clear cell variant has been reported in human [28]. Although the *BHD* gene product, folliculin, has no known function at present, it may play a role in clear cell alteration in the Nihon rat [25].

Approximately 20% of the Nihon rats were found dead or needed to be euthanized in extremis before the age of 1 year, with severe anemia or renal dysfunction as the most likely responsible causes, reflecting hemorrhage from hematomas within RCCs and the replacement of the normal renal parenchyma, respectively. These observations suggest malignant biologic behavior of the renal cell tumor of the Nihon rat, even though no metastasis have so far been observed, unlike the human RCC case where metastasis is reported to occur in nearly 30% [24]. In addition, the vascular lesions noted in the Nihon rat found dead or euthanized in extremis strongly indicated a hypertensive status. Hypertension is subdivided into essential and secondary types [31]. The former has no known cause, while the latter has an identifiable cause such as renal artery stenosis and renal parenchymal disease [31]. Thus, it is likely that large nodules or cysts of RCCs lead to the secondary hypertension in the Nihon rat, resulting ultimately in death.

In conclusion, we have established the Nihon rat model of hereditary RCC and, in this communication, document characterization of phenotypic and genotypic aspects in comparison with human BHD syndrome. The Nihon rat will provide a useful tool for analyzing the series of events that lead to renal tumorigenesis and for studying *BHD* gene function.

Early cardiac hypertrophy induced by thyroxine is accompanied by an increase in VEGF-A expression but not by an increase in capillary density

Received: 1 November 2005 / Accepted: 30 December 2005 / Published online: 27 January 2006
© Springer-Verlag 2006

Abstract Cardiac hypertrophy in response to hyperthyroidism is well known. However, the effects on cardiac microcirculation are still controversial in this model. The present study evaluated the effects of acute administration of two different thyroxine (T4) dose levels on the angiogenic response in the myocardium. Capillary density (CD), the CD to fiber density (FD) ratio (CD/FD), and intercapillary distance (ICD) were assessed, as was ventricle weight (VW) to body weight (BW) ratio (VW/BW). Collagen I and III messenger ribonucleic acid (mRNA) expression and VEGF-A expression were also determined by reverse transcriptase polymerase chain reaction (RT-PCR). Immunohistochemical detection of proliferating cell nuclear antigen (PCNA) expression in endothelial cell nuclei was also carried out. We simulated an acute hyperthyroidism situation in male Wistar rats by daily intraperitoneal injection of T4 (0.025 or 0.1 mg kg⁻¹ day⁻¹) for 7 days. Hemodynamic parameters showed that T4 did not alter systolic blood pressure (SBP) but significantly increased heart rate (HR). Both T4 doses significantly increased VW. Morphologically, the higher T4 dose resulted in a 33% greater myocardial mass, which was not accompanied by alterations in collagen I and III mRNA expression. The CD and CD/FD parameters were significantly lower in the hyperthyroid rats treated with the higher dose than in the control animals, and PCNA-labeling analysis indi-

cated total absence of marked capillary growth. However, although the acute treatment with T4 did not induce any alteration in capillary number and endothelial cell proliferation, the vascular endothelial growth factor (VEGF)-A mRNA and protein expression were significantly increased with the higher T4 dose. These data indicate that the cardiac hypertrophy induced by acute treatment with thyroid hormone precedes the angiogenic process, which probably occurs later.

Introduction

Adaptive growth of the heart in response to hypertrophic stimuli involves functional and morphological changes that are predictable depending upon the stimulus and its duration. In recent years, some studies have described the thyroid-hormone-induced cardiac hypertrophy and the characteristics that separate it from other hypertrophic models. However, the effect that thyroid-hormone-induced cardiac hypertrophy has on myocardial capillarization has not always been consistent [4, 7, 12]. Furthermore, considering that hyperthyroidism increases cardiac load, which leads to cardiac hypertrophy in many species, it is not clear in these studies if the thyroid-hormone-induced coronary vessel alteration is due to direct hormonal effects or is secondary to the hemodynamic effects, such as increasing the blood pressure. In a previous study conducted in our laboratory, we confirmed that acute hyperthyroidism is able to promote cardiac hypertrophy [14]. In this study, there was no difference in systolic blood pressure (SBP) between thyroxine (T4)-treated animals and control animals, indicating that the cardiac hypertrophy was not due to elevated hemodynamic parameters. In addition, using the same experimental model, we have recently showed that this cardiac hypertrophy is notably characterized by disorganization of intercellular junctions, suggesting damage for effective cardiac contraction [15].

In general, most models of cardiac hypertrophy are accompanied by an increase in the formation of new capillaries (angiogenesis) and this adaptative process is dependent and secondary to a net balance between molecules that have positive and negative regulatory activity [22]. Numerous inducers of angiogenesis have been identified, including members of the fibroblast growth factor (FGF) family, vascular endothelial growth factor (VEGF), platelet-derived growth factor, and others [25]. The modification of the expression or activity of one of the vascular growth factors will result in a functional dysbalance within the vessel wall, leading to vascular dysfunction [31]. Of these, VEGF-A, one functionally relevant growth factor, has been most carefully studied for its crucial role in vascular development, angiogenesis, collateral growth, and enhancement of collateral perfusion [1, 20]. In vivo, myocardial expression of VEGF-A is significantly augmented by ischemia or hypoxia and stretch [23]. Once VEGF-A increased, this factor is beneficial to the ischemic region as a therapeutic agent promoting collateral formation, indicating that VEGF-A exerts a potent effect on angiogenic response in cardiovascular disease [27]. Although the VEGF has been related to some hypertrophic processes [26], nothing is known about VEGF in hyperthyroidism-induced hypertrophy.

Because most types of cardiac hypertrophy are accompanied by an increase in vascularization and as hyperthyroidism promotes a rapid increase in cardiac mass, the present study was designed to assess the effects of two different acute dose levels of T4—0.025 and 0.1 mg/kg body weight (BW), for 7 days—on capillary density (CD) and also to evaluate the potential involvement of VEGF-A in this cardiac hypertrophy model.

Materials and methods

Animals

Male Wistar rats, weighing 200–260 g, were obtained from the Instituto de Ciências Biomédicas, University of São Paulo. All of the animals were cared for and handled according to National Institutes of Health guidelines.

The rats were housed in Plexiglas cages on a 12-h light/dark cycle and received a rat pellet diet and water ad libitum before and during the experiment. L-Thyroxine was purchased from Sigma (St. Louis, MO, USA). Rats were randomized into two hyperthyroid groups, T4-25 and T4-100. Hyperthyroidism was simulated in T4-25 and T4-100 rats by daily intraperitoneal injections of T4 (0.025 and 0.1 mg kg BW⁻¹ day⁻¹, respectively) for 7 days. These doses have been described previously as sufficient to cause a significant augment in the circulating thyroxine levels [17]. Animals from the control group received daily intraperitoneal injections of saline. All rats were killed 24 h after their treatments. All surgical procedures and protocols were performed in accordance with the Ethical Principles in Animal Research set forth by the Brazilian College of Animal Experimentation and were approved by

the Biomedical Sciences Institute/USP Ethics Committee for Animal Research.

Hemodynamic parameters

In all rats, SBP and heart rate (HR) were measured every 2 days at the same time of day by tail-cuff plethysmography (Kent Scientific, Litchfield, CT, USA). The rats were familiarized with the apparatus for 7 days before the taking of measurements. In addition, BW was measured daily. The final SBP and BW measurements were taken immediately before the rats were killed.

Heart preparation

After 1 week, the animals were deeply anesthetized with sodium pentobarbital (3.3 ml/kg, intraperitoneal) and the thorax was opened. The animals were then submitted to transcardiac perfusion with saline solution. Cardiac arrest in diastole was induced by perfusion of potassium chloride (14 mM), followed by a fixative solution of 10% paraformaldehyde. The perfusion pressure was maintained within the same range as that of the conscious animals. The heart was then quickly excised, all surrounding fat and connective tissue were removed, and the heart (minus the atrium) was weighed. The left ventricle (LV) was isolated from the right ventricle (RV) free wall, leaving the septum and LV intact. Both RV and LV were weighed separately. However, only the LV free wall was used for histological and quantitative analysis.

Ventricle hypertrophy was assessed by measurement of wet ventricle weight (VW), and the ratio of VW in milligrams to animal BW in grams (VW/BW, mg/g) was determined. Cardiac hypertrophy was confirmed by analyzing VW as dry weight (data not shown).

Microscopic studies

The LV was transversely sectioned at the midpoint between apex and base. A cross-sectional slice was fixed in 10% paraformaldehyde at room temperature for 12–24 h. The slice was dehydrated in a graded alcohol series (70, 80, 95, and 100%) and embedded in paraffin. The samples were sectioned at 5 μm, and nine nonconsecutive sections were collected and stained with toluidine blue for morphometric analysis.

Following the method described by Amaral et al. [1], four microscopy fields per slice were analyzed from each of the nine slices. Only fields where the fibers were transversally sectioned were used because in the myocardium the fibers run in multiple directions. The fields were randomly chosen from different areas of the transverse sections. The morphometric analysis was made in transversal tissue sections using a light microscope (Nikon E1000) coupled to an analysis system (Cool-Snap-Prom, Image ProPlus) to determine the CD, fiber density (FD), and CD/

FD ratio. A magnification of $\times 40$ was used for the morphometric analysis. All measurements were made under blind conditions. Capillaries were defined as small vessels lined by a single layer of endothelial cells. To avoid possible confusion with lymphatic capillaries, vessels with irregular profiles were excluded from the counts. Values for CD and FD (always obtained in a 0.0203-mm^2 field) were expressed as number per square millimeter. The number of capillaries and muscle fibers was counted using the correction-of-edge effect. These counts were used to calculate the CD/FD ratio for hearts in each group, expressed as CD/FD. The intercapillary distance (ICD) was estimated assuming a hexagonal array of capillaries by the formula $ICD (\mu\text{m}) = 1.076 \sqrt{DC}$, according to the method described previously by Olivetti et al. [21].

Finally, the immunohistochemical detection of proliferating cell nuclear antigen (PCNA) protein in combination with haematoxylin and eosin staining was used.

Immunohistochemistry for PCNA

This method enables the identification of the different myocardial cell types that are within the synthesis phase of the cardiac cycle identifying the expression of proliferating cells. PCNA data were used to corroborate morphometric data [13].

Cross-sections ($3 \mu\text{m}$) from control or T4-treated hearts obtained from paraffin-embedded tissue were dewaxed and mounted using conventional techniques. Sections were then subjected to microwave irradiation in citrate buffer to enhance antigen retrieval. The cardiac tissue was incubated with 1:200 primary mouse anti-PCNA antibody (Zymed). After rinsing in PBS, a secondary biotinylated antimouse IgG peroxidase-conjugated antibody (Vector, CA, USA) was applied to sections. Sections were then incubated with 3'-diaminobenzidine solution (DAB, Sigma, St. Louis, MO, USA), stained with haematoxylin and eosin and held with a coverslip. PCNA-positive nuclei were identified in cross-sections by their brown color. The same conditions, but in the absence of antibody, were used as negative control for the PCNA immunohistochemistry. Sections obtained from rat testicle tissue were used as a positive control. In general, only cells found on the margin of testicular tissue are in proliferation phase. The labeling for PCNA was analyzed using the magnification of $\times 20$.

RT-PCR analysis

Total ribonucleic acid (RNA) was obtained from control or T4-treated hearts using Trizol LS reagent (Life Technologies) in accordance with the manufacturer's instructions. The complementary deoxyribonucleic acid (cDNA) species were synthesized with SuperScript II (Life Technologies) from $2 \mu\text{g}$ of total RNA in a total volume of $20 \mu\text{l}$ with an oligo (dT) primer in accordance with the manufacturer's instructions. cDNA reactions were performed for 1 h at 42°C and stopped by boiling for 5 min. cDNA was used as

a template for polymerase chain reaction (PCR) with specific primers for VEGF-A. A 210-base-pairs sequence of the β -actin messenger ribonucleic acid (mRNA) was chosen as an internal standard RNA for PCR. β -Actin was selected as an internal RNA standard because its expression was not affected by either thyroid hormone [6] or myocardial hypertrophy [18]. To better characterize this cardiac hypertrophy model, collagen I and III mRNA expressions were also analyzed. To find the ideal conditions for the PCR, a curve of the number of cycles performed for each gene studied and another temperature curve were initially constructed and then points that were always localized in the linear phase were chosen.

The PCR cycling conditions were as follows: for VEGF-A (product 256 bp), 1 min at 94°C , 1 min at 66°C , and 1 min at 72°C , using 26 cycles; for collagen I (product 221 bp) and for collagen III (product 266 bp) 1 min at 94°C , 1 min at 60.4°C , and 1 min at 72°C , using 30 cycles; for β -actin (product 210 bp) 1 min at 94°C , 1 min at 59.8°C , and 1 min at 72°C , using 34 cycles and a $\times 20$ diluted primer concentration. An initial denaturation step (3 min at 94°C) and a final extension (10 min at 72°C) were included in all PCRs. Ten microliters of the PCR were analyzed on 1.5% agarose gel. The following set of primers were used for VEGF-A: 5' ACT GGA CCC TGG CTT TAC TC 3' and 5' ACG CAC TCC AGG GCT TCA TC 3'; for collagen I: 5' CTT CGT GTA AAC TCC CTC C 3' and 5' CAC TTT TGG TTT TTG GTC AC 3'; for collagen III: 5' GCG GCT TTT CAC CAT ATT AG 3' and 5' GCA TGT TTC TCC GGT TTC 3'; and for β -actin: 5' TAT GCC AAC ACA GTG CTG TCT GG 3' and 5' TAC TCC TGC TTC CTG ATC CAC AT 3'. All oligonucleotides were obtained from Invitrogen, Brazil. Ten microliters of the PCR were analyzed on 1.5% agarose gel. Using an Image Analysis System, the densitometric intensity related to VEGF-A, collagen (I and III), and β -actin bands were converted to numeric values. The mRNA expression was expressed as mRNA of the gene of interest and mRNA β -actin ratio in arbitrary units (densitometric intensity).

Western blot analysis

Samples from the left ventricle of rat were homogenized in an extraction buffer (90 mM KCl, 10 mM Hepes, 3 mM MgCl_2^+ , 5 mM EDTA, 1% glycerol, 1 mM DTT, 0.04% SDS, pH 7.4). Protein concentrations were determined by Bradford method and $150 \mu\text{g}$ of protein were then separated by electrophoresis on a 15% SDS-polyacrylamide gel, and then transferred to nitrocellulose membrane (Bio-Rad). The membrane was stained with Ponceau solution to demonstrate that the protein concentration was similar in the different lanes and, after that, the membrane was washed with Tris-buffered saline Tween-20 (TBST) (50 mM Tris, 150 mM NaCl, pH 7.5, and 2% Tween-20) for 10 min at room temperature. The membrane was then incubated at 37°C for 1 h and 30 min with a primary polyclonal antibody against VEGF, which recognizes the 165-, 189-, and 121-amino acid splice variants of VEGF (sc507,

Santa Cruz Biotechnology, Santa Cruz, CA, USA) at 1:500 dilution in TBST. The three isoforms of VEGF-A can be visualized at the same protein weight, once they all have similar weights. Washed blots were then incubated for 1 h at room temperature with a secondary goat antirabbit IgG antibody conjugated with peroxidase (Amersham Biosciences) at a 1:1,000 dilution in TBST. Washed blots were subjected to the ECL Western blotting detection reagent kit (Amersham Biosciences), which allowed the production of a signal by a chemiluminescence reaction that was detected by exposure to X-ray film. The protein bands, related to the three isoforms of VEGF-A, were quantified by densitometry and then the band densities were calculated. Molecular weight markers were commonly used to determine the relative molecular weight of the labeled bands and an immunoreactive band was regularly detected at ~45 kDa.

Statistical analysis

The data are expressed as means±SD. In the capillary density calculation, n was considered as the number of animals used in each group. Statistical analysis was performed using ANOVA, and p values <0.05 were accepted as statistically significant. Tukey's post hoc test was used to make individual comparisons between groups when a significant change was observed with ANOVA.

Results

The parameters of SBP and HR after T4 administration are summarized in Table 1. Both dose levels of thyroid hor-

mone significantly increased HR but did not affect SBP, compared to control animals. The changes in HR and the BW gain during treatment served as an index of thyroid hormone activity.

The BW at the beginning of the experiment was the same in all groups of rats. Although BW after treatment with T4 had not been significantly different among all experimental groups, in hyperthyroid rats, BW gain during the 7 days of treatment was different to that of control animals (Table 2). In the hyperthyroid groups (T4-25 and T4-100), VW was significantly greater (19.4 and 37.5%, respectively) than in the control group (Table 2). However, VW/BW was significantly increased only in the T4-100 group (p<0.01, Table 2).

Wet-to-dry weight ratios did not differ significantly among the groups (data not shown). This indicates that the hormone-induced changes were due to changes in cardiac muscle mass and not to changes in myocardial water content.

Although the increase in cardiac muscle mass is mainly due to a significant increase in transverse diameter of cardiomyocytes [14], the levels of collagen I and III mRNA expression in the hypertrophic myocardium were analyzed (Fig. 1). The concentric hypertrophy obtained in the T4-100 group (Fig. 1a) was not accompanied by any alteration in collagen I or III mRNA levels (Fig. 1b), apparently indicating that at this early stage of hyperthyroidism, the increase in cardiac mass is just the result of myocyte growth and is not accompanied by a fibrosis process.

Figure 2 shows a representative transverse section of cardiac muscle obtained from a control animal and Fig. 3 presents the relationship between CD and CD/FD in the various groups studied. Treatment with different doses of T4 promoted a significant decrease in CD compared with the control group. However, there were no significant differences in the CD among both hyperthyroid groups (T4-25 and T4-100). Although the mean values for FD tended to be lower in all T4 groups than in the control group, it was significantly (17%) lower only in the T4-100 group (1,246±126 for T4-100 vs 1,507±134 for control, p<0.05). In fact, this lower FD in the T4-100 group was reflected by an accentuated decrease in the CD/FD (approximately 25% lower than in the controls), which was significantly lower only in this group (p<0.01). Furthermore, the average center-to-center ICD increased only in the T4-100 group as the result of myocyte size being greater than in the control group (39.6±2.1 vs

32.8±0.6, respectively) because no significant difference in capillary diameter was observed (3.15±0.30 μm in controls vs 3.35±0.80 μm in the T4-100 group).

With regard to the ability of thyroid hormone to decrease the CD in the myocardium, the effect of hormone on VEGF-A levels, a potent angiogenic factor in cardiovascular disease, was also evaluated. A representative electropho-

resis gel obtained by reverse transcriptase polymerase chain reaction (RT-PCR) analysis is shown in Fig. 4a. The VEGF-A mRNA expression levels were not altered in the T4-25 group, but they were significantly higher in the T4-100 group than in the control group. The increased VEGF-A mRNA expression was accompanied by a significant elevation in VEGF-A protein levels, as shown in Fig. 4b.

Fig. 5 a Immunohistochemistry for PCNA in a transverse section of the left ventricle from the control group and **b** group submitted to hyperthyroidism by daily intraperitoneal injection of T4 (0.1 mg kg⁻¹ day⁻¹) for 7 days. **c** A section from rat testicle used as a positive standard for PCNA. The *red arrow* indicates a positive label for PCNA in the nucleus of a proliferating cell and the *black arrow* indicates absence of staining for PCNA in a cell localized out of the proliferative region. 20 \times magnification

However, despite the augmented VEGF-A levels, the lack of PCNA-positive endothelial nuclei in the control and T4-100 groups indicated an absence of endothelial cell proliferation, possibly reflecting a lack of capillary growth (Fig. 5a,b). Furthermore, no difference in PCNA-labeling in myocytes between control and T4-100 groups was detected; this absence agrees with the idea that myocyte proliferation is rare in adult animals and that this phenomenon is not changed by hyperthyroidism.

Discussion

The thyroid hormones play an important role in maintaining an optimal level of cardiac function and tissue oxygen consumption. Nevertheless, in hyperthyroidism, the increases in cardiac load and tissue metabolism usually result in a concomitant increase in tissue oxygen consumption and myocardial mass. In adults, in whom the angiogenic capacity is known to be diminished, excess thyroid hormone induces myocardial hypertrophy. Cardiac hypertrophy was produced in adult rats with excess thyroxine and the increase in cardiac mass observed in this study was in accordance with our own previous findings and with those of other authors [4, 14]. The increase in ventricular mass observed in both hyperthyroid groups was due to an increase in the myocyte component and not to an increase in myocardial water content or collagen expression. The physiological data show that the hearts of T4-treated animals are functioning under an increased cardiac rate, a condition that characterizes this model. In addition, a dissociation between elevated arterial pressure and increased myocardial mass was observed in this acute model of cardiac hypertrophy. This dissociation suggests the existence of stimuli, other than blood pressure, that are responsible for the development of intense cardiac hypertrophy [19]. Thus, the indirect effects of thyroid hormone seem to be mediated mainly by up- or down-regulation of alpha- and beta-adrenergic receptors [3], while the direct effects of the hormone result from its binding to nuclear receptors, which function as transcription factors [5, 30]. Furthermore, a series of studies have recently shown important nongenomic effects of thyroid hormone, inducing different cytosolic signaling cascades, which can directly affect gene expression [2, 9, 16].

The coronary microvasculature changes that occur in response to hypertrophy, as well as the increased oxygen demand, are potentially important factors in maintaining adequate oxygen supply to the myocardium. In this study, CD and CD/FD ratios were significantly lower after treatment with the hormone, despite the presence of myocardial hypertrophy. The CD, provided that it is expressed per square millimeter of muscle fiber, and the CD/FD ratio are valid and common indexes used in a wide range of animal models [10]. Although some studies that use a longer administration of thyroxine have previously demonstrated a potent angiogenic effect for thyroid hormone [4, 7, 28], the absence of labeled nuclei by PCNA immunohistochemistry in this acute study corroborates the fact that there was no endothelial proliferation. Thus, the cardiac hyper-

trophy induced by T4 in the early phase is a different model, which presents peculiar characteristics when compared to other models that are induced by overload pressure [24, 29]. In part, our results are in agreement with those from other previous studies involving the same model but evaluating the CD in different cardiac regions. Weiss and Grover [32] observed, in rabbits, that after 16 days of T4 administration, there was a significant decrease in the average number of capillaries per square millimeter in the subendocardium and subepicardium regions. Gerdes et al. [12] also observed a decrease in CD (endocardium, 12%; epicardium, 17%) during hyperthyroidism. The decrease in CD observed by these authors, however, was accompanied by approximately 69% hypertrophy, suggesting that, although there was severe ventricular hypertrophy in the hyperthyroid group, there was some degree of active capillary angiogenesis because the decrease in CD was less severe than the increase in ventricular mass. In contrast, the results obtained in this study show that the decrease of approximately 32% in CD observed after treatment with the higher T4 dose was similar to ventricular hypertrophy in this group (33%), suggesting that the capillary supply in the heart was not altered during treatment with thyroxine.

On the basis of the predictions made by Weiss and Grover [32], one might expect to find anoxic foci in the thyroid-treated animals of our study because we found no difference in the capillary diameter between the hyperthyroid (T4-100) and control groups (data not shown). On the other hand, Weiss and Grover [32] showed that an important compensation for the reduced size of the microvascular bed is a significant increase in the proportion of the bed that is perfused. It is possible that, in this model, the greater number of perfused capillaries (despite the lower CD) observed by the authors represents an attempt to maintain at least the minimum physiological conditions. It may be speculated that there is no immediate increase in capillary area in the early phase of T4-induced cardiac hypertrophy (the phase studied in our model). Therefore, this phenomenon may account for the ischemia and significant increase in mitochondrial volume that characterizes the myocardial hypertrophy seen under certain conditions in this model [8, 15].

Although we found no angiogenic effect for thyroid hormone in this study, the increased VEGF-A mRNA and protein levels suggest that the capillary proliferation may be observed after a longer treatment, as VEGF, a functionally relevant vascular growth factor [11], plays a crucial role in vascular development, angiogenesis, and collateral growth. Furthermore, because ischemia or hypoxia is a potent factor in inducing the expression of VEGF-A [23] and T4 promotes an increase in ICD as observed in the present study, this relationship appears to be understandable.

According to our data, we postulate that the increase in VEGF-A mRNA levels corresponds to the initial event that deflagrates the angiogenic process. As such, the observation of the formation of new microvessels may require a longer period of treatment with the hormone. Thus, our data indicate that cardiac hypertrophy installation precedes the formation of new microvessels.

In conclusion, our findings show, for the first time, a relationship between the development of cardiac hypertrophy, induced by acute hyperthyroidism and elevated VEGF-A levels (an important angiogenic growth factor) in the myocardium. This increase, however, was not accompanied by parallel endothelial cell proliferation or by any increase in the number of capillaries, at least during the early stage of myocardial hypertrophy, as represented by this study. It may be speculated that, perhaps in the later phase of thyroxine-induced cardiac hypertrophy, development of new microvessels occurs, possibly caused by the increased levels of VEGF-A observed herein.

The significance of the P504S expression pattern of high-grade prostatic intraepithelial neoplasia (HGPIN) with and without adenocarcinoma of the prostate in biopsy and radical prostatectomy specimens

Received: 10 November 2005 / Accepted: 25 January 2006 / Published online: 28 February 2006
© Springer-Verlag 2006

Abstract Diagnosis of prostatic adenocarcinoma is usually not difficult in biopsy specimens. Problems may occur in biopsy specimens, containing only a few suspicious lesions. Recently, P504S has been tested as a new marker for prostatic carcinoma. When over-expressed in atypical glands without basal cells, it establishes the diagnosis of prostatic carcinoma. We analysed the staining intensity of P504S in 208 biopsy specimens from prostates (1) with adenocarcinoma ($n=132$), (2) with high-grade prostatic intraepithelial neoplasia (HGPIN) with adenocarcinoma ($n=36$), (3) with HGPIN alone ($n=40$) and in radical prostatectomy specimens with HGPIN adjacent to ($n=54$) or distant from adenocarcinoma ($n=64$). P504S expression was negative to weakly positive in biopsy specimens showing HGPIN without carcinoma and weakly positive in radical prostatectomy specimens revealing HGPIN distant from adenocarcinoma. In biopsy specimens with a combination of HGPIN and adenocarcinoma and in radical prostatectomy specimens with HGPIN adjacent to adenocarcinoma, P504S was strongly expressed. The same findings were made in radical prostatectomy specimens containing adenocarcinoma and HGPIN adjacent to or distant from adenocarcinoma and in preoperative biopsies revealing adenocarcinoma and HGPIN. These results suggest that moderate to strong P504S expression in HGPIN of biopsy specimens is indicative of an associated adenocarcinoma and may be helpful in the choice of therapy.

Keywords Prostatic adenocarcinoma · Prostatic intraepithelial neoplasia · P504S

Introduction

High-grade prostatic intraepithelial neoplasia (HGPIN) is the most likely precursor of prostate adenocarcinoma [2, 3]. The frequency of HGPIN in biopsy specimens that do not show any invasive prostate carcinoma ranges between 8 and 16% [2, 5]. When in these cases repeat biopsies were performed, they revealed adenocarcinoma in up to 15–30% of the cases [2, 3, 5, 8–10, 19, 20]. However, in 70–85% of the cases, the diagnosis remained HGPIN even after four and more repeat biopsies [5, 10]. This is a very problematic situation for the patient and the urologist, especially when the prostate-specific antigen level rises from year to year. In these circumstances, it would be helpful to have an immunohistochemical marker that is indicative of the presence of an adenocarcinoma of the prostate. Recently, the new tumour marker P504S (alpha-methylacyl-CoA racemase, AMACR) was used in the evaluation of diagnostic needle biopsy specimens from the prostate. P504S (AMACR) has been shown to be over-expressed in carcinoma of the prostate [1, 6, 11–16, 18].

In a preliminary study, we analysed the neoplastic potential of atypical small glandular lesions seen in biopsy specimens of the prostate by immunohistochemical screening for the expression of P504S and the basal cell markers P63 and 34BE12. In 35.8% of the suspicious cases, an adenocarcinoma of the prostate was found [6]. In this study, we analysed the relationship between high-grade PIN and adenocarcinoma of the prostate in preoperative biopsy specimens and radical prostatectomy specimens by means of P504S immunostaining.

Materials and methods

Patients

For this study, core needle biopsy specimens and radical prostatectomy specimens were examined. Of the core needle biopsy specimens, 132 were from patients diagnosed as having prostatic adenocarcinoma, 36 HGPIN and

adenocarcinoma, and 40 HGPIN without adenocarcinoma. Radical prostatectomy specimens were available from 118 patients with HGPIN and adenocarcinoma. These were analysed by means of classic histology and immunohistochemistry. In addition, we studied 67 radical prostatectomy specimens, which had been diagnosed in our laboratory as prostatic adenocarcinoma on preoperative biopsy specimens from both lobes. Forty-two of the 67 cases showed HGPIN (62.7%).

Immunohistochemistry

Formalin-fixed, paraffin-embedded tissue blocks were cut into 4 µm sections and stained with hematoxylin and eosin. The sections were treated with Tris EDTA citrate buffer (pH 7.8) in an 800-W microwave oven for 30 min for antigen retrieval before immunostaining. The slides were stained on a Ventana–Nexes automated immunostainer (Ventana Medical System, Strasbourg, France) using an avidin–biotin complex staining procedure. The sections were incubated with a rabbit polyclonal antibody against AMACR (P504S) undiluted, or with a mouse monoclonal antibody against p63 protein (dilution of 1:50). Parallel to p63 immunostaining, the sections were incubated with a mouse monoclonal antibody against a high molecular weight cytokeratin clone 34βE12 at a dilution of 1:20 for 32 min at 37°C followed by brief buffer washes. All sections were then incubated with I VIEW DAB (Ventana) for 30 min in a Ventana immunostainer. The sections were counter-stained with hematoxylin.

The P504S staining intensity in average of 100 carcinoma cells or HGPIN lesions was graded as negative, weak (focal apical granular staining), moderate (diffuse weak cytoplasmic staining), or strong (diffuse cytoplasmic staining) [20]. CK 34βE12 or p63 immunohistochemical staining was recorded as positive or negative [17].

All 118 radical prostatectomy specimens showed high-grade prostatic carcinoma (Gleason >3+4=7) and clusters of HGPIN. In 64 cases, there were clusters of HGPIN at a distance of more than 5 mm from the adenocarcinoma. In 54 cases with HGPIN and carcinoma, the distance between the carcinoma and HGPIN lesions was less than 5 mm. In each of these cases, the P504S staining intensity was analysed in a mean of 50 foci of HGPIN distant from or adjacent to the carcinoma. The same procedure was used on the 42 preoperative biopsy cases and radical prostatectomy specimens with HGPIN and high-grade prostatic adenocarcinoma.

When we started immunohistochemical staining for P504S, we noticed, like other authors did previously [4, 6, 16], similar staining intensities in normal glands, PIN glands and carcinomatous glands. We overcome these difficulties by standardizing the fixation and staining procedure, as described in the “Materials and methods” section. After standardisation, we performed the analysis on archival material. On each slide, a control sample of moderately to strongly stained adenocarcinoma and one of nonstaining normal prostate tissues had been mounted for comparison with the test sample. The staining intensity in the test sample

was only evaluated if the benign glands of the prostate tissue were negative. All sections were evaluated blindly by three independent pathologists (Ch.F., U.O. and B.H.), who reached a concordance rate of 95%.

For the statistical analysis, the Fisher’s exact test was used.

Results

Biopsy specimens

In 132 biopsy specimens from the prostate, adenocarcinoma was diagnosed. Seventy percent had a Gleason score of 3+4=7, 25% a Gleason score of 6 and 5% Gleason scores of 8 and 9. P504S was expressed in all areas of the carcinomas. Moderate staining intensity was found in 42.2% and strong intensity in 57.8% (Fig. 1; Table 1).

In 40 of the biopsy specimens, we found HGPIN without adenocarcinoma of the prostate. In these specimens, the basal cell layer was moderately to strongly fragmented. The distinctly enlarged nuclei in this flat atypical epithelial layer showed prominent nucleoli like in a carcinoma *in situ*. The p63 staining revealed some positive nuclei. In these cases without adenocarcinoma, the P504S expression was mostly weak with focal apical granular staining (75%) but sometimes negative (25%) (Figs. 2, 3; Table 1).

In 36 biopsy specimens, we found HGPIN combined with adenocarcinoma of Gleason grade 6 or 7 (Fig. 4). The carcinomas did not express the basal marker p63 and the basal cell layer of HGPIN lesions was fragmented (Fig. 5). P504S was expressed in all foci of the adenocarcinoma and HGPIN. In 55.6% of the HGPIN lesions, the staining intensity was moderate and in 44.4% strong. This percent distribution of the staining intensity of HGPIN with adenocarcinoma was not significantly different from the staining intensity of the carcinomas but significantly different from the staining intensity of HGPIN without adenocarcinoma ($p > 0.0001$) (Figs. 1, 6; Table 1).

Radical prostatectomy specimens

Also examined were 118 radical prostatectomy specimens, 54 with HGPIN adjacent to the adenocarcinoma (distance

less than 5 mm) and 64 farther away from the adenocarcinoma (distance more than 5 mm). In 48.2% of the HGPIN lesions adjacent to adenocarcinoma, P504S staining was moderate and in 22.2% strong. In 29.6%, the staining intensity was weak. HGPIN lesions (12.5%) distant from prostate adenocarcinoma were negative for P504S. The

65.6% stained weakly, and 21.9% showed moderate staining intensity. No HGPIN lesions distant from adenocarcinoma showed strong P504S expression (Table 1). The differences in staining intensity between HGPIN lesions adjacent to and distant from adenocarcinoma were highly significant $p > 0.0001$.

Comparison of preoperative biopsy specimens and radical prostatectomy specimens

We additionally investigated 67 patients in whom we had diagnosed adenocarcinoma in needle biopsy specimens before they underwent radical prostatectomy. Forty-two of the biopsy specimens additionally showed HGPIN lesions (62.7%). In 32 of the 42 cases (76.2%), the HGPIN lesions were adjacent to the adenocarcinomas (less than 5 mm distance). Ten cases of HGPIN were analysed by means of immunohistochemistry. They showed moderate to strong P504S expression (Table 2). This morphological and immunohistochemical pattern corresponded to the pattern seen in HGPIN and adenocarcinomas in the radical prostatectomy specimens from the same lobe. Ten of the preoperative biopsy specimens (23.8%) showed HGPIN lesions distant from the carcinomatous glands (more than 5 mm distance). Five of these cases were analysed immunohistochemically. They showed weak or negative P504S expression in the same lobe of the prostate (Table 2).

The difference in the staining intensity of HGPIN adjacent to or distant from adenocarcinoma in biopsy specimens was also significant ($p = 0.0110$).

Discussion

P504S is an AMACR. P504S (AMACR) is a mitochondrial and peroxysomal enzyme involved in the metabolism of branched chain fatty acid and bile acid intermediates [1, 6, 11–22]. P504S has been found to be expressed in variants of prostatic adenocarcinoma, in cases treated with brachytherapy or hormones and in cases of HGPIN [1, 20, 21, 23]. In all these latter conditions, the staining intensity is weakly positive (granular and apical) [15]. However, the conventional adenocarcinoma of the prostate shows strong, diffuse cytoplasmic staining.

We studied the significance of P504S expression in two groups of patients. In the first study group, we detected strong diffuse P504S staining in core needle specimens from the prostate showing adenocarcinoma of Gleason score 6 or 7 and in core needle specimens showing HGPIN adjacent to adenocarcinoma of the prostate. Only in biopsy specimens revealing HGPIN without adenocarcinoma was the intensity of P504S staining negative to weakly positive.

In the second study group, P504S expression in HGPIN was determined in 118 radical prostatectomy specimens. HGPIN foci adjacent to adenocarcinoma (less than 5 mm) had a significantly higher P504S positivity rate than HGPIN foci at a distance of more than 5 mm from the adenocarcinoma. These results are in agreement with the study by Wu et al. [20].

To confirm these findings, we analysed 67 radical prostatectomy specimens of patients in whom preoperative biopsy specimens were available. In 76.2% of the biopsy specimens, the HGPIN lesions were adjacent to the adenocarcinomas in one or both lobes and showed moderate to strong P504S expression similar to the adenocarcinoma in the same lobe of the radical prostatectomy specimens. The remaining 23.8% of the biopsy cases in which the HGPIN lesions were distant from foci of adenocarcinoma were negative for P504S or stained only weakly. In the corresponding lobe of the radical prostatectomy specimens, the distance between HGPIN foci and the adenocarcinoma was more than 5 mm and in most cases, the foci of adenocarcinoma were very small.

Table 2 Intensity of P504S (AMACR) expression in high-grade PIN and adenocarcinoma of the prostate ($n/\%$) in preoperative biopsy specimens and subsequent radical prostatectomy

P504S (AMACR) staining intensity					
Diagnosis	<i>n</i>	Negative	Weak	Moderate	Strong
HGPIN adjacent to PCa ^{1,2§}	10/15	–	–	6/15	4/15

Therefore, we agree with the conclusion of Wu et al. [20] that HGPIN showing strong P504S positivity in HGPIN is more closely associated with carcinoma than HGPIN distant from adenocarcinoma that is negative or weakly positive for P504S. This immunohistochemical reaction in biopsy specimens may be helpful in the discussion of further diagnostic steps, e.g. control biopsies at very short intervals or surgery. In such a case, we diagnosed an invasive adenocarcinoma in radical prostatectomy specimens after repeated preoperative core needle biopsies had revealed HGPIN without invasive adenocarcinoma [7].

Upregulation of nestin, vimentin, and desmin in rat podocytes in response to injury

Received: 20 July 2005 / Accepted: 15 November 2005 / Published online: 18 January 2006
© Springer-Verlag 2006

Abstract Podocytes in the renal glomerulus express unusual intermediate filament (IF) proteins for epithelial cells. To gain insight into the role of IF proteins in podocytes, we investigated the expression of nestin, vimentin, and desmin in puromycin aminonucleoside (PAN) nephrosis. A Western blot analysis for nestin, vimentin, and desmin demonstrated their exclusive expression in glomeruli and showed their increase in expression in nephrotic glomeruli. Immunolocalization studies showed nestin and vimentin to be located predominantly in the podocytes in both normal and nephrotic glomeruli and that enhancement of desmin staining only occurred in podocytes. A ribonuclease protection assay showed high levels of vimentin and nestin expression in normal glomeruli and an upregulation of all three IF transcripts in nephrotic glomeruli. One day after the PAN injection, however, the vimentin transcripts were found to already have significantly increased, whereas those of nestin or desmin showed no such increase. These findings indicate that podocytes express three IF proteins, namely, vimentin, desmin, and nestin, which are differentially regulated in response to injury. An upregulation of IF proteins

may increase the mechanical stability of cells, thus enabling podocytes to undergo morphological changes on the tensile glomerular capillary wall.

Keywords Kidney · Intermediate filament · Nestin · Vimentin · Injury

Introduction

Visceral epithelial cells of renal glomeruli, referred to as podocytes, are located on the glomerular basement membrane (GBM) as the terminal element in the filtration barrier. They have adapted themselves to facilitating the bulk flow of the glomerular filtrate through the intercellular spaces or filtration slits. Such adaptation has made podocytes a unique epithelium regarding their morphology, especially their cytoskeleton. Podocytes consist of a cell body, several primary processes, and numerous foot processes. In their cell body and primary processes, microtubules and intermediate filaments (IFs) dominate, whereas microfilaments are densely accumulated in the foot processes. Among the known cytoskeletal proteins, IF proteins are the most characteristic of podocytes. IF proteins are characterized by a considerable divergence, which derives from a variety of gene products employed in a fashion that is specific to both the cell type and stage of differentiation. Cytokeratins are typically found in epithelia, vimentin in mesenchyme, desmin in muscle, glial fibrillary acidic protein (GFAP) in astrocytes, and nestin in neuroepithelial stem cells [4, 29]. Although podocytes can be considered epithelial cells according to the classic definition [2], IFs of podocytes do not contain cytokeratins, but instead, react strongly to immunostaining for vimentin [1, 10, 16, 25, 30].

IFs form a continuous structural network extending from the nuclear surface to the cell periphery. In addition to their significant contribution to the mechanical integrity of cells and tissues, IFs play a crucial role in a variety of cellular functions, which range from the determination of cell shape and motility to cell cycle control and signal transduction [4, 29]. Tissue injury is often accompanied by changes in the IF

gene expression [5]. Podocytes have also been reported to alter their IF expression in response to injury. Enhanced desmin staining in podocytes is observed in a variety of experimental rat models of podocyte injury including puromycin aminonucleoside (PAN) nephrosis, Masugi nephritis, Heymann nephritis, diabetic nephropathy, and age-related glomerulosclerosis [11, 12, 17, 37]. Regarding vimentin, a main IF protein of podocytes, whether its expression changes in podocyte injury has yet to be elucidated. In addition, GFAP has been reported to be stained in podocytes [3]. A predominant nestin expression has been shown in the glomerulus using a DNA microarray [15]. As a result, the IF proteins expressed in podocytes and their response to cell injury still remain to be clarified. In the present study, we examined the IF protein expression in podocytes at the protein and transcript levels during PAN nephrosis, and thereby showed podocytes to express at least three IF proteins, which are differentially regulated in response to injury.

Materials and methods

Animals and antibodies

Female Wistar–Kyoto and Wistar rats, from 8 to 12 weeks of age, were purchased from Charles River Japan (Atsugi, Japan) and were used in these experiments. The following murine monoclonal antibodies were used: anti-vimentin antibody (clone V9, Sigma, Saint Louis, MO, USA), anti-nestin antibody (clone 25, BD Bioscience Pharmingen, San Diego, CA, USA), anti-desmin antibody (clone D-33, DakoCytomation, Glostrup, Denmark).

Induction of PAN nephrosis

A total of 91 rats were used in this experiment. PAN nephrosis was induced in 60 rats by a single intravenous injection of PAN (Sigma) at a dose of 5 mg/100 g of body weight in phosphate-buffered saline (PBS). In addition, 31 same-aged, normal rats were used as controls. The rats were housed in individual metabolic cages, and their 24-h urine specimens were collected before the injection of PAN 2, 4, 6, and 10 days after the injection. To examine IF proteins by Western blot analysis, the rats were killed under diethyl ether anesthesia, on days 2 (3 rats), 4 (3 rats), 6 (3 rats), and 10 (16 rats) in the PAN nephrosis group and in the control group (16 rats). To perform immunolocalization studies, rats from the PAN nephrosis group (2 rats) and from the control group (2 rats) were killed at day 10. To examine the transcript levels by a ribonuclease protection assay, the rats from the PAN nephrosis group were killed on days 1 (10 rats), 3 (10 rats), and 10 (13 rats) and from the controls (13 rats). The glomeruli isolated from four or six kidneys were pooled and used as one sample of glomerular protein or RNA. The procedures for the present study were approved by the Animal Committee at Niigata University

School of Medicine, and all animals were treated according to the guidelines for animal experimentation of Niigata University.

Western blotting

The glomeruli were homogenized in lysis buffer (8 M urea, 1 mM dithiothreitol, 1 mM EDTA, 50 mM Tris–HCl, pH 8.0) with a sonicator on ice. The protein in the samples was quantified by Lowry's method after precipitation by trichloroacetate with sodium deoxycholate [32]. Western blotting was performed as described previously [26, 39]. In brief, a 10- μ g sample of each protein was loaded onto 10% sodium dodecyl sulfate–polyacrylamide gel and the bands were transferred to a polyvinylidene difluoride membrane. The membranes were preincubated with 5% nonfat milk in PBS containing 0.05% Tween 20 for 1 h, incubated with 1:1,000 diluted anti-nestin, vimentin, or desmin antibody overnight, and then were washed in PBS containing 0.05% Tween 20. Next, they were incubated with a 1:2,000 diluted goat anti-mouse immunoglobulin-conjugated peroxidase-labeled dextran polymer (EnVision, DakoCytomation), and the immunoreactivity was visualized by use of an ECL plus Western blotting detection system (Amersham Biosciences, Buckinghamshire, UK). A densitometric analysis was performed with the NIH image software package (version 1.62).

Immunofluorescence microscopy

The indirect immunofluorescence technique was applied to frozen kidney sections [39]. In brief, the adult and neonatal rat kidneys were snap-frozen at -70°C , sectioned at a thickness of 3 μm in a cryostat, fixed in 2% paraformaldehyde in PBS for 10 min, and processed for double-label immunostaining. Murine monoclonal antibodies against vimentin (1:40 dilution), desmin (1:40 dilution), or nestin (1:100 dilution) in combination with rabbit anti-laminin antibody were applied as primary antibodies for double-labeling. After washing with PBS, the specimens were stained with fluorescein isothiocyanate (FITC)-conjugated goat anti-mouse IgG, rewashed with PBS, and subsequently reacted with tetramethylrhodamine isothiocyanate (TRITC)-conjugated goat anti-rabbit IgG. PBS, normal rabbit serum, or murine IgG1 monoclonal antibody (against rotavirus), which has been shown not to react with rat glomeruli, were used as negative controls for the primary antibodies. Immunofluorescence of the sections and cultured cells were observed with an Olympus microscope (BX50) equipped with epi-illumination optics and appropriate filters.

Immunoelectron microscopy

Immunoelectron microscopic observations of kidneys from rats with PAN nephrosis and from control rats were carried

out with a few modifications, as reported previously [19, 20]. In brief, 1-mm³ tissue blocks from paraformaldehyde-lysine-periodate (PLP)-perfused kidneys were placed in the PLP fixative for 4 h at 4°C, hydrated, and then embedded in hydrophilic methacrylate resin. The ultrathin sections collected on nickel grids were stained with an immunogold technique. The sections were incubated with 5% normal goat serum for 1 h, transferred to the first antibody against nestin (1:200 dilution), and then incubated for 1 h at room temperature followed by 5 nm colloidal gold-AffiniPure goat anti-mouse IgG + IgM (H + L) (1:100 dilution; Seikagaku Corporation, Tokyo, Japan) for 2 h. The gold particles bound to IF proteins were then enhanced using an IntenSE M silver staining kit (Janssen Life Sciences, Beerse, Belgium) for 10 min. After washing in PBS and fixing with 2.5% glutaraldehyde, the sections were contrasted with uranyl acetate and lead citrate, and then were viewed with a Hitachi H-600A electron microscope.

Ribonuclease protection assay

A ribonuclease protection assay was performed as described previously [26, 39]. Isolated glomeruli, cortices, and medullae were homogenized in TRIzol (Life Technologies, Inc., Grand Island, NY, USA) with a sonicator, and total cellular RNA was extracted from these samples. Plasmids containing the cDNA corresponding to 4,534 to 4,797 (263 bp) of rat nestin (AF538924), 1,030 to 1,294 (264 bp) of rat vimentin (NM031140), and 759 to 1,054 (295 bp) of rat desmin (X73524) were prepared by cDNA amplified in a polymerase chain reaction, inserted in a pGEM-T Easy vector (Promega, Madison, WI, USA), and then were cloned and sequenced by DNA sequencer (ABI PRISM 310, Applied Biosystems Japan, Tokyo, Japan). The detection and analysis of bands were performed by phosphor-imaging techniques by use of the Molecular Imager FX (Bio-Rad Laboratories, Hercules, CA, USA). The results of the ribonuclease protection assay were

Fig. 1 A Western blot analysis of nestin, vimentin, and desmin in lysates from glomeruli (G), cortices (C), and medullae (M) in the normal and PAN-treated kidney. **a** Bands specific to each of the IF proteins are seen exclusively in the glomeruli. **b** A quantitative analysis of Western blotting using glomerular samples reveals

significant increases of nestin, vimentin, and desmin at day 10 after PAN injection. All data from five samples are presented as means \pm SD. **c** In the time course of PAN nephrosis, each of the IF proteins in the glomeruli shows different increasing pattern

represented as the ratio of IFs to glyceraldehyde-3-phosphate dehydrogenase (*GADPH*), a housekeeping gene.

Statistics

All data were presented as means \pm SD. A statistical assessment of the significance between control animals and PAN-treated animals was made using Student's *t* test. Differences were considered statistically significant at $p < 0.05$.

Results

Urinary protein in PAN nephrosis

The measurement of the 24-h urinary protein levels revealed that a single intravenous injection of PAN induced massive proteinuria on day 6 (129.9 ± 69.2 mg/day) and day 10 (190.6 ± 71.0 mg/day) after the injection. Either no increase in urinary protein or only a slight increase was detected at 2 or 4 days in comparison with control rats (1.4 ± 0.5 mg/day).

Fig. 2 Double-label immunofluorescence micrographs of frozen sections of rat kidneys incubated with murine monoclonal antibodies against nestin (**a, b**), vimentin (**c, d**), or desmin (**e, f**) in combination with rabbit anti-laminin antibody. Murine monoclonal antibodies were detected with FITC-conjugated goat anti-mouse IgG; rabbit anti-laminin antibody was detected with TRITC-conjugated goat anti-rabbit IgG. **a, c, and e** show a glomerulus of a normal kidney. **b, d, and f** are glomeruli of PAN-treated rats on day 10. **a–d** In both normal and PAN-treated glomeruli, the signals for nestin and vimentin are located predominantly at podocytes (*arrows*) outside the glomerular capillary wall stained with anti-laminin antibody. **e, f** Desmin staining is found in the mesangium (*asterisks*) in a normal glomerulus and in podocytes (*arrows*) in a PAN-treated glomerulus. Bar: 25 μ m

IF proteins in the glomerulus in PAN nephrosis

A Western blot analysis was performed to confirm the specificity of the antibodies used in this study and to compare the levels of IF proteins in samples of glomeruli, cortices, and medullae from rats at day 10 in PAN nephrosis with those from normal rats. Each of the antibodies against nestin, vimentin, and desmin revealed a specific band with an apparent molecular mass of 260, 57, and 53 kDa, respectively (Fig. 1a). In both normal and PAN nephrotic kidneys, all IF proteins were detected exclusively in the glomeruli, although no signals for desmin or extremely faint ones were observed in the normal glomeruli (Fig. 1a). No signals were found in the cortices or medullae.

Because the signals in the glomeruli looked more intense in the nephrotic kidney, a densitometric analysis was done by increasing the sample number ($n=5$) (Fig 1b). Consequently, it was demonstrated that PAN nephrotic glomeruli showed significant increases in the protein levels of nestin, vimentin, and desmin in comparison to normal glomeruli.

To examine how the glomerular IF proteins increased in PAN nephrosis, glomerular samples were analyzed by Western blotting at 2, 4, 6, and 10 days after PAN injection (Fig. 1c). The pattern of increase was different among the IF proteins. Nestin and vimentin tended to increase before the onset of massive proteinuria, whereas desmin started to increase on day 6 after the onset of proteinuria. On day 10, vimentin started to decrease, whereas nestin continued to increase.

Immunolocalization of IF proteins in the glomerulus

The location of IF proteins in the normal and PAN nephrotic glomeruli was examined by double-label immunofluorescence microscopy using murine monoclonal antibodies against IF proteins in combination with rabbit anti-laminin

antibody (Fig. 2). In the normal glomerulus, immunostaining for nestin was restricted to the podocytes located on the GBM facing Bowman's space (Fig. 2a). The GBM was outlined by laminin staining. In PAN nephrosis, nestin was also only observed in the podocytes (Fig. 2b). No parietal epithelial cells of Bowman's capsule showed any nestin staining. Vimentin staining in the normal glomerulus was observed predominantly in the podocytes and weakly in mesangial cells (Fig. 2c). The podocyte predominance of vimentin was the same in PAN nephrosis (Fig. 2d). In the normal kidney, anti-desmin antibody mainly reacted with the mesangial cells and vascular smooth muscle cells, and very weak staining was observed in the podocytes (Fig. 2e). In PAN nephrosis, conspicuously enhanced staining for desmin was seen in the podocytes, whereas no change in desmin staining was detected in the mesangium as shown in our previous study [37] (Fig. 2f). No significant staining for GFAP was observed in the glomerulus (data not shown).

The precise localization of nestin in the podocytes was examined by immunoelectron microscopy. Intensified immunogold particles for nestin were localized in the cell body and primary processes, but not the foot processes in both normal and PAN nephrotic glomeruli (Fig. 3a,b). No significant accumulation of nestin immunogold particles was detected in the endothelial cells, mesangial cells, or parietal epithelial cells of Bowman's capsule.

IF mRNA in the normal and PAN nephrotic kidney

The transcript levels of nestin, vimentin, and desmin were examined in the normal kidney by a ribonuclease protection assay. In parallel with the findings of a Western blot analysis, glomeruli predominated in the IF expression in the kidney (Fig. 4a). Significant signals for nestin and desmin were detected only in the glomeruli, but not in the cortices

Fig. 3 Immunogold localization of nestin in the podocytes in a normal rat (a) and a PAN-treated rat at day 10 (b). Intensified immunogold particles for nestin are observed in the cell bodies and primary processes, but not in the foot processes in podocytes. Bar: 5 μ m

All data from five samples are presented as means \pm SD. * p <0.01, ** p <0.05 vs normal glomeruli

or the medullae, although the expression levels in the glomeruli were high in nestin and low in desmin. Vimentin signals were intensely found in the glomeruli, but they were weakly found in the cortices and medullae.

To examine the changes in the IF transcript levels after the PAN injection, IF mRNA were quantified on days 1, 3, and 10 by a molecular imaging analysis. As a result, significant increases in the IF transcripts were observed in the mRNA from the glomeruli in PAN nephrosis (Fig. 4b). It is interesting that the timing for the upregulation in PAN nephrosis was different among the IF transcripts. One day and 3 days after the PAN injection, vimentin was found to already be upregulated, but nestin and desmin did not show any significant increase. At day 10 of PAN nephrosis, the expression of all three IF proteins were significantly upregulated.

Discussion

In the present study, the distribution and expression of IF proteins was examined in the rat kidney with PAN nephrosis. Several relevant observations resulted from this

analysis. First, nestin, vimentin, and desmin were expressed exclusively in the glomerulus, especially in the podocytes. Second, these IF proteins were upregulated in the nephrotic stage in PAN nephrosis. Third, the timing for the upregulation in PAN nephrosis was different among the three IF proteins.

The Western blot analysis and ribonuclease protection assay in this study detected distinct signals for nestin in the glomeruli at both protein transcript levels, and the immunolocalization study showed a nestin expression restricted to podocytes. These findings demonstrated that podocytes in adult rats express nestin at a significant level, thus indicating that podocytes contain three different IF proteins, i.e., nestin, vimentin, and desmin. GFAP expression was not detected by immunoblots and immunofluorescence, although the antibodies against GFAP worked on rat brain tissue (data not shown). Nestin, which was initially identified as a marker of neural stem and neural progenitor cells [23], is abundant in migrating and proliferating cells during the early stages of development in the peripheral and central nervous systems and in myogenic and other tissues. In general, nestin becomes downregulated on differentiation, and it is replaced by tissue-specific IF proteins. An excep-

tional expression in the adult brain is observed in the subventricular zone and dentate gyrus, where cell proliferation can continue throughout life [7, 14]. Podocytes do not conform to this case. In spite of the distinct expression of nestin, podocytes in the adult rarely undergo cell division even after a subtotal nephrectomy [13, 31, 33]. In addition, nestin is upregulated during podocyte differentiation: nestin weak staining in presumptive podocytes at the S-shaped body stage and enhanced staining at the capillary loop stage (data not shown). As a result, the mechanism controlling the nestin expression in podocytes is very unique.

Immunoelectron microscopy in this study revealed that nestin is localized in the cell bodies and primary processes of podocytes, but not in the foot processes, which show the same distribution as that of vimentin and desmin [8, 37]. Nestin is unable to form filaments on its own, and can readily form copolymer IFs when combined with type III IF proteins such as vimentin [24] or desmin [35]. Considering that vimentin and desmin can form heterodimers and heterotetramers, it is likely that nestin, vimentin, and desmin co-assemble together into mixed polymers in podocytes.

The present study revealed that nestin, vimentin, and desmin were upregulated in the podocytes in the nephrotic stage of PAN nephrosis. PAN nephrosis is widely used as a model of nephrotic syndrome progressing to focal segmental glomerulosclerosis [6]. A striking morphological feature in PAN nephrosis is the focal detachment of podocytes from the GBM coinciding with the onset of massive proteinuria [34]. Kim et al. [21] reported that PAN injection caused a marked decrease in the podocyte number and an increase in the glomerular size. Because of the lack of cell proliferation, podocytes adapt to the decrease in cell number and glomerular growth by cell hypertrophy [13, 27]. Extreme podocyte hypertrophy has also been observed in a primary culture [38]. The cultured cells exhibit intense immunostaining for desmin in addition to vimentin and nestin (data not shown) [38]. As desmin staining in podocytes is either not detected in vivo under physiological conditions or is only weakly detected, the intense signals for desmin indicate the upregulation of desmin in cultured podocytes [37, 38]. These findings thus suggest the existence of an intimate relationship between IF protein upregulation and podocyte hypertrophy. The idea of the relation between IFs and cell hypertrophy is corroborated by a study using reactive astrocytes lacking IFs [36]. Absence of IF proteins prevented hypertrophy of astrocytic processes. Podocytes are generally attached to several capillaries by way of their foot and primary processes. Therefore, cell hypertrophy on enlarged glomeruli itself increases the mechanical stress to the entire cytoskeleton. The function of IFs is primarily to increase the mechanical resistance of cells [29]. It is therefore tempting to speculate that the upregulation of IF proteins allow podocytes to progress to cell hypertrophy, which is suitable for glomerular growth.

Unexpectedly, the timing for the upregulation in PAN nephrosis differed among nestin, vimentin, and desmin, although it is likely that the three IF proteins co-assemble together into mixed polymers. The transcriptional levels of vimentin already increased 1 and 3 days after the PAN

injection, but the nestin and desmin transcripts did not, although all three IF proteins showed a significant upregulation on day 10 in PAN nephrosis. In preliminary experiments, no significant glomerular hypertrophy could be detected until day 4 in spite of a 1.2-fold increase in the diameter of the glomeruli on day 10 (data not shown). Although the biological significance of vimentin upregulation remains obscure, studies on vimentin-deficient fibroblasts provide some interesting data. Eckes et al. [9] reported that not only mechanical stability but also mobility and contractile capacity were impaired in vimentin-deficient fibroblasts, thus revealing the significant contribution of IFs to cell functions dependent upon the dynamics of an actin microfilament system. The early morphological changes of podocytes in PAN nephrosis are mainly related with the foot processes, which are equipped with a complete microfilament-based contractile apparatus [8, 18]. The loss or retraction of the foot process structure is noticeable by day 2 of PAN nephrosis [34]. A significant alteration in the width of the foot processes has been found as early as 24 h following PAN injection [28]. It has been proposed that the foot processes have considerable tension to counteract the expanding forces exerted on the glomerular capillary wall by the pressure gradient across the filtration barrier [22]. Vimentin upregulation in the early phase of PAN nephrosis may enable the foot processes to retract on the tensile capillary wall by increasing the mechanical stability of the cytoskeletal network.

In conclusion, the present study has showed that podocytes express three IF proteins, namely nestin, vimentin, and desmin, all of which are upregulated in PAN nephrosis. The upregulation of IF proteins may thus play a critical role in the morphological changes of podocytes in response to injury.

Podoplanin is expressed in subsets of tumors of the central nervous system

Received: 10 September 2005 / Accepted: 7 November 2005 / Published online: 13 January 2006
© Springer-Verlag 2006

Abstract Immunohistochemical analyses with the monoclonal antibody D2-40 were performed to ascertain the expression of podoplanin (a.k.a. T1-alpha, gp36, or aggrus) in tumors of the central nervous system (CNS) and to determine the diagnostic utility of the antibody. The analyses were performed on 325 tumors of various histologic types. The chief finding was almost constant immunoreactivity in ependymal tumors (37/40, 92.5%), choroid plexus papillomas (8/8, 100%), and meningiomas (100/100, 100%). The reactivity was considered “tissue-specific,” as the corresponding normal tissue of each tumor was also found to express podoplanin. In addition, expression, not committed to the lineages, was found in many other tumor types, including astrocytic tumors, medulloblastomas, and hemangioblastomas, with variable frequency and intensity. The way of expression was not fully understood, but the expression in astrocytic tumors seemed to be associated with pronounced fibrous properties or malignant phenotype, as was shown by high-frequency expression in pilocytic astrocytomas (12/12, 100%) and glioblastomas (29/35, 82.9%). The present study has shown that podoplanin is expressed in several types of CNS tumors with variable frequency and intensity. Given the widespread expression of podoplanin, the antibody D2-40 is of little use in diagnostic practice for CNS tumors.

Introduction

Podoplanin—otherwise known as T1-alpha [10], gp36 [17], or aggrus [7]—is a mucin-type transmembrane glycoprotein which was first identified in the rat glomerular epithelial cells (podocytes) [1]. Podoplanin is now established as a specific marker of the lymphatic endothelium [2]. D2-40, a monoclonal antibody originally raised against an unidentified M2A protein derived from germ cell tumors [11], has been shown to recognize podoplanin specifically [15]. Immunohistochemical analysis using D2-40 has detected the expression of podoplanin in many organs and tissues, including the lymphatic endothelium, mesothelial cells, osteocytes, glandular myoepithelial cells, and stromal reticular cells and follicular dendritic cells of lymphoid organs [15]. Expression of podoplanin, or positive immunoreactivity to D2-40, has also been confirmed in lymphangiomas, Kaposi’s sarcomas, germ cell tumors, squamous cell carcinomas, mesotheliomas, and a subset of angiosarcomas [2, 4–6, 9, 15]. Lacking detailed knowledge on podoplanin expression in tumors of the central nervous system (CNS), we decided to perform immunohistochemical analyses on various CNS tumors with the antibody D2-40 to determine the distribution of podoplanin in the tumors and the diagnostic utility of the antibody.

Materials and methods

Tumor specimens

All the tumor specimens were retrieved from the archives of University of Tokyo Hospital. Most of the specimens had initially been selected for construction of tissue microarrays (TMAs) for use in future research. Selection was based on the availability of paraffin blocks and whether the tissues in the paraffin blocks were adequately thick. We prepared several unstained sections from each selected block before constructing the TMAs, then used these slides for the present study. We also added several

more cases to the study to increase the range of tumor types and the number of cases examined. Autopsy specimens and nonneoplastic regions of the tumor specimens were used to examine the nonneoplastic brain.

The histology of each tumor sample was reevaluated according to the World Health Organization (WHO) classification for tumors of the CNS (2000). In total, we examined 83 astrocytic tumors, including 12 pilocytic astrocytomas (WHO grade I), 19 diffuse astrocytomas (WHO grade II), 17 anaplastic astrocytomas (WHO grade III), and 35 glioblastomas (WHO grade IV); 19 oligodendroglial tumors, including 12 oligodendrogliomas (WHO grade II) and 7 anaplastic oligodendrogliomas (WHO grade III); 9 mixed gliomas, including 5 oligoastrocytomas (WHO grade II) and 4 anaplastic oligoastrocytomas (WHO grade III); 40 ependymal tumors, including 1 subependymoma (WHO grade I), 2 myxopapillary ependymomas (WHO grade I), 29 ependymomas (WHO grade II), 7 anaplastic ependymomas (WHO grade III), and 1 chordoid glioma of the third ventricle (a tumor now considered a specific type of ependymoma of subcommissural organ origin [3, 13]; WHO grade II); 16 neuronal and mixed neuronal–glial tumors, including 2 dysembryoplastic neuroepithelial tumors (WHO grade I), 12 central neurocytomas (WHO grade II), and 2 gangliogliomas (WHO grade II); 22 embryonal tumors, all of which were medulloblastomas (WHO grade IV); 110 meningeal tumors, including 100 meningiomas (WHO grade I) and 10 hemangiopericytomas/solitary fibrous tumors (WHO grade I; included together due to difficulty in clearly discriminating between them); 8 choroid plexus papillomas (WHO grade I); and 18 hemangioblastomas (WHO grade I). We also added a craniopharyngioma and a cavernous hemangioma to evaluate reactive piloid gliosis around the lesions.

Immunohistochemistry

The mouse monoclonal antibody D2-40 (Signet, Dedham, MA) was used in all cases. In some cases, expression of glial fibrillary acidic protein (GFAP) was also examined by a monoclonal antibody (Dako Corporation, Santa Barbara, CA) to ascertain the state of the reactive gliosis, a condition which often manifested positive D2-40 labeling. Immunohistochemical staining was performed by the avidin-biotinylated immunoperoxidase method. Briefly, 5- μ m sections were deparaffinized and rehydrated. Antigen retrieval was performed by autoclave in a 10-mM citrate buffer (pH 6.0) for 5 min at 120°C. All the tissue was then exposed to 3% hydrogen peroxidase for 5 min (to block endogenous biotin reactivity), primary antibody for 25 min, biotinylated secondary antibody for 25 min, diaminobenzidine as a chromogen for 5 min, and hematoxylin counterstain for 5 min. All immunohistochemical staining was performed by an automatic stainer (Kyowa Hakko, Tokyo, Japan). The stained slides were then coverslipped using the Tissue-Tek.SCA automatic coverslipper (Sakura Finetek, Tokyo, Japan) and evaluated by two investigators (JS and YK). The validity of the D2-40 staining was

confirmed by positive control (mesothelial cells) and internal negative control (blood vessels in the specimens). Leptomeningeal immunoreactivity was frequently used as internal positive control, as the staining was appreciated not only on the brain surface but also on the limiting membrane of perivascular space (Virchow–Robin space) due to the pial coat. Staining intensity of the normal leptomeninges (not infiltrated by tumor cells) was used as a standard for the following semiquantitative evaluation. It could also be applied to cases lacking the normal leptomeninges in the specimens, as the automatic stainer made little difference concerning the staining results of the normal leptomeninges. The staining intensity was evaluated as weak (lower intensity than the normal leptomeningeal staining), moderate (intensity almost equivalent to the normal leptomeningeal staining), or strong (intensity apparently stronger than the normal leptomeningeal staining). Immunohistochemical expression was graded as follows: 0, $\leq 5\%$ of cells stained; 1+, 6–25% cells stained with weak intensity; 2+, $>25\%$ cells stained with weak intensity or 6–25% cells stained with variable intensity; +3, $>25\%$ cells stained with variable intensity; +4, $\geq 50\%$ of cells stained with strong intensity. “Variable intensity” was meant to indicate any staining intensity except for entirely weak one (i.e., moderate or strong intensity was found somewhere).

Results

Podoplanin expression in normal structures and reactive states of the CNS

In the nonneoplastic brains, reactivity to D2-40 was observed in the ependyma, choroid plexus epithelium, and leptomeninges (pia and arachnoid mater; Fig. 1a–c). Reactivity to the ependymal cells and choroid plexus epithelium was noted on the surface aspect of the cell membrane. Leptomeningeal staining also labeled the cluster of arachnoid cells (arachnoid granulation). The cerebral parenchyma was almost nonreactive except for the subpial and paraventricular regions, where laminar immunoreactivity to D2-40 was frequently observed. Besides, the white matter, especially that of the aged patients, exhibited very low intensity of immunoreactivity. The molecular layer of the cerebellar cortex was also immunoreactive, and the radiating manner of staining denoted the labeling of the fibrillary processes of Bergmann glia (Fig. 1d). The staining on the cell surfaces of the Purkinje cells was problematic, as it was difficult to determine whether the staining was against the cell membrane or derived from glial processes towards the cell membrane. The granular layer and the white matter of the cerebellum exhibited much lower intensity of immunoreactivity.

Reactive gliosis, especially fibrous gliosis of the piloid type, was immunoreactive to D2-40, as was typically observed in piloid gliosis accompanying craniopharyngioma and cavernous hemangioma. In the analyses of the neuroepithelial tumors, peritumoral regions of relatively well-demarcated, slow-growing tumors such as epen-

Fig. 1 Podoplanin expression in normal structures of the central nervous system (CNS). Expression was determined by the monoclonal antibody D2-40.

a The ependyma showed immunoreactivity on the apical surface. The paraventricular parenchyma was also immunoreactive. **b** The choroid plexus epithelium demonstrated immunoreactivity on the surface aspect of the cell membrane. **c** Immunoreactivity was observed in the pia and arachnoid maters. The cluster of the arachnoid cells was also immunoreactive. **d** The cerebellar cortex was also immunoreactive. The radiating pattern of staining indicates expression in Bergmann glias

dymomas were accompanied by fibrillary gliosis immunoreactive to D2-40. Diffusely infiltrated tumors such as diffuse astrocytomas and oligodendrogliomas usually did not induce immunoreactive fibrillary gliosis. The exceptions were subpial and paraventricular regions of the involved sites, where D2-40 labeling was found to be fairly frequent. Moreover, reactive fibrillary gliosis commonly appeared in variable tumor types in the brain stem, spinal cord, and cerebellum (both cortex and white matter). Pilocytic astrocytomas, ependymomas, gangliogliomas, medulloblastomas, and hemangioblastomas were all frequently observed in these anatomic locations. We forewent evaluation at the tumor periphery, as this would have led to possible misinterpretation of the reactive gliosis. No other histologic types involving these locations were included in the study.

Expression of podoplanin in various CNS tumors

Podoplanin expression was observed in a number of tumor types with variable levels of intensity and frequency, as summarized in Table 1.

Astrocytic tumor

Among astrocytic tumors, constant immunoreactivity to D2-40 was confirmed in pilocytic astrocytomas (12/12, 100%). The immunoreactivity in this biphasic tumor was more intense in densely fibrous areas than that in loose, myxoid areas (Fig. 2a). Diffuse astrocytomas, including protoplasmic, fibrillary, and gemistocytic types, usually showed little to no reactivity (Fig. 2b), and only 3 of 19 cases (15.8%) were considered positive. One case exhibiting a relatively strong degree of immunoreactivity (3+) had

been treated by preoperative irradiation. Anaplastic astrocytomas were immunoreactive to D2-40 more frequently (8/17, 47.1%) and exhibited variable degrees of staining. Most glioblastomas exhibited positive immunoreactivity (29/35, 82.9%), with membranous, cytoplasmic or diffuse (glial) staining of a generally strong intensity (Fig. 2c). Intense immunoreactivity was constantly observed adjacent to necroses.

Oligodendroglial tumor

Oligodendrogliomas were generally not shown to be positive for D2-40 (0/12, 0.0%; Fig. 2d). As an exception, small numbers of cells with “astrocytic” features, i.e., gliofibrillary astrocytes or minigemistocytes, showed weak cytoplasmic immunoreactivity. Two of seven anaplastic oligodendrogliomas (28.5%) showed positive reactivity. The reactivity was preferentially noted in gliofibrillary astrocytes or minigemistocytes.

Mixed glioma

Four of five oligoastrocytomas (80.0%) and two of four anaplastic oligoastrocytomas (50.0%) showed positive reactivity. Reactivity was noted in the astrocytic component rather than in the oligodendroglial component, and the staining was usually somewhat weak.

Ependymal tumor

Twenty-eight of 29 ependymomas (96.6%) and 6 of 7 anaplastic ependymomas (85.7%) showed positive reactivity with generally strong staining. The immunostained

Table 1 Podoplanin expression in central nervous system tumors

areas contrasted well with the surrounding brain parenchyma in some cases, whereas the peritumoral reactive gliosis showed more intense immunoreactivity than the tumor itself in others. Membranous, cytoplasmic, diffuse (glial), and dot- or ring-like patterns of staining were noted (Fig. 2e,f). Unlike the normal ependyma, membranous staining was not restricted to the luminal surfaces of the ependymal canals or tubes. Diffuse glial staining was prominent at the perivascular areas, highlighting perivascular pseudorosettes. Dot- and ring-like patterns of staining, presumed to be staining against microlumens formed by tumor cells, were characteristic to ependymomas. One subependymoma exhibited diffuse immunoreactivity, whereas myxopapillary ependymomas showed little to no reactivity. One chordoid glioma of the third ventricle exhibited membranous and cytoplasmic staining.

Neuronal and mixed neuronal–glial tumor

Immunoreactivity was absent in two dysembryoplastic neuroepithelial tumors (0.0%). One of 12 central neurocy-

tomas (8.3%) exhibited focal immunoreactivity, while all of the others were almost entirely nonreactive (Fig. 2g). The single positive case was a “liponeurocytoma,” an unusual neurocytoma with prominent lipidized tumor cells. The D2-40 reactivity in the tumor was against considerable numbers of GFAP-positive astrocytic tumor cells admixed in the tumor. The reactivity in the other cases was identified in limited areas where immunostaining for GFAP concurrently revealed increased numbers of astrocytic cells, presumably reactive ones. In addition, the tumor periphery was often labeled with D2-40 due to reactive gliosis against the tumor. Both gangliogliomas analyzed in this study showed positive reactivity (100%; Fig. 2h). The glial component was apparently reactive, whereas it was difficult to determine whether the staining on the ganglion cells was against the cell membrane or the surrounding glia.

Embryonal tumor

Six of 22 medulloblastomas exhibited positive immunoreactivity (27.3%) in the form of membranous and cytoplasmic

Fig. 2 Podoplanin expression in various tumors of the CNS. Expression was determined by the monoclonal antibody D2-40. **a** Pilocytic astrocytomas were strongly immunoreactive, especially in the fibrous areas. **b** Diffuse astrocytomas usually showed little to no immunoreactivity. **c** Glioblastomas frequently showed strong immunoreactivity. **d** Oligodendrogliomas were not reactive. **e, f** Ependymomas exhibited membranous (**e**), diffuse and dot- and ring-like patterns (**f**) of immunoreactivity. **g** Most central neurocytomas contained a few reactive cells, if any. **h** Reactivity was apparent in the glial component of gangliogliomas. **i** Some of the medulloblastomas exhibited strong cytoplasmic and membranous staining. **j** All meningiomas showed positive immunoreactivity. **k** Choroid plexus papillomas showed membranous immunoreactivity. **l** Some hemangioblastomas were immunoreactive. However, it was difficult to determine whether the staining was against the cell membrane or interstitium in most of the positive cases

mic staining (Fig. 2i). Many other cases also showed partial positive reactivity with an interstitial pattern of staining. These cases were not considered positive, however, as concurrent interstitial immunoreactivity to GFAP in the positive areas indicated that this reactivity was largely against preexisting glias or reactive gliosis. D2-40-reactive cells also exhibited intense cytoplasmic immunoreactivity to GFAP, a finding indicative of glial phenotype, in some of the positive cases. Reactivity to GFAP was hardly discernible in the D2-40-reactive cells in the other positive cases.

Meningeal tumor

All of the meningiomas (100/100, 100%) were immunoreactive to D2-40 with a generally high degree of staining, irrespective of their histologic subtypes (Fig. 2j). Seven of 10 hemangiopericytomas/solitary fibrous tumors were also immunoreactive for D2-40, albeit with a generally lower degree of staining than most meningiomas.

Others

All cases of choroid plexus papilloma (8/8, 100%) were reactive to D2-40 (Fig. 2k). The staining was membranous

and always diffuse. Nine of 18 hemangioblastomas (50%) were positive for D2-40 (Fig. 2l). It was difficult to determine whether the staining was against the cell membranes of the stromal cells or the interstitium, however, as diffuse interstitial staining of GFAP was noted in most of the positive cases.

Discussion

Immunohistochemical analysis using the antibody D2-40 has confirmed the expression of podoplanin in various types of CNS tumors.

The podoplanin expressions observed in the ependymomas of all grades, the choroid plexus papillomas and the meningiomas, were “tissue-specific” and could be predicted from the staining results of the normal structures corresponding to the tumors (ependyma, choroid plexus epithelium, and leptomeninges). Schacht et al. [15] and Roy et al. [14] have confirmed podoplanin expression or immunoreactivity to D2-40 in these normal structures of the mouse and human brains, respectively. Coarse dot- and ring-like patterns of staining observed in ependymomas were presumed to highlight microlumens formed by tumor cells. Similar patterns have been described in immunohistochemical staining of epithelial membrane antigen (EMA) [8]. One case of chordoid glioma of the third ventricle

showed membranous and cytoplasmic staining. This result is consistent with the presumed tumor origin from the specific ependyma of the subcommissural organ [3, 13]. All meningiomas expressed podoplanin, and most did so strongly. The hemangiopericytomas/solitary fibrous tumors, on the other hand, exhibited relatively weak to no immunoreactivity. The result supports the theory that the latter tumors are not of meningeal cell origin, as podoplanin expression seems to be an inherent trait of the leptomeninges.

Expression in astrocytic tumors was not committed to the lineage, but reflected certain phenotypic manifestations. Podoplanin cannot be a lineage-specific marker of astrocytes, given that the native astrocytes in the cerebrum and most of the diffuse astrocytomas were negative for D2-40. However, the pronounced fibrous property of both neoplastic and reactive conditions has been shown to lead to podoplanin expression, as typically manifested in the pilocytic astrocytomas and piloid gliosis around the craniopharyngioma and the cavernous hemangioma. Reactivity in the molecular layer of the cerebellar cortex also seems to result from the fibrillary nature of Bergmann glias. The diffuse (glial) expression pattern, prominent at the perivascular areas, of ependymomas might reflect a similar feature in the cell processes. Podoplanin expression was also associated with the malignant phenotype: expression was observed in the diffuse astrocytomas, the anaplastic astrocytomas, and the glioblastomas, in ascending order of frequency.

Podoplanin expression was usually absent in oligodendroglial tumors and neuronal tumors such as oligodendrogliomas and central neurocytomas, respectively. Immunoreactivity to D2-40 was almost exclusively confined to cells with astrocytic features (minigemistocytes or gliofibrillary astrocytes) in the oligodendroglial tumors and the astrocytic components of the mixed tumors. One central neurocytoma manifesting a histology of "liponeurocytoma" was focally immunoreactive to D2-40, but the positive areas were also labeled with GFAP, a finding indicative of the glial (astrocytic) phenotype. Several of the medulloblastomas, an embryonal tumor that typically manifests a neuronal immunophenotype, also exhibited concurrent immunoreactivity to D2-40 and GFAP in some parts of the stained tissue. The staining was cytoplasmic and membranous and could be differentiated from the reactivity of the native or reactive condition of cerebellum. Immunoreactivity to D2-40 in medulloblastomas, however, did not always result from the glial phenotype, as D2-40-positive tumor cells were not reactive to GFAP in the other cases.

Among the other tumor types, half of the hemangioblastomas exhibited positive immunoreactivity. This conflicted with the result by Roy et al. [14], who found constant immunoreactivity in the stromal cells of hemangioblastomas. Moreover, the positive finding was less than certain, as it was difficult to determine whether the staining was against the cell membranes of the stromal cells or the interstitium. We should note here that reactive astrocytes are sometimes numerous within the substance of heman-

gioblastomas [12]. Most of the positive cases in our study were diffusely immunoreactive to GFAP. While some of the stromal cells may have been reactive, these findings tell us that the reactivity was chiefly against the intervening astrocytes. The angioblastic nature of the stromal cells [16] also seems inconsistent with podoplanin expression.

This study also sought to elucidate the diagnostic utility of D2-40. We initially expected that podoplanin expression would be limited to "tissue-specific" ones, noted in ependymomas, choroid plexus papillomas, and meningiomas. Given the widespread expression in various CNS tumors and reactive condition, however, we found that the antibody is of little use in diagnosis of CNS tumors. Combinations with other makers will be required for diagnostic practices.

Expression of E-cadherin, α -catenin, and β -catenin in tubulolobular carcinoma of the breast

Received: 18 June 2005 / Accepted: 8 September 2005 / Published online: 15 March 2006
© Springer-Verlag 2006

Abstract Tubulolobular carcinoma (TLC) of the breast is a rare subtype of breast carcinoma categorized by Fisher et al. (Hum Pathol 8:679–683, 1977) as a tubular variant of lobular carcinoma. E-cadherin is a transmembrane glycoprotein, and complete loss of E-cadherin expression has been observed in invasive lobular carcinoma. Ductal carcinoma retains at least some expression of E-cadherin. Moreover, the adhesive function of E-cadherin is dependent on the integrity of the catenin components, which link E-cadherin to the actin filaments. In order to achieve improved categorization of TLC, we decided to investigate both E-cadherin and the catenins in TLCs and invasive lobular carcinomas. We reviewed all 1,430 cases of primary breast carcinoma that were surgically resected at

Saitama Medical Center, Saitama Medical School, and at Saitama Red Cross Hospital between 1990 and 2005. Among these, 16 cases of TLC were reported retrospectively. The results were compared with those of 20 cases of invasive lobular carcinomas that were included as controls. Tumor tissue was immunostained for E-cadherin, α -catenin, and β -catenin. The presence of immunoreactivity in the TLC was seen in 12 (75%) cases for E-cadherin, in 8 (50%) cases for α -catenin, and in 10 (62.5%) cases for β -catenin. However, plasma-membrane-associated staining for E-cadherin, α -catenin, and β -catenin was completely absent in invasive lobular carcinomas. These results suggest the possibility that TLCs are not a variant of lobular carcinoma, but rather ductal carcinomas with a lobular growth pattern.

Introduction

In 1977, Fisher et al. described their experience of a rare type of tumor of the breast that shares histologic features of both tubular and lobular carcinoma of the breast [7]. They described the first series of this tumor, which they called “tubulolobular carcinoma” (TLC), as a tubular variant of lobular carcinoma. The characteristic histological features of this tumor are composed of intermixed, round to angulated tubules and single-file cell cords. Both the tubular and cell cord components demonstrate a diffuse and targetoid pattern as in classical lobular carcinoma. However, this histological subtype of breast carcinoma has still remained unclear due to the rarity of cases. Many questions exist about the clinicopathological significance of this subtype, especially regarding differential diagnosis [9, 28].

E-cadherin is a transmembrane glycoprotein that functions as an epithelium-specific cell-to-cell adhesion molecule [10, 19, 25, 26]. Previous studies have described the differential expression of E-cadherin in lobular and ductal mammary carcinomas [1, 5, 15, 22, 23, 28]. The expression of E-cadherin is significantly reduced in invasive lobular

carcinoma compared with invasive ductal carcinoma. Moreover, the cytoplasmic domain of E-cadherin interacts with groups of cytoplasmic proteins called catenins (α and β) [2, 11, 14, 18, 27]. These cytoplasmic proteins are necessary for cadherin function in cell–cell contact and organizing the cytoskeleton. Deletion of the intracellular catenin-binding domain of E-cadherin or alterations in the functionally active catenins result in the loss of E-cadherin's ability to promote cell adhesion [12, 16, 21]. α -Catenin binds E-cadherin to the cytoskeleton through β -catenin. β -Catenin links E-cadherin and α -catenin by interacting directly with the cytoplasmic domain of cadherin [4, 8, 17, 20, 29]. Furthermore, in several previous studies, the expression of catenins was examined in a series of human breast carcinomas [4, 13, 29]. Although these evaluations were based on a small number of cases, catenin expression was found to be reduced or lost, like E-cadherin expression, in invasive lobular carcinoma compared with invasive ductal carcinoma.

The recent development of immunohistochemical markers has provided another diagnostic tool that may be useful in addition to conventional histological criteria for differential diagnosis. In order to achieve improved categorization of TLC, we decided to investigate the clinicopathological features and morphological findings and the expression of both E-cadherin and the catenins in TLCs.

Patients and methods

The subjects were 1,430 patients with primary breast carcinomas that were examined at Saitama Medical Center, Saitama Medical School, and at Saitama Red Cross Hospital between 1990 and 2005. Sixteen of these cases were identified as TLC cases. The case histories were reviewed for age, stage, and tumor size. Clinical data were obtained from hospital records and contact with physicians. Follow-up examinations were performed either at our institute or at the patient's local hospital. Patients were followed until 2005, and the diagnosis of recurrent disease was based on clinical and radiological examinations and was confirmed by pathological findings.

The resected specimens were reviewed histologically to detect TLC. Classification was performed according to the histologic criteria previously described by Fisher et al. [7]. Paraffin-embedded slides stained with hematoxylin and eosin were used for the histological analysis. All histological slides were reviewed independently by two pathologists.

The expression of E-cadherin, α -catenin, and β -catenin was studied in 16 cases of invasive breast carcinoma. Twenty cases of classic lobular carcinoma were also stained for E-cadherin, α -catenin, and β -catenin for comparison. The primary antibodies and dilutions used are summarized in Table 1.

Immunohistochemical staining was performed according to the following protocol. Consecutive sections from formalin-fixed, paraffin-embedded tissue blocks were cut at 5- μ m thickness, deparaffinized, and dehydrated with xylene and graded alcohol. Pressure cooker pretreatment (one cycle of 1 min) was performed at pH 6.0 for E-

Table 1 Monoclonal antibodies used in the study

Antibody	Clone	Source	Dilution
E-cadherin	NCH-38	DAKOCytomation	X50
α -catenin	25B1	Novocastra	X50
β -catenin	17C2	Novocastra	X50

cadherin and α -catenin and at pH 8.0 for β -catenin. Endogenous peroxidase activity was quenched with 3% hydrogen peroxide at room temperature for 30 min. Sections were blocked with 10% goat serum for 60 min and then incubated with the primary antibody for 1 h at room temperature.

Evaluation of immunohistochemical staining was made according to the following criteria. The number of immunopositive cells was semiquantitatively estimated: grade + corresponded to 10–50% positive cells, and grade ++ to more than 50% positive cells (Fig. 4). Only tumor cells with clear membrane staining were scored as positive, and tumors were scored negative when less than 10% of the cells showed staining. Normal ductal epithelial cells were used as an internal control. Statistical analyses were performed by the Mann–Whitney *U* test. Differences in all statistical tests were considered significant at the $p < 0.05$ level.

Results

All of the patients were women, and their ages ranged from 32 to 74 years (mean 51.5). The mean tumor size was 3.19 cm in maximum diameter. Six patients (37.5%) presented with stage I disease, six patients (37.5%) with stage II, four (25.0%) with stage III, and no patient with stage IV disease. Axial lymph node metastases were present in seven of 16 cases (43.7%). The treatments applied to operable patients included radical mastectomies in 13 cases and focal resections in three cases. Fourteen patients received post-operative radiation therapy. Follow-up data were available for 12 of the 16 patients diagnosed with TLC for 6 to 72 months. Of these 12 patients, no patient died of the disease following the initial diagnosis of the primary lesion.

Fig. 1 The tumor demonstrates a diffuse and targetoid growth pattern at low magnification (hematoxylin and eosin stain)

Fig. 2 The tumor is seen to be composed of single-cell file cords at high-power magnification (hematoxylin and eosin stain). Notice that traces of gland formation are evident (arrow)

Only two patients had local recurrence, and there was no systemic recurrence. Ten patients were alive and well with no evidence of disease.

Pathologic examination showed a diffuse and targetoid growth pattern at low magnification (Fig. 1). The tumors demonstrated a lobular pattern of infiltration comprising a mixture of single-cell file cords and small, round to angulated tubules on high power (Fig. 2). As most of these tumors showed a heterogeneous pattern with respect to the proportion of the TLC component (Fig. 3), we contend that TLC of the breast should be defined as a carcinoma that has a predominantly tubulolobular pattern.

Grading of the tumors was based on the recommendations made by Elston and Ellis [6]. The tumors were Elston and Ellis modified Bloom–Richardson grade I in 14 cases (87.5%) and grade II in two cases (12.5%). An in situ component was present in 12 of 16 cases: it was lobular in 5 of 12

Table 2 Immunohistochemical staining for E-cadherin and catenins in mammary carcinoma

Carcinoma type	Staining intensity	E-cadherin ($P=0.0001$)	Catenins	
			α ($P=0.0109$)	β ($P=0.0013$)
TLC (16 cases)	+	10	5	8
	+	2	3	2
	–	4	8	6
Usual lobular carcinoma (20 cases)	+	0	0	0
	+	0	0	0
	–	20	20	20

All statistical analyses were performed by the Mann–Whitney *U* test

cases, ductal in 3 of 12 cases, and contained separate ductal and lobular foci in 4 of 12 cases.

The results of the immunohistochemical analysis of immunophenotype are summarized in Table 2. In TLC, marked plasma-membrane-associated staining for E-cadherin was observed in 12 (75%) cases (indicated as +/+, Table 2). The staining pattern of TLC was predominantly characterized by plasma-membrane-associated staining of tumor cells at the cell–cell boundaries (Fig. 4). In most tumors, some areas also showed membranous E-cadherin staining at the epithelial–stromal boundary. Only four cases showed no significant staining.

However, in invasive lobular carcinomas, plasma-membrane-associated staining for E-cadherin was completely absent in 19 of 20 cases. Very weak cytoplasmic staining was seen in only 1 of the 20 lobular carcinomas without membranous E-cadherin expression. However, we could not classify this case as +/++.

Fig. 3 Another area with targetoid growth pattern in the tumor is seen to be composed of single-cell file cords (b) and small tubules (arrows) (c, d) at high-power magnification (hematoxylin and eosin stain)

Fig. 4 TLC showing strong immunoreactivity for E-cadherin (a), α -catenin (b), and β -catenin (c) in both the cell cord and the tubular component

Expression of α -catenin and β -catenin was also investigated in the cases of TLC. In the cases of TLC, we observed marked plasma-membrane-associated staining for the two catenins. α -Catenin and β -catenin were observed in 8 (50%) and 10 (62.5%) cases of TLC (indicated as +/++ , Table 2). Immunoreactivity for α -catenin and β -catenin was located at the cell–cell boundaries in most tumor cells. One case positive for α -catenin and two cases positive for β -catenin showed no significant staining of E-cadherin. In most of the cases of invasive lobular carcinoma, plasma-membrane-associated staining of catenins was completely absent. Weak cytoplasmic staining of β -catenin was seen in only 1 of 20

lobular carcinomas without membranous expression. However, we could not classify this case as +/++.

No plasma membrane staining of E-cadherin or the two catenins was observed in in situ lobular carcinoma around the TLC. On the other hand, the ductal in situ component around the TLC had plasma membrane staining in all seven cases that expressed E-cadherin. Five of seven cases of ductal carcinoma in situ showed expression of α -catenin, while six cases showed expression of β -catenin.

When the protein expression of E-cadherin, α -catenin, and β -catenin was compared in TLC vs classical lobular carcinoma, a significant association was found between expression of these proteins and TLC ($p < 0.05$).

Discussion

The immunohistochemical data presented in this study showed that, in addition to the expression of E-cadherin, the expression of catenins was positive in a high percentage of tubulolobular carcinoma (TLC) compared with lobular carcinoma. Thus, TLC seemed to be a tumor of ductal origin rather than a variant of lobular carcinoma. Immunohistochemical detection of the expression of E-cadherin and catenins can be useful as a diagnostic tool for differentiation between tubulolobular carcinoma and classical lobular carcinoma.

Previous studies have described the differential expression of E-cadherin in ductal carcinoma and lobular carcinomas [1, 5, 15, 22, 23, 28]. Despite the lobular-like growth of TLCs, most of our cases demonstrated E-cadherin expression in both the tubular and single cell cord components. This result was in contrast to our control group of 20 classic lobular carcinomas, in which E-cadherin expression was reduced or lost. These results are in accord with a previous study that demonstrated a higher incidence of E-cadherin expression in TLC than in invasive lobular carcinomas. Wheeler et al. reported that E-cadherin was present in all 27 cases of TLC and E-cadherin expression was uniformly lost in all five control cases of lobular carcinoma [28]. They contended that the high incidence of expression of E-cadherin in TLC supports the ductal differentiation of these tumors.

In addition, we found that the reduction or loss of the catenins was more obvious in lobular carcinoma than in TLC. Investigations of α -catenin and β -catenin expression have been performed in ductal and lobular carcinoma in the breast in other studies. The expression of E-cadherin, α -catenin, and β -catenin was studied in 48 cases of invasive ductal breast carcinoma and 38 cases of lobular breast carcinoma by De Leeuw et al. [5]. They reported marked plasma-membrane-associated staining for α -catenin and β -catenin in ductal carcinoma, except in one case that was negative for α -catenin. Invasive lobular carcinomas that were negative for E-cadherin were also negative for α -catenin and β -catenin. Of 38 invasive lobular carcinomas, 32 showed complete loss of α -catenin and β -catenin, which is in agreement with our results and those of others.

From these results, it seems that TLC is of a ductal origin rather than a variant of lobular carcinoma.

As mentioned above, there have been suggestions in several reports that the protein expression of E-cadherin and catenins is higher in ductal carcinoma and lower in lobular carcinoma. However, Fisher et al. originally described TLCs as a tubular variant of lobular carcinoma based not only on their lobular growth pattern, but also their biological behavior [7]. They defined treatment failure as local recurrence, metastasis, or death and reported that the failure rate of TLC over a 32-month follow-up period was closer to that of pure lobular carcinoma than pure tubular carcinoma. However, in our study, no patients died of the disease and only two patients had local recurrence following the initial diagnosis of the primary lesion in the 12 patients available for follow-up. Probably due to the small number of cases followed up, the biological behavior could not be characterized in our study.

Furthermore, as in a previous study, we found many foci of in situ lobular carcinoma around TLCs, and this also seems to conflict with an explanation of TLC as being of ductal carcinoma origin [28]. The mechanism accounting for this result is still unclear. However, an interesting hypothesis that could explain this phenomenon was proposed in several reports. Buerger et al. reported based on a study of comparative genomic hybridization that a "high degree of genetic homology" was observed between lobular carcinoma in situ and well-differentiated intraductal carcinoma, an observation that led them to speculate that the two lesions might be "different phenotypic forms of a common genotype" [3]. Such a phenomenon is supported not only by the existence of the hybrid tubulolobular carcinoma phenotype, but also by the frequent coexistence of ductal proliferation with lobular carcinoma in situ and tubular carcinoma [24].

In addition, Wheeler et al. reported high-molecular-weight cytokeratin antibody 34 β E12 to be a helpful marker for invasive lobular carcinoma, and in 25 of 27 of their TLC cases, dual immunostaining for both 34 β E12 and E-cadherin was positive. From this result, they hypothesized that TLC may be a hybrid invasive tumor of the breast. However, of the 14 of 27 cases of TLC with immunostaining available for the in situ component, only two cases demonstrated hybrid staining for both 34 β E12 and E-cadherin. Furthermore, they found the same hybrid immunophenotype in all five cases of pure tubular carcinoma in their comparison group, of which none of the cases was associated with a hybrid carcinoma. These findings finally led them to speculate that TLC as a ductal origin and hybrid immunophenotype may not be specific for tumors with dual ductal and lobular histology. In our results, there were some cases of TLCs that failed to stain for E-cadherin and catenins. This result might also reinforce the notion that TLC has hybrid histologic feature. However, there were only a small number of negative cases for E-cadherin and catenins, and the meaning of these results could not be determined in our study. Further studies will be needed with large numbers of E-cadherin-negative and catenin-negative TLCs.

In summary, this report describes the clinical and pathologic features and expression of E-cadherin, α -catenin, and β -catenin in 16 cases of TLC. Our findings show that TLC of the breast undoubtedly does not have the usual immunohistochemical features of invasive lobular carcinomas, and a ductal origin of TLC is suggested. E-cadherin, α -catenin, and β -catenin may be useful as markers for distinguishing TLC from lobular carcinoma in the majority of cases. Further studies will be necessary to elucidate the mechanism of this unique pattern of invasive carcinoma.

Ocular adnexal marginal zone B cell lymphoma: a clinical and pathologic study of 23 cases

Received: 11 September 2005 / Accepted: 22 September 2005 / Published online: 2 December 2005
© Springer-Verlag 2005

Abstract To better characterize ocular adnexal marginal zone lymphoma of mucosa-associated lymphoid tissue (MZL-MALT), we analyzed the clinical and pathologic features of 23 patients (11 men, 12 women, median age 66 years). The tumor was confined to one ocular structure in 18 cases (conjunctiva, $n=8$; orbit, $n=8$; or lacrimal gland, $n=2$). Concurrent extraorbital disease was detected by the staging procedure in five patients, and preferentially involved other MALT sites. Histogenetic B cell marker studies, available in 13 cases, showed an early post-germinal center (GC) phenotype ($BCL-6^-/IRF4^+/CD138^-$) ($n=5$) or a late post-GC phenotype ($BCL-6^-/IRF4^+/CD138^+$) ($n=8$), which could be helpful for discrimination from other types of small-B cell lymphoma. BCL10 was positive in 12 of 13 patients tested, with nuclear ($n=4$) or cytoplasmic ($n=8$) immunoreactivity. These staining patterns ruled out $t(1;14)(p22;q32)$ translocation. $T(11;18)(q21;q21)$, another MZL-MALT-specific translocation, was detected by reverse transcriptase polymerase chain reaction in four of 15 patients tested. Clinical

outcome was excellent but the overall relapse rate was 26.1% with a median follow-up of 39 months (range 6–132 months). Regardless of the disease stage at diagnosis, combined chemotherapy and radiotherapy seemed to be more effective than chemotherapy alone in ocular adnexal MZL-MALT, as persistent complete remission was achieved in nine patients receiving combination therapy, while six of 14 patients treated with chemotherapy alone relapsed.

Keywords MALT · Lymphoma

Introduction

Ocular adnexal lymphomas, which may involve the conjunctiva, orbital connective tissue and/or lacrimal glands, account for 8% of all extranodal non-Hodgkin lymphomas [18]. Most cases are classified as extranodal marginal zone B cell lymphomas of mucosa-associated lymphoid tissue (MZL-MALT) according to the World Health Organization (WHO) classification of lymphomas [5, 12, 22, 37, 43]. The diagnosis of MZL-MALT in the ocular adnexa can be difficult. MZL-MALT can consist of small lymphocytes without cytologic atypia, mimicking benign lymphoid hyperplasia. Immunohistochemical and molecular methods are powerful discriminatory tools. Differential diagnosis is also difficult between MZL-MALT and other low-grade B cell lymphomas such as mantle cell and follicular lymphoma (which can also involve the ocular adnexa), because of the lack of specific immunophenotypic markers of the marginal zone [21]. Furthermore, the pathologist cannot rely on the presence of lymphoepithelial lesions characteristic of MZL-MALT, owing to the absence of epithelial structures in intraorbital extrabulbar connective tissues. The study of histogenetic marker expression, such as BCL-6, MUM1/IRF4 (for multiple myeloma-1/interferon regulatory factor-4), and CD138/syndecan-1 (syn-1), could help to better characterize ocular adnexal MZL-MALT, thereby facilitating its discrimination from other subtypes of low-grade B cell lymphomas. BCL-6 is a POZ/zinc finger transcriptional repressor, mainly expressed by B cells of the germinal

center (GC) [10]. The transcription factor MUM1/IRF4 is expressed at the final step of B cell differentiation within the GC (late centrocyte) and during subsequent steps in plasma cell differentiation [17]. CD138/syn-1 is a marker of the later stage of B cell differentiation (post-GC cells) [8].

Two chromosomal translocations have been described in gastric and lung MZL-MALT but data on ocular adnexal lymphomas are lacking [1, 4, 24, 27, 35, 36, 39, 41]. The first translocation is t(11;18)(q21;q21) which fuses the amino-terminal end of the *API2* gene to the carboxy terminal end of the *MALT1* gene and generates a chimeric fusion product [14] that activates NF- κ B [31, 42]. The second nonrandom cytogenetic alteration associated with MZL-MALT is t(1;14)(p22;q32), which deregulates *BCL10* [44], a factor that binds to its normal partner MALT1 and affects the NF- κ B signaling pathway, resulting in NF- κ B activation [40]. A high level of *BCL10* expression in both the nucleus and cytoplasm of neoplastic cells is highly predictive of t(1;14)(p22;q32) [47].

Many reports on ocular adnexal lymphomas [3, 16, 23, 25, 34, 37, 43, 46] were published before the advent of the revised European–American lymphoma classification in 1994 [20] and the WHO classification in 2001 [22]. A few studies specifically focused on ocular adnexal MZL-MALT, or provided detailed clinicopathologic data on a large series of patients [11, 26, 32, 33]. This prompted us to examine the clinicopathologic characteristics and outcome of 23 patients with ocular adnexal MZL-MALT treated in the same institution, with special emphasis on the expression of B cell histogenetic markers and the occurrence of two chromosomal translocations: t(11;18)(q21;q21) assessed by reverse transcriptase polymerase chain reaction (RT-PCR), and t(1;14)(p22;q32) evaluated indirectly by *BCL10* immunostaining.

Patients, materials and methods

Case selection

Thirty-eight cases of lymphoma involving the ocular adnexae were identified in the files of the Pathology Department, Pitié-Salpêtrière, France, between January 1990 and December 2001. They were classified according to the WHO classification of tumors of hematopoietic and lymphoid tissues [22]. The 38 cases comprised 29 MZL-MALT, two follicular lymphomas, six large-cell lymphomas, and one T/NK cell lymphoma. Six of the 29 MZL-MALT cases were excluded because tissue samples or clinical data were lacking. The same pathologist (Frédéric Charlotte), who was unaware of clinical data, reviewed each case.

Clinical evaluation

The following clinical data were recorded in each case: the medical history (with special emphasis on autoimmune diseases, age, sex, and anatomical location of the tumor,

disease stage at diagnosis according to the Ann Arbor staging modified for extranodal disease) [9]; the type and extent of therapy; the disease course; and the last follow-up data. Patients with bilateral ocular adnexal involvement without extraorbital extension were considered to have stage IE disease. The staging evaluation included physical examination, full blood count, serum lactate dehydrogenase (LDH) and β 2-microglobulin assay, serum electrophoresis and immunoelectrophoresis, bone marrow biopsy, chest radiography, computerized tomography (CT) and/or magnetic resonance imaging of the orbit, CT scan of the thorax and abdomen, and gastroscopy.

Light microscopy

All tissue samples were obtained by surgical biopsy. They were fixed in 10% formalin and embedded in paraffin. Four-micrometer thick tissue sections were stained with hematoxylin and eosin, and also with the Giemsa and Gordon-Sweet methods.

Immunohistochemistry

The immunostaining procedure was performed on formalin-fixed, deparaffinated 4- μ m thick tissue sections by using a commercial kit (LSAB, DakoCytomation, Glostrup, Denmark,) or the EnVision+DAB system (DakoCytomation), and an automated immunostainer (DakoCytomation) according to the manufacturer's instructions. The primary antibodies used in this study are listed in Table 1. The sections were heated in a water bath at 98°C for 30 min in citrate buffer pH 6.1 (DakoCytomation Target Retrieval solution), before incubation with antibodies against CD20, kappa and lambda light-chain immunoglobulin; or in DakoCytomation Target Retrieval solution High pH before incubation with antibodies against CD3, CD5, CD10, cyclin D1, *BCL-6*, IRF4/MUM1, CD138/syn-1 and *BCL10*. The immunostaining reaction was visualized using 0.05% 3,3'-diaminobenzidine in Tris–HCl buffer containing 0.01% hydrogen peroxide, pH 7.6. The sections were lightly counterstained with hematoxylin. *BCL-6*, IRF4 and CD138 immunostaining was quantified as follows: negative if <5% of cells positive; 1 if more than 5% and less than one-third of cells are positive; 2 if one-third to two-third of cells are positive; and 3 if more than two-third of cells are positive.

Detection of t(11;18)(q21;q21) by reverse transcriptase polymerase chain reaction

The results of t(11;18)(q21;q21) detection by RT-PCR in 15 patients with sufficient material have been reported elsewhere [48]. Total RNA was extracted from formalin-fixed and paraffin-embedded tissues by using the Ambion RNA isolation kit (AMS Biotechnology, Oxon, UK) as previously described [28]. Five to ten 5- μ m paraffin sections were deparaffinated in xylene, digested with proteinase K

1 mg/ml for 2 h at 45°C, and solubilized in guanidinium-based buffer. RNA was extracted with acid phenol: chloroform and precipitated in isopropanol. Precipitated RNA was washed in 75% ethanol and redissolved in 20 µl of RNA Storage Solution. The complementary DNA was synthesized using the SuperScript Preamplification System (Invitrogen, Paisley, UK) with a mixture of gene-specific primers (including a primer for *G6PD*), specially designed for use with formalin-fixed paraffin-embedded tissues [28]. Three sets of PCR primers, with a common sense primer covering 93% of the known breakpoints on the *API2* gene (p-S: 5'-GGAAGAGGAGAGAGAAAGAGCA) and three antisense primers (p-AS1: 5'-CCAAGACTGCCTTTGACTCT, p-AS2: 5'-GGATTCAGAGACGCCATCAA, and p-AS3: 5'-CAAAGGCTGGTCAGTTGTTT) targeting all four breakpoints on the *MALT1* gene were used for PCR of the *API2-MALT1* fusion transcript, as previously described [28]. *G6PD* was amplified in parallel as a control. PCR was performed separately with each primer set, in duplicate. PCR products were analyzed by electrophoresis on 10% polyacrylamide gels.

Results

Clinical findings

The main clinical features of the 23 patients are listed in Table 2. The patients consisted of 12 women and 11 men aged 32 to 95 years at presentation (median, 66 years). In 18 cases (78.3%), the tumor was confined to one anatomical ocular site as follows: conjunctiva (eight cases, 34.7%), orbit (eight cases, 34.7%), and lacrimal gland (two cases, 8.7%). In five cases (21.8%), more than one anatomical ocular site was involved. Five patients (21.8%) had bilateral involvement of the ocular adnexa. None of the patients had a history of autoimmune disease. The staging procedure revealed extraorbital involvement (stomach, lung, parotid, thyroid, liver, spleen, lymph node, or bone marrow) in five patients (21.8%). No B symptoms (fever, weight loss or night sweats) were present. The serum LDH level was normal in 20 patients (87%) and elevated in three (13%). The serum β2-microglobulin level was always normal. Four patients (17.3%) had a serum M-component consisting of monoclonal IgM (patients 1, 15, 19, and 21).

Histologic findings

The histologic features of the 23 patients are listed in Table 3. The lymphoid proliferation was located in a fibroadipose tissue without epithelial structures in 18 patients, and in the lamina propria of a conjunctival mucosa in five cases. No lymphoepithelial lesions were observed in the latter five patients. The lymphoid infiltration was diffused in 19 cases, with vague nodular areas in four cases. These nodular areas corresponded to reactive GCs with (patient 10) or without follicular colonization (patients 6, 19, and 22). The cytologic aspect was lymphocytic in seven cases, lymphocytic with monocytoid cells in one case, and centrocyte-like in 15 cases, with and without monocytoid cells in 11 and 4 cases, respectively (Fig. 1). Areas of plasmacytic differentiation were noted in seven cases.

Immunophenotypic findings and t(11;18)(q21;q21) reverse transcriptase polymerase chain reaction results

All the patients exhibited immunophenotypic features of MZL-MALT, as the neoplastic cells expressed CD20 and were always negative for CD5 and CD10. All the cases with centrocytic-like cells tested for cyclin D1 were negative. A few T lymphocytes intermingled with tumor cells were revealed by CD3 and CD5 immunostaining. Four of the seven cases with areas of plasmacytic differentiation expressed a monotypic kappa light-chain, and three expressed a monotypic lambda light-chain (Table 3).

Because of a lack of paraffin-embedded tissue, only 13 patients could be evaluated for B cell histogenetic markers and BCL10 (Table 3). None of these 13 cases expressed BCL-6. Residual GCs not colonized by tumor cells were positive for BCL-6 in three cases (patients 6, 19, and 22). MUM1/IRF4, expressed in the nucleus, was consistently positive with weak expression by tumor cells in five cases, moderate expression in seven cases and strong expression in one case. CD138/syn-1, expressed by the cytoplasmic membrane, was positive in eight cases, with weak expression by tumor cells in six cases and moderate in two cases. According to the expression profile of the histogenetic markers, BCL-6, MUM1/IRF4 and CD138, the 13 cases fell into two groups, namely five cases with an early post-GC B cell

phenotype ($BCL6^-/IRF4^+/CD138^-$) and eight cases with a late post-GC B cell phenotype ($BCL6^-/IRF4^+/CD138^+$) (Fig. 2).

$BCL10$, which was positive in 12 of 13 tested cases, exhibited weak nuclear expression in one case, moderate nuclear expression in three cases, and cytoplasmic expression in the other eight cases (Fig. 2). The pattern of $BCL10$ expression did not suggest the presence of $t(11;14)(p22;q32)$ in any of these cases.

Four (26.7%) of the 15 cases tested were positive for $t(11;18)(q21;q21)$ by RT-PCR. Three of these cases, in which material was available for immunostaining, showed nuclear expression of $BCL10$ (Table 3). It should be mentioned that the 11 cases without detectable $t(11;18)$ by RT-

PCR were truly negative because all of them demonstrated $G6PD$ amplification as an internal control.

Treatment and clinical outcome (Table 2)

Eleven patients were given anthracycline-containing regimens (ChOP), i.e., cyclophosphamide, vincristine and prednisone, and doxorubicin at low dose, i.e., 25 mg/m^2 [19]. Eight of these patients also had orbital radiotherapy. Twelve patients received an alkylating agent, chlorambucil combined with corticosteroids. One of these patients was also treated with orbital radiotherapy.

Fig. 2 B cell histogenetic markers and $BCL10$ immunostaining in ocular adnexal MZL-MALT. A case of early post-GC case (no. 6) with moderate IRF4 (nuclear) (a), and negative CD138 (membranous) expression (b). One late post-GC case (no. 15) with moderate

IRF4 (nuclear) (c), and CD138 (membranous) expression (d). $BCL10$ immunoreactivity was cytoplasmic in case no. 6 (e) and nuclear in case no. 15 (f)

Fig. 3 Overall survival (OS) and disease-free survival (DFS) for 23 patients with ocular adnexal MZL-MALT

The follow-up lasted for 6 to 132 months, with a median of 39 months. The overall survival- and disease-free survival were not reached (Fig. 3). Six patients (26.1%) relapsed, but at the last follow-up, no evidence of lymphoma was detected in the 22 patients who lived and in another patient who died of gastric carcinoma after 36 months.

Complete remission was achieved and persisted throughout follow-up (median 43 months, range 12–132 months) in the nine patients who received both chemotherapy and radiotherapy. By contrast, after a median follow-up of 37.5 months (range 6–84 months), six of the 14 patients treated with ChOP or chlorambucil alone had local ($n=5$) or extraorbital ($n=1$) relapses 8 to 42 months after initial diagnosis. A second complete remission was obtained in all the relapsed patients, with systemic chemotherapy (patients 6, 12, 16, 17, and 22) or anti-CD20 monoclonal antibody (patient 1).

The orbital radiotherapy dose ranged from 30 to 45 Gy, with a median of 30 Gy (Table 2). Four patients experienced side effects such as dry eye, conjunctivitis and cataract. One patient, who received a dose of 45 Gy, developed blindness due to radiation-induced retinopathy.

Discussion

The clinicopathologic features of ocular adnexal MZL-MALT have previously been described in a few detailed reports (Table 4) [1, 5, 7, 11, 13, 26, 32, 33, 43], but only four studies specifically focused on this lymphoma subtype with detailed clinical and biological data from a large series [11, 26, 32, 33]. We found that MZL-MALT accounted for 76.4% of all lymphomas involving the ocular adnexa, compared to 50 to 86% in previous series [5, 7, 32, 33, 43].

Our patients' median age was 66 years, a value similar to that in previous studies (44 to 66 years) (Table 4) [1, 5, 7,

11, 13, 26, 32, 33, 43]. Orbit connective tissue and the conjunctiva are the most involved anatomical sites (Table 4). One particular characteristic of ocular adnexal MZL-MALT in our study is the high rate of bilateral tumors (21.8% of patients) and the frequent involvement of several intraorbital sites (21.8% of patients).

The diagnosis of ocular adnexal MZL-MALT can be difficult when the neoplastic infiltrate is composed of small lymphoid cells, mimicking a reactive lymphoid hyperplasia. This difficulty is compounded by the fact that lympho-epithelial lesions, which are helpful for MZL-MALT diagnosis, are rare in ocular adnexal localizations as no case was observed in our series. Nevertheless, the pathologist can rely on the monomorphic aspect of the infiltrate and the predominance of centrocyte-like or monocytoid cells to establish the diagnosis of malignancy [34]. By applying these histologic criteria to our series, we had difficulty making the diagnosis in four cases (patients 8, 13, 18, and 23), in which the infiltrate was purely lymphocytic and the immunoglobulin light chain restriction could not be demonstrated on paraffin-embedded material. However, the immunohistochemical study revealed that these cases were lymphoma as the infiltrating cells expressed CD20 antigen almost exclusively without lymphoid follicles, whereas reactive diffuse lymphoid hyperplasia is mainly composed of T lymphocytes.

Because no specific marker of the marginal zone is available, it can also be difficult to distinguish MZL-MALT from follicular or mantle cell lymphomas. The phenotypic profile of MZL-MALT is characterized by the absence of CD5 and CD10 antigen expression, but it has been reported that mantle cell lymphomas and follicular lymphomas may also lack CD5 and CD10, respectively [6, 29, 45]. The use of cyclin D1 immunostaining is particularly helpful in the diagnosis of CD5-negative mantle cell lymphomas, a form that appears to be frequent in the orbit [30]. Using the histogenetic B cell markers BCL-6, MUM1/IRF4 and CD138/syn-1, we found that our cases had an early post-GC B cell phenotype ($BCL-6^-/IRF4^+/CD138^-$) or a late post-GC B cell phenotype ($BCL-6^-/IRF4^+/CD138^+$). These markers, together with CD5, CD10, and cyclin D1, could be helpful for distinguishing between MZL-MALT and B cell lymphomas originating from the germinal center or mantle zone.

Seven of our patients had ocular adnexal MZL-MALT with plasmacytic differentiation, illustrating the problem of distinguishing MZL-MALT from lymphoplasmacytic lymphoma/Waldenström macroglobulinemia (WM). In two of these cases (patients 15 and 19), the possibility of ocular adnexal involvement by WM was supported by the presence of a serum monoclonal IgM. However, neither patient met the WHO criteria for WM [22]. One patient (patient 19) exhibited monocytoid differentiation, which is not observed in WM [2]. The other patient (patient 15) presented with involvement of several extranodal MALT sites, including the stomach, lung, parotid, and thyroid without spleen enlargement, which does not match the anatomical distribution of WM [15]. The MALT origin was confirmed in both cases by the nuclear localization of BCL10 immunostaining, which is specific for MZL-MALT. This demon-

strates the utility of BCL10 for distinguishing MZL-MALT from ocular adnexal involvement by WM.

T(11;18)(q21;q21), which is exclusively found in MZL-MALT, occurs in 35–50% of gastric and 55–75% of pulmonary involvement by this lymphoma subtype but is rarely found in other locations such as the thyroid and salivary glands [27, 28]. The incidence of t(11;18)(q21;q21) in ocular adnexal lymphomas has previously been investigated in a few small series [4, 24, 27, 35, 36, 39]. In the present study, t(11;18)(q21;q21) was detected by RT-PCR in 26.7% of the 15 patients tested. Recently, two larger series were reported with contradictory results: Takada et al. [41] found that 3 of 23 (13%) ocular adnexal lymphomas harbored t(11;18), whereas Adachi et al. [1] could not detect this translocation in a series of 69 cases. Further studies are needed to clarify this point but all these data suggest that similar mechanisms of carcinogenesis may be implicated in gastric MZL-MALT and at least a subset of ocular adnexal MZL-MALT. As previously described in gastric MZL-MALT, in which t(11;18) is preferentially found in the most advanced stages [27], two of our four cases harboring this translocation had bilateral orbital involvement or were at an advanced stage of the disease. It has been reported that another specific chromosomal translocation, t(1;14)(p22;q32), found in only 5% of MZL-MALT [44], is associated with strong immunohistochemical BCL10 expression in the nucleus and cytoplasm of lymphoma cells [47]. It is highly unlikely that any of our cases harbored t(1;14)(p22;q32) as none displayed this pattern of BCL10 immunostaining.

As in previous reports [1, 5, 7, 11, 26, 32, 33, 43], 75% of our patients presented with localized stage IE ocular adnexal MZL-MALT. This study underlines the interest of the staging procedure in cases presenting with ocular adnexal MZL-MALT because five of our patients (1, 12, 15, 17, and 18) had concurrent extraorbital disease at diagnosis involving the lymph nodes, spleen, and bone marrow and also other MALT sites such as the stomach, lung, parotid, thyroid, and liver. Three of these patients (1, 12, and 17) relapsed after treatment, suggesting that extraorbital involvement might be a factor of poor prognosis. Our results confirm that the search for neoplastic involvement of other MALT sites should be routinely included in the lymphoma staging procedure [38].

Chlorambucil or low-dose anthracycline-based regimens (ChOP), with or without local radiotherapy, yielded complete remission in every case. However, relapses were frequent (26.1% of patients) as in previous reports. In contrast to previous series [5, 7, 11, 26, 32, 33, 43], a high proportion of our patients received a combination of chemotherapy and local radiotherapy, and none received local radiotherapy alone (Table 4). Combination therapy appeared more effective than chemotherapy alone in preventing recurrences, even in patients with localized stages. Indeed, persistent complete remission was achieved in all the patients who received a combination therapy (median follow-up 43 months), whereas 43% of patients relapsed after treatment with ChOP or chlorambucil alone (median follow-up 37.5 months). Local radiotherapy alone offers

excellent local control but appears inadequate to prevent systemic relapses, as previous studies with sufficient follow-up data (Table 4) showed a higher rate of systemic recurrence (5–32%) than that observed among our patients (4.3%). The choice of chemotherapy in our series was based on the results reported by Raderer et al. [38] who performed an extensive staging in patients with MZL-MALT and showed that apparently localized MZL-MALT lymphoma occurred in fact simultaneously at different MALT sites in nearly a quarter of patients at diagnosis with a higher frequency of multi-organ involvement in case of extra-gastrointestinal MZL-MALT. It is worth noting that in this study, these lymphomatous sites were clinically occult and were proved by biopsy. This suggests that chemotherapy may prevent systemic relapses by controlling early and occult dissemination of the disease. It should be mentioned that the inclusion of anti-CD20 therapy in first-line treatment could also be a future possibility for reducing the rate of systemic relapses.

Although combined with chemotherapy, orbital radiotherapy (total dose 30–40 Gy) was relatively well tolerated (Table 2). Only one severe adverse effect occurred (blindness due to radiation-related retinopathy) in a patient (patient 23) who received 45 Gy. In keeping with most published data [1, 5, 7, 11, 26, 32, 33, 43], death was rarely related to MZL-MALT: Twenty-two of our 23 patients were alive at the cut-off date for this analysis. The only death was due to gastric carcinoma in a patient with no evidence of lymphoma. This was partly due to the efficacy of second-line treatment, consisting of systemic chemotherapy or anti-CD20 monoclonal antibody.

In conclusion, MZL-MALT is the most frequent type of lymphoma involving the ocular adnexa. Its diagnosis is challenging, but immunohistochemistry helps to distinguish MZL-MALT from lymphoid hyperplasia and other types of small B cell lymphoma. T(11;18)(q21;q21), which is specific to MZL-MALT, was present in 27% of our patients, while the BCL10 immunostaining pattern ruled out t(1;14)(p22;q32) in every cases. The clinical outcome of ocular adnexal MZL-MALT is excellent, despite a relapse rate of 26.1% in our series. Combined chemotherapy and radiotherapy seems to be more effective in preventing recurrences, but prospective studies are needed to confirm these retrospective data.

α -fetoprotein expression in a dedifferentiated liposarcoma

Received: 14 December 2005 / Revised: 21 December 2005 / Accepted: 21 December 2005 / Published online: 18 February 2006
© Springer-Verlag 2006

Abstract Extremely rare cases of paraneoplastic syndromes or ectopic production of proteins associated with liposarcoma are reported in literature. We describe a unique case of relapsing retroperitoneal dedifferentiated liposarcoma with biochemical, immunohistochemical, and molecular evidence of alpha-fetoprotein (AFP) ectopic production. The lesion was associated to elevated AFP plasma levels that subsided after tumor removal. Immunohistochemical studies showed AFP production by a minority of tumor cells and reverse transcriptase polymerase chain reaction confirmed AFP mRNA expression. Finding of MDM2 and CDK4 overexpression by immunohistochemistry confirmed the diagnosis of dedifferentiated liposarcoma.

Keywords Dedifferentiated liposarcoma · Alpha-fetoprotein · Ectopic production

Introduction

Liposarcoma is the most common soft tissue sarcoma in adults and occurs in four main forms: atypical lipomatous tumor/well differentiated, myxoid/round cell, dedifferentiated, and pleomorphic liposarcoma. Dedifferentiated liposarcoma is defined as a malignant adipocytic neoplasm showing transition from atypical lipomatous tumor/well-differentiated liposarcoma to high-grade nonlipogenic sarcoma. The neoplasia most frequently involves the retroperitoneum, while other anatomic sites are less frequently involved [6].

Sporadic cases of paraneoplastic syndromes associated with liposarcomas, including paraneoplastic pemphigus, leucocytosis, and granulocyte colony-stimulating factors ectopic production, are reported in literature [7, 9, 13].

In this study, we report a case of dedifferentiated liposarcoma arising from retroperitoneum producing α -fetoprotein (AFP) at the time of relapse.

Case report

In September 2004, a 72-year-old male patient came to medical attention for intestinal subocclusion. A nephrectomy with surgical removal of a perirenal retroperitoneal well-differentiated liposarcoma had been performed 7 years previously. Abdominal tomography and ultrasound examinations disclosed a large mass infiltrating the retroperitoneal spaces. Hematochemical analysis showed normal values for gastrointestinal cancer-associated antigen, carcinoembryonic antigen, and prostate-specific antigen and elevated α -fetoprotein (AFP) levels (705 ng/ml, normal range in adult <30 ng/ml). The patient was human immunodeficiency virus and hepatitis C virus-negative and anti-HbcAg-positive. Serum levels of alanine transaminase, aspartate transaminase, alkaline phosphatase, gamma-GT were in the normal range and image studies showed no focal or diffuse lesions in liver. The patient underwent surgical removal of the retroperitoneal lesion. After surgery, levels of AFP decreased to 20 ng/ml.

Two months after the surgical resection the patient had clinical evidences of relapse with progressive increase of AFP serum concentration (up to 200 ng/ml) and died for septic shock. Autopsy was not performed.

Materials and methods

Immunohistochemistry

All specimens were fixed in 4% formalin and embedded in paraffin. For immunocytochemistry, the endogenous peroxidase in formalin-fixed, paraffin-embedded tissue was inhibited by incubating specimens with 3% H₂O₂ for 5 min before incubation with the primary monoclonal antibody or polyclonal rabbit serum. Immunohistochemical staining was performed using the streptavidin–biotin peroxidase method. Primary antibodies and working dilutions used are reported in Table 1. Heat-based antigen retrieval was performed for all immunohistochemical reactions in 10 mm citrate buffer, pH 6.

RT-PCR analysis for AFP mRNA

The presence of AFP mRNA was investigated in formalin-fixed, paraffin-embedded tissue by means of reverse transcriptase polymerase chain reaction (RT-PCR). A set of primers was designed which amplifies a 172-bp fragment between exon 4 and exon 5 of AFP gene: the sequence of the primers are 5'-TGTCACAAGCTGTGAAGCAT -3' for the forward and 5'-GCTTTGCAGCAAGATGGAAT -3' for the reverse oligonucleotide, respectively. Amplification reactions were carried out with 40 cycles made by three steps: denaturation at 94°C for 30 s, annealing at 60–50°C for 30 s, and extension at 72°C for 1 min; the initial annealing temperature of 60°C was reduced by 2°C after every two cycles to reach 50°C for the final 30 cycles.

Table 1 Primary antibodies and working dilutions used in this work

Antigen	Clone	Source	Dilution
AFP	ZSA06	Zymed	1:200
Cytokeratins	AE1/AE3	DAKO	1:50

CD30	Ber-H2	DAKO	1:50
Vimentin	V9	DAKO	1:50
MDM2	IF2	Zymed	1:100
CDK4	DCS-31	Biosource	1:200

Results

The tumor removed in 1997 originated from the retroperitoneal space and infiltrated left kidney and left psoas muscle. Grossly, the lesion was 12 cm in diameter and was represented by fat intermixed with small amount of compact, white tissue. Microscopically, it was mainly composed by small mature adipocytes and fibrous/myxoid areas with mostly typical spindle cells. Moreover, cells with atypical, enlarged plurilobated nuclei with dense chromatin were found, particularly in myxoid areas (Fig. 1) but no multivacuolated lipoblast was found. A diagnosis of atypical lipomatous tumor/well-differentiated liposarcoma was made.

The lesion removed in 2004 was a large mass (30 cm in largest dimension), with irregular margins and a yellow–white cut surface with many necrotic and hemorrhagic areas. The lesion was localized in retroperitoneal space and infiltrated the body and the tail of pancreas.

Microscopically, it showed a heterogeneous cellular composition which included atypical spindle cells, small round cells, epithelioid elements, and focal areas composed by large, pleomorphic, occasionally multinucleated cells (Fig. 2a,b). The neoplastic population displayed a high proliferation rate, with mitotic figures per 10 high power fields and 68% of ki-67 positive cells. Unequivocal lipoblasts could not be found. The lesion was grade 3 according to Federation National des Centres de Lutte Contre le Cancer grading system [4]. Surgical margins were positive.

Immunohistochemical studies showed diffuse vimentin positivity, absence of cytocheratin expression, faint S100-protein positivity, focal positivity for desmin (mostly in areas morphologically suggestive of rhabdomyoblastic differentiation), focal positivity for MDM2 and CDK4 (Fig. 3a,b), intense, focal positivity for AFP (particularly in the most pleomorphic areas) (Fig. 3c,d), negative staining for antihepatocyte and antihuman chorionic gonadotropin (hCG), and faint, focal membrane expression of CD30 in

Fig. 1 Retroperitoneal mass removed in 1997. Large, atypical cells with hyperchromatic and plurilobated nuclei with prominent nucleoli scattered in myxoid stroma with prominent small vassells (×400)

Fig. 2 Retroperitoneal mass removed in 2004. The lesion was largely composed by atypical spindle cells vaguely arranged in bundles (a), with sparse areas composed by epithelioid, pleomorphic cells with large eosinophilic cytoplasm (b) ($\times 400$)

few areas prevalently composed by small round elements. RT-PCR expression of AFP mRNA was detected in the tumor (Fig. 4).

Altogether, the morphological, immunohistochemical, and molecular features displayed by this lesion, together of a previous history of well-differentiated liposarcoma, suggested the diagnosis of dedifferentiated liposarcoma with ectopic production of AFP.

A retrospective immunohistochemical evaluation of AFP protein on sections from the lesion excised in 1997 was made and resulted completely negative.

Discussion

AFP is a single chain α -globulin with a molecular weight of ~ 70 KDa. In the developing fetus, AFP is produced by both yolk sac and fetal liver. AFP is thought to serve biochemical functions similar to that of albumin [12]. In addition to this function, many studies have established that AFP can act as a growth regulator during ontogenesis and tumor progression [14]. In the adult life, its expression is reactivated and its serum levels increase in chronic liver diseases and in malignances such as hepatocellular carcinoma,

embryonal carcinoma and yolk sac tumors [1]. Cases of AFP-producing adenocarcinoma, commonly exhibiting histological features of hepatoid differentiation, are reported in literature [8, 10, 11].

We describe a unique case of relapsing dedifferentiated liposarcoma with biochemical, immunohistochemical, and molecular evidence of AFP production. The morphological and immunohistochemical features of this lesion are not reminiscent of anyone of the usual causes of AFP production. In particular, absent expression of hepatocellular antigen (clone OCH1E5) and cytokeratin, together with morphological findings and clinical history, exclude an extrahepatic diffusion of a hepatocellular carcinoma. No histopathological evidence of a yolk sac tumor could be found in this lesion, except for focal CD30 expression. The focal expression of MDM2 and CDK4, which is strongly correlated to amplification status of their respective genes, also confirmed the diagnosis of dedifferentiated liposarcoma [3].

To our knowledge, no other case of AFP-producing sarcoma has been described so far, except for a report of a rhabdomyosarcoma of the urinary bladder [2]. However, rare paraneoplastic syndromes or ectopic productions associated to liposarcomas are described in literature [7,

Fig. 3 The tumor showed focal expression of MDM2 (a) and CDK4 (b). Focal, intense reactivity with anti-AFP antibody was found in some areas with pleomorphic elements (c, d)

Fig. 4 Agarose gel of RT-PCR for AFP mRNA. Bands at 114 and 172 bp correspond to beta2-microglobulin and AFP amplification products, respectively. *Line 6* and *7* are sample from two different areas of the lesion, one of which showing presence of AFP mRNA. *Line 1* markers; *line 2* beta2-microglobulin, fetal liver; *line 3* beta2 microglobulin, sample; *line 4* no RNA; *line 5* AFP, fetal liver; *line 6, 7* AFP, sample

9, 13]. One of them is a report of leucocytosis associated with liposarcoma recurrence [7].

Reactivation of AFP gene transcription in tumors is thought to be mediated by several mechanisms which include overexpression of specific transcription factors [15] and loss of function of proteins involved in postnatal *AFP* gene silencing [5]. Some of these mechanisms could be involved in reactivation of *AFP* gene expression in this case of dedifferentiated liposarcoma.

This report adds dedifferentiated liposarcoma to the list of the unusual neoplastic causes of high AFP serum levels.

Melanin bearing myoepithelial cells in a pigmented salivary gland carcinoma: a new avatar of myoepithelial cell? A case report

Received: 12 September 2005 / Accepted: 21 September 2005 / Published online: 21 January 2006
© Springer-Verlag 2006

Abstract Melanocytes can be found in the stroma of salivary glands and their tumors. However, the presence of melanin pigment in the tumor cells of salivary gland origin is exceedingly rare. A 42-year-old man presented with a nasal tumor that was black in color. The histology was that of a minor salivary gland carcinoma with foci resembling an adenoid cystic carcinoma. The myoepithelial cells of this tumor contained melanin pigment. The possible histogenesis of this lesion and an explanation for the occurrence of melanin pigment in a salivary gland tumor are discussed.

Introduction

The myoepithelial cells can take on a variety of different forms in neoplastic conditions. However, the presence of melanin pigment within the cells of a minor salivary gland carcinoma is exceedingly rare. We report here a case of a melanotic nasal tumor of minor salivary gland type in which the pigment-bearing cells expressed a myoepithelial phenotype.

Case report

A 42-year-old man presented with a mass in the nose. The mass was present on the lateral wall of the nasal cavity in relation with the nasal mucosa. The radiographs revealed a tumor invading the maxillary bone. An enlarged neck node was also identified. A medial maxillectomy was performed to excise the tumor together with ipsilateral dissection of the neck nodes.

Pathological findings

The tumor mass measured 1.5 cm. It was solid, firm and black in color. The lymph nodes were enlarged and black-brown in color.

On histology, the nasal mass was a minor salivary gland tumor. The tumor was focally circumscribed, while at some places the tumor infiltrated into the bone (Fig. 1a). This tumor consisted of sheets and nests of cells, with focal areas showing glandular structures and squamous differentiation (Fig. 1b,c). Furthermore, the tumor showed cribriform and tubular pattern of an adenoid cystic carcinoma (Fig. 2). The tumor did not fit neatly into any particular World Health Organization (WHO) type, although it most resembled an adenoid cystic carcinoma. The tumor cells showed the presence of brown pigment akin to melanin in their cytoplasm (Fig. 3a). The pigment was also noted in the stroma. This pigment could be bleached with peroxidase and potassium permanganate, and it did not give a positive reaction with Prussian blue.

The lymph node showed tumor metastasis. Here too, the tumor cells had adenoid cystic pattern and showed the presence of brown–black pigment. There was no extra-capsular spread of the tumor.

Immunohistochemistry

Immunohistochemical analysis was done using the avidin–biotin complex after bleaching the sections with potassium permanganate and confirming under the microscope that there was no residual pigment. All the antibodies were applied after the sections were bleached so as to negate the interference of melanin pigment in the evaluation of immunohistochemical reactivity. The tumor cells expressed myoepithelial markers, viz. cytokeratin (MNF 116), epithelial membrane antigen, S-100 protein, calponin, CD10, smooth muscle actin and p63. They also expressed HMB-45 (Fig. 3b), a marker for immature melanosomes. The stromal cells did not react with either S-100 protein or HMB-45, and thus, were not thought to be of melanocytic

Fig. 1 a Tumor infiltrating the bone (H & E, $\times 4$). b Parts of the tumor show glandular architecture (H & E, $\times 10$). c In some places, the tumor formed a solid nest and showed squamous differentiation (H & E, $\times 10$). Note the brown pigment in all the photomicrographs

origin, and were fibroblasts or histiocytes (some were CD68-positive).

Histological diagnosis

The tumor was labeled as a pigmented minor salivary gland carcinoma showing myoepithelial differentiation and resembling an adenoid cystic carcinoma.

Discussion

Melanin pigment has been previously described in rare salivary gland tumors, one being an adenoid cystic carcinoma where the melanin has essentially been found in the stromal cells [4]. The other cases were of mucoepidermoid tumors, where the pigment-producing cells were proved to be melanocytes [1–3, 8]. More recently, a case of pleomorphic adenoma with melanin pigment has been described [7].

The salivary gland carcinoma of the nose described in the present case report was so heavily pigmented that it clinically resembled a melanoma. The melanin pigment

Fig. 2 Adenoid cystic carcinoma pattern. a Tubular and cribriform structures (H & E, $\times 10$). b Photomicrograph from the lymph node metastasis showing tubular complex, with the central space containing hyaline eosinophilic material, and lined by an inner layer of cells with eosinophilic cytoplasm and an outer layer of basaloid cells. Some of the cells contain brown pigment (H & E, $\times 40$)

Fig. 3 a Nests of myoepithelial tumor cells with clear cytoplasm and containing brown pigment (H & E, $\times 40$). b These cells exhibit strong immunoreactivity for HMB-45 antibody

was present within the clear myoepithelial cells. The nature of the pigment was discerned by HMB-45 immunoreactivity, bleaching with potassium permanganate, positive reaction with Fontana–Masson, and a negative Perls reaction. The panel of immunohistochemistry performed points toward myoepithelial differentiation of these cells.

Myoepithelial cells are known for their divergent phenotypes, viz clear, spindle, plasmacytoid, and epithelioid. In addition, they can also show keratinizing squamous and lipocytic differentiation. However, to the best of our knowledge, the presence of intracellular melanin pigment within these has not been described. The possibility of this being a collision of malignant melanoma and a salivary gland tumor can be excluded because there were no two distinct tumors. This tumor looked like a salivary gland tumor, and the only difference was that it had pigment in the tumor cells.

The question arises as to the origin of melanin in the present tumor. The melanin was undoubtedly in the cells that expressed the myoepithelial characteristics. Were the myoepithelial cells the source of the pigment or were these cells merely storing it? Melanin is normally produced by cells of neural crest origin, and the salivary glands do not belong to this lineage. However, melanocytes can be found in salivary glands [5, 6]. Stromal melanocytes are the source of abnormal melanin accumulation in the tumor cells of some adnexal tumors of the skin, viz. eccrine poroma and cylindromas, which are analogous to basal cell adenomas of the salivary glands. A case of mucoepidermoid carcinoma has been recently described, wherein the tumor was colonized by melanocytes, and the tumor cells phagocytosed the melanin pigment [2]. Could this be the explanation for the pigmentation in our case? Occasional stromal cells containing pigment were noted in the tumor. However, these did not have the histological appearance of the dendritic melanocytes nor were they S-100 protein or HMB-45-positive. Although we have no ultrastructural proof, the presence of heavy pigmentation present mainly in the myoepithelial cells, their strong reaction with HMB-45 and the lack of dendritic melanocytes in the stroma leads us to believe that the myoepithelial cell can, under unusual conditions, produce melanin. It is interesting

to note that adenoid cystic carcinoma, a tumor rich in myoepithelial cells, is one of the three salivary gland tumors in which pigment has previously been reported. Perhaps, melanin production should be added to the long list of phenotypic avatars that this most fascinating and plastic cell type assumes under conditions of neoplasia.

1–3 June 2006

**Technology Transfer in Diagnostic Pathology
1st Central European Regional Meeting: Liver & Pancreas
Pathology**
Eger, Hungary

The Hungarian Division of the International Academy of Pathology announces the *Liver & Pancreas Pathology* both for young and well-trained pathologists and clinicians.

The Meeting will focus on the practical clinicopathological aspects of liver and pancreatic diseases and conclude in a consensus. Among the highlights will be the differential diagnosis of hepatic and pancreatic tumors and premalignant alterations presented by *internationally renowned* experts, in active interaction with the attendants.

Plenary lectures will cover the themes of steatohepatitis, reversibility of cirrhosis, chronic hepatitis, classification and diagnosis of liver tumors, progenitor cells in the liver, pancreatitis, tumors of the pancreas.

Slide seminars will discuss autoimmune liver diseases (PBC, PSC, CAH), toxic liver injuries, benign and malignant liver tumors, tumor-like lesions of the liver, pancreatitis and pancreatic tumors.

Poster presentations will be reviewed and discussed individually by the participants.

15–16 June 2006

Thyroid Pathology for the Practicing Pathologist
15 rue de l'Ecole de Médecine, Paris, France

A 2-day course will take place in Paris again under the auspices of the French Division of the I.A.P.

This course will be given in English by Prof. M. Sobrinho-Simões (Porto) and Prof. R. Heimann (Brussels).

It will consist of lectures alternating with slide reviews and a slide seminar over a multihead microscope. The cases of this seminar will be sent (on CD) before the meeting.

The audience will be limited to 22 participants.
Course fees: 390 euros (320 euros for members of any I.A.P. division).

The fees include registration, hand-out, CD of the slide seminar and coffee breaks.

For further information please contact

The enigmatic nature of apocrine breast lesions

Received: 27 March 2005 / Accepted: 12 September 2005 / Published online: 29 March 2006
© Springer-Verlag 2006

Abstract Epithelial cells of fetal breast glandular structures, at the third trimester of pregnancy (28 weeks), produce GCDFP-15, in the absence of specific apocrine morphology. Apocrine epithelium of the breast may be a normal process of differentiation rather than a result of metaplasia, and it has been demonstrated that it is estrogen-receptor, progesterone-receptor and bcl-2 negative, but androgen-receptor (AR) positive. The significance of AR expression in apocrine epithelium is uncertain. Apocrine epithelium is seen in a wide spectrum of breast entities, ranging from benign lesions to invasive carcinoma. Breast cancer accounts 32% of all cancer cases among women and is the most common type of cancer in women. Little is known about breast carcinogenesis. Widely, it is accepted that breast cancer, like most other type of cancer, is being developed through the accumulation of genetic aberrations. Apocrine epithelium may reflect instability of the breast epithelium, creating an environment favouring further oncogenic alterations. In the last decade, several lines of evidence support the idea that some breast benign epithelial apocrine lesions are clonal lesions and may be considered as truly pre-malignant or precursors of breast carcinoma. Apocrine changes in many cases do not present any diagnostic difficulty; on the other hand, apocrine proliferations with cytologic atypia can be particularly difficult and challenging. The purpose of this study is to collect and

highlight the areas of consensus in the literature as well as the controversial areas concerning the apocrine epithelium of the breast.

Keywords Breast · Apocrine epithelium · GCDFP-15 · Fibrocystic changes · Apocrine carcinoma · Molecular alterations

Introduction

The apocrine epithelium, from the Greek word *από + έκκριση*, is a normal constituent of apocrine glands of axillary, anogenital skin, eyelids (Moll), ears (ceruminous) and mammary gland, which consists of cells with eosinophilic cytoplasm that may contain lipid, iron, lipofuscin, PAS-positive diastase-resistant granules and a large nucleus located near the base of the cell (Fig. 1). Fragments of apical cytoplasm are found in the lumen of these glands. The apocrine glands develop as epithelial buds from the outer root sheath of the hair follicles in 5 to 6-month-old fetuses and continue into late embryonic life as long as new hair follicles develop [81, 67]. Nevertheless, morphologically and functionally, the apocrine epithelium is different from cutaneous, sebaceous and sweat glands [69]. A wide spectrum of benign and malignant breast lesions contains epithelial cells that are identical to those that consist the apocrine glands [37, 48]. Immunohistochemical studies of benign and malignant breast lesions, showing apocrine differentiation, report that cells stain positive for androgen receptors (AR) and lack estrogen receptor (ER), progesterone receptors (PR) and exhibiting bcl-2 negativity in normal breast epithelium. Morphological features of apocrine differentiation were valuable criteria, leading the Pathologists to a benign diagnosis. In a review paper of Love et al. [49] on fibrocystic disease, the authors are wondering whether it is reasonable to consider apocrine cells a pathological phenomenon inasmuch as about 90% of adult breasts show evidence of them. To date, with the advent of new technologies, there are compelling molecular data on these lesions that change the existing concept [40, 80].

Apocrine markers

The glycoprotein GCDFP-15 (15 kDa), the major component of cyst fluid, represents an immunocytochemical marker of apocrine differentiation that is more reliable than morphology and the detection of prolactin inducible protein (PIP)/GCDFP-15 mRNA using in situ hybridization (Fig. 2) [27, 59, 48]. It is identical to the gene of the PIP described in the breast cancer cell line T-47D [77, 57, 33]. The gene is expressed in apocrine glands and in exocrine organs that have common phylogenetic features with apocrine glands, such as the bronchial epithelium, the sweat, salivary and lacrimal glands and the seminal vesicles. According to human genome sequencing data, the GCDFP/PIP is localized at 7q34 [45].

The GCDFP-15 had 95% specificity and 74% sensitivity as a marker for breast cancer [93, 94] and has been used to support breast origin in metastatic carcinoma of unknown primary origin (Figs. 3, 4 and 5). GCDFP-15 is present at a very low concentration in the plasma of physiological women and is 140,000 times higher in breast cyst fluid compared to plasma. The concentration in amniotic fluid of pregnant women is 7.200 ng/ml [34].

Fig. 2 GCDFP-15, immunostaining in apocrine cysts (DAB ×200)

Fig. 3 Intense cytoplasmic immunostaining for GCDFP-15 in: in situ (Fig. 4), infiltrating (Fig. 5) and metastatic to a lymph node (Fig. 6) apocrine carcinoma

An appreciable discriminating feature between apocrine cells and normal luminal epithelial cells of the breast is that while the former expresses AR and lacks ER, PR and bcl-2, the latter is ER/PR positive and AR negative. The apocrine cells differ from normal cells not only morphologically but also biologically [72, 30].

Theories

The origin of apocrine cells has always been a contradictory issue. Several answers have been given for the presence of this enigmatic entity. The existence of apocrine cells in the breast has generally been regarded as a metaplastic process [86], but this issue has recently been debated [3, 14, 16, 84, 90]. Some authors believe that apocrine metaplasia, in general, is a terminally differentiated entity [10, 66], others considered that the apocrine epithelium is a degenerated epithelium [19, 92]; several authors suggested that these cells are normal element of the glandular structure of the breast [27] or a metabolic active epithelium [53]. These different opinions in the international literature make the

Fig. 4 Intense cytoplasmic immunostaining for GCDFP-15 in in situ apocrine carcinoma

Fig. 5 Intense cytoplasmic immunostaining for GDFP-15 in infiltrating apocrine carcinoma

subject of apocrine epithelium very controversial. Despite the fact that apocrine changes have been considered a metaplastic process in the mammary gland, usually associated with physiological changes in the hormonal milieu and ageing, there is a strong evidence to suggest that a part of apocrine changes show molecular alterations using the existing reliable technology. The molecular changes are more frequently observed in entities such as apocrine adenosis and apocrine hyperplasia. We would suggest that, nowadays, there is overwhelming molecular data that some of these apocrine changes in proliferative lesions maybe precursors of malignant transformation [40, 74–75, 90, 91]. It would be possible that those data are misleading, but nevertheless they should be considered mandatory for further investigation in interesting “hot area” of breast research.

Epithelial cells, in some very primitive structures with no particular distribution, produce CDFP-15 in normal fetal breast, where their overall number was increased with gestational age [89]. McKiernan et al. [51] studied the histology of breast development and reported the existence of lobular structures, dilated ducts and apocrine secretion. In the newborn breast, the epithelial cells have an eosinophilic cytoplasm with typical apocrine secretion [70]. It was mentioned in the infant under development that apocrine metaplasia was observed as part of the post neonatal involution [38]. Others suggest that apocrine epithelium belong to entrapped cutaneous apocrine glands in the area of mammary gland during the process of development [89].

Apocrine cell-epithelial lesions

Apocrine phenotype is observed in a spectrum of breast epithelial lesions spanning from benign metaplasia to apocrine carcinoma. Apocrine metaplastic epithelium (APM) is a frequent finding, occurring in approximately 40% of benign breast biopsies [25]. Apocrine cells in the breast appear frequently in benign breast lesions such as fibrocystic disease (Fig. 6) [17, 26–29, 56], papillomas [65],

fibroadenomas [4, 25], sclerosing adenosis [13, 79] atypical apocrine proliferations, apocrine ductal carcinoma in situ (DCIS), invasive apocrine carcinoma [47, 1] and lobular carcinoma [26].

Fibrocystic changes (FCC) are a common finding, and it is clinically evident in about 50% of women of reproductive age. In the western countries, 7% of women develop palpable breast cysts [33]. Single or multiple cysts are the most prevalent lesion of the female breast [42]. Gross cystic changes, a common finding in premenopausal women, generally present as a single cyst. Cysts are thought to arise through obstruction of the ducts. There are two types of cysts. Type I cysts (apocrine or secretory) have high levels of potassium ions (Na^+/K^+ ratio < 3), large concentrations of steroid hormones, epidermal growth factor and gross cystic disease fluid protein, and it is thought to be under androgen regulation [36, 7, 52]. Apocrine changes are prevalent in flat to cuboidal cells lining type I cysts. Type II cysts with content Na^+/K^+ ratio > 3 are lined by flattened epithelium. The morphological presentations of hyperplastic changes include papillary or micropapillary lesions composed of apocrine cells.

However, several follow-up studies have suggested that apocrine epithelium may be a predictor of the subsequent development of malignancy [35, 60].

Several reports have assessed the relation between palpable breast cysts and breast carcinoma and suggested that there is an increased risk of breast carcinoma, which ranges from 1.7 to 7.5 times [68, 17, 8, 11, 6]. Haagensen et al. found a fivefold-increased incidence of carcinoma associated with papillary apocrine metaplasia in fibrocystic changes, although this fact has subsequently been questioned [12, 35]. Dixon, et al., has shown no significant association between cyst type and breast-cancer risk [20]. Dupont and Page [22], in their long-term follow-up study of women with benign breast lesions, found an increased relative risk only of 1.7 in cases without complications. A slightly elevated relative risk of 2.4 for subsequent development of malignancy has been noticed for those cases with complex papillary lesions [61].

Fig. 6 Apocrine cysts in a breast with fibrocystic changes (H+E × 100)

The presence of focal apocrine metaplasia within epithelial breast proliferations is generally considered as an important indicator in the histopathologic diagnosis of benignity [78].

The definition of apocrine metaplasia is based on the following criteria: (a) eosinophilic cytoplasm with fine granularity, (b) large and moderately vesicular nuclei with an occasional prominent red nucleoli and (c) sporadic presence of apical snouts [83, 58].

Borderline apocrine lesions are classified into two categories: atypical apocrine adenosis and atypical ductal hyperplasia of apocrine type [46]. In 1963, Papanicolaou [63] used the descriptive term of “non-malignant atypia” for apocrine cells, “the individual cells or cellular clusters that show enlargement, metaplasia, engulfment and vacuolation, which is often extreme”.

O’Malley et al. [58] used morphologic–cytologic criteria and extent criteria. Apocrine lesions that measured less than 8 mm were called benign. The human breast epithelium is a dynamic entity that is remodeled under the influence of sex hormones and growth factors. This dynamic ability of breast cells reflects instability of the breast epithelium, creating an environment susceptible to carcinogenesis. Breast lesions with APM epithelium appear to demonstrate abnormal oncoprotein and apoptosis-related protein expression associated with a high proliferation rate [74]. Increased cellular and architectural atypia may indicate an increased risk of developing apocrine carcinoma [97].

Apocrine adenosis (AA) is a rare breast lesion, which is characterized as sclerosing adenosis associated with marked apocrine metaplastic changes [79, 13]. Simpson et al. [79] identified in a retrospective study of 10,000 benign biopsies of 55 cases of apocrine adenosis.

AA has been misdiagnosed as carcinoma due to the cytologic atypia of the apocrine cells, and it is occasionally so florid that it gives rise to a distinct mass, which can be mistaken clinically for cancer [93, 76]. Wells et al. [93] have suggested that apocrine adenosis may be a precancerous lesion, mainly on the basis of the expression of c-erbB2 protein.

Apocrine adenoma is another rare breast neoplasm, composed exclusively of apocrine cells, which is sharply demarcated and shows back-to-back glands with papillary fronds projecting into the lumina. This rare lesion should be distinguished from well-differentiated apocrine carcinoma [10, 5].

Neoplastic transformation may occur in metaplastic epithelium. Cancer of the bladder, stomach, lung and cervix have their origin in these metaplastic areas. The metaplastic epithelium returns to the normal epithelium when the stimulus is removed. The stimuli leading to metaplasia could also lead to carcinogenesis of the metaplastic epithelium. The stimulus for apocrine metaplasia is unknown. Chemicals, vitamins, and growth factors play a significant role in metaplasia [18].

It is well known that some hyperplastic breast lesions might actually be clonal in origin. The detection of allelic imbalances in ductal hyperplasia and papillomas suggested

that these lesions might be neoplastic (monoclonal) rather than hyperplastic (polyclonal) proliferations [44, 87].

The findings of molecular alterations in benign proliferative apocrine lesions such as APM, apocrine hyperplasia and apocrine adenosis support the idea that these lesions are clonal. Several authors using comparative genomic hybridization demonstrated loss of 1p, 2p, 10q, 16q, 17q and 22q and gain of 1p, 2q and 13q [40], and analyses of heterozygosity/allelic imbalance have demonstrated that the average number of genetic changes (overall gains and losses) at 1p, 11q, 13q, 16q and 17q is frequent event in APM, AA and apocrine hyperplasia [73, 75, 89, 90].

Two studies have shown aneuploidy in apocrine metaplastic cells [39, 88]. Abnormal oncogene expression has been discovered in apocrine metaplastic epithelium by Papamichalis et al. [62] using an antibody to c-myc oncoprotein. Agnantis et al. [2] studied 12 cases of apocrine breast carcinomas, 5 of these cases were associated with benign apocrine lesions, either adjacent to the tumor or distant, and demonstrated the expression of c-myc p62 and GCDP-15 (Agnantis et al., unpublished data presented at 4th International Symposium and Workshop, Problèmes Actuels de Pathologie Mammaire, Paris December 5–8, 1988). Four years later, Agnantis et al. [2] reported that the great majority of complex cystic disease shows elevated expression of both c-myc p62 and ras p21, when associated with apocrine metaplastic papillary proliferations.

Apocrine DCIS-apocrine carcinoma

Apocrine lobular in situ neoplasias and apocrine ductal in situ carcinomas are well-defined entities [26, 83, 1]. The consensus conference on the classification of DCIS recognized apocrine DCIS as a special variant, which is characterized by remarkable proliferation of apocrine cells showing nuclear pleomorphism with enlarged nuclei, multiple prominent nucleoli and irregular nuclear membranes. The presence of necrosis is not mandatory for the diagnosis of DCIS [85]. On the other hand, based on the World Health Organization (WHO) histological classification of breast tumors of 2003, apocrine DCIS is not recognized as a distinct entity, but is incorporated in the morphological changes of DCIS [84]. Apocrine differentiation may be present in up to 50% of the cases of DCIS, although Eusebi et al. [27] consider it an infrequently recognized phenomenon. Simpson et al. [80] supported that the common assumption at Diagnostic Pathology that a proliferative lesion with the pattern of micropapillary DCIS is thought to be benign because it has abundant pink cytoplasm that may be erroneous. There are substantial molecular data that some of these lesions may be the precursors of high grade DCIS and invasive cancer.

The recognition of apocrine carcinoma as a special type of breast carcinoma continues to be a subject of debate, due to the lack of uniform criteria for reliable recognition by light microscopy. Apocrine carcinoma is an unusual variant of breast carcinoma, probably of ductal origin or sweat

gland duct [42, 28]. The incidence of apocrine carcinoma varies from 0.3 to 4% of all cases. Rosen [69] stated that the term should be used for neoplasms as composed entirely or predominantly of apocrine-type epithelium [4, 54].

On the other hand, scattered areas or focal apocrine cells were found in about 60% of carcinomas of no special type (ductal, NST) [35]. Eusebi and Azzopardi [25] suggested that the basic criteria for a diagnosis of apocrine carcinoma should include neoplastic cells with copious, variably granular eosinophilic cytoplasm and vesicular nuclei with prominent nucleoli. Three years later, Haagensen et al. [35] proposed the following criteria: large size of the neoplastic cells, acidophilia of the cytoplasm and cytoplasmic “snouts” projecting into the lumina of glands. The degree of atypia varies, and tumor cells may occasionally present with bizarre, multilobulated nuclei containing multiple nucleoli [29]. The nuclear chromatin is irregular and often condensed along the periphery of the nuclear membrane. Most apocrine carcinoma cells are recognized as grade 2 or 3 according to a modified Scarff–Bloom–Richardson grading [23]. Cytologic smears of apocrine carcinoma yield abundant, pleomorphic tumor cells. The cells occur singly and with syncytia in the background of numerous degenerated apocrine cells, and characteristic cell detritus are found. The cells have abundant basophilic to eosinophilic granular cytoplasm. The nuclei are enlarged and vesicular and are centrally or eccentrically located. The nuclei measure $>$ or $=$ 12 μ m in diameter, when compared to benign apocrine metaplasia with atypia. The nucleoli are prominent and may be multiple [21, 32, 95, 96]. Apocrine carcinoma is a rare variant of breast carcinoma that occurs in advanced age, the peak incidence being the sixth and seventh decades of life [2]. Apocrine carcinoma occurs in both females and males and manifests as a solid or cystic mass ranging from 0.5 to 5 cm in diameter [9]. Mammographic presentation did not present differences from those of ductal carcinomas [31]. Apocrine carcinomas are mostly variants of ductal carcinomas, but areas of apocrine differentiation have been reported in pleomorphic lobular carcinoma [26, 41, 82] and papillary [64]. They are predominantly ER and PR negative, but AR positive [30, 71]. On the other hand, 35–91% of breast cancers are also reported to express AR [43, 55, 24, 15]. The prognosis of apocrine carcinoma is the same with other types of breast carcinoma. Matsuo et al. [50] have reported that the positive rate of p53, HER2 and BCL-2 in apocrine carcinoma was almost the same as that of non-apocrine carcinomas.

Conclusions

In conclusion, we propose the term apocrine precursor cells, for GCDFP-15 positive breast epithelium cells, without apocrine morphology. Based on the existing recent molecular data, we conclude that benign proliferative apocrine lesions showing molecular alterations could be considered as clonal and precursors of malignant transformation. We believe that more clinical follow up and molec-

ular data are needed for a comprehensive knowledge of the natural history of these lesions.

The histological appearance of oesophageal adenocarcinoma— an analysis based on 215 resection specimens

Received: 31 August 2005 / Accepted: 30 January 2006 / Published online: 24 February 2006
© Springer-Verlag 2006

Abstract The current study was performed to determine whether the histopathological appearance of oesophageal adenocarcinoma (AC) differs significantly from that of cardiac or gastric AC. Therefore, HE-stained slides of 215 primarily resected oesophageal AC, 108 cardiac and 184 gastric AC were classified according to a variety of clinicopathologic parameters. According to Lauren's classification, oesophageal AC (1.4%) less frequently belonged to the diffuse type than cardiac (2.8%) and gastric AC (23.9%; $p < 0.0001$). Tubular and papillary AC, as defined by the WHO classification, were more frequent among oesophageal (94.4%) than among cardiac (87.0%) and gastric AC (59.2%; $p < 0.0001$). Solid carcinomas, according to Carneiro's classification, were less frequent among oesophageal (2.8%) than among cardiac (10.2%) and gastric AC (9.2%; $p < 0.0001$). Oesophageal AC were graded more frequently G1/G2 (53.9%) than cardiac (30.6%) and gastric AC (27.7%; $p < 0.0001$). Among oesophageal AC, Lauren's classification ($p = 0.0067$), Carneiro's classification ($p = 0.0170$), tumour grade ($p = 0.0005$), lymphatic vessel invasion ($p < 0.0001$) but not WHO classification were histological predictors of post-operative survival. In conclusion, oesophageal AC displays the same histological spectrum as cardiac and gastric AC. However, the relative proportion of differentiated, gland-forming carcinomas is significantly more frequent in the oesophagus than in the cardia and in the stomach.

Introduction

Barrett's oesophagus is the predisposing condition of the vast majority of oesophageal adenocarcinomas. Under the chronically damaging effect of gastrooesophageal reflux, the metaplastic Barrett's epithelium is promoted through a (low-grade/high-grade) intraepithelial neoplasia sequence towards invasive cancer [20]. Oesophageal (Barrett's) adenocarcinoma (AC) is an entity of increasing clinical importance due to a rapidly rising incidence during the previous decades [4].

In spite of the rapidly growing number of publications on oesophageal AC, systematic investigations on the histological appearance of this tumour type are sparse and based on small, probably non-representative series of cases. Thus, a Medline-based search revealed only five systematic investigations on the histological appearance of oesophageal AC between 1980 and 2004, comprising a total of 151 oesophageal AC [8, 9, 13, 18, 26]. Three of these investigations [8, 9, 26] included a morphologic comparison with the most related tumour entities, i.e., cardiac cancer [8, 9] and gastric cancer [8, 26]. Only one investigation [8] tested oesophageal AC on the basis of Lauren's classification but none on the basis of the current WHO classification. Nonetheless, the histologic spectrum of oesophageal AC is generally considered to be well defined. Thus, the current issue of the AFIP atlas of oesophageal and gastric tumours [11] states that oesophageal AC "shows a spectrum virtually identical to that found in the stomach" and a current gastrointestinal pathology textbook points out that "histologically, cancers arising in the setting of Barrett's oesophagus and those arising in the cardia are virtually identical" [6].

Given the obviously limited evidence of these statements, the current study compares the histological features of three large series of oesophageal, cardiac and gastric AC based on well-defined histological classifications and criteria.

Materials and methods

The current study is based on 215 primary AC of the oesophagus that underwent surgical resection ($n=204$) or endoscopic mucosal resection (EMR) ($n=11$) between 1 January 1987 and 31 January 2004. Of the surgically treated cases, 143 had been resected at the Department of Surgery at the Technical University, Munich; and 61 had been resected at the Department of Surgery at the University of Dusseldorf, Germany. The EMR specimens were obtained from various contributing hospitals of the Department of Pathology by the University of Dusseldorf. As control groups, 108 cardiac and 184 gastric AC were included that underwent surgical resection at the Department of Surgery at the University of Dusseldorf between 1 January 1984 and 31 December 2002. None of the tumours had been treated by preoperative radio- or chemotherapy. Differentiation between oesophageal and cardiac AC was based on a review of the original macroscopic pathologic descriptions of the operation specimens by the author. Therefore, standard criteria were applied [19]: tumours with their epicentres more than 1 cm above the gastro-oesophageal (GO) junction were regarded as oesophageal in origin and tumours with their epicentres between 1 cm above and 2 cm below the GE junction were regarded as cardiac in origin. The GO junction was defined as the oral end of the gastric folds and/or the border between the tubular oesophagus and the sacular stomach. In the forefront of the study, 20 AC at the GO junction could not be classified according to these criteria as oesophageal or cardiac because the macroscopic description did not allow localization of the tumour's epicentres in relation to the GO junction. These cases were, therefore, excluded from any analyses described in this manuscript. The pT and the pN category of the tumours were re-determined according to the current TNM classification [24]. Cardiac carcinomas were classified as tumours of the stomach.

Histological classification

All cases were histologically classified by the author on the basis of H&E stained tumour slides. Between one and 45 slides per tumour (median: 4) were available for histological review. As no generally accepted histological evaluation system exists for oesophageal AC, all tumours were typed according to histological classification systems originally defined for gastric cancer, i.e. the WHO classification [7], Lauren's classification [10] and Carneiro's classification [3]. Tumours with a proportion of more than 5% of the tumour mass with diffuse or gland-forming cancer cells were grouped into the mixed categories according to Lauren's classification and according to Carneiro's classification [3]. According to the WHO classification, beside tubular AC and papillary AC, the category of papillotubular AC was considered, which is described as an optional subcategory of

papillary carcinomas that is characterized by tubular differentiation [7]. Carcinomas were categorized as papillotubular when they were composed of a mixture of tubular and papillary structures.

Tumour grading for all carcinomas was determined according to the WHO classification of gastric carcinomas [7]. In accordance with the WHO recommendations for colorectal carcinomas, mucinous carcinomas and tumours with diffuse or signet-ring cell component comprising more than 5% of the tumour mass were categorized as G3. Additionally, invasion of tumour cells into lymphatic vessels was determined as described previously [16].

Mucosal AC was separated from high-grade intraepithelial neoplasia either by the presence of neoplastic cells that had penetrated through the basement membrane and that were located in the lamina propria or in the muscularis mucosae. In addition, the presence of architecturally complex collections of neoplastic cells in the lamina that could not be explained by the presence of pre-existing Barrett's mucosa was considered as evidence of mucosal AC [12]. The patients' and tumours' characteristics are summarized in Table 1.

Statistical analyses

Correlation analysis between tumour types and clinicopathologic parameters were done using the chi-square test. Survival analyses were performed by means of the log-rank test and Cox regression analysis. *P* values smaller 0.05 were considered as statistically significant.

Table 1 Clinicopathological parameters in oesophageal ($n=215$), cardiac ($n=108$), and gastric adenocarcinomas (AC) ($n=184$) under investigation

	Oesophageal AC	Cardiac AC	Gastric AC
Age – median (range)	64 (33–83)	63 (29–83)	68 (30–90)
Gender			
Male	194 (90%)	89 (82%)	103 (56%)
Female	21 (10%)	19 (18%)	81 (44%)
pT category			
1 (mucosa)	50 (23%)	2 (2%)	20 (11%)
1 (submucosa)	50 (23%)	9 (8%)	17 (9%)
2	40 (19%)	55 (51%)	74 (40%)
3	75 (35%)	33 (31%)	59 (32%)
4	0	9 (8%)	14 (8%)
pN category			
0	118 ¹ (58%)	23 (21%)	58 (32%)
1–3	86 (42%)	85 (79%)	126 (68%)
Tumour size (mm) – median (range)	40 (4–160)	55 (14–135)	70 (6–220)

¹In 11 oesophageal AC, nodal status could not be determined because they had been treated by endoscopic mucosal resection

Results

Clinico-pathological parameters

Preference of male sex was more pronounced in oesophageal (90%) and cardiac AC (82%) than in gastric AC (56%). Oesophageal AC belonged more frequently to early tumour stages (pT1 46%; pN0 58%) than cardiac AC (10%; 21%) and gastric (20%; 32%) AC. No differences between the three tumour entities became apparent by comparison according to patient's age and tumour size (Table 1).

Histological parameters

According to Lauren's classification, oesophageal AC (1.4%) less frequently belonged to the diffuse type than cardiac (2.8%) and gastric AC (23.9%). The difference was statistically significant when the three groups were compared as a whole ($p < 0.0001$) and when oesophageal AC was compared with cardiac AC ($p = 0.0010$) and with gastric AC ($p < 0.0001$) separately. Tubular, papillotubular and papillary AC, as defined by the WHO classification, were more frequent among oesophageal (94.4%) than among cardiac (87.0%) and gastric AC (59.2%; $p < 0.0001$; oesophageal vs cardiac AC: $p = 0.0097$; oesophageal vs gastric AC: $p < 0.0001$). In particular, the papillotubular growth pattern was more frequent in oesophageal (32.5%) than in cardiac (17.6%) and gastric (8.1%) AC (Fig. 1) Solid carcinomas, according to Carneiro's classification, were less frequent among oesophageal (2.8%) than among cardiac (10.2%) and gastric AC (9.2%; $p < 0.0001$; oesophageal vs cardiac AC: $p < 0.0001$; oesophageal vs gastric AC: $p < 0.0001$). Oesophageal ACs were graded G1/G2 more frequently (53.9%) than cardiac (30.6%) and gastric AC (27.7%; $p < 0.0001$; oesophageal vs cardiac AC: $p = 0.0003$; oesophageal vs gastric AC: $p < 0.0001$) (Table 2).

Subgroup analysis of histological parameters according to depth of infiltration (pT category)

As oesophageal AC belonged to early tumour stages more frequently than cardiac and gastric AC, a subgroup analysis according to pT category was performed. This was done to exclude that the above-described histological differences were caused by differences in stage distribution only.

Among locally advanced carcinomas (pT2–pT4), the above-described differences in histological growth patterns remained significant for Lauren's classification (oesophageal vs cardiac AC: $p = 0.0275$; oesophageal vs gastric AC: $p < 0.0001$) and Carneiro's classification (oesophageal vs cardiac AC: $p = 0.0233$; oesophageal vs gastric AC: $p < 0.0001$). Concerning WHO classification, oesophageal ACs were significantly different from gastric AC ($p < 0.0001$) but not from cardiac AC. The distribution of tumour grades was not significantly different among advanced oesophageal, cardiac and gastric AC (Table 3).

Fig. 1 **a** Oesophageal adenocarcinoma of the papillotubular subtype according to the WHO classification (original magnification: $\times 50$; H&E). **b** Oesophageal adenocarcinoma of the mucinous subtype (original magnification: $\times 50$; H&E). Squamous epithelium-lined duct, indicating intraoesophageal location of the tumour (asterisk)

Furthermore, a subgroup analysis of oesophageal and gastric AC confined to the mucosa was performed. Cardiac ACs were excluded from this analysis due to the low number of cardiac pT1m tumours ($n = 2$). According to this analysis, oesophageal AC ($n = 50$), again significantly more often, belonged to the intestinal type, according to Lauren ($p < 0.0001$), to the tubular and papillotubular type, according to the WHO ($p < 0.0001$) and to the glandular type, according to Carneiro ($p < 0.0001$) than gastric AC ($n = 20$). Moreover, oesophageal AC, more frequently, were graded G1 or G2 than gastric AC ($p < 0.0001$) (Table 4).

We, furthermore, determined whether the histological appearance of oesophageal AC confined to the mucosa differs from more advanced tumours (Table 5). In that analysis, it became apparent that mucosal carcinomas more frequently belonged to the intestinal type, according to Lauren ($p = 0.0244$), and to the glandular type, according to Carneiro ($p = 0.0143$), than advanced tumours. Moreover,

Table 2 Comparison of histological and clinical parameters in oesophageal ($n=215$), cardiac ($n=108$) and gastric adenocarcinomas ($n=184$)

	Oesophageal AC (OAC)	Cardiac AC (CAC)	Gastric AC (GAC)	OAC vs CAC vs GAC p value	OAC vs CAC p value	OAC vs GAC p value

Chi-square test

mucosal carcinomas more frequently were well differentiated (G1) than advanced tumours ($p<0.0001$).

Survival analyses

Follow-up data were available from 163 of the 215 oesophageal ACs under analysis. The follow-up ranged between 1 and 115 months (median: 17 months). Thirty-five cases were excluded from survival analyses because they either died within the first 30 days after resection or had tumour infiltrated resection margins (R1 resection) or had evidence of distant metastasis (M1). Of the 128 cases left for survival analyses, 47 were dead at the end of the follow-up.

According to Lauren's classification, the mean survival time of intestinal carcinomas was 67 months as compared to 16 months of mixed carcinomas (only two diffuse carcinomas; $p=0.0067$, log-rank test). According to Carneiro's classification, mean survival times were 68 months for glandular carcinomas, 17 months for mixed carcinomas and 19 months for solid carcinomas

(only two isolated cell carcinomas; $p=0.0170$). According to the WHO classification, survival was best for tubular carcinomas (53 months) followed by papillotubular (37 months) and signet-ring cell carcinomas (29 months) (only two mucinous and two papillary carcinomas; not significant). Grading according to the WHO was associated with survival with G1 (49 months) and G2 (77 months) tumours showing better outcome than G3 tumours (33 months; $p=0.0005$). Calculation of mean survival time among G1 carcinomas was limited by short follow-up period in this group. Tumours with lymphatic vessel invasion ($n=30$) showed poorer outcome (20 months) than tumours without ($n=98$; 78 months; $p<0.0001$). Multivariate Cox regression analysis indicated that lymphatic vessel invasion ($p<0.0001$), but none of the other histological parameters, was an independent predictor of survival.

Discussion

The current study indicates that the currently held view that the histological appearance of oesophageal adenocarcino-

mas is virtual identical to that of cardiac and gastric AC is not correct. Based on the so-far largest histologically investigated series of oesophageal AC, we could show that the relative proportion of differentiated, gland-forming carcinomas is significantly more frequent in the oesophagus than in the cardia and in the stomach. On the other hand, we can corroborate the findings of others that nearly all histological variants of adenocarcinoma found in the stomach can also develop in the oesophagus. This is true also for rare histological variants, including mucinous and solid carcinomas, and also for signet-ring cell carcinomas.

Until now, only three studies systematically compared the histological appearance of oesophageal AC with AC of the cardia [8, 9] and the stomach [8, 26]. The studies of Kalish et al. [9] and Wang et al. [26] did not find distinguishing features between the three tumour entities. In contrast, Heidl et al. [8] reported significant differences in the histological appearance of oesophageal and gastric AC, but not between oesophageal and cardiac AC. However, all three studies have methodological disadvantages, i.e. the small number of oesophageal AC included and poor definition of histological features under analysis. The results of Heidl et al. [8] and those of the current investigation are partially congruent; however, the former study does not allow definitive conclusions, as it included a

mixture of oesophageal AC diagnosed on resection specimens ($n=36$) or on biopsy specimens ($n=30$), and it did not provide reproducible definitions of the histopathological categories used.

As shown in the current study, loss of tumour differentiation with increasing depth of infiltration is a characteristic histological feature of oesophageal AC. Similar observations have already been published by others [13, 25]. Again, this is a discriminating feature from mucosal gastric AC where poor differentiation and signet-ring cell-growth pattern is found in a substantial number of cases. The high prevalence of well or moderately differentiated, gland-forming mucosal AC in the oesophagus has important therapeutic implications. Thus, oesophageal AC confined to the mucosa has obviously a very low risk of lymph node metastasis. In a recent literature review of 150 mucosal ACs of the oesophagus [2], lymph node metastases were documented only in three cases (2%). Similarly, in our own series of 39 mucosal AC that underwent oesophageal resection, neither lymph node metastasis nor lymphatic vessel invasion was present. The relatively benign behaviour of oesophageal AC confined to the mucosa opens the opportunity for limited treatment options such as endoscopic resection [14] and limited surgical resection [21].

Determination of a tumour's origin is considered problematic when the tumour infiltrates the gastrooesophageal junction (GOJ), which means that parts of the tumour are located in the oesophagus and parts in the stomach. In the classification proposed by Siewert and Stein [19], adenocarcinomas of the GOJ are defined as tumours having their epicentre within 5 cm proximal and distal of the anatomical cardia. Among these tumours, three different subtypes are considered, i.e. adenocarcinoma of the distal oesophagus (type I tumour), true carcinoma of the cardia (type II tumour) and subcardial gastric carcinoma (type III tumour). In this classification system as well as in the recommendations by the Association of Directors of Anatomic and Surgical Pathology [1], the anatomic location of the epicentre or predominant tumour mass is used to determine whether the tumour is oesophageal, cardiac or gastric in origin. In contrast, the recent WHO classification has lumped together all tumours that cross the GOJ as carcinomas of the gastrooesophageal junction, regardless of the localization of the tumour centre [7].

We confirm that separation between oesophageal and cardiac AC may be impossible in some cases, i.e. due to

distortion of anatomic landmarks by tumour growth or hiatal hernia. However, based on our histological findings, we believe that lumping together of oesophageal AC (involving the GOJ) and cardiac AC into one category—as proposed by the WHO—may blur obvious differences between the two entities. Thus, we could clearly show that in terms of histological appearance, cardiac AC takes an intermediate position between oesophageal and gastric AC. This point of view is also supported by immunohistological [23] and molecular pathologic [17, 22] studies as well as by a study that investigated patterns of lymph node metastases [5] where significant differences between oesophageal and cardiac AC have been demonstrated. Therefore, the need of separation between (distal) oesophageal and cardiac AC is increasingly considered [15].

In conclusion, our data provide evidence that oesophageal, cardiac and gastric AC are distinct pathologic entities. Oesophageal AC is characterized by a relatively high proportion of differentiated, gland-forming tumours.

Expression of cyclin-dependent kinases and CDC25a phosphatase is related with recurrences and survival in women with peri- and post-menopausal breast cancer

Received: 6 December 2005 / Accepted: 8 December 2005 / Published online: 27 January 2006
© Springer-Verlag 2006

Abstract Progression through the mammalian cell cycle is regulated by cyclin—cyclin-dependent kinase (CDKs) complexes that are activated throughout the cell cycle. Alteration in cell cycle control could lead to proliferation and tumorigenesis. This study was designed to analyse, at messenger RNA (mRNA) level, cyclins and CDKs involved in the retinoblastoma pathway, as well as cell division cycle 25a phosphatase (CDC25a), which activates some of the CDKs that were analysed. The aim of the study was to determine the possible prognostic relevance of these molecules in 73 women with peri- and post-menopausal breast cancer. Cyclins A, D1 and E; CDKs 2, 4 and 6 and phosphatase CDC25a expression status were analysed in primary tumours at mRNA level, by reverse transcriptase polymerase chain reaction analysis in paraffin-embedded primary breast cancers. High expression levels of CDK2, CDK4 and CDC25a were related to tumour recurrence. Over-expression of CDK2 and CDC25a was also associated with reduced overall survival; moreover, the CDK2

expression level was able to define a short-living cohort of patients with tumour-positive lymph nodes. CDK2, CDK4 and CDC25a can be used as reliable biomarkers to predict prognosis in women with peri- and post-menopausal breast cancer.

Keywords Breast cancer · Survival · Quantitative RT-PCR · Formalin-fixed and paraffin-embedded tissues · CDK2 · CDK4 · CDC25a

Introduction

Breast cancer is the most common internal malignancy in women [12]. Treatment response and overall outcome can differ among women with breast cancers characterised by the same histological features and the same stage at diagnosis. New tools such as complementary DNA expression profiles [20, 21] and proteomics [22] are not able to give uniform, simple and reliable predictions of the patient's clinical outcome. The aim of the present study is to quantify the expression of seven cell-cycle-regulating molecules involved in the retinoblastoma (RB) pathway and G2/M checkpoint at the messenger RNA (mRNA) level, and to investigate the relationship between their expression and breast cancer prognosis.

The RB pathway plays a critical role in eukaryotic cell cycle progression. It acts as a crucial negative regulator of cellular proliferation when cells exit G0 or G1 phases and enter S phase [14]. The loss of the G1/S checkpoint during cell cycle progression is a common paradigm in the oncogenic transformation of human cells. Alterations in at least one of the components of the RB pathway were found in the majority of sporadic human cancers [15]. Like most human solid neoplasms, breast cancer harbours frequent alterations in the RB pathway, including over-expression of cyclins and the silencing of p16 and RB [15]. The phosphatase cell division cycle 25a (CDC25a) also seems to play an important role in cell cycle progression and in malignant transformations in breast cancer. This enzyme removes inhibitory phosphates from serine and threonine

residues of cyclin-dependent kinases (CDKs), and it has also been found to be over-expressed in breast cancer [4]. Furthermore, it was reported that this over-expression is correlated with higher levels of CDK2 enzymatic activity in vivo [4].

We analysed cyclins, CDKs involved in the RB pathway and the G2/M checkpoint at the mRNA level, to obtain an insight into breast cancer progression.

Materials and methods

Seventy-three women permanently residing in the north-eastern Italian province of Trieste, and whose first primary cancers were unilateral invasive breast carcinomas, were selected from the database of the Surgical Pathology Department of the University of Trieste. Cancers were diagnosed at the age of 45 years or older between 1971 and 1989 and were only treated with Halsted radical mastectomy and complete axillary dissection. All the slides from the diagnosed tumours were reviewed by one of the authors (G.S.). Carcinomas were histologically graded according to Elston and Ellis [5] and grouped in stages according to the *TNM Classification of Malignant Tumours*, 6th edition [9].

The cohort of women was followed through the general population-based Cancer Registry of the Province of Trieste from the diagnosis of breast cancer until death or until 31 December 2001, whichever came first [11]. No patient was lost at follow-up. During the observation period, 60 women died and all of these underwent complete autopsies at the Surgical Pathology Department of Trieste University.

Formalin-fixed paraffin-embedded specimens from primary breast cancers were used to isolate and quantify the RNA, as described in detail elsewhere [2, 17, 18]. In brief, RNAs were extracted from 6-µm sections of paraffin-embedded tissues. Ten sections were cut for each specimen. Reverse transcriptase polymerase chain reaction (RT-PCR) was performed, as previously reported [16], by using the oligonucleotides described in Table 1 for Cyclin A, Cyclin D1, Cyclin E, CDK2, CDK4, CDK6 and CDC25a genes and the amount of total RNA and the amplification program shown in Table 2. We used paraffin

Fig. 1 Quantitative determination of CDK2 expression in the case study, according to the development of recurrences during the follow-up period. *Box plot* summarises the confidence interval (lower and higher horizontal lines), 25th–50th and 75th percentiles (horizontal lines of the box)

blocks without tissues as negative controls. The basal level of expression of the genes was quantified by analysing ten normal mammary glands. RNA extracted from breast cancer cell line (BT-549) was used as a positive control. To test the reproducibility of the method, for every gene analysed we randomly selected ten samples from the case study for resubmission for RT-PCR analyses. Amplification products were quantified by dot hybridisation as previously reported [16].

One-way analysis of variance was applied to compare the mean value of the expression of each gene in cells from normal mammary glands with that of cells from breast cancers which had not developed metastases in regional lymph nodes or in other sites, and with that of cells from breast cancers which had spread into regional nodes or into other organs. The Scheffé test was used to identify statistically significant differences between these groups.

The log-rank test [10] was used to check the dependence of the survival of the women with breast cancer on the seven molecular markers, the patients’ age at diagnosis, the

Fig. 3 Quantitative determination of CDC25a expression in the case study, according to the development of recurrences during the follow-up period. *Box plot* summarises the confidence interval (lower and higher horizontal lines), 25th–50th and 75th percentiles (horizontal lines of the box)

degree of differentiation [5] and the stage of the primary tumour [9], taken one at time. Subsequently, to estimate the joint effects of the above-mentioned covariates on patients’ survival, the data were analysed by fitting the Cox proportional hazards regression model [10]. The proportional hazards assumption was evaluated according to Grambsch and Therneau [8]. In these analyses, tumours with expressions of molecular markers lower or higher than the mean value were classified as low or high status, respectively.

Statistical analyses were performed with the Stata/SE 8.0 package (Stata, College Station, TX, USA).

Results

The cohort of 73 women with breast cancer showed a median age at diagnosis of 63 years (25th–75th percentile=55–71). All of them were affected by infiltrating duct carcinoma of the breast, the diameter of which was not larger than 3.0 cm at pathological examination. The primary cancer was well differentiated in 21 women, moderately differ-

Fig. 4 Kaplan–Meier survival curves according to the presence of metastatic lymph nodes at the diagnosis

Fig. 5 Kaplan–Meier survival curves with respect to CDK2 expression level in the subgroups of low CDK2 (CDK2 expression lower than the mean value) or high CDK2 (CDK2 expression higher than the mean value)

entiated in 39 women and poorly differentiated in 14 women (Table 3). In 38 patients, the axillary lymph nodes were tumour-negative, while in 35 they were tumour-positive at the time of diagnosis of the breast cancer. The median number of tumour-positive nodes was three (range=1–15). During the period of observation, 36 patients developed distant metastases. The median duration of follow-up was 7 years (25th–75th percentile=3–8 years). Of the 60 patients who died during the follow-up period, 36 died from breast cancer metastases and 23 from non-neoplastic diseases.

For the cyclins genes, there were no significant differences between the group of patients who developed metastases and the patients who did not do so (Cyclin A, $p=0.1$; Cyclin D1, $p=0.1$; Cyclin E, $p=0.5$). For CDKs CDK2 and CDK4 the level of expression was significantly higher in women with recurrences ($p=0.005$ and $p=0.03$, respectively) (Figs. 1 and 2), while CDK6 expression showed no significant differences ($p=0.2$). A higher expression of phosphatase CDC25a was also found in

Fig. 6 Kaplan–Meier survival curves with respect to CDC25a expression level in the subgroups of low CDC25a (CDC25a expression lower than the mean value) or high CDC25a (CDC25a expression higher than the mean value)

Fig. 7 Kaplan–Meier survival curves for patients with metastatic lymph nodes at diagnosis with respect to CDK2 expression level in the subgroups of low CDK2 (CDK2 expression lower than the mean value) or high CDK2 (CDK2 expression higher than the mean value)

patients with metastases ($p=0.02$, Fig. 3). On the other hand, gene expression did not differ between women with lymph node involvement and those without node metastasis.

Women with lymph nodes positive for metastases showed a lower overall survival in comparison with those characterised by no metastasis ($p=0.002$, Fig. 4). Patients characterised by high CDK2 status presented a decreased overall survival in comparison to those with low CDK2 ($p=0.001$, Fig. 5). A similar result was found for CDC25a ($p=0.01$, Fig. 6).

The prognostic contribution of CDK2 and CDC25a combined with lymph node status was investigated in more detail. Survival analysis revealed the worst prognosis in patients with high CDK2 or CDC25a status and tumour-positive lymph nodes ($p=0.0002$, $p=0.04$, respectively; Figs. 7 and 8). The same analysis restricted to tumour-negative lymph node patients was not statistically significant ($p=0.31$ and $p=0.491$). Cox regression analysis

Fig. 8 Kaplan–Meier survival curves for patients with metastatic lymph nodes at diagnosis with respect to CDC25a expression level in the subgroups of low CDC25a (CDC25a expression lower than the mean value) or high CDC25a (CDC25a expression higher than the mean value)

Fig. 9 Survival curves related to Cox proportional hazard regression with respect to CDK2 expression level in the subgroups of low CDK2 (CDK2 expression lower than the mean value) or high CDK2 (CDK2 expression higher than the mean value)

confirmed the results obtained with the log-rank test for CDC25a and CDK2. In particular, for CDK2 the hazard ratio was 3.1 (95% confidence interval, 1.25–7.69) (Fig. 9). In the multivariate analysis of prognostic factors on survival, tumour stage, as expected, showed an independent influence on cancer-specific death. Conversely, tumour grade, age of the patient at the diagnosis and the remaining molecular markers analysed did not have an effect on survival.

Discussion

Cyclins, CDKs and CDK inhibitors are frequently deregulated in cancer. In our study carried out on 73 women with peri- and post-menopausal infiltrating duct carcinoma of the breast, the expression level of cyclin A, E and D1 at the mRNA level was higher in tumours in comparison with normal mammary glands (data not shown). However, none of these cyclins presented differences in the expression level between carcinomas characterised by recurrences and those with no recurrences.

Despite the fact that previous studies have shown some correlation between cyclin A, D and E over-expression and breast cancer development and/or progression [3, 6, 7], and despite the fact that cyclin E has been shown to be the best prognostic marker for breast cancer to date [19], we have failed to find evidence that the expression of these cyclins influences the survival probability of women with breast cancer, at least in the present study. The exact cause of this discrepancy is difficult to explain, but it may be due to a different composition of patient groups, with regard to clinicopathological parameters, and also to the different techniques employed in the studies (Western blot or immunohistochemistry). With regard to cyclin E, the existence of low and high molecular weight isoforms of this enzyme could explain our results. It seems that high levels of low-molecular-weight isoforms are the true prognostic indicators because of their influence on cell proliferation and genetic instability [1].

In our study, over-expression of CDK2 and CDK4 seems to be related to breast cancer progression during the follow-up period; moreover, CDK2 over-expression also seems to have an influence on patients' survival. It is well known that progression through the G1/S phase and the initiation of DNA synthesis, or entry to S phase, are regulated by CDKs, which are sequentially regulated by cyclins D, E and A through the formation of cyclin-CDK complexes [13]. To our knowledge, this is the first report showing that CDK2 and CDK4 could influence breast cancer prognosis, although our results are derived from only 73 women with breast cancer.

A high expression level of phosphatase CDC25a was found in breast carcinomas with recurrences and was associated with poor survival. Our findings confirm those of Cangi et al. [4]. CDC25a is involved in cellular progression at the level of the G1/S checkpoint. It dephosphorylates CDK2 at serine and threonine residues with the activation of the kinase [4].

The results presented here suggest that high expression of CDK2, CDK4 and CDC25a could represent crucial factors in breast cancer progression and could be used as prognostic biomarkers especially in those patients with positive regional lymph nodes. Furthermore, specific inhibitors of both CDC25a, CDK2 and CDK4 could be developed as possible targeted drugs.

Clinico-pathological features of a series of 11 oncocytic endocrine tumours of the pancreas

Received: 20 October 2005 / Accepted: 29 December 2005 / Published online: 21 February 2006

Abstract Oncocytic changes may occur very infrequently in neuroendocrine tumours. To estimate the prevalence, pathological features and clinical behaviour of oncocytic endocrine tumours of the pancreas, we reviewed a series of 227 lesions from two institutions. Eleven cases with predominant oncocytic features were selected, representing 4.85% of the whole series. The morphological features and immunophenotype of such tumours did not differ from conventional endocrine pancreatic tumours, except for the presence of abundant eosinophilic and granular cytoplasm. Anti-mitochondrial antigen was positive in all cases tested, and by electron microscopy, numerous mitochondria were observed in the cytoplasm of tumour cells. The majority of cases were nonfunctioning, and in most cases, pathologic signs of malignancy, leading to a diagnosis of endocrine carcinoma, were observed. In addition, the three non-malignant cases matched the criteria of well-differentiated tumours of uncertain malignant potential. Nearly 50% of the cases were clinically aggressive, and lymph node and liver metastases were present at the time of diagnosis in a minority of cases. Therefore, oncocytic endocrine pancreatic tumours represent a peculiar morphological and clinical variant characterised by frequent hormonal inactivity and malignant behaviour, which should be considered in the differential diagnosis, especially when dealing with a metastatic lesion.

Introduction

Oncocytic cells are traditionally defined by the presence of an abundant granular acidophilic cytoplasm. Such cells, also called oxyphilic or—in the thyroid gland—Hürthle cells, are rich in mitochondria, as revealed by special cytochemical stainings and ultrastructural studies [27, 39]. Non-neoplastic lesions formed of oncocytes are described in the thyroid, parathyroid, salivary and respiratory mucosal glands, whereas oncocytic tumours are more widely distributed and can be observed in all the above tissues as well as in several other organs such as the kidney and pituitary. Neuroendocrine tumours with oncocytic features are very rare, and few case reports have been published of tumours in the thyroid [16], lung [14, 21], larynx [41], stomach [5, 6] and thymus [24].

In the pancreas, although no oncocytic cells have been described in the normal endocrine component, single cases of oncocytic neuroendocrine tumours have been reported [8, 15, 28, 33, 36, 37]. In a recent report, a biphasic tumour with typical endocrine cells and oncocytes was associated with Von Hippel–Lindau disease [10]. Among these, accounting to a total of eight cases so far reported in the literature to our knowledge, all cases but one were malignant, and the majority was nonfunctioning. The functioning tumours were two insulinomas [33, 37], whereas one other reported case [36] was associated with the glucagonoma syndrome with insulin-dependent diabetes mellitus and chronic diarrhea and focal immunohistochemical positivity for insulin, glucagon and somatostatin. It is interesting that in the case reported by Chetty and co-workers [10], the oncocytic component showed widespread vascular invasion and lymph node involvement. In the recent WHO classification of tumours of endocrine organs [11], oncocytic features in endocrine pancreatic tumours are mentioned as occasional findings but not defined as a specific morphological or clinico-pathological variant.

The occurrence of pancreatic tumours composed of oncocytes is not strictly related to the neuroendocrine phenotype and may represent a pitfall in the differential diagnosis of such lesions. In fact, cases of oncocytic tumours of the pancreas lacking neuroendocrine marker expression have been described [4, 19, 32, 38, 42]. Moreover, oncocytic

changes have been described in mucinous exocrine pancreatic tumours [3], in pancreatic intraepithelial neoplasia [1] and in intraductal papillary neoplasms [20, 31]. In addition, when diagnosed as metastatic deposits in the liver, differential diagnosis with primary hepatocellular carcinoma or with metastases from oncocyctic tumours from other sites should also be considered.

To determine the prevalence of pancreatic endocrine tumours with oncocyctic features, we reviewed a series of 227 cases from our two institutions. The clinico-pathological features of the 11 selected cases are reported.

Materials and methods

Case selection

Two hundred and twenty-seven cases from the files of the Department of pathology at the University of Torino and the University of Varese were collected. Two to ten histological slides, stained in haematoxylin and eosin, were available for review. For most cases, representative paraffin blocks were also available for further histology or immunohistochemical reactions. Eleven cases showing prominent oncocyctic changes were selected. Two cases (cases 7 and 8, see Table 1) have been previously reported [33]. In one case (case 7, Table 1), only cytological material from a liver fine-needle aspiration biopsy was available. In two other cases (cases 9 and 11, Table 1), cytological material was available in adjunct to the surgical specimen. All cases were classified according to the recent WHO classification of tumours of endocrine organs [11].

Clinico-pathological data for the selected cases were collected, and follow-up information were available in all cases.

Immunohistochemistry

To confirm the endocrine nature of the tumours, serial sections coated on Superfrost (Ventana Medical Systems, Illkirch, France) slides from all 11 selected cases were stained for pan-endocrine marker chromogranin A (monoclonal, LK2H10, diluted 1:500; Biogenex, San Ramon, CA, USA) and synaptophysin (monoclonal, SP11, diluted 1:100; NeoMarker, Fremont, CA, USA), and for pancreatic (insulin: monoclonal, HB125, diluted 1:400, Biogenex; glucagon: polyclonal, pre-diluted, Biogenex; somatostatin: polyclonal, diluted 1:400, DakoCytomation, Glostrup, Denmark; and PP polyclonal, diluted 1:2,000, Dako) and ectopic (gastrin: polyclonal, pre-diluted, Ventana; calcitonin: monoclonal, undiluted, Ortho Diagnostic System, Raritan, NJ, USA) hormones in an automated immunostainer (Ventana Benchmark XT). Four cases were also stained for chromogranin B (monoclonal, B11, diluted 1:4,000, Dr. Siccardi, University of Milan, Italy).

To confirm their oncocyctic morphology, all cases but one were stained with anti-mitochondrial antigen (monoclonal, 113-1, diluted 1:75, Biogenex) [34]. Proliferation index

was evaluated by means of Ki-67 immunostaining (monoclonal, MIB-1, diluted 1:50, Dako) and counted as the percentage of positive cells/1,000 tumour cells, in the most positive areas.

Endogenous biotin blocking procedure before primary antibodies incubation was performed to prevent unspecific background [7].

Electron microscopy

Electron microscopy was performed in four cases. In case 17, tumour samples were directly fixed in Karnovsky fixative (2% paraformaldehyde and 2% glutaraldehyde in 0.05 M, pH 7.3 cacodylate buffer), while in the other three cases (9, 11 and 14), formalin-fixed wet tissues were fixed in Karnovsky fixative, post-fixed in osmium tetroxide and embedded in epoxy resin. Thin sections were stained with uranyl acetate and lead citrate and subsequently examined using a Philips Morgagni electron microscope.

Results

The main clinico-pathological features of our series of 11 oncocyctic endocrine tumours of the pancreas are summarised in Table 1.

Among our series of 227 endocrine pancreatic tumours, the 11 oncocyctic lesions represented 4.85%. The mean age was 49 years (range 30 to 70 years), and the male to female ratio was 3:8. The mean tumour diameter was 8 cm (range 1.8 to 20 cm), and most tumours were located in the body or tail of the pancreas (9 of 11). Most cases clinically presented with nonspecific symptoms such as abdominal pain or asthenia. In two cases, jaundice occurred as a sign of a mass in the head of the pancreas (cases 12 and 14, Table 1). Hypoglycemia was the main symptom in the insulin-producing tumour (case 8, Table 1). Two and five cases presented lymph node and liver metastases at diagnosis, respectively. Vascular invasion (Fig. 1) was evident in all but one case (case 13, Table 1). The mean mitotic index ($\times 10$ high power fields) was 2 (limits <1–7), and the proliferation status as evaluated by Ki-67 immunostaining was 4.2% (range 0.2 to 15%). Six patients were alive and well, three were alive with disease at the time of follow-up and the two remaining died of the disease (mean survival 68 months). As compared to the complete series, 9 of 11 (81%) were nonfunctioning (as compared to 112 of 227, 49%), and 8 of 11 (73%) were malignant (as compared to 87 of 227, 38%; χ^2 test, $p < 0.05$). In accordance with the recent WHO classification of pancreatic endocrine tumours [11], the three non-metastatic cases matched the criteria of well-differentiated tumours of uncertain malignant potential, for the size larger than 2 cm, a mitotic rate greater than 2 and the presence of vascular invasion, either alone or in combination.

The morphological features of the 11 oncocyctic tumours did not differ from those of conventional endocrine pancreatic tumours, except for the presence of abundant eosinophilic and granular cytoplasm, mild pleomorphism and large

Fig. 1 Case 16 (see Table 1). Histological aspect of the oncocytic tumour which is composed of monomorphic cells with mild nuclear atypia and abundant eosinophilic cytoplasm (a). At the periphery of tumour, neoplastic thrombi within vascular vessels lined by CD31-positive endothelial cells were found (b). Most tumour cells were positive for mitochondrial antigen (c)

ground-glass nuclei (Figs. 1 and 2); prominent nucleoli were observed in about half of the cases, being either diffusely present within the tumour or in focal areas. Predominant trabecular and pseudocanalicular growth patterns were observed, with occasional rosette-like and glandular formations. Oncocytic features were extensive in all but two cases (cases 10 and 17, Table 1), where they represented patch-like changes (covering more than one third of the tumour) in otherwise conventional endocrine tumours. By immunohistochemistry, chromogranins A and B, synaptophysin and mitochondrial antigen were positive in all cases tested. The latter antibody showed in all tumours tested the typical granular cytoplasmic pattern of staining, in the majority of tumour cells. Chromogranin A staining showed a strong and diffuse cytoplasmic positivity in one third of the cases (including the two functioning tumours), whereas a more patchy immunoreactivity was observed in the remaining cases. Synaptophysin presented a diffuse, moderate to strong cytoplasmic immunostaining in all tumours. By contrast, chromogranin B was mainly focal in the four cases tested. Concerning pancreatic hormones, insulin and glucagon were positive in the majority of tumour cells in the two functioning tumours (cases 8 and case 9, respectively; Table 1), while a focal positivity for calcitonin, pancreatic polypeptide and somatostatin was observed in case 15, 16 and 17, respectively (Table 1). Whenever available from surgical excision, lymph node and liver metastases presented the same morphological and immunocytochemical features as the corresponding primary tumour. In the three cases in which pre-operative fine-needle aspiration material from liver metastasis was available, the cytological features of tumour cells were comparable to those of the corresponding surgical samples (Fig. 2).

In the four cases examined, electron microscopy demonstrated the presence of numerous tumour cells with the cytoplasm densely packed with innumerable round or oval, sometimes distorted, mitochondria (Fig. 3). The mitochondrial structure was often abnormal, as the pattern of the cristae, forming circles, clubs, arcades, and three-dimensional tubular networks, was disturbed. Moreover, the intermembrane spaces were often distended. Occasional intramitochondrial dense inclusions could be found, especially in case 11. Secretory granules with dense cores were rare in the typical oncocytic cells. A few densely

granulated non-oncocytic cells containing small D1-type secretory granules or targetoid glucagon-type granules were found in case 11 and in cases 14 and 17, respectively.

Discussion

Tumours composed entirely or partially of oncocytic cells may occur in a variety of tissues, including endocrine and neuroendocrine ones. Most typical examples in neuroendocrine tissues are represented by oncocytic adenomas [2] and carcinomas [12] of the parathyroid and adenomas of the pituitary, where a more aggressive behaviour has been postulated by some authors [29] but not confirmed by others [30].

Neuroendocrine tumours in other organs containing dispersed neuroendocrine cells have been occasionally reported [5, 6, 14, 16, 21, 23, 41]. In the pancreas, endocrine tumours composed of oncocytic cells have been described also, either sporadic [8, 15, 28, 33, 36, 37] or associated to inherited multiple endocrine tumour syndromes such as Von Hippel–Lindau disease [10].

Although in the endocrine and neuroendocrine organs where oncocytic tumours most frequently occur (namely, thyroid, parathyroid and pituitary) no evidence exists of a peculiar clinical behaviour as compared to the non-oncocytic counterpart, most of the above-mentioned reported cases, especially those described in the pancreas, clinically showed a malignant behaviour. Therefore, we aimed to review a large consecutive series of endocrine pancreatic tumours, searching for oncocytic morphological changes, and to determine peculiar clinico-pathological features of oncocytic lesions. Of the 11 oncocytic cases selected in a series of 227 endocrine pancreatic tumours (representing 4.85%), eight cases were classified as carcinomas, presenting lymph node, liver or visceral metastases at the time of diagnoses, and five cases had an aggressive clinical behaviour, such that the patients are either alive with disease or had died of the disease at time of follow-up.

Mostly investigated in the thyroid gland, oncocytic changes are driven by several molecular defects in mitochondrial DNA, and alterations in mitochondrial metabolism have been detected in oncocytic cells and related tumours, including over-expression of regulatory proteins [13], mutations and/or deletions of mitochondrial DNA and

Fig. 2 Case 9 (see Table 1). CT scan (**a**) revealed a mass in the tail of the pancreas (*arrow*) infiltrating the spleen, with multiple liver metastases; an ill-defined, whitish, dys-homogeneous lesion was observed at macroscopic examination (**b**), with focal areas of haemorrhage and necrosis. Cytological sample of a liver metastasis by fine needle aspiration showed the presence of neoplastic cells with abundant cytoplasm (**c** and **d**), positive for Chromogranin A by immunohistochemistry (**e**). In the surgical sample, the lesion infiltrated the spleen parenchyma (**f**) and was composed of atypical tumour cells similar to those in the cytological sample, in a solid/trabecular growth pattern (**g**). Tumour cells were strongly reactive by immunohistochemistry for glucagon (**h**) and anti-mitochondrial antigen (**i**)

cytochrome C oxidase deficiency [22, 25, 26]. Very recently, mutations in the GRIM-19 gene, a member of the interferon-beta and retinoic-acid-induced pathway of cell death, have been detected in oncocytic thyroid tumours [23]. In different organs, where tumours bearing oncocytic features have been described (namely, kidney and salivary gland), such features are constantly associated with a more benign behaviour, a phenomenon which was interpreted as related to the slow proliferation rate and to the long time

required for the process of cytoplasmic accumulation of mitochondria, necessary for acquiring the oncocytic phenotype [40]. The prevailing aggressiveness associated to the occurrence of oncocytic features in endocrine tumours of the pancreas (overall 13 of the 17 cases, including the present series and those reported in the literature) is, therefore, surprising and still unexplained.

It should be noted that, probably as a consequence of late diagnosis due to the absence of specific symptoms of

Fig. 3 Ultrastructural feature of an oncocyctic cell (case 17) showing numerous packed mitochondria in the cytoplasm (original magnification $\times 14,000$)

hormonal secretion, most of the lesions here reported presented with a large tumour size which, in endocrine pancreatic tumours, is related to a more aggressive behaviour. Moreover, it is interesting that both small tumours of our series did not relapse. Therefore, the possibility that the malignant phenotype in oncocyctic endocrine pancreatic tumours could be related to the late diagnosis and advanced stage in most tumours cannot be excluded.

Another interesting observation concerns the hormonal profile of such tumours. In agreement with the majority of previously published cases, all but two cases of our series were clinically nonfunctioning, thus explaining the delay in their clinical and nonspecific onset and the large mean tumour size (8 cm). The metabolic alterations, particularly in the energetic machinery, that characterise oncocyctic cells may be responsible for the deficiency in hormone production of such lesions, but functional data *in vivo* would be needed to clarify this aspect.

No other peculiar clinical or morphological features were observed, being both the location and the histological growth patterns comparable to conventional non-oncocyctic pancreatic endocrine tumours.

In the pancreas, oncocyctic changes are not restricted to neuroendocrine tumours. In most instances, tumours with oncocyctic features are well-defined entities, such as mucinous exocrine pancreatic tumours [3], pancreatic intraepithelial neoplasia [1], intraductal papillary neoplasms [20, 31], thus, not representing difficulties in their differential diagnosis. However, oncocyctic carcinomas, lacking neuroendocrine markers of differentiation or neurosecretory granules by electron microscopy, with predominant solid growth patterns and tumour cells with abundant eosinophilic cytoplasm have been observed and may represent a diagnostic problem [4, 19, 32, 38, 42]. These neoplasms must be distinguished from oncocyctic endocrine tumours because of their more aggressive behaviour. Another possible pitfall in the differential diagnosis with oncocyctic endocrine tumours is represented by pancreatic acinar cell carcinoma, composed of tumour cells with abundant eosinophilic cytoplasm arranged in a solid-trabecular, pseudo-glandular growth. By electron microscopy, the granularity of the cytoplasm is due to abundance of zymogen-like granules rather than mitochondria, but the occurrence of

focal expression of neuroendocrine markers in about one third of the cases of acinar cell carcinoma [17] may lead to misdiagnoses. The presence of atypical large nuclei with prominent nucleoli, periodic acid–Schiff-positive cytoplasmic granules and immunoreactivity for trypsin and lipase all favour the diagnosis of acinar cell carcinoma. Conversely, a diffuse immunoreactivity for general endocrine markers, including synaptophysin and chromogranins and/or specific pancreatic hormones, combined with less atypical nuclear features, points to a diagnosis of an endocrine neoplasm. A further pancreatic primary tumour which may show prominent oncocyctic features and enter in the differential diagnosis with oncocyctic endocrine tumours is pancreatoblastoma, where an endocrine component is recognisable in a high percentage of cases [18]. Age is one of the major helpful criterion to differentiate pancreatoblastoma from endocrine tumours because the latter are very rare in the first decade of life. In addition, the presence of squamoid nests, acinar structures and the reactivity for α -fetoprotein support the diagnosis of pancreatoblastoma. Finally, the recently described pancreatic endocrine tumours with “rhabdoid” features [9] may mimic oncocyctic endocrine tumours because of the abundance of eosinophilic cytoplasm of their cells, due to the presence of characteristic inclusion formed by aggregates of intermediate filaments. Immunohistochemistry can help in differentiating “rhabdoid” tumours from oncocyctic endocrine neoplasms, as the former show a typical paranuclear dot-like or globular immunoreactivity for cytokeratin AE1/3. Moreover, ultrastructurally, rhabdoid tumours are characterised by juxtannuclear deposition of aggregates of intermediate filaments, corresponding to the globular cytokeratin immunoreactivity, while oncocyctic tumours are characterised by the presence of abundant mitochondria.

In three of our cases, a preoperative diagnosis was made on a liver fine-needle aspiration biopsy. In such cases, additional differential diagnoses should be taken into account, from primary hepatocellular carcinomas (namely, the fibrolamellar variant) to other oncocyctic neoplasms metastatic to the liver (among them gastrointestinal hepatoid carcinomas, oncocyctic carcinomas from various sites or even soft tissue tumours or melanomas with prominent eosinophilic features) [35].

In conclusion, oncocyctic endocrine pancreatic tumours represent a peculiar morphological and clinical variant of endocrine pancreatic tumours, characterised by oncocyctic features comparable to those of oncocyctic tumours from other sites, by frequent hormonal inactivity and malignant behaviour. When looking at a metastatic oncocyctic tumour and looking for the possible organ of primary origin, the pancreas should be considered among the alternatives.

Pancreatic malignant fibrous histiocytoma, inflammatory myofibroblastic tumor, and inflammatory pseudotumor related to autoimmune pancreatitis: characterization and differential diagnosis

Received: 24 November 2005 / Accepted: 10 January 2006 / Published online: 15 March 2006
© Springer-Verlag 2006

Abstract Malignant fibrous histiocytoma (MFH) and inflammatory myofibroblastic tumor (IMT) are uncommon primary non-epithelial cell tumors of the pancreas. In addition, there are inflammatory pseudotumors (IPT) that may arise in the course of autoimmune pancreatitis (AIP). In the English language literature, only 24 cases of IMT and nine cases of MFH in the pancreas have been reported to date. We investigated three individual spindle cell tumors of the pancreas that were identified as MFH, IMT, and IPT, respectively, using immunohistochemical and molecular analysis. Both the MFH and the IMT, but not the IPT, showed nuclear p53 expression and mutations of the *p53* gene. The MFH and the IMT also had higher mitotic and Ki-67 (MIB-1) indexes than the IPT. The IPT was found to be a tumor-like case of AIP. Many IgG4-positive plasma cells, which are considered to be a feature of AIP, were found in all three tumors. It is concluded that in this series of spindle cell tumors of the pancreas, apart from immunohistochemical features, the demonstration of *p53* mutations may be helpful in distinguishing true neoplastic tumors from pseudotumors such as IPTs arising in the context of AIP.

Keywords Pancreatic tumor · Malignant fibrous histiocytoma · Inflammatory myofibroblastic tumor · Autoimmune pancreatitis · *p53* mutation

Introduction

Malignant tumors of the pancreas are mostly of epithelial origin, predominantly ductal adenocarcinomas. Non-epithelial malignant tumors of mesenchymal origin are extremely rare and account for only 0.6% of the cases [4, 25]. The most common among the latter are leiomyosarcomas, liposarcomas, neurogenic sarcomas (schwannomas or peripheral neuroectodermal tumors), and malignant lymphomas [25, 43]. These tumors may cause difficulties in the differential diagnosis, even after extensive immunohistochemical analysis [25, 43]. In particular, in tumors with a spindle cell pattern, it may be difficult to distinguish malignant fibrous histiocytomas (MFH) (now often called myxofibrosarcomas [11]) from inflammatory myofibroblastic tumors (IMT) or inflammatory pseudotumors (IPT), but this distinction is crucial for predicting the prognosis and selecting the proper treatment [7, 11, 43].

In the pancreas, so far, only nine cases of MFH [1, 3, 12, 14, 23, 26, 27, 33, 46] and 24 cases of IMT [2, 8, 10, 17, 20, 24, 28, 31, 32, 34–36, 39, 41, 42, 44, 47, 48, 50, 52] have been reported in the English language literature. Furthermore, IPT and IMT have often been used synonymously [10, 48, 50], though they can differ in their pathogenesis [29, 30]. We recently encountered representative cases of primary MFH, IMT, and IPT. On these cases, we conducted immunohistochemical and gene mutational analyses which, we believe, provide valuable clues for the characterization of these tumors and important information for the differential diagnosis. We will also discuss the relation of IPT to autoimmune pancreatitis (AIP).

Patients' histories

Case 1

A 44-year-old woman was admitted to the hospital in May 2003 with a mass in the left upper abdomen and epigastralgia. She had a history of uterine cervical cancer (early stage) that had been successfully operated on 4 years earlier. Blood tests revealed mild anemia and slightly elevated levels of the tumor marker immune-suppressor acid protein (IAP) (521 $\mu\text{g/ml}$, normal $<500 \mu\text{g/ml}$). C-reactive protein (1.1, $<0.3 \text{ mg/dl}$) was elevated, but immunoglobulins were not examined. Liver function tests and pancreatic enzymes were normal and there was no elevation in markers of cholestasis (alkaline phosphatase, bilirubin, etc). Ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI) revealed a tumor mass in the dorsal area of the stomach and enlarged peripancreatic and para-aortic lymph nodes. The latter lymph nodes appeared to obstruct the left ureter, causing hydronephrosis. Angiography results revealed that the tumor originated from the pancreas. A creatinine clearance test for 24 h showed dysfunction of the kidney. Administration of Ga-diethylenetriamine pentaacetic acid (DTPA) did not result in enhancement of the mass. A malignant pancreatic tumor with lymph node metastasis was diagnosed and the tumor and a lymph node were resected. However, as the tumor adhered firmly, radical resection was not achieved. After the operation, the patient received extensive chemotherapy. During a follow-up period of 20 months, there was no recurrence.

Case 2

A 64-year-old male was admitted to the hospital in October 1995 for left lower thoracic pain at inspiration and an abdominal mass in the left upper abdomen. His past history was not informative. A blood test revealed mild anemia and elevated serum amylase (269, 50–228 IU/l), elastase (470, 100–400 ng/dl), and IAP (739, $<500 \text{ mg/ml}$). Liver function tests were normal, and there was no sign of bile duct stenosis. Immunoglobulin was not examined. US, CT, and MRI results revealed a well-circumscribed homogeneous mass originating in the pancreas body. After administration of Ga-DTPA, the area surrounding the mass was enhanced. Endoscopic retrograde pancreatography showed an irregular stricture of the pancreatic duct in the body. A pancreatic carcinoma was suspected and a resection of the tail and body of the pancreas was performed. No metastasis was found during operation. Five years after the operation, the patient is disease-free.

Case 3

A 40-year-old male was admitted to the hospital with epigastric pain and fever. He had been free of disease until this event. He had noticed thirst, polydipsia, and weight loss for the last 6 months and was found to have diabetes and acute hepatitis. Two months later, he developed jaundice, general fatigue, epigastric pain, and restlessness. He was referred to our hospital and diagnosed as having a pancreatic mass and acute obstructive cholangitis. Laboratory data revealed marked anemia, leukocytosis, elevated levels of bilirubin, bile tract markers, CA19-9 (41.3, $<37 \text{ IU/ml}$), and serum ferritin (941, 25–280 ng/ml). Immunoglobulin was not examined. Abdominal ultrasound and CT results disclosed a large low-density mass in the head of the pancreas with diffuse swelling of the body. A diagnosis of pancreatic carcinoma was made clinically and a Whipple procedure was performed.

After the operation, the patient suffered from diabetes, which was controlled by insulin injection. However, 8 months after the operation, his general condition worsened and he died. An autopsy was not performed.

Materials and methods

Tissues

Specimens from the pancreatic tumors were fixed in 10% formalin and processed to obtain 4- μm paraffin sections that were stained with hematoxylin and eosin, Azan, silver, elastica van Gieson, periodic acid–Schiff, and alcian blue.

Immunohistochemistry

For immunohistochemistry, the standard streptavidin–biotin technique was applied. The list of antibodies used and their sources as well as staining conditions are summarized in Table 1. Negative control stains were performed by omitting the primary antibodies or substituting nonimmune rabbit or swine sera. The number of cells showing nuclear staining for p53 and Ki-67 (MIB-1) was determined in areas with high cellularity and recorded as the number of positive cells per 100 tumor cells.

Genetic analysis

For the detection of *p53* and *K-ras* mutations, genomic DNA was extracted from sections cut from paraffin-embedded tissue blocks. Briefly, the sections were depar-

affinized with xylene, washed with 100% ethanol, and subsequently dried. Tumor tissue was scratched off the slides with a fine needle. DNA was extracted and purified with DNAeasy extraction kits (QIAGEN, Valencia, CA, USA). Polymerase chain reaction (PCR) was performed as previously described [37]. PCR Amplicon was ligated to the vector with a TOPO cloning kit (Invitrogen, Carlsbad,

CA, USA). After blue–white selection, purified vector was digested with *EcoRI*. An about 100-bp insert clone was loaded onto a 3% agarose gel. The positive clone was amplified using a VIC dye sequence kit (Applied Biosystems, Foster City, CA, USA) and a purified Qiagen kit. Direct sequencing was carried out with a Perkin Elmer ABI Prism 310 sequence analyzer (Applied Biosystems).

Results

Pathological findings

Case 1

The left-sided pancreatectomy specimen contained a well-encapsulated, light yellowish firm mass measuring 8.3×5.6×6.0 cm (Fig. 1a). Microscopic spindle- to oval-shaped tumor cells mixed with variable numbers of polymorphic or multinucleated giant cells were arranged in a storiform pattern (Fig. 2a). There were some areas with high cellularity, and atypical mitoses were also seen. Lymphocytes, plasma cells, and eosinophils infiltrated within the tumor area (Fig. 2b). There were areas of stromal myxoid changes, but no necrosis or hemorrhage was found. The resected lymph node revealed a metastasis of the pancreatic tumor.

Case 2

The left-sided pancreatectomy specimen contained a light yellowish firm mass in the pancreatic body measuring 10.0×9.0×8.5 cm (Fig. 1b). The tumor consisted of mainly

Fig. 1 Macroscopic appearances of pancreatic MFH (case 1) (a) and IMT (case 2) (b). Both tumors show large expansive masses with a fibrous capsule. On cut surface, they are multinodular and whitish with some yellow areas

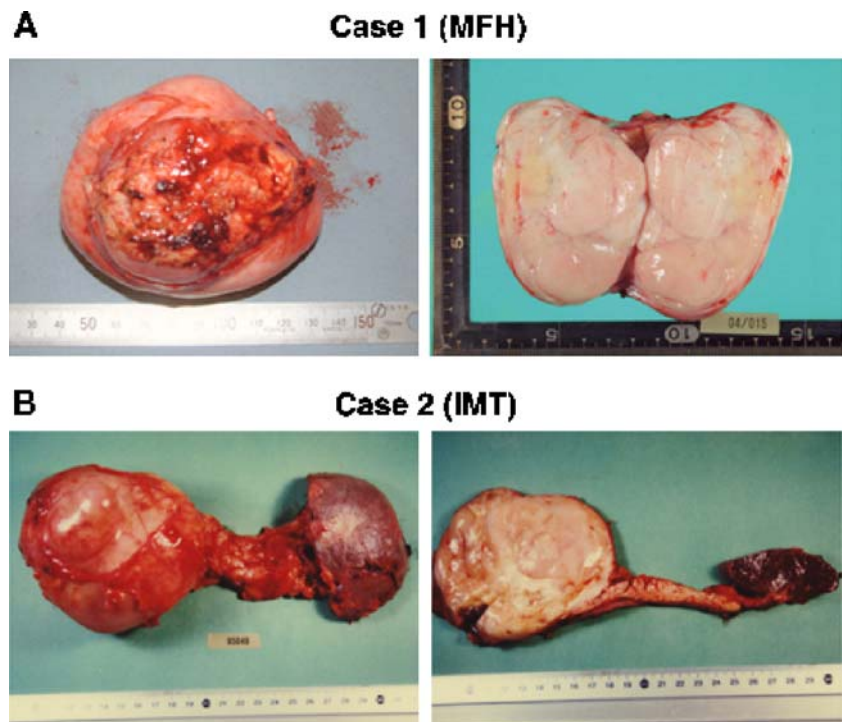

Fig. 2 Light microscopic appearances of pancreatic MFH (case 1), IMT (case 2), and IPT (case 3). Case 1: the low power view shows a diffuse eosinophilic fibrous area mixed with sporadic lymphoid aggregates (a). The high power view shows haphazardly oriented large pleomorphic cells with a typical storiform-like growth pattern (b). Case 2: the low power view shows conspicuous inflammatory changes occupying a large area (c). Some atrophic exocrine tissues are visible. The high power view reveals spindle cells admixed with eosinophilic and lymphoid cells (d). Case 3: the low power view shows a large inflammatory area with marked proliferation of spindle cells adjacent to atrophic exocrine tissues (e). In the high power view, spindle cells show nuclear enlargement and pleomorphism growing with a typical storiform pattern mixed with inflammatory cells (f)

microscopic spindle- to oval-shaped cells arranged in a storiform pattern. There were scattered polymorphic or multinucleated cells (Fig. 2c,d), but nuclear polymorphism was less than in case 1. Mitoses were not found. The stroma was rich in collagen, and there was extensive lymphoplasmacytic infiltration.

Case 3

The Whipple resection specimen contained a mass 7.5×3.6×2.0 cm in size in the head of the pancreas. The

tumor had a hard consistency and its cut surface was solid, lobulated, and relatively well circumscribed. The normal pancreatic tissue was replaced by a meshwork of microscopic spindle-shaped fibroblastic cells arranged in a storiform pattern and some foamy histiocytes (Fig. 2e). The spindle cells showed nuclear enlargement and hyperchromatism (Fig. 2f). Mitoses were not found. Detailed examinations of the tumor and its surrounding pancreatic tissue revealed features of autoimmune pancreatitis, such as periductal lymphoplasmacytic infiltration or venulitis. The lymphoplasmacytic infiltration extended into the pancreatic parenchyma, replacing most of the acinar cells

Table 2 Clinicopathological features of the three tumors

	Case 1	Case 2	Case 3

Fig. 3 p53 and MIB-1 expression in pancreatic MFH (case 1), IMT (case 2), and IPT (case 3). Case 1: large pleomorphic tumor cells show positive reactions to p53 at a level of 25% (a). They also show a high level (19%) of MIB-1 expression (b). Case 2: similar to Case 1, the tumor cells show strong p53 positivity in some areas reaching 9% (c). They also show high MIB-1 index up to 7% level, but the reaction is less intense compared to case 1 (d). Case 3: in contrast to the above cases, p53 is negative (e). The MIB-1 index is also very low (<1%) (f)

and encasing medium-sized ducts. Mild inflammatory changes were also seen in the bile duct wall, the gallbladder, and the ampulla of Vater.

All clinicopathological features are summarized in Table 2.

Immunohistochemistry

Table 1 summarizes the immunohistochemical results. In case 1, spindle cells and pleomorphic cells showing a storiform pattern were positive for vimentin but negative for epithelial, muscle, neural, adipocytic, or lymphoma markers as well as anaplastic lymphoma kinase (ALK) and

Fig. 4 Direct sequencing of the p53 gene. In case 1, there are two point mutations at codon 238 and 272. In case 2, a point mutation at codon 294 is detected

SP Storiform–pleomorphic, ND not described, NED no evidence of death

^aCases accompanied with mucinous cystic tumors are excluded

CD34. Between the tumor cells, there were CD68 positive macrophages. The tumor cells showed frequently positive for p53 to an extent of 25% level (Fig. 3a). The MIB-1 index of the tumor cells was 19% of the cells (Fig. 3b). In case 2, the spindle cells were also positive for vimentin and negative for epithelial, neural, and lymphoma markers, including ALK and follicular dendritic cell markers. Single spindle cells were positive for smooth muscle actin (SMA) and HHF35 but negative for CD34. They were positive for p53 at a level of 9% and the MIB-1 index was 7% of the cells (Fig. 3c,d). CD68 positive macrophages were present. In case 3, the spindle cells were positive for vimentin but negative for CD34, cytokeratin, EMA, S-100, myoglobin, or desmin. P53 was negative (Fig. 3e). The MIB-1 index was less than 1% (Fig. 3f).

Scattered IgG4-positive plasma cells were consistently detected in all three cases but most conspicuous in case 3.

Genetic analysis

Because nuclear p53 expression was found in cases 1 and 2, direct DNA sequencing for *p53* exon 5–8 was carried out (Fig. 4). In case 1, two point mutations were detected: G-to-A transversion at codon 238, resulting in an amino acid change from cysteine to tyrosine, and T-to-C transversion at codon 272, resulting in an amino acid change from valine to alanine. In case 2, one point mutation was found, G-to-T transversion at codon 294, resulting in an amino acid change from glutamate to aspartate. On the other hand, the tumors in both cases 1 and 2 carried a wild-type *K-ras* oncogene.

Discussion

In this study, we analyzed the immunohistochemical and molecular features of three pancreatic tumors that shared a microscopic spindle-cell pattern with abundant collagen

production admixed with inflammatory cells. This analysis revealed that individual features of the three tumors allowed them to be typed as MFH, IMT, and AIP-associated IPT.

The first step in the investigation of these tumors was to distinguish them from undifferentiated carcinomas, which may show a sarcomatoid pattern [16, 43]. As our tumors were negative for cytokeratin, this possibility could be easily excluded. The next tumor to be ruled out was a sarcomatous nodule in association with a mucinous cystic neoplasm [49, 53]. We, therefore, examined multiple sections but failed to find any evidence of a cystic lesion. The diagnoses we finally considered were MFH, IMT, and IPT.

The diagnosis of MFH, which was made in the first patient, was based on the tumor's microscopic features (i.e., anaplastic spindle cells arranged in a storiform pattern), its sole positivity for vimentin, and the immunohistochemical exclusion of any other tumor, such as malignant peripheral nerve sheath tumor, by the negativity for the respective tumor markers. So far, only nine cases of MFH of pancreatic origin have been reported [1, 3, 12, 14, 23, 26, 27, 33, 46] (Table 3). A review of these cases revealed that their features compare well with those of our case. In addition, we detected nuclear p53 expression and a *p53* mutation. This finding is in accordance with the 35% positivity rate for nuclear p53 expression recently reported in MFHs of various origins [9]. In our case, the demonstration of a *p53* mutation clearly established the neoplastic nature of the tumor and distinguished it from any non-neoplastic pseudotumor.

In the second patient, we diagnosed an IMT. This is a low-grade tumor composed of fibroblasts and myofibroblasts in association with inflammatory cells, whose molecular pathogenesis was partially elucidated recently. In approximately 50% of IMTs, various gene aberrations including the anaplastic lymphoma kinase gene at chromosome 2p23 have been identified [13, 15, 32, 38, 45]. In our case, no ALK gene abnormality was found. However,

IPT Inflammatory pseudotumor, *IMT* inflammatory myofibroblastic tumor, *AIP* autoimmune pancreatitis, *NA* not available, (sex) *F* female, *M* male, (follow-up) *M* months, *Y* years

an ALK gene abnormality is more often seen in children or young adults than in elderly people. This may explain why we did not detect an ALK gene abnormality in our case [6, 22]. The diagnosis of an

IMT was, therefore, based on the microscopic diagnostic criteria such as fasciitis-like, fascicular, and sclerosing areas with a prominent chronic inflammatory infiltrate. In addition, we found nuclear p53

expression and a *p53* mutation, findings that have also been reported in IMTs [51].

In the third patient, the tumor expressed neither SMA, S100 and CD34 nor nuclear *p53*. Together with its histological features, we concluded that the tumor represented an IPT. IPTs that arise in the course of AIP must be clearly distinguished from MFHs or IMTs, considering their different pathogenesis and therapy (i.e., its treatment with steroids). However, many previous reports of IMTs in the pancreas did not give any consideration to IPTs arising in the course of AIP (Table 4). Judging from the published illustrations and the descriptions, we believe that many previous cases of IMTs and IPTs arose in the setting of AIP [2, 8, 10, 17, 19, 20, 24, 28, 31, 32, 34–36, 39, 41, 42, 44, 47, 48, 50, 52] (see Table 4).

IMTs and IPTs associated with AIP have many clinicopathological features in common. First, both are mass-forming lesions which commonly focus on the pancreas head and cause obstructive jaundice. Therefore, such patients are often suspected to suffer from pancreatic ductal adenocarcinoma [18, 19]. Second, involvement of the distal bile duct, as reported in many IMTs, is a common finding in patients with AIP [18, 19]. Third, a lymphoplasmacytic infiltrate and myofibroblasts arranged in a storiform pattern are seen in both lesions [10, 26, 48, 50].

It has been reported that IgG4-positive plasma cells are abundant in AIP which help to establish its diagnosis [18, 54]. In this study, the demonstration of IgG4-positive plasma cells was not useful for the differential diagnosis as these cells were also found in both the MFH and the IMT. Nevertheless, constant presence of IgG4 cells in these tumors might indicate non-incidental occurrence of mesenchymal tumors with background of AIP.

In summary, we report three cases of tumorous spindle cell lesions of the pancreas, two of which were found to be neoplasms and the other an inflammatory process. *p53* expression and gene mutation provided an important clue for distinguishing the two true neoplasms from the pseudotumor.

Solid–pseudopapillary neoplasms of the pancreas in men and women: do they differ?

Received: 9 January 2006 / Accepted: 6 February 2006 / Published online: 8 March 2006
© Springer-Verlag 2006

Abstract Solid–pseudopapillary neoplasms (SPNs) of the pancreas are uncommon and occur preferentially in young women. The question whether the features of SPNs occurring in men differ from those in women has not yet been studied. For a better understanding of the clinicopathological features of SPNs of both sexes, we studied a series of 14 tumors surgically resected at a Japanese hospital within a period of 14 years. This series was composed of seven men and seven women. All these SPNs demonstrated nuclear and cytoplasmic accumulation of β -catenin protein in immunohistochemistry and 86% of them had activating mutations of β -catenin gene. No pancreatic neuroendocrine tumors showed such immunohistochemical findings and genetic alterations. In our series, most SPNs in women showed encapsulation by thick fibrous tissue and massive degenerative changes. Most SPNs in men exhibited solid components without prominent degenerative changes, even though they were of a similar size to those in women. These findings suggest that SPNs in men tend to be a solid mass with slower progression of degenerative changes during their growth compared to that in women. Nuclear accumulation of β -catenin appears to be a useful marker of SPN, which allows male SPNs to be correctly diagnosed despite their less typical features.

Keywords Solid–pseudopapillary neoplasm of the pancreas · β -Catenin · Sex distribution

Introduction

Solid–pseudopapillary neoplasm (SPN) of the pancreas is a distinctive but uncommon neoplasm which is classified as a tumor of the exocrine pancreas according to the World Health Organization (WHO) tumor classification system [12]. It is known to occur preferentially in young women and has a favorable prognosis [9, 10, 23]. The clinicopathological characteristics of SPN have been well described in recent years [9, 23], although it remains uncertain if the features of SPNs occurring in men differ from those in women.

It can be difficult to differentiate between SPN and other pancreatic neoplasms especially pancreatic neuroendocrine tumor (PET) as these two can share morphological features, such as solid monomorphous growth and rosette-like structures. In addition, a SPN often expresses neuroendocrine markers, such as synaptophysin, neuron-specific enolase (NSE), and CD56 [3, 9, 13, 16, 23]. In fact, there are many reported cases of SPN being initially misdiagnosed as PET [2, 4, 8, 16]. However, an accurate distinction between SPN and PET is important because SPN is generally curable, even though it may present as a huge, locally invasive tumor with or without multiple metastases.

β -Catenin is a submembranous component of the cadherin-mediated cell adhesion system and is a downstream transcriptional activator in the Wnt signaling pathway. Mutations of β -catenin have been reported in various tumors [21]; these are thought to cause stabilization of β -catenin leading to constitutive activation of TCF/LEF-1-dependent transcription [7, 20]. Genetic studies have recently shown that neither ductal adenocarcinomas nor PETs are associated with mutations in the β -catenin gene [5], whereas Tanaka et al. [25, 26] and Abraham et al. [1] demonstrated that aberrant accumulation of β -catenin protein in the tumor cell nuclei and activating β -catenin

oncogene mutations occurred in almost all of the SPNs they tested. They concluded that almost all SPNs show alterations in the adenomatous polyposis coli (APC)/ β -catenin pathway, even though K-ras, DPC4, and P-53 do not play a major role in the neoplastic progression of SPN [1].

To understand the clinicopathological characters of SPNs between the genders, we re-evaluated all pancreatic tumors (except ductal adenocarcinomas) that had been surgically resected at a single institution using immunohistochemical and genetic analyses for β -catenin alterations in addition to conventional histopathological examination. There were 14 SPNs identified from seven women and seven men and we investigated their clinicopathological features.

Materials and methods

Case selection

This study was approved by the Ethics Committee of the National Cancer Center, Japan. The study population consisted of 14 Japanese patients with pancreatic SPN who underwent surgical resection at the National Cancer Center Hospital, Tokyo, Japan between 1991 and 2004. Information on age, sex, the location of the tumor within the pancreas, and the presence or absence of distant metastases was retrieved from the patients' medical records. The patients' tumor samples, which had been fixed in 10% buffered formalin and embedded in paraffin, were retrieved from the archive. For histopathological examinations of the tumor tissues, 4- μ m sections were prepared and stained with hematoxylin and eosin (HE). In addition to conventional histopathological observations, the following pathological factors were carefully examined: encapsulation of the tumor, presence or absence of calcification or ossification in the tumor, and counts of mitotic figures in tumor cells per ten high-power fields (HPFs) on microscopy.

As controls, clinical data and archive samples for 15 patients with PET were also retrieved. All 15 had undergone curative resection at the same hospital over the same time period. The PET patients were aged 18 to 81 years (median, 58 years) and none had hormonal symptoms. Their tumors comprised three benign, well-differentiated endocrine tumors, five well-differentiated endocrine tumors of uncertain biological behavior, and seven well-

differentiated endocrine carcinomas according to WHO classification criteria [22]. Tumor size ranged from 1 to 8 cm in diameter (median, 3.6 cm).

Immunohistochemistry

Immunohistochemical staining was performed on the formalin-fixed, paraffin-embedded tissues using the avidin-biotin complex method. In brief, 4- μ m-thick sections of representative blocks were deparaffinized and rehydrated using an alcohol gradient. After blocking endogenous peroxidase with methanol containing 0.3% H₂O₂, the sections were autoclaved at 121°C for 10 min in citrate buffer (10 mM sodium citrate, pH 6.0) for antigen retrieval. After blocking with normal goat serum, the sections were reacted overnight with appropriately diluted primary antibodies (listed in Table 1). The sections were then sequentially reacted with biotin-conjugated anti-mouse or anti-rabbit immunoglobulin G antibodies (Vector Laboratories, Burlingame, CA, USA) and Vectastain Elite ABC reagent (Vector Laboratories). Diaminobenzidine was used as the chromogen, and the nuclei were counterstained with hematoxylin.

Semiquantitative assessments of the immunohistochemical results (except for Ki-67) were obtained by calculating the histoscore (multiplying the percentage of positive cells by their staining intensity) [6]. Scores for the percentages of positive cells were evaluated as follows: 0, <5% labeled cells; 1, 5–30% labeled cells; 2, 31–70% labeled cells; and 3, >71% labeled cells. Islet cells were used as an internal positive control; the intensity of immunolabeling of the tumor cells was compared to that of the islet cells in an adjacent nontumor area, and the labeling intensity of the tumor cells was evaluated as follows: 0, negative; 1, weaker than the intensity of islet cells; 2, equal intensity to that of islet cells; and 3, stronger intensity than that of islet cells. Multiplying the score for the percentage of positive cells by the score for the intensity of immunolabeling then gave overall staining scores as follows: –, 0; 1+, 1 or 2; 2+, 3 or 4; and 3+, 6 to 9. The Ki-67 labeling index (LI) was determined by counting a minimum of 1,000 nuclei in the most densely positively stained areas [19]. Three different counts were performed for each sample, and the highest score was taken as the index value.

Table 1 Primary antibodies used in the immunohistochemical study

Antigens (clone names)	Host species	Working dilution	Source
Chromogranin A (poly)	Rabbit	1:400	DAKO (Glostrup, Denmark)

DNA extraction, polymerase chain reaction, and sequencing analysis of the β -catenin gene

Mutation analysis of the β -catenin gene was performed as previously described [21]. The samples were fixed with 10% (*v/v*) formalin and embedded in paraffin. Four-micrometer-thick sections from each specimen were stained briefly with HE, and DNA was extracted as follows. The tumor areas were microdissected separately using a sterile toothpick under a microscope. Adjacent non-tumor tissue was dissected separately as a control. Three PETs were also dissected in the same way. The dissected samples were incubated in 200 μ l DNA extraction buffer [50 mM Tris-HCl, pH 8.0, 1 mM ethylenediaminetetraacetic acid (EDTA), 0.5% (*v/v*) Tween-20 and 200 μ g/ml proteinase K (Roche Diagnostics, Mannheim, Germany)] at 56°C overnight, then the proteinase K was inactivated by heating at 100°C for 10 min. The extracted genomic DNA was purified by phenol extraction, dissolved in 20 μ l TE buffer (10 mM Tris-HCl, pH 8.0, and 1 mM EDTA), and subjected to polymerase chain reaction (PCR) with a pair of primers that encompassed codons 22–63 of exon 3 of the β -catenin gene. This region includes the glycogen synthase kinase-3 β (GSK-3 β)-phosphorylation sites. The structures of the forward and reverse primers were CT-S-F (5' ATGGAACCAGACAGAAAAGCG-3') and CT-S-R (5' CAGGATTGCCTTTACCACTCA-3'), respectively [21]. PCR was performed under the following conditions: 3 min at 94°C for initial denaturing, followed by 35 cycles at 94°C for 30 s, 55°C for 30 s, and 72°C for 30 s, and a final extension at 72°C for 3 min. The PCR products were checked by agarose gel electrophoresis and purified using a QIAquick PCR Purification Kit (QIAGEN, Hilden, Germany). The isolated PCR products were directly sequenced with the CT-S-F primer using the ABI Prism 3100 Genetic Analyzer system (Applied Biosystems, Foster City, CA, USA) according to the manufacturer's instructions. Mutated sequences were sometimes not

clearly detected, in which case we subcloned the PCR products into a TA vector (TOPO TA Cloning Kit, Invitrogen, Carlsbad, CA, USA) and sequenced the PCR products from their subcloned plasmids, extracted from at least 30 different clones. Each experiment, including DNA extraction, was performed at least twice.

Results

We tested the usefulness of β -catenin immunohistochemistry in differentiating between SPN and PET. We initially identified ten patients (seven women and three men) with SPNs from our pathology files (Table 2, patients 1–7, 8, 9, and 13). Preliminary immunohistochemical studies revealed nuclear accumulation of β -catenin protein in the tumor cells in all ten of these SPNs, whereas it was not observed in the 15 PET controls. We then re-evaluated all pancreatic tumors (except ductal adenocarcinomas) that had been surgically resected at the National Cancer Center Hospital, Tokyo, Japan between 1991 and 2004 (a total of 514 pancreatic tumors when ductal adenocarcinomas were counted). At first, we evaluated them by conventional histopathological examination and identified 14 SPNs which included ten cases previously diagnosed as SPNs and four suspected cases. It was easy to differentiate these ten SPNs from PETs by their characteristic cellular and structural findings. Four tumors being suspected SPN, which had initially been diagnosed as PETs, in four male patients revealed solid proliferation of the uniform polygonal cells with round to oval and indented nuclei arranged in sheets with an abundant microvasculature, though there were no prominent degenerative changes including cystic degeneration and pseudopapillary structure. These findings were consistent with the features of SPN, whereas these tumors did not have any apparent features of PETs such as characteristic trabecular or gyriform growth pattern that was usually seen as minor

Table 2 Clinicopathological findings in 14 patients with SPNs

component even if the tumor showed predominantly solid or glandular growth pattern. The tumor cells in these four tumors also showed the expression of vimentin diffusely and no expression of chromogranin A in immunohistochemical examination that were consistent with SPN than PET as described later. After these careful reviewing, we considered these four tumors as SPNs. Then, we examined the nuclear accumulation of β -catenin protein in the tumor cells by immunohistochemistry and these four tumors revealed nuclear and cytoplasmic β -catenin accumulation. We also searched for mutations in the β -catenin gene and these tumors were also confirmed to have β -catenin gene mutations, as described below. Thus, a total of 14 SPNs was identified (seven in women and seven in men).

Clinicopathological features of SPNs in women

The mean age of the female SPN patients was 45.5 years (range, 24–70 years). Their SPNs were distributed throughout the pancreas without a particular site of predilection (Table 2). The average size of these SPNs was 5.1 cm (range, 1.5–8.5 cm) in diameter. All the female patients showed characteristic clinicopathological features of SPN as described previously. Only one (patient 2) presented

with simultaneous multiple metastases in the liver and underwent resection of both the primary lesion and the liver metastases. All the SPNs in the female patients were globular or oval-shaped and well demarcated. Most of them (in patients 1, 2, and 4–6) were completely encapsulated by thick fibrous tissue; only one (in patient 3) was incompletely encapsulated. There were macroscopic cystic changes with extensive hemorrhages and necrodegenerative changes (Fig. 1a,b). A small proportion of each tumor was histologically occupied by solid proliferations of fairly uniform, small-to-medium-sized, polygonal epithelial cells with prominent nuclear grooves. These were arranged in a sheet or so-called patternless arrangement and had a rich microvasculature. The majority of each tumor showed cystic or degenerative changes. Extensive calcification, often with ossification, was observed in these areas (Fig. 1c). In areas of relatively mild degeneration, the tumor cells were arranged around delicate fibrovascular stalks displaying pseudopapillary and pseudoglandular formations (Fig. 1d,e). No cellular mitosis was observed in the majority of the samples, but mitosis was seen in one of ten HPFs in two patients, including patient 2, who had coexisting liver metastases and vascular invasion. All of the patients were followed-up and remain alive without any disease recurrence (Table 2).

Fig. 1 Pathological features of SPNs in female patients.

a,b The cut surfaces of the SPNs show extensive degeneration surrounded by a thick fibrous capsule with calcification and ossification. These massive degenerative changes are apparent even in the relatively small tumor shown in **a** (**a**, patient 6; **b**, patient 1). **c** Ossification is present in extensively calcified areas (HE, $\times 50$). **d** Gradual degenerative changes comprising pseudoglandular and pseudopapillary formations can be seen (HE, $\times 20$). A cholesterol crystal deposit can be seen on the *right*. **e** The pseudopapillary and pseudoglandular formations are formed by the tumor cells around microvasculature left from collapsing by the degeneration. (HE, $\times 100$)

Clinicopathological features of SPNs in men

The group comprised three patients originally diagnosed as having SPN (patients 8, 9, and 13) and four rediagnosed after originally being diagnosed as having PET (patients 10–12 and 14) (Table 2). The mean age of the male group was 45.0 years (range, 35–61 years). The average size of the SPNs was 3.8 cm (range, 0.8–7.5 cm) in diameter, which was smaller than that in cases among women. Regarding their gross appearance, most of the tumors had a predominant solid area with few prominent cystic changes, except in one case (patient 10) (Fig. 2a,b). They were generally circumscribed but not encapsulated; only one tumor (patient 8) had a thin fibrous capsule, but this did not resemble the thick fibrous capsules seen around the female patients' tumors. The majority of the tumor area was histologically occupied by a solid proliferation of tumor cells. A few cystic changes were located in the center of the tumor in some patients, while others showed microcysts scattered within the solid areas. The basic tumor histology of the solid area in the male tumors was indistinguishable from that in the female ones (Fig. 2e,f). The tumors did not have capsules but infiltrated directly into the adjacent pancreatic parenchyma without any inflammatory cell reaction or fibrous proliferation. The pancreatic parenchyma just

seemed to be replaced with tumor nests (Fig. 2c,d). Isolated, small, non-neoplastic parenchymal cells were often left among the tumor cells. Degenerative changes were present in only small areas of the tumors and three patients (patients 8, 10, and 13) showed a small amount of calcification without ossification. One patient (patient 8) showed partial nuclear pleomorphism, in which the mitotic rate was slightly increased (three mitoses per ten HPFs). Neither perineural invasion nor regional lymph node metastasis was observed in the male patients, and all patients were alive and disease-free after a mean follow-up period of 81.7 months (range 4–154 months). The smallest tumor (in patient 14) was initially found by his health check-up.

Immunohistochemistry

The details of the immunohistochemical results are summarized in Table 3. SPN cells showed strong nuclear and cytoplasmic accumulation of β -catenin protein. Positive cells were distributed diffusely throughout every SPN (Fig. 3a). Patient 2 exhibited a similar amount of staining in both her primary and metastatic tumors. In the adjacent non-tumorous pancreatic tissue, the ductal epithelial cells, acinar cells, and some islet cells expressed β -catenin

Fig. 2 Pathological features of SPNs in male patients. **a,b** The cut surfaces of the SPNs show well-demarcated, whitish, solid masses with minimal cystic changes and hemorrhages and no fibrous capsule, even in the large tumor shown in **b** (**a**, patient 12; **b**, patient 9). **c,d** In the solid area, uniform polygonal epithelial cells with a rich microvasculature are arranged in a sheet. At the periphery of the tumor, the tumor cells infiltrate directly into the adjacent pancreatic parenchyma without any stromal reaction (HE, **c** $\times 50$, **d** $\times 100$). **e** In the solid area, the pale cytoplasmic tumor cells are arranged around the abundant microvasculature with their nuclei lined up along the vessels. This formation appears as a rosette-like structure in cross-section (HE, $\times 100$). **f** Eosinophilic inclusion bodies can sometimes be seen in the tumor cells. (HE, $\times 200$)

protein in their membrane, especially in the cell borders (data not shown). In contrast, all 15 PETs showed membranous and rarely cytoplasmic (i.e., no nuclear) immunoreactivity for anti- β -catenin antibody (Fig. 3b).

Neuroendocrine cell markers were almost always expressed in both SPN and PET (Table 3). Staining for chromogranin A was absent in SPNs, except in two samples which showed weak focal reactivity, whereas PETs were strongly and diffusely stained. Intense, diffuse vimentin expression was observed in every SPN, whereas only infrequent focal expression was seen in PETs. All SPNs were negative for estrogen receptors; however, they were almost all positive for progesterone receptors, even in men. No overt differences in the sex distribution were observed for the four neuroendocrine markers, vimentin, or the two sex hormone receptors.

With regard to the Ki-67 LI in SPNs, positive cells were scattered throughout the tumor area and indices tended to be higher in the larger tumors. The LI appeared to reflect a low proliferation capacity and showed no definite correlation with biological malignancy.

Mutations in the β -catenin gene

β -Catenin gene mutations were detected in most of the SPNs (12 of 14, 85.7%), which occurred in exon 3 encoding the amino acids corresponding to the GSK-3 β phosphorylation sites and their flanking regions (Table 4). Eleven patients showed 1-bp missense mutations in the region between codons 32 and 37 as follows: codon 32 (five patients), codon 34 (two patients), and codon 37 (four

Table 4 Mutations of the β -catenin gene (exon-3) in SPNs

Patient	Mutated codon	Base change/deletion	Amino acid substitution
1	32	GAC→TAC	Asp→Tyr
2	32	GAC→AAC	Asp→Asn

14	32	GAC→GGC	Asp→Gly

^aCompared with the corresponding wild-type sequence (g, tct, tac, ctg, ga), (cag, tct, tac, ctg, gac) was deleted, thus codon 28 was mutated from cag to cac and codons 29–32 were deleted

patients). These codons are known mutation ‘hot spots’, as reported previously [1, 25]. In one patient (patient 11), there was a 12-bp deletion (g tct tac ctg ga) corresponding to codons 28 to 32. Because of this deletion, the amino acid at codon 28 was changed from Gln to His and the four amino acids corresponding to codons 29 to 32 were deleted, but no frame-shift occurred. This mutation has not previously been reported in pancreatic tumors. No muta-

Discussion

Most SPNs have recently been reported to contain somatic mutations in the β -catenin gene. Alterations in the APC/ β -catenin pathway have also been observed, and these appear to be associated with the neoplastic progression of SPN [1, 25]. Immunohistochemical detection of aberrant β -catenin protein accumulation in SPN cell nuclei is suggestive of these mutations, as mutations in the β -catenin gene always occur at GSK-3 β phosphorylation sites or in their flanking regions. These impair normal phosphorylation by GSK-3 β and subsequent ubiquitin-mediated degradation of β -catenin protein. Indeed, we (this study) and other groups [1, 25, 26] have demonstrated strong accumulation of β -catenin protein in the nuclei and cytoplasm of the tumor cells in SPN. In this study, 100% (14 of 14) of the SPNs showed intense, widespread nuclear and cytoplasmic accumulation of β -catenin protein (Table 3) and 86% (12 of 14) contained β -catenin gene mutations caused by exchange or deletion of the amino acids at GSK-3 β phosphorylation sites or in their flanking region (Table 4). Other groups have also demonstrated nuclear and cytoplasmic accumulation of β -catenin protein in the majority of tumor cells in all SPNs tested [1, 25, 26], while 83% (15/18) [25] to 90% (18/20) [1] of these SPNs had mutations in the β -catenin gene at GSK-3 β phosphorylation sites or in their flanking region. Constitutive production of cyclin D1, one of the intranuclear targets of the β -catenin complex, was also frequently apparent in these SPNs [1, 16]. We (this study) and others [5, 26] have conversely demonstrated the absence of nuclear accumulation of β -catenin protein and mutations in exon 3 of the β -catenin gene in PETs, even though membranous localization (and rarely cytoplasmic accumulation) of β -catenin protein was observed.

The initial clinical appearance of SPN and PET is often similar. It can sometimes be quite difficult to differentiate between SPN and PET, especially for SPT showing solid monomorphous growth without characteristic degenerative changes including massive cystic degeneration or pseudopapillary feature. Expression of neuroendocrine markers by SPN can also cause confusion in the pathological differential diagnosis. From this study combined with previous

reports [2, 3, 5–7], chromogranin A and vimentin seem to be relatively good markers for differentiating between SPN and PET, although even a combination of markers including vimentin and the four neuroendocrine antigens could not distinguish SPN from PET completely. In contrast, nuclear accumulation of β -catenin protein appeared to be a useful marker of SPN, which allowed it to be differentiated from PET. We, therefore, believe that pathological investigations on a combination of vimentin, neuroendocrine markers, and β -catenin would make the differential diagnosis of SPN more accurate.

SPN has been reported to occur preferentially in young women and fewer than 10% of SPNs arise in male patients. In contrast, we found that the male-to-female ratio of SPNs at a single institution was 7:7. The proliferating tumor cells in the male and female SPNs were basically similar with regard to both histological and immunohistochemical analyses. No apparent differences of β -catenin gene mutations and expressions of sex hormone receptors between genders were also found in this study. However, solid components that lacked prominent pseudopapillary or pseudoglandular formations occupied the majority of the tumor area in almost all the specimens from men. In contrast, SPN samples from women showed the typical features of SPN, i.e., nearly complete cystic degeneration, encapsulation by thick fibrous tissue, and extensive calcification with ossification (Table 2). Smaller tumors generally consist mainly of solid components while larger ones show cystic and/or hemorrhagic and marked degenerative changes [9, 15]. The SPNs in our male patients tended to be predominantly solid tumors without massive degenerative changes, even when they were large.

A detailed information on SPNs in male patients is available from nine previously published case reports [11, 15, 17, 18, 24, 27, 28]. Except in one case [27], all of these tumors were surrounded by a fibrous capsule and contained large cystic areas filled with hemorrhagic and necrotic material. Most of them were larger (median diameter, 9 cm; range, 4.5–13 cm) than those described here and had classical morphological features; thus, they were relatively easy to diagnose as SPNs, even though they occurred in men. However, SPNs with no cystic formations and few pseudopapillary structures, such as in the case reported by Tomioka et al. [27], might be confused with PETs. These published findings combined with the results of this study suggest that, compared to SPNs in women, SPNs in men are more likely to occur as a solid mass and to degenerate

less frequently and more slowly during their growth. There is currently no good explanation to this phenomenon. In addition to this, Lam et al. [14] conducted a review of the literature on SPN. They identified a total of 452 cases, of which 189 occurred in Asian and 59 in Black populations. The highest number of cases occurred in Japan. In these Japanese cases, SPNs tended to be found in older patients and were more frequent among men than usual. It is possible that there are regional or ethnic differences in the frequency of SPN in male patients.

In summary, we have demonstrated that nuclear accumulation of β -catenin protein is a useful pathological hallmark of SPN which allows it to be differentiated from PET. We carried out clinicopathological investigations on 14 SPNs (seven from men and seven from women) surgically resected at a Japanese institution, and all of the SPNs had β -catenin alterations. Marked degenerative changes which could have occurred earlier in tumor growth were the features of SPNs in women, whereas those in men tended to be a solid mass with slower progression of degenerative changes. These less typical features of SPNs in male patients can make them difficult to diagnose with conventional methods. In this situation, male SPNs are diagnosed correctly by immunohistochemical detection of nuclear β -catenin accumulation combined with immunohistochemical findings for vimentin and neuroendocrine markers.

Increased density and diameter of lymphatic microvessels correlate with lymph node metastasis in early stage invasive colorectal carcinoma

Received: 18 September 2005 / Accepted: 25 January 2006 / Published online: 22 February 2006
© Springer-Verlag 2006

Abstract To determine whether lymphangiogenesis was associated with the development of colorectal carcinoma and whether the mean maximal diameter of lymphatic microvessels (LMMMD) or lymphatic microvessel density (LMVD) is associated with lymph node metastasis in early stage invasive colorectal carcinoma (T1 carcinoma), we used immunohistochemical staining with podoplanin to measure LMMMD and LMVD in intratumoral (LMMMDit, LMVDit) and peritumoral areas (LMMMDpt, LMVDpt) of T1 carcinomas ($n=87$). By comparing the LMMMD and LMVD in normal large intestine ($n=10$), adenoma ($n=15$), and Tis carcinoma ($n=15$), we found out that the LMVDpt in T1 carcinoma with lymphatic vessel invasion (LVI) was significantly high ($P<0.001$), and there was a significant decrease in LMMMDpt in T1 carcinoma ($P=0.031$). Both LMMMDpt and LMVDpt were significantly increased in the T1 carcinomas, with LVI compared with the T1 carcinomas without LVI ($P=0.018$, $P=0.003$). Multivariate analysis revealed that LVI and combined greater LMMMDpt and greater LMVDpt were associated with lymph node metastases ($P=0.005$, $P=0.036$). These results indicate that lymphangiogenesis might be induced in the surrounding tumor areas of the T1 colorectal

carcinoma with LVI; thus, evaluation of the diameter and density of lymphatic microvessels is important in T1 colorectal carcinoma to predict lymph node metastases.

Introduction

Early carcinoma of the colon and rectum is defined as carcinoma that is limited to the mucosa (Tis carcinoma) or that infiltrated into the submucosa (T1 carcinoma). One reasonable treatment method of these colorectal carcinomas would be endoscopic mucosal resection (EMR). However, lymph node metastasis is one of the main reasons for recurrence of T1 carcinoma after EMR [10, 17]. In such cases, a radical excision after the EMR would be necessary, as in advanced colorectal carcinomas. Thus, it is very important to accurately assess the risk of lymph node metastasis after EMR for T1 carcinoma. Recent evidence suggests that cancer cells frequently spread quickly to regional lymph nodes via lymphatic vessels [24]. Tumor lymphangiogenesis promotes lymphatic metastasis [14, 20]. However, the absence of specific markers for lymphatic microvessels has made the identification of tumor lymphatic microvessels difficult. Recently, podoplanin, a specific lymphatic microvessel marker, has enabled us to investigate lymphatic microvessels in paraffin-embedded sections [4, 26]. However the mean maximal diameter of lymphatic microvessels (LMMMD) expressed by podoplanin has not been reported before, and the significance of lymphatic microvessel density (LMVD) in colorectal carcinoma remains unclear. We therefore used immunohistochemical staining with podoplanin to measure LMMMD and LMVD in a retrospective series of T1 colorectal carcinomas and correlated the findings with the

expression of desmoplastic response, lymphatic endothelium proliferation (Ki67), and clinicopathologic data.

Materials and methods

Patients and tissues We studied 87 patients with T1 carcinoma, who underwent resection from 1985 to April 2005 in our department. The 59 men and 28 women had a mean age of 67.9 years old (range 39–83). Of these, 67 tumors were in the colon and 20 in the rectum. Depth of tumor invasion and lymph node status were classified according to the tumor–node–metastasis classification. The depth of submucosal invasion in T1 carcinoma was divided into three classes according to the method of Kudo [9]: (1) SM1, carcinoma invading into the upper one-third of the submucosa, thus showing minimal submucosal invasion; (2) SM2, carcinoma invading into the middle part of the submucosa; and (3) SM3, carcinoma invading into the lower layer of the submucosa. Among 87 patients, 8 (9.2%) patients had lymph node metastasis. As controls, we randomly selected normal large intestine tissues (NLI, $n=10$) from the proximal or distal margins of resection (at least 10 cm away from the edge of primary carcinoma), adenomas ($n=15$), and Tis carcinomas ($n=15$).

Immunohistochemistry Immunostaining procedures for podoplanin and Ki67 were performed using the Envision+ /HRP method with heat-induced antigen retrieval. Two representative blocks of each tumor were selected for immunostaining analysis of podoplanin, Ki67, and serial 3- μ m paraffin sections containing the tumor margin were dewaxed in xylene, then rehydrated in alcohol. For podoplanin staining, the sections were heated to 95°C in an oven (650 Watts) for 45 min to reactivate the antigen. The endogenous peroxidase activity was suppressed by a solution of 3% hydrogen peroxide in methanol for 20 min. After being rinsed three times in phosphate-buffered saline (PBS), sections were incubated for 90 min at room temperature with monoclonal antibody against podoplanin (11-003, AngioBio, Del Mar, CA, USA) and monoclonal antibody against Ki67 (MIB-1, DakoCytomation, Glostrup, Denmark). After washing in PBS, the sections were treated with goat anti-mouse immunoglobulins conjugated to peroxidase-labeled dextran polymer (Dako, Carpinteria, CA, USA) for 1 h at room temperature. The sections were then washed in PBS and developed in 0.05 M Tris–HCl buffer (pH 7.5), containing 0.6 mg/ml 3,3'-diaminobenzidine tetrahydrochloride, for 6 min for Ki67 staining and 10 min for podoplanin staining at room temperature. After washing in water, the nuclei were counterstained with Mayer's hematoxylin. Negative control sections were stained by omitting the primary antibody.

Desmoplastic response was diagnosed by the hematoxylin and eosin specimen [6]. Determination of desmoplastic response was performed according to the method of Nakada et al. [15]. No or mild response was considered negative, and moderate or severe response was considered positive.

Determination of LMVD was performed according to the method of Straume et al. and Weidner et al. [25, 27]. Briefly, the sections were scanned at low magnifications ($\times 40$ and $\times 100$) to identify the areas of the tumors with the highest amount of lymphatic vessels ("hot spots"). Within these areas, five fields at $\times 200$ magnification [high power field (HPF), 0.708 mm²/field] were examined, and the mean values of these fields were calculated. Vessels more than one-half HPF ($\times 200$) away from the invasive margin were not counted. Any endothelial cell or cell cluster, highlighted by podoplanin reactivity and clearly separated from adjacent vessels, tumor cells, and connective tissue elements, was regarded as a distinct countable vessel [13]. The calculation of LMVD in intratumoral (LMVDit) and in peritumoral areas (LMVDpt) was established for each case, and the result given as vessels per millimeter squared.

The calculation of LMMMD in intratumoral (LMMMDit) and in peritumoral areas (LMMMDpt) was also recorded. The smallest diameter of the largest lymphatic vessel in each hot spot field was recorded as the diameter at $\times 400$ magnification and the mean value of five diameter was calculated. For LMMMDit, all lymphatic microvessels with less than five lymphatic microvessels within all tumor areas were selected. Five of the largest axis lymphatic vessels in the mucosa and in the submucosa near the tumor in adenoma and Tis carcinoma were selected for calculation.

Lymphatic vessel invasion (LVI) in a given tumor was considered to be present if tumor cells could be seen within any one podoplanin positive profile in the entire field [13, 18]. Sections were scored by two independent investigators who had no clinical knowledge of the patients.

Statistics

The Kruskal–Wallis test, Mann–Whitney test, and logistic regression analysis were used. For all tests, a value of 0.05 or less was considered to indicate a statistically significant difference.

Results

Lymphatic microvessel density and mean maximal diameter of lymphatic microvessels in different tissues

Lymphatic microvessels were more prominent in submucosal loose connective tissue than in mucosa of the colon and rectum. There were no differences in the lymphatic densities and diameter among normal large intestine, adenomas, and Tis carcinomas groups, either in the mucosa or in the submucosa (Table 1).

In T1 carcinomas, most lymphatic vessels were located in the peritumoral areas, near the margin of invasive tumors, as reported previously [13]. Intratumoral lymphatic vessels were extremely rare and were observed only in narrow or collapsed lymphatic spaces. The LMVD and LMMMD in peritumoral areas was significantly greater

Table 1 LMVD (mean±SD, mm⁻²) and LMMMD (mean±SD, μm) in normal large intestine, adenomas, and Tis carcinomas

	LMVD		LMMMD	
	Mucosa	Submucosa	Mucosa	Submucosa
Normal large intestine	4.2±1.9	5.1±2.5	17.9±8.8	26.1±14.2
Adenoma	4.4±2.3	5.7±3.1	19.4±10.5	26.7±15.3
Tis carcinoma	3.9±1.1	5.2±2.7	18.6±8.6	24.5±11.8

No significant difference was found between any groups (all $P>0.05$, Kruskal–Wallis test)

than in intratumoral areas (both $P<0.001$, Table 2). Neither LMVD nor LMMMD in intratumoral areas was associated with any clinical parameters.

LMVD, LMMMD, and lymphatic vessel invasion (Figs. 1 and 2)

The LMMMD and LMVD in peritumoral areas (Figs. 1 and 2) were significantly increased in the T1 carcinomas with LVI than in the T1 carcinomas without LVI ($P=0.0033$, $P=0.0182$, respectively; see Table 2). By comparing

LMMMD and LMVD among different groups (Fig. 3a,b), we found out through the Kruskal–Wallis test that the LMMMA in peritumoral areas of T1 carcinoma was significantly smaller and the LMVD in peritumoral areas in the T1 with LVI was significantly greater than the LMVD in the submucosa of normal large intestine, adenoma, and Tis carcinoma.

LMVD, LMMMD, and lymph node metastases

For logistic regression analysis, the median values of LMVDpt (≤ 7.4 vs >7.4 lymphatic microvessels/mm⁻²) and LMMMDpt (≤ 1.8 vs >1.8 μm) were used as cut-off values defining groups with low and high LMVDpt or LMMMDpt, respectively. Univariate analysis showed that the tumors with high LMVDpt or LMMMDpt tended to have high rate of lymph node metastasis. Among the significant correlations with lymph node metastases indicated by univariate analysis, multivariate analysis indicated that the LVI and combined high LMVDpt and high LMMMDpt, but not high LMVDpt or LMMMDpt only, were independent factors associated with lymph node metastases (Table 3). Only one LVI within a tumor area was found in eight cases with lymph node metastases, while LVI in surrounding tumor areas were found in all eight cases ($P=0.008$, Mann–Whitney test).

LMMMD, LMVD, and desmoplastic response

The desmoplastic response was not related to the LMMMA or LMVD in these specimens (Table 2).

Lymphatic endothelial proliferation and expression of Ki67

In all samples, serial sections were taken and stained for proliferating lymphatic endothelial cells using successive podoplanin and Ki67 staining. No Ki67 positive staining was seen in any lymphatic microvessel. There was no clear evidence supporting the presence of proliferating lymphatic endothelial cells either within or near the early-stage

colorectal carcinomas, regardless of whether the tumor cells were clearly stained with Ki67.

Discussion

Although lymphangiogenesis has been proven in some human carcinomas [1, 20, 26], information on the organization of lymphatic network in human colorectal cancer is limited. Little is known about density and diameter of

Table 3 Logistic regression analysis in relation to lymph node metastasis

lymphatic vessels in early-stage colorectal cancer. According to the adenoma–carcinoma sequence theory, most colorectal carcinomas arise from adenomas, which gradually increase in size and dysplastic grade. In this study, we present data about lymphatic microvessels in normal large intestine, adenomas, Tis carcinomas, and T1 carcinoma tissues using immunohistochemistry staining with antibodies to human podoplanin.

The peritumoral LMVD in the T1 carcinomas with LVI was greater than the submucosal LMVD of normal large intestine, adenoma, and Tis carcinoma; thus, the increased LMVD could be speculated to be caused by the tumor compacting the peritumoral areas, with overgrowing tumor cells (therefore increasing LMVD), or due to lymphangiogenesis. However, there was no significant difference among four groups, the peritumoral LMVD in the T1 carcinomas, LMVD in the submucosa of normal large intestine, adenoma, and Tis carcinoma, which supports the concept that lymphangiogenesis might be induced in the surrounding tumor areas of the T1 colorectal carcinoma with LVI. Similar results were also found in human breast cancer and malignant melanoma [20, 21]. Recent studies indicated that increased tumor expression of endothelial growth factors such as vascular endothelial growth factor C and VEGF-D could increase lymphangiogenesis around the primary tumor, and increase the number of tumor lymphatic vessels [22, 23].

Lymphatic vessels were almost exclusively found at the invasion margin of tumor, not within the tumor, a finding that agrees with recent studies [12, 13, 16, 20]. Unlike cardiovascular microvessels, which possess smooth muscle cells, lymphatic microvessels are highly sensitive to interstitial pressure [5, 11]. The increased interstitial pressure within the tumor, generated by overgrowing tumor cells, collapses lymphatic vessels, rendering them nonfunctional [12, 16]. The fact that we found rare lymphatic vessels with small LMMMD within tumor and that both main lymphatic vessels and most LVI were located in peritumoral areas also supports this theory. This fact also provides evidence that the lymphatic vessels, which are in areas surrounding the tumor, but not within tumor, are functional lymphatic vessels, which play a role in lymphatic metastases in T1 colorectal carcinoma.

It has been speculated that different type of extracellular matrices may cause difference in interstitial pressure [2]. Desmoplastic response, a kind of extracellular matrix change with highly fibrous stroma around invasive carcinomas [15], was not associated with LMMMD either within or surrounding tumor in these specimens. We speculated that the difference of LMMMD between peritumoral area of T1 carcinoma and in the submucosa of normal large intestine, adenoma, and Tis carcinoma might be related to tumor cells or combined tumor cells and stroma but not by stroma only.

The positive association between both LMVD and LMMMA in the peritumoral areas and LVI in T1 carcinoma could be explained through a lymphangiogenesis-induced increase of the “lymphatic window” or an increase of “lymphatic window areas” providing tumor

cells with more opportunities to enter into lymphatic vessels. However, multivariate analysis indicated that high LMVDpt or LMMMDpt were not independent factors for lymph node metastases. Therefore, it is easy to speculate that high density or large diameter of lymphatic vessels is a prerequisite for lymphovascular invasion by tumor cells, but one has also to keep in mind that multiple factors, steps, and molecular participants are probably involved in the process of metastases from primary tumor cells to lymph nodes through the lymphatic system [2, 3, 7, 8, 14, 19].

In this study, there was no evidence of lymphatic endothelium proliferation at the time of excision. Therefore, active lymphangiogenesis could not be detected immunohistochemically. This neither confirms nor denies that lymphangiogenesis has occurred, as the increase in LMVD could have occurred while the tumor was growing before excision, and the newly formed, tumor-stimulated lymphatic microvessels may be in a mature state rather than in a proliferative state.

Our results also indicate that analysis of LMMMD and LMVD surrounding tumor before operation or after EMR could thus be useful for predicting lymph node metastasis and could contribute to the correct selection of treatment (EMR or radical excision) in patients with T1 carcinoma.

In conclusion, our results showed that the increased LMVDpt of T1 carcinoma in cases with LVI might be brought about by lymphangiogenesis; thus, evaluation of diameter and density of lymphatic vessels is important and is a good predictor of lymph node metastases in T1 colorectal carcinoma.

Immunohistochemical and in situ hybridization studies of the liver and kidney in human leptospirosis

Received: 22 August 2005 / Accepted: 18 January 2006 / Published online: 16 March 2006
© Springer-Verlag 2006

Abstract An in situ hybridization (ISH) assay for the detection of leptospiral DNA in tissues was described and its diagnostic and pathogenetic usefulness in combination with immunohistochemistry (IHC) was evaluated in formalin-fixed, paraffin-embedded liver and kidney samples from human fatal cases of leptospirosis. IHC assays with anti-E-cadherin antibodies assessed the liver-plate disarray frequently observed in leptospirosis. Immunohistochemistry detected leptospiral antigen (LAg) in macrophages, both in human liver and kidney. In guinea pigs, in addition to these findings, staining on cell membranes of hepatocytes and, occasionally, in apical membrane of kidney tubular cells was demonstrated. Positive ISH signal was observed chiefly in the nuclei of human hepatocytes and in the cytoplasm and nuclei of liver cells of experimentally infected guinea pigs. Loss of E-cadherin membrane expression is associated with liver-plate disarray. These findings were discussed in the contention that, in leptospirosis, cell membrane damage might be important for the pathogenesis of the disease. Finally, it was suggested that both IHC and/or ISH might be used for both diagnostic and research purposes.

Introduction

Leptospirosis is an acute septicemic febrile illness, caused by *Leptospira interrogans*, which affects humans or animals in all parts of the world. In humans, it is a zoonosis and its reservoirs are chronically infected carrier animals. There is a worldwide strong occupational association and a universal risk from rodent-carrier-mediated infection, especially prevalent in tropical countries where it occurs in endemic and epidemic bouts, chiefly during the rainy season [7, 14].

Leptospirosis has a biphasic clinical presentation, beginning with a septicemic phase followed by an immune phase with antibody production and urinary excretion of leptospire. In severe cases, leptospirosis is a multisystemic febrile illness, chiefly with hepatic, renal, and pulmonary involvement. The most severe form of leptospirosis is known as Weil's syndrome and can lead to fatality in a short time [18].

Microscopic agglutination test remains an excellent serological assay and yields information on the presumptive infecting serogroup. In fatal human cases [1] and in farm animals [13], diagnosis by immunohistochemistry (IHC) is specific and also offers clues to the understanding of the pathogenesis of the disease.

Morphology and antigenic structure as well as the genetic composition and organization of ribosomes and nucleic acids of leptospire were recently reviewed [14]. rRNA genes are very conserved throughout the bacterial kingdom and partial sequences have been analyzed in terms of oligonucleotide signatures. Mérien et al. [19] reported the development of a sensitive assay for leptospire DNA based upon amplification of oligonucleotide sequences of the *Leptospira* rrs (16S) gene [15]. Recently, the complete genomic sequence of a representative virulent serovar type (*Lai*) of *L. interrogans* was obtained by the

Chinese National Human Genome Center at Shanghai [28]. The genomic sequence of *L. interrogans*, serovar *Copenhageni*, was established by a Brazilian group [21, 22].

In the light of these results, this paper describes an in situ hybridization assay (ISH) for the detection of leptospire DNA in tissues. Liver and kidney lesions were chosen for analysis because, with vascular lesions, they form an important part of the systemic manifestations of leptospirosis. The diagnostic and chiefly the pathogenetic usefulness of this technique were evaluated and compared to immunohistochemistry in formalin-fixed, paraffin-embedded liver and kidney samples from human fatal cases of leptospirosis. In addition, E-cadherin expression was used as a marker of cell-cell junction integrity to assess the specificity and potential pathogenetic role of liver-plate disarray, a common histological finding in leptospirosis.

Materials and methods

Human samples

Ten patients, eight males and two females, ranging from 20- to 68 years old, were autopsied with a diagnosis of Weil's syndrome. Major clinical and laboratory findings

are shown in Table 1. In brief, illness duration ranged from 3 to 15 days (average of 7.8 days) and all patients commenced suddenly with headache, malaise, muscle pains and, except for one, high fever. All of them developed marked jaundice, palpable enlarged liver, acute renal failure, and, with one exception, pulmonary and digestive tract hemorrhage with conjunctival suffusions. Epidemiological data showed that most patients had had contact with contaminated water, mainly from floods and sewage cleaning. Serology was performed in five patients. One of them had enzyme-linked immunosorbent assay (ELISA) IgM+seroagglutination 1/3,200 for *L. interrogans*, serovar, and serogroup *Cynopteri*. In three other patients, with 5 days of illness, serological tests were negative. In another patient, also with 5 days of illness, blood culture was positive for *L.interrogans* serovar *Butembo*, serogroup *Autumnalis*.

Kidney and liver samples were obtained from autopsies performed after 6 to 12 h of death (average 9 h). The tissues were fixed in formalin, embedded in paraffin, and routinely stained with hematoxylin eosin. The kidney and liver samples of eight non-leptospirotic patients were obtained from autopsies performed within the same post-mortem interval; three normal liver biopsies obtained from liver

Table 1 Leptospirosis: clinical and laboratory data

Case no./sex/age (years)	Clinical and epidemiological information	Illness duration (days)	Laboratory data related to leptospirosis
1/f/54	Contact with contaminated water (floods); fever, headache, conjunctival suffusion, muscular pain, acute renal failure, hemorrhagic sputum, jaundice, dehydration	11	ELISA IgM+, seroagglutination 1/3,200 (<i>L. interrogans</i> serovar and serogroup <i>Cynopteri</i>)
2/m/58	Contact with contaminated water (floods); fever, jaundice, muscular pain, acute renal failure, dehydration, pulmonary hemorrhage	5	Serological tests for leptospirosis, negative
3/m/59	Contact with contaminated water (fall into a well); muscular pain, acute renal failure, jaundice, dehydration	3	Blood culture positive for <i>L. interrogans</i> serovar <i>Butembo</i> , serogroup <i>Autumnalis</i>
4/m/53	Contact with contaminated water (floods); fever, jaundice, muscular pain, acute renal failure, dehydration, hemorrhagic syndrome (pulmonary and digestive tract)	15	None available
5/m/46	Contact with contaminated water (floods); fever, jaundice, muscular pain, dyspnea and hemorrhagic sputum	5	None available
6/m/68	Fever for the last 5 days, muscular pain, jaundice, acute renal failure	7	Seroagglutination negative, ELISA IgM positive
7/m/27	Contact with sewage and rats; fever for the last 5 days, jaundice, muscular pain, acute renal failure, hemorrhagic syndrome (pulmonary and digestive tract)	5	Seroagglutination negative, ELISA IgM positive
8/m/51	Fever for the last 7 days, marked jaundice and muscular pain for the last two days, anemia, leukocytosis, thrombocytopenia and renal failure; patient was HIV+	7	None available
9/m/20	Fever, muscular pain for the last 5 days, jaundice for the last 4 days, bipalpebral edema and acute renal failure, pulmonary hemorrhage, abdominal pain and vomits, low platelets count	5	None available
10/f/67	Contact with rats and contaminated water; fever and muscular pain for the last 8 days, jaundice for the last 6 days and conjunctival hemorrhage, dyspnea and hemorrhagic sputum, acute renal failure	8	None available

transplant donors were used as negative controls. The samples were processed as described above.

Guinea pig samples

Fifteen guinea pigs were infected with a virulent culture of *L. interrogans*, serovar *Copenhageni*. The animals developed the disease 5 days after inoculation. Liver and kidney samples were obtained and processed as described above. The tissues were compared to the human samples and used as positive controls. Liver and kidney samples of nine non-infected guinea pigs were used as negative controls.

Immunohistochemistry assay

IHC studies were performed to assess the presence of leptospiral antigen/s (LAG) and abnormalities in cell–cell junctions. Two primary sera were used for the detection of LAG. One serum was obtained by hyper-immunizing the sheep with sequential intravenous doses of 1, 2, 3, and 4 ml of *L. interrogans*, serogroup *Icterohaemorrhagiae*. The leptospire were obtained from 7 to 10 days of cultures grown at 28°C in Ellinghausen–McCullough–Johnson–Harris medium (DIFCO). Seven days after the last inoculation, an 80-ml blood sample was drawn. IgG was obtained by octanoic acid fractionation, purified, and used in a 1:30,000 concentration in 1% bovine serum albumin (BSA) in phosphate-buffered saline (PBS). The second immune serum was raised in rabbits according to a previously described standard procedure [12].

Anti-E-cadherin monoclonal antibody was employed to assess cell–cell attachment status in liver. These studies were restricted to five leptospiric and five non-leptospiric patient autopsies and three liver transplant donor biopsies. All autopsies were performed within 6 h post-mortem and showed well-preserved histopathological structures.

Kidney and liver 3- μ m sections were analyzed using EnVision (Dako, USA)-based immunohistochemistry methods. Antigen retrieval protocol, primary antibodies clones, sources, and concentrations are summarized in Table 2. Staining was completed with the chromogen 3,3' diaminobenzidine. All specimens were then lightly counterstained with hematoxylin.

The presence of nonspecific staining with the LAG sheep antibody was assessed in experiments with pre-cleared

sera. In brief, 1-ml aliquots of anti-*L. interrogans* antibody was absorbed at 4°C, overnight, with 100 mg of normal human liver and 30 mg of normal human kidney powder, and used for immunohistochemistry in tissues not subjected to antigen retrieval. In this procedure, the primary sheep antibody was diluted at 1:40,000 in 1% BSA in PBS. Reactions in which primary antibody was replaced with saline or normal human serum were also performed as negative controls.

In situ hybridization

Two oligonucleotide probes were synthesized to detect leptospiral nucleic acids. Probe one (5'-CAA GTC AAG CGG AGT AGC AAT ACT CAG CGG CGA ACG GGT G-3', Eurogentec S/A) is a sense fluorescein-labeled probe complementary to sequences A and C used for polymerase chain reaction (PCR) assays described by Mérien et al. [19].

Probe two (5'-GAT CTG AAC TTT ATA GAT TGA TTT CTA AAA TGT-3', Invitrogen, USA) was designed based on the published genomic sequence of *L. interrogans*, serovar *Lai*, serogroup *Icterohaemorrhagiae*. Genes coding for small proteins of unknown function, conserved in *Leptospira* but with low identity levels in vertebrates, were chosen as candidates for probe generation. Thirty to thirty-three base sense cDNA probes were designed using PRIMER3 [25] with default conditions. The probes thus obtained were tested for nonspecific human complementary sequences using short-sequence nucleotide–nucleotide Blast (<http://www.ncbi.nlm.nih.gov/BLAST>); those with least similarity were also checked against hepatitis B virus genome to minimize the chances of cross-reaction. Using this approach, a sequence also present in *L. interrogans*, serovar *Copenhageni*, was chosen from the sequence AEO11585.1:119–250 and used for fluorescein-labeled cDNA synthesis. Both probes recognize sequences conserved in several species of leptospire, both pathogenic and saprophytes. Probe one has 45% identity (a sequence of 18 nucleotides) and probe two 57% (sequence of 19 nucleotides) with the human genome.

A negative control probe (scrambled probe 5'-CAG AAC GCG AGA CGT TAG ACC TCA ATG ACG GAG GGC AGG T-3', Invitrogen) was obtained from probe one using a scrambling algorithm developed by T. Schubert (<http://www.personal.uni-jena.de/~sth/scramble.html>). To reduce the possibility of cross-reactions with other genes, the scrambled probe was compared to genomic banks of

Table 2 Immunohistochemical protocols

Primary serum	Clone	Source	Antigen retrieval	Primary serum titer	Secondary antibody
<i>L. interrogans</i> (sheep polyclonal)	–	See text	Steamer in citrate, pH 6.0	1:30,000	EnVision peroxidase (DAKO code K1490)
<i>L. interrogans</i> (rabbit polyclonal)	–	[12]	Steamer in citrate, pH 6.0	1:5,000	EnVision peroxidase (DAKO code K1490)
E-cadherin (mouse monoclonal)	Clone 36B5	Novocastra Lab, Newcastle, UK	Steamer in in TRS (DAKO code S1699)	1:25 (autopsies) 1:50 (liver biopsies)	EnVision peroxidase (DAKO code K4001)

various organisms using the BLAST program (<http://www.ncbi.nih.gov/BLAST>) showing no significant similarities.

For ISH, 3- μ m sections were deparaffinized, rehydrated through a graded series of ethanol, and washed with water treated with 0.1% diethylpyrocarbonate (DEPC) for 5 min. The sections were incubated with 25 μ g/ml of Proteinase K (Sigma, St Louis, MO, USA) in PBS for 10 min at 37°C and then permeabilized with 2% Triton in Tris-HCl, 10 mM, at room temperature. The sections were rinsed with DEPC water for 10 min and incubated at 95°C for 7 min in hybridization buffer (50% dextran sulphate, 20 \times SSC, 50 \times Denhart's, 10 mg/ml of salmon sperm DNA, 10 mg/ml of yeast tRNA, 1 mg/ml of Poly A-Poly C, 100 mg/ml of inorganic pyrophosphate in 1 M Tris buffer, pH 7.4, deionized formamide, and DEPC). The sections were then incubated overnight at 55°C, with the corresponding probe, at a concentration of 0.340 μ g/ μ l in hybridization buffer. After incubation, the sections were washed in Tris-HCl, pH 7.4, at 37°C for 10 min and further washed with water, five times for 5 min. The slides containing the tissue sections were finally air dried and mounted with Vecta-

Shield and the reactions were visualized under epifluorescence microscope.

As an alternative, after proteinase K 12.5 mg/ml during 10 min at 37°C, the probes were incubated overnight at 42°C in a different hybridization buffer (50% deionized formamide, 10% dextran sulphate, 2 \times SSC, and 0.4 mg/ml salmon sperm DNA).

Results

The clinico-epidemiological data of the selected patients were highly suggestive of leptospirosis. The illness was usually of short duration and this, associated with delayed clinical diagnosis, contributed to the lack of some important confirmatory laboratory tests. Autopsies showed classical findings described in patients dying of Weil's syndrome [5, 8, 24], including acute myositis with hyalin change of necrotic muscular fibers affecting chiefly calf musculature; pulmonary and/or digestive hemorrhage; focal myocarditis; and liver pathology manifested chiefly by cholestatic hepatitis with complete or partial liver-plate

Tubules dilated with flat epithelial lining (acute tubular necrosis), $\times 400$. **f** Kidney in human fatal leptospirosis. Focal LAg deposit on the luminal side of proximal tubule cells. Reactive nonspecific mesangioproliferative glomerulitis is also present. IHC and hematoxylin, $\times 300$

disarray, occasional mitotic figures, and binucleation of hepatocytes; portal spaces' edema with acute and chronic inflammation; and proliferation of Kupffer cells along the sinusoidal lining [5]. Renal pathology showed focal interstitial nephritis, with lymphocytes, macrophages, plasma cells, and occasionally few eosinophils. Interstitial edema was observed in areas of tubular necrosis. In all cases, mild focal nonspecific reactive mesangio-proliferative glomerulonephritis was seen.

IHC analysis showed similar results with both immune sera. In addition, the experiments with pre-cleared sera confirmed the staining pattern. In nine of the ten patients, LAg was detected usually as dots, rarely as deposits in the cytoplasm of isolated macrophages which are part of the mixed portal inflammatory infiltrate, and more frequently in the cytoplasm of macrophages along the sinusoidal lining (Kupffer cells and circulating macrophages) (Fig. 1a,b). LAg expression was not observed on hepatocytes' membrane, except for one case in which a faint focal LAg deposit was detected on the cell membrane of two adjacent hepatocytes (Fig. 1d). In the kidney, LAg deposits were observed also in the cytoplasm of macrophages associated with the focal interstitial infiltrate (Fig. 1e). LAg deposits were seldom seen on the luminal side of tubular cells (Fig. 1f).

Diseased guinea pigs showed areas of liver-plate disarray and linear deposits of LAg on the hepatocyte membrane (Fig. 1c) as well as granular deposits in macrophages detected in portal spaces and Kupffer cells. In the kidney, the LAg deposits were observed in macrophages of the interstitial infiltrate. Linear deposits of LAg were occasionally seen on the luminal side of tubular cells.

Expression of E-cadherin was prominent on the cell membrane of hepatocytes both in liver transplant donor

biopsies and in autopsy control specimens (Fig. 2a). In leptospirotic patients, expression of E-cadherin in liver cells was irregular. In areas of liver-plate disarray, hepatocytes without any expression of E-cadherin were present adjacent to hepatocytes with partial presence of E-cadherin on the cell membrane (Fig. 2b). In hepatic areas without disarray, the E-cadherin expression was similar to the control livers.

In situ hybridization staining revealed similar results with both probes and protocols. In nine patients, signal was observed in a few hepatocytes as an apple-green round or ring-like structure in the nuclei of liver cells (Fig. 2c). Only one patient (Table 1, case 9), in whom frequent mitotic figures could be detected in the liver, showed both cytoplasmic and nuclear signal (Fig. 2d). No convincing signal was seen in cells of the portal inflammatory infiltrate. Definite nuclear ISH signal was not observed in kidney tubular cells and was absent in macrophages of the interstitial focal inflammatory infiltrate.

The liver of 8 of 15 infected guinea pigs exhibited nuclear signal similar to that seen in human cases. In two of the eight guinea pigs, a small round cytoplasmic signal was also detected in the liver cells. No convincing signal was observed in the kidney. Human and guinea pig negative controls displayed no leptospiral ISH signals.

Discussion

Leptospirosis is an acute septicemic disease involving several organs. The demonstration by immunohistochemistry of LAg in cells of the inflammatory infiltrate both in human liver and kidney is expected as a response to circulating antigen/s. In the experimental model, LAg is

Fig. 2 **a** Control (non-leptospirotic) human liver showing normal E-cadherin expression over the cell membrane. IHC and hematoxylin, $\times 200$. **b** Human fatal leptospirosis. demonstrated not only phagocytized by macrophages but also adhering to hepatocyte membrane, particularly at the zone III of the liver lobule where liver-plate disarray is usually more pronounced [2, 3, 20]. Adhesion of leptospire and/or their degradation products to cell and even to basement membranes and extracellular matrix has been described [2, 3, 14]. In our previous studies, immunoelectron microscopy in the guinea pig model of leptospirosis had revealed gold-labeled LAg close to cell membranes of hepatocytes, kidney tubular cells, and endothelial cells of the interstitial capillaries. The antigen/s were afterward internalized by hepatocytes and renal tubular cells and eventually found in lysosomes within damaged cells [12]. The affinity of leptospire for cell and basal membranes is directly related to its virulence. It is interesting that a fibronectin-binding protein expressed on the surface of virulent *L. interrogans*, serovar *Icterohaemorrhagiae*, is believed to be important for adhesion and invasion of leptospire [6].

In humans, LAg deposits are usually not found on the membrane of hepatocytes and can seldom be detected at the luminal side of renal tubular cells. The difference in expression pattern between the human disease and the guinea pig model may be attributed to several reasons: (1) in the experimental model, the number of injected leptospire could be much larger than in average human infection, leading to higher detection rate in the animals; (2) as mentioned earlier, LAg is initially localized to the cell membranes but is later found in lysosomes and is finally degraded; therefore, it is conceivable that different phases in the disease progression might account for differences in staining patterns; (3) the disease process might be different between both species; and (4) finally, post-mortem alterations might be responsible for decreased signal intensity in human samples.

Cadherins are members of a family of adhesion molecules involved in calcium-dependent homotypic cell-cell interactions [4]. E-cadherin is a 120-kDa glycoprotein that is highly expressed during development and is the predominant cadherin of the liver epithelium. It is concentrated in the adherens junction, where it interacts with actin filaments. In the absence of E-cadherin, epithelial cells are not capable of a stable intercellular adhesion.

Our results suggest an irregular expression of E-cadherin in liver cells in human leptospirosis. This alteration might be primarily related to cell membrane lesion or secondary to other hepatocyte injuries. In either case, the persistence, at least partially, of E-cadherin expression might be a marker for restoration of a normal liver cell membrane function in cases of recovery from the disease and merits attention as a potential prognostic marker and/or factor.

Liver cell-plate disarray, when present at autopsy, is a major histopathologic marker of liver involvement in leptospirosis [5, 8, 24]. However, it was not observed in biopsy studies [1, 10, 11] and its absence raised the hypothesis that this aspect might appear only at a more acute phase of the disease or during the agonal period. The proponents of this idea argued that human biopsies could only be performed when the hemorrhagic phase had

subsided and the patients, therefore, were in an early recovery phase of the disease. Furthermore, experimental work on a sequential daily basis validated the liver-plate disarray [3, 20]. Taken together, these results suggest that, even if agonal and post-mortem changes can worsen the liver pattern, the lesion is genuine and regresses rapidly, which justifies its absence in biopsy studies.

Deposits on the host cell membrane of LAg and loss of E-cadherin membrane expression in leptospirotic patients might corroborate previous suggestions that cell membrane damage is the primary lesion in leptospirosis, mediated by a glycolipoprotein (GLP) [12, 26, 27] or lipoproteins transported to the leptospiral surface and/or secreted [22]. In agreement with these suggestions is the demonstration that GLP in the experimental model has also an intense affinity for hepatocyte cell membranes and is detected by IHC only at the late phase of the disease as granules both in the cytoplasm of macrophages and on the cell membranes, suggesting that its presence is the result of partial leptospiral degradation secondary to phagocytosis [2, 3, 23]. Vinh et al. [27] suggested that such adherence of leptospire and/or their products might lead subsequently to the microorganism fatty acids to be intercalated into the cell membrane. It is worth remembering, however, that leptospire have, as the major carbon and energy sources, long-chain fatty acids from which energy is derived mainly by beta-oxidation [14]. Therefore, as an alternative to Vinh's [27] suggestion, we might speculate that the microorganism's adherence to cell is necessary to supply its energy requests which would be provided by cell membrane fatty acids.

ISH detected sequences of leptospire chiefly in the nuclei of liver cells in human cases. The relevance of this finding, if any, is unknown at the moment. However, when we take into account the occasional human and experimental ISH findings showing also a cytoplasmic signal together with the immunoelectron findings of the experimental disease [12], it is possible to suppose that leptospiral nucleotide sequences, initially localized on the cell membrane and subsequently internalized by the endocytic lysosomal pathway, might migrate to the nucleus. Supporting this hypothesis, Darji et al. [9], working with an attenuated strain of *Salmonella typhimurium*, observed a similar nuclear staining pattern and suggested that lysis of bacteria in the phagolysosome compartment and escape to the cytosol of the host cell should precede the plasmid DNA transfer into the nucleus. Moreover, Holmgren et al. [17] demonstrated that cultivation of apoptotic bodies derived from Epstein-Barr virus (EBV)-carrying cell lines with either fibroblasts, monocytes, or endothelial cells resulted in the uptake of DNA and expression of EBV-specific markers in the recipient cells. Therefore, it is conceivable that specific nuclear staining could be visualized in leptospirotic patients. The weaker signal observed with ISH when compared to IHC might have several explanations: (1) IHC reactions were performed using amplification-based protocols, which usually increase the signal by several folds and (2) the LAg sera were obtained from whole *Leptospira*, and it is expected to recognize several

different epitopes, which would result in stronger signal when compared to the single-sequence-based small ISH probes.

The characteristics mentioned above might render the IHC reactions prone to nonspecific results. Our results, however, confirm that the available antibodies are specific and might be used, as previously reported [16, 29], for diagnostic purposes in situations in which leptospirosis is suspected and/or to study disease process in leptospirosis animal models [1–3, 20]. ISH and IHC apparently can detect leptospirosis with the same sensibility. The unique ISH staining pattern, however, suggests that this technique might be more useful in human and experimental pathogenetic assays.

In conclusion, this study brings further support to the idea that cell membrane lesion might play an important role in leptospirosis pathogenesis. Furthermore, we show herein that the loss of E-cadherin membrane expression is associated with liver-plate disarray, stressing that this feature is a genuine lesion in leptospirosis and suggesting that this finding might have prognostic relevance. Finally, we suggest that IHC and ISH might be used for both diagnostic and research purposes.

Extracellular matrix alterations in conventional renal cell carcinomas by tissue microarray profiling influenced by the persistent, long-term, low-dose ionizing radiation exposure in humans

Received: 7 June 2005 / Accepted: 27 December 2005 / Published online: 9 March 2006
© Springer-Verlag 2006

Abstract The present study was carried out in order to examine molecular alterations of extracellular matrix (ECM), associated with cell–cell communication in conventional (clear-cell) renal cell carcinomas (cRCCs) influenced by persistent long-term, low-dose ionizing radiation (IR) exposure to patients living more than 19 years after the Chernobyl accident in Cesium 137 (^{137}Cs)-contaminated areas of Ukraine. The ECM major components such as fibronectin, laminin, E-cadherin/ β -catenin complexes and p53 tumor suppressor gene protein, and transforming growth factor beta 1 (TGF- β 1) were immunohistochemically (IHC) evaluated in cRCCs from 59 Ukrainian patients, which represented 18 patients living in non-contaminated areas and 41 patients from ^{137}Cs -contaminated areas. In contrast, a control group of 19 Spanish patients with analogue tumors were also investigated. For IHC evaluation, a tissue microarray technique was used. Decrease or loss and abnormal distribution of fibronectin, laminin, E-cadherin/ β -catenin complexes accompanied by elevated levels of p53 and TGF- β 1 were detected in the Ukrainian cRCCs from ^{137}Cs -contaminated areas with statistically significant differences. Thus, our study sug-

gests that chronic long-term, low-dose IR exposure might result in global remodeling of ECM components of the cRCCs with disruption in peri-epithelial stroma and epithelial basement membranes.

Keywords Conventional renal cell carcinoma · Extracellular matrix · Ionizing radiation

Abbreviations cRCCs: Conventional renal cell carcinomas · BM: Basement membrane · ECM: Extracellular matrix · ^{137}Cs : Cesium-137 · IR: Ionizing radiation · TGF- β 1: Transforming growth factor- β 1 · IHC: Immunohistochemistry · TMA: Tissue microarray

Introduction

The biologic effects of chronic low doses of ionizing radiation (IR) and its relationship with carcinogenesis have received a great deal of attention in the last few years [6]. Redox homeostatic processes in the microenvironment, involving interaction between cell–cell and cell–extracellular matrix (ECM), could be targets for chronic low-dose IR. The accident at the Chernobyl power plant in Ukraine on April 1986, introduced for the first time the problem of chronic persistent long-term human low-dose exposure to IR. Recent studies by our group showed increases in morbidity, aggressivity, and proliferative activity of Conventional renal cell carcinomas (RCCs) in patients living permanently in Cesium 137 (^{137}Cs)-contaminated areas of the Ukraine. We have previously documented for the first time that chronic persistent long-term low-dose IR exposure leads to the development of a previously unknown “radiation sclerosing proliferative atypical nephropathy” in peritumoral kidney tissue and which demonstrated a good correlation with the duration of radiation exposure [21, 22].

Microenvironment composition is a critical determinant of cancer suppression or promotion. Nonmutagenic effects of IR can have persistent effects that perturb the multicellular system in a manner that clearly promotes, and may

initiate, the neoplastic processes [1]. The mediators of cellular responses to DNA damage caused by radiation are very well characterized, and the *p53* tumor suppressor gene is considered to be the major cellular sensor and signal of DNA damage. Whereas intracellular mediators of *p53* stability after radiation exposure have been the subject of intense study, little is known about the extracellular factors that affect the *p53* response to IR. An early and persistent event in irradiated tissues is the activation of the pluripotent cytokine, transforming growth factor beta 1 (TGF- β 1). TGF- β is produced as a latent complex that is secreted and requires extracellular activation that permits TGF- β 1 to bind to ubiquitous receptors and to function as a specific link between cell stress response to damage (IR) and the signaling mediated through the microenvironment [1].

It has been pointed out that laminin is also present in the basement membrane (BM) of invasive RCCs [10], and it has even been suggested that laminins accompany cancer cells and may play a significant role in the initial phase of cancer invasion [18].

The migration of RCC cells is stimulated in a different manner by various components of the ECM, whereby, fibronectin is the most stimulating factor. Fibronectin is an extracellular glycoprotein that binds to and signals through heterodimeric cell surface receptors known as integrins [4, 13]. This molecule is known to be regulated by the von Hippel–Lindau (VHL) gene, and VHL inactivation results in defective fibronectin extracellular matrix assembly. Furthermore, fibronectin gene expression has been correlated with increased tumor cell growth and invasiveness of VHL-defective RCCs [4, 13].

Adhesion of tumor cells to the endothelium and invasion into the ECM is mediated by cell adhesion and membrane-bound surface molecules from various molecular families, including among others, cadherins [5, 15]. The cadherin gene superfamily contains more than 40 members that encode for transmembrane proteins regulating calcium-dependent cell–cell adhesion [3]. Epithelial (E)-cadherin is a crucial epithelial adhesion molecule that links cells via a homophilic extracellular domain and is anchored intracellularly to the cytoskeleton via dynamic interactions with the catenins [12].

β -catenin is a key regulator located within the Wingless signal transduction (Wnt) cascade, involved in the control of cell adhesion and cell polarity [16]. Several studies have shown that loss or reduction of either E-cadherin or catenin expression is linked to a decrease in cellular and tissue differentiation and increased histological grade of different epithelial neoplasms and with increased risk for the development of metastases in human tumors [14, 26]. It has previously been suggested that immunohistochemical cytoplasmic E-cadherin staining could be associated with poorly-differentiated clear-cell renal carcinomas and demonstrated that the loss of E-cadherin resulted as a poor prognostic marker for RCCs [17].

The present study was, thus, designed to compare ECM molecular alterations in cRCCs of three groups of patients: group 1 from Valencia University Hospital (Spain), group 2 from the so-called “clean” (no radioactive contamination)

areas of the Ukraine, and group 3 from radio-contaminated areas of the Ukraine. TGF- β 1, laminin, fibronectin, and components of the E-cadherin/ β -catenin complex were evaluated in cRCCs, in an attempt to detect molecular lesions of ECM with a possible role in renal carcinogenesis in patients chronically exposed to low-dose IR after the Chernobyl accident in Ukraine.

Materials and methods

Case selection

Paraffin-embedded specimens from 78 patients (47 men and 31 women; male/female ratio 1.5:1) were selected for the present study. Patients with 19 primary cRCCs who underwent surgery between 1993–2003 in the University Clinic Hospital of Valencia (Spain), represented control group 1, in comparison with 59 analogue patients with cRCCs, who underwent surgery between 1999 and 2005 in the Institute of Urology, Academy of Medical Sciences of Ukraine in Kiev (Ukraine). The Ukrainian patients were selected as group 2 (18 patients from “clean” areas, with no indicated radio-contamination), and group 3 (41 patients from radio-contaminated areas, including Kiev city). These patients resided in the same areas during the pre- and post-Chernobyl accident periods. All specimens were reevaluated with regard to pathological tumor (pT) stage, grade and histologic subtype. The pT stage was adjusted according to the International Union Against Cancer tumor, nodes, metastasis (TNM) system [8, 27]. Histologic nuclear grading was determined according to the method of Fuhrman et al. [11]. Moreover, we evaluated the presence and percentage of sarcomatoid changes, plus the presence and intensity of inflammatory response and the presence of necrotic areas.

Immunohistochemistry

For immunohistochemical (IHC) evaluation, a tissue microarray (TMA) technique was used. It allows the staining of a large number of specimens in only one slide. Two different TMAs were constructed containing cRCCs from groups 1–3 and normal kidney for the histologic control. A manual tissue arraying instrument (Beecher Instr, Sun Prairie, WI) was used. With respect to the known histologic heterogeneity of cRCCs, at least two different cylinders of tissue (1.5 mm in diameter), were taken from different sites of each tumor and arrayed in a recipient paraffin TMA block. Initial sections were stained with hematoxylin–eosin (H&E) to verify the histopathological findings. Sections (3 μ m) from TMA blocks were mounted on ChemMate capillary gap microscope (Dako Cytomation, Denmark slides for IHC analysis).

The slides were baked overnight in a 56°C oven. Sections were deparaffinized in xylene for 20 min, rehydrated through a graded ethanol series and washed with PBS. Antigen retrieval was achieved by a 2-min heat

treatment in autoclave at 1.5 atm and using citrate buffer pH 6.5 (10 mmol/l sodium citrate buffer, Dako, Denmark). Endogenous peroxidase activity was *inhibited* with 1.5% hydrogen peroxide in methanol for 10 min. IHC staining was performed on these sections using the primary antibodies against p53 (1:50, Dako-Cytomation); fibronectin (1:200, Dako-Cytomation); laminin (1:50, Dako-Cytomation); E-cadherin (1:20, Novocastra); β -catenin (1:50, S. Cruz Technology); TGF- β 1 (1:50, S. Cruz Technology). Immunodetection was performed with the LSAB visualization system (Dako) using 3,3-diaminobenzidine chromogen as substrate. As controls, known positive tissue sections were used, and for negative controls, exposure to the primary antibody was omitted. The IHC analysis was performed independently by at least two pathologists in a blind fashion without knowledge of the patient group.

Quantitative analysis

The IHC score was evaluated according to the extent, intensity, and distribution patterns. Intensity of staining was scored using the following criteria: no detectable staining, low, moderate, and strong staining. The extent of staining was scored as 0—no detectable staining; 1—low (less than 10% scattered cells); 2—moderate (more than 10 but less than 50% stained cells); 3—strong homogenous staining (more than 50% stained cells). Immunoreactivity scoring was determined by the average positivity of all core biopsies.

Statistical analysis

For analysis of variables, each had a qualitative or quantitative connotation, depending upon their possibility for evaluation. Ages of patients and tumor size had a quantitative connotation, and the others (clinical, histological, and immunohistological) had qualitative ones. Statistical analysis was performed to determine whether pathological and IHC data were related to each other, and to the different groups of patients. We applied a χ^2 test for statistical analysis between qualitative variables. ANOVA and mean difference tests were used to assess the relationships between qualitative and quantitative variables.

Results

Histopathology

Characteristics of all patients associated with TNM stage, grade, and pathological features of cRCCs in the different groups are summarized in Table 1. The Ukrainian patients were significantly younger than the Spanish ones, and TNM stage was significantly more localized in both Ukrainian groups, in comparison with the Spanish control group ($\chi^2=22.52$; $p=0.004$). Comparative analysis between all Ukrainian and Spanish groups showed significantly

more frequent incidences of high grade conventional RCCs in Ukrainian patients, particularly, in group 3 patients.

Sarcomatoid transformation was present in less than 10% of the total tumor volume in 14 (18%) cases and predominantly showed the perivascular extent and was detected only in tumors from Ukrainian patients. Intratumoral inflammatory response was more frequently associated with the Spanish control group 1 tumors with significant differences between groups. The reverse correlations demonstrate the incidence of tumoral necrosis, which was more frequent in groups 2 and 3 with significant differences.

Immunohistopathology

IHC results for p53, fibronectin, laminin, β -catenin, E-cadherin, and TGF- β 1 in cRCCs in groups 1, 2, and 3 are shown in Table 2. Immunohistochemical findings in cRCCs from the Ukrainian patients inhabiting in radiocontaminated areas (group 3) are illustrated in Fig. 1.

The nuclear p53 protein overexpression was detected in nine tumors from Ukrainian patients, which were predominantly high grade, with sarcomatoid transformation, and from patients living in radiocontaminated areas. P53 expression was negative in the Spanish group of tumors.

Fibronectin was positive in 100 and 85% of cases from Spanish and Ukrainian cRCCs, respectively. In the majority of cases, the nests of positive tumor cells were surrounded

by extracellular stroma that had weak or negative fibronectin staining in both Spanish and Ukrainian cRCCs, with predominant disappearance of cytoplasmic fibronectin in group 3 cRCCs (Fig. 1f). In comparison, the Spanish group 1 cRCCs demonstrated a high percentage and strong intensity of staining in ECM and tumor cells in 100% of cRCCs. Moreover, high grade (3 and 4) tumors revealed a loss of IHC staining against fibronectin compared to low grade (1 and 2) cRCCs with significant differences ($\chi^2=13.9$; $p=0.03$).

Overall, laminin was positive in 44% of 78 cRCCs. The laminin-positive staining in cRCCs of groups 2 and 3 was predominantly membranous with frequent fragmentation of basement membranes (Fig. 1e). Remarkably, the homogeneous laminin staining in tumor cell cytoplasm was detected in 24% of group 3 cRCCs associated with weak or even loss of the membranous staining in the same tumors. Statistically significant differences were obtained for laminin between groups. The indicative tendency to lose laminin immunoreactivity was shown in high grade (grades 3 and 4) compared with low grade (grades 1 and 2) tumors; however, there were no significant differences. Within p53 positive Ukrainian cRCCs, 77% were laminin-negative. There was no significant correlation between laminin-immunoreactivity and TNM or with other clinicopathological features of cRCCs.

Additionally, β -catenin and E-cadherin were positive in 56 and 55% of 78 cRCCs, respectively. There was a relationship between groups with β -catenin and E-cadherin positive tumors, with a decrease of intensity and of the percentage of stained cells in the Ukrainian group 3 cRCCs. It is important to note that both β -catenin and E-cadherin had accumulated in cytoplasm (Fig. 1c,d) in 29 and 24% of the Ukrainian cRCCs, respectively, in comparison with 15 and 10% of the Spanish group 1 tumors, where β -catenin and E-cadherin showed predominantly membranous staining. Interestingly, the intensity of the granular or homogeneous cytoplasmic β -catenin and E-cadherin immunoreactivity was inversely related with the intensity of the membranous staining in the same tumors. Moreover, the inverse relation was obtained between p53 overexpression and decreased levels of predominantly cytoplasmic β -catenin in six of nine p53 positive Ukrainian cRCCs. There were no statistical associations between β -catenin and E-cadherin with TNM stage, grade and other morphologic features.

In total, TGF- β 1 was positive in 60% of 78 cRCCs. All group 1 TGF- β 1 positive tumors showed only membranous staining. Furthermore, both cytoplasmic (Fig. 1b) and cytoplasmic and membranous TGF- β 1 staining were represented in 38 and 44% of cRCCs from Ukrainian groups 2 and 3 with significant differences ($\chi^2=16.45$; $p=0.012$). Strong cytoplasmic TGF- β 1 staining was also

noted in the stromal endothelial cells and fibroblasts of the Ukrainian group 3 cRCCs (Fig. 1b). Moreover, moderate and high levels in percentage of stained cells were detected in both Ukrainian groups (55 and 75% of cRCCs in groups 2 and 3, respectively), with significant differences between them. On the other hand, only six (31%) in Spanish group 1 cRCCs were positive, with less than 50% of stained cells. Interestingly, we can see a strong membranous and cytoplasmic overexpression in 89% of the p53 positive Ukrainian group 3 cRCCs. Moreover, high grade Ukrainian cRCCs showed a tendency for increased TGF- β 1 staining, without significant differences. No relationships were found between TGF- β 1 expression, TNM stage and other histological features.

Discussion

This is the first study attempting to characterize the local expression of the three major components of the extracellular matrix: fibronectin, laminin, E-cadherin/ β -catenin complexes and to examine their association with the TGF- β 1 signaling pathway and with p53 tumor-suppressor gene protein overexpression in cRCCs from the Ukrainian patients chronically exposed to long-term, low-dose rate IR, in comparison with the non-exposed Spanish patients.

We found disruption of all the above mentioned ECM components associated with strongly activated TGF- β 1 in

cRCCs of patients who have lived longer than 19 years in ^{137}Cs -contaminated areas of Ukraine, and therefore, these alterations might, in our opinion, be a result of chronic long-term low-dose IR exposure. This suggestion is supported by our recent study [23], which showed that the analogue RCCs patients living in the ^{137}Cs -contaminated areas of Ukraine demonstrate the highest levels of urinary ^{137}Cs excretion which is known to constitute roughly 90% of internal radioactivity and is concentrated and eliminated through the kidneys [19]. However, it is necessary to note that there were no significant correlations between the above mentioned IHC markers of ECM and TNM stage, nor with other histopathological features of cRCCs.

In our study, IHC staining of the basement membrane for laminin demonstrated significant differences in the incidences, intensity and distribution of laminin expression between three groups of tumors. Predominantly, membranous and less disrupted laminin immunoreactivity was observed in Spanish cRCCs. Although the majority of the Ukrainian cRCCs from patients living in radio-contaminated areas were laminin-negative, 17% of cRCCs demonstrated the cytoplasmic staining for laminin associated with a weak discontinuous membranous staining. Subsequently, fragmentation and disruption of basement membrane continuity in RCCs with reduced local presence of laminin has been associated with the process of tumoral invasion [17]. Moreover, it has been pointed out that

laminin is often also present in the cytoplasm of cancer cells, indicating a high invasive potential of the tumor and possibly related to distant metastasis and poor prognosis [22, 28, 29].

Adhesion of tumor cells to the endothelium and the invasion into ECM is known to be mediated by cell adhesion molecules with E-cadherin/ β -catenin complexes among them. Our findings indicate that alterations of E-cadherin/ β -catenin are frequent in the Ukrainian cRCCs, especially of people living in radio-contaminated areas. Interestingly, increased protein levels and abnormal intracellular location of β -catenin, in our study, was associated with p53 protein overexpression in six (67%) of nine p53 positive cRCCs of Ukrainian patients. Recent studies showed that aberrant activation of β -catenin signaling is common in cancers of different origins and results from mutations that induce the accumulation of p53 [25]. This elevation in p53 is achieved, at least in part, by induction of the ARF gene promoter [7]. The pivotal role of the p14ARF promoter hypermethylation in the pathogenesis of the Ukrainian RCCs from patients living in radio-contaminated areas was recently documented by our group [23]. The possibly mutated oncogenic β -catenin expression in analogue Ukrainian cRCCs might activate the p53 response which, in turn, can enhance the degradation of β -catenin by a negative feedback loop during increased tumor progression [24]. The loss of β -catenin in our group 3 tumors was accompanied by a reduction in E-cadherin associated with abnormal cytoplasmic location which might be related to the metastatic process and to poorly differentiated forms of these tumors [17, 25].

Evidence has accumulated that nonmutagenic effects of IR, however, can have persistent effects that result in interactions with the microenvironment: stromal–epithelial, cell–cell and cell–extracellular matrix [1]. While excess reactive oxygen species production generated by IR clearly damages DNA, persistent low levels of IR might affect cell-signaling, particularly, redox modulation. TGF- β 1 is a major extracellular signaling sensor of damage as it mediates redox homeostasis in cells and contributes to cell–cell communication [2]. TGF- β 1 is also known as a mediator of tissue response to IR, pointing to a role in orchestrating changes due to oxidative stress [9]. The present results indicate the significantly high levels and alteration of TGF- β 1 expression in the cRCCs of the Ukrainian patients living in the radio-contaminated areas, as compared to both Spanish and Ukrainian controls. Furthermore, TGF- β 1 immunostaining was found to be most pronounced as stromal, membranous and infrequently even as tumor cell cytoplasmic expression. Remarkably, TGF- β 1-positive stromal endothelial cells and fibroblasts were also detected. Therefore, our data support the idea that the irradiated stroma dramatically increases the ability of the tumor progression [1].

Our results showed that the presence of TGF- β 1 was associated with a loss of E-cadherin immunoreactivity in 24% of the Ukrainian cRCCs. Moreover, 89% of the Ukrainian p53-positive cRCCs showed strongly enhanced levels of TGF- β 1. A variety of studies have linked p53

status and TGF- β 1 responsiveness in cancer cells [20, 30]. A number of striking similarities exists between p53 and TGF- β : both are induced by a variety of damaging factors, specifically by IR, both exhibit redox modulation of protein activity, both are very rapidly activated and so on. However, p53 is accumulated intracellularly and mediates individual cell fate, while TGF- β 1 is extracellular and orchestrates diverse multicellular fates. The functional intersection of TGF- β 1 and p53 supports the hypothesis that genomic stability can be significantly affected by the character and activity of the microenvironment [1].

Thus, there is mounting evidence that IR exposure can promote malignant tumor progression by pathways other than gene mutation. Our study suggests that chronic, long-term, low-dose IR exposure might result in global remodeling of ECM components with changes in per-epithelial stroma and epithelial basement membranes (including fibronectin, laminin, E-cadherin/ β -catenin complexes alterations). We found that cRCCs from the Ukrainian patients chronically exposed to long-term, low-dose IR are characterized by significantly disrupted ECM with a lack of orchestrated communication between cells and between cells and ECM, that leads to loss of cellular differentiation. These factors may also become relevant targets for novel therapeutic strategies.

Histone mRNA in situ hybridization and Ki 67 immunohistochemistry in pediatric adrenocortical tumors

Received: 26 October 2005 / Revised: 9 December 2005 / Accepted: 22 December 2005 / Published online: 18 February 2006
© Springer-Verlag 2006

Abstract Adrenocortical tumors in the pediatric population are rare. Classification of these tumors as adenomas or carcinomas using histological criteria is often difficult. Immunohistochemical expressions of proliferative markers are currently under investigation for utilization in the differential diagnosis and prediction of clinical outcomes. The value of histone proteins as prognostic markers in adrenocortical tumors has not yet been elucidated. We evaluated the histological features, immunohistochemical staining of Ki 67, and in situ hybridization for histone mRNA in 30 pediatric adrenocortical tumors. We investigated the relationship between these parameters and the prognosis. Using the classification proposed by Weiss, 19 tumors were classified as carcinomas and 11 as adenomas. Ki 67 and histone mRNA labeling indices (LIs, the percentage of Ki 67-positive and histone mRNA-positive tumor cells, respectively) were significantly higher in carcinomas than in adenomas (Ki 67 LI was 14.62 ± 5.79 in adenomas and 20.35 ± 6.23 in carcinomas, $p=0.02$. Histone mRNA LI was 1.73 ± 1.71 in adenomas and 6.62 ± 2.28 in carcinomas, $p=0.00$). The proliferative activity assessed by histone mRNA was lower than that assessed by Ki 67 in both diagnostic groups. The cut off point for the diagnosis of malignancy was found to be 14.55 for Ki 67 LI and 5.75 for histone mRNA LI. A correlation was found between a histone mRNA LI ≥ 5 and poor prognosis (recurrence, metastasis, or death). We concluded that the proliferative activity of the tumor assessed by Ki 67 and histone mRNA may assist in differentiating adrenocortical adenomas and

carcinomas. In addition, our results suggest that the most reliable parameter to predict prognosis in pediatric adrenocortical tumors is the histone mRNA LI.

Introduction

Adrenocortical tumors are rare in children with an incidence of 0.3 cases per 1,000,000 children per year, and these tumors represent 0.2% of all childhood tumors [17]. The distinction between benign and malignant adrenocortical tumors is difficult [6, 17]. Despite histological criteria by which such a distinction may be possible, the behavior of adrenocortical tumors in childhood is usually unpredictable, and distinction based only on histological classification is difficult. Many reports conclude that the adrenocortical tumors in children and adolescents differ from those occurring in adults, both clinically and histologically [3, 17, 19, 25]. Due to the low incidence of these tumors in childhood, there is paucity of data on the histological and molecular markers that could help in differential diagnosis or in predicting clinical outcomes. In recent studies, the proliferative activity of tumor cells is being investigated to assess their role in differentiating benign and malignant tumors. For this purpose, immunohistochemical expressions of Ki 67 and PCNA were evaluated in many human tumors. The diagnostic and prognostic value of the immunohistochemical Ki 67 expression in adrenocortical tumors remains unclear [11, 17]. A recent method for the identification of proliferating cells in tissue sections is the use of in situ hybridization for the localization of histone mRNA. Nonisotopic histone mRNA in situ hybridization allows the detection of cells in the S phase of the cell cycle in paraffin-embedded tissues [5, 15]. There have been studies evaluating the in situ hybridization of histone mRNA in cerebral astrocytomas, head and neck tumors, and benign tissues [2, 5, 16]. To our knowledge, in situ hybridization

of histone mRNA in adrenocortical neoplasms has not undergone investigation as a diagnostic tool and a prognostic marker.

The aim of this study was to evaluate the relevance of the immunohistochemical staining with Ki 67 and non isotopic in situ hybridization of histone mRNA in the differential diagnosis and clinical course of pediatric adrenocortical tumors.

Materials and methods

Pathological examination

Thirty pediatric adrenocortical tumors diagnosed in Hacettepe University, Faculty of Medicine, Children's Hospital, Division of Pediatric Pathology, were included in the study group. All patients had undergone a minimum of 4 years of clinical follow-up. All cases were reviewed (DO) and classified as either adenoma or carcinoma using the histopathological criteria according to the methods of Weiss [26]. Hematoxylin and eosin-stained histological sections of each case were evaluated for nine histopathological features. The nuclear grade was assessed using the criteria of Fuhrman et al. [8]. Mitosis was evaluated by counting at random 50 high power fields (hpf; magnification at $\times 40$ with a $\times 10$ objective lens using an Olympus BX51 microscope) in the area of the greatest number of mitotic figures. Presence of atypical mitosis was also noted. The percentage of clear cells resembling the normal zona fasciculata was evaluated. Architecture was defined as diffuse if more than one-third of the tumor formed sheets of cells with no pattern. Necrosis was considered to be positive when it involved confluent nests of cells. Invasion of sinusoids (endothelium-lined vessels with no smooth muscle in the wall) and veins (vessels with smooth muscle in the wall) was recorded. Capsular invasion was scored as present when nests or cords of tumor extended into or through the capsule.

A tumor with two or fewer of the criteria below was classified as an adenoma; tumors with three or more criteria were considered carcinomas:

1. High nuclear grade (III or IV) assessed using the criteria of Fuhrman et al
2. Mitotic rate $>5/50$ hpf
3. Presence of a typical mitosis
4. Clear tumor cell cytoplasm ($<25\%$ of the tumor cells)
5. Diffuse architecture
6. Necrosis
7. Venous invasion
8. Sinusoidal invasion
9. Capsular invasion

Immunohistochemistry

Immunohistochemical staining was performed using the primary antibody against Ki 67 (Neomarkers, CA, USA; clone: MIB-1, dilution:1/100) with streptavidin-biotin

peroxidase method (Dako LSAB 2 System, Peroxidase, CA, USA). Pretreatment in citrate buffer was performed for antigen retrieval by heating in a microwave oven. For negative control, primary antibody was replaced with normal mouse serum. Sections of tonsils were used as positive control. All tumor cell nuclei with dark brown staining, even those with vague speckling patterns, were considered to be Ki 67-positive. Ki 67 counts were performed according to these staining criteria. The count of Ki 67-positively stained nuclei was performed in areas of greatest labeling density within each tumor. About 1,000 tumor cells were counted at a magnification of $\times 400$. Ki 67 labeling index (LI) was defined as the number of Ki 67-positive tumor cell nuclei per 100 tumor cells.

Nonisotopic in situ hybridization assay

For the nonisotopic in situ hybridization, 10- μm sections were obtained from paraffin-embedded tissue blocks and placed on 3-aminopropyltriethoxy-sialine slides (Novocastra Laboratories, New Castle upon Tyne, UK). A commercial fluorescein-labeled oligonucleotide cocktail was used for the detection of histone H2B, H3, and H4 mRNA sequences (Novocastra Laboratories). The nonisotopic in situ hybridization protocol was the same as that recommended by the manufacturer. Tissue sections were deparaffinized in xylene, rehydrated through ethanol series and immersed in distilled water. The sections were then treated with proteinase K (Novocastra Laboratories) (20 $\mu\text{g}/\text{ml}$ in 5 mM Tris-HCl buffer, pH 7.6) for 30 min at 37°C . After washing in distilled water and dehydrating through 95% and 99% ethanol, the sections were air dried and hybridization with fluorescein isothiocyanate (FITC)-labeled cocktail was performed in the supplied buffer overnight at 37°C . The Novocastra histone probe ISH kit (Novocastra Laboratories), which included alkaline phosphatase conjugated rabbit Fab anti-FITC, enzyme substrate (5-bromo-4-chloro-3-indolyl-phosphate and nitro blu tetrazolium), and an inhibitor (levamisole), was used for the detection of histone mRNA-positive cells. All solutions and equipment used for the stages up to the hybridization were treated with H_2O_2 and diethyl pyrocarbonate to remove ribonuclease, and all procedures were carried out while wearing gloves.

Histone mRNA-expressing tumor cells were counted by light microscope at $\times 400$ magnification. The total number of cells counted was 1,000. Histone mRNA LI was defined as the number of histone mRNA-positive tumor cells per 100 tumor cells.

Statistics

All statistical analyses were performed with the Statistical Package of Social Sciences for Windows 12.0. A p value <0.05 was considered statistically significant. An independent t test was used to determine whether Ki 67 LI and histone mRNA LI differed significantly between adenoma-carcinoma groups and prognostic groups.

Table 1 Histological features of 30 pediatric adrenocortical tumors

	Nuclear grade III, IV	Mitosis (>5/50 hpf)	Abnormal mitosis	Clear cells (<25%)	Diffuse architecture	Necrosis	Capsular invasion	Venous invasion	Sinusoidal invasion
Carcinoma (n=19)	17	11	10	16	15	17	17	11	12
Adenoma (n=11)	9	4	0	2	1	2	0	0	0

Receiver operating characteristics (ROC) curve analyses were used to determine how well Ki 67 LI and histone mRNA LI discriminate between adenoma and carcinoma patients. The prognostic value of Ki 67 LI and histone mRNA LI was also analyzed by ROC curve analysis. Comparison of Ki 67 LI and histone mRNA LI was made using the area under the ROC curves. The best cut off points for both diagnostic and prognostic groups were found at the points where the sum of false positive and false negative rates was at the minimum value.

Results

Based on the histopathological classification proposed by Weiss, 19 tumors were classified as adrenocortical carcinomas and 11 as adenomas. Microscopic findings of the tumors are summarized in Table 1. All adenomas had two or fewer Weiss criteria. No single histological criterion could be used to distinguish a carcinoma from an adenoma. However, none of the adenomas showed abnormal mitosis, capsular, venous, or sinusoidal invasion.

Among the patients with adenoma, one had local recurrence during follow-up. Three of the patients that had carcinomas were alive with no evidence of disease, and the others showed poor prognoses (recurrence, metastasis, or death).

The staining of nonisotopic histone mRNA in situ hybridization was localized to the cytoplasm and nuclear membrane (Fig. 1). Immunohistochemical expression of Ki 67 was observed as nuclear immunostaining (Fig. 2). There

Fig. 1 Brown cytoplasmic and nuclear staining of nonisotopic histone mRNA in situ hybridization in adrenocortical carcinoma (×100)

was a statistically significant difference of Ki 67 LI between adenoma (mean 14.62 ± 5.79) and carcinoma (20.35 ± 6.23) groups ($p=0.02$). Histone mRNA LI also differed significantly between adenoma (1.73 ± 1.71) and carcinoma (6.62 ± 2.28) groups ($p=0.00$) (Table 2). Individual results of Ki 67 and histone mRNA labeling are shown in Table 3.

To evaluate the discriminatory power of histone mRNA and Ki 67, the area under the ROC curves was evaluated. The area under the ROC curve for Ki 67 LI was 0.78 ($p=0.012$), and for histone mRNA LI, the area was 0.957 ($p=0.00$), indicating that there is a statistically significant difference between the two parameters ($p=0.049$) (Table 4).

The best cut off point for the diagnosis of malignancy was found to be 14.55 for Ki 67 LI and 5.75 for histone mRNA LI. Considering these cut off points, the sensitivity and the specificity of Ki 67 LI were 94.7% and 63.6%, respectively. A histone mRNA LI ≥ 5.75 was significant for the diagnosis of malignancy with 84.2% sensitivity and 100% specificity (Fig. 3).

Both Ki 67 and histone mRNA LIs were significantly higher in tumors with poor prognosis. Mean Ki 67 LI and histone mRNA LI with standard deviations for good and poor prognostic groups are shown in Table 5. The cut off point for poor prognosis was also determined for both Ki 67 and histone mRNA LIs. Tumors with a Ki 67 LI ≥ 12.65 showed poor prognosis with 100% sensitivity and 38.5% specificity. As a prognostic marker, the best cut off point for histone mRNA LI was 5. Ki 67 turned out to be almost significant when the area under the ROC curve was considered. Histone mRNA appeared to be a gold standard

Fig. 2 Immunohistochemical expression of Ki 67 in an adrenocortical carcinoma (×100)

Table 2 Ki 67 and histone mRNA LIs in adrenocortical adenomas and carcinomas

	Diagnosis	<i>n</i>	Mean	Standard deviation	
Ki 67 LI	Adenoma	11	14.62	5.79	<i>t</i> =2.49, <i>p</i> =0.02
	Carcinoma	19	20.35	6.23

	Carcinoma	19	6.62	2.28	

test for prediction of prognosis (Fig. 4). The difference between the discriminatory power of the two parameters was also statistically significant (*p*=0.00) (Table 6).

Three patients with carcinoma who showed good prognoses had Ki 67 LIs (18.8, 19.6, and 16.4) greater than the cut off point for Ki 67 LI, but the histone mRNA LIs of these tumors were all lower than the cut off point for mRNA LI (1.4, 1.2, and 4.6). An adenoma with local recurrence had a Ki 67 LI of 13.1 and a histone mRNA LI of 5.4 (higher than the cut off point for poor prognosis for histone mRNA LI).

Table 3 Ki 67 and histone mRNA LIs of individual patients

Patient no	Diagnosis	Ki 67 LI	Histone LI
1	Carcinoma	15.2	7.3
2	Carcinoma	23.6	8.4
3	Carcinoma	24.1	6.2
4	Carcinoma	15.8	9.3

30	Adenoma	8.4	0.9

Discussion

Despite the presence of well-established histological criteria in the differential diagnosis of adrenocortical tumors in adults, it may be extremely difficult to distinguish between benign and malignant tumors [7, 14]. Weiss, Hough et al. and Van Slooten et al. proposed a variety of parameters to differentiate these tumors [11, 23, 26]. Aubert et al. confirmed the value of the Weiss system [1]. Because of the lack of histological criteria for the discrimination of adrenocortical adenomas and carcinomas in the pediatric population, the current classifications of adrenocortical tumors based on adult criteria are used in pediatric patient studies [17, 18, 24]. We too applied the Weiss criteria to classify the tumors in our study group as adenomas or carcinomas. Pediatric adrenocortical tumors are histologically different from those in adults [4, 12, 17, 19]. Although Weieneke et al. found only 31% of histologically malignant pediatric tumors behaving badly, Sawin and colleagues reported the long-term survival rate of children with adrenocortical carcinomas to be between 10 and 46%. Complete resection was associated with an improved survival rate (67%) despite a 38% local recurrence rate. Mortality, recurrence, and metastasis rates of the current series are within the limits mentioned in literature.

Weiss et al. reported that in pediatric patients, adrenocortical adenomas showed mitotic activity, broad fibrous bands, and nuclear pleomorphism more frequently than in adult adenomas [26, 27]. Supporting this knowledge, in our series, 4 of 11 adenomas had mitosis >5/50 hpf and 2 had necrosis. Similar to the results of the study by Weieneke and colleagues, there was no adenoma with capsular or vascular invasion in our series. As reported previously, we found no single histologic feature that reliably identified malignancy, either. All adenomas but one in our study diagnosed according to the Weiss criteria had a good clinical outcome. One patient with adenoma showed local recurrence during follow-up. Three patients with diagnosis of adrenocortical carcinoma were alive with no evidence of disease, and the others had poor prognoses. These results suggest that the Weiss criteria were not very valid in all pediatric adrenocortical tumors and that other parameters are also needed to predict the clinical outcomes of these tumors.

Table 4 Area under the ROC curve for diagnosis

	Area	Standard error	<i>p</i>
Ki 67 LI	0.78	0.098	0.012
Histone mRNA LI	0.95	0.033	0.000

Fig. 3 Comparison of ROC curves of Ki 67 and histone mRNA for the diagnosis of malignancy

Fig. 4 Comparison of ROC curves of Ki 67 and histone mRNA for prognosis

Reports on the role of molecular markers, such as cellular DNA content and proliferative activity of tumor cells, in the differential diagnosis and prognoses of adrenocortical tumors are seen in literature. There are several studies suggesting flow cytometric DNA analysis to be a reliable prognostic factor in adrenocortical tumors [3, 21]. Some other studies, however, indicate that ploidy is not a significant indicator of histological diagnosis or prognosis in these tumors [6, 14].

Another approach to make differential diagnosis and to find reliable prognostic factors for adrenocortical tumors involves the use of immunohistochemical proliferation markers such as Ki 67. Ki 67 is a nuclear protein expressed by proliferating cells in G₁, G₂, S, and M phases of the cell cycle. Ki 67 expression can be observed immunohistochemically in paraffin-embedded material by using the primary antibody MIB 1 [7, 9, 13, 16, 19, 20, 24]. Goldblum et al. and Vargas et al. found a strong correlation between Ki 67 expression and the malignancy of adrenocortical tumors in adults [9, 22]. Vargas et al. showed that the tumor's proliferative activity, determined by the percentage of Ki 67-positive tumor cells, was 1.49% in adenomas, 20.8% in carcinomas, and 16.1% in recurrent and metastatic tumors [22]. Aubert and colleagues also observed a statistically significant difference in Ki 67 labeling between adenomas (2.4±1.3%) and carcinomas (21.2±18.44%) [1]. Weieneke et al. and Sbragia and colleagues have investigated Ki 67 expression in pediatric adrenocortical tumors, and they have reported that Ki 67 immunostaining did not have a value in predicting clinical outcomes [19, 25]. In our series, we found that Ki 67 expression was significantly higher in carcinomas than

adenomas, and a Ki 67 LI ≥ 14.55 was found to be an indicator of malignancy for pediatric adrenocortical neoplasms. The assessment of cells in the S phase of the cell cycle is an alternative method for evaluating proliferating cells [2, 5, 10]. In situ hybridization of histone H3 and/or H4 mRNA is an assay used to detect S-phase cells in archival paraffin-embedded material [15, 16]. Histones are a class of nuclear proteins that play an essential role in the packing and expression of the eukaryotic genome. Synthesis of histone protein is restricted to the S phase. During the S phase of the cell cycle, the level of histone mRNA increases over 50-fold and rapidly disappears at the start of G₂. The rapid degradation of the histone mRNA after the S phase provides an opportunity to distinguish the proliferating cells in S phase by in situ hybridization for histone mRNA [2, 10, 15]. Rauttiainen et al. reported that nonisotopic histone mRNA in situ hybridization is a reproducible method for measuring the proliferative activity of tumor cells and an independent prognostic factor in astrocytomas [16]. In our study, we found that all carcinomas had a higher histone mRNA LI than adenomas, and that a histone mRNA LI ≥ 5.75 was significant for malignancy with 84.2% sensitivity and 100% specificity. Both Ki 67 and histone mRNA LIs exhibited a striking difference between adenomas and carcinomas. In our series, the number of Ki67-positive cells was greater than histone mRNA-bearing cells both in adenomas and carcinomas. This may be because Ki 67 is expressed not only in the S phase of the cell cycle, but also in G₁, G₂, and M phases. In contrast, histone mRNA in situ hybridization labels the cells only in the S phase [16]. Ki 67 LI did not demonstrate a sensitivity or specificity of 100% in the differential diagnosis. However, histone mRNA showed 100% specificity for both differential diagnosis and clinical outcome.

Table 5 Ki 67 and histone mRNA LIs of 30 pediatric adrenocortical tumors according to the prognostic groups

	Prognosis	n	Mean	Standard deviation	
Ki 67 LI	Good	13	15.58	5.53	$t=2.04, p=0.05$
	Poor	17	20.30	6.76	
Histone mRNA LI	Good	13	1.60	1.42	$t=11.38, p=0.00$
	Poor	17	7.30	1.30	

Table 6 Area under the ROC curve for prognosis

	Area	Standard error	p
Ki 67 LI	0.706	0.098	0.057
Histone mRNA LI	1.000	0.000	0.000

A single patient with an adenoma diagnosed according to the histological criteria showed local recurrence, and this patient's tumor had a histone mRNA LI >5. All other adenomas had histone mRNA LIs lower than 5. Three patients having carcinomas with histone mRNA LIs of less than 5 had disease-free survivals of at least 4 years. All these carcinoma patients had Ki 67 LIs higher than the cut off point for Ki 67 LI for poor prognosis. These data could indicate that children with adrenocortical tumors with histone mRNA LIs of less than 5 may have good prognoses. Statistical analysis showed that nonisotopic in situ hybridization of histone mRNA was a better predictor of prognosis in pediatric adrenocortical tumors than immunohistochemical Ki 67 expression.

The results of this study indicate that the assessment of Ki 67 and histone mRNA LIs complements histological criteria in the diagnosis of malignancy in adrenocortical tumors. In addition, histone mRNA LI may also prove to be a valuable marker in predicting the clinical outcomes of pediatric patients with adrenocortical neoplasms.

p16^{INK4A} overexpression and HPV infection in uterine cervix adenocarcinoma

Received: 29 September 2005 / Accepted: 23 November 2005 / Published online: 22 February 2006
© Springer-Verlag 2006

Abstract Human papillomaviruses (HPVs) are causally involved in the genesis of cervical carcinomas and their precursors, and there is a strong relationship between the cyclin-dependant kinase inhibitor p16^{INK4A} and HPV infection. This study was carried out to assess the correlations between p16^{INK4A} expression as an early biomarker of the endocervical adenocarcinoma and HPV infection. p16^{INK4A} expression and HPV typing were performed on 46 samples including 5 normal endocervix, 9 benign lesions of the endocervix, 25 endocervical adenocarcinomas, and 7 endometrioid adenocarcinomas of the uterine corpus. A semiquantification of the p16^{INK4A} immunostaining was realized (using both the staining intensity and the percentage of positive cells) and was graded from 0 to 15. All of the 25 endocervical adenocarcinomas overexpressed p16^{INK4A}; the adjacent epithelium and the connective tissue were strictly negative. No p16^{INK4A} was detected in nine benign endocervical lesions and in five normal endocervix. Few endometrioid adenocarcinomas of the uterine corpus that infiltrate the endocervix exhibited a low immunoreactivity (score 0/15 or 1/15). This pattern of expression is significantly associated with HPV infection ($p < 10^{-3}$), mainly high-risk HPV types ($p = 0.02$). Our results suggest that p16^{INK4A} is a putative molecular biomarker that consistently discriminates uterine cervix adenocarcinomas from benign lesions and from endometrioid adenocarcinomas of the uterine corpus.

Keywords Uterine cervix · Adenocarcinoma · p16^{INK4A} · HPV

Introduction

Worldwide, uterine cervix carcinoma is one of the most prevalent cancers and is a major cause of cancer-related mortality in women [25]. The majority of these tumors are squamous cell carcinomas, whereas adenocarcinomas are relatively rare [44]. Although the incidence of squamous cell carcinomas has decreased during the last decade due to screening programs, uterine cervix adenocarcinomas are diagnosed more frequently [44]. The early detection of precursors of invasive uterine cervix cancer still represents a major challenge in screening programs. In fact, the cytological screening of invasive adenocarcinoma and its precursors is affected by a high rate of false negative reports as a result of sampling errors and interpretation problems, which especially influence the diagnosis sensitivity of Pap smears [15]. Colposcopy is also ineffective in recognizing endocervical lesions [36]. Therefore, well-differentiated adenocarcinomas are also difficult to identify in histopathology, and precursors may be interpreted as reactive changes [16]. Moreover, these lesions are reported to progress faster than squamous intraepithelial lesions [28]. An improvement of the diagnostic capabilities may be reached using new tools and new specific markers of uterine cervix cancerogenesis.

Numerous epidemiologic and molecular studies have demonstrated that high risk types of human papillomavirus (HPV) are the agents of the overwhelming majority of cases of invasive cervix squamous cell carcinoma and of the great majority of endocervical carcinomas and precursors [47, 48]. HPV infection has been detected in almost all precancerous and cancerous lesions of the cervix [29, 48]. Malignant transformation of the cervical epithelial cells is associated with persistent high-risk HPV infections, such as HPV 16 and 18 [48, 49]. HPVs encode E6 and E7 oncoproteins, multifunctional immortalizing and growth-promoting proteins, that bind to and inactivate the tumor suppressor proteins p53 and the retinoblastoma family of tumor suppressor, respectively [43, 48]. E7 contributes to cellular transformation by interfering with the p16^{INK4A}/CDK4/Cyclin D1/pRb cell cycle regulatory

pathway and by directing the catabolism of tumor-suppressor protein pRb [10]. The inactivation of these tumor suppressor genes through high-risk HPVs results in uncontrolled cellular proliferation of the host cell [22].

The CDKN2A gene product, p16 protein (p16), is a tumor suppressor protein that inhibits CDK4 and CDK6 which phosphorylate pRb [5, 31]. p16^{INK4A}, a member of the INK4A family of cell cycle regulatory proteins, specifically inhibits the formation of cyclin D/CDK4, 6 complexes by interacting with CDK4 and 6 which in turn counteract the activity of pRb by phosphorylation. The retinoblastoma tumor-suppressor protein, pRb, regulates the cell cycle at the G1/S restriction point by complexing with and inhibiting the activity of E2F, which serves as a transcription-dependent promoter of cell cycle progression. The E2F-pRb complex dissociates activating E2F, which in turn initiates the transcription of genes required for DNA replication [5, 12].

Overexpression of p16^{INK4A} protein has been demonstrated in squamous cell carcinoma and precursors associated with high-risk HPV types [1, 11, 13, 14]. Klaes et al. [13, 14] reported that p16^{INK4A} immunostaining may be a powerful tool to identify squamous cell carcinomas and their precursors with prognostic implications.

This study was carried out to assess the correlations between p16^{INK4A} expression and the HPV infection and to ascertain the role of p16^{INK4A} immunostaining as an early biomarker of uterine cervix adenocarcinoma.

Material and methods

Tissue samples

Forty-six specimens were retrieved from the surgical pathology files of the Department of Pathology, Farhet Hached University Hospital, Sousse, Tunisia, and the Department of Pathology, Edouard Herriot University Hospital, Lyon, France.

The cases studied were distributed into the following groups, according to the World Health Organization (WHO) Classification of Tumors of the Breast and Female Genital Organs, 2003 [40]: normal endocervix ($n=5$), benign lesions of uterine cervix including florid immature squamous metaplasia, microglandular hyperplasia, papillary hyperplasia, and decidual reaction ($n=9$), primary uterine cervix adenocarcinomas ($n=25$), and endometrioid adenocarcinomas with infiltration of the uterine cervix ($n=7$). The five cases of normal endocervix were selected mainly among women in their reproductive years who scheduled for hysterectomy due to benign gynecological abnormalities. These cases were selected randomly, and the slides were reviewed by two pathologists. All tissues had been routinely fixed in 4% buffered formalin and paraffin embedded.

HPV detection and typing using PCR

DNA extraction was realized on sections fixed in formaldehyde and included in paraffin using DNA Master Pure Technique (Tebu, France). Fetal liver was used as negative control and β -globine (268 bp) gene amplification as quality control of DNA extraction.

HPV detection and typing were performed by polymerase chain reaction (PCR) using general primers GP5/GP6 which amplify a 140-bp fragment in the L1 region common to numerous HPV as described before [38], and type specific primers for E6/E7 sequence region of HPV 6/11 (product size: 302 bp), as described by Soler et al [39], and for E6 and E7 sequence region of HPV 16 (465–292 bp), HPV 18 (419–266 bp), HPV 31 (434–270 bp), and HPV 33 (429–292 bp).

Thereafter, PCR products indicating infection with HPV 6/11, 16, 18, 31, or 33 were identified on agarose gels with ethidium bromide and reading under an ultraviolet lamp.

Immunohistochemistry for p16^{INK4A} protein

The immunostaining procedure was then carried out as already described for other issues [13, 14]. Briefly, one or two paraffin blocks containing representative portions of the tumors were selected for each case, and 4- μ m-thick serial sections were obtained and mounted on silanized slides. Sections were incubated for 30 min with primary monoclonal antibodies against anti-p16 antibody (Dako Cytomation, K5334, clone E6H4, dilution 1:50). The remaining part of the procedure was performed as previously published [8, 18]. One uterine cervix squamous cell carcinoma with known diffuse and strong immunoreactivity with p16 antibody was used as a positive control. Negative controls, using monoclonal mouse immunoglobulin G (IgG2a) antibody at a comparable concentration, were included.

Quantification of p16^{INK4A} immunostaining

Immunoreactivity was evaluated as described previously [20, 35, 46]. Briefly, two independent pathologists carried out a semiquantification of the p16^{INK4A} immunostaining with both the staining intensity (0, no staining; 1, weak staining intensity; 2, intermediate; and 3, strong staining intensity) and the percentage of positively stained tumor cells (0, no positive cells; 1, <25%; 2, 26–50%; 3, 51–75%; 4, 76–99%; 5, 100% positive tumor cells). After multiplication of both values, the immunostaining results were graded from 0 (no reactivity in tumor cells) to 15 (100% positive tumor cells with strong staining intensity).

Statistical analysis

The data were examined by Chi-square statistics using the Epi Info 2002 software as previously described [9, 46]. Probability values of 0.05 or less were considered statistically significant.

Results

HPV Detection and Typing in uterine cervix adenocarcinoma

HPV typing was carried out on 25 endocervical adenocarcinomas, 7 endometrioid adenocarcinomas of the uterine corpus with infiltration of the endocervix, and 9 benign lesions of the uterine endocervix. HPV results were considered contributory in 23 cases (56.1%); of these, 12 were GP5/GP6-positive (52.2%) (Table 1). All HPV-positive cases were endocervical adenocarcinomas. Among 12 HPV-positive uterine cervix adenocarcinomas, eight cases were positive for HPV 16 (66.7%), two cases were positive for HPV 31 (16.7%), one case was positive for HPV 18 (8.3%), and only one patient had an unknown HPV type. HPV DNA were detected in none of the endocervical benign lesions and the endometrioid adenocarcinomas that infiltrate the endocervix, and they were therefore regarded as HPV-negative. In this study, no positive case for low-risk HPV 6/11 was observed.

Immunostaining for p16^{INK4A}

Immunohistochemical analysis for p16^{INK4A} was performed in all 46 specimens investigated with E6H4 clone,

and the results are summarized in Table 1. p16^{INK4A} immunoreactivity was not detected in the normal glandular epithelium or connective tissue cells of five control cases. However, p16^{INK4A} was expressed in all uterine cervix adenocarcinomas investigated: 22 cases were scored 15, with strong and diffuse p16^{INK4A} immunostaining uniformly observed in both the nuclei and the cytoplasm of 100% of the tumor cells. The three remaining uterine cervix adenocarcinomas were scored 12, with strong and diffuse p16^{INK4A} immunoreactivity observed in 76–99% of tumor cells. The in situ component observed at the border of the invasive uterine adenocarcinoma is always highly positive (Fig. 1c,d). Endocervical neoplastic lesions were always clearly distinguishable from the adjacent normal or reactive epithelia and connective tissue cells (Fig. 1e,f). In nine benign endocervical lesions, no p16^{INK4A} immunoreactivity (score 0) was detected (Fig. 1a,b). In endometrioid adenocarcinoma that infiltrated the endocervix, there was a focal and very low immunostaining with p16^{INK4A} involving less than 25% of tumor cells (score 1) for four cases; three endometrioid adenocarcinomas were scored 0 (Fig. 1g,h).

Relationship between p16^{INK4A} immunoreactivity and HPV subtype

In our study, data of HPV infection were contributory for only 12 uterine cervix adenocarcinomas. All 12 HPV-positive uterine cervix adenocarcinoma cases showed strong and diffuse p16^{INK4A} overexpression in 100% of cancer cells (score 15). p16^{INK4A} overexpression was significantly associated with HPV infection ($p < 10^{-3}$), mainly high-risk HPV types including HPV 16, 18, and 31 ($p = 0.02$) and HPV 16 ($p = 0.02$).

Table 1 HPV typing and p16^{INK4A} expression in benign endocervical lesions, endocervical and endometrioid adenocarcinomas

Histopathology	N	β-Globine	HPV detection and typing						p16 ^{INK4A} immunostaining score

Discussion

The carcinogenesis of glandular epithelium has not been fully elucidated, and there is no clear agreement concerning the association with HPVs [2, 17, 44]. In contrast to cervical squamous cell carcinoma, the overall HPV DNA prevalence in uterine cervix adenocarcinoma varies between 32 and 84% in different studies, depending on the method chosen [3, 41]. The method must be highly sensitive because of a lower viral load, fewer episomal viral particles, and loss of portions of the viral genome during integration in glandular cells [6, 32]. In our study, using

PCR, 12 cervical adenocarcinomas investigated were HPV DNA-positive, with 75% (9/12) with the high-risk types (HPV 16 and 18) and 66.7% (8/12) with the HPV 16 type. Anderson et al. [2] reported PCR-detected HPV DNA in 71% of cervical adenocarcinoma. In different histological subtypes of cervical adenocarcinoma and related tumors analyzed using broad-spectrum HPV DNA amplification and genotyping performed with the SPF10 primer set and line probe assay, Pirog et al. [27] detected a high prevalence of HPV DNA (91%) among mucinous adenocarcinomas and adenosquamous carcinomas of the cervix similar to that reported for cervical squamous cell carci-

noma. Thus, they considered that only rare histological variants of cervical adenocarcinomas seem unrelated to HPV infection. This is more in line with the findings of Zielinski et al. [46] that reported high-risk HPV-positive adenocarcinoma prevalence (94%) identical to that found in squamous cell carcinoma, with HPV 18 being the most common type in adenocarcinoma.

Several recent reports describe the value of p16^{INK4A} as a specific antibody for the detection of cervical neoplasia [1, 9, 11, 13, 14, 24, 30]. A strong overexpression of p16^{INK4A} in cervical squamous cell carcinomas has been associated with HPV infection [11] and occurs when pRb is inactivated by HPV E7 or by mutation [23, 26]. Interestingly, we found that all 25 cases of cervical adenocarcinoma exhibited p16^{INK4A} overexpression, and among them, 22 were very strongly and diffusely stained with the antibody (100% of tumor cells); however, this p16^{INK4A} immunoreactivity was absent in all nine benign lesions of the endocervix as well as in adjacent normal endocervical glands. Therefore, p16^{INK4A} immunostaining appears to be a useful tool to distinguish cervical adenocarcinomas from benign conditions and glandular atypia which may be associated with inflammation or irradiation.

Recently, Tringler et al. [42] found a strong, uniform, p16^{INK4A} expression in all cases of endocervical glandular dysplasia, in situ and invasive adenocarcinoma studied. They observed also a weaker or focal expression in benign ciliated columnar cells of normal endocervical glands, tubal metaplasia, reserve cells, and Nabothian cysts. They suggested that p16^{INK4A} immunostaining would be used, with caution, as an objective marker to increase the diagnostic reproducibility for both glandular dysplasia and in situ adenocarcinoma.

In our study, the lack of p16^{INK4A} immunoreactivity in all normal glandular cells and benign lesions does not necessarily imply loss of p16^{INK4A} expression with gene inactivation, but may represent a physiological normal state in nonneoplastic or nonproliferative cells [7]. Interestingly, in most normal cells, p16^{INK4A} expression is known to be low at both the mRNA and protein levels [7].

These immunohistochemical results clearly evidenced that p16^{INK4A} is a putative molecular biomarker that consistently discriminates cervical adenocarcinomas from benign lesions of the endocervix, endometrial carcinoma, and its precursors [34]. These findings are in agreement with those reported by Negri et al. [24]: using E6H4 clone, all eight in situ adenocarcinomas and 17 (94%) of 18 invasive cervical adenocarcinomas exhibited diffuse positive p16^{INK4A} overexpression. However, in endocervical glandular atypia, only focal expression was observed, and no p16^{INK4A} immunoreactivity was found in atypia of repair [24]. In 95 cases, including benign endocervical controls, a strong, diffuse p16^{INK4A} positivity occurred exclusively within adenocarcinoma in situ [30]. However, in other studies with different p16^{INK4A} antibodies and conditions, detectable expression has been described in 58 to 86% of cervical adenocarcinoma [9, 21].

In this study, we demonstrated a significant correlation between a diffuse and strong p16^{INK4A} immunoreactivity, the presence of high risk HPVs (HPV 16 and 18) and a malignant lesion of the endocervix ($p < 0.05$). These results confirmed the study of Sano et al. [33]. Strong p16^{INK4A} overexpression indicates that the suppressor function of cyclin-CDK complexes may be overcome in the presence of viral oncogenes (E6 and E7 oncoproteins) and malignant transformation can still occur [35].

However, all endometrial adenocarcinomas were HPV-negative, showing that in these tumors, an HPV-independent pathway of carcinogenesis would be postulated. Two main types have been described: type I, in which hyperestrogenism seems to be causally related to the development of endometrioid carcinomas, and type II, with an independent estrogen pathway of endometrial carcinogenesis in which p53 mutation plays a central role [37]. The histological distinction between primary endometrial, especially endometrioid and endocervical adenocarcinomas, may be problematic particularly in small biopsies and when a tumor is present in both endometrial and endocervical specimens [19]. Moreover, ascertaining the exact origin of an adenocarcinoma may be difficult or even impossible when the tumor involves the lower uterine segment or uterine isthmus and upper endocervix. This origin distinction is important, because it governs primary surgical modalities and even adjuvant treatments [19, 45]. Several recent studies have investigated the interest of different antibodies, such as carcinoembryonic antigen, estrogen receptor, and vimentin, to distinguish between primary endometrial and endocervical adenocarcinoma with some success [20]. However, there is an immunohistochemical overlapping in some cases, suggesting the limits of these antibodies to distinguish definitively the origin of an adenocarcinoma [4]. Interestingly, in our study, we found diffuse and strong positivity with p16^{INK4A} involving 100% of cells in 22 primary uterine cervix adenocarcinomas (including the in situ component) and more than 75% of tumor cells in three cases. However, four endometrioid adenocarcinomas that infiltrate the endocervix exhibit just a focal staining involving less than 25% of tumor cells. Thus, we believe that p16^{INK4A} may be of value to distinguish an endometrioid from an endocervical adenocarcinoma. These results confirm the study of McCluggage and Jenkins [19], who proposed that p16^{INK4A} immunoreactivity would assist in the distinction between endometrial and endocervical adenocarcinoma. Moreover, Schorge et al. [35] postulated that p16^{INK4A} would be a biomarker with a potential clinical utility as an adjunct to current screening methods.

In summary, we have found that p16^{INK4A} overexpression is common in uterine cervix adenocarcinoma; this pattern of overexpression is significantly associated with HPV infection (mainly high-risk HPV types). We propose that p16^{INK4A} immunoreactivity is of value to differentiate an adenocarcinoma from endocervical or endometrial origin. p16^{INK4A} overexpression may be a clue in the elucidation of the carcinogenesis of cervical adenocarcinoma.

Patterns of invasion and histological growth as prognostic indicators in urothelial carcinoma of the upper urinary tract

Received: 21 November 2005 / Revised: 22 December 2005 / Accepted: 22 December 2005 / Published online: 9 March 2006
© Springer-Verlag 2006

Abstract The biological significance of squamous and glandular differentiation and different patterns of invasion in upper urinary tract urothelial carcinoma is unclear. We reviewed 268 cases of consecutive upper urinary tract carcinomas with respect to the presence of squamous and/or glandular differentiation and different patterns of invasion (nodular, trabecular, and infiltrative) and correlated data with patient outcome. Squamous or glandular differentiation occurred in 47/268 (18%) tumors and its presence correlated with high tumor stage ($P<0.001$) and grade ($P<0.001$). Invasive patterns were nodular in 49/227 (22%), trabecular in 95/227 (42%), and infiltrative in 83/227 (37%) tumors. The nodular pattern prevailed in low stage ($P<0.001$) and low-grade ($P<0.001$) tumors, whereas the infiltrative pattern prevailed in high stage ($P<0.001$) and high-grade ($P<0.001$) tumors. Multivariate analysis proved that tumor stage ($P<0.001$) and the infiltrative pattern ($P<0.001$) are independent predictors of metastasis-free survival, whereas tumor grade and squamous and glandular differentiation lacked independent influence on patient outcome. In conclusion, the infiltrative pattern of invasion significantly correlated with advanced disease and poor patient outcome. In contrast, the presence of squamous

and/or glandular invasion did not prove independent influence on patient outcome. The pattern of invasion should be commented upon separately in the pathology report.

Keywords Urothelial carcinoma · Squamous differentiation · Glandular differentiation · Pattern of invasion · Prognosis

Introduction

Upper urinary tract urothelial carcinoma (UC) is relatively uncommon, accounting for approximately 5% of all epithelial tumors of the urinary tract with most tumors occurring in the bladder [10]. Standard treatment for localized upper tract UC is radical nephroureterectomy with bladder cuff resection [18]. Although numerous investigations showed that stage is the most important predictor of outcome [3, 5–8, 12–15, 19, 24, 31, 32, 34, 35], the clinicopathologic features predictive of metastatic disease are not well defined and the assessment of tumor grade shows considerable variation due to observer subjectivity [2, 44]. Thus, the identification of other prognostic variables that can easily be determined in routinely hematoxylin and eosin (H&E)-stained sections is required to select candidates for adjuvant therapy.

The majority of primary epithelial neoplasms of the urinary tract display conventional urothelial morphology but some tumors may additionally show aberrant differentiation thought to arise from metaplastic change [22, 39]. These areas are most frequently squamous or glandular in nature and their frequency was shown to increase with tumor grade and stage [1, 11, 42, 43, 45]. Thus, most urological oncologists share the view that mixed histology implies more aggressive disease, which may be less susceptible to radio- or chemotherapy [16, 25, 29]. However, there is only one study analyzing the prognostic impact of squamous and/or glandular differentiation in a series of 70 bladder carcinomas [30], whereas a systematical investigation analyzing the clinical significance of squamous and/or glandular differentiation in upper urinary tract cancer,

including both univariate and multivariate statistical analysis, is currently lacking.

Recently, Jiminez et al. [17] described three different patterns of invasion (nodular, trabecular, and infiltrative) in a series of 93 muscle-invasive bladder cancers. According to their data, the infiltrative growth pattern may be associated with unfavorable patient outcome despite lack of significance in multivariate analysis. In a subsequent study by Krüger et al. [20] involving 153 muscle-invasive bladder cancers, the infiltrative pattern proved to be an independent predictor of poor disease-related survival. The authors concluded that the classification by Jiminez et al. [17] may serve as an additional tool to predict the prognosis of patients undergoing radical cystectomy for bladder cancer.

In the present study, we aimed to evaluate the potential prognostic significance of squamous and/or glandular differentiation in a large consecutive series of upper urinary tumors. Moreover, our study is the first to apply the classification introduced by Jiminez et al. [17] to this type of urothelial cancer and to assess its role in predicting metastasis-free survival. By performing a multivariate analysis, we analyzed the potential of the different histological variables to serve as independent predictors of patient outcome.

Materials and methods

Case selection

Two hundred sixty-eight consecutive upper urinary tract UCs (169 pelvic and 99 ureteral tumors) from 239 consecutive patients (108 women and 131 men) undergoing surgery between January 1984 and December 2004 were retrieved from the files of our institute. The mean and median ages of patients were 70 and 71 years (range 39–89), respectively. Seventeen out of 239 (7%) patients presented with local lymph node metastases at the time of their primary operation. All tumor specimens were examined by the same protocol including multiple sections obtained from the tumor itself, the kidney, and the pelvic wall adjacent to and distant from the tumor, along with the ureter and lymph nodes, if present.

For the correlation of histopathological data with metastasis-free survival, all noninvasive cancers (41 tumors from 33 patients) and all tumors from patients with multiple invasive cancers (37 tumors from 16 patients) were excluded resulting in a final sample of 190 UCs (134 pelvic and 56 ureteral tumors) from 190 patients (77 women and 113 men). Standard treatment included nephroureterectomy with bladder-cuff resection ($n=130$), alternatively, nephrectomy alone ($n=40$) or distal ureteral resection with reimplantation ($n=20$) were performed. Patients did not receive adjuvant therapy. Follow-up regimen included abdominal ultrasound and cystoscopy every 3 months for the first 3 years, every 6 months for the subsequent 2 years, and yearly thereafter and chest X-ray and computerized tomography every 6 months for the first 3 years and yearly thereafter. All procedures were in accord

with the ethical standards established by our institution. Informed consent is not required for retrospective analyses dealing with archival material obtained during routine medical treatment.

Histopathology

H&E-stained slides from routinely formalin-fixed and paraffin-embedded material were systematically reevaluated by one pathologist (C. L.) who was blinded to regional lymph node status and the subsequent disease course. pT-stages were adjusted according to the International Union Against Cancer 2002 issue of the Tumor, Nodes, Metastasis system [41]. Grading was performed according to the recently published two-tiered WHO grading system following the WHO/International Society of Urological Pathology consensus classification [27]. During the process of reviewing the slides, special attention was drawn toward the presence of aberrant histological differentiation. According to the WHO criteria for the diagnosis of histological variants of urothelial cancer [27], squamous differentiation was defined as the presence of intercellular bridges or keratinization. Glandular differentiation was defined as the presence of true glandular spaces and gland-like lumina within tumor cell nests; special care was taken to differentiate these glandular structures from pseudoglandular spaces caused by drop-out of necrotic cells or artifact. A significant proportion of tumors displayed both squamous and glandular differentiation. In these cases both patterns were recorded. Three main architectural patterns of tumor invasion were recognized following the definition by Jiminez et al. [17]: The nodular pattern was composed of well-delineated round nests of tumor cells. These nests varied in diameter but a tendency of roundness was maintained throughout (Fig. 1a). Desmoplasia was usually not prominent and necrosis was not observed. The trabecular pattern consisted of infiltrating broad trabeculae that usually anastomosed with each other and were sometimes associated with extensive necrosis and a desmoplastic stroma (Fig. 1b). The trabeculae were at least three cells thick. The infiltrative pattern showed infiltrating narrow cords or single tumor cells (Fig. 1c). Desmoplasia and necrosis were common. Cells were usually highly pleomorphic or small and undifferentiated. Tumor heterogeneity represents a well-known phenomenon in urothelial cancers and different subclones with different phenotypes are known to coexist within the same tumor, among which, those bearing the most aggressive biological potential eventually determine patient outcome [4]. Accordingly, in cases showing two or more patterns of invasion, only the most aggressive type of tumor growth (infiltrative > trabecular > nodular) was recorded.

Statistical analyses

Associations between patterns of invasion or histological differentiation and tumor stage as well as tumor grade were

Fig. 1 Urothelial carcinoma of the upper urinary tract with nodular (a H&E), trabecular (b H&E), and infiltrative (c H&E) pattern of invasion according to the definition by Jiminez et al. [17]

Fig. 2 Urothelial carcinoma of the upper urinary tract with squamous (a–b H&E) and glandular differentiation (c–d PAS) as demonstrated in low-grade (a and c) and high-grade (b and d) tumors

analyzed using the Fisher's exact test. Patient outcome was investigated using the Kaplan–Meier method and compared by the log-rank test. Disease progression was defined as the occurrence of nodal and/or distant metastases. Metastasis-free survival was calculated from definitive treatment of upper tract disease (e.g., nephroureterectomy) to the occurrence of metastatic disease or the last follow-up in patients with no evidence of disease progression. For multivariate testing, a Cox's proportional hazards regression model was performed. All reported *P* values were two-sided with significance at $P < 0.05$.

Results

Overall, stage pTa was present in 41 (15%), pT1 in 102 (38%), pT2 in 37 (14%), pT3 in 80 (30%), and pT4 in eight (3%) cases. One hundred forty-one (53%) tumors were of low tumor grade and 127 (47%) were of high tumor grade. Pelvic and ureteral tumors showed a comparable distribution regarding the different categories. High tumor grade was associated with high tumor stage [53/139 (38%) pT1/pT2 vs 74/88 (84%) pT3/pT4, $P < 0.001$]; no high-grade tumors were detected among noninvasive cancers.

Squamous differentiation occurred in 47/268 (18%) tumors. The majority of them showed small interspersed islands of squamous epithelium with mild to moderate atypia in otherwise typical urothelial carcinoma (Fig. 2a). In some cases, however, poorly differentiated tumor cells showing squamous differentiation (with or without keratinization) gradually merged with the surrounding urothelial tumor cells, ultimately representing the predominant histological growth pattern (Fig. 2b). Squamous differentiation prevailed in high stage [15/180 (8%) pTa–pT2 vs 32/88 (36%) pT3/pT4, $P < 0.001$] and high grade [8/141 (6%) low grade vs 39/127 (31%) high grade, $P < 0.001$] cancers (Table 1).

Table 1 Squamous differentiation in upper urinary tract urothelial carcinomas related to tumor stage (pT1a–pT4) and tumor grade [low grade (LG) and high grade (HG)]

	All tumors		Pelvic tumors		Ureteral tumors

pT1	8/102	8	6/60	10	2/24	5
pT2	6/37	16	3/20	15	3/17	18
pT3	29/80	36	21/62	34	8/18	44
pT4	3/8	38	3/8	38	–	–
LG	8/141	6	4/48	5	4/57	7
HG	39/127	31	30/85	35	9/42	21
Total	47/268	18	34/169	20	13/99	13

Glandular structures were observed in 47/268 (18%) tumors. The amount of glandular differentiation was variable with the majority of cases showing only focal glands bordered by a single layer of cuboidal or columnar cells or gland-like lumina scattered among nests of otherwise typical urothelial carcinoma (Fig. 2c). In some cases, however, the glandular differentiation represented the predominant histological growth pattern (Fig. 2d). Glandular differentiation prevailed in high stage [22/180 (12%) pTa–pT2 vs 25/88 (28%) pT3/pT4, $P=0.002$] and high grade [17/141 (12%) low grade vs 30/127 (24%) high grade, $P=0.02$] cancers (Table 2). Occasionally, the glands underwent cystic dilatation, resulting in a microcystic appearance. One case displayed a colloid-mucinous pattern characterized by nests of cells “floating” in extracellular mucin. It is interesting to note that the glandular growth pattern was associated with the presence of squamous differentiation. Thus, 20/47 (43%) tumors with glandular lumina simultaneously showed foci of squamous differentiation compared with 27/221 (12%) tumors without glandular differentiation ($P<0.001$).

According to Jiminez et al. [17], patterns of invasion were nodular in 49/227 (22%), trabecular in 95/227 (42%), and infiltrative in 83/227 (37%) tumors. The nodular pattern prevailed in low stage [45/139 (32%) pT1/pT2 vs 4/88 (5%) pT3/pT4, $P<0.001$] and low grade [44/100 (44%) low grade vs 5/127 (4%) high grade, $P<0.001$]

cancers, whereas the infiltrative pattern prevailed in high stage [20/139 (14%) pT1/pT2 vs 63/88 (72%) pT3/pT4, $P<0.001$] and high grade [0/100 (0%) low grade vs 83/127 (65%) high grade, $P<0.001$] cancers (Table 3).

Follow-up data were available from 186/190 (98%) patients. After a mean and median follow-up of 46 and 31 months, respectively, progressive disease was observed in 74/186 (40%) patients including 60 patients who died from cancer and 14 patients who are currently alive with metastatic disease. Mean time to progression was 19 months (median 8.3, range 0–110). Twenty-five patients died from causes not related to cancer. Actuarial overall and metastasis-free survival rates were 63 and 56% at 5 years and 52 and 45% at 10 years.

The development of distant metastases was associated with the presence of squamous and/or glandular differentiation. Thus, 25/43 (58%) UCs with squamous differentiation developed disease progression compared with 49/143 (34%) UCs without squamous differentiation ($P=0.001$; Fig. 3). Actuarial 5-year metastasis-free survival rates for patients with UCs with and without squamous differentiation were 33 and 63%, respectively. Similarly, 19/36 (53%) UCs with glandular differentiation developed disease progression, compared with 55/150 (37%) UCs without glandular differentiation ($P=0.04$; Fig. 4). Actuarial 5-year metastasis-free survival rates for patients with UCs with and without glandular differentiation were 45

Total (<i>n</i> =227)	49	22	95	42	83	37

and 59%, respectively. In addition, disease progression was associated with the pattern of invasion. Thus, only 3/41 (7%) UCs with a nodular pattern developed disease progression compared with 18/78 (23%) UCs with a trabecular pattern and 53/67 (79%) UCs with an infiltrative pattern ($P<0.002$; Fig. 5). Actuarial 5-year metastasis-free survival rates for UCs with nodular, trabecular, and infiltrative pattern of invasion were 94, 74, and 12%, respectively (Table 4). No significant prognostic influence was observed for tumor location, patient age, and gender.

In a Cox's proportional hazards regression model including age, gender, tumor stage, grade, and location (pelvis vs ureter), squamous and glandular differentiation, as well as the different patterns of invasion, pT-stage >1 [$P<0.001$, risk ratio (RR)=4.02, 95% confidence interval (CI)=1.82–8.84] and the infiltrative pattern of invasion ($P<0.001$, RR=3.88, 95% CI=1.87–8.05) proved to be independent predictors of metastatic disease. Patients with UCs showing a nodular pattern of invasion were less likely to develop disease progression but this difference was not statistically significant ($P=0.16$, RR=0.39, 95% CI=0.11–1.43). Tumor grade and location and presence of squamous

and/or glandular differentiation lacked independent influence on patient outcome.

Discussion

According to literature, metastatic disease occurs in 19–54% of upper tract urothelial cancers and a significant proportion of patients eventually die due to tumor dissemination [6, 8, 13–15, 31, 32, 34, 35, 37]. Thus, the identification of independent prognostic factors is an essential step for the evaluation of affected patients not only to predict disease evolution, thus aiding surveillance strategies, but also to identify subgroups that might benefit from adjuvant cancer therapy.

Primary squamous cell carcinoma and adenocarcinoma of the renal pelvis and ureter, defined as tumors showing pure squamous or pure glandular phenotype, are highly uncommon, representing less than 1% of all primary tumors of the upper urinary tract [36]. Their pathogenesis was related to urothelial metaplasia due to long-standing chronic irritation and/or inflammation leading to dysplasia (intraepithelial neoplasia) and ultimately to squamous cell carcinoma or adenocarcinoma [28]. Thus, medical history of affected patients commonly discloses information regarding chronic pyelonephritis and/or nephrolithiasis. Patients often present at an advanced stage of the disease and the outcome is generally poor [23, 33, 38, 40].

In contrast, aberrant squamous and/or glandular differentiation in otherwise typical urothelial cancers is by far more common, occurring in 7–60% of bladder [1, 9, 22, 26, 29, 30, 42, 45] and 10–15% of upper urinary tract UCs [7, 11]. In our series, squamous or glandular differentiation occurred in 74/268 (28%) upper urinary tract tumors, its presence being significantly correlated with high tumor stage and grade. Both squamous and glandular differentiation indicated poor prognosis in univariate analysis. However, multivariate analysis revealed that neither squamous nor glandular differentiation possessed independent influence on patient outcome. Our data are in line with a previous study investigating bladder cancer by Mazzucchelli et al. [30] who reported a significant correlation between squamous differentiation and prognosis in univariate analysis ($P=0.05$), but not in multivariate analysis.

The high frequency of squamous and/or glandular differentiation in otherwise typical urothelial cancers is

not easy to understand because the urinary tract is normally exclusively lined by urothelial cells. To bring light in this topic, Kunze and Francksen [21, 22] systematically investigated carcinoma tissues from human and rat urinary bladder. The authors were able to show that the underlying histogenetic principle is based on the pluripotent metaplastic potential of normal and neoplastic urothelium to undergo several pathways of cellular and architectural differentiation. By demonstrating a direct conversion of typical urothelial carcinoma cells into squamous and/or glandular cells, they concluded that squamous and glandular differentiation develop by a metaplastic process within preexisting conventional UC. This process occurs during tumor progression and dedifferentiation, most probably owing to the embryologic origin of the urinary tract from pluripotent tissues of the cloacal endoderm and the mesodermal Wolffian ducts.

The infiltrative pattern according to Jiminez et al. [17] was significantly associated with the development of metastatic disease and proved to be a new independent prognostic marker that can be determined in routinely H&E-stained sections and is thus easily applicable worldwide. The original analysis by Jiminez et al. [17] and a subsequent study by Krüger et al. [20], which were both restricted to bladder tumors, revealed comparable results. The infiltrative pattern serves as an independent histological prognosticator with a relative risk comparable to that of tumor stage, emphasizing the necessity for pathologists to comment specifically on its presence (or absence).

Tumor heterogeneity represents a well-known phenomenon in urothelial cancers and a significant proportion of tumors in our study and in the previous reports on bladder cancer displayed two or more patterns of invasion. For this reason, a major and a minor pattern was recorded for each patient in both previous reports [17, 20]. However, because both previous studies clearly showed that the presence alone of a minor infiltrative component had the same impact on patient outcome as the presence of a major infiltrative component, we recorded only the most aggressive type of tumor invasion (infiltrative > trabecular > nodular) to improve practicability of the system in daily routine work. In contrast to Krüger et al. [20] who suggested an abbreviated two-tiered classification of invasion

(infiltrative vs noninfiltrative), we retained the original three-tiered system because analogous to the negative prognostic effect of the infiltrative pattern, the nodular pattern indicated a tendency toward a more favorable outcome.

In summary, tumor stage and the infiltrative pattern of invasion significantly correlated with advanced disease and enhanced local and distant metastatic spread, clearly indicating that the pattern of invasion is a reliable prognostic factor for patients with upper urinary tract cancer. In contrast, the presence of squamous and/or glandular invasion did not prove independent influence on patient outcome. The pattern of invasion should be commented upon separately in the pathology report.

Mixed germ cell sex cord–stromal tumors of the testis and ovary. Morphological, immunohistochemical, and molecular genetic study of seven cases

Received: 7 October 2005 / Accepted: 2 January 2006 / Published online: 15 March 2006
© Springer-Verlag 2006

Abstract We present the morphological, immunohistochemical, and molecular genetic features of three cases of testicular and four cases of ovarian mixed germ cell sex cord–stromal tumors (MGST). The germ cells in the testicular MGSTs morphologically differed from those in classical seminomas by lacking the typical “square off” quality of the nuclei. In contrast to the nuclei in classical seminomas, their size in testicular MGSTs was smaller and nucleoli were inconspicuous and the cytoplasm was

Periodic Acid-Schiff (PAS) negative. Quite on the contrary, the variability in the size of the nuclei of the germ cells in the testicular MGSTs was more similar to that seen in the germ cells of spermatocytic seminomas. Immunohistochemically, the germ cells of MGSTs in one case reacted positively with antibody to AE1–AE3 by paranuclear dot-like or rodlike positivity. All three testicular MGSTs had a negative reaction with the rest of antibodies, including placental alkaline phosphatase (PLAP), OCT4, and c-kit protein. Ovarian MGST in our series differed from the testicular lesions in both the germ cell component and the sex cord component. The germ cells in all four ovarian cases had cytomorphological and immunohistochemical features identical to those in classical seminomas/dysgerminomas. They possessed the typical “square off” quality of the nuclei, which were much more blastic, with more mitoses compared with the testicular tumors in our series, and they were PLAP (4/4), OCT4 (4/4) and c-kit protein (3/4) positive immunohistochemically. The cytoplasm of the germ cells in ovarian neoplasms contained PAS positive glycogen. Germ cells in one ovarian MGSTs showed amplification of 12p. All other germ cells were negative for amplification of 12p. All five successfully analyzed cases showed no mutation in all studied exons and exon–intron junctions in c-kit and PDGFR genes.

Introduction

A distinctive gonadal neoplasm composed of germ cells associated with sex cord stroma derivatives has been described and designated as “Pflügerome” [5, 21] or mixed germ cell sex cord–stromal tumor (MGST) [33, 34]. Most cases of MGST were described in the ovaries [1, 14, 19, 27, 32, 33, 35, 37, 38, 41, 47]; however, there were also a few cases of MGST reported in the testis [3, 8, 28]. Yet the existence of these tumors in the testis had recently been

questioned by a group of authors, who considered these lesions to represent sex cord–stromal tumors with entrapped germ cells rather than genuine MGSCT [43, 46]. We present morphological features, as well as immunohistochemical and molecular genetic findings in three testicular and four ovarian cases of MGSCT. One case of testicular MGSCT [23] and two cases of ovarian MGSCT [1, 47] included in our series have been published previously.

Materials and methods

Tissues from three cases of testicular and four cases of ovarian MGSCT were available. In one testicular case, only a limited amount of unstained reserve slides was available. In one testicular case, practically the entire tumor was sampled and its tissue was histologically processed. Two cases were seen in consultation by one of the authors (AT), two cases were seen in consultation by another author (MM), two cases were contributed by two other authors of the study (JM and AZ), and tissue from one case was contributed by generosity of Dr. J. Arroyo. Tissues were fixed in 4% formaldehyde and embedded in paraffin using routine procedures. Five-micrometer thick sections were cut from the tissue blocks and stained with routine staining methods.

Immunohistochemistry

For immunohistochemical investigations, the following primary antibodies were used: MIB1 (MIB1, 1:1,000, NeoMarkers, Fremont, CA, USA), c-kit protein (polyclonal, 1:100, DakoCytomation, Glostrup, Denmark), CD30 (Ber-H2: DakoCytomation), Inhibin (R1, Serotec, Düsseldorf, Germany), cytokeratins (AE1/AE3, 1:1,000, Boehringer), low molecular weight cytokeratin (CAM 5.2, 1:50, Becton Dickinson, San Jose, CA, USA), placental alkaline phosphatase (polyclonal: DakoCytomation), α -smooth muscle actin (1A4; DakoCytomation), neuron specific enolase (polyclonal; DakoCytomation), and EMA (E29, DakoCytomation). A polyclonal primary goat-anti-OCT4 antibody (Santa Cruz, CA, USA) raised against the –COOH terminus of the protein was used.

Microwave pretreatment of the tissue sections was used before applying of the primary antibodies. The primary antibodies were visualized using the anti-goat antibody labeled with peroxidase (Santa Cruz, CA) for the anti-OCT4 antibody and supersensitive streptavidin–biotin–peroxidase complex (BioGenex, San Ramon, CA, USA) for all the rest of the primary antibodies. Appropriate positive and negative control slides were employed.

Molecular genetics and cytogenetics

DNA extraction

DNA was extracted from formalin-fixed, paraffin-embedded tissues. Several 5- μ m thick sections were placed on the slides. Hematoxylin eosin stained slides were examined for determination of area of tumor tissue. Then, tumor tissue from unstained slides was scraped, and DNA was isolated by the DNeasy Tissue Kit (QIAGEN, Hilden, Germany) according to the manufacturer's protocol. In several cases where quality or amount of extracted DNA was low, concentration with Microcon 100 (Millipore, Billerica, MA, USA) according to the manufacturer's protocol was carried out.

Mutation status of the exons 9, 11, 13, and 17 of the c-kit gene (accession number U63834) and exons 12 and 18 of PDGFRA gene (accession number D50017) by PCR and direct sequencing

PCR was carried out using primers shown in Table 1. The reaction conditions were as follows: 12.5 μ l of HotStart Taq PCR Master Mix (QIAGEN), 10 pmol of each primer, 100 ng of template DNA and distilled water up to 25 μ l. The amplification program consisted of denaturation at 95°C for 15 min and then 40 cycles of denaturation at 95°C for 1 min, annealing at 54°C for 1 min, and an extension at 72°C for 1.5 min for all amplicons. The program was finished by 72°C incubation for 7 min.

Successfully amplified PCR products were purified with a QIAquick spin PCR purification kit (QIAGEN), side sequenced using a Big Dye Terminator Sequencing kit (PE/Applied Biosystems, Foster City, CA, USA) and run on an automated sequencer ABI Prism 310 (PE/Applied Biosystems) at a constant voltage of 11.3 kV for 20 min.

Tissue pretreatment and fluorescence in situ hybridization using CEP 12 and 12p probes

From each specimen, 4- μ m thick sections were placed onto positively charged slide. Hematoxylin and eosin stained slides were examined for determination of areas for cell counting. The unstained slides were routinely deparaffinized and treated by a 30% sodium bisulfite for 30 min at 42°C. Then, the slides were washed twice in 2 \times sodium salt citrate (2 \times SSC) and immersed into digestion solution consisting of 2 \times SSC/proteinase K (0.25 mg/ml) for 30 to 60 min at 42°C. The slides were then placed into distilled water for 2 min, dehydrated in a series of ethanol solution, and air-dried. Probes for 12p Spectrum Green, CEP 12 Spectrum Orange (factory premixed) and LSI/WCP hybridization buffer (VYSIS/Abbott, IL, USA) were mixed in

a 1:2:7 ratio. An amount of 10 µl of probe mix was applied on specimens and co-denatured simultaneously at 85°C for 10 min. After hybridization overnight in a humidified chamber at 37°C, the slides were washed for 2 min in washing buffer consisting of 0.4×SSC/0.3% NP-40 at 73°C and then in buffer consisting of 2×SSC/0.1% NP-40 at room temperature. The slides were air-dried in the dark, counterstained with 4',6-diamidino-2-phenylindole-2HCl (DAPI) in an antifade medium, and immediately examined.

FISH interpretation

The sections were examined with an Olympus BX60 fluorescence microscope using a 100× objective and filter sets Triple Band Pass [DAPI/fluorescein isothiocyanate (FITC)/Texas Red] and Dual Band Pass (FITC/Texas Red). Scoring of amplification was performed by counting the ratio of the number of both fluorescent signals (12p: CEP12) in 60 randomly selected nonoverlapping tumor cell nuclei. Each slide was independently enumerated by two observers (TV and RS). Tumors with a ratio of signals <1.5 as a mean per nucleus were interpreted as non-amplified, whereas cases exhibiting a ratio of signals ≥1.5 as a mean were classified as amplified ones [17]. In all cases, counting of germ cell nuclei population was performed.

Results

Case histories

Case 1

A 35-year-old phenotypically normal man with karyotype 46XY presented with a gradually enlarging, asymptomatic

left testicular mass that had been present for 25 years. Otherwise, the affected testis was elastic and painless, and the contralateral testis had normal size and consistency; both testes were normally descended. No enlarged lymph nodes or metastases were revealed by ultrasonography and computed tomography. Serum levels of α-fetoprotein, β-human chorionic gonadotropin (HCG), and carcinoembryonic antigen were within the normal range. A left orchiectomy was performed. Grossly, the parenchyma of involved testis was replaced by a uniform whitish soft tissue; no involvement of testicular adnexa and tunica albuginea was noted. The tumor was round-shaped, well-circumscribed, white in color, and measured 4×5×5 cm. The unaffected testicular tissue was compressed by the tumor. No adjuvant chemotherapy and radiotherapy was given or administered. The patient is free of disease 11 years after the surgical excision.

Case 2

A normally developed 41-year-old man consulted an urologist because of urinary frequency that was attributed to the cystitis. He also noticed a slowly progressive, painless enlargement of the right testis during the last 4 years, which was unrelated to his current complaint. The urologic examination disclosed a right-sided testicular tumor that was solid and firm. The left testis was normal. Both testes were normally descended. Relevant laboratory and radiological investigations, including serum α-fetoprotein and HCG determinations, showed no abnormalities. Two years after the right radical orchiectomy, the patient was well without any evidence of recurrence or metastases.

Case 3

A 27-year-old man presented with complaints of pain in the right scrotum. Clinical examination revealed a testicular mass. Orchiectomy was performed. The affected testis measured 7×4 cm and was replaced by a well-circumscribed tumor, two-thirds of which exhibited a cystic change. There were no signs of necrosis or hemorrhage. The follow-up of the patient is not available.

Case 4

The patient, a 30-year-old woman, nullipara and nulligravida with normal karyotype (46XX) was admitted for treatment because of a persistent pelvic pain. Examination revealed a right adnexal mass 7×4-cm in size. There was no evidence of residual tumor in the pelvis at operation. The postoperative recovery was uneventful. Sixty-seven months later, a large, palpable pelvic mass was found above the uterine fundus. At laparotomy, a 7-cm tumor adherent to the serosa of the uterus was identified and surgically removed. Postoperatively, the patient was further treated with chemotherapy (bleomycin, cisplatin, and etoposide) with an excellent response. She was clinically free of disease 10 months later.

Case 5

A 4-year-old girl presented with symptoms of precocious isosexual pseudopuberty, including mammary enlargement. The gynecological examination revealed an infantile uterus and a left adnexal mass. The vulva was slightly swollen and no pubic hair could be demonstrated. The vaginal cytology revealed estrogenic stimulation. The serum levels of somatotropin, luteinizing hormone, α -fetoprotein, prolactin, and β -HCG were within normal limits. The karyotype of the patient was 46XX and her sex chromatin was normal. She was treated with a right oophorectomy. A bosselated, irregular, 8×4×4-cm mass was found in the right ovary. The patient subsequently received radiotherapy (total dose 40 Gy applied during 4 weeks) and chemotherapy (5-fluorouracil, actinomycin D, and cyclophosphamide). After surgery, the vaginal cytology returned to normal in 2 months. Her breast enlargement regressed slowly to the normal size 1 year after the operation. Thirteen years after the oophorectomy, the patient achieved normal puberty and there was no evidence of recurrence or metastasis.

Case 6

A 39-year-old woman presented with a round-shaped tumor mass in the left ovary measuring 9 cm in diameter. The patient suffered from ascites. She underwent a bilateral ovariectomy. The contralateral ovary proved to be normal both grossly and histologically. The karyotype of the

patient was 46XX. Seven years after the ovariectomy, the patient is well and free of disease.

Case 7

An 11-year-old girl was noted to have precocious pseudopuberty and was found to have an ovarian tumor affecting the right ovary and measuring 6×4×3 cm. The left ovary was normal. The karyotype of the patient was 46XX. After the operation there was regression of the pseudopuberty symptoms. She achieved normal puberty and was followed for 6 years without any evidence of recurrent disease.

Histology

Histologically, all seven cases of MGSCCT revealed two components: germ cells and sex cord stromal component (SCC). No evidence of other type of germ cell tumors such as seminoma/dysgerminoma, embryonal carcinoma, yolk sac tumor, or teratoma [37, 44] and no sarcomatous differentiation, as described in spermatocytic seminomas [8, 11, 24, 42], were seen in our cases of MGSCCT. Neither HCG secreting multinucleated cells, as seen in 5% of dysgerminomas and in seminomas, nor calcifications were present in our cases. Because histology of the germ cells, stromal SCC, and immunohistochemical findings of testicular and ovarian tumors differed they will be described separately.

Testicular tumors All three testicular MGSCCTs had a similar histological appearance. The tumors showed germ cells arranged in groups or as solitary units within the background of dense, diffuse proliferations of spindle-shaped sex cord stromal cells. Within a tumor, there were areas where the SCC predominated (Fig. 1), as well as areas where the dominant cells were the germ cells (Fig. 2). The germ cells were characterized by an abundant clear cytoplasm and a variably blastic nucleus with a fine chromatin, having one to several inconspicuous nucleoli. No areas, in which the germ cells resembled entrapped cells within testicular tubules or within a sex cord stromal tumor were observed in any of the reviewed slides. At low magnification, it was apparent that the germ cells formed an integral part of the neoplasm (Fig. 3). The germ cells often demonstrated variation in the size of their nuclei, and these ranged from small, deeply basophilic to large blastic ones (Fig. 2). In Cases 1 and 3, they revealed mitoses including atypical ones (Fig. 4). A copious amount of the cytoplasm and relatively smaller nuclei of the germ cell often rendered the germ cell a targetoid appearance (Fig. 5). The germ cells in the testicular MGSCCTs morphologically differed from those in classical seminomas by lacking the typical "square off" quality of the nuclei. In contrast to the nuclei in classical seminomas, their size in testicular MGSCCTs was smaller and nucleoli were inconspicuous. In addition, Periodic Acid-Schiff

Fig. 1 Testicular MGST showing predominance of spindle cell stromal component in some areas. Hematoxylin and eosin staining

(PAS) revealed no glycogen in the cytoplasm of MGSTs. SCC was composed of spindle cells with nuclei having longitudinal clefts and inconspicuous nucleoli (Fig. 5). Focally, SCC formed peripheral palisading. In many areas, the tumor cells were intermixed with dense collagen (Fig. 6). Rarely, the collagenous extracellular matrix formed Call-Exner-like bodies. Leydig-like and lutein cells and concentric calcifications typical of gonadoblastoma were lacking. Immunohistochemically, the germ cells of MGSTs in Case 1 reacted positively with antibody to AE1–AE3 (Boehringer: Mannheim) by paranuclear dot-like or rod-like positivity (Fig. 7). The germ cells in the other two cases of testicular MGSTs were AE1–AE3 negative. All three testicular MGSTs were negative with the rest of antibodies, including placental alkaline phosphatase (PLAP), OCT4, and c-kit protein. MIB1 antibody stained almost exclusively the germ cell component, and in Case 1, as many as 40% of all germ cells stained with the MIB1 antibody (Fig. 8), while the SCC revealed only very rare MIB1 positive cells (less than 1%). Inhibin stained the cells of SCC (Fig. 9). Actin antibody stained only capillary pericytes (Table 2).

Ovarian tumors Ovarian tumors in our series differed from the testicular lesions in both the germ cell component and the SCC. The germ cells in all four ovarian cases had

Fig. 2 Testicular MGST showing that the germ cells often varied in size, ranging from small deeply basophilic cells to large blastic cells. Hematoxylin and eosin staining

Fig. 3 Testicular MGST showing at low magnification that the germ cells form an integral part of the neoplasm and that they do not represent entrapped nonneoplastic germ cells in testicular tubules. Hematoxylin and eosin staining

cytomorphological features identical to those present in classical seminomas/dysgerminomas. They possessed the typical “square off” quality of the nuclei (Fig. 10), which were much more blastic with more mitoses compared with the testicular tumors in our series. The cytoplasm of the germ cells in ovarian neoplasms contained PAS positive glycogen. SCC differed from case to case. In Case 4, it formed lobules composed of cells with clear to eosinophilic cytoplasm forming either hollow microfollicles inside the lobules or microfollicles filled with collagen. These features, along with a peripheral palisading of the lobules (Fig. 11), imparted to the tumors an appearance somewhat similar to the sex cord tumors with annular tubules [45] (Fig. 12). In Cases 6 and 7, the SCC formed less well-defined lobules with greater amount of fibrous septa dividing them. In Case 6, the sex cord stromal cells focally differentiated into a columnar glandular epithelium with a ciliated brush border (Fig. 13). The SCC in Case 5 differed from the other three ovarian cases in that it formed trabeculae with stromal cells lying perpendicular to the long axis of the trabeculae (Fig. 14). The germ cells and SCC formed sharply circumscribed lobules (Fig. 15). In no case in our series did the germ cells grow outside the confines bordered by the SCC. There were no Leydig-like cells, lutein cells, or concentric calcifications typical of gonadoblastoma whatsoever.

Fig. 4 Testicular MGST. Atypical mitoses were found in the germ cells. Giemsa staining

Fig. 5 Testicular MGSCT. A copious amount of cytoplasm and relatively smaller nuclei of the germ cell rendered them a targetoid appearance. The SCC was composed of spindle cells with nuclei having longitudinal clefs and inconspicuous nucleoli. Hematoxylin and eosin staining

Immunohistochemically, the germ cells in all four ovarian tumors stained positively with the antibodies to neuron specific enolase (NSE), PLAP (Fig. 15), OCT4 and, with the exception of Case 7, they reacted positively for the c-kit protein antibody. Rare germ cells in Case 5 stained positively with the antibody to cytokeratins AE1–AE3; otherwise, the germ cells in all cases were negative with all the rest of the antibodies. SCC was immunohistochemically positive with inhibin antibody in all four cases (in Case 5 only focally) and with cytokeratin AE1–AE3 antibody in three out of four cases. It was negative with the rest of the antibodies. The MIB1 antibody reacted in 20–30% of the germ cells, and only very rare cells of the SCC (less than 1% in all four cases) were positive with this antibody (Table 2).

Molecular genetic findings

Of the seven cases studied, mutation status of c-kit and PDGFRA genes was successfully analyzed in five cases (Cases 1, 2, 4, 5, and 7). In Case 6, no amplifiable DNA was presented probably due to wrong fixation. In Case 3, no tissue was at hand for molecular genetic study. All

Fig. 7 Testicular MGSCT. Many germ cells reacted positively with the antibody to AE1–AE3 revealing a paranuclear dot- or rod-like signal

successfully analyzed cases showed no mutation in all studied exons and exon–intron junctions.

Molecular cytogenetics finding

Of the seven studied cases, FISH was successfully performed in four cases (1, 4, 5, and 7). In Cases 2 and 6, no signals of 12p and CEP 12 probe were visible after repeated FISH analysis. In Case 3, no tissue was at hand for molecular cytogenetic study. Of all successfully analyzed cases, only Case 7 showed amplification of 12p (Fig. 16). All others were negative for amplification of 12p. Results of FISH are summarized in Table 3.

Discussion

MGSTs occur in the gonads of phenotypically and genetically normal subjects. They were first described by Masson as a Pflügerome in 1912 [21] and later as “epitheliomas pflugeriens” in 1923 [22]. Later, there were several cases published in the ovaries [1, 14, 19, 27, 32, 33, 35, 37, 38, 41, 47] and occasional cases in the testes [3, 28, 36, 37]. However, the existence of these

Fig. 8 Testicular MGSCT. In Case 1 as many as 40% of all germ cells stained with the MIB1 antibody

Fig. 9 Testicular MGSCT. Inhibin stained the sex cord stromal cells

tumors in the testis has recently been questioned by a group of authors who reviewed nine testicular sex cord–stromal tumors containing germ cells, which closely mimicked MGSCT but differed from the latter, in that the germ cells were entrapped and nonneoplastic rather than neoplastic [43, 46]. They thought that these tumors closely resembled MGSCT, but represented sex cord stromal tumors with entrapped germ cells, which they considered were nonneoplastic. The evidence presented to support this view was that the germ cells were distributed peripherally and were associated with entrapped seminiferous tubules. They were also said to occur in clusters with vaguely tubular shapes, consistent with preexisting seminiferous tubules. Although some of these cases may have represented sex cord–stromal tumors with entrapped germ cells, germ cells seemed not to have any relation to preexistent seminiferous tubules in some of them and were scattered haphazardly forming true predominant part of the lesion, while in other parts of the sex cord elements predominated. The germ cells showed variable appearances. In one of those cases, inhibin stain showed an association of the germ cells with nonneoplastic Sertoli cells. The germ cells in their cases lacked large, vesicular nuclei with prominent nucleoli, closely resembling type A spermatogonia [43].

Fig. 10 The germ cells in all four ovarian cases had cytomorphological features identical to those seen in the classical seminomas/dysgerminomas. The cells possessed the typical “square off” quality of the nuclei. Hematoxylin and eosin staining

Our testicular cases differed from the cases of Ulbright et al. [43]. Our tumors were composed of germ cells with vesicular nuclei and spindle-shaped sex cord–stromal cells. No association whatsoever was found, even on intentional search, between the germ cells and preexisting seminiferous tubules in any of the 20 sampled blocks of Case 1, nor was this feature observed in multiple sections in Cases 2 and 3. Furthermore, in most of the slides, the germ cells formed a predominant part of the microscopic fields. In addition, the size of the germ cells varied, ranging from cells with small hyperchromatic nuclei to large blastic cells with vesicular nuclei. In that respect, the nuclear variations in the germ cell component in our case had some similarities to nuclear variations seen in spermatocytic seminomas [30]. Atypical mitoses in germ cells present in two of the three testicular cases are another argument supporting their neoplastic nature. Immunonegativity with the antibodies to PLAP, NSE, c-kit protein, and OCT4 [6, 12] and the absence of cytoplasmic glycogen within the germ cells in our testicular cases do not necessarily preclude their nonneoplastic nature, because germ cells in spermatocytic seminomas, in our experience, lack cytoplasmic glycogen and they are consistently negative with

all these antibodies as well. Positivity with the anti-cytokeratin antibody AE1–AE3 in one testicular and one ovarian MGST is an interesting and hitherto unreported feature of MGST. Cytokeratin immunoreactivity, including AE1–AE3, has been repeatedly described in classical seminomas [7, 10]. Chevillet et al. [7] for example showed that 36% of classical seminomas reacted with this antibody. Occasional cytokeratin positivity in spermatocytic seminomas was described as well [8]. However, no such cytokeratin immunoreactivity can be seen in germ cells of the normal testes.

When judging the figures of other published cases of testicular MGST [3, 28], it seems that they were morphologically very similar to our cases. Typical for testicular MGSTs in our series and those in the literature [3, 28] is the SCC composed of spindle-shaped cells incorporating clusters of germ cells with a copious cytoplasm rendering them a targetoid appearance. In contrast, the SCC and germ cells of the ovarian MGSTs differed from testicular MGSTs. The SCC either formed trabeculae with perpendicularly arranged sex cord stromal cells or it formed lobules or tubules with peripheral palisading. A clear to eosinophilic and homogeneous cytoplasm of these sex cord stromal cells imparted a vague similarity of sex cord tumor with annular tubules to one

ovarian MGST in our series [45]. Besides the patterns of SCC seen in our cases, several other patterns were described in the literature in the ovaries including a retiform tubular pattern [41], a pattern forming hollow tubules [19], and others [14, 37]. Moreover, germ cells in ovarian MGSTs had a “square off” appearance [44] of classical seminomas/dysgerminomas. They contained PAS positive diastase sensitive glycogen in their cytoplasm and further they lacked the targetoid appearance of germ cells in the testicular MGSTs. Immunohistochemistry revealed additional differences between the germ cells in the testicular and ovarian MGSTs, inferring their different nature. The ovarian MGSTs were PLAP, OCT4, and NSE positive, while no positivity with these markers was found in the testicular neoplasms. All four ovarian tumors were immunohistochemically c-kit protein positive. All these markers are typically positive in classical seminomas/dysgerminomas [2, 40].

KIT protein is expressed in most cases of classical seminomas/dysgerminomas, both in gonadal [40] and extragonadal location [25], while it is negative in nonseminomatous germ cell tumors. We have not found KIT protein expression in any of the 14 cases of spermatocytic seminomas in our files. To date there have

been several reports of Kit mutations found in exon 17 in germ cell tumors. Tian et al. found c-kit exon 17 mutations in 2/23 cases of the gonadal [39] seminomas/dysgerminomas. Przygodzki et al. [26] found it in 3/17 cases of mediastinal seminomas with mutations and Kemmer et al. [16] found exon 17 of *c-kit* gene mutations in 14/54 cases

of gonadal seminomas/dysgerminomas. Pauls et al. [25] described a case of primary retroperitoneal seminoma with a point mutation in codon 557 of exon 11 of *c-kit* gene. No mutations were found in this case in exon 17. We searched for activation mutations in exon 9, 11, 13, and 17 of *c-kit* gene and exon 12 and 18 of the PDGFRA gene, which are mutations often found in gastrointestinal stromal tumors [9]. While 75% of ovarian cases expressed KIT protein at immunohistochemical level, we found no activating mutations on any exons of *c-kit* and PDGFRA genes in any of MGSCTs in our series.

Another point supporting the similarity of germ cells in the ovarian MGSCTs to germ cells in dysgerminomas is the fact that several cases of ovarian MGSCTs progressed into invasive dysgerminoma [13, 18, 19, 37]. In four children, there is a described malignant overgrowth by other malignant germ cell elements, including choriocarcinoma and yolk sac tumor [18]. In three of these patients, the tumor metastasized and resulted in the deaths of the patients [18]. No such events have ever been described in testicular MGSCTs.

The finding of excess genetic material of the short arm of chromosome 12 in one of our two ovarian MGSCTs is of great interest. This genetic abnormality occurs in all primary sites and histologic types of all human germ cells tumors [4, 17, 20] with the exception of spermatocytic seminomas and prepubertal teratomas of the testis. Data suggest that the consistent gain of genetic material from chromosome 12 may be crucial for the development of an invasive germ cell tumor [29]. Overrepresentation of 12p renders the tumor cells independent from the supporting Sertoli cells. Cells of intratubular germ cell neoplasia therefore lack overrepresentation of 12p [20]. The presence of gain in the short arm of chromosome 12 in our case 7 is in accordance with the well-documented ability of ovarian MGSCTs to produce invasive dysgerminoma and other neoplastic germ cell components [13, 18, 19, 37]. The longer follow-up and more cases would be necessary to find out whether this genetic event in ovarian MGSCTs has a prognostic significance in relation to development of an invasive component.

In contrast to the ovarian MGSCTs, germ cells in all three cases of testicular MGSCTs in our series lacked cytoplasmic glycogen and immunohistochemical positivity with PLAP, OCT4, and *c-kit* protein. Interestingly, in our

experience and that of others [8], all these markers, including OCT4 [15, 44] are absent in spermatocytic seminomas. MIB1 immunoreactivity revealed that the germ cells are a quickly proliferating component of the neoplasms, while the sex cord stromal cells represent a relatively slowly proliferating part of the tumors. This militates against the suggestion that germ cells in the testicular MGSTs represent nonneoplastic, possibly entrapped germ cells [43, 46].

Another interesting feature of the tumors was the relation of the sex cord stromal cells and the germ cells. In no case in our series did the germ cells grow outside the confines bordered by the SCC. It looked as though the sex cord stromal cells of the tumors possessed a homing phenomenon to the germ cells. In the differential diagnosis, MGST should be distinguished especially from gonadoblastoma [31]. In contrast to our cases, all of which had normal karyotype, the gonadoblastomas nearly always occur in patients with pure or mixed gonadal dysgenesis with an altered karyotype or, in men, pseudohermaphrodites in streak gonad or testis. Leydig-like and lutein cells and concentric calcifications typical of gonadoblastoma were uniformly lacking in our cases. In contrast to gonadoblastomas, there is no evidence of virilization in MGSTs and, if there are signs of abnormal endocrine activity in MGSTs, they manifest themselves as feminization. MGSTs show also proliferative activity in the sex cord–stromal component, while in gonadoblastoma, proliferative activity is seen in only the germ cells.

The widespread presence of germ cells distinguishes MGSTs from Sertoli–Leydig cell tumors, especially from those neoplasms showing a retiform component.

In summary, we presented three cases of testicular and four cases of ovarian MGSTs. The morphology and immunohistochemical profile of testicular and ovarian MGSTs differed. The immunoprofile of the germ cells in testicular MGSTs was similar to that observed in spermatocytic seminoma, and the immunoprofile of the germ cells in ovarian lesions was similar to that seen in classical seminoma/dysgerminoma. However, the number of published testicular examples of MGSTs is too small to generalize that all of them differ from ovarian MGSTs. It cannot be excluded that, in addition to the testicular MGSTs in which the germ cells have immunohistochemical properties of the spermatocytic seminomas as in our series, there might exist MGSTs with immunohistochemical properties of classical seminoma/dysgerminoma indistinguishable from the ovarian examples of MGSTs.

Acknowledgement We would like to thank to Dr. J. Arroyo for allowing us to use a tissue from his case [1] for the study.

Dendritic cells interacting mainly with B cells in the lymphoepithelial symbiosis of the human palatine tonsil

Received: 23 May 2005 / Accepted: 31 August 2005 / Published online: 8 March 2006
© Springer-Verlag 2006

Abstract The lymphoepithelial symbiosis (LES) of the human palatine tonsil is composed of spindle- or star-shaped epithelial cells forming a loose meshwork, containing numerous lymphocytes and dendritic cells (DCs). In the present study, we immunohistochemically characterized DCs in the LES (LES-DCs). LES-DCs were phenotypically immature DCs that were S100 β ⁺, fascin⁻, HLA-DR⁺, CD1a⁻, CD80⁻, CD83⁻, CD86⁻, and CD123⁻. The most characteristic feature of LES-DCs was that they contacted many B cells, which were mostly IgM⁺ IgD⁺ resting naive B cells. Langerhans cells (LCs) located in the nonsymbiotic squamous epithelium were immature DCs that were S100 β ⁺, fascin⁻, and CD1a⁺ and did not contact lymphocytes. In contrast to LES-DCs, interdigitating dendritic cells (IDCs) in the T zone were mature DCs that were HLA-DR⁺, CD1a⁻, fascin⁺, CD80⁺, CD83⁺, and CD86⁺ and contacted numerous CD4⁺ T cells. Two subsets of IDC, S100 β ⁺ fascin⁺ IDC (IDC-1) and S100 β ⁻ fascin⁺ IDC (IDC-2), were identified, and the majority of IDCs are IDC-2. In contrast to IDCs, which were distributed in the T-cell area in groups, LES-DCs were distributed along the crypt as if forming a barrier. These findings suggest that LES-DCs

are a novel type of DC playing an important role in the induction of humoral immune response against incoming air- or food-borne pathogenic antigens.

Introduction

It is well established that dendritic cells (DCs) have a unique ability to stimulate resting naive T cells to proliferate in an antigen (Ag)-specific manner [3], but it has long been believed that DCs are not directly involved in the regulation of B-cell-mediated immunity. To become activated, Ag-specific resting naive B cells require simultaneous exposure to native Ag and Ag-specific CD4⁺ T cells [14]. However, the question of how rare resting naive B cells can encounter native Ag and simultaneously and efficiently interact with rare Ag-specific CD4⁺ T cells remains to be answered. It has been suggested that DCs act as a matrix upon which Ag-specific T and B cells interact efficiently and that DCs can deliver native Ags to Ag-specific resting naive B cells [13, 15, 31]. Thus, DCs may play an important role in the induction of the humoral immune response.

Several recent investigations have demonstrated that DCs are directly involved in regulating T-cell-mediated humoral immune responses [7, 5]. Bjork et al. reported evidence indicating that naive B cells actually interact with DCs in human tonsils [5]. We also previously demonstrated that interdigitating dendritic cells (IDCs) sometimes interact with resting naive B cells directly in the T-cell area of the lymph node [29]. However, because such B cells are usually detected infrequently and in small numbers, we search for such types of DCs that usually interact with the large number of resting naive B cells.

In the present study, we demonstrated the presence of a special type of DCs in the lymphoepithelial symbiosis (LES) of the human palatine tonsil. We showed that these DCs in the LES (LES-DCs) are phenotypically different from Langerhans cells (LCs) and IDCs and usually contact many resting naive B cells. The present study suggests that LES-DCs are involved in the induction of the humoral

immune response against incoming air- or food-borne pathogenic Ags.

Materials and methods

Antibodies

Mouse monoclonal antibodies (mabs) to HLA-DR (LN-3; Nichirei, Tokyo, Japan), CD1a (O10; Immunotech, Marseille, France), CD3 (Novocastra, Newcastle, UK), CD4 (Ventana, Yokohama, Japan), CD8 (Nichirei), CD20 (L26; Nichirei), CD79 α (Nichirei), human cytokeratin (CK) AE1/AE3 (DAKO, Glostrup, Denmark), and human fascin (Research Diagnostics Inc., Flanders, NJ, USA) were purchased. These mabs can detect Ag in paraffin-embedded tissues. Rabbit polyclonal antibody (pab) to S100 β subunit had been prepared previously [29]. Rabbit pab to human IgG, IgM, IgD, or IgA were purchased from DAKO. In addition, mabs to CD11a, CD11b, CD11c, CD13, CD14, CD16 (Fc γ RIII), CD32a (Fc γ RII), CD33, CD34, CD35, CD64 (Fc γ RI), CD68, CD80, CD83, and CD86 were purchased from DAKO; the mab to CD123 was supplied by Pharmingen (Tokyo, Japan).

Tissue preparation

Human palatine tonsils without inflammation were obtained at the time of surgery from two adult patients with benign squamous papilloma of the tonsil. Prior consent was obtained from both patients. Tissues were routinely fixed in formalin and embedded in paraffin. Sections (3- μ m-thick) were cut from the paraffin blocks and examined immunohistochemically. Unfixed tissues were snap-frozen in Tissue-Tek OCT compound (Salura Finetek, Torrance, CA, USA). Frozen sections (6- μ m-thick) were cut, mounted on glass slides, fixed in acetone for 10 min at 4°C, air-dried, and examined immunohistochemically.

Immunohistochemistry

Dewaxed paraffin sections were immersed in citrate buffer (0.01 mol/l citrate, pH 6.0), microwaved for 15 min at 600 W, and then cooled at room temperature for 20 min. Paraffin sections were rinsed with phosphate buffered saline (PBS) and examined immunohistochemically.

Immunoperoxidase methods

Some sections were stained by immunoperoxidase methods using DAKO Envision System Peroxidase (Carpinteria, USA) according to manufacturer's instructions. After washing, sections were counterstained with hematoxylin.

Immunofluorescent staining

Paraffin or frozen sections were examined by two-color immunofluorescence methods using a combination of rabbit pab and mouse mab. Rabbit pab was detected by fluorescein isothiocyanate (FITC)-conjugated anti-rabbit IgG (DAKO), and mouse mab was detected by phycoerythrin (PE)-conjugated anti-mouse IgG (DAKO). Preparations, which included dewaxed paraffin sections and frozen sections, were immersed in PBS containing 10% normal goat serum (DAKO) for 30 min. After rinsing with PBS, sections were simultaneously incubated for 12 h at 4°C with rabbit pab (at a dilution of 20 μ g/ml of anti-S100 β subunit or at a dilution of 1:500 of antibody to each class of human immunoglobulin heavy chains) and each of the mabs. Sections were then washed with PBS and further treated for 30 min at room temperature with a combination of FITC-conjugated goat anti-rabbit IgG (DAKO) at a dilution of 1:50 and PE-conjugated goat anti-mouse IgG at a dilution of 1:50. After washing with PBS, sections were immersed in fluorescent mounting medium (DAKO) and examined with an LSM 510 confocal laser scanning microscope (Carl Zeiss, Tokyo, Japan).

Results

Enzyme immunohistochemistry

The human palatine tonsil is covered by squamous epithelia, which form many deep crevices called tonsillar crypt, and numerous secondary lymphoid follicles are located along the crypt (Fig. 1). The LES is the specific region of the squamous epithelia covering these follicles. Immunoperoxidase staining for CK AE1/AE3 indicated that the epithelial cells of the LES, which were positive for CK AE1/AE3, were spindle- or star-shaped cells forming a loose meshwork, containing numerous leukocytes (Fig. 2a,b).

In order to elucidate the distribution of DCs in the human palatine tonsil, we performed enzyme immunohistochemistry for S100 β and fascin. Immunoperoxidase staining for S100 β or fascin indicated that the distribution of S100 β + DCs was quite different from that of fascin+ DCs. Specifically, S100 β + DCs were densely distributed along the crypt as if forming a barrier (Fig. 2c), whereas fascin+ DCs were distributed in the T-cell area (Fig. 2d).

Immunofluorescent analysis of tonsillar tissue

DCs and lymphocytes in the LES were examined by two-color immunofluorescent microscopy using a confocal laser scanning microscope. Analysis of frozen sections by two-color immunostaining for immunoglobulin heavy chains (FITC) and CK AE1/AE3 (PE) showed that the vast majority of lymphocytes in the LES were IgM+ IgD+ resting naive B cells (Fig. 3a,b). IgA+ B cells were also

Fig. 1 A general view of the human palatine tonsil and lymphoepithelial symbiosis (LES)

detected in small numbers, but no IgG⁺ B cells (data not shown).

S100 β subunit cannot be detected in frozen sections because of its extremely water-soluble nature. We therefore used formalin-fixed, paraffin-embedded tissue sections to detect S100 β ⁺ DCs. Two-color immunofluorescent analysis for S100 β (FITC) and CK AE1/AE3 (PE) demonstrated a considerable number of S100 β ⁺ CK-DCs (green) among the S100 β -CK⁺ epithelial cells (red) in the LES (Fig. 3c,d). Two-color analysis for S100 β (FITC) and each of the antigens HLA-DR, CD79 α , CD20, CD3, and CD4 (PE) indicated that S100 β ⁺ LES-DCs were weakly positive for HLA-DR and that they attached to many B cells, which were HLA-DR⁺ (Fig. 3e), CD79 α ⁺ (Fig. 3f), and CD20⁺ (Fig. 3g). LES-DCs also attached to a small num-

ber of CD3⁺ CD4⁺ T cells (Fig. 3h,i). CD8⁺ T cells were rare in the LES (data not shown). When 100 LES-DCs were analyzed, one LES-DC contacted a mean of 4.0 ± 0.7 B cells and 0.6 ± 0.21 T cells ($p < 0.001$). These findings indicated that LES-DCs interact mainly with B cells and also with a small number of CD4⁺ T cells. Taken together with the finding that lymphocytes in LES were mostly IgM⁺ IgD⁺ resting naive B cells, we concluded that S100 β ⁺ LES-DCs interact mainly with resting naive B cells.

The vast majority of S100 β ⁺ LES-DCs were negative for CD1a, although a small number of them were found to be positive for CD1a (Fig. 3j). To further confirm that LES-DCs are negative for CD1a, two-color immunofluorescent analysis using frozen sections was performed since immunohistochemical detection of CD1a in paraffin sections is

sometimes unsuccessful. Because S100 β cannot be detected in frozen sections, we used HLA-DR as a marker for LES-DCs. Two-color analysis for HLA-DR (FITC) and CD1a (PE) indicated that the vast majority of HLA-DR+ LES-DCs, which contacted to HLA-DR+ B cells, were negative for CD1a (Fig. 3k). In contrast, two-color analysis for IgM (FITC) and CD1a (PE) indicated that CD1a^{bright} LCs in non-LES epithelia did not contact IgM+ naive B cells (Fig. 3l).

the vast majority of LES-DCs are negative for CD1a. **k** Frozen section: immunofluorescent staining of the LES for HLA-DR (FITC) and CD1a (PE) applied on a frozen section. Note that HLA-DR+ LES-DCs surrounded by HLA-DR+ B cells are negative for CD1a. **l** Paraffin section: immunofluorescent staining of the LES for IgM (FITC) and CD1a (PE). Note that LCs in non-LES epithelia are strongly positive for CD1a and do not attach to IgM+ resting naive B cells. **m** Paraffin section: immunofluorescent staining of the LES for S100 β (FITC) and fascin (PE). CD16, CD32, and CD64; and complement C3-receptors including CD11b, CD11c, and CD35 (Table 1).

IDCs in the T-cell area were also examined by immunofluorescent microscopy. Two-color immunostaining for S100 β (FITC) and fascin (PE) indicated that IDCs, which were morphologically identified as large dendriform cells, were divided into two subsets, S100 β + fascin+ IDC (IDC-1) and S100 β - fascin+ IDC (IDC-2). The majority of IDCs were IDC-2 (Fig. 3n).

Two-color immunofluorescent analysis for S100 β and T-cell antigens including CD3, CD4, and CD8 indicated that IDCs contacted numerous CD4+ T cells (Fig. 3o), but that they rarely contacted CD79 α + B cells (Fig. 3p). IDCs were positive for mature-DC markers including CD80, CD83, and CD86 (Table 1).

A few S100 β + fascin- small lymphoid cells were also detected in the T-cell area. They were mostly T cells expressing CD3 and CD8 (data not shown).

Discussion

In our previous study, we demonstrated that IDCs in the T-cell area of the lymph nodes contact resting naive B cells [29]. However, B cells contacting IDCs are usually detected infrequently and in small numbers. In contrast, as shown in this study, LES-DCs usually contact many B

cells, mostly IgM+ IgD+ resting naive B cells. DCs that habitually interact with so many B cells have not previously been identified outside the germinal centers of lymphoid tissues. LES-DCs have been regarded as IDCs because they are positive for IDC markers such as HLA-DR and S100 β , a member of the S100 protein family present in human IDCs and LCs [6, 27], and are mostly negative for CD1a, a specific marker for LCs [10, 16]. However, as shown in this study, LES-DCs are completely negative for fascin, a 55-kDa, actin-bundling protein highly specific for mature DCs [1, 9, 21–23], whereas IDCs in the T-cell area are strongly positive for fascin. Taken together with the present findings that LES-DCs do not express mature DC markers that are expressed on IDCs (e.g., CD80, CD83, and CD86) [4, 20, 25], it is clear that LES-DCs are immature DCs distinct from IDCs.

Immature DCs, such as LCs, have been demonstrated to be negative for fascin [18, 21]. LCs are strongly positive for CD1a and usually present in nonsymbiotic squamous epithelium, where LCs do not contact any type of lymphocytes. It is therefore clear that LES-DCs differ from LCs and IDCs in distribution, phenotype, and association with neighboring cells. Germinal center DCs, which were recently identified in germinal centers of the palatine tonsil [8], are reported to be strongly positive for fascin [24]. Follicular dendritic cells (FDCs) in germinal centers are

also positive for fascin [12] and express CD35 on their surfaces [2, 30], but LES-DCs are negative for CD35.

LES-DCs are also negative for CD123, a marker expressed on plasmacytoid DCs, a type of DC distributed around the high endothelial venule in the T-cell area of lymphoid tissues including the palatine tonsil [11, 26]. Hence, LES-DCs are phenotypically different from these known DCs in the human palatine tonsil.

The present finding that LES-DCs interact with many resting naive B cells suggests that they are involved in the Ag-specific stimulation of resting naive B cells. It has been well established that both the native form of Ag and Ag-specific CD4⁺ T cells are necessary for the stimulation of resting naive B cells. The present findings that LES-DCs contacted a small number of CD4⁺ T cells is consistent with the view that LES-DCs act as a matrix upon which resting naive B cells efficiently interact with Ag-specific CD4⁺ T cells. Judging from the present findings that LES-DCs are phenotypically immature DCs lacking the expression of costimulatory factors such as CD80 and CD86, it seems likely that the role of LES-DCs is to stimulate resting naive B cells but not resting naive T cells. If this is the case, then the question arises as to how LES-DCs deliver Ag in the native form to resting naive B cells, which is essential for their stimulation. As shown in this study, LES-DCs do not express FcγRs recognized by mabs CD16, CD32, and CD64, or C3R recognized by mab CD35 on their surface. These proteins might allow LES-DCs to retain Ags within cell surface immune complexes [17, 19]. It has been shown that DCs have the ability to retain Ag in the native form for a long time and to deliver it to resting naive B cells to stimulate antibody synthesis [15]. We speculate that LES-DCs are a special type of DC, in which this ability is particularly strong, and that these cells devote themselves to the Ag-specific stimulation of resting naive B cells. The palatine tonsil is one of the first barriers against numerous pathogenic air- or food-borne Ags. The present study suggests that LES-DCs play an important role in the induction of the humoral immune response against such Ags. The origin of LES-DCs and their ontogenic relationship with LCs and IDCs also remain to be determined.

Finally, it is noteworthy that S100β⁺ fascin⁺ small lymphoid cells are present in the T-cell area of peripheral lymphoid tissues including the palatine tonsil. These are CD3⁺ CD8⁺ T cells rather than IDCs and should not be mistaken as IDCs [28]. Their biological significance and association with DCs also remain to be established.

Calcification of myocardial necrosis is common in mice

Received: 24 April 2005 / Accepted: 19 August 2005 / Published online: 7 October 2005

Abstract Independent of the severity, phenotypes and clinical outcomes of myocardial infarction may vary considerably in patients, suggesting a strong genetic influence on healing and adaptive processes. Since little is known about these genetic determinants, we examined the tissue response to myocardial injury in seven inbred mouse strains, including those employed for gene targeting or transgenic overexpression. Myocardial necrosis was produced by non-ischemic, trans-diaphragmal freeze–thaw injury in strains C57BL/6, C3H/He, DBA/2, BALB/c, 129S1, FVB/n and A/J. Two days after injury, necrotic cardiomyocytes calcified in C3H/He, DBA/2, BALB/c and 129S1, a phenotype known as dystrophic cardiac calcinosis (DCC). The susceptibility to DCC of 129S1 was determined by *Dyscalc1*, a locus on chromosome 7, which was identified previously in C3H/He and DBA/2. DCC was also observed in C3H/He following ischemic injury by permanent coronary artery ligation, indicating that DCC was independent of the mode of injury. In contrast, strains C57BL/6, FVB and A/J were resistant to DCC, showing formation of a fibrous scar without calcification. The development of DCC was studied in detail in C3H/He and C57BL/6. In both strains, no calcium deposition and only little structural disintegration were noted in necrotic myocardium 24 h after injury upon

calcium-sensitive fluorescence staining. Ultrastructural examination revealed calcified mitochondria in C3H/He that may have served later as a nidus for rapid intracellular calcification of cardiomyocytes. We concluded that the susceptibility to calcification of myocardial necrosis may be common among inbred strains and should be recognised as a strong genetic modifier of experimental myocardial injury.

Keywords Myocardial infarction · Necrosis · Healing · Tissue calcification · Response to injury · Dystrophic cardiac calcinosis · Dyscalc

Introduction

Myocardial necrosis may result from irreversible cell injury of various aetiologies, most often caused by thromboembolic occlusion of a coronary artery as a consequence of atherosclerotic plaque rupture. The subsequent response of tissue involves inflammation and removal of necrotic tissue and usually results in scarring and thinning of the affected myocardial wall. Interestingly, up to 7.6% of the survivors of acute myocardial infarctions may also exhibit calcified myocardial necrosis [2].

Myocardial calcification was also observed in certain inbred mouse strains, such as C3H and DBA [8]. This form of soft tissue calcification was independent of calcium and phosphate plasma concentrations and was referred to as dystrophic cardiac calcinosis (DCC). Frequency and severity of DCC were influenced by age, sex, hormones, diet and infectious agents [9–11, 13]. Employing trans-diaphragmal freeze–thaw injury of the myocardium, Brunnert and Altman [4] presented the first evidence that myocardial calcifications developed in genetically predisposed strains only after cardiomyocyte death had occurred. A strain-dependent susceptibility to DCC may also explain calcification of severely dystrophic myocardium in some gene-targeted mouse models of cardiomyopathy [12, 16, 17, 22].

Employing non-ischemic freeze–thaw injury, we investigated the phenotypes of myocardial necrosis in seven

frequently studied inbred mouse strains, including those relevant for gene targeting (strain 129S1) or transgenic overexpression (strain FVB). We found calcifying cardiomyocyte necrosis in C3H/He, DBA/2, BALB/c and 129S1 but not in C57BL/6, FVB/n and A/J. Strains C3H/He and C57BL/6 were examined by fluorescence and electron microscopy at several time points to describe the reaction of tissue to necrosis in greater detail and to determine the time and location of first calcium deposits. The susceptibility of some, but not all inbred strains, clearly indicated that DCC depended on strain background and was therefore genetically determined. Our data and the ancestral relationships among the studied strains may facilitate *in silico* mapping of the genetic causes of DCC in the future.

Material and methods

Animals

Mouse inbred strains C3H/HeNCrIBR (C3H/He), C57BL/6NCrIBR (C57BL/6), BALB/cAnNCrIBR (BALB/c), DBA/2NCrIBR (DBA/2), FVB/NCrIBR (FVB) and 129S1/SvImJ (129S1) were purchased from Charles River (Sulzbach-Rosenberg, Germany). A/J mice were obtained from the Jackson Laboratory (Bar Harbor, ME, USA). All mice were housed in groups of up to five animals in a climate- and pathogen-controlled environment (room temperature 22±2°C, relative humidity 55±10%, 15 air changes per hour) with a 12 h light/dark cycle. Mice had free access to standard rodent chow and tap water. Experimental procedures were conducted in concordance with the German Animal Welfare Act and were done on virgin females of 6–8 weeks of age. Ischemic myocardial injury was produced by permanent coronary ligation as reported by others [18]. Non-ischemic myocardial freeze–thaw injury was performed as described previously [1, 3]. Since mortality of freeze–thaw injury was below 5%, we employed this procedure to determine the susceptibility to DCC in all strains. All mice were killed by cervical dislocation 3 days after myocardial freeze–thaw injury or 5 days after coronary ligation. Whole hearts were removed quickly, rinsed in phosphate-buffered saline (PBS; pH 7.4) and stored in 4% paraformaldehyde for paraffin embedding or in tissue-freeze medium (Leica Instruments, Nussloch, Germany) until histological processing.

Histology

Serial 6- to 8- μ m cryostat sections or 2- μ m paraffin sections were prepared throughout the ventricles, and 40–60 sections per heart were collected on poly(D-lysine)-coated slides. Paraffin sections were stained with haematoxylin and eosin (H & E) according to standard protocols using Mayer's haematoxylin (Sigma, Taufkirchen, Germany) and 0.5% eosin Y aqueous (Shandon, Germany). For calcium staining, a 1% solution of alizarin red S (Sigma) was prepared and adjusted to pH 6.4 by adding

drops of 0.1% NH₄OH [6]. Cryostat sections were stained for 2 min, rinsed twice with distilled water, dehydrated and then mounted with a xylene-compatible medium. For more sensitive, fluorescent calcium staining, cryostat sections were immersed in 0.1 mM calcein/50 mM Tris–buffer (pH 9.0; Sigma) for 30 min. After rinsing twice with PBS (pH 7.4), slides were incubated for 1 min in 2 μ g/ml 4',6-diamidino-2-phenylindole-dihydrochloride (DAPI; Molecular Probes, Leiden, the Netherlands) to visualize cell nuclei. After rinsing with PBS, slides were mounted using anti-fade medium (EMD Biosciences, Darmstadt, Germany). Specimens were examined using a green fluorescence setting (excitation 488 nm) for calcein and a blue fluorescence setting (excitation 358 nm) for DAPI on a fluorescence microscope (Leica, Bensheim, Germany). Photomicrographs were obtained separately for each fluorescence channel using a Leica 500 digital camera set-up. Grey-scale pictures displaying calcein and DAPI fluorescence were artificially coloured, using separate colour look-up tables, and were then fused into one picture, using Photoshop 6.0 (Adobe Systems, USA).

Electron microscopy

Myocardial specimens (approximately 1 mm³) of C3H/He and C57BL/6 were fixed in PBS-buffered 3% glutaraldehyde (pH 7.4), treated with 1% osmium tetroxide, dehydrated and embedded in epoxy resin following standard protocols. Semi-thin toluidine-blue-stained sections (1 μ m) were examined to select blocks for ultrathin sectioning and mounting on grids. Grids were analysed with a Philips EM 400 electron microscope after contrasting with uranyl acetate and lead citrate.

Genetic analysis

Genetic linkage of DCC to the *Dyscalc1* locus was tested by analysis of DCC and a genomic marker in 130 female (129S1×C57BL/6)×129S1 backcross progeny. At 6–8 weeks of age, all mice were phenotyped 3 days after freeze–thaw injury as outlined above. DNA was isolated from tail biopsies employing standard protocols. A simple sequence length polymorphism (SSLP), D7Mit229, was genotyped by PCR amplification and subsequent agarose gel electrophoresis as described previously [14, 15]. This genomic marker is located very close to *Dyscalc1* on proximal chromosome 7 and allowed to assess indirectly the segregation of the *Dyscalc1* alleles in the backcross [14].

Results

Common laboratory strains are susceptible to DCC

We examined three to five female mice of each strain C3H/He, C57BL/6, A/J, BALB/c, DBA/2, FVB, 129S1 to determine the histological phenotypes of myocardial necrosis

at the indicated time points. Lesions were detectable by gross inspection as early as 2 days after freeze–thaw injury (data not shown). Transmural necrosis was located in the right ventricular wall and extended into the interventricular septum (Fig. 1). Necrotic tissue was delineated sharply from surrounding vital myocardium. Strains C57BL/6 and FVB exhibited a necrotic lesion without any trace of calcification (Fig. 1a,c). Only a few single-cell calcifications were found in the necrotic lesions of A/J mice (Fig. 1e). Therefore, this strain was also considered resistant to DCC. In contrast, all DBA/2 mice showed very severe calcification comprising the entire necrotic lesion (Fig. 1d). The degree of calcification was similar in all C3H/He (Fig. 1b) and 129S1 (Fig. 1f) and was almost as severe as seen in

DBA/2. In comparison to C3H/He, DCC exhibited less severity and a larger variance among BALB/c mice: only one animal showed extensive calcifications (Fig. 1g), while focal calcifications of few myofibers only were found in the remaining three mice (data not shown).

Dyscalc1 determined the susceptibility to DCC of strain 129S1

The locus *Dyscalc1* was identified previously as the major genetic determinant of the recessively inherited susceptibility to DCC in strains C3H/He and DBA/2 [5, 14, 15]. The susceptibility to DCC of 129S1 was a novel finding

Fig. 1 Myocardial necrosis 3 days after freeze–thaw injury in strains C57BL/6, C3H/He, FVB, DBA/2, A/J, 129S1 and BALB/c (a–g, $\times 12.5$). DCC in C3H/He 5 days after permanent ligation of the left anterior descending artery (h, $\times 100$). Lesion perimeters are delineated by arrowheads. Calcifications stained bright red with alizarin red S

prompting us to test whether *Dyscalc1* determined DCC in 129S1 as well. Since the *Dyscalc1* gene is still unknown, the *Dyscalc1* alleles had to be assessed indirectly by genotyping the alleles of the SSLP D7Mit229, a genomic marker closely linked to *Dyscalc1*. We produced a (129S1×C57BL/6)×129S1 backcross and screened 130 female progeny for DCC 3 days after freeze–thaw injury. Confirmed by calcium-specific alizarin red S staining, 59 mice (45%) exhibited myocardial calcification whereas 71 mice (55%) were resistant to DCC. All 59 susceptible mice exhibited predisposing homozygous 129S1 alleles at the locus of D7Mit229, while 70 resistant mice were heterozygous (129S1×C57BL/6) at this locus. One animal was apparently resistant to DCC despite a predisposing homozygous 129S1 genotype. Since homozygous 129S1 alleles at D7Mit229 were almost exclusively associated with DCC, *Dyscalc1* must be the major genetic determinant of DCC in 129S1.

Ischemic injury also leads to DCC

The mechanisms involved in ischemic damage or reperfusion injury may differ from those involved in non-ischemic freeze–thaw injury. Therefore, we tested in C3H/He, as an

example of a DCC-susceptible strain, whether the mode of injury may be critical for the development of DCC. Permanent ligation of the left anterior descending artery resulted in necrotic calcifications throughout the apical anterior ventricular wall (Fig. 1h). Compared to the myocardial calcifications seen after freeze–thaw injury (Fig. 1b, d, f, g), these calcifications exhibited a more focal pattern of distribution, suggesting that potentially incomplete ischemia may have caused necrosis of single myocytes or some myofiber bundles only. Further attempts to produce large infarctions were not made, because this evidence confirmed that DCC is not dependent on the mode of injury.

Intracellular calcification of necrotic cardiomyocytes

Histological composition of myocardial necrosis in the lesion perimeter was studied in greater detail 3 days after injury. Cellular infiltrates included fibroblasts, lymphocytes and macrophages (Fig. 2). No major differences in cellular composition were noted among the strains upon standard H & E staining. Vital cardiomyocytes displayed strong eosinophilic staining and large, oval, faint blue nuclei with several nucleoli. In strains C57BL/6, FVB and A/J, necrotic cardiomyocytes disintegrated into small

Fig. 2 Necrosis and calcification in the perimeter of myocardial lesions 3 days after trans-diaphragmal freeze–thaw injury in strains C57BL/6, C3H/He, FVB, DBA/2, A/J and 129S1 (a–f, H & E, ×1,000). Calcified necrotic cardiomyocytes (asterisks) stained purple–greyish. Vital cardiomyocytes and their non-calcified remnants were coloured reddish and pale pink. Erythrocytes appeared bright red

pieces with residual eosinophilic staining, which were removed by phagocytosis (Fig. 2a,c,e). In the lesions of DBA/2, C3H/He, 129S1 (Fig. 2b,d,f, respectively) and DCC-positive BALB/c (data not shown), the outlines of calcified necrotic myocytes remained intact and disintegrated only slowly, although calcified myocytes were surrounded by macrophages. Limited by intercalating discs and basal laminae, myocyte calcification was confined strictly to the intracellular compartment. Three days after injury, we were unable to quantify the proportion of necrotic myocytes that entered calcification, because non-calcified myocyte remnants were either completely removed by phagocytosis or, in the process of decay, could not be distinguished reliably from extracellular wound matrix. In the perimeter of the lesions, vital cardiomyocytes and calcified remnants coexisted side by side, giving rise to a gritty pattern of calcification upon gross examination (data not shown). Calcified myocytes attracted macrophage-like cells excluding major defects of chemotaxis and adhesion. Removal of calcified remnants by phagocytosis was delayed and still ongoing in DBA/2, C3H/He, 129S1 and DCC-positive BALB/c 3 days after injury, whereas debridement and formation of a fibrotic scar were much more advanced in C57BL/6, FVB and A/J. Histological characteristics of bone formation were not observed.

Calcification of cardiomyocytes occurs later than 24 h after injury

We examined DCC-resistant C57BL/6 and susceptible C3H/He mice 24 h after freeze–thaw injury by employing highly sensitive, fluorescent calcein staining to determine the time of first appearance and the localization of myo-

cardial calcifications. Both C3H/He (Fig. 3a) and C57BL/6 (data not shown) exhibited lesions with remarkably preserved morphology of myofibers, edema and little inflammatory cell infiltration. Injured myocardium displayed a fainter calcein fluorescence than non-injured myocardium (Fig. 3a). At higher magnification, calcein fluorescence showed a cross-striation pattern consistent with myofilament-bound calcium. In necrotic tissue, the banding pattern appeared patchy and displayed interruptions consistent with a condensation and breakup of necrotic cardiomyocytes (Fig. 3b). Notably, larger circumscribed calcium deposits were absent during the first 24 h after freeze–thaw injury.

Calcified cardiomyocytes were subject to phagocytosis

Phagocyte activity was assessed indirectly by tracking calcein fluorescence of cardiomyocyte remnants in lysosomes of macrophages. These remnants were evident as accumulations of small, green-fluorescent bodies co-localized with the blue-fluorescent, DAPI-stained nuclei of macrophages. DCC-resistant C57BL/6 (Fig. 3c) and susceptible strain C3H/He (Fig. 3d) were compared 3 days after injury. In lesions of C57BL/6, cardiomyocyte remnants disintegrated into small particles exhibiting only very faint calcein fluorescence (the photographic illustration of these cellular remnants was digitally enhanced in Fig. 3c to allow their visualization). These cellular remnants were removed by phagocytosis of macrophages, which were distributed evenly throughout the lesion (Fig. 3c). In C3H/He, the majority of the macrophages appeared to attach to calcified cardiomyocyte remnants, which emitted strong calcein fluorescence (Fig. 3d). We noticed also large macrophages

Fig. 3 Morphological changes in C3H/He myocardium 24 h after freeze–thaw injury (**a**, $\times 100$ and **b**, $\times 1,000$). Calcium stained *green-yellow* with calcein, while nucleic acids stained *blue* with DAPI. Activity of phagocytosis 3 days after injury in the lesion perimeter in C57BL/6 (**c**, $\times 1,000$) and C3H/He (**d**, $\times 1,000$). Calcified cardiomyocyte remnants (*asterisks*) were surrounded by macrophages (identified indirectly by their blue nuclei), which contained multiple, calcium-positive cell remnants in their lysosomes (*arrows*)

containing multiple vesicles filled with calcein-positive material. Electron microscopy confirmed that this fluorescent material was consistent with calcified cardiomyocyte remnants engulfed by phagocytosis (data not shown). There was no evidence of primary calcium deposition in the extracellular matrix of the lesions.

Mitochondrial calcification precedes calcification of cardiomyocytes

In C57BL/6 and C3H/He, we examined ultrastructural changes occurring 2 to 9 days after freeze–thaw injury to identify the potential initiator of calcification of necrotic

Fig. 4 Ultrastructure of myocardial necrosis in C57BL/6 (**a**, $\times 8,280$) and C3H/He (**b–e**) 2 and 7 days after freeze–thaw injury (**a–d** and **e**, respectively). Illustrations **c** ($\times 39,100$) and **d** ($\times 18,400$) are magnifications of areas delineated by *rectangles* in **b** ($\times 6,440$). Condensed mitochondria with amorphous calcium phosphate deposits are marked by *arrows* (**c**, **d**). “*n*” labels the nucleus of a cardiomyocyte, which exhibited complete intracellular calcification consistent with the formation of hydroxyapatite crystals (**e**, $\times 8,280$)

cardiomyocytes. Two days after injury, both strains showed cardiomyocyte necrosis with disintegration of myofibrils and other cytoplasmic contents as well as mitochondrial swelling and aggregation. Mitochondria exhibited various sizes and loss of cristae by fragmentation or extrusion (Fig. 4a–d). Multiple amorphous matrix densities were observed in swollen mitochondria of both DCC-resistant C57BL/6 and susceptible C3H/He mice. Closer examination, however, revealed a subset of mitochondria with a different phenotype observed only in strain C3H/He. These mitochondria were small and condensed and exhibited electron-dense granular bodies consistent with amorphous precipitations of calcium phosphate near one of their poles (Fig. 4c,d). Later stages of DCC revealed the formation of hydroxyapatite crystals comprising the entire necrotic sarcoplasm (Fig. 4e). Calcified cardiomyocytes were subject to phagocytosis by macrophages, which exhibited typical lysosomal bodies (data not shown). Polynuclear osteoclasts were not seen.

Discussion

We investigated the response to myocardial necrosis in common laboratory mouse strains to identify strain backgrounds that account for a calcifying phenotype of myocardial infarction or cardiomyopathy in a mouse model. Thus, we focused on the identification of inbred mouse strains susceptible to DCC, rather than presenting a detailed quantitative analysis of wound healing in a single mouse strain. Many experimenters use genetically manipulated mouse models with various mixed genetic backgrounds that may drastically influence the phenotype under study [19]. Such a phenotype is the healing of myocardial infarction, which may involve necrotic calcification in mice with a susceptible background. In this regard, our analysis of various laboratory strains contributed knowledge on inbred mouse strains as experimental models of myocardial diseases. A strain-related, genetically determined susceptibility to DCC was first proposed by Dipaolo et al. [8], who demonstrated spontaneous myopericardial calcification in strains DBA, Swiss ICR and C as well as strains derived from the latter, including C3H, CHI and CBA. DCC was noticed in BALB/c in studies of viral myopericarditis [13] and in NMRI as a result of dietary magnesium and phosphorus imbalances [24]. Even direct freeze–thaw injury of the myocardium may lead to necrotic calcification [4]. Thus, accumulated evidence suggested that DCC required myocyte death irrespective of the nature of the preceding irreversible injury. In contrast, strain C57BL/6 was reported to be resistant to DCC in several studies, because it exhibited a fibrotic lesion devoid of calcific deposits in response to injury.

Including strains used for gene targeting (strain 129S1) or transgenic overexpression studies (strain FVB), several novel findings in this study were presented: (a) We identified the susceptibility to DCC of strain 129S1 and confirmed *Dyscalc1* as the major genetic determinant of DCC in this strain. Interestingly, 129S1 was found pre-

viously to exhibit some genetic contamination with C3H that might involve the *Dyscalc1* locus as well [21, 23]. (b) FVB exhibited a resistant phenotype similar to C57BL/6. Consistent with this, there are, to our knowledge, no transgenic mouse models on a FVB background exhibiting necrotic myocardial calcifications. (c) We demonstrated that A/J was almost resistant to DCC. (d) We added chronic ischemic injury by coronary ligation to the list of aetiologies leading to necrotic calcifications in susceptible C3H/He.

DCC is a common response of myocardium to injury in mice

Our results suggested that DCC may be rather common in mice, because four of seven different inbred strains exhibited DCC [21, 23]. The classical laboratory strains have a common *Mus musculus* ancestor, which gave rise to at least six groups or major branches of more closely related strains [28]. One major branch of this mouse family tree included DBA and C3H exhibiting a high penetrance of DCC, while BALB/c and A/J [in which we found a low (one of four mice) and a very low penetrance of DCC, respectively] belonged to a more distally related side branch of the same major branch. The different degrees of penetrance suggested that the genetic basis of DCC is complex and may have arisen early in the history of laboratory mouse breeding [8]. Although most strains were inbred independently, they may share some additional genomic homology due to early interstrain contaminations. Recently, analysis of single nucleotide polymorphisms (SNP) revealed that the genome of substrain 129S1 contained a single, large piece of chromosome 7 (approximately 60 Mb) from DCC-susceptible C3HeB/FeJ [20]. This chromosomal piece includes *Dyscalc1* and may therefore explain the susceptibility to DCC of 129S1. This hypothesis remains to be confirmed in other potentially DCC-resistant substrains of 129 which have not been contaminated. Therefore, the determination of susceptibility to DCC in many different strains may provide the opportunity to locate and identify the causative genes by ancestral haplotype mapping [7, 27]. The availability of increasingly dense SNP maps will greatly facilitate *in silico* mapping of quantitative trait loci in the future.

The development of DCC

To understand the mechanisms leading to DCC, we employed several histological techniques to determine time and location of the initial calcification. Our results compared well to data reported previously [3]. Within the first 24 h after freeze–thaw injury, lesions exhibited little cell infiltration. Although cardiomyocytes remained mostly intact in peripheral lesion areas, sensitive, fluorescent calcium staining revealed the beginning of disintegration of myofibrils. Necrotic and vital cardiomyocytes were distributed heterogeneously in this lesion area. Even on the cellular level, necrotic cardiomyocytes exhibited various

stages of disintegration of their cytoplasmic content. Swollen mitochondria contained matrix densities and formed intracellular aggregates. In C3H/He, however, some mitochondria exhibited also electron-dense calcific deposits and complete mineralization 2 days after injury. After ≥ 3 days, mineralization has proceeded to comprise the entire cardiomyocyte, which was still delineated by basal lamina [25, 26]. The process of calcium deposition may have occurred very rapidly, because we did not observe partial sarcoplasmic calcification as seen by others [3]. It is possible that calcified mitochondria may have served as a nidus for further calcium precipitation once the local calcium \times phosphate solubility product was exceeded. Mitochondrial mineralization was implicated previously as the initial event in the development of DCC [3]. Mitochondria sequester calcium, protecting the cell against toxic intracellular calcium concentrations following injury. Pathways of apoptosis and calcium homeostasis as well as mitochondrial channel and matrix proteins may be involved in the initial events of necrotic calcification. In this regard, our study is limited, since we have not examined specific candidate genes. Further studies of apoptosis should include the examination of B-cell-activated X-protein, Bax, which is a major pro-apoptotic switch. Bax is an interesting candidate gene, because its locus is closely linked to the *Dyscalc1* locus.

The tissue response to cardiomyocyte calcification included removal by phagocytosis and "neutralisation" by fibrosis. At day 3 after injury, macrophage-like cells adhered to calcified necrotic tissue presumably attracted and immobilized by the calcium-binding, chemotactic protein osteopontin that is expressed strongly in calcified myocardial lesions [1]. Although we have seen large macrophages containing calcified cell remnants, debridement appeared delayed in DCC-susceptible compared to resistant strains. Based on our morphological evidence, we consider this difference a consequence of the calcification of the necrotic cardiomyocytes. Presumably, more effective phagocytosis of calcified necrosis may have required osteoclasts, a highly specialized macrophage population, which was absent in the lesions. A week after injury, fibroblasts surrounded calcified cardiomyocyte remnants. At this point, increasing fibrosis may have insulated myocardial calcifications from phagocytes, preserving them for many weeks [14]. Further investigations are needed to clarify whether phagocytosis was impaired by a malfunction, an exhausted capacity (relative insufficiency), or by excessive fibrosis, and to what extent such an abnormality may have contributed to DCC.

Acknowledgements We thank Mrs. Scheurer for assistance in histological sectioning and staining. We are very thankful to Prof. E. Schramm, who carried out electron microscopy, and to Dr. Klinger and Dr. Berger for discussions of the ultrastructural data. We are indebted to Dr. Aherrahrou and Mr. Kaczmarek for assistance in work related to the model of ischemic injury and other mouse work. Molecular characterization of composite mantle cell and follicular lymphoma

Received: 3 October 2005 / Accepted: 8 January 2006 / Published online: 21 February 2006
© Springer-Verlag 2006

Abstract Composite lymphomas are rare associations of two distinct lymphoma types at the same anatomical site. Reporting of such cases is important because they pose major biologic, diagnostic, and therapeutic dilemmas. In this study, we describe the third reported case of mantle cell and follicular lymphoma. We performed accurate immunohistochemical and molecular studies to define the mono- vs biclonal nature of this neoplasm. We used both manual and LASER-capture microdissection combined to multiple molecular approaches for clonality determination, including detection of heavy and light chain recombination, as well as presence of κ /Kde recombination and sequence analysis. By immunohistochemistry and FISH, we confirmed the presence of two distinct lymphoma types characterized by specific translocations [namely, t(11;14) and t(14;18)], while we demonstrated two distinct and not clonally related cell populations by molecular techniques. The light chain approach, and particularly the kappa and κ /Kde recombination detection, proved very useful for solving the clonality issue.

Keywords Composite lymphoma · Mantle cell lymphoma · Follicular lymphoma · Laser-capture microdissection · Clonality

Introduction

Only two cases of composite mantle cell (MCL) and follicular (FL) lymphoma have been described from two different groups [7, 11]. In this study, we describe a third case of composite MCL and FL, which showed a particular clinical course that distinguishes it from the two previously reported. This case has been extensively immunophenotyped, characterized using fluorescence in situ hybridization (FISH) probes, and then studied at the molecular level using multiple PCR-based approaches, manual and LASER-assisted microdissection, and sequence analysis. These techniques allowed us to verify the diagnosis and to clarify that the two entities are not clonally related.

Materials and methods

Case history A 65-year-old man presented with persistent left inguinal adenopathy in May 2001. Laboratory tests showed a mild lymphocytosis ($6.7 \times 10^9/l$). A lymph node biopsy, bone marrow biopsy, and immunophenotypical study of peripheral blood were performed. In October 2003, the patient underwent splenectomy. At the last follow-up in November 2005, the patient was in a good condition despite the stable condition of his disease, with a WBC count of $36.9 \times 10^9/l$ (neutrophils $8.0 \times 10^9/l$, lymphocytes $20.1 \times 10^9/l$).

Immunohistochemistry Antibodies used were CD3 (SP7, Labvision), CD5 (4C7, Novocastra), CD10 (56C6, Novocastra), CD20 (L26, Dako), CD23 (1B12, Novocastra), CD79a (JCB117, Dako), Bcl-2 (124, Dako), Cyclin D1 (SP4, Neomarkers), and p27 (SX5348, Dako). Immunostaining was performed using a semiautomated cell-staining system (GenoMx i6000, Biogenex, San Ramon, CA, USA). For a more precise characterisation, p27^{KIP1} staining was used in addition to the standard panel of markers [5]. For cyclin D1 staining, a newly available rabbit monoclonal antibody with superior performance was used [4].

Western blotting for cyclin D1 Immunoblot analysis for cyclin D1 (Cyclin D1 H295 rabbit polyclonal antibody, Santa Cruz Biotechnology, Santa Cruz, CA, USA) was performed by standard procedures on the peripheral blood (PB) cells, alongside with positive (Granta-519 MCL cell line, obtained from DSMZ, Braunschweig, Germany) and negative (a case of FL) controls.

Extraction of DNA from peripheral blood and spleen samples DNA was obtained from 10^7 cells (peripheral blood) or 3 mg of frozen tissue (spleen) by standard proteinase K digestion and phenol–chloroform extraction.

Microdissection All microdissection experiments were performed on formalin-fixed and paraffin-embedded tissue sections of the lymph node sample. Manual microdissection was performed using a sterile 25-gauge needle. Laser-capture microdissection (LCM) was performed on a PixCell II instrument (Arcturus, Mountain View, CA, USA). Neoplastic follicles, perifollicular areas, and the diffuse component were discriminated morphologically on hematoxylin and eosin stained slides. The center of three or four follicles and corresponding perifollicular areas, as well as about 300 cells from the diffuse component, were microdissected in three independent sessions. For immuno-LCM (I-LCM), slides were first stained for CD10 or cyclin D1 before LCM. Microdissected tissue was digested in 50 μ l lysis buffer. The presence of amplifiable DNA was tested by PCR amplification of *c-KIT* exon 8 (protocol details available from the authors upon request).

Detection of *t(14;18)* by PCR BCL-2 translocation was detected by PCR as previously described [3], with some modifications.

Clonality detection Detection of rearranged *Ig* genes was performed using the FR1, FR2, and FR3A approach for heavy chain (IgH) as previously described [2, 9], and the FR3 approach was used for light chains [6]. For the V κ /kappa-deleting element (Kde) approach, we used the same V κ primers combined with one Kde primer. We used a primer designed with DNAsis Max software (Hitachi software, Hamburg, Germany) using GenBank X05286 sequence. Primer sequence is TGC TCG CCT AGT CCT CAT CT. Amplification products were either run on 6% acrylamide gels or on an Agilent 2100 bioanalyzer (Agilent Technologies, Waldbronn, Germany). For heteroduplex analysis, samples were denatured at 95°C for 5' and then cooled at 4°C for 1 h. Purified products were either directly sequenced or after cloning using the pSTBlue-1 Giga kit (Novagen, Madison, WI, USA). Sequences were compared using DNAsis Max software (Hitachi software); gene usage was analyzed using IgBLAST database [1].

FISH FISH studies for the *t(11;14)* and *t(14;18)* were performed by standard procedures (details available upon request) on paraffin sections of the lymph node sample, using commercially available probes (LSI IGH/CCND1

and LSI IgH/BCL2, Abbott GmbH) according to manufacturer's instructions.

Sequence analysis Sequence analysis was performed using BigDye 3.1 chemistry and ABI 310 automated sequencer (details available upon request).

Results

Histology and immunophenotype The lymph node presented an effaced architecture, with an evident follicular pattern of infiltration; the neoplastic follicles lacked polarity and tingible body macrophages and were composed of small cells with centrocytic morphology. Few nonneoplastic follicles were present, mostly at the periphery. On one side, a band-like nodular and diffuse area was present; this rim was separated from the follicular component by a thin fibrous band (Fig. 1). The follicular component showed a classic FL phenotype (CD20+, CD79a+, CD10+, BCL-2+, CD5-, CD23-, cyclin D1-, p27+), while the peripheral nodules showed MCL markers (CD20+, CD79a+, CD5+, CD10-, CD23-, cyclin D1+, p27-) (Fig. 2). Interfollicular areas were mostly CD5+ and showed a distinct cyclin D1 staining on many cells, especially at the periphery of neoplastic follicles (mantle zone pattern) (Fig. 2). Proliferative activity, ascertained by Ki-67 staining, was almost absent in the follicles and low in the perifollicular area and peripheral nodules.

The bone marrow trephine showed an interstitial and nodular infiltration by small intermediate cells. Cells were CD20+, CD5+, and p27 negative.

The spleen showed a marked nodular infiltration by cells of variable size; these elements were present also in the portal tracts of the liver biopsy. The immunophenotype was typical for MCL, including cyclin D1 expression.

The PB immunophenotype by flow cytometry was CD20+, CD5+, CD23-, λ +, CD79a+, CD10-. Western blotting was positive for cyclin D1.

FISH FISH analysis was performed on the lymph node and showed that in the MCL area 36% of cells harbored the *t(11;14)(q13;q32)*, while a minority showed the *t(14;18)(q32;q21)*. In the FL area, 42% of cells had evidence of the *t(14;18)(q32;q21)* and 35% of the cells harbored the *t(11;14)(q13;q32)* (Fig. 3).

PCR detection of *t(14;18)* BCL-2 translocation was evident by PCR on the follicular component of the manually microdissected sample but absent from all the MCL components (lymph node, spleen, and peripheral blood).

Microdissection and clonality detection of the lymph node A first round of analyses, including FR1, FR2, and FR3A VH approaches performed on DNA obtained from whole sections or manually microdissected samples and on the peripheral blood DNA, showed a single amplifiable clonal band. A second round of experiments, including only

Fig. 1 Histology. **a** Low power view (1 \times , PAS stain) shows the larger follicular area and the rim containing broad nodules. **b** Medium power view (100 \times , H&E stain) at the border between the follicular area and the peripheral rim containing the broad coalescent nodules

FR3A, kappa and lambda rearrangements with careful cell selection by immuno-LASER-capture microdissection, showed that despite the presence of amplifiable DNA, no FR3A product in the FL component was obtained (Fig. 4a). Using the light chain approach, a clonal band for kappa was visible only in the FL samples (Fig. 4b). On the contrary, all the MCL components (peripheral nodules and perifollicular areas in the lymph node, neoplastic nodules in the spleen, and DNA from peripheral blood) were kappa-negative and positive for the lambda and kappa/Kde rearrangement. Sequence analysis showed that the rearranged κ gene in the FL component was A23, while the κ gene rearranged to the Kde region in the MCL component was L14. Further sequence analysis of the FR1 products of the MCL component showed the VH4-34/D2-15, with a 3% somatic mutation rate.

Discussion

Based on reported frequencies, composite MCL and FL is extremely rare, this report representing the third recognized case [7, 11]. In accordance to previous reports, our case followed an indolent course. FL and MCL were present

Fig. 2 Immunohistochemistry. **a** Cyclin D1 is positive both in the broad nodules and in the perifollicular areas (also depicted in the *inset*) (100 \times , inset 200 \times). **b** CD10 is positive in the follicles and negative in the MCL area. **c** Bcl-2 is positive in the follicles and also in the MCL area; one residual reactive follicle is negative

simultaneously, but progression was due to the MCL component exclusively, with progressive increase of spleen size, mild lymphocytosis, and thrombocytopenia. However, 1 year after splenectomy, the condition of the disease remains stable and relatively controlled, with mild lymphocytosis.

Fig. 3 FISH. **a** t(11;14), **b** t(14;18)

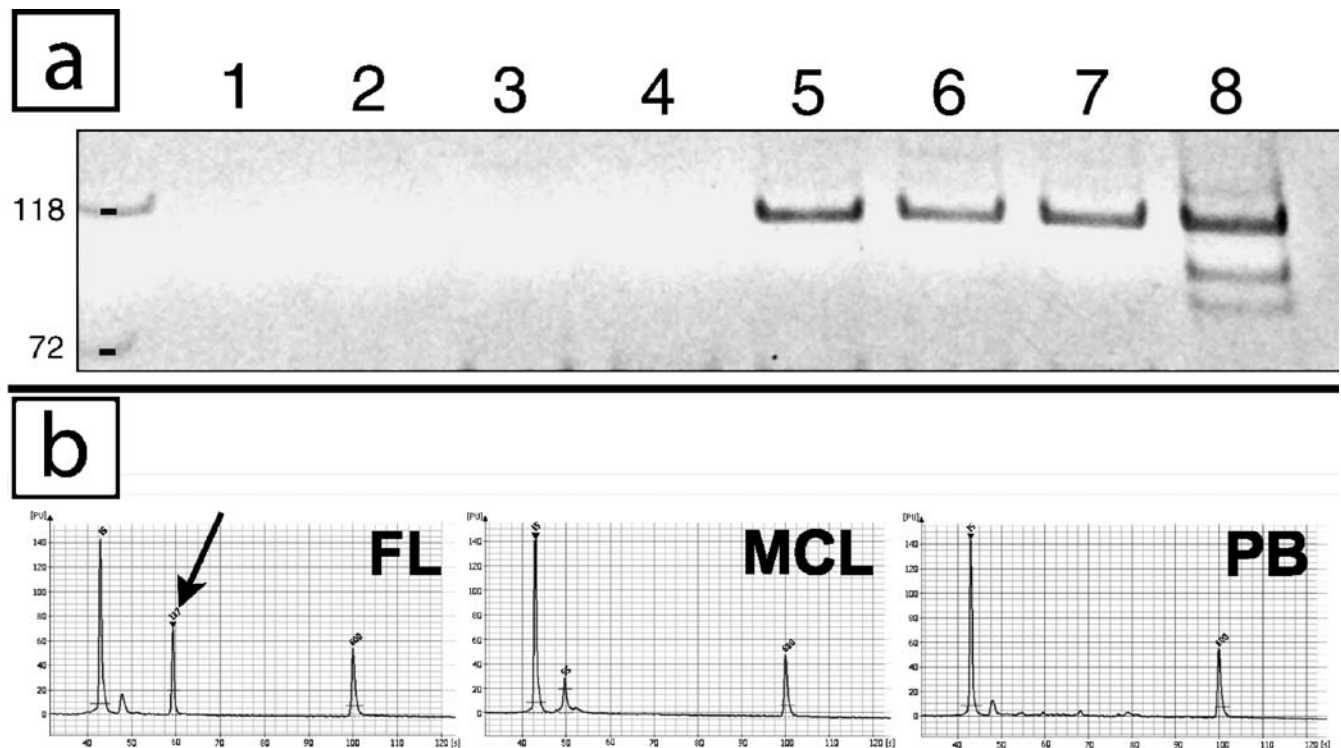

Fig. 4 Most relevant molecular biology data. **a** FR3 amplification of rearranged immunoglobulin heavy chain genes shows a product only in peripheral blood (*lane 8*) and MCL areas, both peripheral (*lane 5*) and perifollicular (*lanes 6 and 7*). FL areas (*lanes 1 to 4*) do not show any product, despite the presence of amplifiable DNA (not shown). (PCR products run on polyacrylamide gel) **b** Light chain

FR3 amplification shows that kappa rearrangement is present only in the FL component (*arrow*), while it is absent in the MCL component, both in tissue and peripheral blood. (PCR products run on Agilent 2100 bioanalyzer; first and last peaks: size markers, 15 and 600 bp, respectively; small peaks after 15 bp peak: primers)

Histologically, all the cases reported share the common pattern of MCL cells surrounding neoplastic FL follicles, in addition to more diffuse areas. In our case, the MCL cells also formed a separate rim at the node periphery, reminiscent of a “node in node.” The cytology of our case and that of other cases was classical, with no evidence for blastoid transformation.

Immunohistochemically, all cases are quite typical, except for the lack of demonstrable cyclin D1 protein expression in the cases reported by the other groups. Tsang and colleagues, however, demonstrated presence of the t(11;14) by Southern blot. Our case is more straightforward, as the expression of cyclin D1 was readily demonstrated by immunohistochemistry on both lymph node and spleen specimens, and by Western blotting on the PB sample. These data were further supported by the unequivocal demonstration of the t(11;14) and t(14;18) by FISH in the two neoplastic components.

The issue of clonality is a very intriguing one, and as expected, it is a matter of debate [8]. The group of Tsang et al. brought evidence favoring the hypothesis of monoclonality, while the group of Fend et al. stated that unless a very careful microdissection is performed, a minor clonal component might be missed. In fact, as clearly shown by cyclin D1 staining, neoplastic follicles can be surrounded and often partially infiltrated by MCL cells, whose DNA is readily amplifiable and can thus take over on the poorly

primed (due to somatic hypermutations) FL DNA. We therefore used multiple microdissection techniques, and only when we carefully captured CD10+ and cyclin D1+ cells by immuno-LASER-capture microdissection did we not obtain a PCR product for rearranged VH genes in the FL component, despite the presence of amplifiable DNA. However, the strongest proof in favor of a biclonal origin was provided by the use of the light chain FR3 and κ /Kde PCR. Using these techniques, we were able to demonstrate a rearranged κ chain only in the FL component. We also demonstrated that the MCL component deleted the κ allele by juxtaposing the Kde to a V κ gene, a rearrangement that would render the rearrangement nonamplifiable by standard techniques [10]. Indeed, the κ V segment juxtaposed to the Kde (L14) in the MCL component is different from the one that appears to be rearranged in the FL component (A23), thus providing the final proof of the true biclonality of this unusual composite neoplasm.

The usefulness of the κ and κ /Kde approach has been stated by a multicenter study, although using different primers [12]. The aforementioned study on the light chain FR3 approach [6] does not suppose the use of a Kde primer. We actually combined the two approaches, optimizing conditions to work with the kappa FR3 primers. This might provide a simple solution to the issue of clonality detection in composite lymphomas, even without the use of high-cost LASER-capture microdissection.

Composite adenocarcinoma and large cell neuroendocrine carcinoma of the rectum

Received: 30 November 2005 / Accepted: 30 January 2006 / Published online: 1 March 2006
© Springer-Verlag 2006

Abstract Composite glandular-endocrine tumors of the gastrointestinal tract are rare neoplasms. Even more uncommon are the so-called amphicrine tumors, lesions in which dual epithelial and endocrine differentiation occurs in the same cell. We describe a patient who complained of rectal pain and bleeding with a mixed or composite adenocarcinoma and neuroendocrine carcinoma of the rectum. Histological examination revealed a distinct adenocarcinoma of conventional type with glandular structures admixed intimately with a neuroendocrine carcinoma. The latter component was deeply infiltrative, while the adenocarcinoma occupied the more superficial aspect of the tumor. What was interesting was the immunophenotype of the lesion: cytokeratin (CK) 20 expression was very focal in the adenocarcinoma component and negative in the neuroendocrine carcinoma, while CK 7 was expressed strongly in the adenocarcinoma and only focally in the neuroendocrine component. This cytokeratin profile suggests a possible origin from the anal transitional zone.

Keywords Rectum · Adenocarcinoma · Neuroendocrine carcinoma · Combined carcinoma · Cytokeratin

Introduction

Tumors composed of both glandular and endocrine components are rare and were given a somewhat confusing and misleading collection of terminologies. Basically, these dual-natured tumors can be divided into three subtypes as

proposed by Lewin [10] in 1987: composite (mixed) tumors, collision tumors, and amphicrine tumors. The term mixed or composite tumor applies to those neoplasms that contain intimately mixed glandular and endocrine components in near equal proportions. The term “collision” applies when glandular and endocrine components are closely juxtaposed but the individual cell types are not mixed. Lastly, Lewin [10] emphasized that the term “amphicrine” should be used only when dual differentiation was present within the same cell.

Cases of amphicrine tumors in the rectum are not yet encountered, although there are a few isolated reports describing the presence of such tumors in other sites of the gastrointestinal (GI) tract [10, 14–17, 19]. Composite carcinomas, on the other hand, are usually a mixture of adenocarcinoma with carcinoid or an atypical carcinoid [1, 8, 9, 11, 13, 16]. We report a case of a composite carcinoma of the rectum consisting of conventional adenocarcinoma and large cell neuroendocrine carcinoma and review the literature on these uncommon neoplasms.

Clinical features

A 94-year-old Caucasian woman presented with rectal bleeding and pain of a few weeks duration. Colonoscopy revealed hemorrhoids and a large ulcerative lesion 1.5 cm from the anal verge that was biopsied. Subsequently, an abdominoperineal resection (the anal verge was not included in the resection specimen) was performed from which the patient made an uneventful recovery. In view of the patient’s age, no further treatment was offered.

Materials and methods

The specimen was fixed in 10% formal saline, routinely processed, and hematoxylin and eosin stain sections were evaluated. Immunohistochemistry was performed on paraffin embedded, formalin fixed tissue for the following antibodies: cytokeratin (CK) 7 (monoclonal, OV-TL 12/30,

Dakocytomation, Ontario, Canada, dilution 1 in 2,000), CK 20 (Dakocytomation, KS 208 1/100), chromogranin (monoclonal, LK2H10, Biomeda, Foster City, CA, USA, 1/400), synaptophysin (polyclonal, 27G12, Dakocytomation, 1/10), CD56 (monoclonal, 123C3, Zymed, San Francisco, CA, USA, 1/100), and carcinoembryonic antigen (CEA) (monoclonal, Biomeda, 1/5,000).

Tissue from the formalin-fixed paraffin wax block was taken for electron microscopic examination.

Pathology

The resection specimen consisted of a 20-cm segment of the bowel including the rectum. On opening the specimen, a slightly elevated tumor measuring 6.0×3.0×1.5 cm was present. The lesion was very clear of both proximal and distal resection margins.

Fig. 2 The infiltrating adenocarcinoma was of conventional type with well-formed glandular structures permeating muscularis propria (H&E×400)

Fig. 3 The large cell neuroendocrine component consisted of large polygonal to round cells with focal rosette formation (H&E×400)

Histological examination showed a tumor composed of two elements (Fig. 1). Approximately 60% of the tumor was composed of an adenocarcinoma in which glandular structures were easily identified (Fig. 2). Surface epithelium displayed foci of both high-grade and low-grade dysplasia. At the base of the tumor, intimately admixed with the adenocarcinomatous component, were nests and sheets of large tumor cells (Fig. 3). This second component consisted of large round to polygonal cells with salt and pepper nuclear chromatin, occasional prominent nucleoli, and a moderate amount of eosinophilic cytoplasm. The mitotic rate was in excess of 10 mitoses per 10 high power fields. Foci of single cell necrosis or apoptosis and more confluent areas of coagulative tumor necrosis were also identified. Focally, rosette formation was noted (Fig. 3). A small cell component was not present. The morphological features of the second component conformed to that of a large cell neuroendocrine carcinoma.

Both components extended through the rectal wall into the serosal fat. Metastatic tumor was found in three of 18

Fig. 4 CK20 staining in the adenocarcinomatous component was patchy and focal in distribution. Even well-formed glandular structures were not well decorated (CK20×400)

Fig. 5 CK7 staining, in contrast to CK20, was strong and diffuse in the adenocarcinoma (CK7×400)

regional lymph nodes. It is interesting to note that two of the lymph nodes consisted only of metastatic conventional adenocarcinoma while the third lymph node showed both adenocarcinoma and large cell neuroendocrine carcinoma.

Immunohistochemistry showed the adenocarcinoma to exhibit focal CK 20 positivity (Fig. 4) but strong and diffuse CK 7 expression (Fig. 5). CEA was also positive in the adenocarcinomatous component. The adenocarcinoma was negative for chromogranin, synaptophysin, and CD56. The large cell neuroendocrine component was positive for chromogranin, synaptophysin and, CD56 (Fig. 6); focally positive for CK 7; and negative for CK 20.

Electron microscopy showed poor preservation of cells, however, occasional membrane-bound neurosecretory granules were seen.

Taking the morphological and immunohistochemical features into account, this is a composite tumor of the rectum composed of conventional adenocarcinoma and coexistent large cell neuroendocrine carcinoma.

Fig. 6 The large cell neuroendocrine carcinoma displayed strong and diffuse immunopositivity with CD56 (CD56×400)

Discussion

There were several isolated reports describing composite colorectal tumors, most of which describe mixed carcinoid and adenocarcinoma [3, 10, 17] and mixed carcinoid with adenoma [10, 17]. Small cell carcinoma of the rectum occurring on its own was described [4, 12]. In addition, large cell neuroendocrine carcinoma of the rectum was also documented [2]. This is a rare tumor that accounts for less than 1% of all colorectal cancers [2]. In the latter publication, cases of neuroendocrine carcinoma coexisting with foci of adenocarcinoma within the colon and rectum was mentioned [2]. It is assumed that some of these cases containing both components are similar to the case reported herein. However, there is no description of the relationship between the large cell neuroendocrine carcinoma focus and the adenocarcinoma [2]. The criteria employed in making the diagnosis of large cell neuroendocrine carcinoma of the rectum is identical to their lung counterparts [2]. There is a predilection for large cell neuroendocrine carcinoma to occur in the cecum and rectum [2]. In general, neuroendocrine carcinomas have an aggressive course and the prognosis is poor. Prognosis of composite tumors is a matter of debate. It was suggested that a mixed endocrine tumor and adenocarcinoma leads to a more aggressive form of malignancy [3]. It is generally accepted that composite appendiceal tumors, namely, goblet-cell carcinoids, carry an intermediate prognosis between that of a classical carcinoid and adenocarcinoma [19]. Initially, it was believed that composite tumors of the colon had a better prognosis than ordinary adenocarcinomas; however, recent evidence shows that composite tumors of the colon may carry a poorer prognosis [10]. A recent study of colorectal adenocarcinomas, neuroendocrine cells within the conventional adenocarcinoma, was seen in 20–50% of cases and these tumors were associated with a poor prognosis [5]. It should be remembered that these are cases of conventional adenocarcinoma harboring a significant proportion of neuroendocrine cells and not two separate tumors. Because very few, if any, combined large cell neuroendocrine carcinoma and conventional adenocarcinoma cases were documented, very little information is available regarding behavior of this specific entity. It is safe to assume that the neuroendocrine component would confer an adverse prognosis compared to cases with only conventional adenocarcinoma of similar stage.

The histogenesis of tumors containing both glandular and endocrine components has aroused much interest although it was not fully elucidated. There are two main views: (1) simultaneous and coincidental malignant change in mature cells of different cell lines and (2) monoclonal origin of the two components that arise from multipotential stem cells that show biphenotypic differentiation after carcinogenesis is initiated. Histological and molecular studies suggest that both the glandular and endocrine components of a mixed tumor share a multipotential stem cell origin. Two different studies of mixed tumors of the GI tract found a strong genetic relationship between the two tumor components regardless of the combination of tumor

types, grade, or primary site [6, 18]. It was further suggested that amphicrine tumors originate from pluripotential cells with dual differentiation abilities [10]. It is tempting to speculate that this case, although within the rectum, arose from the anal transitional zone. Multi-differentiation is a well-recognized phenomenon in the anal transitional zone and would account for the two components encountered in this tumor. In addition, the cytokeratin immunoprofile of the tumor described in this paper most closely resembles that of the anal transitional zone. The normal anal transitional zone is usually CK 7 positive and CK 20 negative. It is noteworthy that the adenocarcinoma component showed only focal positivity for CK 20. Neuroendocrine carcinomas on the other hand, are typically negative for CK 20. A single case of CK 20 positive large cell neuroendocrine carcinoma of the colon was described [7]. Based on this immunohistochemical finding together with CK 7 negativity, the authors suggested a link between neuroendocrine carcinoma and conventional adenocarcinoma [7].

Composite tumors of the rectum are rare, especially those composed of an admixture of conventional adenocarcinoma and large cell neuroendocrine carcinoma. In the case described herein, the cytokeratin immunoprofile fits in with origin from the anal transitional zone. Not only is this case unusual in terms of it being a composite tumor of the rectum, but the focal CK 20 positivity in the adenocarcinoma component is also somewhat unusual. Given the usual cytokeratin expression pattern of the anal transitional zone and its propensity for divergent differentiation, we feel that the composite rectal tumor encountered in this case is most likely of anal transitional zone origin.

Sporadic EBV-associated lymphoepithelial salivary gland carcinoma with EBV-positive low-grade myoepithelial component

Received: 11 July 2005 / Accepted: 29 September 2005 / Published online: 1 March 2006
© Springer-Verlag 2006

Abstract Salivary gland lymphoepithelial carcinomas (LECs) are associated with Epstein–Barr virus (EBV) in endemic areas, whereas sporadic cases are usually EBV negative. We have studied two EBV-associated LECs from Caucasian patients for their EBV gene expression profile and their immunophenotype. Tumour cells of case 1 showed expression of EBNA1 only, corresponding to an EBV latency type I. Tumour cells of this case expressed various basal and glandular cytokeratins. In case 2, the LEC was accompanied by a low-grade spindle cell lesion with an immunophenotype of myoepithelial cells, whereas the high-grade tumour expressed cytokeratin (Ck) 8 only. In case 2, the high-grade tumour showed an EBV latency II pattern with expression of EBNA1, LMP1 and LMP2A (latency II). The spindle cell lesion of this case was also EBV-infected and showed low levels of EBNA1 and LMP1 expression, while LMP2A was not detectable. The detection of EBV in both components of case 2 together with immunophenotypic evidence of transition between both components supports the notion that at least some LECs arise through a low-grade myoepithelial intermediate. Expression of LMP2A may be of therapeutic interest because it may make such cases amenable to immunotherapy with EBV-specific cytotoxic T cells.

Keywords Salivary gland · Carcinoma · Myoepithelial lesions · Epstein–Barr virus

Introduction

Lymphoepithelial carcinomas (LECs) were originally described in their two major histological patterns by Schmincke [28] and Regaud et al. [25] as distinct neoplasms of the nasopharynx characterized by undifferentiated epithelial tumour cells associated with an abundant lymphoid stroma. Subsequently, morphologically similar tumours were described at various primary sites such as lacrimal and salivary glands, tonsil, thymus, lung, breast, uterus, stomach, urinary bladder and skin [9]. For some of these tumours, peculiar geographic patterns of distribution were observed. LEC of the nasopharynx, generally a rare tumour, occurs at high incidence rates in Southeast Asia, particularly in Hong Kong, and in the Arctic regions [9]. Similarly, salivary gland LECs display a high incidence in native populations of Greenland and Alaska and also occur more frequently in Southeast Asia [4, 13, 16, 19, 27].

In the nasopharynx, both endemic and sporadic LECs are invariably associated with Epstein–Barr virus (EBV) infection [9]. By contrast, LECs of the uterine cervix, urinary bladder and skin have been reported to be EBV negative [9]. LECs occurring at other sites show more complex patterns of EBV association. Approximately 80% of gastric LECs harbour the virus regardless of the geographical origin [20]. The association of salivary gland and thymic LECs with the virus is largely restricted to areas where nasopharyngeal LEC is endemic, whereas morphologically indistinguishable tumours arising in Caucasians are mostly EBV negative [1, 6, 10, 12, 14, 16, 26, 29, 30].

Except for limited periods of replicative infection, EBV infection is latent and then characterized by the variable expression of a limited set of so-called latent gene products, including two small non-polyadenylated nuclear RNAs (EBER1, EBER2), six nuclear antigens (EBNA1–6) and three latent membrane proteins, LMP1, LMP2A and LMP2B [9]. Nasopharyngeal carcinoma displays expres-

sion of the EBERs, EBNA1, LMP1 and LMP2A (latency type II) [7, 9]. A more restricted pattern of EBV latent gene expression, characterized by the presence of only the EBERs and EBNA1 (latency type I), is found in Burkitt lymphoma [9].

In virtually all cases of EBV-associated undifferentiated carcinoma, the cell of origin is not known because of the absence of dysplastic changes and EBV from normal epithelial cells adjacent to the tumour. Salivary gland LECs may be informative in this respect because, in a proportion of cases, the LECs are accompanied by so-called benign lymphoepithelial lesions (BLEL), the relationship of which to the neighbouring LECs is a matter of debate. Some authors postulated that LECs represent the malignant counterpart of BLEL and thus proposed the term “malignant lymphoepithelial lesion” for these tumours [3, 11, 13, 24]. Other authors explicitly rejected the idea of such a relationship [17, 27], particularly in view of the absence of EBV infection from BLEL.

Here, we report two cases of sporadic EBV-associated LECs, one of which was accompanied by an EBV-positive low-grade spindle cell proliferation. We have determined the EBV gene expression profile and the immunophenotype of tumour cells and tumour infiltrating lymphocytes. Controls comprised four cases of typical BLEL in Sjögren syndrome and five marginal zone B-cell lymphomas (MZBCL). The findings may be relevant for the understanding of the pathogenesis, the histopathologic diagnosis and immunotherapy of salivary gland LECs.

Materials and methods

Patients

Case 1 A female Caucasian patient, 45 years of age, showed a left parotid gland enlargement. The firm whitish tissue measured up to 65 mm. Frozen section and paraffin diagnosis revealed an undifferentiated carcinoma with lymphoid stroma. No additional manifestations were found in the neck dissection specimen. Tumour extension and spread were classified as pT2pN0.

Case 2 A 64-year-old Caucasian man was admitted with a right cervical tumour. After excision, histology revealed the metastasis of a LEC. The search for the primary tumour with emphasis on the nasopharynx revealed no pathological findings except for an enlarged right submandibular gland. Upon ectomy, sectioning of the gland showed a firm, white nodule of 20 mm diameter with a rim of regularly lobulated gland parenchyma. At the periphery of the node, several small cystic spaces up to 2 mm were noted. The tumour extension and spread were classified as pT1pN1.

Parotid gland tissues from four cases of so-called myoepithelial sialadenitis (MESA), clinically characterized as Sjögren’s disease, five cases of MZBCL as well as five tonsils served as controls.

Immunohistology

Four-micrometer sections of paraffin-embedded tissue blocks were stained with antibodies directed at EBV proteins EBNA1 (clone 1H4, kindly provided by E. Kremmer, Munich, Germany), LMP1 (clones CS1–4, DakoCytomation, Hamburg, Germany) and LMP2A (clone 15F9, kindly provided by E. Kremmer) as well as cytokeratins (Ck) 5/6 (clone D5/16B4; Zymed, San Francisco, CA, USA), Ck7 (OV-TL-12/30, DakoCytomation), Ck8/18 (clone 5D3; Dianova, Hamburg, Germany), Ck13 (clone DE-K13, DakoCytomation), Ck14 (LI002, Dianova), Ck19 (RCK 108, DakoCytomation), Ck20 (Ks20.8, DakoCytomation), vimentin (clone V9; DakoCytomation), smooth muscle α -actin (SMA, clone 1A4; Sigma-Aldrich, St. Louis, MO, USA), S-100 protein (rabbit polyclonal; DakoCytomation), epithelial membrane antigen (EMA, clone E29, DakoCytomation) and the proliferation-associated Ki-67 nuclear antigen (clone MIB-1, DakoCytomation) using the peroxidase–anti-peroxidase method with diaminobenzidine (DAB) as a chromogen or employing streptavidin–biotinylated alkaline phosphatase complex in conjunction with Fast Red (Sigma) as described [7, 18]. For the detection of LMP2A and EBNA1, a tyramide signal amplification system was used as described [7].

In situ hybridization

Transcription and labelling of EBER RNA probes were performed as outlined recently [18]. The procedure, including pre-hybridization, hybridization, removal of non-specifically bound probe by RNase A digestion and further washing procedures, was carried out as described [18].

Results

Morphology

Case 1 displayed a high-grade tumour in a Regaud-type pattern comprising solid cords of undifferentiated neoplastic epithelium embedded in a lymphoid stroma with numerous germinal centres.

The high-grade component of case 2 showed the classical Schmincke-type pattern with syncytial clusters of undifferentiated tumour cells intermingled with lymphoid cells (Fig. 1a). In this case, the high-grade component was associated with a low-grade spindle cell proliferation with microcyst formation at the periphery of the high-grade neoplasm (Fig. 1b). In addition to its different cell morphology and cytological grade, this component was characterized by a comparative scarcity of infiltrating lymphoid cells (Fig. 1a,b).

Fig. 1 Histological examination of case 2 shows an undifferentiated lymphoepithelial carcinoma (LEC, **a**) accompanied by a low-grade spindle cell component (**b**). Immunohistochemistry shows expression of cytokeratin (Ck) 8 in the undifferentiated LEC (**c**), while only rare cells of the accompanying spindle cell proliferation express Ck8 (**d**). By contrast, immunostaining for basal cytokeratins Ck5/6 (**e, f**) and S-100 protein (**g, h**) yields negative results in the LEC (**e, g**) and is strongly positive in the spindle cell lesion (**f, h**)

EBV gene expression

Virtually all tumour cells of both cases harboured EBV as shown by strong nuclear in situ hybridization signals when probed for EBER1 and EBER2 (Fig. 2a; Table 1).

Interestingly, the spindle cell component of case 2 was also EBER positive (Fig. 2b). Strong nuclear immunostaining for EBNA1 was observed in both high-grade tumours (Fig. 2c), whereas the nuclei of the spindle cell lesion of case 2 were only weakly labelled (Fig. 2d). LMP1

Fig. 2 By in situ hybridization with ^{35}S -labelled probes and subsequent autoradiography, expression of EBER transcripts is detected in the LEC (a) and the spindle cell (b) components of case 2. Similarly, EBNA1 (c, d) and LMP1 (e, f) are detectable, although labelling is weaker in the spindle cell component (d, f). Expression of LMP2A is detectable only in the LEC (g) but not in the accompanying spindle cell lesion (h)

and LMP2A were absent from case 1 but were strongly expressed in a proportion of the high-grade tumour cells of case 2 with a patchy membranous and cytoplasmic staining (Fig. 2e,g). The spindle cell component of case 2 showed

weak expression of LMP1 and no detectable expression of LMP2A (Fig. 2f,h). All BLEL were EBV negative as assessed by EBER-specific in situ hybridization.

Immunophenotype

The undifferentiated carcinoma cells of case 1 expressed various cytokeratin types as well as EMA, whereas cytokeratin expression in the high-grade component of case 2 was restricted to Ck8 (Table 1; Fig. 1c). The spindle cell component of case 2 lacked Ck8 expression and displayed an immunophenotype reminiscent of myoepithelial cells with expression of basal cytokeratins Ck5/6 and Ck14 as well as of vimentin, S-100 protein and, weakly, SMA (Table 1; Fig. 1f,h). Ck5/6, Ck14 and S-100 protein were absent from the undifferentiated carcinoma component of case 2 (Table 1; Fig. 2e,g). Both high-grade tumours showed a growth fraction of more than 60% as determined by immunostaining with antibody MIB-1, while the spindle cell lesion displayed a small growth fraction of less than 4% (Table 1). The epithelial cells of BLEL in so-called MESA, MZBCL and tonsillar crypts expressed Ck5/6 and Ck14 in the absence of S-100 protein, vimentin and SMA (not shown).

Discussion

Salivary gland LECs occur as endemic tumours in Arctic and Southeast Asian populations but are exceedingly rare among Caucasians [4, 13, 16, 19, 27]. In high incidence areas, virtually all cases of salivary gland LECs are associated with EBV infection [1, 14, 16, 26, 29, 30]. By

contrast, the association of sporadic salivary gland LECs with EBV appears to be variable with only one well-documented EBV-positive case in the literature [6, 10, 12].

We report two cases of sporadic salivary gland LECs in Caucasian patients. Both cases were EBV positive as demonstrated by in situ hybridization. Thus, it appears that association with EBV is not restricted to cases occurring in high incidence areas. Further immunohistological characterization revealed an EBV latency type II in case 2 (EBNA1 and LMP1/LMP2A positive) as characteristically seen in nasopharyngeal LEC. This is in agreement with a previous reverse transcription-polymerase chain reaction (RT-PCR) study of salivary gland carcinoma [23]. The expression of LMP2A is of particular interest because it might make EBV-associated salivary gland LECs amenable to immunotherapeutic approaches based on the application of EBV-specific cytotoxic T cells [15]. Case 1 revealed expression of EBNA1, but both LMPs were not detectable by immunohistology. Thus, similar to nasopharyngeal LEC, viral gene expression patterns in salivary gland LECs as detected by immunohistochemistry are heterogeneous. As a consequence, exclusion of EBV as a cofactor in salivary gland LECs requires the application of EBV in situ hybridization and cannot solely rely on LMP1 immunohistochemistry.

Case 2 was unusual because, in addition to the undifferentiated high-grade carcinoma component, it showed a focal proliferation of spindle cells displaying only minor cytological atypia and microcyst formation. Morphologically, this spindle cell component was reminiscent of the “dysplastic BLEL” described by Nagao et al. [17] which, however, were EBV negative, and of the EBV-positive spindle cell LECs reported by Christiansen et al. [2]. It has previously been established that BLEL, as typically found in so-called myoepithelial sialadenitis (MESA), in lymphoepithelial cysts and in MZBCL, do not display a myoepithelial phenotype [8]. Rather, the phenotype corresponds to basal epithelium similar to the lining of crypts in oropharyngeal lymphatic tissue [8]. In contrast, the EBV-positive spindle cell lesion of case 2 displayed staining for vimentin, S-100 protein, SMA, Ck5/6 and Ck14, the combination of which is an attribute of myoepithelial cells. It is possible that the previously described spindle cell BLEL accompanying salivary gland LECs as well as the EBV-positive spindle cell LECs were also proliferations of true myoepithelial cells [2, 17]. Our case 2 is also reminiscent of a case reported by Piana et al. [21]. In that case, an EBV-positive LEC was accompanied by a low-grade tumour classified as epi-myoeplithelial carcinoma which was also EBV-associated [21].

To assess the relationship between low- and high-grade tumour components in case 2, we determined the immunophenotype with emphasis on expression of cytokeratins and myoepithelial markers. Whereas the high-grade component of case 1 displayed no significant expression of cytokeratins except for Ck8 and of EMA, the spindle cell proliferation expressed Ck5/6 and Ck14 in the absence of the other specific cytokeratin types tested. However, small complexes

of larger cells at the periphery of the spindle cell component expressed Ck5/6, EMA, and vimentin, suggesting areas of transition between these otherwise distinct tumour components. The fact that both components were associated with EBV infection also suggests that these morphologically distinct cell populations formed part of the same neoplastic process since EBV has been shown to be absent from salivary gland tumours other than LECs [1, 22].

Like its high-grade component, the entire spindle cell proliferation of case 2 was characterized by EBV latency type II. However, expression levels of EBNA1 and LMP1 were, by comparison, modest, and there was no detectable expression of LMP2 in these cells. This correlates well with the smaller growth fraction in the spindle cell component because EBNA1 is required for the maintenance of viral episomes in proliferating cells [32]. The smaller proportion of infiltrating lymphocytes in the spindle cell component is also in support of this interpretation. Thus, our observation of EBV infection of both components and areas of phenotypic transition lends support to the notion that a true myoepithelial lesion may be an immediate precursor of LEC in this case. Tumour cells of case 2 expressed Ck5/6, Ck8, Ck13 and Ck18, indicating immunophenotypic heterogeneity among salivary gland LECs.

The mode of infection of myoepithelial cells by EBV is not clear. Some authors postulated that EBV persisted in the parotid gland [31]. However, this has not been confirmed by others [5]. Other parotid gland tumours have been reported to be EBV negative, suggesting that EBV infection in salivary gland neoplasms is restricted to LECs [1, 22].

In conclusion, the detection of EBV in both components of case 2 supports the notion that at least some LECs arise through a low-grade myoepithelial lesion. This idea is also supported by a similar case reported previously [21]. The mode of viral infection of these myoepithelial cells remains undisclosed. The detection of a low-grade component accompanying a salivary gland LEC is indeed an argument to consider the tumour primary to the gland and makes a metastatic tumour unlikely. The proportion of EBV-associated LECs in Caucasians may be larger than previously anticipated. EBV-associated LECs may differ in their latency form, so that assignment of EBV infection should always rest on detection of EBER transcripts. LMP expression, in particular LMP2A, may be of therapeutic interest because it may make such cases amenable to immunotherapy with EBV-specific cytotoxic T cells.

Primary intrahepatic malignant mesothelioma of epithelioid type

Received: 22 November 2005 / Accepted: 12 February 2006 / Published online: 16 March 2006
© Springer-Verlag 2006

Abstract A case of epithelioid mesothelioma presenting as a primary intrahepatic tumor is described. The patient was a 62-year-old man with a 5.8-cm intrahepatic mass on an incidental intra-abdominal CT scan. Thorough clinical and radiographic examination did not reveal any evidence of tumor elsewhere. Macroscopic and microscopic examination demonstrated an intrahepatic tumor consisting of tubular and papillary proliferations of large epithelioid cells, surrounded by a densely mixed inflammatory infiltrate. The tumor cells were strongly positive for pancytokeratin, CK7, CA-12.5, and calretinin, as well as D2-40, and were faintly positive for thrombomodulin and vimentin. The proliferative rate was focally increased up to 20% by Ki-67 staining and the tumor expressed focally p53. Ultrastructurally, numerous microvilli on the cell surface, and abundant desmosomal plaques, characteristic of mesothelial cells, were found. To date, this is the third reported case of a primary intrahepatic mesothelioma.

Keywords Liver · Epithelioid mesothelioma

Introduction

Primary malignant nonepithelial neoplasms in the liver are rare and encompass angiosarcomas, fibrosarcomas, and leiomyosarcomas in descending order. Mesothelioma occurring primarily inside the liver has been reported

exceedingly rarely in the world literature [7, 10]. Malignant mesotheliomas are observed in the pleural cavity (70%) and less often, in the peritoneum (20–25%; see p. 25 of [1]). In up to 70% of patients, mesotheliomas are associated with prior asbestos exposure [12]. They most often present with diffuse spread and advanced clinical stage. Less commonly they occur as solitary, localized lesions, as benign multicystic mesotheliomas [4], or benign papillary mesotheliomas [2]. Mesotheliomas locally occurring in the liver are exceedingly rare; more often, they occur as peritoneal tumors that involve the liver secondarily [11]. Previously designated “localized fibrous mesotheliomas” [8, 9], in retrospect, should better be classified as solitary fibrous tumors, if CD34-positive [13].

We report a case of a primary intrahepatic epithelioid mesothelioma in a 62-year-old patient who presented with nonspecific complaints of upper abdominal discomfort. This is the third reported instance of this type of lesion in this particular location. The clinicopathologic features and differential diagnosis of this tumor are described.

Clinical history

The patient was a 62-year-old accountant with no significant history of asbestos exposure, who presented with minor upper abdominal discomfort.

By ultrasound and computer tomography, a mass with cystic areas in the right liver lobe near the right adrenal gland was found. NMR studies revealed an encapsulated mass within the liver, most likely benign. The patient underwent radiographically guided biopsies that demonstrated mesothelial cell proliferations; a malignancy could not be excluded. Thorough clinical and radiographic intra- and extra-abdominal examination showed no other mass lesion. Subsequently, he underwent hepatic segmentectomy. Abdominal laparotomy showed no extrahepatic lesions. Five months after surgery, metastatic mesothelioma was detected within three periaortic lymph nodes.

Materials and methods

The tissues were fixed in neutral buffered formalin and embedded in paraffin for histologic processing. Tissue sections were stained with hematoxylin and eosin (H&E) and periodic acid-Schiff stain for conventional histology. Representative paraffin-fixed tissue blocks were cut and processed for immunohistochemical studies. The antibodies tested included the following: pancytokeratin MNF 116 (DAKO), calretinin (Chemicon), calretinin (DAKO), cytokeratin 7 (DAKO), D2-40 (Signet), WT-1 (DCS), thrombomodulin (DAKO), desmin (DAKO), CA 12-5 (DAKO), vimentin (DAKO), Ki-67 (DAKO), cytokeratin 5/6 (DAKO), cytokeratin 20 (DAKO), BerEp4 (DAKO), CA 19-9 (DAKO), prostate specific antigen /PSA (DAKO), prostate secretory protein /PSP (DAKO), thyroid transcription factor 1/TTF1(DAKO), HepPar-1 (DAKO), alpha-feto-protein/AFP (DAKO), CD31 (DAKO), CD34 (DAKO), carcinoembryonic antigen/CEA (DAKO), and p53 (DAKO). Immunohistochemical stains were performed on an immunostainer (Techmate 500; DAKO) and detected by means of the avidin–biotin complex (ABC method) using AEC (3-amino-9-ethylcarbonyl) as chromogen.

For electron microscopy, formalin-fixed tissue in paraffin was dewaxed and diced into 1-mm³ cubes, postfixed in 3% glutaraldehyde, and embedded in EPON. Ultrathin sections were stained with uranyl acetate and lead citrate and viewed in a Philips electron microscope CM10.

Results

The liver specimen showed a subcapsular, intrahepatic tan-white mass that measured 5.8 × 3.3 × 5.3 cm. The tumor was sharply demarcated against the surrounding normally appearing liver, but not encapsulated. The cut surface showed gray-white glossy tissue containing foci of recent hemorrhage (Fig. 1).

On scanning magnification of cytological and histological preparations, the tumor consisted of numerous epithelioid tumor cells arranged in cords, solid and papillary patterns (Fig. 2a–c). On higher magnification (Fig. 2b) and on cytologic preparations (Fig. 2c), the tumor contained islands and cords composed of round to polygonal cells

Fig. 1 Intrahepatic gray-white tumor, confined to the liver

with abundant pale eosinophilic cytoplasm. Other areas showed a more solid proliferation of epithelioid cells containing large atypical nuclei with prominent central or slightly eccentric nucleoli. Few mitotic figures were found and nuclear pleomorphism was noted. The tumor background consisted of rich inflammatory infiltrate composed of histiocytes, lymphocytes, and plasma cells (Fig. 2b). The tumor grew with blunt borders towards the surrounding liver tissue. Furthermore, the overlying liver capsule showed a dense inflammatory and fibrosing reaction with clefts lined by reactive mesothelial cells. Tumor cells did not reach the peritoneal cavity.

The tumor cells were strongly positive for pancytokeratin, cytokeratin 7, D2-40, WT-1, CA 12-5, calretinin; focally and faintly positive for thrombomodulin (Fig. 2d–h); and weakly positive for vimentin. Focally, the tumor stained intensely positive for p53 in a nuclear pattern (Fig. 2i). Interestingly, similar focal expression was observed for the proliferation marker Ki-67 in up to 20% of tumor cells. Stains for cytokeratin 5/6, cytokeratin 20, BerEp4, CA 19-9, PSA, PSP, TTF1, HepPar-1, alpha-fetoprotein, CD31, CD34, and carcinoembryonic antigen were negative in the tumor cells.

Ultrastructural examination revealed flattened to polygonal tumor cells closely apposed to each other and delimited by a well-developed basal lamina (Fig. 3a). The cell surfaces abundantly contained long and slender microvilli (Fig. 3b). The tumor cells were connected to each other by well-formed desmosomes with attached tonofilaments (Fig. 3b). The nuclei were oval to round with occasional indentation of the nuclear envelope and they contained a single, prominent nucleolus (Fig. 3a). The cytoplasm contained scattered mitochondria, short strands of rough endoplasmic reticulum, polysomes, and abundant intermediate filaments. No secretory or mucin granules or any other specific organelles could be identified in the tumor cells.

Discussion

Localized malignant mesothelioma of the peritoneal cavity is rare. Even more uncommon are cases of mesotheliomas occurring primarily in the liver; therefore, they represent an important pitfall in pathologic practice. They are currently not listed in the World Health Organization classification of hepatic tumors [6]. Review of the literature only disclosed two previously reported instance of this rare occurrence [7, 10]. Interestingly, these mesotheliomas also were of epithelioid type.

Histomorphologically, mesotheliomas can be separated into localized and diffuse types. They are further subdivided into predominantly epithelioid, sarcomatoid, and biphasic types. Within the epithelioid category, morphologic variations such as tubulopapillary and solid can be distinguished [1]. In some cases, extensive leukocytic infiltrations can be observed adjacent to the tumor cells. The diffuse dense infiltration by leukocytes has been previously described as “mesothelioma with leukocytic

Fig. 2 Intrahepatic epithelioid mesothelioma, with **a** tubular and papillary patterns and clefts surrounded by an extensive mixed inflammatory infiltrate (H&E, 200 \times), **b** epithelioid tumor cells with atypical nuclei and prominent nucleoli (H&E, 400 \times), **c** papillary fronds in cytologic scrape preparation (H&E, 400 \times). Tumor cells express **d** CK7, **e** D2-40, **f** CA 12-5, **g** thrombomodulin, and **h** calretinin, and they are focally stained with **i** anti-p53 (DAB, 200 \times)

infiltrate” [5]. The case presented here showed an extensive, tumor-associated leukocytic infiltration, which was in contrast to the bland surrounding liver tissue.

With the extensive inflammatory background, it sometimes becomes exceedingly difficult to distinguish malignant mesothelial cells from their benign reactive counterpart. However, the intrahepatic localization of this tumor, the histomorphological features with monomorphic tumor cells, and highly atypical nuclei argue against reactive mesothelial cells. Furthermore, negative desmin stain on most tumor cells and positive focal p53 and Ki-67 positive nuclei support the diagnosis of a malignant epithelioid mesothelioma [3, 14]. In contrast, the intrahepatic mesothelioma observed by

Imura et al. [7] showed a diffuse p53 staining pattern and a proliferative rate of 25%.

Based on clinical grounds primary liver tumors as well as a metastasis from a distant site enter the differential diagnosis. Cholangiocarcinoma, although CK7-positive, can be ruled out due to expression of mesothelial markers such as calretinin, thrombomodulin, and D2-40, as well strong expression of CA-12-5. The negative staining for HepPar-1 and the aforementioned positive mesothelial markers rule out a hepatocellular carcinoma. In terms of a metastasis, helpful findings are a lack of BerEp4, CA19-9, PSA, PSP, and TTF1.

The further differential diagnosis includes adenomatoid tumors, that can have an identical immunohistochemical

Fig. 3 Electron microscopically, epithelioid tumor cells show **a** atypical nuclei with prominent nucleoli and nuclear notches and **b** prominent microvilli and desmosomes (arrowhead)

staining pattern due to their similar histogenesis. The occurrence of these tumors in extragenital locations is however distinctively rare. In our tumor, the morphologic appearance of large polygonal cells, which are clearly malignant and morphologically consistent with the diagnosis of mesothelioma, and the observation of a dense leukocytic infiltrate support our interpretation.

It remains to be shown in more cases whether the prognosis of primary intrahepatic mesotheliomas is similar to peritoneal mesotheliomas and whether epithelioid morphology and circumscription is a common feature of these rare tumors.

Undifferentiated (sarcomatous) carcinoma of the liver with osteoclast-like giant cells presenting as tumor thrombus in the inferior vena cava

Received: 3 March 2005 / Accepted: 28 April 2005 / Published online: 13 September 2005
© Springer-Verlag 2005

Dear Editor:

Hepatic tumors containing osteoclast-like giant cells (OGC) are very rare, and only few cases have been published since they were first reported by Munoz and co-workers in 1980 [4]. The nature of these tumors and the histogenetic origin of the giant cells have remained obscure for a long time. However, the association of hepatocellular carcinoma with highly pleomorphic tumor areas containing OGC has been recently described [3], a finding that was also confirmed by other authors. On the other hand, hepatic sarcomatous cholangiocarcinomas are also very uncommon, with only 17 cases published to date [2], and only one single cholangiocarcinoma with OGC has been reported [1].

We describe an extraordinary case of a cytokeratin 19-positive undifferentiated carcinoma with OGC and predominantly intravascular tumor growth into the heart, a manifestation of tumor spread resembling leiomyosarcomas of the inferior vena cava.

The patient, a 77-year-old Caucasian woman suffering from diabetes and liver cirrhosis, suddenly died of thrombotic occlusion of the inferior vena cava. The thrombus extended from the main branch of the right liver vein (Fig. 1a, arrow) to the ostium of the vena cava inferior in the right atrium (Fig. 1b). Metastases were noted in hilar lymph nodes and in the myocardium of the left ventricle, as well as in the thyroid. The tumor thrombus consisted of sarcomatoid anaplastic tumor cells (Fig. 1c) without mucus formation, intermingled with osteoclast-like giant cells (Fig. 1d). Neither chemotherapy nor chemoembolization of the tumor was performed. The tumor cells were strongly immunopositive for cytokeratins (Fig. 1e, antibody AE1/AE3), cytokeratin 19 (Fig. 1f), and vimentin. Cytokeratin 7

was weakly positive, whereas CD68 was exclusively detectable in giant cells and macrophages within the tumor thrombus. Tumor cells were immunonegative for hepatocyte antigen (HepPar1), alpha-fetoprotein, carcinoembryonic antigen, carbohydrate antigen 19-9, actin, smooth muscle-specific actin, desmin, CD31, CD34, S100, Melan A, HMB45, cytokeratins 5/6 and 20, thyroid transcription factor 1, thyroglobulin, and CD117. After extensive examination, we noted a small invasive tumor area beneath the right liver vein (Fig. 1g), which was considered the primary hepatic tumor. Having assessed a total of over 30 tumor and liver tissue blocks, neoplastic glandular formations, atypia of intrahepatic bile ducts, and tumor areas resembling hepatocellular carcinoma were not detected. The lesion described here originated in a complete liver cirrhosis, with no morphologic or anamnestic clue as to its cause. A primary tumor of extrahepatic origin was excluded by autopsy.

Considering the results of our immunohistochemical examinations, we excluded several differential diagnoses, i.e. carcinosarcoma, nonhepatocytic malignant mixed tumor, epithelioid haemangioendothelioma, leiomyosarcoma, and other mesenchymal tumors. The strong expression of cytokeratins, including cytokeratins 19 and 7, supports our diagnosis of an undifferentiated (sarcomatous) carcinoma of the liver with cholangiocellular rather than hepatocellular differentiation.

Among the hepatic carcinomas, tumor expansion within the vena cava is more typical for hepatocellular carcinomas, as cases reaching the right atrium are known. However, caval invasion does not seem to be an exclusive feature of this carcinoma type, because even the first hepatic tumor with OGC, reported by Munoz et al. [4], invaded the hepatic vein. Interestingly, they considered the latter tumor an osteoclastoma-like giant cell tumor of Kupffer cell origin; however, later studies have clarified the reactive histiocytic nature of the osteoclast-like giant cells against the background of carcinoma cells in these tumors [3, 5]. Also, in our case, the benign-appearing, non-neoplastic giant cells were immunopositive for CD68 but not for epithelial markers.

Ectopic pancreatic tissue in the anterior mediastinum

Received: 28 December 2005 / Accepted: 3 January 2006 / Published online: 1 March 2006
© Springer-Verlag 2006

Dear Sir:

Heterotopia of pancreatic tissue is a common developmental anomaly reported in about 2% of all autopsies. Ectopic pancreatic tissue is most frequently found in the stomach (25–35%), duodenum (30%), jejunum (15–20%) and ileum (5%) [2]. In contrast, pancreatic tissue within the thoracic cavity and mediastinum is distinctly uncommon and is generally seen as a component of gastroenteric duplication cyst, intralobar pulmonary sequestration, or mature teratoma [4, 8]. Even rarer are benign mediastinal cysts with pancreatic tissue as their sole component. To our knowledge, the literature reports only five earlier examples of this lesion [2, 3, 7, 9, 10]. We report this case because of its rarity and the differences in the clinical presentation as well as part of the histological pattern from other reports.

A 40-year-old man presented with high fever, neck swelling, and difficulty in breathing for a few days. On examination, his body temperature was 39.4°C and his blood pressure 144/74 mmHg. The chest was clear and the abdomen was soft. Magnetic resonance imaging (MRI) revealed an anterior mediastinal cystic mass measuring 8×6×6 cm, with no evidence of any pulmonary lesion or pleural effusion (Fig. 1). The complete blood picture showed leukocytosis with a white blood cell count of 12,700/mm³ and a high erythrocyte sedimentation rate of 81 mm/h. All biochemical tests including blood sugar and urine analysis were normal. A diagnosis of anterior mediastinal abscess was suggested. A drainage tube

inserted under general anesthesia to drain the cyst, yielded 100 ml of turbid fluid, which was sent for cytological and microbiological examination, all of which were negative. After 1 week of antibiotic administration had failed to produce any clinical or radiological improvement, the decision was made to remove the lesion surgically under general anesthesia and the specimen was submitted for histopathologic examination.

Histologically, the cyst wall, which was in continuity with the thymic tissue, was lined by cuboidal to columnar epithelium with focal areas of pseudostratified ciliated columnar epithelium. The cyst wall itself was fibrotic and contained a disorganized mixture of ducts, acini, and islets of cells with typical appearance of pancreatic tissue. The ducts were variable in size and resembled interlobular and intralobular ducts. The ductal epithelium was simply columnar and mucinous. The exocrine acini were formed by polygonal cells with prominent eosinophilic apical cytoplasm with the characteristic appearance of zymogen granules (Fig. 2). These acini ranged in size from small, irregular aggregates of three to four cells to large lobules containing intralobular ducts and islet cells. The endocrine component was also variable in size and appearance; the islets ranged from small cellular aggregates to hyperplastic islets with irregular contour intermixed with exocrine acini. In numerous areas, the endocrine cells were connected directly to ducts and formed ductuloinsular complexes (Fig. 3). The distribution of the exocrine and endocrine components was highly variable within the cyst wall, but areas with large exocrine components tended to have few islets just as those with predominantly endocrine appearance had very few acini. In addition, areas of fibrosis were seen between islets and acini, which are not seen in normal pancreatic tissue (Fig. 3).

The cells of the examined tissue were phenotyped immunohistochemically by the streptavidin–biotin method using antibodies (DAKO), all diluted to 1:50. The neuroendocrine elements “neuron-specific enolase, chromogranin, PGP 9.5 and synaptophysin” were uniformly positive throughout the islets (data not shown), while immunoreactivity to insulin was seen in the majority of islet cells and

Fig. 2 Showing the cyst wall which is lined by low columnar epithelium and containing a mixture of a predominantly exocrine component with a few foci of endocrine component.H&EX50

in ductuloinsular complexes (data not shown). Glucagon and pancreatic polypeptide were discernible in a few cells in the periphery of the islets of Langerhans. In addition, pancreatic polypeptide was detectable in ductuloinsular complexes (data not shown). The immunoreactivity for somatostatin was seen in many more islet cells and in a few cells in ductuloinsular complexes (data not shown). Immunoreactivity to gastrin was seen in a large number of islet cells and in cells within exocrine ducts (Fig. 4). A diffuse staining for cytokeratin was also observable among the exocrine ducts, acini, and the lining of the cyst (data not shown).

Fig. 3 A predominantly endocrine component of the ectopic pancreatic tissue showing the ductuloinsular complex.H&E, X50

Fig. 4 Gastrin immunostaining, showing position staining of a large number of islet cell as well as scattered intraductal cell of the exocrine pancreatic component. Immunoperoxidase, X50

Mediastinal cysts formed only by pancreatic tissue are extremely rare, with only five cases being previously reported in the literature. In the report by Carr et al. [3], the exocrine component was described as predominant, whereas, Shilltoe and Wilson [9], both reported that islets were the more abundant tissue. In the reports by Perez et al. [7], Cagirici et al. [2], and Tamura Y et al. [10], the distribution and architecture of acini and islets were irregular and haphazard as in the present case. It is noteworthy, however, that there were identifiable areas showing predominance of either acini or islets. In addition, there were hyperplastic islets and ductuloinsular complexes reminiscent of the microscopic appearance of diffuse nesidioblastosis [6].

Immunohistochemical staining confirmed the presence of the endocrine and exocrine pancreatic constituents of the cyst wall. This demonstrated a predominance of insulin-secreting cells in islets and ductuloinsular complexes. The similarity between the lesion and the fetal pancreas is

further supported by the increase in the number of gastrin-containing islet cells [5]. Gastrin-producing cells are present in a large number in fetal pancreas but are rarely, if ever, seen in adult pancreas and seem to play an important role as a trophic factor during intrauterine pancreatic development [5].

The presence of isolated neuroendocrine cells within ductal epithelium supports the hypothesis of a common duct epithelial stem-cell origin for ductal, acinar, and endocrine cells [6]. Our patient had no symptoms suggestive of hyperinsulinism or hypoglycemia, similar to other reports of mediastinal cysts and extragonadal teratomas [2, 3, 6, 8]. It has been suggested that the lack of clinical symptoms in these patients is due to the relatively small amount of functional neuroendocrine tissue present in these lesions and to its responsiveness to homeostatic mechanisms [1].

The pancreas and the lower respiratory tract share a common embryologic origin, the primitive foregut [7]. Therefore, we think that this lesion might represent a derivative of the ventral wall of the primitive foregut. Alternatively, it might have arisen as a result of unidirectional differentiation of primordial germ cells, which are frequently the source of anterior mediastinal teratomas. It is also probable that the lesion in our patient represents a developmental anomaly of undifferentiated endodermal epithelium, which, under unknown influences, differentiated into ventral fetal pancreatic tissue instead of into lower respiratory tract tissue [1]. This is supported by the presence of foci of pseudostratified ciliated columnar epithelium as a component of the lining epithelium of the cyst. Reports of pancreatic tissue within intralobar pulmonary sequestration provide evidence of the capacity of primitive foregut to differentiate along these seemingly dissimilar pathways [4]. The significance of gastrin in the histogenesis of this lesion is unclear; it is likely, however, that it plays a significant part in the growth and differentiation of this lesion, given its role as a growth factor in the neonatal pancreas [5]. In conclusion, the histogenesis of the lesion is unclear. We think that this lesion represents a

derivative of the ventral wall of primitive foregut, but unidirectional differentiation of a benign cystic teratoma cannot be excluded. Anatomic location of the lesion and associated clinical observation may be important factors in establishing the final diagnosis.

Acknowledgements The authors would like to acknowledge Prof. Jean-François Fléjou in the Pathology department, St-Antoine Hospital, Paris, France as well as Prof. Ernest Adeghate in the Anatomy department and Dr. Samir Attoub in the Pharmacology department, in the Faculty of Medicine and Health Sciences, United Arab Emirates University, Al Ain, UAE, for their support during this work.

ANNOUNCEMENTS

1–3 June 2006

**Technology Transfer in Diagnostic Pathology
1st Central European Regional Meeting: Liver &
Pancreas Pathology**
Eger, Hungary

The Hungarian Division of the International Academy of Pathology announces the *Liver & Pancreas Pathology* both for young and well-trained pathologists and clinicians.

The Meeting will focus on the practical clinicopathological aspects of liver and pancreatic diseases and conclude in a consensus. Among the highlights will be the differential diagnosis of hepatic and pancreatic tumors and premalignant alterations presented by *internationally renowned* experts, in active interaction with the attendants.

Plenary lectures will cover the themes of steatohepatitis, reversibility of cirrhosis, chronic hepatitis, classification and diagnosis of liver tumors, progenitor cells in the liver, pancreatitis, tumors of the pancreas.

Slide seminars will discuss autoimmune liver diseases (PBC, PSC, CAH), toxic liver injuries, benign and malignant liver tumors, tumor-like lesions of the liver, pancreatitis and pancreatic tumors.

Poster presentations will be reviewed and discussed individually by the participants.

15–16 June 2006

Thyroid Pathology for the Practicing Pathologist
15 rue de l'Ecole de Medecine, Paris, France

A 2-day course will take place in Paris again under the auspices of the French Division of the I.A.P.

This course will be given in English by Prof. M. Sobrinho-Simoes (Porto) and Prof. R. Heimann (Brussels).

It will consist of lectures alternating with slide reviews and slide seminar over a multthead microscope. The cases of this seminar will be sent (on CD) before the meeting.

The audience will be limited to 22 participants.

Course fees: 390 euros (320 euros for members of any I.A.P. division).

The fees include registration, hand-out, CD of the slide seminar and coffee breaks.

For further information please contact

2ND INTER-CONGRESS OF THE EUROPEAN SOCIETY OF PATHOLOGY

SESSION A

DISPLAYED ON THURSDAY, MAY 25TH, 08.30-14.00

BONE & SOFT TISSUE PATHOLOGY

NEUROPATHOLOGY

HEAD & NECK PATHOLOGY

CARDIOVASCULAR PATHOLOGY

P001-P031

P032-P038

P039-P052

P053-P063

SESSION B

DISPLAYED ON THURSDAY, MAY 25TH, 15.00-20.00

HEMATOPATHOLOGY

LUNG PATHOLOGY

KIDNEY PATHOLOGY

UROPATHOLOGY

NEW TECHNIQUES IN PATHOLOGY

P064-P083

P084-P093

P094-P103

P104-P126

P127-P131

SESSION C

DISPLAYED ON FRIDAY, MAY 26TH, 08.30-14.00

BREAST PATHOLOGY

GYNECOPATHOLOGY

ENDOCRINE PATHOLOGY

P132-P152

P153-P176B

P177-P196

SESSION D

DISPLAYED ON FRIDAY, MAY 26TH, 15.00-20.00

GASTROINTESTINAL PATHOLOGY

DERMATOPATHOLOGY

P197-P246C

P247-P260

Paget's disease of bone in young man

Psarelis Savvas¹, Gazi Sousana¹, Trovas Georgios², Syrou Alexantra³, Mahera Helen³, Lyritis Georgios².

¹Department of Rheumatology, ²Laboratory for the Research of Musculoskeletal System, ³Department of Pathology General Hospital of Attica "KAT", Athens Greece

Background: Paget disease of bone is an idiopathic metabolic disease of bone which is characterized by abnormal bone remodeling. Most often remains asymptomatic and usually occurs after age 40 years.

Objectives: We present a case of twenty years old young man who was referred to our department because of a high level of alkaline phosphatase (ALP) in a routine blood test.

Case presentation: A complete clinical, laboratory, imaging investigation and bone biopsy from fourth lumbar vertebra was performed. **Laboratory findings:** ESR, CRP were within normal levels, BUN=36, Cr=1, Cholesterol=262, HDL=56, LDL=148,8, VLDL=83, triglyceride=286, uric acid=6,2, SGOT=20, SGPT=36, bilirubin=0,8, albumin electrophoresis $\alpha_1=2,7$, $\alpha_2=9,5$, $\beta=13,1$, $\gamma=12,6$, Bence-Jones (-), CEA<0,8, AFP=1,35, CA19-9=0,1, PSA=0,53, HBsAg(-), Anti HCV(-), Anti HIV(-), TSH=1,843, T3=1,03, T4=8,63, $Ca^{++}=10,1$, P=3,6, ALP=149 (<128), Bone ALP=133 (<41,3), CTX serum=0,878(0-0,58), NTX serum=53,9 (5,4-24,2), PTHrP=7 (2,3-5,4), NTX urine=81 (20-50), LH=4,37, FSH=4,48, PRL=300,5, 25(OH) D3=32, PTH=23,5, Testosterone=4,38, $Ca^{++}/Cr=0,054$, P/Cr=0,62 **Imaging findings:**

- The plain radiographs of lumbar spine (F/P) raised a suspicion of sclerosis of L₄ vertebra,
- The bone scan with Tc99 revealed increased radionuclide uptake at L₄ vertebra, at right sacroiliac joint and at the caput of right femur
- The Computer Tomography (CT) of lumbar spine showed mixed lytic and blastic lesions of L₄ vertebra.
- The MRI of lumbar spine revealed collapse of the superior part of the body of L₄ vertebra with disturbance of bone architecture
- Bone biopsy: Histologically, trabecular plates with abundant cement lines are recognized, which give rise to a "mosaic" pattern. Small pieces of fibrous tissue are intermingled between and bone tissue and only few osteoclasts are included. Moreover, the trabeculae have an osteoblastic rimming. After exclusion of others bone diseases the diagnosis of Paget's disease was made and the patient was treated with pamidronate 120 mg intravenously. The patient's blood test for ALP, every three months, was within normal limits and one year later a new MRI of lumbar spine showed the same lesions of bone but reduced bone oedema.

Conclusion: The Paget's disease of the bone rarely occurs at ages under 40 years old. In these cases the diagnosis is based on a detailed clinical, laboratory and imaging study to exclude other bone diseases but bone biopsy is always necessary to confirm the diagnosis.

P002

Acral skeletal metastases

J. Sopta*, M. Atanackovic*, A.Djordjevic**

*Institute of Pathology, School of Medicine, Belgrade, Serbia

**Institute for orthopedic surgery "Banjica", Belgrade, Serbia

Metastatic bone tumors are 25 times frequent than prime bone tumors, but skeletal metastases in distal bones than elbow and knee, are very rare. Phalanges of finger is extremely rare localization for metastases and occurred less than 1% from all localizations.

During the last 10 years (1996-2005) in the Register of bone biopsy, Institute of Pathology, School of Medicine, Belgrade is registered 624-bone metastases and just 3 cases of metastatic carcinoma in phalanges with present 0,48% of all metastases. All patients were males (47, 55 and 77 years old, middle age 59). Clinically all of them had swelling and pain of finger. Radiological all lesions were

osteolytic, but without cortical destruction and no fracture. The clinical diagnosis was (in all cases) cystic lesion of phalanges, suspect enchondroma. After biopsy 2 cases were diagnosed as metastases of adenocarcinoma (we suggested lung or digestive tract as a primary localization) and one case as metastatic renal cell carcinoma. Patient with metastases of renal cell carcinoma had a diagnosis of prime tumor and nephrectomy was performed one year before. Patients with adenocarcinoma had no anamnesis of malignant disease and first clinical sign was swelling and pain of hand finger. On bronchoscope bronchial carcinoma was confirmed as a prime malignant tumor in both cases.

Acral skeletal metastases are very rare but they confirmed that haematogenous dissemination of carcinoma is unpredictable. Unfortunately presence of acral bone metastases is sign of progressive malignant disease and poor prognostic factor.

P003

Malignant transformation of chronic fibroblastic periosteal lesions

J. Sopta*, M. Atanackovic*, A.Djordjevic**

*Institute of Pathology, School of Medicine, Belgrade, Serbia

**Institute for orthopedic surgery "Banjica", Belgrade, Serbia

On the Register of bone biopsy, Institute of Pathology, Belgrade was registered 2 cases of malignant transformation of chronic proliferate fibroblastic periosteal lesions. In our opinion these lesions should be analyzed as separate entities in bone tumors pathology. Both patients were males. First patient, 24 years old BM had a slow growing tumor in proximal part of tibia with 5 years long anamnesis. After the first biopsy lesion was described as a proliferate, posttraumatic fibroblastic lesion of periosteum. Patient had 6 relapses during the 13 years until the final diagnosis - osteosarcoma. Second patient, ST was 34 years old when was performed the first biopsy of femoral lesion after trauma. In the period of 9 years he had 3 relapses and repeated biopsies. The final diagnosis was again osteosarcoma (low grade superficial). Proliferate potential of these lesions was investigated by Ki67. Expression of Ki67 were less intensive. These cases have in common a few elements: sex of patients, long evolution of lesions (13, and 9 years), trauma in anamnesis, many relapses (6 and 3), primary diagnosis of proliferate periosteal lesions and finally, lesions were firstly clinically manifested when patients were young adults (period of life when osteosarcoma is the most frequent). Radiography, CT scan, MR, scintigraphy and histopathology characteristics of lesions firstly pointed to fibroblastic periosteal proliferate lesions with expressive osteoid production up to mature bone. After many relapses and repeated biopsies with identical morphological findings - no malignancy but intensive proliferation of periosteal fiber tissue and production of mature bone arise transformation and lesions become low grade malignant tumors (low grade malignant in first biopsy and it become intensive in relapses, finally it was the most intensive in the last biopsy when was made diagnosis osteosarcoma. We conclude that increase of expression's intensity of Ki 67 prove to malignant transformations of posttraumatic proliferate fibroblastic periosteal lesions.

P004

Fibrocartilaginous dysplasia. A very rare bone-tumor

Syrou Alexandra, Apostolou George, Staikidou Ioanna,

Babis George, Mahera Helen

General Hospital of Attikis "KAT", Department of Pathology

Fibrocartilaginous dysplasia is an extremely rare, mainly monostotic lesion, involving the femur, which is considered as fibrous dysplasia with massive cartilaginous differentiation. We present this case, concerning a 46-year old woman who visited our hospital complaining about a pain in her right knee which appeared 2 years ago, because of its rarity and bifocal appearance. On x-rays, an

osteolytic tumor at the distal metaphysis of the right femur was discovered. The tumor was eccentric originating from the bone cortex of the condylus lateralis, with a sclerotic rim and stippled calcifications, measuring 4×3cm. Subsequent CT and MRI imaging revealed the presence of fat in the central region of the lesion. There was another osteolytic eccentric lesion at the condylus medialis measuring approximately 1cm in diameter. It did not show any calcifications or fat. The lesions showed homogeneously high signal intensity on T2W images. The removed lesions was fixed in 10% buffered formalin and routinely processed for microscopic examination. The paraffin-embedded tissues were investigated by means of histopathology using hematoxylin and eosin stain and immunohistochemistry. Histologically, the first tumor consisted of a fibro-osseous lesion, characteristic of fibrous dysplasia, in juxtaposition to a large amount of hyaline cartilage, creating islands or nodules sharply demarcated from the surrounding fibro-osseous tissue. Enchondral ossification was focally seen as well as an infiltration of foamy histiocytes, which was visible between larger areas of predominantly fibrous tissue. Bone trabeculae around the cartilage islands were surrounded by osteoblasts. Immature osteoid formation was barely present. The second lesion, on the lateral condylus, also had the characteristic feature of fibrocartilaginous dysplasia.

P005

Uncommon site of chondrosarcoma development in a young adult

Alexandra Syrou, Patroklos Katafygiotis, Pikoulas Konstantios, George A. Apostolou, Christos Eliadis, Helen Mahera
Department of Pathology, General Hospital of Attikis "KAT",
2 Nikis St., Kifisia, Greece

Chondrosarcoma is a rare malignant bone neoplasm, which usually develops in the proximal extremities and the ribs and the majority of patients are older than 50 years. Chondrosarcomas in people younger than 45 years are rare and only individual cases are reported in very young patients. Our case concerns a 25-year-old woman who visited our hospital due to pain in the mean of her left tibia, with a 2-year duration, which occurred during touch, strike, or humidity. Radiologically, in the diaphysis of the left tibia an osteolytic region 10 cm in vertical dimension is found with explicit limits, that causes bone expansion and thick periosteal reaction. In the CT, linear calcifications are demonstrated in the superior and inferior department of the lesion. The removed lesion was fixed in 10% buffered formalin and routinely processed for microscopic examination. The paraffinembedded tissues were investigated by means of histopathology using hematoxylin and eosin stain. Histologically, features of a well-differentiated chondroblastic neoplasm are seen. The combination of the histological features, clinical and radiological data leads to the diagnosis of a well-differentiated chondrosarcoma, Grade I.

P006

Dedifferentiated chordoma – a case report

Vogiatzis P.¹, Kaltsa R.¹, Kritselis A.², Lekka I.¹
¹Pathology Department, ²1st Department of Surgery,
METAXA Cancer Hospital, Piraeus, Greece

Chordoma is a rare malignant bone tumor of adult age that is restricted to the axial skeleton. The most common location is the sacrum (50%), followed by the skull base (35%) and the mobile spine (15%). Dedifferentiated chordoma is an even more rare subtype of chordoma which contains areas of high grade sarcoma in an otherwise conventional or chondroid chordoma. A 53 years old man with a clinical history of neurologic symptoms of radiculopathy at the lower extremities was admitted to the hospital with dramatically increasing pain, bladder and bowel dysfunction. Computed tomogra-

phy of the pelvis showed a 15x13x10cm unencapsulated mass, centered in the upper portion of the sacrum, extending caudally and involving the sacrum and the small pelvis. The surgical specimen biopsy showed the presence of conventional chordoma. Radiation therapy for two months was performed with no sign of improvement followed by a wide surgical operation. The histologic examination reported the presence of foci of dedifferentiated chordoma, with high grade sarcomatous features. Forty two months later, radical pelvic resection was performed due to recurrence. Chordoma with diffuse necrosis was found. According to the literature dedifferentiated chordoma has a worse biologic behavior than conventional/ chondroid chordoma due to its high metastatic potential. Because of this fact, all chordomas and particularly recurrent lesions, should be sectioned carefully, in order to exclude the possibility of a high grade sarcomatous component.

P007

Chondrosarcoma of the spine with an unusual presentation

Panelos J.D.¹, Batistatou A.¹, Voulgaris S.²,
Michos E.², Agnantis N.J.¹
Departments of ¹Pathology and ²Neurosurgery,
University of Ioannina Medical School, Greece

Chondrosarcoma is the third most common primary malignancy of bone affecting primarily the bones of pelvis and being extremely rare in the spine. Herein, we present a case of a 65-year-old woman who presented with a persistent dry cough. Radiographic examination revealed the presence of a solitary nodule of the lung, with morphologic features most consistent with metastasis. Magnetic resonance imaging (MRI) and CT-scan revealed an ill-defined osteolytic lesion of the L5 vertebra with extension to the surrounding soft tissues. The patient underwent surgery and the mass was excised. The histopathologic examination revealed a moderately cellular multilobular neoplasm, with chondroid and myxoid matrix and focal necrosis. Under high power view multicellular lacunae of chondrocytes with moderate nuclear pleomorphism and hyperchromasia were observed. Mitotic figures were conspicuous. The tumor was diagnosed as chondrosarcoma, grade II. The patient underwent radiotherapy and is alive 6 months later. This is the first case of the rare chondrosarcoma of the spine presenting initially with symptomatology from the lung metastasis.

P008

Condensing osteitis of the clavicle (OCC). Report of two cases in males.

K. Revelos^{1,2}, M. Kalfa², A. Ntinis², Th. Filippidis^{1,2}.
¹Pathology Department, 251 Hellenic Air Force General Hospital,
Athens, Greece. ²Micromedica Histopathology Laboratories,
Athens, Greece.

Condensing osteitis of the clavicle is a rare, benign, variably painful condition affecting the medial end of the clavicle and it is characterised by sclerosis, expansion of the clavicular head and increased radiodensity. It is most commonly seen in middle-aged women. Reports of cases affecting males are few in the literature. Histologic examination reveals mature lamellar bone with thickened and irregularly broadened trabeculae and with slightly irregular cement lines. The trabeculae are focally lined by a single rim of osteoblasts. The intervening marrow is slightly fibrotic. A thickening of the cartilage, periosteal hyperplasia and fibrosis were recognised. We are adding two new histologically proved cases of the above entity occurring in men. The exact etiology of OCC still remains obscure but it has been postulated as a response to abnormal mechanical stress at the sternoclavicular joint (athletic stress, repeated episodes of heavy lifting, direct or repetitive trauma). Our first patient did not mention any previous trauma but the histological

findings were strongly suggestive of such a history and the second one used to exercise himself regularly. Further investigation and explanation of the discrepancy in the number of reported cases of OCC in men versus women is needed.

Implication of the IL-6 – STAT3 signal transduction pathway and VEGF in the pathogenesis and progression of human chondrosarcomas

Dionysios J. Papachristou*, Odysseas A. Papaefthymiou*, Michael Doukas, Dimitrios Strefanou, Anna Batistatou and Niki J. Agnantis (*)

Equal contribution to the study

Department of Pathology, University Hospital of Ioannina, Greece

The molecular mechanisms that underlie chondrosarcoma (CS) pathogenesis are unclear. The STAT family of proteins is pivotal in mediating cytokine signaling. STAT3 is frequently activated in human malignancies and transformed cell lines, primarily via up-regulation of the IL-6/IL-6 Receptor – JAK1 signaling axis. In vitro and in vivo data suggest that IL-6 and the JAK1-STAT3 pathway induce up-regulation of the major angiogenic factor, VEGF. In the present study we evaluated by immunohistochemistry the expression levels of IL-6, JAK1, its substrate STAT3 and VEGF, in 45 conventional CS, 21 enchondromas (EC) and in normal cartilage. Positive immunostaining for the examined proteins was observed in the majority of the CS, but in a small fraction of EC. The expression levels of all proteins were significantly and positively correlated to each other. These levels were substantially augmented in high-grade compared to low-grade CS and to EC. Our findings provide novel evidence that the IL-6 - STAT3 pathway is implicated in CS development and progression, either independently or through coordinated up-regulation of VEGF. Furthermore, our results reveal that VEGF can qualify as reliable molecular marker for the prediction of high-grade CS.

P010

Molecular Detection of Ewing Sarcoma Translocation T(11;22) by RT-PCR

Dabić M.M.¹, Meljanac K.¹, Bonevski A.², Seiwerth S.¹.

¹Laboratory of Molecular Pathology, Institute of Pathology, Medical Faculty, ²Department of Oncology, Children Hospital Center Klaićeva, Zagreb, Croatia

Objectives: The Ewing sarcoma (ES) family of tumors appears as a bone or soft tissue lesion in a child or young adult and it is characterized with EWS-FLI1 t(11;22)(q24;q12) translocation. Our aim was to follow-up patients with detected translocations in paraffin blocks/fresh tissue, peripheral blood and/or bone marrow.

Patients and Methods: From October 2003 until January 2006 we received tumor samples paired with blood samples of eleven patients diagnosed with Ewing sarcoma during the treatment according to EURO EWING 99 protocol and also, we received six blood samples and six bone marrow samples collected from patients who finished the treatment. Total RNA was isolated and the EWS-FLI1 fusion transcripts were detected by RT-PCR using primers EWS22.2 Bam and FLI1C that specifically amplify both 125 pb type I fusion and 191 pb type 2 variant.

Results: Nine paraffin samples were positive for type I EWS-FLI1 fusion of which two didn't survive, and two for type II. Two blood samples were positive, one for type I, and another one for type II

fusion in patients who finished the treatment. Conclusion: This specific RT-PCR assay is essential for Ewing sarcoma diagnosis and monitoring minimal residual disease, especially in EWS-FLI1 positive patients who have finished the treatment protocol.

Mast cell sarcoma of tibia

Brčić L., Batelja, Vuletić L., ¹Stepan J.,

¹Bonevski A., ¹Jakovljević G., Seiwerth S.

Institute of Pathology, Medical Faculty University of Zagreb, Croatia; ¹Oncology Department, Children's Hospital Zagreb, Croatia

Mastocytosis is a rare and mainly sporadic disease. Its main feature is an abnormal proliferation and tissue accumulation of mast cells. Mast cell sarcoma is a very rare disease, with 3 well-documented cases described in literature. It is characterized by local proliferation of atypical mast cells, destructive growth and very poor prognosis. A 4-year-old boy, presented with painful edema and deformation of his right lower leg. X-rays and CT revealed destructive tumorous mass. Histopathology showed tumour very rich with large, atypical cells, with hyperchromatic oval and polygonal nuclei. Cytoplasm around them was eosinophilic with many PAS-positive and Toluidine-Blue-positive granules. Immunohistochemically mast cells were positive for CD68, vimentin, CD 117 and CD 45. Soon rush developed with elevated serum tryptase level. One month after biopsy, disease progressed to mast cell leukemia. Follow-up computed tomography showed oval masses in both lower limbs. Targeted biopsy of the right tibia showed same pathohistological findings as the first one. Despite intensive chemotherapy patient died 8 months after first symptoms. Based on pathological findings, histochemistry and immunohistochemistry, we diagnosed for the first time a mast cell sarcoma of a bone, leading to leukemic transformation and death.

P012

Solitary plasmacytoma of the rib: analysis of a case

Bonitsis NG, Andrulaki M, Raptis L, Gossios K*, Stefanaki S**, Kakadellis I***, Soutopoulos A, Mastora M, Akritidis N
Departments of Internal Medicine, Radiology*, Pathology** and Thoracosurgery Clinic***, Hatzikosta G. H. of Ioannina, Greece

Objectives: Solitary plasmacytomas occur mainly at male patients ≥ 50 years old and they reflect the 3-5% of all the plasmacytoma lesions.

Methods: Herein, we describe the clinical, histopathologic and immunohistochemical features of a case of a solitary plasmacytoma in a 45 - year-old man.

Results: The patient complained of chest pain and a mass parasternal at the right anterior chest wall. A chest X-ray showed a tumor shadow in the 8th right rib. Thoracic CT revealed a well-circumscribed mass measuring 11×7×6 cm infiltrating the anterior border of the 8th rib and extending into the 7th and 9th rib. The patient had no fever or fatigue. Laboratory findings were as following: Hct: 38%, ESR: 29 mm/h. IgA: 1875, IgE: 1150, IgM: 205. Serum sample: kappa chains: 1040, lamda chains : 365, TPR: 8.5mg/dl. Urinalysis was normal. Serum electrophoresis showed a low band monoclonal gammopathy. Bone marrow biopsy revealed 10% plasmacytosis. Histopathologic and immunohistochemical findings were compatible with k-monoclonal mature plasma cell myeloma. The mass had been excised completely and the patient remains asymptomatic and the M-proteins were disappeared.

Conclusions: Solitary plasmacytoma is a rare thoracic tumor, whose complete surgical excision appears to be curative.

P013

Primary osseous classical Hodgkin's lymphoma: a rare entity.

Ipatia Doussis-Anagnostopoulou¹, Efthymia Giannitsioti², Fani Pliarchopoulou², Vassiliki Pappa³, Kostantinos Soultanis⁴, Christos Kittas¹.

¹Laboratory of Histology and Embryology, National and Kapodistrian University, Athens Medical School, ²⁴th and ³²nd Department of Internal Medicine and ⁴¹st Orthopedic Department, University of Athens, Attikon University Hospital, Chaidari, Athens, Greece

Classical Hodgkin's lymphoma (CHL) can involve extranodal sites, with bone being one of them. However, primary osseous CHL is a rarity. We present here a case of CHL localized in the pelvis in a 34 year old female, who presented with pelvic pain and fever. An x-ray and CT scan revealed a lytic lesion in the right pelvis and a first biopsy was reported as inflammatory pseudotumor. A second surgical biopsy that followed fifteen days later revealed typical Hodgkin Reed-Sternberg cells surrounded by a reactive cell population, infiltrating intertrabecular areas and the surrounding soft tissues. The neoplastic cells were CD30+, CD15, LCA-, L26-, CD3-, EMA- and a diagnosis of CHL, mixed cellularity type was made. Clinical and laboratory investigation excluded systematic localisation of the disease. The patient received full chemotherapy (ABVD) for stage IV CHL. Last circle of chemotherapy was induced in November 2005. Since then, no relapse of the disease was noticed, while bone lesions have been partly restored. Primary osseous CHL should be differentiated from secondary infiltration of bone in nodal CHL and from osseous metastasis in advanced disease, as it carries a better prognosis.

P014

Constitutional Disorders of Bone of the Fetus and Infant: the Pathologist's Contribution

A.E. Konstantinidou¹, G. Agrogiannis¹, M. Petersen², H. Karadimas², E. Patsouris¹, G. Adamopoulos³.

¹Dept. Pathology, Medical Faculty, National Kapodistrian University of Athens, Greece, ²Dept. Genetics, Institute of Child Health, Agia Sofia Children's Hospital, Athens, Greece, ³6th Orthopaedic Clinics, Asklepieion Hospital, Voula, Athens, Greece

Constitutional bone disorders (CBDs) are a large group of genetic disorders, comprising skeletal dysplasias (osteochondrodysplasias) and dysostoses. Skeletal dysplasias are a group of disorders with a disturbance in the development of cartilage and bone, resulting in growth defects of the skeleton. Dysostoses are defined as localized skeletal malformations occurring singly or in combination. Skeletal disorders may be prenatally detected by ultrasonography or result in intrauterine or early postnatal death. In this study, we present radiological, histopathological and molecular data of 21 CBDs diagnosed among 1322 fetal and perinatal autopsies over an 8-year period. The overall frequency of CBDs was 1:63 autopsies. Osteogenesis Imperfecta types IIa and IIb, Thanatophoric Dysplasia type I and the group of Short Rib with or without Polydactyly were the more frequently encountered disorders. Osteochondrodysplasias were diagnostically approached by prenatal ultrasound in 76% of cases, with a correct typing of the disorder achieved only in 19%. Dysostoses were represented only by Spondylocostal Dysplasia autosomal recessive type (Jarcho-Levin syndrome) and evaded prenatal ultrasonographic detection. The pathologist at autopsy is responsible of the correct interpretation of the radiographical, gross

and histological findings, in order to accurately classify particular CBDs and enable genetic counseling.

P015

Eosinophilic fasciitis. A case report

Psarelis Savvas¹, Gazi Sousana¹, Mouflouzeli Helen¹, Nirakis Konstantinos¹, Tsatsani Panagiota¹, Mahera Helen².

¹Department of Rheumatology, ²Department of Pathology General Hospital of Attica "KAT", Athens Greece

Background: Eosinophilic fasciitis (EF) is an idiopathic, fibrotic disorder with the histopathologic hallmark of fascial fibrosis. The presentation is acute with painful, swollen extremities progressing to disabling cutaneous fibrosis.

Objectives: We present a woman sixty four years old who referred to our department because of diffuse sclerosis of extremities and upper part of the body.

Case presentation: The symptoms began one year ago and she hospitalised in internal medicine clinic with possible diagnosis of scleroderma. The laboratory and imagine study were normal. The skin biopsy was compatible with her age. The patient was treated with D-Penicillamine 500mg/day and Prednisolone 10mg/day.

One year later she referred to our department complained for progressiveness of skin induration despite the therapy.

Physical examination revealed a diffuse, erythematous tenderness of the upper extremities and upper torso and cutaneous induration with a finely dimpled appearance (peau d'orange) of the extremities with normal skin of the hands.

Laboratory: WBC=6970, NEUT=65%, LYMPH=25%, EOS=3,4%, HGB=12,2, HCT=38,2, PLT=156000, Glu=96, Cr=0,9, Bun=29, LDH=417, SGOT=19, SGPT=14, G-GT=16, ALP=172, ESR=20, CRP=11,8 ANA= 1/160, ds-DNA=(-), ENA=(-), SCL-70=(-), CA125=7,9, CA19-9=2, AFP=4,1, AFP=4,1, CEA=4.

Imagine: Plain radiographs of chest, Ultrasound of abdomen, U/s of heart, Computer Tomography of Chest were normal. A full-thickness incisional biopsy specimen obtained including skin, fat, fascia, and superficial muscle in continuity.

Histologic Findings: The epidermis was normal. Inflammatory infiltrate, including lymphoid follicles, involves the lower dermis, the septae, the fascia, and the muscle. The inflammatory infiltrate is mild to moderate and consists of lymphocytes, histiocytes and plasma cells. Eosinophils were not found. The findings were suggestive for the diagnosis of Eosinophilic fasciitis. Because of the EF diagnosis the patient was treated with Methotrexate 25mg/week subcutaneously and Prednisolone 20mg/day per os with good response.

Conclusion: The Eosinophilic fasciitis is a rare autoimmune disease and there is a debate whether EF represents a variant of scleroderma or it is a different disease. It is essential to put precise diagnosis because EF is not a systemic disease with better prognosis. For this reason biopsy is always necessary and the specimen must include skin, fat, fascia, and muscle in continuity.

P016

Angiomatoid fibrous histiocytoma containing cystic epithelial inclusions

T. Koletsis, D. Televantou, P. Hytiroglou, N. Fakhouri, G. Karkavelas.

Department of Pathology, Aristotle University, Medical School, Thessaloniki, Greece

We present two cases of angiomatoid fibrous histiocytoma (AFH) containing cystic epithelium-lined spaces. The tumors occurred in young women and were located in the subcutis of the lower extremities. On microscopic examination, they were moderately cellular and consisted of relatively uniform spindle or ovoid cells that

were arranged diffusely. A number of blood-filled cystic spaces were present. Hemosiderin deposits were observed. On immunohistochemical stains, the neoplastic cells were positive for vimentin and CD68, whereas stains for SMA, desmin, CD34, CD31, factor VIII-RA, S-100, EMA and various cytokeratins (CKs) were negative. In addition, the first tumor contained several cystic spaces of sweat duct origin, lined by a double cell layer with focal squamous metaplasia. On immunohistochemical stains, the inner layer of cells showed positivity for EMA and CKs cam5.2, AE1/AE3 and 17, while the outer layer was positive for SMA, and CKs cam5.2 and 17. The second tumor also contained a cystic structure, lined by keratinizing stratified squamous epithelium. To our knowledge, these are the first reported cases of AFH containing cystic epithelial inclusions of adnexal origin. These cases illustrate a mechanism of adnexal dilatation, which may be operative in neoplasms involving the dermis and subcutis, resulting in formation of tumors with unusual histologic features.

P017

Expression of Vascular Endothelial Growth Factor and its receptor, KDR/Flk-1, in Soft Tissue Sarcomas

Ann C. Goussia¹, Emiliou E. Pakos², Pericles G. Tsekeris³, Ioannis Nesseris¹, Evangeli S. Lampri¹, Dionysios J. Papachristou¹, Dimitrios Stefanou¹, Theodore Xenakis², Niki J. Agnantis¹
Departments of Pathology¹, Orthopaedics² and Radiation Therapy³, Medical School, University of Ioannina, 45110 Ioannina, Greece

Vascular endothelial growth factor (VEGF) is a protein that acts as a mitogen for endothelial cells and induces angiogenesis and changes in vascular permeability, both involved in tumor vascularization and growth. The aim of the study was to evaluate the association of VEGF and its receptor, KDR/Flk-1, with tumor grade, microvessel density (MVD) and clinical outcome in patients with soft tissue sarcomas (STSs). Tissue specimens of 28 patients with STSs were analyzed immunohistochemically using specific monoclonal antibodies. Tissue specimens were obtained prior to treatment. Half of the STSs exhibited strong expression of VEGF that was associated statistically significantly with high tumor grade ($p=0.006$). Strong expression of KDR/Flk-1 was detected in only 2 sarcomas. No association was demonstrated between VEGF and KDR/Flk-1 expression. MVD was significantly associated with tumor grade ($p=0.035$) and was higher in sarcomas with strong VEGF expression. Limited data on clinical outcome precluded solid analyses for an association with disease progression. This study provides further evidence on the role of VEGF and MVD in tumor aggressiveness in STSs.

P018

Sclerosing rhabdomyosarcoma in a young adult

S. Barbanis, E. Kostopoulou, M. Ioannou, M. Nakou, D. Kourtis, G. Koukoulis.
Department of Pathology, University Hospital, Larissa, Greece.

Rhabdomyosarcoma (RMS) is rare in adults, represented primarily by its pleomorphic subtype. Recent reports present a novel variant of adult rhabdomyosarcoma, characterized by hyalinizing, matrix-rich stroma and designated as "sclerosing RMS". Sclerosing RMS is rare in children, with 14 cases reported. Only eight cases of sclerosing RMS have been reported in adults. We present a case of a 26 year old man with a thigh tumor rapidly growing in the soft tissues and invading the femoral bone. The tumor and portion of the femoral bone were resected. The neoplasm showed moderate cellularity with short spindle cells embedded in a peculiar hyalinized matrix, reminiscent of primitive osteoid. No calcifications were present.

Areas of necrosis were found. Many neoplastic cells showed strong nuclear immunoreactivity for MyoD1 but not for myogenin, an immunophenotype closer to embryonal RMS. One year later, the patient developed metastasis in his right arm with similar histological and immunohistochemical features and died 10 months later, despite aggressive treatment.

Sclerosing RMS is a rare variant which can be easily mistaken for other sarcomas such as osteosarcoma, sclerosing epithelioid fibrosarcoma and chondrosarcoma. Recognition of this rare variant is important in order to avoid a diagnostic pitfall and in order to clarify if this morphologic variation reflects genetic or biologic/prognostic differences.

P019

Epithelioid MPNST: Report of two cases.

Gerasimidou D, Manthou M-E, Kontopoulos A, Hytiroglou P, Karkavelas G.
Department of Pathology, Aristotle University Medical School, Thessaloniki, Greece.

Five percent or less of malignant peripheral nerve sheath tumors exhibit epithelioid features (EMPNST), which can raise difficult issues of differential diagnosis. We present two cases of EMPNST, encountered in women (both 43 years of age), one of whom had a history of NF1. This patient developed a lobulated neck mass, measuring 8.2 cm. The second patient had a relapsing tumor occupying the left cerebellopontine angle and measuring 3 cm. On microscopic examination, both cases consisted of diffusely arranged spindle or oval neoplastic cells with clear or eosinophilic cytoplasm. The cells had round or ovoid nuclei, some containing prominent nucleoli. In the first case, the epithelioid cells formed fascicles and whorls, sometimes surrounding vessels. A large peripheral nerve was seen in the fibrous pseudocapsule surrounding the tumor. Both cases exhibited large areas of necrosis. Immunophenotype: Case 1: (+) for vimentin, S-100, Leu7, CD117; focally (+) for NSE, GFAP, SMA, cam 5.2, CD34, (mild), NF (rare cells); and (-) for desmin, AE1/AE3, EMA, HMB-45. Case 2: (+) for vimentin, NSE; focally (+) for S-100, Leu7, GFAP, NF, cam 5.2, AE1/AE3; and (-) for SMA, desmin, EMA, CD117, CD34, HMB-45. Our findings emphasize the importance of immunohistochemistry in making the diagnosis of EMPNST. History of NF1 and origin from a peripheral nerve, as seen in our first case, are strongly suggestive of this diagnosis.

Elastofibroma: Immunohistochemical Study of 5 Cases

Banu D. Gun*, Burak Bahadir*, Kemal Behzatoglu**, Mustafa O. Gun***, Sukru O. Ozdamar*
Departments of Pathology; Zonguldak Karaelmas University School of Medicine *, Istanbul Training and Research Hospital**, Zonguldak Ataturk State Hospital***, Turkey

Elastofibroma is a rare fibrous lesion characterized by accumulated abnormal elastic fibers and its etiology remains largely unknown. In this study, we analyzed five cases of elastofibroma to further explore the characteristics of its cellular composition and to learn more about their histogenesis. Immunohistochemistry was performed for mast cell tryptase, S-100, vimentin, CD34, smooth muscle actin (SMA) and collagen IV. Histochemical staining for Gomori's trichrome and Verhoeff elastica-von Gieson, were also evaluated. Histopathologically a haphazard array of collagen, eosinophilic amorphous fibers, and globules in a fibrous tissue was seen. The elastic nature of the fibers was confirmed by elastic stain and with trichrome, collagen fibers were also demonstrated. The interspersed spindle or stellate cells were almost consistently positive for vimentin and frequently

positive for CD34. Mast cell triptase positive cells were present in three of the cases; collagen IV immunoreactivity was seen in two. No staining was observed with SMA and S-100. In conclusion, these findings suggest that CD34-positive mesenchymal cells are an integral component of elastofibroma and the presence of mast cells may play a role in the production of abnormal elastic fibers as a constant of subclinical trauma and repair.

Soft tissue malignant tumors with epithelioid pattern - study of 15 cases.

Violeta Comanescu¹, Corina Gruia¹, Camelia Foarfa²,
Mirela Ghilusi¹, Iancu Emil Plesea², Bogdan Zaharia²
Departments of Pathology, ¹Emergency University Hospital,
²University of Medicine and Pharmacy, Craiova, Romania

Introduction, Aims: The study established the histogenetic type of soft tissue epithelioid malignant tumors using an immunohistochemical algorithm.

Materials and methods: 15 cases with epithelioid pattern were selected from a group of 135 soft tissue malignant tumors. Serial sections were stained with H-E and a wide panel of antibodies.

Results: 4 of the cases arised in males and 11 in women. Most of them were in the 5th and in the 7th decades of life. The most frequent sites of occurrence were the trunk and the lower limbs. In 1st step, 5 tumors were PCK. + and labeled as malignant synoviomas. In the 2nd step, the rest of 10 cases were all Vimentin + thus excluding neuroendocrin origin or other anaplastic tumors. In the 3d step, 3 cases were SMA +. and labeled as leiomyosarcomas. In the next step, 4 tumors were anti-S100 + and additionally, anti-HMB45 -, being thus considered malignant peripheric nervous sheet tumors. From the 3 cases S100 -, one case was CD31 CD34 + being considered angiosarcoma; one case, considered hemangioendothelioma, was CD31 + CD34 -; one was CD31 CD34 - and additionally anti-CD68+ being considered malignant fibrous histiocytoma.

Conclusion : The use of a guided multistep IHC algorithm resulted in establishing the correct histogenetic type in all studied cases.

Expression of bone morphogenetic proteins and their receptors in neural tumors

Cheva A, Hytiroglou P, Kotoula V, Papadimitriou C, Karkavelas G.
Department of Pathology, Aristotle University Medical School,
Thessaloniki, Greece

Bone morphogenetic proteins (BMPs) belong to the transforming growth factor β superfamily of proteins and play important roles in the regulation of cell survival, proliferation, differentiation and apoptosis. A variety of normal and neoplastic cell types have been found to express BMPs and BMP receptors. We investigated the expression of BMP-2, BMP-4, BMP-6, BMP-7, BMP receptor Ia and BMP receptor Ib in 12 paragangliomas, 5 pheochromocytomas and 7 glioblastomas multiforme by immunohistochemistry. Paragangliomas were characterized by moderate to strong, often extensive staining for BMP-6, while pheochromocytomas showed moderate to strong staining in significant numbers of tumor cells for all four BMPs assessed. Glioblastomas also showed moderate to strong positivity for all four BMPs, but the number of positive cells was usually small (<10%). All three tumor types were found to express BMP receptor Ia and BMP receptor Ib. These findings suggest that BMP signaling is involved in the development of these tumors. Despite their morphological similarities, paragan-

gliomas and pheochromocytomas may have different mechanism of development.

Axonal regeneration stimulated by erythropoietin after end-to-side nerve repair

Lykissas MG¹, Sakelariou A¹, Batistatou A², Korompilias AV¹, Mitsionis GI¹, Agnantis NJ², Beris AE¹.

¹Department of Orthopaedics, University Hospital of Ioannina, Greece, ²Department of Pathology, University Hospital of Ioannina, Greece

Aim of this study is to evaluate the effects of erythropoietin (Epo) in an end-to-side (e-t-s) nerve repair model. Forty-five male Wistar rats were evaluated in four groups: (A) e-t-s neurorrhaphy, (B) e-t-s neurorrhaphy and Epo administration for 20 days, (C) end-to-end neurorrhaphy, and (D) nerve stumps buried into neighboring muscles. Evaluation included functional and histologic examination, and wet weights of the tibialis anterior muscle. Quantitative evaluation included axonal counting and calculation of percent neural tissue (100 x neural area/intrafascicular area). During the first three weeks after surgery, the comparison between the four groups showed that there was significant difference between groups A, C, D and group B, with group B having clearly better results (P<0.001). However, there was rapid deterioration in the functional recovery when Epo's administration was discontinued. As a consequence, at the end of this study, erythropoietin failed to maintain its initial stimulating effect in axonal regeneration. Epo appears to facilitate peripheral nerve regeneration at the initial phase of its administration. Further investigation will be necessary to optimise the conditions (dose, mode of administration) in order to maintain its effects.

P024

Can end-to side neurorrhaphy bridge large defects?

Lykissas MG¹, Sakelariou A¹, Batistatou A², Vekris MD¹, Mitsionis GI¹, Agnantis NJ², Beris AE¹.

¹Department of Orthopaedics, University Hospital of Ioannina, Greece, ² Department of Pathology, University Hospital of Ioannina, Greece.

This study was undertaken to evaluate collateral sprouting capability in an end-to-side repair model with long regenerative distance. Forty-five male Wistar rats were divided into four groups: (A) end-to-side neurorrhaphy with regenerative distance of 0.6 cm, (B) end-to-side neurorrhaphy with regenerative distance of 1.2 cm, (C) end-to-end neurorrhaphy, and (D) nerve stumps buried into neighboring muscles. Evaluation 150 days after surgery included peroneal and tibial nerve histologic and morphometric examination, and wet weights of the tibialis anterior muscle. Quantitative evaluation included axonal counting and calculation of percent neural tissue (100 x neural area/intrafascicular area). Functional evaluation using Peroneal Function Index demonstrated that there was no statistically significant difference between groups A and B, neither between groups B and C (P>0.01). Statistically, the differences in muscle weight of the reinnervated tibialis anterior between groups A, B, and C were insignificant (P>0.01). Furthermore, preliminary data on axonal counting did not reveal significant difference between groups A, B, and C. Our data support that a collateral sprouting mechanism can effectively bridge 1.2 cm nerve gaps. Thus end-to-side neurorrhaphy may be useful for the repair of divided human nerves with long gaps.

Parachordoma or Myoepithelioma: Case Report

Kemal Behzatoglu*, Burak Bahadır**, Banu D. Gun**, Sule Canberk*, Erol R. Bozkurt*, Sukru O. Ozdamar**.
 Departments of Pathology; Istanbul Training and Research Hospital*, Zonguldak Karaelmas University School of Medicine **, Turkey
 Parachordoma is a rare soft tissue tumor with characteristic histologic appearance similar to chordoma. However, immunohistochemically they express different staining patterns; both chordoma and parachordoma express S100 protein, unlike chordoma parachordoma also expresses cytokeratins. Having significant differences in therapy and prognosis, the distinction between these two entities are clinically important. Histogenesis of parachordoma has remained uncertain. In the recent WHO classification, myoepithelioma and parachordoma were included in the same category. Studies suggesting that they should be regarded as separate entities also exist. The current case represents a 65-year-old woman with a slowly growing, immobile and deeply located mass on her left popliteal region. Microscopically, the tumor was composed of multinodular nests of epithelioid cells many with vacuolated cytoplasm resembling physaliferous cells typically found in chordomas. Immunohistochemically, the cells were reactive with GFAP, LMW cytokeratin, vimentin, S-100, SMA and calponin. In summary, histologic findings of the current case were typical of parachordoma; nevertheless immunohistochemistry supported a myoepithelial origin. Parachordoma needs to be studied more to uncover its nature.

Myxoid liposarcoma in a child. A comparative morphological and immunohistochemical study with benign pediatric adipose tumours

C. Kaprilian¹, A.M. Athanassiadou¹, K. Stefanaki¹, C. Van Vliet, Konstantinidou¹, E. Dimitriadis², A. Patereli¹, N. Pandis², O. Karentzou¹.
 Dept of Pathology¹, Aghia Sofia Children's Hospital, Dept of Genetics, ²Agios Savvas Anticancer Hospital, Athens Greece

Adipose lesions account for only 6% of pediatric soft tissue neoplasms, while liposarcoma comprises less than 1% of pediatric sarcomas. Prompted by the diagnosis of a myxoid liposarcoma in the thigh of a 11 year old girl, we have reviewed our archives for 7 years and investigated the features of adipose lesions. Our material comprised 29 lipomas, 9 lipoblastomas, 3 lipofibromatoses and 1 myxoid liposarcoma. The Steptavidin Biotin method was performed for the detection of Smooth muscle actin, Desmin, CD34, S-100, bcl-2, Ki-67, p53, p75/NGFR, c-kit. Three lipoblastomas were diffuse and 6 circumscribed, while the myxoid liposarcoma did not invade the adjacent skeletal muscle. Six lipoblastomas demonstrated a variable proportion of cellular and myxoid areas. S-100 and CD34 were detected in variable stellate cells in all lipoblastomas and the myxoid liposarcoma, while bcl-2, p75 and p-53 were detected in 2 lipoblastomas. Ki-67 was detected in 1-15% of the nuclei in lipoblastomas and in 5-15% of the liposarcoma. The diagnosis of myxoid liposarcoma was confirmed by the detection of the FUS/CHOP fusion gene by long PCR. Morphology and genetics play the major role in the differential diagnosis of pediatric myxoid liposarcoma from lipoblastomas.

P028

Extra-abdominal desmoid tumor. Case report and literature review

Ch. Tsobanidou¹, Th. Jivannakis², A. Kapraki², N. Papadopoulos³, A. Eleftheriadis⁴
¹Department of Pathology, Theagenio Anticancer Institute, Greece, ²Department of Pathology, General Hospital of Drama, Greece, ³Dep. Histopathology-Embryology, Democritus University of Thrace, Greece, ⁴Medical Center of Alexandria, Greece

Objectives: Desmoid tumor (aggressive fibromatosis) is an aggressive fibroblastic proliferation of well circumscribed, locally invasive, differentiated fibrous tissue. Is a rare tumor with a high potential for recurrence.

Case Report: We report a case of 59 years old woman with a slowly growing tumor on the buttock, which was completely surgically removed. Grossly the tumor was firm and whitish with ill-defined outline and with a diameter 4,5 cm. Microscopically composed of proliferating cells with features of fibroblast and smooth muscle cells without cytologic atypia or mitotic activity. These cells infiltrate the adjacent muscle bundles. Between the proliferated cells there are small amount of collagen. The diagnosis of desmoid tumor was done. The patient remains asymptomatic 43 months after surgery.

Conclusions: Desmoid tumor is a rare lesion having intermediate biological behavior between benign fibrous lesion and fibrosarcoma. Genetic, endocrine and physical factors have been implicated as causative agents. The diagnosis is made histologically. Reactive fibromatosis and fibrosarcoma must be eliminated in differential diagnosis. A high incidence of recurrence was seen. The rarity of cases in even anticancer centers has traditionally limited the ability to study this disease. The treatment of choice is a prompt radical excision including a wide margin of involved tissue. Adjuvant therapy, such as x-ray treatment, chemo-and hormone therapy, are indicated when the tumor is inoperable or too extensive for surgery.

P029

Desmoplastic small round cell tumor

Ch. Tsobanidou¹, N. Vladika¹, A. Dimasis², D. Paikos³, P. Xirou¹, Th. Toliou¹
¹Pathology Department, Theagenio Anticancer Institute, Thessaloniki, Greece, ²Surgery Department, Theagenio Anticancer Institute, Thessaloniki, Greece, ³Gastroenterology Department, Theagenio Anticancer Institute, Thessaloniki, Greece

Objectives: Desmoplastic small round cell tumor (DSRCT) is a rare, highly aggressive neoplasm with characteristic age incidence, anatomic location, histologic appearance, immunohistochemical profile and molecular genetic features. This tumor characterized by nests of small undifferentiated cells that show immunohistochemical evidence of epithelial mesenchymal and neural differentiation.

We report the morphologic and immunohistochemical features of a case of DSRCT

Material and Methods: A 29-year-old man presented to the hospital with a short history of severe hypogastric pain. Computed Tomography (CT) revealed an ovoid solid mass located within the mesentery, which attached to large bowel. Evaluation of metastatic disease yielded no evidence of metastasis. Laboratory values for human chorionic gonadotropin, alpha-fetoprotein and carcinoembryonic antigen were within normal limits.

Results: Macroscopically, the mass consisted of a well circumscribed, non encapsulated, ovoid, nodular tumor, measuring 8,5×8×5,5 cm. A segment of unremarkable large bowel was attached to the superior surface of the tumor. The surrounding omentum was studded with numerous variably sized but overall small tumor nodules.

Microscopically, the tumor and tumor nodules composed of compact nests of round and oval cells separated by desmoplastic stroma. The tumor cells were relatively uniform with round-to-oval hyperchromatic nuclei and inconspicuous nucleoli. The cytoplasm was scarce and the cell borders were indistinct. Mitosis were frequent. Immunohistochemically, the tumor cells showed strongly positivity for NSE, Neurofilament, Myoglobin, SMA, Vimentin, CEA, EMA, Ker 8/18, focal positivity for S-100, Ker AE1/AE3 and they were negative for Chromogranin, Calretinin, PLAP, TTF-1, CD-99, CD117, CerbB2, Synaptophysin, Desmin, Ker7, KerHMW.

The patient was treated with chemotherapy and was alive 14 months after the operation.

Conclusions: Tumors with divergent differentiation often posed problems of diagnosis particularly with regard to distinction from a number of small cell tumors. The immunohistochemical evidence is particularly useful to confirm the diagnosis of these rare tumors.

P030

Mechanisms of tumor progression in Kaposi's sarcoma.

MT Fernández-Figueras, L Puig**, E Musulen, RM Penín, C Ferrándiz*, G Sirera, I Bielsa*, A Ariza. Depts. of Pathology and Dermatology*, Hospital Universitari Germans Trias i Pujol, Badalona, Spain, and Dermatology**, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain

The most common clinical presentations of Kaposi's sarcoma (KS) in our environment are classic KS (C-KS), and AIDS-associated KS (AIDS-KS).

Objectives: Tissue arrays representative of 79 biopsy specimens of KS (51 AIDS-KS: 16 plaques, 16 tumors, 12 extracutaneous lesions and 7 regressive lesions, and 28 C-KS: 15 plaques and 13 tumors) were studied in order to compare mechanisms of tumor progression in both forms of KS.

Methods: We evaluated the immunohistochemical expression of molecules involved in cell cycle acceleration, apoptosis inhibition, angiogenesis and local invasion: p53, Skp2, p38, c-kit, Bcl-2, survivin, NFkappa, VEGFR2, VEGFR3, beta-catenin, CD44H, CD44v3, CD44v6, metalloproteinases (MMPs) 3,7,10,14,15,16 and 23, and tissue inhibitors of metalloproteinases (TIMPs) 1,2, 3 and 4. We also evaluated the intensity of HHV8 expression, proliferation index (Ki68), and presence of iron deposits.

Results: We found statistically significant differences between C-KS and AIDS-KS as regards the expression of survivin, VEGFR2 and MMP10 and, differences in the expression of HHV8, beta-catenin, p53, Skp2, Bcl-2, p38, VEGFR2, MMP10, TIMP3 and TIMP4 in relation to stage.

Acknowledgement: Work financed by Grant FIS PI020514 of the Spanish Ministerio de Sanidad y Consumo.

Soft tissue malignant tumors with small round cells - study of 21 cases

Camelia Foarfa¹, Serenada Bala², Stelian Danut Enache², Iancu Emil Plesea¹, Mirela Ghilusi², Bogdan Zaharia¹ Departments of Pathology, ¹University of Medicine and Pharmacy; ²Emergency University Hospital, Craiova, Romania

Introduction, Aims: The study established the histogenetic type of soft tissue small round cells (SRC) malignant tumors using an immunohistochemical algorithm.

Material and Methods: 21 cases with SRC pattern were selected from a group of 135 soft tissue malignant tumors. Serial sections were stained with H-E and a wide panel of antibodies.

Results: 9 of the cases arised in males and 12 in women. 1/3 of them were in the 7th decade of life. The most frequent sites of occurrence were the trunk and the lower limbs. In 1st step, all tumors were PCK. – excluding SRC carcinoma and polyphenotypic tumor. In the 2nd step, all cases were Vimentin, + suggesting the use of myogenic markers. In the 3d step, 11 cases were Desmin and Myoglobin + SMA – and labeled as rhabdomyosarcomas. In the next step, the remaining 10 tumors – to myogenic markers, were stained simultaneously for neuroendocrine markers and S100-protein. 5 cases were synaptophysin (Sy), chromogranin (Ch) and S100+ and considered as Ewing sarcomas. 4 cases were Sy and Ch – and S100 +, being considered as liposarcomas. The case Sy, Ch and S100 – and also CD31 CD34 –, CD68 – and collagen IV – was considered fibrosarcoma.

Conclusions: The use of a guided multistep IHC algorithm resulted in establishing the correct histogenetic type in all studied cases.

P032

Intraspinal Melanocytoma (A Case Report)

Banu D. Gun*, Burak Bahadir*, Mustafa O. Gun**, Sukru O. Ozdamar*, Gamze M. Kuzey***. Departments of Pathology; Zonguldak Karaelmas University School of Medicine*, Zonguldak Ataturk State Hospital**, Hacettepe University School of Medicine***, Turkey

Melanocytoma is a primary melanocytic neoplasms of the central nerve system and accounts for %0.06–0.1 of all brain tumors. These tumors are biologically benign and originate most frequently from the melanocytes of the leptomeninges that are derived from the neural crest. Here a rare case of melanocytoma in the spinal cord of a 49 year-old woman is presented. Histopathologically the tumor cells were arranged in tight nests, sheets and fascicles with a variable amount of pigment. Mitotic rates ranged from zero to one per 10 high-power fields and no necrosis was seen. Immunohistochemically positivity with S100 and HMB 45 favored melanocytic origin, but there were no reaction with GFAP, vimentin and EMA. It has been expressed that melanocytoma must be distinguished from other pigmented CNS lesions and especially from malign melanoma, that has a different biological behavior.

P033

Primary central nervous system lymphoma. A case report

Vasilakaki Th, Petrakopoulou N, Nikolaidou ME, Katsamagkou E, Zizi – Serbetzoglou A Department of Pathology, Tzaneion General Hospital of Piraeus, Piraeus, Greece

Primary central nervous system lymphoma is an uncommon form of non Hodgkin's lymphoma that has been increasing in incidence over the past three decades. It is seen in immunocompetent and immunodeficient population, the later group associated with the Epstein-Barr virus. The causative factors accounting for this increase in the number of cases are unknown. Primary central nervous system lymphoma can affect the brain, leptomeninges, spinal cord or eyes. PCNSL shows a male preponderance with a peak incidence in the 5th-7th decade (3rd-4th in AIDS). The initial symptoms are specific neurologic deficits, mental status changes, seizures and symptoms and signs of increased intracranial pressure (headache, nausea, vomiting). We report a case of a 72-year-old woman who came to our hospital with headache and neurological deficits for the last 2 months. CT scan image have shown a mass in the right bregmatic region. The diagnosis was based on the histological study of the specimen obtained through a stereotactic biopsy. The surgical specimen was histologically high malignant non Hodgkin Lymphoma of the diffuse large B cell type. Immunohistochemically the tumor cells were positive for LCA and L26 but were negative for EMA, cytokeratins, vimentin, GFAP, BerH2 and S-100 protein. After additional clinical and laboratory screening there was no other evidence of lymphatic disease. The patient was submitted to the anticancer hospital for further treatment. The majority of primary central nervous system lymphomas are large B cell variants of high grade malignancy. Low grade subtypes and T cell lymphomas are rare. The treatment is based on a combination of methotrexate based chemotherapy followed by whole brain radiotherapy. Unfortunately, treatment related neurotoxicity is common, especially in the elderly. Treatment of recurrence also remains controversial and the mortality rate is still high.

P034

Vascular endothelial growth factor immunohistochemical expression in meningiomas

Zagorianakou P¹, Voulgaris S², Zagorianakou N¹, Zissi A², Pachatouridis D², Polyzoidis K², Stefanou D¹, Agnantis NJ¹. Departments of Surgical Pathology¹, Neurosurgery², University Hospital of Ioannina, Medical School of Ioannina, Greece

Background: In human meningiomas, histological evaluation alone does not always predict the clinical outcome and behavior. Monoclonal antibody to Ki-67 (MIB1), a nuclear protein related to cell proliferation has therefore, become a potential tool in the histopathological grading of these tumors. Meningiomas are hypervascular tumors and require neovascularization for growth. Vascular endothelial growth factor (VEGF) is a key factor in vasculogenesis. Morphologically tumor vasculogenesis is assessed by measuring microvessel density (MVD). The purpose of this study was to investigate the MVD in 55 cases with primary diagnosis of meningioma, and the possible correlations with VEGF and ki-67 immunohistochemical expression, peritumoral edema and disease progression.

Methods: A total of 55 intracranial meningiomas, classified as benign (51cases), atypical (3 cases), and anaplastic (1 case) were analyzed. VEGF expression and microvessel density (MVD) were immunohistochemically investigated; the expression of CD34 was examined by immunohistochemistry so as to calculate the microvessel density (MVD).

Results: Six of the cases presented with recurrence during the period of observation (7.5 years). The histological type of primary tumor did not change in recurrences; with the exception of one case where classical initial tumor became atypical in recurrences. Cases with large peritumoral edema had elevated expression of VEGF. A statistical significant correlation was found between MVD and

VEGF ($p < 0.001$). A statistical significant correlation was found between VEGF and MIB-1 ($p < 0.001$). No significant statistical correlation was found between VEGF and Ki-67 ($p < 0.001$).

Conclusions: VEGF inhibition can be an attractive therapeutic strategy because it is highly specific and may be less toxic than cytotoxic therapy and best suited for long-term therapy. Antioangiogenic therapy in meningiomas may require additional studies and larger group of patients.

P035

The expression of tissue and serum VEGF in patients with brain tumours. The prognostic value

Miliaras G^{1,2}, Goussia A³, Kostoula A⁴, Katsaraki A⁵, Mitlianga P^{2,7}, Tachmazoglou F², Panelos J.D³, Kyritsis A^{1,6}, Stefanou D³, Levidiotou S⁴, Polyzoidis K^{1,2}.

¹ Neurosurgical Institute of University of Ioannina. Departments of Neurosurgery ² Pathology ³ Microbiology ⁴ Statistics ⁵ Neurology ⁶ of University Hospital of Ioannina, Greece

Brain tumours from sixty six patients were studied immunohistochemically for VEGF, flk-1 (the main of receptor of VEGF), CD34 (a microvascular density index), thrombospondin-1 (TSP-1) and MIB-1 expression. From preoperative blood samples full blood count was assessed in all patients, and using ELISA, VEGF was measured in the serum Serum VEGF was also measured in eight healthy controls. VEGF expression was statistically correlated to flk-1 expression and CD34 ($P < 0,001$). Moreover, MIB-1 (a strong prognostic factor) expression was correlated with VEGF, flk-1, and CD34 ($P < 0,001$). Serum VEGF was elevated only in patients with metastatic brain tumours compared to healthy controls ($P < 0,05$). The number of platelets in the peripheral blood was elevated according to the levels of serum VEGF ($P < 0,05$). In conclusion, like MIB-1, tissue VEGF, flk-1, and CD34 seem to have a prognostic value in patients with a brain tumour. VEGF in the serum can help differentiate patients with primary and secondary brain neoplasms. The platelets seem to intervene in VEGF circulation.

P036

Expression of EGFR, VEGF-R3 AND MDM-2 in human gliomas

Diamantopoulou K., Leodara V., Chranioti S., Thoma-Tsangli E. Pathology Dep., Gen. Hospital Asklepieio Voula, Athens, Greece.

Epidermal growth factor receptor (EGFR) is considered to play a major role in the control of cell proliferation and contribute to the evolution of human gliomas. Vascular endothelial growth factor (VEGF) and its receptors (VEGF-R) are involved in tumor angiogenesis and are variably detected in human low and high grade gliomas. MDM-2 protein, related to the pathway of tumor suppressor gene p53, may be involved in progression of gliomas and play an important role as a prognostic marker. The expression of EGFR, VEGF-R3, MDM-2 and Ki-67 (MIB-1) was analyzed by immunohistochemistry in 15 human gliomas, 12 (80%) of which were high grade (gr III & IV) and 3 (20%) were low grade (gr II). The expression of EGFR was different in intensity and distribution in 88,89% of high grade gliomas, with no expression in low grade gliomas. VEGF-R3 was expressed in 85,71% of gliomas (glioblastomas, astrocytic gliomas gr II & III, and oligodendrogliomas). MDM-2 was mainly expressed in high grade gliomas (75%). Low grade gliomas did not express MDM-2. MIB-1 (Ki-67) indices showed a highly significant increase from low grade gliomas (mean 1,33%) to high grade gliomas (mean 12,67%). The importance of EGFR, VEGF-R3 and MDM-2 expression is correlated to therapy. Especially, the treatment of glioblastoma multiforme, except for the

conventional surgical resection and radiotherapy, may include new therapies like anti-angiogenic agents and EGFR-inhibitors. MDM-2 expression is correlated to drug chemoresistance.

P037

Profound Hypothermic Circulatory Arrest is Associated with Increased Bcl-2 Immunoreactivity in Selectively Vulnerable Brain Regions

Bibou AN¹, Ananiadou OG², Charchanti A¹, Drossos GE², Bai M³, and Johnson EO¹.

¹Department of Anatomy-Histology-Embryology, ²Department of Cardiac Surgery, and ³Department of Pathology, University of Ioannina, Medical School, Ioannina, Greece

Profound cooling to 10 C compared to traditional 18 C was found to significantly reduce neurological injury during HCA as assessed by the Tunel assay. The present study assesses the effects of HCA at both 18 C and 10o C on Bcl-2 expression in the porcine brain. 12 piglets underwent 75 minutes of HCA after cardiopulmonary bypass at 18 C (n=6) and 10 C (n=6), and 4 were normal controls. After 80 minutes of gradual rewarming and reperfusion, brains were collected. H/E histology was used as counterstaining. Bcl-2 positive cells were scored on a scale of 0 to 3 (0: negative; 1: weakly positive; 2: positive; 3: moderately positive) and were compared using the Mann Whitney-U test. Positive bcl-2 immunostaining was observed in the neocortex and hippocampus. The cerebellum, medulla and thalamus were negative for Bcl-2. Profound cooling to 10oC resulted in a significant increase in bcl-2 immunostaining in the neocortex as compared to 18o C (P<0.05). These findings support the activation of anti-apoptotic mechanisms and mechanisms of cell survival during profound hypothermia.

P038

Caspase-3 immunohistochemical expression correlates with ssDNA expression and predicts early recurrence of patients with intracranial meningiomas

Konstantinidou A.E.¹, Givalos N.¹, Gakiopoulou H.¹, Korkolopoulou P.¹, Agrogiannis G.¹, Kotsiakis X.², Boviatsis E.³, Mahera H.⁴, Patsouris E.¹.

¹Department of Pathology, Medical Faculty, National Kapodistrian University of Athens, 75 Mikras Asias, 11527, Athens, Greece, ²Department of Neurosurgery, General Hospital of Hania, Creta, Greece, ³Department of Neurosurgery, "Evangelismos" Hospital, Athens, Greece, ⁴Laboratory of Pathology, "KAT" General Hospital, Athens, Greece

Caspase-3 is the ultimate executioner caspase that is essential for the nuclear changes associated with apoptosis. In this study, we investigated caspase-3 immunohistochemical expression (CPP32) in 56 primary nonmalignant intracranial meningiomas in relation to baseline apoptosis - as illustrated by the expression of anti-single stranded DNA (ss-DNA), the antiapoptotic protein bcl-2, proliferation indices (Ki-67, PCNA, topoisomerase IIa, mitosis C), hormonal status (estrogen, progesterone, androgen receptors), standard clinicopathological parameters and patients' disease-free survival. Immunostaining for caspase-3 was observed in 60.7% of cases and its labeling index (LI) was significantly correlated with ss-DNA LI (p=0.038), as expected. Caspase-3 LI positively correlated with the mitotic index (p=0.001) and PCNA LI (p=0.004). Grade II meningiomas demonstrated a significantly increased caspase-3 labeling index (p<0.0001), as related to grade I tumors. In univariate and multivariate survival analyses caspase-3 predicted meningioma recurrence, independently affecting disease-

free survival (p=0.011 and p=0.047 respectively). The apoptotic index and mitosis LI were additional prognosticators of shorter disease-free survival. Our findings confirm previously published observations on the prognostic implication of apoptotic markers in meningioma recurrence. Caspase-3 may prove to be a useful predictor of early recurrence in this group of neoplasms characterized by the frequent discordance between histology and clinical behavior.

Malignant Solitary Fibrous Tumor of the Tongue

Parasi A, Pantoula P, Mennonna R, Sotiriou E, Karayannis M, Karakosta A, Moschovakis E*. Pathology and Otolaryngology* Department, General Hospital of Nikaia-Piraeus «Agios Panteleimon», Greece

A case of malignant solitary fibrous tumor of the tongue is reported. The patient, a 25 year old man, presented with a nodular lesion, infiltrating the lingual muscle, measured 1cm in maximum diameter. Microscopically, areas of the tumor had a patternless spindle cell appearance with collagenized stroma and thin-walled branching vessels. A transition to a more cellular area, consisting of round epithelioid cells with prominent nucleoli and high mitotic activity (6 mitoses per 10 HPF) was found. Immunohistochemically, the tumor cells stained for Vimentin, CD34 and CD99, while pan-keratin, EMA and S-100 protein were negative. The patient underwent a broader excision and is now free of disease within a follow up period of 21 months. The diagnostic difficulties in the recognition of this neoplasm in unusual sites and the differential diagnosis of CD34-positive mesenchymal neoplasms are discussed. Solitary fibrous tumors of the tongue are extremely rare and this is the second reported malignant case in literature.

P040

VEGF in inverted sinonasal papillomas

Čorić M., Bilić M., ¹Nagy P., Brčić L., Batelja Vuletić L., Bura M., Seiwert S. Institute of Pathology and ENT Clinic Medical Faculty University of Zagreb, Croatia; ¹National Medical Center Budapest, Hungary

Although for inverted papillomas (IP) local aggressiveness and marked tendency to recur have been known for decades, association with squamous cell carcinoma (SCC) is still a subject of investigation since neither histologic feature nor local aggressiveness can be used as prognostic marker. According to our previous results and to results of other p53 and Ki67 immunohistochemistry have some diagnostic but little prognostic potential. We analyzed 50 cases of IP including 6 cases of synchronous SCC. The patients had diagnosed IP in the period from 1982 to 2005 at the Departments of Pathology, University in Zagreb, University of Osijek and the National Medical Center Budapest, Hungary. Immunohistochemistry for VEGF was performed according to manufacturers' specification (Santa Cruz, USA). A PC based image analysis system (ISSA/SFORM, Vamstec, Zagreb) was used to determine the rate and intensity of nuclear staining. The histological pattern and intratumoral distribution of immunoreactivity was accessed together with the immunoreactivity of neighboring normal epithelium. Although the normal sinonasal epithelium shows VEGF immunoreactivity, the epithelium of both benign and malignant inverted papillomas demonstrated stronger reactivity following the histological pattern.

P041

Expression of annexin, and decorin in the corneas of cats with mucopolysaccharidosis VI

C Mura, O Villa, M Haskins, J Alroy. New England Medical Center, Tufts University Schools of Medicine and Veterinary Medicine, Boston, MA; University of Pennsylvania, School of Veterinary Medicine, Philadelphia, PA

Background: Lysosomal storage diseases are a group of over 45 distinct inherited disorders. Lysosomes are a recycling center they catabolize cellular and extracellular macromolecules and provide substrate for resynthesis of cellular and extracellular molecules. A common biochemical feature of lysosomal storage diseases is the intra-lysosomal accumulation of undegraded or partially degraded substrate leading to cell dysfunction. One of the phenotypic characteristic of human and animals affected with mucopolysaccharidosis (MPS)-I, (Hurler disease) and MPS-VI (Maroteaux-Lamy disease) is cloudy cornea. MPS-I there is deficient activity of α -L-iduronidase, and storage of dermatan sulfate and heparan sulfate. In MPS-VI there is deficient activity of arylsulfatase B and storage of dermatan sulfate. Currently morphologic explanations for this clinical manifestation include the presence of enlarged secondary lysosomes packed with storage material and the disorganization of collagen in the corneal matrix; however, the molecular basis remains unknown.

Results: Using differential display proteomic analysis we previously showed expression of α , β and γ crystallins in corneas of cats with MPS-I and MPS-VI. Subsequent analysis also indicated changes of expression of decorin and annexin. To confirm these results we have used Western blot analysis and specific antibodies against decorin and annexin. To determine the levels of expression of these two genes they were normalized against β -actin as housekeeping gene. Preliminary results indicate upregulation of decorin between normal cat corneas and MPS-VI cats corneas. In contrast, annexin expression appears down regulated when normal cat corneas are compared with corneas of MPS-VI cats.

Conclusions: In the current study we demonstrate that interruption of recycling of dermatan sulfate caused by deficient enzyme activity in MPS-VI leads also to an accumulation of decorin, which is the protein component of proteoglycan to which the dermatan sulfate is attached. Although the accumulation of decorin resulted in upregulation of α , β and β crystallins, there is down regulation of annexin. The α , β and β crystallins have a chaperone-like activity that is needed to degrade the accumulated decorin

P042

Mesectodermal leiomyoma of the ciliary body

T. Koletsa, G. Karayannopoulou, P. Hytiroglou, C. Papadimitriou. Department of Pathology, Aristotle University Medical School, Thessaloniki, Greece

We present a case of mesectodermal leiomyoma of the ciliary body emphasizing the immunohistochemical features of this rare tumor and the differential diagnosis from malignant melanoma. A 53 year-old woman presented because of decrease in visual acuity. On examination, a ciliary body tumor was found in the right eye. A malignant melanoma was highly suspected due to her age and the growth rate, and the globe was enucleated. A well-defined ciliary body tumor was found on macroscopic examination, measuring 12x9x7mm. The lesion was moderately cellular and consisted of spindle and ovoid cells with normochromatic, mostly roundish nuclei. There was no appreciable mitotic activity. Immunohistochemical stains revealed positivity of the tumor cells to vimentin, smooth muscle actin, caldesmon, CD56 and NSE. Stains for desmin, cytokeratins AE1/AE3, chromogranin, synaptophysin, NF, Leu-7, S-100, peripherin, GFAP, CD34, CD117, CD105, calcitonin, EGFR

and fascin were negative. On Ki-67/mib-1 stain less than 1% of tumor cell nuclei were positive. Mesectodermal leiomyoma is considered to originate from the ciliary body smooth muscle, which is a neural crest derivative. In a review of the literature we found only 15 cases of this tumor. Pathologists should be aware of this rare entity that often masquerades as malignant melanoma on clinical examination.

P043

Primary ameloblastoma of the maxilla diagnosed by FNA. cytological and immunocytochemical features

Bobos M¹, Mandrali A¹, Koletsa T¹, Telioussi S¹, Asimaki A², Kommata A³, Ioannou-Banava O¹
Departments of Cytopathology¹, Pathology² and Oral and Maxillofacial Surgery³ General Hospital "G. Papanicolaou", Thessaloniki, Greece

Ameloblastomas (ABL) are extremely rare tumors and represent the most frequent primary epithelial odontogenic neoplasms. We present a case of a 60 years-old male patient with a painless cystic non-tender mass in the right maxilla. FNA was performed and the material was processed using Thin-Prep method. The material showed a moderate cellularity. The predominant population was composed of small round cells, arranged in clusters or nests with vague peripheral palisading, little cytoplasm and hyperchromatic nuclei. The cytologic pleomorphism was minimal. The specimen also contained small number of squamous epithelial cells, singly or in small nests, foamy macrophages and neutrophils. On immunocytochemical investigation the neoplastic cells were positive for cytokeratins 5 and AE1/AE3 and negative for cytokeratin CAM5.2. Based on cytomorphology and immunocytology the case was diagnosed as ameloblastoma. Following complete excision of the mass, the histopathological examination was consistent with follicular ameloblastoma. Cytologic features of ameloblastoma are unique and well defined, suggesting that FNA is a valuable tool in the initial diagnosis.

P044

Caspase-3 expression in head and neck squamous cell carcinoma

Maky Hafidh, Andrew Jones, Tim Helliwell.
Departments of Pathology and Surgery,
University of Liverpool, Liverpool, U.K.

Caspase-3 is a key protease involved in the initiation of apoptosis. Expression has been linked to apoptosis in several human malignancies but there is little information on its role in head and neck carcinomas. The objective of this study was to evaluate the patterns of expression of caspase-3 in head and neck squamous carcinomas and to examine the association with other apoptosis-related markers and prognosis. A tissue microarray was created from archived wax blocks of 200 primary squamous carcinomas (83 larynx, 72 pharynx and 45 oral cavity). 75 cases had tissue from nodal metastases available for study. Immunocytochemical labelling was performed for caspase-3, p53, mdm2, bcl-2 and bax proteins. Caspase-3 labelling is seen in both the nucleus and cytoplasm of a small proportion of malignant cells, and in apoptotic nuclear debris. Nuclear labelling is present in a mean of 3.79% cells in laryngeal carcinomas, 2.53% cells in pharyngeal carcinomas and 2.09% cells in oral carcinomas. A similar extent of expression occurs in primary carcinomas and their nodal metastases. The % cells showing nuclear caspase-3 expression correlates with poorly-differentiated carcinomas and with nodal metastasis. Cytoplasmic caspase-3 expression does not show similar correlations. Nuclear caspase-3 expression is positively correlated with the expression of mdm-2, bax and survivin, and negatively correlated with involucrin expression. We conclude that nuclear caspase-3 expression may be a useful measure of apoptotic activity in head and neck squamous carcinoma.

P045

Nerve growth factor p75 receptor, cytokeratin 18 neoantigen expression and TUNEL data in human normal salivary gland and pleomorphic adenoma

Groma V.¹, Kazanceva A.², Kornevs E.².¹Institute of Anatomy and Anthropology and ²Department of Oral Maxilla Facial Surgery, Riga Stradins University, Riga, Latvia

It has been generally appreciated that pleomorphic adenoma shows a great degree of pathohistological variability, which, in turn, reflects peculiarities of the epithelial component differentiation and growth pattern as well as the stromal component morphological diversity. Modulations of cell proliferation and biological behaviour of this tumour are common, and reflect the action of some genetic, environmental and other factors. A mechanism which regulates the balance of proliferative activity and apoptosis in this tumour is not completely understood. The aim of this study was to evaluate the occurrence and extent of apoptosis based on appearance of nerve growth factor p75 receptor (p75), cytokeratin 18 neoantigen expression, and terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick-end labeling method (TUNEL) in human normal salivary gland and pleomorphic adenoma. The estimation of morphological details of cell death events was assessed by immunohistochemistry applying the anti-p75 antibody and M30 antibody for evaluation of the cytokeratin 18 cleavage, as well as by use of TUNEL kit. The salivary gland tissue (N=7) was obtained during parotidectomy and fixed according to standard light microscopy procedure in 10% formalin, embedded in paraffin. Immunohistochemistry was performed using ABC peroxidase kit according to the manufacturer's instructions. Identification of positive nuclei for DNA fragmentation was performed after application of TUNEL kit. The results of the pleomorphic adenoma analysis were compared with those obtained from the residual normal nontumorous gland parenchyma and, additionally, with gland parenchyma obtained during surgery for the removal of the entire gland because of sialolithiasis and sialadenitis. P75 consistently displayed membrane reactivity in myoepithelial cells arranged as a continuous layer around normal ducts and acinar parenchyma units, vascular adventitia and nerve bundles. This myoepithelial expression became stronger in case of sialolithiasis with prominent atrophy (N=2) revealing the presence of immunostaining around the remnants of the lobular units. In pleomorphic adenoma p75 expression was detected on the myoepithelial cells outlining ductal structures, and in some solid proliferative zones composed by myoepithelial-like cells. Positive M30 reaction products were found in the cytoplasm of acinar cells in the restricted lobules of nontumorous gland parenchyma and parenchyma obtained due to sialolithiasis and sialadenitis, as well as in the luminal contents of duct-like structures in pleomorphic adenomas. In the normal salivary gland cells with different pattern of cytoplasmic positivity, from weak to very strong, were found. The cytokeratin cleavage product localization was restricted to the lobular parenchyma, but not the chondroid and osseous (N=2) stroma. Identification of apoptotic nuclei DNA fragmentation in human normal salivary gland and parenchyma removed due to sialolithiasis revealed some TUNEL-positive cells nuclei within lobular acinar units. The TUNEL-positive cells nuclei were also present in the inflammatory parenchyma areas in case of sialadenitis, the occasional reactivity was restricted to these areas lymphocytes. In pleomorphic adenoma apoptosis was suppressed – TUNEL reaction was negative. These results suggest that suppression of apoptosis takes a place in case of pleomorphic adenoma comparing with normal salivary gland. Suppression of death events in particular epithelial and/or stromal cells may cause changes that are thought to be linked to the growth of tumour. The values of different cell death markers – cell surface, cytoplasmic as well as DNA fragmentation applied in this study require a further elucidation and explanation. Detection of DNA fragmentation by TUNEL method seems to be

sensitive; identification of cytoskeleton cleavage along apoptosis process can be additionally used for evaluation of extent of apoptosis; the varying degree of staining may reflect the stage of process.

P046

STRUCTURAL MARKERS OF THE GUM TISSUES REMODELLING AT PATIENTS WITH CHRONIC PERIODONTITIS

Valentina M Mudra, Olga S. Reshetnikova, Sergiy A. Morozov. Department of Pathologic Anatomy, Lugansk State Medical University, 1, kv. 50-let Oborony Luganska, 91045, Lugansk, Ukraine

Numerous data suggested that periodontal diseases have high incidence rate worldwide Treatment plans involving tooth replacement, often used for sites diagnosed with chronic periodontitis (CP). Thus, there is a problem of finding pathogenetically based methods of structural changes correction in gum in case of CP. Morphological study was undertaken to help further evaluate gum tissues remodelling with and without pre-implantation treatment of CP. Methods. 10 gums biopsies were taken from volunteers without CP symptoms (group of comparison), 10- from patients with CP undergoing surgical operation without therapy (group 1) and 10- from CP patients with pre-implantation treatment by glutarginum and vector-therapy (group 2). Histological slides were studied stereologically. Collagen I and III types were stained with specific antibodies. The results have shown that the increase of volume fractions of inflammatory infiltrates, vessels, foci of periodontal connective tissue dystrophy and necrosis are determined in group I. Immunohistochemical analyses showed that both expression and distribution of the I type collagen was diminished here too. Unlike this, the III type collagen was registered here more often with increased intensity of expression. In group 2 the resulting data clearly demonstrate a reduction of hyperemia, vessels number, inflammatory infiltrates and areas of connecting tissue dystrophy. Type I collagen dominated over the III type collagen expression. These findings suggested the CP without adequate treatment stimulates the forming of immature connective tissue and persistent inflammation in the gum of patients. There is braking of repair processes, which can unfavorably affect implant osteointegration. The use of glutarginum, possessing antioxidant and membranes protective properties, in conjunction with the mechanical debridement by vector-therapy, allows normalizing gum tissue's metabolism, to recover the normal parameters of collagen stromal components. These seem to be effective in maintaining structure and function of the gums and periodontal tissues at pre-implantation period of patient's treatment.

P047

The Value of CDX2 and P63 in diagnosis of Primary Intestinal-Type Sinonasal Adenocarcinomas

Parasi A, Pantoula P, Karayannis M, Sotiriou E, Mennonna R, Karakosta A. Department of Pathology, General Hospital of Nikaia-Piraeus «Agios Panteleimon» Greece

Objectives: Non Salivary Sinonasal Adenocarcinomas are rare, interesting tumors, divided into intestinal (SN ITACs) and non-intestinal type of low and high-grade differentiation. SN ITACs are morphologically similar to intestinal type GI adenocarcinomas, especially colonic adenocarcinomas and share the same immunohistochemical features, with the exception of the variability in CK7 and CK20 expression. Cdx2, the highly specific for intestinal type adenocarcinomas marker, has recently been demonstrated in ITACs, allowing their distinction from the non-intestinal type. P63, on the other hand, is consistently expressed in SN Non Keratinizing

Squamous cell Carcinomas (NKSCCs). The possibility of p63 expression in SN ITACs, due to their common origin from Schneiderian epithelium, has not, to our knowledge, been examined.

Methods: Antibodies to Cdx2, p63, CK7 and CK20 were used to examine 8 (biopsy and surgical material of 4 patients) primary SN adenocarcinomas of moderate to low differentiation with intestinal type morphology. The expression of cdx2 and p63 was also examined in 5 colonic and 5 intestinal type gastric adenocarcinomas and in 5 NKSCCs.

Results: All specimens of SN adenocarcinomas (100%) were diffusely positive for Cdx2, even the isolated tumor cells in cases with almost necrotic biopsy material. All intestinal type GI adenocarcinomas were also diffusely positive and, as expected, all NKSCCs were negative. In 3 out of 4 patients (75%), a focal (5%–25%) p63 nuclear positivity was found, especially in cells with oval or elongated nuclei in more solid areas of the tumors. The NKSCCs were diffusely p63 positive and the GI adenocarcinomas were negative. CK7 and CK20 expression in ITACs was variable: 2 cases were CK20-positive and CK7-negative (colonic type immunophenotype), 1 case was CK7-CK20-positive and 1 case was CK7-CK20 negative.

Conclusion: Cdx2 appears to be a sensitive marker for the diagnosis of SN ITACs, even in small biopsies and in lower-differentiated tumors. P63 expression, although only focally found, could be a useful complementary marker for the recognition of SN ITACs and the exclusion of a metastatic intestinal type GI adenocarcinoma in the Head and Neck region. The specific value of this marker needs to be evaluated in additional studies.

P048

Molecular detection of Epstein – Barr virus (EBV) in nasopharyngeal carcinoma

Ceausu Mihai, Iosif Cristina, Butur Georgeta, Georgescu Alina G.M., Florea Gramada Zenaida, Ardeleanu Carmen

“Victor Babes” National Institute of Pathology, Splaiul Independentei, 99-101, sector 5, 050096, Bucharest, Romania

EBV is the etiological agent of infectious mononucleosis, but it can determine also, various types of cancer: nasopharyngeal undifferentiated carcinoma, Burkitt lymphoma, esophageal or gastric carcinomas. The study was carried out on 9 formalin fixed paraffin embedded samples of nasopharyngeal type undifferentiated carcinoma (with different locations: ethmoidal sinus and maxillar sinus), using the indirect triserial ABC method for IHC detection of EBNA2 nuclear antigen and latent membrane protein of Epstein-Barr virus (LMP-EBV), as well as in situ hybridization (ISH) for the Epstein-Barr RNA transcripts EBER 1. A positive reaction for LMP-EBV or EBNA 2 was founded in 4 cases (44%). The IHC reaction showed positivity in cytoplasm for LMP-EBV and nuclear for EBNA 2. These tumors had a high proliferating index demonstrated by PCNA stain, in correlation with IHC stain for EBV antigens in tumor cells. ISH for EBV RNA transcript EBER1 confirmed infection in all 4 cases with positive IHC reaction. IHC expression of LMP-EBV may be one stage in the diagnosis of undifferentiated nasopharyngeal carcinoma, Epstein-Barr virus infection being closely associated with the development of this type of tumor. Also, the etiological identification of EBV can be completed by molecular techniques such as ISH for EBV RNA transcript EBER1.

P049

Initial diagnosis of T cell lymphoblastic lymphoma in parotidectomy for warthin tumor. A rare colision tumor.

K. Giaslakitiotis¹, K. Kokkori¹, P. Alexandrou¹, E. Bariami², P. Korkolopoulou³, A. Androulaki¹

¹Department of Pathology, ²First Department of Internal Medicine,

³Pathology Laboratory, University of Athens Medical School, Laiko General Hospital, Mikras Asias 75, 115 27 Athens, Greece

Warthin tumor (WT) is a benign neoplasm of the salivary gland epithelium composed of varying proportions of bilayered columnar and basaloid oncocytic epithelium associated with lymphoid stroma. The latter, uncommonly, may give rise to or be involved by malignant lymphoma. We report a case of T-cell lymphoblastic lymphoma (TdT +, CD99+, CD3 +, CD5 +, CD 43 +, CD4 +, CD8-) initially diagnosed in the WT diagnostic specimen. Staging procedures immediately after diagnosis demonstrated disseminated disease (stage IVA). The patient received combination chemotherapy treatment. 6 months after remission he is free of relapse. To best of our knowledge this is the first report in the English literature of a collision tumor composed of T-cell lymphoblastic lymphoma and Warthin tumor. Our report indicates that the lymphoid stroma of WT, as part of the systemic lymphoid tissue, is likely to be involved in disseminated lymphoma. The association of a T-cell lymphoblastic lymphoma with Warthin tumour does exist, although extremely rare.

P050

Salivary gland carcinomas express c-erbB2 oncoprotein according to different subtypes.

Kiziridou A., Moysidis I., Andreadis Ch., Maganaris A. Toliou T. Pathology Department, “Theagenion” Anticancer Hospital, Thessaloniki, Greece.

Objective: Salivary gland carcinomas (SGC) are rare neoplasms (less than 1% of all cancers) thus there are limited data about the biological behaviour and the appropriate therapeutical management. This study will attempt to evaluate the use and incidence of immunohistochemical marker c-erbB2 in SGC.

Materials and Methods: We studied 32 samples from salivary gland carcinomas (8 mucoepidermoid, 10 adenoid cystic and 14 adenocarcinomas) using the monoclonal antibody p185/Her2 for immunohistochemical detection of the oncoprotein. Expression was positive if more than 10% of the neoplastic cells expressed strong (3+) or moderate(2+) membrane staining.

Results: 1/8 mucoepidermoid carcinomas and 10/12 adenocarcinomas expressed moderate and strong immunoreactivity with the antibody. None of the adenoid cystic carcinomas was positively expressed.

Conclusions: The c-erbB family gene products are expressed in salivary gland carcinomas. The overexpression is frequently associated with high grade tumors and poor prognosis. Given the suboptimal response rate and toxicity of chemotherapy, a complete understanding of the biology of these tumors may allow a better prognosis and an improved treatment strategy. With the emergence of molecular targeted therapy they become an optimal candidate for trials of new drugs.

P051

Kaposi's sarcoma of the nasal mucosa

Venizelos I¹, Andreadis H², Tasiou Z¹, Chatzitoliou A¹, Moulla A¹

¹Department of Pathology, Hippokratio General Hospital,

²Department of Internal Medicine, Theagenio Hospital, Thessaloniki, Greece

Kaposi's sarcoma (KS) is an unusual vascular tumor characterized by multiple reddish blue nodules, which usually present on the skin of the lower and upper extremities. KS may also involve mucosal sites, lymph nodes and visceral organs. During the last two decades, with the large increase in the incidence of this tumor associated with the acquired immune deficiency syndrome (AIDS), there has been increasing number of cases with KS presenting on the skin or mucosa of the head and neck. A review of the literature

revealed that only one case of KS of the nasal cavity has been reported. We report the case of a 59-year-old woman who presented 4 years ago with a tumor in her left nasal vestibule, associated with nasal obstruction and rhinorrhea. Physical examination revealed the presence of a fleshy tumor arising from the nasal septum, which was excised. Histological examination of the tumor showed morphological and immunohistochemical features of Kaposi's sarcoma. The tumor was excised within free surgical margins. A complete physical and laboratory examination revealed no other pathological findings. The patient received no further treatment and 4 years later she is in a good condition. In the present study we report a very rare case where the primary manifestation of the KS was in the nasal mucosa in a patient with an adequate immune system.

P053

Acute growth hormone administration enhances angiogenesis in a porcine model of myocardial infarction

K Hatzistergos, A Mitsi¹, L Pappa, D Niokou², GG Baltogiannis¹, A Papalois³, T Kolettis¹, V Malamou-Mitsi.
Departments of Pathology, ¹Cardiology, ²Anaesthesiology, University of Ioannina, Ioannina Greece, ³ELPEN Research Laboratory Athens Greece.

We examined the angiogenic effects of a single, high dose of Growth Hormone (GH), administered acutely after myocardial infarction (MI) in pigs. MI was generated in 35 pigs while 5 were sham operated. Ten minutes after reperfusion, pigs were randomised (2:1) to GH (1 IU/kg) or normal saline (NS) and sacrificed 4 weeks later. Immunohistochemistry against α -smooth muscle actin (Biogenex) was performed in a) infarcted myocardium (IZ) and subendocardium (SIZ), b) remote noninfarcted myocardium (NIZ) and subendocardium (SNIZ) c) border zone (BZ). Positive stained vessels with obvious lumen and diameter $<20\mu\text{m}$, (neovessels) were counted by three independent observers, blinded to treatment assignment. Microvascular densities (MVD, number of neovessels per high power field) were compared using oneway ANOVA, followed by Tukey's multiple comparisons test. Results are shown in table 1. Intracoronary GH administration enhanced angiogenesis in the IZ, the BZ and the NIZ.

Table 1 Microvascular densities

	IZ	SIZ	BZ	NIZ	SNIZ
NS	66, 2±27,5	64, 6±46,8	68, 9±56,5	78, 1±86,1	33, 9±12,9
GH	91, 5±23,1*	178, 3±59,8*	129, 8±48,8*	196, 8±70,9*	172, 8±69,9*
SHAM				53, 8±18,3	48, 2±9,9

*p<0.05 compared to either NS or sham (where applicable)

Batista's partial left ventriculectomy: histomorphometric semiquantitative assessment one-year later

Jovan D. Vasiljević, Petar Otašević, Siniša Gradinač, Sofija Glumac, Zoran V. Popović, Aleksandar Nešković
Institute of Pathology, Belgrade University School of Medicine, Serbia and Montenegro Dedinje Cardiovascular Institute, Belgrade, Serbia and Montenegro

Objectives: Left ventricular contractility may be improved by partial left ventriculectomy (PLV) in patients with severe heart failure. Histological assessment by using semiquantitative morphometric parameters of the left ventricle after surgery, and endomyocardial biopsies (EMB) one-year postoperatively.

Method: The study group consisted of 15 consecutive PLV survivors, predominantly male (13/15), aged 45±12 years. Surgical specimens were taken from the inferior- and/or lateral wall of the LV, processed routinely, and stained with Masson-trichrome. Postoperative EMB, 3 to 5 per patient, were taken 12 months later and processed in the same manner. The following morphometric parameters were assessed: (1) degree of hypertrophy and attenuation (fibre diameter); (2) nuclear evidence of hypertrophy (diameter); (3) myofibrillar volume fraction; (4) degree of degenerative, vacuolar changes, and (5) fibrosis volume fraction. These parameters were graded in the usual fashion (0-none, 1-mild, 2-moderate, 3-severe).

Results : Both NYHA functional class and EF improved 12 months following operation as compared to preoperative values (2.40±0.69 vs. 3.33±0.49, p<0.001, and 33.21±12.05% vs. 20.21±9.07%, p<0.001, respectively). Semiquantitative morphometric analysis demonstrated postoperative decrease in the degree of attenuation as compared to preoperative values (1.40±0.51 vs. 2.47±0.64, p<0.01), as well as decrease in fibrosis volume fraction (2.07±0.80 vs. 2.67±0.49, p<0.001) and nuclear hypertrophy (1.27±0.46 vs. 1.67±0.62, p<0.05). There was postoperative increase in myofibrillar volume fraction (1.87±0.61 vs. 1.40±0.61, p<0.01). There was no difference in post- and preoperative degree of myofibrillar hypertrophy and degenerative changes.

Conclusion: One-year postoperatively, PLV had favourable effects on myocardial morphology that parallels improvement in patient's functional status and LV systolic function.

P055

Autopsy findings in corrected transposition of the great arteries

Sofija Glumac, Zoran Popovic, Sanja Radojevic-Skodric, Zorica Stojsic, Darko Babic, Jovan D. Vasiljevic
Institute of Pathology, Medical School, University of Belgrade, Serbia and Montenegro; Department of Pathology, Bezanijaska Kosa Hospital, New Belgrade, Serbia and Montenegro

Objectives: Congenitally corrected transposition of the great arteries (C-TGA) represents the combination of atrio-ventricular and ventriculo-arterial discordance, with completely normal circulation. The aim of this study was to analyze the cases of C-TGA (sex, age and causes of death, atrial situs), and presence of associated cardiac and/or extra-cardiac anomalies.

Method: During the period from 1926-2006, a total number of 1.444 cases of congenital heart diseases (CHD) were diagnosed at the Institute of Pathology, Medical School, University of Belgrade. All autopsies were performed using standard or modified Rokitansky technique and accepted segmental approach. C-TGA was found in 31 cases (2.15 % of all CHD).

Results: There were 20 males (64.52%) and 11 females (35.48%); in 25 cases the heart was in situs solitus (80.65%) and in 6 in situs inversus (19.35%). The viscera was always in situs solitus. Majority of the patients had 2 or more associated cardiac anomalies (25 ASD, 11 VSD, 3 AVSD, 7 PDA), and only 1 case had no communications between heart chambers; in 11 cases we found 1 communication, in 17 cases 2, and in 1 case 3. In addition, pulmonary atresia was present in 7 cases (22.58 %), and pulmonary stenosis in 4 (13%). Anomalous connection of pulmonary veins was found in 5 cases (16.13%), and anomalies of the coronary arteries too (hypoplasia in 3 and single coronary artery in 2). Most of patients died within the first month of life (20 or 64.52%), 6 within the first year (19.35%), 2 in the second year (6.45%), 1 in the third year (3.23%), and 2 lived over 20 years (6.45%). Extra-cardiac causes of death were predominant within the first year of life: bronchopneumonia (14 or 45.16%), atelectasis (7 or 22.58%), cerebral hemorrhage (3 or 9.68%), acute heart failure (3 or 9.68%), and myocarditis/endocarditis (2 or 6.45%).

Conclusion: Our results show higher incidence of C-TGA among CHD, male and situs solitus predominance, and the most frequent cause of death due to extra-cardiac complications.

Majority of patients in our series died within the first year of life, and

the most often associated cardiac anomalies were: ASD, VSD, pulmonary atresia or stenosis, and AVSD.

P057

Morphological characteristics of unstable atherosclerotic plaques of the carotid arteries

Fedorina T.A., Bugaeva L.N.
Samara State Medical University, Samara, Russia

Research to understand the role and importance of atherosclerotic damage of the carotids is essential for effective surgical correction of blood flow in arteries of the head and neck aiming to decrease the risk of acute cerebro-vascular events (ACVE). **The aim** of this study was to determine early signs of unstable or prone-to-damage plaques in the carotids in patients with increased risk of ACVE. **The study material** consisted of tissues samples of the carotids removed during endoscopic surgery for blood flow restoration performed on the arteries. In total we examined 102 fragments of the carotids received from 86 patients aged 42-67 years; the majority were males.

Methods: the fragments were examined microscopically and morphologically. Histological preparations (of 8 μ m thickness, stained with hematoxylin-eosine, by histochemical methods and using p-53 and Ki-63 immunohistochemical markers) of 134 atherosclerosis plaques were examined. Separate smooth muscles cells of the median arterial membrane were examined using alkaline dissociation methods. A set of morphometric techniques was applied. Study material was divided into 2 groups: 65 samples of damaged atherosclerotic plaques and 69 samples of plaques without signs of damage that included 44 stable plaques and 25 unstable plaques.

Results: damaged atherosclerotic plaques had macro- and microscopic signs of hemorrhage, destruction of fibrotic cover and thrombosis formation and were easy to diagnose. Differential diagnosis between stable and unstable plaques without signs of damage is of a greater importance. Stable atherosclerotic plaques had a compact lipid nucleus, insignificant destruction of elastic fibers and poorly developed capsule fibrosis. Unstable atherosclerotic plaques had the following characteristics: increased volume of the lipid nucleus and fibrotic and smooth muscular tissues, substantial destruction of elastic fibers and presence of glycosamine sulfate in their walls. The parenchymal cellular density index in stable atherosclerosis plaques was 2.7 while it was 6.4 in the group of unstable plaques. Morphologically these cells belonged to macrophages, lymphocytes, smooth muscles cells. Examination of separate smooth muscles cells demonstrated their high proliferative activity in unstable atherosclerosis plaques. A high level of expression to apoptotic factors was detected in this group of unstable plaques and may be a cause of their destruction and disruption resulting in manifestation of clinical symptoms of atherosclerosis. The thickness of stable atherosclerosis plaques cover was 1.14 0.03 μ m and 0.67 0.04 μ m in unstable plaques.

Conclusions: the results of our study demonstrate that susceptibility to damage of atherosclerosis plaque as a form of atherosclerotic progression in the carotids plays a significant role in realization of ACVE. Morphological characteristics of unstable atherosclerotic plaques shows disconnection between the process of lipoidisation, cellular density of proliferating smooth muscular cells and degree of death of cellular elements in the arterial wall.

P059

Different type of cardiac mast cells in rats acutely poisoning by T-2 toxin: a morphometric classification

Vesna Jacevic, Iivica Milosavljevic, Dubravko Bokonjic, Lidija Zolotarevski, Katarina Jelic, Milos P. Stojiljkovic
National Poison Control Centre, Military Medical Academy, Belgrade, Serbia and Montenegro

We evaluated basic classes of cardiac MCs according to the following quantitative morphometric parameters: perimeter (P), area (A) and roundness (R) using commercial morphometric software (Camia, 2005). Wistar rats were treated by T-2 toxin (1 LD50 0.23 mg/kg sc) and sacrificed on day 1, 3, 5, 7, 14, 21 and 28 after treatment, as well as control ones. In the control groups the majority of MCs were tiny ($P \dot{=} 7.99 \mu\text{m}$), hypogranular (H0-MCs) ($A \dot{=} 14.3 \mu\text{m}^2$) and ovoid ($R \dot{=} 0.65 \mu\text{m}$). MCs with discreet granules, hypergranular (H1-MCs), had quantitative values of the parameters ($P \dot{=} 14.9 \mu\text{m}$; $A \dot{=} 20.0 \mu\text{m}^2$; $R \dot{=} 0.38 \mu\text{m}$). Minority of MCs were determinate as degranular (D-MCs) had large ($P > 15.0 \mu\text{m}$), irregular shapes ($A > 20.0 \mu\text{m}^2$) and showed degranulation ($R < 0.3 \mu\text{m}$). In the heart of T-2 toxin-treated rats the quantitative parameters values of H0-MCs and H1-MCs were similar to the control group. D-MCs showed significantly increase in perimeter and area ($p < 0.05$), while their roundness were decreased ($p < 0.05$). We concluded that chosen quantitative morphometric parameters of cardiac DMCs are useful for evaluation of a functional state of the heart both under normal and pathological conditions, such as during the acute T-2 poisoning.

P060

Immunohistochemical investigation of calretinin, VEGF-C and CD34 in distinction between cardiac myxomas and mural myxomatous thrombi

Bobos Mattheos, Pappas Dimitrios, Hatzibougias Dimitrios, Tzioufa Valentini, Nenopoulou Eleni
Department of Pathology, Aristotle University Medical School, Thessaloniki, Greece

Objective: Cardiac myxoma is the most common primary cardiac tumor in adults. The histogenesis is still controversial, as well as the differential diagnosis from a myxomatous mural thrombus. The aim of our study was to investigate the usefulness of specific immunohistochemical markers in order to distinguish myxomas from mural myxomatous thrombi.

Methods: Formalin-fixed paraffin-embedded tissues from 10 cardiac myxomas $>2\text{cm}$ in greatest diameter and 5 mural myxomatous thrombi were analyzed immunohistochemically for the expression of calretinin, VEGF-C and CD34 using the LSAB visualization system.

Results: All cardiac myxomas showed diffuse and moderate to strong positivity for calretinin with predominantly cytoplasmic staining pattern. VEGF-C detected virtually in all stromal and endothelial cells with strong cytoplasmic staining. CD34 antigen was positive in endothelial and scattered stromal cells, as well as in a variable number of neoplastic cells. Mural myxomatous thrombi were not reactive for calretinin whereas VEGF-C was strongly and diffusely positive. CD34 was expressed in endothelial and in a small number of stromal cells.

Conclusion: Calretinin can be important diagnostic marker for cardiac myxoma and useful marker in differential diagnosis from myxomatous mural thrombus.

P061

The Pathology of Diastolic Heart Failure

Patrick J Gallagher and Ruth Mathers
Department of Pathology, Southampton University Hospitals, Southampton SO16 6YD UK

Traditionally heart failure has been viewed as a disorder of ventricular function produced by ischaemic heart disease, valvular disorders or hypertension. Although survival is improved with modern therapy heart failure remains a disorder with a poor long term outcome and a substantial risk of sudden death. Echocardiography is the most reliable method of confirming the diagnosis. Cardiologists now recognise that a proportion of patients with typical signs and symptoms of heart failure appear to have

preserved ventricular function with a normal or near normal ejection fraction ($\geq 50\%$). This is generally termed diastolic heart failure. We have studied the macroscopic changes at post mortem in 116 patients who died suddenly of cardiac disease. Our intention was to identify patients who might have fulfilled criteria for the clinical diagnosis of diastolic heart failure. Features of established heart failure such as oedema and hepatic congestion were recorded and graded and wherever possible the cause of cardiac failure was identified. Mitral valve circumference, left ventricular thickness and the distance from the valve ring to apex were recorded. We classified the shape of the left ventricular cavity as globular (31), normal conical (27), cylindrical (36) and pencil shaped (22). 89 of the 116 sudden deaths had clear evidence of cardiac disease. 53 of these had obvious ischaemic or valvular disease. Of the remaining 36 patients 6 had no evidence of chronic heart failure and 15 had dilated ventricles. Of the remaining 15 patients 8 had evidence of cardiac hypertrophy. We believe that the macroscopic changes in these patients meet the requirements for the diagnosis of diastolic heart failure. All had died of cardiac disease but had no clear evidence of ischaemic or valvular disease. In each case the ventricular cavity had a non globular shape. Whilst we must accept that diastolic heart failure is a significant clinical problem it is not a common entity at post mortem (8 out of 116 cases). We may have underestimated the number of cases by excluding patients with ischaemic heart disease. We also suspect that patients who initially develop so called diastolic heart failure progress to a more typical pathological form of disease by the time of their death.

P062

p53 and bcl-2 expression in dilated cardiomyopathy

A. Tsipis, N. Kavantzias, A.-M. Athanassiadou, P. Athanassiadou, I. Giannopoulou, G. Agrogiannis, E. Patsouris
Department of Pathology, Medical School,
University of Athens, Greece.

Dilated cardiomyopathy (DCM), a disease of unknown etiology and pathogenesis, is associated with heart failure and compensatory hypertrophy. Apoptosis has been attributed an essential role in DCM. In order to investigate the pathogenesis of DCM we examined the expression of bcl-2 and p53 oncoproteins in tissues from patients with DCM. Twenty five cardiac tissue postmortem specimens (20 with DCM and 5 control subjects) included in this study. An immunohistochemical method was performed with the use of anti-p53 and anti-bcl-2 antibodies. Samples from the DCM patients stained more intensely with anti-p53 antibody than those from control group ($p < 0.05$). The tissues showed little expression for bcl-2. Our results suggest that p53 and bcl-2 expression and apoptosis may play some role in the pathogenesis of DCM.

P063

Isolated eosinophilic coronary periarteritis: A post – mortem diagnosis case of unusual Churg – Strauss syndrome presentation

Agapitos E, Glava C, Agrogiannis G
Department of Pathology, National and Kapodistrian
University of Athens, Athens, Greece

Introduction: Eosinophil coronary arteritis is rare and occurs principally as a manifestation of cardiac involvement in Churg – Strauss syndrome.

Case Report: A 33-year-old woman was found dead of ventricular fibrillation in her bath in June 2005. The woman was autopsied. Macroscopically, lungs showed passive congestive pulmonary edema. Her heart weighed 340g and all measurements corresponded to maximum physiological limits (thickness of right wall 0,5cm, thickness of left wall 1,3cm, thickness of interventricular septum 1,2cm). Configuration of the valves was normal. Coronary arteries

did not show significant alterations, except for a left anterior descending artery tract where, on cross section, transmural thickening, greyish white colour and elastic hard consistence were observed. Histological examination was accomplished on sections of heart, lungs, liver and kidney. Microscopic examination of heart sections revealed the presence of old infarcted areas and dense eosinophil infiltration of the coronary adventitia. Some eosinophils invaded the media and the intima, which additionally presented type Va arterosclerotic lesions and stenosis up to 50%. On the ventral inferior wall an extensive old infarcted area of the myocardium was observed. Microscopic examination to the other sections evidenced grey sclerosis of the lung and passive hyperaemia of liver and kidney.

Discussion: Pericoronaric eosinophilic infiltration is mainly associated with advanced stages of Churg – Strauss syndrome. In the present case, this microscopic finding was not accompanied by eosinophilic infiltration of the lung and this renders the expression of the syndrome unusual. Additionally, in the present case no myocarditis and no extravascular granulomas or extravascular eosinophilic infiltration were detected. In bibliography, three other similar cases are reported. In 1989, Kajihara et al reported the sudden death of a 40-year-old man of instable angina. Microscopic examination revealed inflammatory infiltration, mostly eosinophilic, localized in adventitia of coronary arteries located in the subepicardial region. In 2005, Taira et al reported the sudden cardiac death of a 52-year-old man. The only finding the eosinophilic infiltration of the coronary adventitia. In 2005 as well, Lepper et al described the case of a 43-year-old woman who died after spontaneous dissection of all three coronary arteries. Microscopic examination of coronary vessels showed severe eosinophilic infiltrates, whereas all extracardiac arteries were intact and free of inflammatory cells. There have been described several limited forms of presentation of Churg – Strauss syndrome. However, to the best of our knowledge, this is the fourth reported case of sudden cardiac death whose only finding was isolated eosinophilic coronary periarteritis.

Conclusion: Clinical and histological expression of the Churg – Strauss syndrome is various. In bibliography, several uncommon forms are reported. Coronary eosinophilic periarteritis may constitute part of the expression of the Churg – Strauss syndrome. The absence in the present case of lung involvement, extravascular granulomas or extravascular tissue eosinophilic infiltration renders this expression unusual. In fact, to the best of our knowledge, this is the fourth case reported.

P064

Apoptosis profile of normal human thymus

Michael Doukas¹, Alexandra Papoudou-Bai¹, Evangelia Lampri², Sevasti Kamina², Antonia Charchanti¹, Dimitra Rontogianni³, Niki J. Agnantis², Panagiotis Kanavaros¹, Maria Bai².
Departments of Anatomy¹ and Pathology² University of Ioannina, Ioannina 45110, Greece, Department of Pathology, Evangelismos Hospital of Athens³, Greece

We analysed the immunotopographical distribution of the apoptosis associated proteins bcl2, bcl-xl, mcl1, bim, bak, bax, bid, FLIPs/1 and the apoptotic cells (TUNEL and active caspase3 positive) in twenty normal human thymuses. Bcl-xl was mainly found in the cortical thymocytes, while Bcl2, mcl1 and bim were mainly detected in the medullary thymocytes. Bax and bid were strongly expressed in all thymocytes, whereas Bak was undetectable in thymocytes and was mainly expressed in Hassal bodies. Expression of FLIPs/1, Fas and FasL were found only in the thymic epithelial cells (TECs). Fas expression was higher in medullary TECs and in Hassal bodies. FLIPs/1 was observed in all TEC types except subcapsular epithelial cells. Apoptotic cells (TUNEL and active caspase3 positive) were mainly found in the cortex and the corticomedullary junction. Our study suggests that bcl2 and mcl1 expression may reflect the surviving medullary, while bcl-xl

expression may reflect the surviving cortical thymocytes. Bax and bid may be involved in thymocyte apoptosis, whereas bak does not seem to play major role in thymocyte apoptosis.

P065

Primary cutaneous T-cell rich B-cell lymphoma

Venizelos I¹, Tatiou Z¹, Chatzitoliou A¹, Moulla A¹, Mandala E².
¹Department of Pathology, ²Department of Internal Medicine, Hippokratio General Hospital, Thessaloniki, Greece

T-cell rich B-cell lymphoma (TRBL) is a lately recognized B-cell lymphoma variant, characterized by a minor population of neoplastic B-cells existing in a background of predominant reactive T-lymphocytes. It is a rare entity, accounting for approximately 1-2% of all non-Hodgkin's lymphomas. It has both nodal and extranodal presentation. Primary cutaneous TRBL is an extremely rare lymphoma and only 17 cases have been documented thus far in the medical literature. We report the case of a 46-year-old man who presented in our hospital due to a slowly growing, painless skin nodule on the left temporo-frontal region of the scalp. A complete surgical excision was performed and histological examination revealed morphological and immunohistochemical features of cutaneous TRBL. On physical examination there was no hepatosplenomegaly, peripheral lymphadenopathy or other skin abnormalities. Hematological examination was within normal ranges. A metastatic work-up, including chest X-ray, CT-scan of the abdomen, bone scan and bone marrow aspirate and biopsy revealed no evidence of disease. The patient received 6 courses of systemic chemotherapy with Mabthera and CHOP and 2 years later he is in good condition, without evidence of local recurrence or metastatic disease. In this study we report a very rare case of TRBL presented primarily in the skin. Although rare, it is important to make the correct diagnosis using the appropriate immunohistochemical stains.

P066

Morphological criteria and molecular markers as possible prognostic factors in Hodgkin's lymphoma

Kovrigina A., Probatova N.
 Department of Pathology, N.N. Blokhin Cancer Research Center, Kashirskoye shosse 24, 115478 Moscow, Russia

Objective: In spite of using clinical prognostic factors for dividing pts with Hodgkin's lymphoma (HL) into 3 groups: early, intermediate and advanced stage there are about 10% of early and late relapse in each groups of pts. Besides the late toxicity is well known complication of modern chemotherapy (such as BEACOPP and escalated BEACOPP). So the majority of patients should not be exposed superfluous treatment. The aim of our study is revealing of morphological and molecular factors of poor prognosis in primary patients with HL.

Material and methods: We examined lymph node's biopsies of 2 groups of patients with HL before treatment. The groups of pts were formed using the results of standard chemotherapy+RT (1987-2001). 1-st group included 71 pts with favorable prognosis, mediana-25,5 years, I stage-9, II-42 pts, III-11pts, IV-9 pts. 2nd group was generated by results of treatment with presence failure of complete remission, early and late relapses - 70 pts, mediana-25,5 years, I stage-7 pts, II-35 pts, III-8 pts, IV-20 pts. NS and mixed cellularity variants were predominated in both groups: 1st group - NS I 34,3%, NS II 15,7%, mixed cellularity 34,3%; 2nd group- NS I 35,2%, NS II

31.0%, mixed cellularity 28,2%. We used morphological codification with semiquantitative estimation of neoplastic cells, reactive cellular background, character of growth (separately neoplastic cells and tumor in lymph node), fibrosis, necrosis. Expression of p53, p27, BCL-2 was also evaluated in 2 groups of pts. Multifactor dispersive analysis, discriminant and factor analyses were performed.

Results: Expression of BCL-2 was independent factor of poor prognosis in I-IV stages ($p < 0.001$). Following morphological criteria had significant difference: I stage- amount of neoplastic cells, lymphocytes, eosinophils, neutrophils, character of neoplastic cell's growth; II stage- neoplastic cells, necrosis ($p < 0.01$). III and IV stages hadn't significant difference by morphological analysis. Eosinophils were significant higher in 2nd group in NS ($p < 0.01$).

Conclusion: Morphological features may be used as prognostic factors in I-II stages in pts with HL. Clinical prognostic factors (such as tumour masses, expansion of neoplastic process) have conducting value in advanced stages.

P067

Diagnostics of "grey zone" large lymphomas

Kovrigina A.
 Department of Pathology, N.N. Blokhin Cancer Research Center, Kashirskoye shosse 24, 115478 Moscow, Russia

Objective: Grey zone is complicated for the account of TCRBCL, anaplastic variant of DBCL, primary mediastinal B-cell large lymphoma (PMBL), anaplastic large-cell lymphoma (ALCL). We analyzed a group of large cell lymphomas (prospective consultative material 2002-2004) and revealed cases which had morphological difficulties of differential diagnostics between Hodgkin's lymphoma (HL) (classical HL and nodular lymphoid predominance NLPHL).

Materials and methods: We investigated morphological picture and immunophenotype of paraffin embedded lymph node specimens 159 large cell lymphomas using wide panel of antibodies CD3, CD4, CD8, CD10, CD15, CD20, CD21, CD23, CD30, CD43, CD45, CD57, Granzyme B, ALK, EMA, BCL-2, BCL-6, PAX 5, MuM.1

Results: We diagnosed 22 cases of TCRBCL (m:f 0,8:1,0; mediana 47,5 years, range 21-67). In 20 cases of TCRBCL diffuse growth was marked and in 2 cases- nodular growth. Concerning peculiarities of cytomorphology of neoplastic cells and histological picture differential diagnostic between TCRBCL and HL (NLPHL and mixed cellularity) was fulfilled in 31,8% cases TCRBCL. 59 cases with large mediastinal masses in debut of disease (m:f 1,0:3,5; mediana 31,5 years, range 16-62.) were diagnosed as PMBL. 16,9% cases of PMBL were differentiated with NSII. 2 cases of PMBL (using morphological features) were characterized by "chimeric phenotype": CD45+, CD15+, CD20+, CD23+, CD30+, MuM.1+. Neoplastic cells were 23-positive in 60,8% cases. Anaplastic variant of DBCL was detected in 2 cases which were characterized by monomorphic expression CD20, CD30 and markers of postfollicular origin MuM.1+, CD138+. ALCL was diagnosed in 76 cases (m:f 1,1:1,0; mediana 22 years, range 2,5-79). Expression of ALK was detected in 53,9% cases. 70,8% cases of ALK-negative had characterized by marked polymorphism and multinuclear cells like R-S cells among abundant reactive background. These cases of ALCL have been needed to differentiation with HL (NS II, lymphocyte depletion). The cytotoxic molecules (Granzyme B was positive in 93,7% cases) and B-transcriptional factors (PAX 5 together with MuM.1) must be included in immunohistochemical differential panel between ALCL, ALK-negative and HL as decision of differential diagnostic problem.

Conclusion: Detail comparison of morphological and immunohistochemical features allow us to suggest 2-step diagnostic algorithm of “grey zone” large lymphomas.

P068

The prognostic significance of the percentage and pattern of bone marrow infiltration in patients with multiple myeloma

Hadjileontis C¹, Zervas K², Papadimitriou C¹, Kaloutsi V¹.

¹Pathology Dept, Medical School, Aristotle University of Thessaloniki, Greece. ²Haematology Clinic, Theagenion Cancer Hospital of Thessaloniki, Greece.

Within the frame of drawing new strategies for the confrontation of multiple myeloma (MM), the reevaluation of parameters that are considered to be prognostic for the disease, is inevitably included. We investigated the percentage and pattern of bone marrow (BM) infiltration in BM biopsies from 100 patients with newly diagnosed MM. These parameters were reevaluated after the treatment of the patients with conventional chemotherapy. In order to determine the prognostic significance of the above parameters, our results were statistically correlated with the survival of the patients during the years 1994-2004 (Spearman's and Kruskal-Walis's tests). Statistical analysis brought up a significant correlation between the alterations of the percentage of BM infiltration before and after treatment and the patients' survival ($R=0,51$ και $p<0,05$), exhibiting therefore the importance of the percentage of BM as an independent prognostic marker for the disease. The comparison of the pattern of BM infiltration with the patient's survival on the other hand, did not reveal a statistically significant correlation.

P069

Investigation of the prognostic significance of multiple myeloma differentiation and type of paraproteinaemia, through a retrospective study of 100 cases

Hadjileontis C¹, Zervas K², Papaioannou M², Papadimitriou C¹, Kaloutsi V¹.

¹Pathology Dept, Medical School, Aristotle University of Thessaloniki, Greece. ²Haematology Clinic, Theagenion Cancer Hospital of Thessaloniki, Greece.

The degree of multiple myeloma (MM) differentiation as well as the type of paraproteinaemia (TP) are thought to be parameters of independent prognostic value for the disease. We studied MM differentiation and the TP in bone marrow (BM) biopsies of 100 patients with newly diagnosed MM. The study was performed at first diagnosis and after treating the above patients with conventional chemotherapy. The TP was determined both immunohistochemically in BM biopsies, as well as by electrophoresis of the patients' urine and serum. The prognostic significance of these parameters was evaluated as the degree of the statistical correlation they showed with the survival of the patients during the years 1994-2004 (Spearman's and Kruskal-Walis's tests). Our results oppose the authors suggesting the prognostic significance of these two parameters, since no statistically significant correlations between either the degree of MM differentiation (with or without plasmablasts) or the TP detected and the patients' survival were found.

P070

Primary CD 30 + T-Lymphoproliferative disorders of the skin in childhood. Report of 3 cases

C. Michail-Strantzia¹, I. Bonou¹, P. Giamarelou¹,

L. Dimitriou², H. Kosmidis³

Pathology¹, Surgical² and Oncology³ Department of Children's Hospital of Athens, P. & A. Kyriakou

The diagnosis and classification of cutaneous lymphomas remain one of the most challenging areas in dermatopathology. The primary cutaneous CD30 + T-lymphoproliferative disorders are linked by the common histological feature of large atypical lymphoid cells expressing CD30 and include Anaplastic Large Cell Lymphoma T/null cell primary cutaneous type, LyP, and borderline cases of the EORTC classification with overlapping features of the other two conditions. We present the clinicopathologic findings in 3 female children with primary cutaneous CD30 + T-lymphoproliferative disorders, presented with a rapidly enlarging and ulcerating mass involving the skin and subcutaneous tissue. The patients' age ranges from 9 to 10 years. The histologic and immunohistochemical investigation evaluated sheets of large atypical lymphoid CD45 positive cells, that were strongly CD30 positive in all cases. Cells were of T-cell phenotype and in 1 case there was a large sharing of CD1a positive cells. Staining for anaplastic lymphoma kinase was negative in 2 cases. No evidence of systemic involvement was noted. The primary cutaneous CD30 + T-LPD are rare in childhood and have different behavior, prognosis and treatment requirements to nodal lymphomas.

P071

Development of intrinsic innervation in human lymphoid organs

Valsamo Anagnostou, Ipatia Anagnostopoulou, Dina Tiniakos, Despina Karandrea, Emmanouil Agapitos*, Christos Kittas
Laboratories of Histology-Embryology and *Pathology, Medical School, National and Kapodistrian University of Athens, Greece

The aim of the study was to assess the distribution of parenchymal nerves in human fetal thymus and spleen. Our material consisted of tissue sections from 23 human fetuses (18-39 gestational weeks). We used the biotin-streptavidin immunohistochemical technique with antibodies specific to NSE, NF, PGP9.5, S100 and TH. In thymus, NSE-, NF-, S100-, PGP9.5- and TH- positive nerves were identified associated with the vasculature from 18 gw, increasing in density during development. Their branches penetrated the septal areas at 20 gw, reaching the cortex at 23 gw. Few nerve fibers were seen close to medullary epithelial thymic cells, at 20 gw. In human fetal spleen, NSE-, NF-, S100-, PGP9.5- and TH- positive nerve fibers were seen surrounding the splenic artery at 18 gw. Perivascular nerve fibers were seen extending into the white pulp in association with the central artery. Scattered nerve fibers were localised in the red pulp from 18 gw. TH- positive cells were observed in the white pulp during the third trimester. Human fetal thymus appears richly innervated in contrast to fetal spleen. The predominant perivascular distribution of most intraparenchymal nerves implies that the intrinsic innervation of lymphoid organs plays an important functional role during intrauterine life.

P072

CD27 and DBA44 expression in splenic marginal zone lymphomas

Theodore Argyrakos¹, Ipatia Doussis-Anagnostopoulou², Dimitra Rontogianni³, Paraskevi Oikonomou, Themis Karmiris⁴, Ioannis Dervenoulas⁵, Christos Kittas²

¹Pathology Department, “G. Gennimatas” General National Hospital, ²Laboratory of Histology and Embryology, National and Kapodistrian University, Athens Medical School, ^{3,4}Evangelismos General Hospital, Athens and Attikon University Hospital, Chaidari, Athens, Greece

CD27 is an activation antigen that characterizes memory lymphocytes (B and T), while DBA44 is an antigen expressed in hairy cell leukemia and naïve mantle B cells. In order to investigate the cell of origin of splenic marginal zone lymphomas (SMZLs),

we studied the expression of DBA44 and CD27 in SMZLs. Twenty four (24) cases of CD20+, CD5-, CD23-, bcl-6-, Cyclin D1-SMZLs were immunohistochemically examined with the monoclonal antibodies CD27 (NOVOCASTRA) and DBA44 (DAKO), using the microwave antigen retrieval method and the Envision polymer method. 13/24(54.1%) cases were DBA44 negative, whereas 11/24(45.9%) cases exhibited partial positivity, either in the neoplastic white pulp (2/24, 8,33%) or in the red pulp (9/24, 37.5%). On the latter the positivity was observed either in a few scattered cells (5/24, 20.83%) or in many neoplastic cells infiltrating the red pulp (4/24, 16%). 20/24 (83.3%) SMZLs exhibited CD27 positive nodules and partial positivity in the neoplastic cells of the white pulp, while 4/24(16.6%) showed negative nodules with few scattered positive cells in the red and white pulp. In conclusion, SMZLs are in their majority CD27 positive in the neoplastic nodules, while DBA44 negative in the nodules and positive in the red pulp. CD27 expression rather supports the theory of memory B cell origin of SMZLs, while DBA44 positivity in the red pulp could correlate with the pattern of infiltration.

P073

Localized castleman's disease associated with systematic AA amyloidosis. Regression of amyloid deposits after tumor removal.

K. Giaslaktiotis¹, K. Kokkori¹, G. Liapis¹, P. Alexandrou¹, X. Giakoumi², P. Korkolopoulou³, A. Androulaki¹.

¹Department of Pathology, ²First Department of Internal Medicine, ³Pathology Laboratory, University of Athens Medical School, Laiko General Hospital, Mikras Asias 75, 115 27 Athens, Greece.

Castleman's disease is a rare B-cell lymphoproliferative disorder, comprising anatomically unicentric and multicentric forms and histologically vascular and plasma cell variants. We report a case of systemic AA amyloidosis complicating Castleman's disease – unicentric, retroperitoneal, plasma cell variant - in a 49 year old white woman, in whom the underlying primary diagnosis was made after years of illness. The patient underwent tumor resection and a rapid clinical and laboratory resolution was achieved. She remains free of disease two years post-operatively. Castleman's disease may be complicated by acquired AA systemic amyloidosis and can be cured surgically even in advanced cases.

P074

The variant form of hairy cell leukaemia. Report of a rare case through retrospective bibliographic study

Alexopoulou E, Lafioniatis S*, Fericean A, Hadjileontis C.

Pathology Department and Unit of Thalassaemia*
"Achillopouleion" General Hospital, Volos, Hellas

Hairy cell leukaemia (HCL) accounts for about 2% of all cases of leukaemia, while its variant form represents less than 10% of these cases. This rare form affects elderly or middle age patients, usually males, exhibiting cytopenia with lymphocytosis and splenomegaly. We present the case of a 56 year-old male patient who presented with anaemia and splenomegaly. Bone marrow biopsy revealed infiltration of the marrow spaces by small to medium sized lymphoid cells, counting up to 40% of the marrow population. The lymphoid cells demonstrated specifically round or ovoid nuclei with prominent nucleoli and abundant irregular cytoplasm with or without hairy projections. Cells of similar morphology that proved to be B-lymphocytes by flow cytometry, were also found in the bone marrow aspirate as well as the peripheral blood of the patient measuring up to 2.7% and 0.6 % of the circulating cells respectively. The immunophenotype of these cells was CD20+, CD11c+, CD22+, CD103+, CD25- and CD123- with monoclonal expression of κ light chains. Immunohistochemistry showed positivity of the bone

marrow lymphoid cells for CD45, CD20, CD22 and DBA44. The above findings were indicative of the variant form of HCL, the patient underwent splenectomy without chemotherapy and two years later he is in good general condition with no signs of relapse.

P075

Pathophysiology of the spleen in the thalassemic HBB^{TH-3} mouse model; Administration of G-CSF ± hydrea (HU) provokes dramatic alterations in spleen size and histology.

Evangelia Athanasiou, Evangelia Yannaki, Garyfallia Karponi, Aglaia Antoniou, Fani Zervou, Angeliki Xagorari, Athanasios Fassas, Achilles Anagnostopoulos
Gene and Cell Therapy Center, Hematology Department-Bone Marrow Transplantation Unit, George Papanikolaou Hospital, Thessaloniki, Greece

Spleen in thalassemic patients can become excessively enlarged, due to extramedullary hematopoiesis and the trapping of damaged red blood cells within splenic sinuses. The collection of autologous hematopoietic stem cells (HSCs) for genetic modification from these patients is a previously unexplored issue as gene therapy only recently has become a realistic potential for thalassemia.

The cytokine G-CSF (Granulocyte Colony Stimulating Factor) is the most widely used inducer of peripheral blood stem cell (PBSC) mobilization in normal donors and in patients with hematologic malignancies. Currently, G-CSF- mobilized PBSC is the preferable source of HSCs for transplantation due to higher yield of stem/progenitor cells compared to bone marrow harvest. A G-CSF-related splenic enlargement has been documented which very rarely may result in splenic rupture. **The aim** of the study was to investigate the G-CSF influence in a condition of splenomegaly as in the thalassemic mouse model, any potential increased risk for rupture as well as the histopathological changes of splenic parenchyma. A possible beneficial effect of HU, which has been shown to reduce extramedullary hemopoiesis, in preventing splenic rupture was also explored.

Material and methods: We used heterozygous knockout thalassemic HBB^{th-3} mice, which clinically resemble the human thalassemia intermedia. Untreated, wild type (wt) C57Bl6 mice were also included in the experiments. In three independent experiments, 8-10 weeks-old mice, were randomly classified in four groups. Group A and B (n=4+4) included untreated wt and thalassemic mice, Group C (n=10) G-CSF (200 μ gr/kgX8days, intraperitoneally)-treated thal mice and Group D (n=11) thal mice treated with HU (60mg/kgX30days, via gavage)+G-CSF. Animals were sacrificed the last day of G-CSF administration. Spleen weight was determined as a ratio to total body weight. Immunohistochemistry was performed for lineage markers with MPO, Glycophorin, CD61, CD45RO, CD45RA, CD20 and histochemistry with Gomori stain.

Results: In Group B, spleens were enlarged due to extramedullary hematopoiesis with no clear distinction between red and white pulp. Red pulp in was almost replaced by erythroid hyperplasia in contrast to Group A, where spleens were smaller in size with a well-organized white pulp and limited red pulp. In Group C, there was a dramatic enlargement in spleen weight (p=0,02) and extreme hypercellularity. Splenic parenchyma was replaced almost entirely of red pulp with predominance of granulocytic hyperplasia and foci of neutrophils homing around splenic cords. Erythroid and megakaryocytic lineages were also hyperplastic. Splenic cords and fibrous septae were ill-defined, discontinued or collapsed. Infarcts and/or capsular micro-ruptures were detected in 5/10 mice although there was no clinically observed splenic rupture in G-CSF-treated (0/21) animals. In Group D, fibrous septae were basically incessant and extramedullary hematopoiesis was still evident however, in lower levels than in Group C. These findings correlated with a reduced rate in splenic infarcts (3/11) and decreased splenic enlargement as compared to Group C.

Conclusions: G-CSF provokes enormous extramedullary hematopoiesis with predominance of granulocytic hyperplasia in the spleen of thalassemic mice leading to further enlargement of the spleen size. The extreme hypercellularity of splenic parenchyma destroys the splenic cords and leads to infarcts and/or capsular microruptures. However, these findings were self-limited resulting in no clinically detected splenic rupture. Pretreatment with HU may prevent these complications potentially increasing the safety of mobilization in thalassemia.

P076

Method concordance for the assessment of ALK abnormalities in anaplastic large cell lymphomas (ALCL) in pathology practice.

Bobos M, Kostopoulos I, Kotoula V, Karayannopoulou G, Kaloutsi V, Papadimitriou CS
Department of Pathology Aristotle University Medical School, Thessaloniki, Greece

Objective: Translocations involving the ALK gene, such as NPM-ALK (t[2;5][p23;q35]), have become the hallmark genetic alterations in ALCL as conferring a better prognosis to these rare tumors. The most common method currently used in pathology practice for the detection of ALK abnormalities is immuno-histochemistry (IHC) for ALK protein. The aim of this study was to evaluate the specificity of molecular methods in comparison to IHC for the assessment of ALK abnormalities in ALCL.

Methods: Forty four ALCL cases were assessed for the presence of ALK abnormalities with IHC (MoAb ALK1), with RT-PCR on material extracted from paraffin sections and dual color FISH with the LSI ALK break-apart probe.

Results: 17 cases were ALK+ and 27 ALK-. NPM-ALK fusion transcripts were detected in 14/44 (32%) cases and ALK rearrangements by FISH in 12/41 (29%) cases. NPM-ALK transcripts were found in 10/17 ALK1+ (59%) and in 4/27 ALK- (15%) cases (P=0,006), including 9/9 cases with nuclear/cytoplasmic ALK1 staining and 1/8 cases with cytoplasmic staining only (P<0,001). ALK gene rearrangements were observed in 8/11 (73%) of ALK+ cases and in 4/30 (13%) of ALK- cases (P=0,001). FISH and RT-PCR results were highly concordant (P<0,001). Combined, FISH and RT-PCR demonstrated ALK abnormalities in 12/16 (75%) ALK+, but also in 5/26 (19%) ALK- cases (P=0,001).

Conclusions: Our results show that the combination of FISH and RT-PCR is more specific than IHC in revealing ALK genetic alterations. These methods may be particularly useful in cases where the production of ALK chimeric proteins is inhibited.

P077

Microvessel density and expression of angiogenic proteins VEGF, VEGFR1, VEGFR2 and HIF1a in Hodgkin and

Reed-Stenberg cell (HRS) of classical Hodgkin lymphoma (cHL)
Evangelia Lampri¹, Evangelos Briasoulis², Lazaros Nikiforidis², Michael Doukas, Anna Goussia¹, Asimina Demou⁴, Nikolaos Pavlidis, Niki J Agnantis¹, Panagiotis Kanavaros³, Maria Bai¹

Department of Pathology¹, Oncology² and Anatomy-Histology-Embryology³, Medical School, University of Ioannina. Department of Pathology of General Hospital of Ioannina, "G. Hatzikosta"⁴

Few studies have focused on angiogenesis in cHL. Therefore in the present study we analysed the immunohistochemical expression of the VEGF, VEGFR1, VEGFR2 and HIF1a proteins in 95 cases of cHL. Moreover, microvessel density (MVD) was estimated after immunostaining for CD34(MVD-CD34) and CD105(MVD-

CD105). Expression (at least 10% positive HRS cells) of VEGF, VEGFR1, VEGFR2 and HIF1a proteins was found in 78/90(86.7%), 32/95(33.7%), 18/89(20.2%) and 46/81(56.8%) cases, respectively. The MVD-CD34 and the MVD-CD105 were 61(±28.7) and 12 (±7.65), respectively. Significant positive correlations were found between VEGF/VEGFR2 and VEGF/MVD-CD34 (p=0.003 and p=0.02, respectively). Furthermore, a reverse correlation was found between VEGFR2 and clinical stage of the disease (p=0.02, r=-0.505). The present study shows that the angiogenic proteins VEGF, VEGFR1, VEGFR2 and HIF1a are expressed in HRS cells of cHL. VEGF produced by HRS cells may act in a paracrine and autocrine fashion in cHL and possibly implicated in the pathogenesis of the disease.

Thymic tumor with partial neuroendocrine differentiation – a case report

Jelena Stojic, Dragan Subotic, Jelena Radojicic
Institute for Lung Diseases and Tuberculosis, Clinical Centre of Serbia, Belgrade, Serbia

Predominance of neuroendocrine elements in thymic tumor differs it from the thymic tumors containing scattered group of neuroendocrine cells. The epithelial neuroendocrine cells of the thymus compose typical or atypical carcinoid and are demonstrated by neuroendocrine monoclonal antibodies. We present a case of thymic tumor with predominant neuroendocrine differentiation. The patient was a male, age of 61. Tumor was detected on chest x-ray examination performed before operation of inguinal hernia. There was no any paraneoplastic or compressive symptoms. Tumor was localised in anterior mediastinum, without infiltration of surrounding mediastinal stuctures measured 110mm. Solid, shiny and fleshy tumor node was separated by a distinct fibrous septa. One part, measured 70x50x50mm, was focally osteocartilaginously changed. Trabecular structures and "rosettes" with a dense fibrovascular stroma were performed. Mitoses and necrosis were absent. There was infiltration of tumor capsula. Neuron-specific enolase and synaptophysin were positive. Beside carcinoid tumor, node was rich of lymphocytes which expressed CD3 and terminal deoxynucleotid transferase. The conclusion was that it was predominant neuroendocrine tumor in B1 thymoma with focal infiltration of capsula. There is not recurrence of the tumor and local and distant metastases until today. It was noted that 75 thymic tumors were diagnosed in a period of ten years. It was the first one with predominant neuroendocrine differentiation.

P079

Immunotopographical distribution of cells expressing neuroendocrine markers in normal human thymus.

Alexandra Papoudou-Bai¹ Michael Doukas¹, George Karatzias¹, Ann Goussia², Sevasti Kamina¹, Kalliopi Stefanaki³, Niki J. Agnantis², Maria Bai², Panagiotis Kanavaros¹
Departments of Anatomy¹ and Pathology², University of Ioannina, Department of Pathology³, Agia Sophia Hospital of Athens, Greece.

Neuroimmune interactions are thought to play key roles in the thymic biology and pathology. We analyzed by immunohistochemistry the distribution of cells expressing neuroendocrine markers in twenty normal thymuses. In subcapsular cortical epithelial cells low expression of NSE, PGP 9.5, TrkA and beta-tubulin II and high expression of beta-tubulin IV were found. In cortical epithelial cells low expression of synaptophysin and beta-tubulin II, intermediate expression of NSE, PGP 9.5 and TrkA and high expression of beta-tubulin IV were observed. In medullary epithelial cells low

expression of chromogranin, synaptophysin, tyrosine hydroxylase and NF 68kDa, intermediate expression of NSE and beta-tubulin IV and high expression of beta-tubulin II were detected. In Hassall's corpuscles low expression of chromogranin, synaptophysin, NF 140-160, NF 200 and p75 and high expression of NSE, NF68, beta-tubulin II and beta-tubulin IV were noticed. All these proteins were undetectable in thymocytes. The diversity of the immunotopographical distribution and the expression levels of neuroendocrine markers in the subtypes of thymic epithelial cells may reflect the diversity of their biological functions and/or their different stages of differentiation. Moreover, the above results may be helpful for the further understanding of the histogenesis of the neuroendocrine thymic tumors.

P080

The expression of p27, PTEN, Cks1 and Skp2 in thymomas.

Vassiliki Zolota¹, Vassiliki Tzelepi¹, Chaido Sirinian¹, Stavroula Salakou², Demetrios Kardamakis³ and Demetrios Dougenis⁴
Departments of Pathology¹, Neurology², Radiotherapy³ and Cardiosurgery⁴, University of Patras, Medical School, Greece

Loss of one of the major cell-cycle inhibitory proteins, p27Kip1, is the result of increased proteasome-dependent degradation, mediated by its specific ubiquitin ligase subunits: Skp2 and Cks1. PTEN is a tumor suppressor gene which upregulates, indirectly, p27Kip1. A total of 20 thymomas (classified according WHO and TNM) were immunostained for p27, PTEN, Cks1 and Skp2 antibodies. Staining evaluation was made according to the percentage of positive tumor (epithelial) cells as follows: <10%: -/+, 10-25%: 1+, 26-50%: 2+ and >50%: 3+. P27 expression was lost in 20% of the cases, whereas 25%, 10% and 45% of the cases showed 1+, 2+ and 3+ respectively. 10% of the cases showed low PTEN expression levels (1+), 20% showed 2+ and 70% showed 3+. Cks1 and Skp2 showed comparative levels of expression as follows: -/+ 35%, 1+ 25%, 2+30%, 3+ 10% for cks1 and -/+ 35%, 1+45%, 2+20% for skp2. Histological type or staging were not associated with the expression of any of the markers studied. These results suggest a) loss of PTEN expression is uncommon in thymomas, b) loss of p27 expression is not associated with ominous histologic type or stage, c) skp2 and cks1 are expressed in low or moderate levels in the majority of the cases and do not seem to play a significant role in p27 loss in thymomas.

P081

Concomitant alterations of the p53, Rb and p27 pathways in diffuse large B-cell lymphomas (DLBCL)

Elena Tsanou¹, Angelos Skyras¹, Ioannis Sainis¹, John D. Panelos¹, Anna Batistatou¹, Vasiliki Malamou-Mitsi¹, Maria Bai¹, Panagiotis Kanavaros²
Departments of Pathology¹ and Anatomy², Medical Faculty, University of Ioannina, Ioannina 45110, Greece

The expression of p14, p21, Hdm2 and cyclin D2 proteins were studied by immunohistochemistry in DLBCL. The results were correlated with other cell cycle proteins. Expression of p14, p21, Hdm2 and cyclin D2 proteins was observed in 39/71, 22/76, 43/74 and 11/77 cases, respectively. Alterations of the p53 [p53-Hdm2-p21-p14], Rb [Rb-p16-cyclin D (D2 or D3)] and p27 [p27-cyclin E] tumor suppressor pathways were found in 50/76, 43/79 and 30/79 cases, respectively. Alterations of at least one of the pathways were found in 60/79 cases. Two or three concomitant alterations of the pathways were found in 40/79 cases. The analysis of the combined

alterations of the pathways with respect to the expression levels of Ki67, cyclin A and cyclin B1 showed that 1) alterations of either p53 or Rb or p27 pathways were not significantly correlated with the expression levels of Ki67, cyclin A or cyclin B1 and 2) two or three concomitant alterations of p53, Rb and p27 pathways were significantly correlated with high expression levels of cyclin A (p=0.032). The present results indicate that concomitant alterations of the p53, Rb and p27 pathways in DLBCL exert a cooperative effect resulting in enhanced tumor cell proliferation.

P082

Expression of bcl2 family proteins and active caspase-3 in Hodgkin and Reed-Sternberg (HRS) cells of classical Hodgkin lymphomas (cHL)

Nikolaos Horianopoulos¹, Alexandra Papoudou-Bai², Elena Tsanou¹, Nafsika Simou¹, Anna Goussia¹, Niki¹ J. Agnantis¹, Panagiotis Kanavaros², Maria Bai¹
Departments of Pathology¹ and Anatomy², Medical Faculty, University of Ioannina, Ioannina 45110, Greece

The expression of the proteins bad, bid, bim, bcl2, bcl-xl, mcl1, bax, bak and activated caspase-3 and the TUNEL index were assessed in order to gain further insight in the apoptosis profile of cHL. In addition, the relations between the apoptosis profile and the proliferation profile were analysed. High expression of bcl2, bcl-xl, mcl1, bax, bak, bad, bid and bim was found in 27/101, 95/101, 27/97, 73/95, 37/102, 85/94, 19/109 and 43/91 cases, respectively. Active caspase-3 and TUNEL positive HRS cells were detected in 47/70 cases (range 0-12%) and 60/71 cases (range 0-19.39%), respectively. Significant positive correlations were found between bax/bcl2, bad/bcl2, bad/bcl-xl, bim/mcl1, active caspase-3/bax, active caspase-3/TUNEL index, bax/cyclin D2, bcl2/cyclin B, mcl1/cyclin A and mcl1/cyclin B (all p<0.05). The results suggest that the proteins bcl-xl, bax and bad may play a predominant role in the regulation of apoptosis in HRS cells. Moreover, the proapoptotic activity of bax, bad and bim may be counteracted by the antiapoptotic activity of the bcl2, bcl-xl and mcl1 in HRS cells.

P083

Is fine needle aspiration cytology is a useful method in the diagnosis of cervical tularemia lymphadenitis?

Banu D. Gun*, Burak Bahadir*, Guven Celebi**, Gamze Numanoglu*, Sukru O. Ozdamar*, Gamze M. Kuzey***
Zonguldak Karaelmas University, School of Medicine, Department of Pathology*, Department of Clinical Microbiology and Infectious Diseases**, Turkey
***Hacettepe University, School of Medicine, Department of Pathology, Turkey

Francisella Tularensis is a gram-negative coccobacillus that causes zoonotic disease tularemia. The clinical features of the disease depend on the route of inoculation and symptoms are nonspecific. Histopathological examination of lymph node biopsy in tularemia reveals suppurative granulomatous inflammation and caseous necrosis may be accompanied. Diagnosis is mainly made on the evidence of elevated agglutinating antibodies to F. Tularensis. In this study, the results of fine needle aspiration cytology (FNAC) of nine cervical lymphadenopathies, that had known tularemia diagnosis clinically and serologically, were evaluated and the cytomorphological features were described. All of the cases revealed suppurative inflammation and some caseous necrosis; in four epithelioid histiocytes and multinuclear giant cells were observed additionally. The differential diagnosis of tularemia principally with tuberculosis and with the other bacterial lymphadenitis was made and the utility of FNAC in tularemia cases were evaluated.

Cytokine effects on Fas-mediated apoptosis in A549 lung carcinoma cells

Vassiliki Galani¹, George Vartholomatos², Eufemia Balasi¹, George Chondrogiannis¹, Michalis Kastamoulas¹, Elizabeth Markatzinou¹, Evangelia Voti¹, Maria Bai³, George Nakos⁴, Marilena Lekka⁵, Panagiotis Kanavaros¹, Department of Anatomy¹; Laboratory of Hematology²; Departments of Pathology³ and Intensive Care⁴; Department of Biochemistry⁵; University of Ioannina, Ioannina 45110, Greece

A549 cells were treated with TNF α , IFN γ , IL1 β , IL13 and Fas (clone CH11) and analyzed by flow cytometry. The results were: 1) IFN γ induces time- and dose-dependent apoptosis, 2) the combinations IFN γ -IL13, CH11-IFN γ -IL13, CH11-TNF α -IL13, CH11-IFN γ -TNF α and CH11-IFN γ -TNF α -IL13 increased apoptosis, 3) in the combination CH11-TNF α , 100 ng/ml of TNF α showed antiapoptotic effects on A549 cells whereas 50 ng/ml of TNF α did not attenuate the proapoptotic effects of CH11. Pretreatment of A549 cells by 50 ng/ml of TNF α for 24 h showed antiapoptotic effects on CH11-treated cells and 4) IFN γ pretreatment (24 h) increased CH11-induced apoptosis whereas IL1 β or IL13 pretreatment (24 h) decreased CH11-induced apoptosis in 48 h. TNF α has dose-dependent antiapoptotic effects on Fas-induced apoptosis of A549 cells; especially when A549 cells are pretreated by TNF α . IFN γ promotes whereas IL1 β and IL13 prevent Fas-mediated apoptosis.

Association of Pleuropulmonary Blastoma (PPB) with Cystic Nephroma and Small Bowel Polyp: Case Report and Data from the International PPB Registry

K. Stefanaki¹, F. Boman², A. Stassinopoulou³, G. M. Williams^{4,5}, J. C. Fournet⁶, D. Bouron - Dal Soglio⁶, A. Chauvenet⁷, A. Hill⁸, Y. Messinger^{4,5}, J. R. Priest⁵
Department of ¹Pathology, Children's Hospital Aghia Sophia, Athens, Greece; ²Pathology, University Hospital of Lille, France; ³Oncology, Athens Pediatric Center, Athens, Greece; ⁴Hematology/Oncology, ⁵International PPB Registry, Children's Hospitals and Clinics of Minnesota, St. Paul, USA; ⁶Pathology, Hôpital Sainte-Justine, Montréal, Québec, Canada; ⁷Pediatrics, Wake Forest University Medical Center, Winston-Salem, USA; ⁸Lauren V. Ackerman Laboratory of Surgical Pathology, Barnes-Jewish and St. Louis Children's Hospitals, Washington University Medical Center, St. Louis, USA.

Pleuropulmonary blastoma (PPB) is a rare malignant mesenchymal tumor of lung in young children. Cystic nephroma (CN) represents one of the most common neoplasms associated with PPB. We report here an infant girl with unilateral Type I PPB; multiple, bilateral, progressive CN; and intussusception due to ileal 3.2 cm juvenile-like polyp. The child had multiple surgeries, and has been receiving chemotherapy according to the recommendations of the International PPB Registry for Type I (purely cystic) PPB. Eighteen patients with PPB from the Registry, and literature, were noted to have renal neoplasia, most often CN, in themselves (11) or close family members, but only two had the association of PPB, CN and intestinal polyps. In the other case we know of, an infant girl presented with Type I and Type II (solid and cystic) bilateral PPB, bilateral CN, intussusception and multiple small bowel juvenile-like polyps; she received chemotherapy but died at 14 months of age. The association of PPB, CN, and small bowel polyps might be a subset of the familial PPB/CN association that represents a new tumor predisposition syndrome.

Comparative characteristics of morphological changes in rat lungs exposed to different regimens of mainstream smoke

Genova S, Damjanov Iv, Popov D, Bojadjev N, Schtere Ph, Yvancheva R, Jankova ZI
Department of Pathology – Medical University - Plovdiv
Department of Physiology – Medical University Plovdiv
Department of Pulmology –University Hospital ‘St. George’

Emphysema and chronic bronchiolitis are major components of chronic obstructive pulmonary disease in smokers. Our aim is to estimate the quantitative and qualitative pulmonary parameters in short-term mainstream smoke exposition (30 days) in lungs of rats, with high concentration of mainstream smoke (MS), applying two different regimens of exposition. Three groups of male Wistar rats (4 months old 30 in total) were studied: Ist group – 10 rats daily exposed to cigarette smoke (20 cigarettes per day). IInd group – 10 rats with 5 days mainstream smoke exposition, followed by 2 days rest. IIIrd group – 10 control rats. All the experimental animals exposed to smoke developed emphysema with different level of emphysematous change. Due to different regimen conditions, we achieved the following results: average – 60%/I group versus 41%/II group developed emphysema in their lungs, centro-acinar type. Hyperplasia of goblet cells is seen in 9 animals from the Ist group versus 2 animals from the IInd group. Epithelial atipia is expressed in 1 animal from the Ist group, squamous metaplasia in 1 from the IInd group. 8 rats from the Ist group developed interstitial pneumonitis versus 1 rat from the IInd group. All experimental animals showed peribronchial lymphoid hyperplasia and increased intraalveolar macrophages. The application of short-term mainstream smoke exposition led to development of different with respect to degree changes in pulmonary parenchyma depending on the specific regimen. More expressed were emphysema, bronchiolar metaplasia into secretory type and inflammatory reaction in long-term exposition.

Immunocytochemical panel for distinguishing between reactive mesothelial cells and adenocarcinoma in pleural effusions

Telioussi S, Koletsis T, Bobos M, Mandrali A, Ioannou-Banava O
Department of Cytopathology, General Hospital
“G. Papanikolaou”, Thessaloniki, Greece

In pleural effusion cytology the distinction of reactive mesothelial cells (RMC) from metastatic adenocarcinoma (MAC) may be a diagnostic challenge. The aim of this study is to investigate whether a panel of four antibodies can potentially be utilized for facilitating this distinction. Fifty-two Thin Prep cytologic specimens of pleural effusions were selected retrospectively, which included 30 cases of RMC and 22 of MAC. Immunocytochemistry was performed using calretinin, HBME-1, CA 125 and cytokeratins 8/18/19 antibodies. Calretinin was detected in 30 (100%) reactive cases while none of the adenocarcinomas was positive for this marker. HBME-1 was detected in 29/30 (96.7%) of RMC cases and in 14/22 (63.6%) of MAC. CA 125 expression was observed in 19/30 (63.3%) of reactive specimens and in 11/22 (50%) cases of MAC. Cytokeratins 8/18/19 was observed in a slightly higher percentage of RMC (29/30-96.7%) than in MAC (21/22-95.4%) cases. Our results demonstrate calretinin the most specific marker for mesothelial cells, whereas CA125 and HBME-1 do not label mesothelial cells with sufficient specificity. However, suspicious cells negative for HBME-1, it is unlikely to be reactive mesothelial cells. Conclusively, calretinin, HBME-1 and cytokeratins 8/18/19 antibodies appears to be a useful panel for differentiating metastatic carcinomas from reactive mesothelial cells.

P088

Correlation of hyperamylasaemia to histologic type in lung cancer

M.Mastora, E. Tsiami, L. Liappis, E. Kitsiou*, A. Katsanou, G. Dimos, S.Stefanaki*, I.Kakadellis**, N. Akritidis
Department of Internal Medicine, Department of Pathology*, Department of Thoracic Surgery**, General Hospital “G. Hatzikosta” Ioannina, Greece

Raised serum amylase in lung cancer due to ectopic amylase production in carcinoma of the lung has been reported in the literature.

Aim of the study: To correlate the raised serum amylase to histological type in neoplasms of the lung.

Material and methods: 65 patients, who diagnosed and treated during 1 year period, were studied retrospectively (57 male and 8 female). Age ranged from 46 – 88 years. We searched for serum and urine amylase and in patient with abnormally raised levels we correlated to histologic type of cancer.

Results: From the 67 patients, raised amylase levels were found in 13 patients (20%). Levels of the amylase in serum ranged from 152-4114 IU/L (normal value=100). Amylase in urine was also raised. Histologic confirmation was possible for 11 patients (males, 46 – 78 years of age). These were 7 adenocarcinomas, 3 squamous cell carcinomas and 1 small cell carcinomas and the majority of them were poorly differentiated.

Conclusion: Adenocarcinoma appears to relate closely to hyperamylasaemia. This finding agrees to the data from the literature.

P089

Lymphoepithelial-like carcinoma of the lung: report of two cases

Valavanis C.^{1,2}, Tzaida O.¹, Konstantoudakis S.¹, Gavresea Th.¹, Vecchini G.¹, Hatzimichalis A.³, Arapantoni-Dadioti P.¹
¹Dept. of Pathology, ²Molecular Pathology Unit, ³Dept. of Thoracic Surgery, METAXA Cancer Hospital, Piraeus, Greece

Two cases of lymphoepithelial-like carcinoma of the lung, a rare malignant epithelial neoplasm, are presented. This tumor is considered as a subtype of undifferentiated large-cell carcinoma with abundant lymphocytic infiltration.

It has morphologic features similar to lymphoepithelial carcinomas arising in the nasopharynx (most cases) and in others anatomic sites (salivary gland, thymus, skin, cervix, stomach, urinary bladder, esophagus). LELC of the lung is strongly associated with Epstein-Barr virus (EBV) mainly in Asians and less commonly in Caucasians. This neoplasm is thought to have a highly variable biologic behavior and to be more chemosensitive than other lung tumors.

The patients, one female 72 years old and one male 66 years old, presented a slowly growing mass located at the right middle lobe and the left upper lobe of the lung, measuring 3 and 6.5 cm, respectively. The microscopical examination of the two specimens after lobectomy revealed malignant epithelial tumors. The neoplasms consisted of irregular shaped islands of large, anaplastic, eosinophilic, epithelioid cells within a mature type lymphocytic-rich stroma. The immunohistochemical study confirmed the epithelial nature of the neoplasms and the concomitant benign lymphocytic infiltration. Immunohistochemical detection of LMP1 expression and in situ hybridization of Epstein-Barr virus DNA were negative revealing no association with EBV infection.

Differential diagnosis to other pulmonary tumors, possible aetiology/pathogenesis and terminology as well are discussed.

P090

Clinicopathological differential diagnostic approach of BOOP/ COP

R. Tringidou MD¹, K. Malagari MD², C. Lambrakis MD¹, I. Scotis MD¹, M.A. Dimadi MD¹
Pathology Dept. – 1st and 2nd Pulmonary Depts and 1st Surgical Thoracic Dept of Athens Chest Hospital “SOTIRIA”, Dept of Radiology – University of Athens - Greece

Background: Bronchiolitis obliterans with organizing pneumonia (BOOP) is a clinicopathological entity described in 1985 by Epler. In the recent ATS-ERS classification of Interstitial Lung Diseases / ILD (2002) was used the term COP (cryptogenic organizing pneumonia) to describe cases of organizing pneumonia of unknown etiology.

Aim: The correlation of clinical, radiological and histological findings, for the correct diagnosis, in difficult cases especially those with clinical suspicion of malignancies or other interstitial diseases.

Methods: We studied four (4) years (2000-2004) archival material from Pathology, 1st-2nd Pneumonology Depts of Athens Chest Hospital, concerning cases diagnosed as BOOP or COP, based on recent criteria proposed by ATS-ERS classification.

Results: From the retrospective study we select a number of fifteen (15) cases, 9 males and 6 females, with known clinical history in eight (8) cases and unknown etiology in the rest seven (7) cases. Three (3) of the seven (7) cases represent radiologically as “solid intrapulmonary lesion” and have differential diagnostic “dilemma” with malignancy and four (4) cases of unknown etiology have “atypical” clinical and CT findings. We categorized the 15 cases in 3 groups. **Group 1:** Eight (8) cases as secondary BOOP, **Group 2:** Four (4) cases as COP and **Group 3:** Three (3) cases as “solid BOOP”.

Conclusions: 1. “Focally organizing pneumonia” may be the final diagnosis in a small proportion of surgical removed cases with “intrapulmonary solid lesion” and clinical suspicion of malignancy. 2. In every case diagnosed as BOOP or COP, the correlation with clinical and CT findings for the final diagnosis must be taken in mind. 3. The diagnosis of BOOP/COP is a diagnosis of exclusion, because similar histological changes can be observed in other interstitial diseases/ILD (EAA, H.P., UIP, DAD).

P091

Intrapulmonary Castleman disease in male with allergic rhinitis

Jelena Stojic, Tatjana Eminovic, Dragan Subotic, Svetlana Krstic
Department of Molecular Genetic Bases of Production Processes, Institute for Lung Diseases and Tuberculosis, Clinical Centre of Serbia, Belgrade, Serbia

Localized Castleman disease (CD) is often reported in mediastinum. CD localised in intrapulmonary lymph nodes is rare. We present a male, aged 25, who went under thoracotomy because of tumorous node in middle lobe of right lung. Tumorous mass was detected on chest x-ray and CT scan examinations, made because of coughing. Patient suffered from allergic rhinitis on Ambrosia (*Ambrosia artemisiifolia*, *Ambrosia elatior*) and was treated by steroids. There was not any immune dysregulation before the thoracotomy: level of immunoglobulins and proteins were regular on routine blood tests. Patient was HIV seronegative. The middle right lobe with tumorectomy was performed. CD of hyalino-vascular type was diagnosed on well circumscribed, solid tumor node, measured approximately 30mm in the largest diameter. Numerous lymphoid follicles of concentric layers of small, inactive lymphocytes without mitoses and interfollicular vascular hyperplasia was found. Post-operatively there was not found recurrence of tumor. He still suffers from allergic rhinitis. CD is of still unknown etiology and remains a question whether CD is a response of organism for

allergic condition. Hyalino-vascular type of CD is most frequently diagnosed in young males, as mediastinal mass according to the Ioachim's checklist. Intrapulmonary localisation of CD is rare. CD could be developed in every organ where lymphoid tissue normally persists.

P092

Prognostic impact of lymphangiogenesis and lymphatic invasion (CD105 expression) in small cell lung carcinomas

Hardavella G², Arkoumani E¹, Nesseris I¹,
Constantopoulos S² and Stefanou D¹

¹Department of Pathology and ²Department of Pneumology,
University of Ioannina, Medical School, Greece

Lymphangiogenesis is an essential process in the metastasis of malignant tumors that has not been thoroughly studied. The aim of this study is to evaluate the prognostic impact of tumor lymphangiogenesis and lymphatic invasion in SCLCs. 49 patients were retrospectively reviewed. Intratumoral lymphatic microvessel density (ILMVD) and lymphatic invasion were determined with an anti-CD105 monoclonal antibody (Menarini Hellas). Tumor specimens exhibiting ILMVD<50 and lymphatic invasion corresponded to a mean survival of 8,75 months being opposed to 11,37 months for patients without lymphatic invasion. ILMVD≥50 with lymphatic invasion corresponded to a mean survival of 7,5 months, while the absence of lymphatic invasion increased the mean survival to 12,67 months. There is a direct correlation between ILMVD and the mean survival in SCLC patients. Increased ILMVD and lymphatic invasion are related with poor patient outcome, therefore constituting a prognostic role on SCLC.

²2nd Department of Internal Medicine, Semmelweis University, Budapest;

³County Hospital of Pulmonology, Törökbalint;

⁴3DHISTECH Ltd, Budapest;

⁵Laboratory of Tumor Pathology and Molecular Diagnostics, Bay Zoltán Foundation for Applied Research, Szeged;

⁶Department of Surgery, University of Szeged; Hungary

This study aimed at the prognostic immunomorphological profiling of non-small cell lung cancer (NSCLC) tumor progression using tissue microarrays (TMA). Donor blocks were from 87 patients, including 33 non-metastatic primary NSCLC (18 SCC, 13 ADC, 1 LCC and 1 APC), 26 metastatic primary NSCLC (14 SCC, 10 ADC, 2 LCC) and the brain metastases of the latter group. TMA sections immunostained for molecules of cell adhesion, cell growth, cell cycle and apoptosis regulation were digitalized and the Mirax TMA software was used for validated scoring and linking image and patients data for analyses. Prominent expression of collagen XVII, CD44v6 and caspase-9, and the reduced production of β -catenin and cellular apoptosis susceptibility (CAS) protein were significantly associated with the brain metastatic primary NSCLC. Survival analyses revealed a highly significant negative correlation with the brain-metastatic NSCLC group, a positive correlation with β -catenin expression and an almost significant inverse link with cyclinD3 or p16 expression. 2/3rd of the brain-metastatic cases (16/26) formed a cluster of 24 cases out of 85, based on cyclinD1, -D3, Ki67, p16, p53,

β -catenin and collagen XVII expression (correlation: 0.74). Members of the in-cluster group showed significantly poorer survival than those set outside the cluster. The metastatic capacity of NSCLC into the brain may be predicted from the concurrent demonstration of cell cycle activation (cyclinD1, -D3, Ki67), the up-regulation of p16 and Collagen XVII, and the down-regulation of β -catenin. The software highly facilitated this study.

I. Sinescu

Department of Pathology, Fundeni Clinical Institute; Center for Surgical Urology, Dialysis and Renal Transplant, Fundeni Clinical Institute, Bucharest; GRHD Foundation, Bucharest.

From 838 parenchymatous renal tumours treated by radical nephrectomy in our Center we recorded clinical and instrumental data which concluded to the diagnosis of parenchymatous renal tumor. All the cases experienced an anterior transperitoneal radical nephrectomy together with regional lymph nodes dissection. For each kidney sagittally sectioned, pelvis, ureteral stump and renal vein opened, we evaluated the weight, the size and the tumor's features; presence/absence of the invasive aspects and the aspect of residual renal parenchyma. Microscopic exam was performed for 3-5 tumor fragments, 1-2 adjacent parenchyma, 1-2 pelvis fragments, elements with pedicle and lymph nodes identified. Four-micrometer tissue sections were stained with H&E, special stains (vanGieson, Masson trichromic, PAS) and examined by two pathologists. In 20 cases immunohistochemical stains were performed. The histology type and tumor staging respect the Classification of the Renal Parenchymatous tumors. Postoperative follow-up was done by imagistic exam every 3-6 months.

P095

The relationship between COX-2 expression, microvessel density and various clinicopathologic parameters in clear cell type renal cell carcinoma

Hasan Gucer, Elife Sahan, Aysenur A. IGDEM, Alpaly Cetin,
Umit S. TETIKKURT, Nusret Erdogan

Department of Pathology, Taksim Training and Research Hospital,
34433 Istanbul, Turkey

Overexpression of cyclooxygenase-2 (COX-2) and its association with angiogenesis is shown in various carcinomas. In this study, we investigated COX-2 expression in the clear cell type renal cell carcinoma (CRCC) and its association with microvessel density (MVD) and clinicopathologic parameters.

Fifty cases of CRCC were included in this study. COX-2 expression was examined immunohistochemically. MVD was estimated using the video-microscope system described. We evaluated the correlation between COX-2 expression, MVD and clinicopathologic findings. COX-2 was expressed in 76% of cases. There was no association with COX-2 expression and MVD, age, sex, tumor size, nuclear grade, stage and cytoplasmic eosinophilia (p=0.616, p=0.844, p=0.920, p=0.631, p=0.251, p=0.385 ve p=0.874). Only there was an association with MVD and cytoplasmic eosinophilia (p=0.003). Most of CRCC expressed COX-2, but there was no relationship between COX-2 and various clinicopathologic parameters.

Prenatal Diagnosis of Joubert Syndrome with Medullary Cystic Kidneys

Diclehan Orhan*, Şafak Güçer*, Özgür Özyüncü**, Lütfü Önderoğlu**, Gülsev Kale*

Hacettepe University Faculty of Medicine, İhsan Doğramacı Children's Hospital, Division of Pediatric Pathology, Ankara, Turkey, ** Hacettepe University Faculty of Medicine, Department of Obstetrics and Gynecology, Ankara, Turkey

We present the autopsy findings of a fetus with Joubert syndrome with medullary cystic kidneys diagnosed prenatally. Twenty-eight years old patient at 19 weeks gestation was admitted to our hospital with gravidity 3, parity 0. Her obstetric history was remarkable. Her first pregnancy was terminated at the 17th week of gestation as the prenatal scan revealed isolated encephalocele. Necropsy was not available. Her second pregnancy was an anembryonic pregnancy and dilatation and curettage was performed at the 6th week of gestation. Prenatal scan at the 19 weeks of this gestation revealed a cyst at the posterior fossa and encephalocele with an occipital bone defect. Elective termination was performed at the 19th week of gestation that revealed a 220 grams female fetus. An autopsy was performed. Examination of the central nervous system at autopsy revealed agenesis of the cerebellar vermis, occipital meningocele, Dandy-Walker malformation and agenesis of the corpus callosum. Extracerebral malformations were medullary cystic kidneys and congenital hepatic fibrosis. This case had bilateral medullary cystic kidneys which has not been previously described in this syndrome.

P097

Morphometric and immunohistochemical study of the fibrosis in the interstitial compartment of kidneys with primary glomerulopathies

Slavica Kostadinova - Kunovska¹, Gordana Petrusavska¹, Rubens Jovanovic¹, Ladislava Grcevska², Momir Polenakovic²

¹Institute of Pathology, Faculty of Medicine, Skopje, Macedonia

²Department of Nephrology, Clinical Center, Skopje, Macedonia

The mechanisms of the interstitial damage in all glomerular diseases are almost the same, resulting in interstitial fibrosis. The interstitial inflammatory cells influence the tubular epithelial cells which undergo the process of epithelial-mesenchymal transdifferentiation, expressing de novo mesenchymal proteins. We made a morphometric and immunohistochemical study on 10 renal biopsies, previously diagnosed as IgA nephropathy or membranoproliferative glomerulonephritis. We found fibrosis occupying more than 10% of the tubulointerstitial surface in all 10 patients and 6 of them had moderate level of fibrosis, occupying more than 20% of the tubulointerstitial space. The inflammatory infiltrate was more prominent in the areas with fibrosis, with a slight predominance of the CD43 positive T-lymphocytes. In these areas the tubules showed marked injury and atrophy. The epithelial cells in the atrophic tubules showed positivity for HLA-DR, vimentin and SMA, acquiring mesenchymal phenotype. These results are consistent with the present understanding of the processes in the interstitium of kidneys with primary glomerular diseases and encourage further investigations in that field.

P098

The prognostic value of several immunohistochemical markers in renal cell carcinoma

M. Strataki, C. Petraki, C. Magkou, A. Rigas, G. Kanellis, K. Demosthenous, S. Stefanakis, M. Koutsilieris.

Department of Pathology, Evangelismos Hospital, Athens, Greece

To evaluate the prognostic value of the immunohistochemical markers ck7, ker34βε12, ck19, ck8-18, rcc, vimentin, ema, cd9, cd10 and e-cadherin, as well as of the hale's iron stain in localized renal cell carcinoma (rcc). the study comprised 94 patients who underwent radical nephrectomy (median follow-up period: 37 months, range: 2-156 months). the streptavidin-biotin-peroxidase method of immunostaining was performed. of 94 rcc cases, 67 (71.3%) were of clear cell type, 3 (3.2%) of chromophobe type, 5 (5.3%) of papillary type i, 5 (5.3%) of papillary type ii, 9 (9.6%) unclassified oncocyctic and 5 (5.3%) unclassified pleomorphic. in univariate analysis, type i papillary, chromophobe and unclassified oncocyctic rccs had better prognosis than type ii papillary, clear cell and unclassified pleomorphic rccs (p=0.0010). nuclear grade, pt stage, mitotic index and vimentin immunoeexpression were inversely correlated with disease specific survival (p<0.0001, p<0.0001, p<0.0001 and p=0.0030, respectively). however, in multivariate analysis, only pt stage, vimentin and cd10 immunoeexpression were proved to be independent prognostic factors (p<0.001, p=0.010 and p=0.036, respectively). we conclude that vimentin and cd10 immunoeexpression in combination with pt stage may predict a poor disease outcome in localized rcc.

P099

The diagnostic utility of several immunohistochemical markers in the subtyping of renal cell carcinoma.

C. Magkou, C. Petraki, M. Strataki, A. Rigas, I. Evangelou, P. Argyriou, D. Malovrouvas, M. Koutsilieris

Department of Pathology, Evangelismos Hospital, Athens, Greece

To evaluate the diagnostic value of the immunohistochemical markers CK7, Ker34βE12, CK19, CK8-18, RCC, vimentin, EMA, CD9, CD10 and E-cadherin, as well as of the Hale's iron stain in localized renal cell carcinoma (RCC). The study comprised 94 patients who underwent radical nephrectomy for RCC (median follow-up period: 37 months, range: 2-156 months). The streptavidin-biotin-peroxidase method of immunostaining was performed for all antibodies assessed. The relationships between markers' expression and the histological type were evaluated by Pearson's 2 test. Three major phenotypes were recognized: i. CK7(-), E-cadherin(-) and Hale's(-) phenotype (in 78% of clear cell RCCs), ii. RCC(-), Vimentin(-), CK7(+), E-cadherin(+) and Hale's(+) phenotype (in 100% of chromophobe RCCs) and iii. CK7(+), E-cadherin(+) and CK19(+) immunophenotype (in 90% of papillary RCCs, type I and II). According to these phenotypes, we attempted to classify the so-called unclassified cases. Of the unclassified oncocyctic RCCs, 7/9 were of clear cell type, 1 case was of chromophobe type and 1 case of oncocyctic type. Of the unclassified pleomorphic RCCs, 4/5 were of clear cell type and 1 case was of papillary type. We conclude that CK7, CK19, E-cadherin, vimentin and Hale's iron stain are useful markers in the subtyping of RCC.

P100

Inflammatory pseudotumor of the renal pelvis associated with tuberculosis

Alexandrou Paraskevi, Liapis George, Kokkori Katerina, Kyriakou Vassiliki, Androulaki Athina

Department of Pathology, LAIKO General Hospital

Inflammatory pseudotumor is an uncommon manifestation of mycobacterial infection predominantly affecting immunosuppressed individuals. Urogenital tuberculosis is still frequent but the pseudotumoral manifestation is a rare entity that has only recently been described in one case. We report a case of 40-year-old male who presented with fever, painless gross haematuria and tenderness in the right lumbar region. The radiological and CT scan findings were suggestive of a pelvic tumor and a radical right nephrectomy was

performed. Macroscopy revealed a white tan tumor (9,2 x 6 x 4,5 cm) hard in consistency, involving the peripelvic fat and protruding into the pelvic system. Microscopic examination exhibited a hypocellular spindle cell lesion with a collagenous fibrous stroma admixed with variable lymphoplasmacytic and neutrophilic infiltrates admixed with isolated Langhans' giant cells. Scattered epithelioid granulomas with foci of caseous necrosis were found at the periphery of the lesion on serial sections. Although Ziehl-Nielsen did not show any acid-fast bacilli, PCR subsequently confirmed the suspicion of mucobacterial inflammatory pseudotumor. By recognizing this entity which may have a misleading clinical presentation the pathologist does not only avoid misinterpretation but also provides an accurate diagnosis of infection that can be treated immediately and specifically.

P101

Solitary fibrous tumor of the kidney

Liapis George, Alexandrou Paraskevi, Giaslaktiotis Konstantinos, kyriakou Vassiliki
Department of Pathology, LAIKO General Hospital, Athens

Solitary fibrous tumor is encountered in many organs while its occurrence in the kidney seems to be a rarity since only fifteen cases have been reported in the reviewed literature. We present a rare case of solitary fibrous tumor of the kidney which was found incidentally in a 26-year old man after a car accident. CT scan revealed a large tumor which occupied the upper pole and the middle portion of the right kidney compressing the pelvis. A right nephrectomy was performed. The tumor measured 7x5,6x4,4 cm, was solid and firm with a whitish cut surface. Microscopically, a spindle cell neoplasm with alternating hyper- and hypocellular areas, hemangiopericytoma-tous pattern and dense keloid-type collagen deposition was found. Immunohistochemically, the tumor cells were consistent positive for CD34, CD99 and bcl-2 while they were negative to HMB-45 and desmin antibodies. A diagnosis of solitary fibrous tumor was established. Differential diagnosis includes high and low grade sarcomas such as synovial sarcoma and low grade myxoid fibrosarcoma as well as neoplasms with a totally benign behavior such as mixed epithelial stromal tumor and angiomylipoma. As far as histogenesis is concerned, most of the published cases favor a capsular or peripelvic origin.

P102

Fetal kidneys stroma remodelling in cases of IUGR

Olexander P. Sysoenko, Olga S. Reshetnikova, Sergiy A. Morozov
Department of Pathologic Anatomy, Lugansk State Medical University, 1, kv. 50-let Oborony Luganska, 91045, Lugansk, Ukraine

It is suggested that fetal intrauterine growth retardation (IUGR) may lead to hypertension in adults. Alteration of kidneys tissue maturation may play an important role in the pathogenesis of a hypertension too. The aim of present study was to determine the distribution of the III type collagen in forming of connecting tissue of the fetal kidneys in cases of IUGR. Methods: 20 pairs of fetal kidneys (including 10 pairs of kidneys in cases of IUGR) from the late medical abortions because of psychotherapeutic reasons at 20-22 weeks of gestation were weighted, studied macroscopically and microscopically, and then the distribution of the III type collagen with the help of antibodies was investigated. Results have shown that kidneys in IUGR group have macroscopic and histological signs of both organ and tissue growth restriction. The intensity of the III type collagen expression and the area of its distribution increased, mainly in the perivascular connective tissue, kidneys cortex and medulla's stroma. Conclusion: Fetal IUGR is accompanied with the lesion of renal tissue formation. The intensified synthesis of collagen III may be a marker of tissue

remodeling when connective tissue formation and sclerosis outrun the parenchyma elements growth and maturation.

P103

Lymphangioma of the kidney: case report

Papanikolaou A¹, Chatzitoliou A¹, Amplianitis I¹, Tougiaris C², Tatsiou Z¹, Salpigdis G²

¹Department of Pathology, Hippokratio Hospital of Thessaloniki, Greece, ²Department of Urology, Hippokratio Hospital of Thessaloniki, Greece

Renal lymphangioma is an exceedingly rare tumor, with only 36 cases reported Worldwide, so far. Our case is about a 32 year old man who was admitted to hospital after a syncopic episode. During the patient's examination an abdominal CT scan was performed which saw a 4,5x3,8 cm. multiloculated cystic mass in the mid-portion of the right kidney. The followed needle biopsy saw a benign neoplasm of the kidney probably multicystic nephroma. Therefore enucleation of the tumor was performed. Pathological evaluation of the specimen diagnosed lymphangioma arising from the kidney. The patient is free of disease after an 1 month follow-up period. The purpose of this paper is to describe the clinicopathological characteristics of the disease, stressing on the differential diagnosis between the renal lymphangioma and the multicystic nephroma.

P104

Paraganglioma of urinary bladder

GHAINI M. Hossein, SAKI Soheil, FROOTAN Kazem,
Presenting author: SAKI Soheil
Student of medicine, Faculty of medicine, Tehran University of Medical sciences, Iran

“Urinary bladder is a rare site of paraganglioma. We describe a paraganglioma of the urinary bladder in a 51-year-old female who presented with painless gross hematuria. Abdominal ultrasonography revealed a protruding well-defined mass, about 3Cm. in diameter over the left lateral wall of the urinary bladder. The tumor was not completely resected by transurethral resection of bladder tumor (TURBT) due to involvement of the bladder wall. Histologic examination of the tumor indicated clusters of polygonal chromaffin cells, arranged in nests (zellballen). Although there was marked pleomorphism and atypia in nuclei, no evidence of recurrence or metastasis has been seen since about 1 year. There is no reliable method for predicting their clinical behavior, so long-term follow-up is required. We also provide a brief review of the literature for comparison.”

P105

Primary signet-ring cell carcinoma of urinary bladder: A case report

Papanikolaou A.¹, Tatsiou Z.¹, Moulla A.¹, Chatzitoliou A.¹, Xiromeritis M.², Brouskelis N.², Athanasiou E.¹
Department of Pathology¹ and Urology², Hippokratio General Hospital, Thessaloniki, Greece

Primary signet-ring cell carcinoma (SRC) of urinary bladder is a rare tumour, accounting for less than 1% of all bladder malignancies. In this study we report a case of a 60-year old man who consulted for complaints of painless gross hematuria. The bladder biopsy showed signet-ring cell carcinoma. The exploration of gastrointestinal tract and prostate did not reveal any other tumour localizations. A total cystoprostatectomy was performed. Macroscopically a large bladder intrawall tumor revealed resembling linitis plastica of the stomach. Microscopically, the tumour consisted entirely of signet ring cells which infiltrated the entire bladder wall and the peribladder lipoid

tissue. The immunohistochemical profile of neoplastic cells was: cytokeratin 7+, cytokeratin 20+, PSA-, PSAP-. The patient died 1 year after the cystoprostatectomy. The aim of this study is to describe the clinicopathological characteristics of this rare and very aggressive tumour.

P106

Fascin expression in urothelial carcinomas

F. Karasavvidou, S. Barbanisa, D. Pappaa, E. Tziastoudi, G. Kalodimos, M. Ioannou, V. Tzortzisz, M. Melekosb, A. Soumelidisa, G. Koukoulisa.
Departments of Pathologya and Urologyb, University Hospital, Larissa, Greece

Fascin is an actin-bundling protein with a role in increased motility of various transformed cells. There is only one report concerning its expression in urothelial carcinomas.

We examined by immunohistochemistry the expression of fascin in 98 samples of urothelial carcinomas, of 98 patients, 84 men and 14 women. Fifty eight cases were of low grade and stage (pTa) and 40 were of high grade, 9 stage pTa, 14 pT1 and 17 pT2.

The intensity of immunoreactivity was semiquantitatively graded by comparing it to the average staining intensity of endothelial cells: "weak", "moderate" and "intense". None of the low grade/pTa tumors showed "intense" staining, with more than 70% of these tumors showing only weak immunoreaction. "Intense" staining was seen exclusively in invasive carcinomas, frequently (more than half of them), and not restricted to the invasive component. pTa carcinomas of low or high grade showed comparable fascin expression. Notably, in 15% of high grade carcinomas, most of them invasive, fascin expression was not detectable immunohistochemically.

Our results show an association between strong intensity of fascin immunostaining and high grade invasive urothelial carcinomas, suggesting that fascin expression may be an indicator of biologic aggressiveness of these neoplasms.

P107

CDX2 expression in urothelial transitional carcinoma

S. Barbanis, F. Karasavvidou, M. Ioannou, G. Kalodimos, R. Papamichali, E. Tziastoudi, G. Koukoulis.
Department of Pathology, University Hospital, Larissa, Greece.

CDX2 (caudal-related homeobox gene 2) is a recently cloned gene that encodes an intestine specific transcription factor, which is important for the establishment and maintenance of intestinal cells. CDX2 is a sensitive marker of intestinal metaplasia and is also expressed in neoplasms of intestinal origin and some neoplasms with intestinal differentiation. Very few reports have investigated CDX2 expression in a small number of urinary bladder metaplasias and neoplasms. It is usually absent in primary adenocarcinomas and totally absent in transitional carcinomas of the urinary bladder. We present a case of urinary bladder carcinoma with CDX2 expression. This was a case of a 59 year old man with a high grade, widely invasive urothelial carcinoma showing areas with glandular differentiation. The glandular component showed strong CDX2 nuclear immunopositivity, in addition to cytokeratins 7 and 20 immunostaining. Interestingly, CDX2 positivity was also seen in foci of conventional urothelial transitional carcinoma without morphologic glandular differentiation. We investigated 10 additional cases of urothelial transitional carcinomas without glandular differentiation, all of which were negative for CDX2. This aberrant expression of CDX2 is reported for the first time in urothelial transitional carcinoma. It may be used as an early marker of glandular/intestinal

differentiation of neoplastic or reactive/metaplastic urothelium, similarly to its proposed application in Barrett's esophagus.

P108

The presence and nature of lipoblast-like cells in urothelial carcinomas.

Dimitris Hatzianastassiou¹, Elias Drakos², Konstantinos Giaslaktiotis², Nikolaos Goutas³, Sofia Havaki¹, Evangelos Marinos¹, Johanna Delladetsima².

¹Laboratory of Histology-Embryology, Medical School, University of Athens, ²Department of Pathology, Laiko General Hospital, ³Laboratory of Forensic Medicine and Toxicology, Medical School, University of Athens, 75 Mikras Asias, 115 27 Athens, Greece.

Lipoblasts-like cells (LBLCs) in urothelial cell carcinomas (UCCs) are rare and their presence defines the lipid-cell UCC variant. 450 cases of urothelial carcinomas, diagnosed in our department over a period of three years, were screened for LBLCs and the selected three cases were stained for mucins and immunohistochemically for cytokeratin 7, low molecular weight keratins, S-100 and vimentin. In one case, paraffin embedded tissue was processed for electron microscopy. The diagnosis of UCC, lipid-cell variant was justified in one case, while the other two cases showed focal presence of LBLCs. All three cases were high grade urothelial carcinomas. LBLCs were negative for mucin, S-100 and vimentin; cytokeratins were strongly positive. EM findings were consistent with intracellular lipid accumulation showing various-sized, predominantly free, and in a lesser number, membrane-bound lipid droplets. LBLCs in the setting of UCC, either as a constituent of lipid cell variant, or as a focal phenomenon, are rarely encountered. EM findings provide evidence of true intracellular lipid accumulation.

P109

The prognostic value of CK20, 34betaE12, p53, bcl2, c-erbB-2, Ki-67, CD44 and PSMA immunohistochemical expression (IHCE) in patients with primary low-stage (pTa/T1) urothelial urinary bladder carcinoma (UUBC).

K. Revelos¹, C. Magkou², I. Kouda², F. Michalopoulou², E. Theophanous², M. Strataki², A. Takou², S. Stefanakis³, D. Malouvrouvas³, C. Petraki².

¹Pathology Dept., 251 Hellenic Air Force Hospital and ²Pathology and ³Urology Depts., Evangelismos Hospital, Athens, Greece.

The prognostic value of the IHCE of CK 20, 34βE12 antigen, p53, bcl2 & c-erbB-2 oncoproteins, the cell proliferation marker Ki-67, the cell adhesion molecule CD44 and the prostate-specific membrane antigen (PSMA), in predicting tumor relapse in patients (pts) with primary low-stage (pTa/T1) UUBC was investigated. Included in the study were 174 consecutive pts, who underwent transurethral resection (TUR) and 132 of them (76%) had a low-stage disease (pTa: 36, T1: 96 pts). Median follow-up period was 11.5 (3-20) months and 46 (35%) pts recurred. CK20, p53, c-erbB-2, Ki-67, CD44 and PSMA showed a statistically significant positive relation with histological grade (HG) and pathological stage and bcl2 only with HG. The recurrence rate of the pTa/T1 subgroup was positively related with HG, pathological substaging, CK20, bcl2 and Ki-67. HG, pathological substaging, CK20, bcl2, c-erbB-2 and Ki-67 had a positive statistically significant relation with the recurrence-free interval. HG, Ki-67 and PSMA were independent unfavourable predictors for recurrence and may be useful markers for decision management in this group of patients.

P110

Correlation between grade and EGFR overexpression in TCC of bladder

M.R. Jalali Nadoushan, F. Zaeri, H. Ahmadi.
Shahed University, Tehran, Iran

Introduction: TCC of the urinary bladder is second common cancer of genitourinary tract several parameters such as clinical, pathological and molecular factor have effect on determination of prognosis and type of treatment. In this study we show that grade in TCC has a direct relationship with EGFR.

Methods: This cross-sectional study was performed in paraffin embedded tissue from 75 patient with TCC of urinary bladder 3micron section were provided from each one in all section grade of tumor was determined an ordering to WHO/ISUP criteria The present of EGFR positive cell were counted from microscopic observation in each section.

Findings: in this study 14 case were LMP (18.7%) that 10 case among them had negative cells about EGFR (71.4%) and 4 case had positive cells (28.6%) 35 case were low grade (46.7%) that 18 case among them had negative cells about EGFR (51.4%) and 17 case had positive cells (48.6%) 26 case were high grade(34.7%) that 9 case among them had negative cells about EGFR (34.6%) and 17 case had positive cells (65.4%).

Conclusion: Over expression of EGFR has direct relationship with tumor grade that some of previous studies had these results too other studies with more case and check over expression of EGFR could be used as prognostic in TCC of urinary bladder.

P111

Evaluation of the role of Vascular Endothelial Growth Factor (VEGF)-C in the urothelial carcinomas of the bladder.

¹Gorandonakis G, ¹Magkou C, ¹Nomikos A, ³Zarogiannos A, ²Giannopoulou I, ¹Zoumbouli C, ³Zervas A,^{1,2}Nakopoulou L.
¹Second Pathology Department, Attikon Hospital, ²First Pathology Department, Medical School, ³Department of Urology, Laikon Hospital.

Vascular endothelial growth factor-C (VEGF-C) is significantly associated with angiogenesis and lymphangiogenesis in cancer. The aim of the present study was to examine VEGF-C expression along with classical clinicopathological parameters and patient survival, and to investigate its possible antiapoptotic and proliferative role in BUC. Immunohistochemistry was applied on 123 paraffin-embedded specimens of BUC for the detection of the VEGF-C, Ki-67 and bax proteins. VEGF-C was mainly expressed in tumor cell cytoplasm. Of 123 BUCs, 27 (22.0%) were VEGF-C positive. VEGF-C was inversely correlated with tumor pathological stage ($p=0.007$) and negatively associated with bax immunoeexpression ($p=0.032$). VEGF-C expression was related neither to classic prognosticators i.e. tumor grade nor to Ki-67. Patients with VEGF-C positive tumors tended to have better prognosis. The present study implies that VEGF-C may be an early event in the carcinogenesis and might have an antiapoptotic role. However, its potential prognostic significance remains to be clarified.

P112

Primary non-Hodgkin lymphoma of urinary bladder with eight years later renal involvement and absence of systemic lymphoma. A case report.

¹Tatjana Terzic, ¹Sanja Radojevic, ²Vesna Cemerikic, ¹Gordana Basta-Jovanovic, ¹Sanja Citlucanin, ¹Dragan Mitrovic, ¹Jasmina Markovic-Lipkovski
¹Institute of Pathology, School of Medicine University of Belgrade, ²Histolab, Belgrade, Serbia and Montenegro

Primary bladder non-Hodgkin lymphoma (PBNHL) is very rare, especially as extranodal B-small lymphocytic lymphoma (B-SLL). Also, late isolated renal manifestation of PBNHL is extremely unusual. The diagnosis was based on morphology and immunostaining. Immunohistochemical analysis was performed on 10% formalin-fixed paraffin embedded sections using streptavidin-peroxidase technique. A case report: A-56-year-old women was presented with a solitary tumor situated outside at the left lateral bladder wall. A transvaginal needle biopsy of the tumor was performed. A diagnosis of primary extranodal B-SLL was made in the absence of lymph node, bone marrow or blood involvement. She was treated with LOP protocol until achievement of complete remission. Eight years later, she developed nephrotic syndrome. The renal biopsy revealed parenchymal involvement by the NHL cells with the same immunophenotype like in bladder wall eight years ago (B-SLL). Restaging procedure showed no evidence of disease elsewhere. Chemotherapy was recently performed and she will be carefully followed up. To our knowledge, it is the first case of very rare primary extranodal bladder B-SLL associated with late renal involvement, but without any evidence of disease elsewhere.

P113

Uncommon Neoplasms of the Urinary Bladder: 4 Case Reports

Kemal Behzatoglu*, Burak Bahadir**, Nilsen Y. Erdogan*, Sule Canberk*, Gulben E. Huq*, Banu D. Gun**, Sukru O. Ozdamar**
Departments of Pathology; Istanbul Training and Research Hospital*, Zonguldak Karamelmas University School of Medicine**, Turkey

We present four cases of uncommon malignant neoplasms of the urinary bladder with more aggressive clinical courses requiring different treatment modalities; two adenocarcinoma in situ, one lymphoepithelioma-like carcinoma, and an additional neoplasm with features resembling yolk sac tumor. Microscopically, the yolk sac-like tumor was hypercellular and composed of undifferentiated cells with high mitotic index. Microcysts lined by flattened cells with luminal eosinophilic material were also observed. No hepatoid appearance was noted histologically. By immunohistochemistry, tumor cells were positive for AFP, β -HCG, and vimentin and focally expressed cytokeratins. CEA, EMA and PLAP were negative. The histologic examination of the second case, previously diagnosed as urothelial carcinoma revealed undifferentiated cells associated with prominent lymphocytic infiltrate consistent with lymphoepithelioma-like carcinoma. Cases diagnosed as in situ adenocarcinoma showed flat columnar surface epithelium without papillary projections fulfilling morphologic criteria of in situ carcinoma. Considering urothelial carcinomas may contain areas differentiating toward other cell origins, pathologists should be aware of these uncommon tumors with pure patterns.

P114

Multiple urogenital neoplasia: a case of a triple carcinoma

Ioannis EFSTRATIOU, Irina ZINOVIEVA Institute of Pathology, Papageorgiou General Hospital, Thessaloniki, Greece

We report a rare case of a patient with three synchronous carcinomas originating from the urinary bladder, the kidney and the prostate gland. A 65-year-old man underwent a transurethral resection of a urinary bladder tumor. The histological diagnosis was transitional cell carcinoma with infiltration of the muscular wall. Meanwhile a CT showed a tumor in the left kidney. A subsequent cystoprostatectomy, pelvic lymphadenectomy and nephrectomy were performed. The histology of the resected specimens revealed: 1) a residual high grade bladder tumor invading the deep muscle (pT3apN0, Grade III), 2) a 0,8cm in diameter adenocarcinoma of

the prostate gland (Gleason score: 3+3=6) and 3) a well differentiated papillary (chromophil) renal cell carcinoma 2,7cm in diameter. Multiple primary neoplasia increases with age and, although rare, it is nowadays more frequent due to the increasing life expectancy and more accurate diagnostic procedures. A combination of bladder and prostate carcinoma is not infrequent. In our case the rare event is a third malignancy also located in the urogenital tract. There are specific predisposing factors for each of the three malignant tumors. Our patient was a heavy smoker. Chromophil renal cell carcinoma has a characteristic pattern of cytogenetic abnormalities. Clinicians should always investigate the possibility of a synchronous or metachronous tumor in patients suffering from cancer.

P115

Prognostic value of EGFR, MIB-1 and P 53 in urothelial bladder carcinoma

Zizi-Serbetzoglou A, Grammatoglou X, Glava C, Vasilakaki Th. Department of Pathology, Tzaneion General Hospital of Piraeus, Piraeus, Greece

Bladder cancer is a common malignancy with highly varied growth patterns. EGFR has been associated with the genesis of bladder tumors. The aim of this study was to investigate the expression of EGFR, MIB-1 cell proliferation and p53 and examine their prognostic value in the progression of bladder cancer.

Material and methods: We examined the immunohistochemical expression of EGFR, MIB-1 and p53 in formalin-fixed paraffin tissue samples from 89 cases of urothelial carcinoma (TUR), 42 low grade and 47 high grade urothelial carcinomas, corresponding in 69 superficial tumors (40pTa,19pT1a,10pT1b) and 20 infiltrative tumors (pT2). EGFR expression was stronger in invasive tumors ($p < 0,0001$) and in high grade tumors ($p < 0,0001$). Median nuclear over-expression of MIB-1 and p53 index were 58% and 12% respectively.

Conclusion: MIB-1 antigen and p53 index correlated significantly with the clinical outcome. There is a link between EGFR expression, cell proliferation and high tumor stage/grade and also between EGFR/MIB-1 expression and poor outcome of bladder. The staining pattern of EGFR and its widespread expression in bladder cancer makes it a good target for antigrowth factor or gene therapy.

P116

Frameshift mutations in target genes of the microsatellite instability pathway in urothelial carcinomas of the bladder

Maria S. Karlou, Angelica A. Saetta, Penelope A. Korkolopoulou, Elias A. El-Habr, Irene Thymara, Euphemia Thomas-Tsagli, Efstratios S. Patsouris Department of Pathology, Medical School, National and Kapodistrian University of Athens, Greece

Microsatellite instability (MSI) is an indicator of deficiency in the DNA mismatch repair system. We searched for mutations at target genes of the MSI pathway in correlation with the expression of MMR genes, hMLH1 and hMSH2, in urothelial carcinomas (UCs) of the urinary bladder and evaluated their possible prognostic significance. Seventy-two tumour samples from patients with primary UC were examined for mutations at repetitive sequences of hMSH3 (A)8, hMSH6 (C)8, Bax (G)8, TGF- β R2 (A)10, IGF1R (G)8 and caspase-5 (A)10 genes and immunohistochemical expression of hMLH1 and hMSH2 in correlation with MSI. Bax gene was altered in one case and TGF- β R2 in 11 cases. Microsatellite alterations at hMSH3, hMSH6, IGF1R and caspase-5 were not observed. Frameshift mutations at mononucleotide repeats in target genes of the MSI pathway in urothelial carcinomas of the bladder are rarely observed in urinary bladder carcinogenesis, in which the MSI pathway is rather uncommon. Nevertheless, hMLH1 protein expression is an important indicator for disease recurrence.

P117

Combined small cell and urothelial carcinoma of the urinary bladder

Tzelepi V¹, Gkermpesi M¹, Zisis FI², Chionis H², Bonikos DS¹ Departments of ¹Pathology and ²Urology, University Hospital, Rio-Patras, Greece.

Small cell carcinoma of the urinary bladder is rare accounting for <1% of urinary bladder carcinomas. In 50% of the cases coexists another carcinoma component, usually urothelial carcinoma. In the vast majority of the cases urothelial component comprises a small percentage of the total tumor. A 58 year old male patient presented to the Urology Department with intermittent hematuria. Cystoscopic evaluation revealed a protruding ulcerated mass in the right lateral wall of the bladder. Preoperative clinical examination and imaging studies showed no evidence of metastatic disease. Radical cystectomy and bilateral iliac lymphectomy was carried out. The pathology report was infiltrating combined small cell carcinoma and high grade (WHO 2004) urothelial carcinoma of the urinary bladder. There was a gradual transition of one component to the other. Each component comprised about half of the tumor mass. No lymph node metastases were found. Cytokeratin profile of the tumor cells of the two components was the same, although the extent of immunostaining was different. The patient received no other treatment and is alive and well, with no evidence of disease 6 months after the initial diagnosis. Gradual transition of the tumor cells of one component to the other and similar cytokeratin expression profile favor a common origin of small cell and urothelial carcinoma of the urinary bladder.

P118

Correlation between transurethral resection of prostate (TURP) and prostate-specific antigen (PSA) screening

Silvia Lacramioara Roznovan¹, Doinita Radulescu¹, Simona Stolnicu²

¹ Department of Pathology, University of Medicine, Iasi, Romania
² Department of Pathology, University of Medicine, Targu Mures, Romania

Prostate-specific antigen (PSA) screening had increased the detection of prostate adenocarcinoma in stage T1c. The aim of our study was to compare the frequency of incidental prostatic adenocarcinoma found in transurethral resection of prostate (TURP) specimens for a two years period before and two years after PSA screening. TURP specimens were routinely processed and evaluated in order to identify incidental prostatic adenocarcinoma, prostatic intraepithelial neoplasia and atypical adenomatous hyperplasia. We collected 217 and 206 TURP specimens respectively. The comparison revealed a significant decrease in prevalence of T1b prostate carcinomas from 9,21% to 5,33%, with the introduction of PSA screening, representing an improvement in prostate carcinoma staging, with no influence on the incidence of T1a stage, prostatic intraepithelial neoplasia or atypical adenomatous hyperplasia in TURP specimens.

P119

Prognostic factors in patients with bone metastasis prostate cancer

Doinita Radulescu¹, Silvia Lacramioara Roznovan¹, Simona Stolnicu²

¹ Department of Pathology, University of Medicine, Iasi, Romania
² Department of Pathology, University of Medicine, Targu Mures, Romania

Although the prognosis of patients with prostate carcinomas metastatic to the bone is poor, several studies have demonstrated that survival is dependent on the extent of metastatic spread within

the skeletal system at presentation. The aim of our study was to examine the clinical and pathologic features in patients who underwent surgery for metastatic prostate carcinoma, in order to identify prognostic markers. Seven patients with underwent surgery for the stabilization of pathological fractures of the femoral neck were diagnosed with metastatic prostate carcinomas. Serum prostate specific antigen (PSA) and bone scintigraphy were performed. Pathologic characteristics examined included Gleason score and immunohistochemical stains for ki-67 and Cytokeratin 7. Features that were found to be statistically significant with poor prognosis were: the interval between the diagnosis of metastasis and the surgery for metastasis, the number of metastatic sites and the Gleason score. The particularity of these cases was that bone metastases permitted the identification of primary prostate carcinomas and that cancer-specific survival may be assessed by tumour differentiation of the metastasis.

P120

Relationship between p16 promoter hypermethylation and protein expression in different histologic parts of heterogenic prostate tumor tissue

Popova O.P., Kekeeva T.V., Kouznetzova A.V., Danilova T.I. and Ivanov A.A.

Research Institute of Molecular Medicine at Sechenov's Moscow Medical Academy, Moscow, Russia.

Purpose of the study: The p16 tumor repressor gene has been found to be inactivated by promoter region hypermethylation in many tumor types including prostate cancer. Relationship between p16 promoter, protein expression and other clinicopathological features can be controversial. The aim of the study is to determine the correspondence between promoter hypermethylation and p16 protein expression in malignant acini, preneoplastic (PIN) and benign hyperplastic glands and adjacent stroma of highly heterogenic prostate tumor tissue.

Materials and methods: Formalin-fixed, paraffin embedded tissues from 80 patients with prostate adenocarcinoma of wide range of histological grade (Gleason score) were stained for p 16 by standard immunohistochemistry. After microscopic analysis and laser microdissection it was investigated the methylation status of morphologically different zones of the tumors by methylation sensitive PCR using HpaII and HhaI restrictases.

Results: Hypermethylation of p16 was found in 44% cases directly within the focuses of adenocarcinoma highly to moderately differentiated (score 2-7), despite the fact that majority of them were immunopositive for p16 protein. In PIN areas immediately adjacent to adenocarcinoma the methylation status and protein immunoreactivity were the same as in associated malignancy with few exceptions. The malignant glands of poorly differentiated tumors (score 8-10) were not immunoreactive for p16 in 87% but no methylation was found. According to our results we could suggest that p16 methylation is not the main pathway of that gene inactivation in the most advanced cases. No significant correlation between p16 promoter hypermethylation and immunohistochemical detection of p 16 was observed in nearest benign glands, although not methylated glands were more frequently p16 positive than those with hypermethylation. Cells of surrounding connective tissue in all cases displayed the same frequency of hypermethylation as in adjacent altered epithelium.

Conclusions: Immunohistochemical detection of p 16 is unrelated to promoter methylation status, being strongerly related to morphologic tumor characteristics of poor prognosis. Other genetic alterations of p16 rather than promoter methylation status could serve as prognostic marker of disease in prostate cancer. The same percentages of methylation in altered glands and surrounding connective tissue may be the evidence for the influence of dysplastic or malignant epithelium to adjacent paraneoplastic stroma.

P121

Invasive cystic hypersecretory carcinoma of the breast. A 2 case report.

Apostolikas N, Papaevangelou M., Psichoyiou H., Patereli A., Koniaris T.

Dept. of Pathology of the Hellenic Anticancer Institute, 'St.Savvas' Hospital, Athens, Greece.

The Invasive Cystic Hypersecretory Carcinoma (I. C. H. C.), first described by Posen in 1984, is a very rare entity of a breast adenocarcinoma. We present the clinical and pathological features of 2 cases of I.C.H.C. and review the literature. The patients were females aged 54 and 52 years. Both tumors were located in the left breast. The presenting symptom was a palpable mass. U/S, FNA and mammography were positive for malignancy in both cases. Gross pathology: the tumors measured 2.5cm and 5.5cm respectively, and were distinct from the surrounding parenchyma. The interesting gross feature was the presence of numerous cysts surrounding the main bulk of both tumors but also within the main lesion itself in the second case. The cysts measured up to 0.4cm and the secretion was mucinous or gelatinous. Microscopy: the invasive part of the tumors was a high grade Non Otherwise Specified ductal carcinoma, surrounded by an widely spread intraductal component, which had all the typical characteristics of a cystic hypersecretory carcinoma (CHC). Especially in the second case the background of the invasive carcinoma showed a wide spectrum of pathologic lesions ranging from cystic hypersecretory hyperplasia (CHH) to atypical CHH and CHC. The first patient was treated with lumpectomy and excision of 12 auxiliary lymph nodes which had no metastases. The second patient had a modified radical mastectomy and 7/27 positive lymph nodes. The expressions of estrogen and progesterone receptors, c-erb-B2, p53, ki-67, CEA, SMA and PAS-Alcian blue are discussed. Only 13 cases have been reported so far in the literature. We add two more cases in order to contribute to the correct diagnosis of a poorly recognized histological entity. More over it seems that the accurate recognition of a CHC may prevent and avoid the development of an ICHC.

P122

Immunohistochemical expression of tissue markers in patients with surgically treated localized prostate cancer and their prognostic value for biochemical failure prediction.

K. Revelos¹, C. Petraki², P. Konstantinou¹, A. Rellaki¹, C. Meristoudis², A. Savvani², S. Stefanakis³, D. Malovrouvas³ and M. Koutsilieris⁴.

¹Department of Pathology, 251 Hellenic Air Force General Hospital, Athens, Greece, ²Departments of Pathology and ³Urology, Evangelismos Hospital, Athens, Greece, ⁴Department of Experimental Physiology, Medical School, University of Athens, Greece.

Objectives: To estimate the prognostic value of the immunohistochemical expression (IHCE) of the cyclin-dependent kinase inhibitor p27, the cell proliferation marker Ki67, bcl2 & p53 oncoproteins, the preapoptotic protein Par-4, androgen receptors (AR) status, neuroendocrine differentiation (NED) assessed by chromogranin A (Chr) & microvessel density (MVD) assessed by CD34.

Patients & methods: Included in the study were 130 consecutive patients (pts) who underwent radical prostatectomy (RP) for localized prostate cancer (PC). Follow-up information was available for 94 pts. The median follow-up period was 28 (1-97) months. A cut-off value of 0.2 ng/ml of serum PSA was established as a biochemical failure (BF) threshold. The immunohistochemical method of streptavidin-biotin-peroxidase was performed. Results: High expression of NED & MVD were significantly correlated with advanced Gleason score (GS) (P=0.003 & 0.021 respectively), high bcl2 with the absence of PIN (P=0.001), low p27, high p53, NED &

MVD with increased tumour volume ($P=0.025, 0.027, 0.00$ & 0.003 respectively) & reduced p27 expression with high preoperative serum PSA values ($P=0.002$). Positive surgical margins were predicted by AR status & increased NED ($P=0.021$ & 0.048 respectively), periprostatic tissue infiltration (PTI) by high p53, NED & MVD ($P=0.010, 0.00$ & 0.005 respectively), seminal vesicles invasion (SVI) by low p27, AR status, high NED & MVD ($P=0.009, 0.016, 0.00$ & 0.012 respectively), & finally pelvic lymph nodes metastasis (PLNM) by high Ki67, Par-4 & NED ($P=0.006, 0.036$ & 0.004 respectively). BF was observed in 35/94 (37%) pts. Kaplan-Meier survival curves showed that significant predictors of BF were low p27 and high Ki67, bcl2, p53, NED, MVD ($P=0.0005, 0.004, 0.0101, 0.0429, 0.0006$ & 0.00 respectively), as well as the synchronous low p27 & high Ki67 IHCE, high bcl2 & p53 IHCE & high NED & MVD ($P=0.0011, 0.0450$ & 0.0003 respectively). Gleason score (GS), periprostatic tissue infiltration (PTI), seminal vesicles invasion (SVI) and pelvic lymph nodes metastasis (PLNM) were significant predictors for BF ($P=0.040, 0.0012, 0.0003$ & 0.0038 respectively). However, in the multivariate analysis (Cox Regression) MVD & bcl2 IHCE were the only independent prognostic factors for BF.

Conclusions: Microvessel density & bcl2 immunoeexpression may be useful markers for biochemical failure prediction and selection of high-risk patients with clinically localized prostate cancer after radical prostatectomy as candidates for adjuvant therapies.

P123

Immunohistochemical detection of Epidermal Growth Factor receptor as a prognostic indicator in prostate cancer

Amelia Petrescu¹, Florin Andrei², Liviu Niculescu³
¹Prof. Dr. Th. Burghel "Hospital, Bucharest, Romania,
²Victor Babes "Institute of Pathology, Bucharest, Romania,
³University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania.

The aim of this study was to evaluate the immunohistochemical expression of epidermal growth factor receptor (EGF-R) in a series of 47 prostate cancer (10 radical prostatectomies, 37 transurethral resection), 10 cases of benign prostate hyperplasia (BPH) and its utility as a prognostic indicator.

Material and methods: A hematoxylin-eosin stained slide from a representative block of each case was examined and Gleason scores were assigned in each case of prostate adenocarcinoma. Additional paraffin sections from the lame blok were stained immunohistochemically for EGF-R using EGFR clone 29.1 (Sigma , St Louis, USA) dilution 1:1000.

Results: Three of 4 well-differentiated tumors (Gleason score 2-4), twelve of 33 moderate differentiated (Gleason score 5-7) and eight of 10 poorly differentiated tumors (Gleason score over 8) expressed EGFR. Overall 40,5% of well and moderate and 80% of poorly differentiated tumors expressed this marker. Only two of 10 benign cases were positive. . An interesting observation was that EGFR source Sigma St. Louis stained vessels in 25% of cases.

Conclusions: We consider EGFR expression correlate with high Gleason score, high tumor proliferation and metastatic rate. For low differentiated cases should be considered a prognostic factor.

P124

Comparative study of correlatios between the amount of intratumoral stromal fibrillary components and grading markers in prostate and breast carcinomas

Carmen Popescu¹, Iancu Emil Plesea², Stelian Danut Enache¹, Mihaela Tenovici³, Claudia Valentina Georgescu¹
 Departments of Pathology, ¹Emergency County University Hospital; ²University of Medicine and Pharmacy,
³National Railways System University Hospital, Craiova, Romania

Objectives: This study compared the relationship between the the amount of stromal fibrillary components (SFC) and the grading factors in prostatic carcinoma (PC) and ductal invasive breast carcinoma (DIBC).

Material and Methods: 20 cases with DIBC and 34 with PC were selected. Stromal fibrillary components were stained with Gömöri technique. Grading factors considered were: degree of tubular formation (T) and nuclear pleomorphism (P) for DIBC and Gleason patterns (dominant and secondary), for PC. 100 fields in DIBC group and 340 fields in PC group were selected randomly using x10 and x20 objectives respectively and subdivided in 3 T subgroups and 3 P subgroups and in Gleason patterns subgroups (G1 - G5) respectively.

Results: The most numerous subgroups were 3-T and 2-P in DIBC and G3 and G4, in PC. In DIBC, SFC ranged between 27,6% and 30% in T subgroups, with and between 25,85% and 34,9% in P subgroups. In PC, there is significant difference between G3 and G4 and between G5 an all the other patterns.

Conclusions: In DIBC, SFC showed no significant variations related with T but seems to correlate with nuclear atypia. In PC, SFC tends to increase both in G3 and G5 areas, with a lower value in G4.

P125

Comparative study of correlatios between vascular density and grading markers in prostate and breast carcinomas

Stelian Danut Enache¹, Maria Comanescu², Iancu Emil Plesea², Carmen Popescu¹, Claudia Valentina Georgescu¹
 Departments of Pathology, ¹Emergency County University Hospital; ²University of Medicine and Pharmacy; Craiova, Romania

Objectives: This study compared the relationship between the the intratumoral capillaries density (Cd) and the grading factors in prostatic carcinoma (PC) and ductal invasive breast carcinoma (DIBC).

Material and Methods: 20 cases with DIBC and 34 with PC were selected. Intratumoral capillaries were marked for CD34. Grading factors considered were: degree of tubular formation (T) and nuclear pleomorphism (P) for DIBC and Gleason patterns (dominant and secondary), for PC. 100 fields in DIBC group and 340 fields in PC group were selected randomly using x10 and x20 objectives respectively and subdivided in 3 T subgroups and 3 P subgroups and in Gleason patterns subgroups (G1 - G5) respectively.

Results: The most numerous subgroups were 3-T and 2-P in DIBC and G3 and G4, in PC. In DIBC, Cd ranged between 39/mm² and 43/mm² in T subgroups and was higher in II- P and III- P groups. In PC, there is high significant difference between Cd in G2 and all the other patterns. G5 presented significant differences compared with G3 and G4.

Conclusions: In DIBC, Cd showed no significant variations related to T and P. In turn, in PC, Cd tends to increase from well differentiated areas to poorly differentiated ones, with the highest values in G4 solid areas.

P126

Complete androgen insensitivity syndrome with bilateral testicular hamartomata and paratesticular leiomyoma and cystadenoma

A. Papanikolaou¹, D.G. Goulis², E. Athanasiou³, D. Hatzibougias³, M. Bobos³, I. Papadimas²
 Department of Pathology¹, Ippokratio General Hospital, Thessaloniki, Greece
 First Department of Obstetrics & Gynecology² and Department of Pathology³, Aristotle University of Thessaloniki, Greece.

Complete androgen insensitivity syndrome (CAIS) is the most common form of male pseudohermaphroditism. It is caused in the majority of the cases by a mutation of the androgen receptor gene.

Patients with CAIS have classically a normal female phenotype with well developed external sexual organs and 46,XY karyotype. We report the case of a 18 year-old girl with CAIS presented as primary amenorhea. After confirmation of CAIS, bilateral orchidectomy was performed. The testis were immature. Multiple hamartomata were found on the testis and two paratesticular tumors (one cystic and one leiomyomatus) on the left. The cystic tumor was a cystadenoma. Benign tumors are developed in 86% of cases of CAIS, being usually hamartomatous nodules of testis. Association of paratesticular cystadenoma to synchronous hamartomata and leiomyomatus tumor is a very rare finding.

P127

An application of web based virtual microscopy as teaching aid in oral pathology

Janusz Szymas¹, Mikael Lundin²

¹Dept. Pathology, Univ. Med. Sciences. 60-355 Poznan, Poland

²Biomed. Inform. Res. Group, Univ. of Helsinki, Helsinki, Finland

Recent advances in microcomputers, high resolution digital cameras and robotized microscopes provide pathologists the opportunity to develop virtual slides. With the use of a microcomputer-based workstation these slides can be viewed in a web browser in a manner that closely simulates examination of glass slides with a real microscope. Aims of our study were to develop an educationally useful aid for teaching and evaluation of student competence in oral pathology. By using a robotic microscope and adopted and modified commercially software, a virtual microscopy system was developed that allows fully automated slide scanning and image distribution system. More than 250 slides were scanned and archived on an image server residing within a high speed university network. Students can view entire specimen at any magnification within a standard web browser. The virtual slides are supplemented with concise textual descriptions. Virtual slides can also be viewed for self assessment or examination. Both students and teaching staff enthusiastically adapted to the use of virtual microscopy. Questionnaire feedback from students strongly indicated that virtual slides solved a number of problems in their learning, while providing excellent image quality. Allocation of two students per workstation promoted collaboration and helped to maintain interest in both oral pathology and digital microscopy. We do believe that the use of web based microscopy can guarantee that microscopic examination of tissues remains both important to the dental curriculum (<http://ampat.amu.edu.pl>).

P128

Virtual slides for second opinion in breast cancer. A comparative study on 81 consecutive needle core biopsies with 5 pathologists from 3 countries.

Marius Nap¹, Paul Theunissen¹, Janina Kulka², Rob Teunissen¹, Nathalie Vandevijver¹ and Anna Batistatou³

¹Institute of Pathology Atrium Medical Center Heerlen NL

²2nd Dept of Pathology, Semmelweis University Budapest, Hungary.

³Dept of Pathology Univ of Ioannina, Greece.

Virtual slides may come to replace real glass slides in second opinions. From 81 breast needle core biopsies, virtual slides were produced using the MIRAX scanning microscope equipped with a 20x objective. No selection was made. The files ranged from 80MB to 500MB. The images were distributed on disc, together with the MIRAX viewer software, for evaluation by 5 pathologists. All reviewers were instructed to use the following scores: 0= no diagnosis possible; 1= normal breast; 2= certainly benign disorder; 3= uncertain benign; 4= uncertain malignant and 5= certainly malignant. Kappa scores with respect to the glass slides were above 80% for 4/5 pathologists. Kappa values between the 5 pathologists

ranged from 70% to 80%. If scores 0 to 3 and scores 4 and 5 were grouped together these values varied from 94% to 99% for the glass slides and among the pathologists a kappa was found between 91% and 97%. The discrimination between benign and malignant appears to be achieved on virtual slides with a high interobserver agreement, making this approach a valuable additional tool in second opinion procedures.

P129

Ploidometry reasons for the law of the stepped staging in cancerogenesis

Avtandilov G.G.

Russian Medical Academy for Postgraduate Education, Moscow.

Background: The problem of unification of tumours and tumour-like lesions diagnosis has gained a special significance in the modern oncology. The aim. Is to use the ploidometry research in epithelial cells clones study in the prostate, mammary glands, uterus and cervix uteri, thyroid glands, and kidneys for substantiation of different stages in cancerogenesis.

The methods: The computer test was carried out for 56000 epithelial cell nuclei in biopsies at different stages of cancerogenesis. Nuclei ploidy was defined by means of the computer image analyzer "Images-CH" ("Avtan-San" software version).

Results: It was established that the ploidy index for normal epithelial cells averages 2.4 c; the ploidy indices for cells in the conditions of hyperplasia, mild and moderate dysplasia, and benign tumours are within the limits of 2.5 ρ to 3.4 ρ (benign tumours). The increasing quantity nuclei with ploidy indices in the range 3.5 c - 4.4 ρ gives evidence for diagnostics of severe dysplasia and cancer "in situ" (*border neoplasm condition*).

Malignant tumours (the first degree of infiltrative carcinoma) are determined by the average ploidy indices within the limits of 4.5 ρ to 5.4 ρ. The following nuclei choice shows the cell clones with the average ploidy indices from 5.5 ρ to 6.4 ρ (the second degree of carcinoma) and the average ploidy indices from 6.5 ρ to 7.4 ρ (the third degree of carcinoma). The higher ploidy indices (above 7.5 c) - give evidence for non-differentiated forms of malignant tumours. Revealed principles of cancerogenesis are described mathematically by the linear dependence between the stage (time of development) and the quantitative indication - average indices of ploidity of nuclei cells on the certain stage of cancerogenesis: $\sigma = N + xc$, where σ - average of tumour nuclei ploidity; N - average of normal nuclei ploidity index; ρ - ploidy unit; x - ordinal number of cancerogenesis stage - «the code of malignancy»: 1,2, 3-6 [$x = (y-N)/c$].

The presented mathematical model provides some evidence for the stepped staging of neoplasm development owing to predominance of cells with increasing nuclei ploidity. The change to the consequent stage of cancerogenesis arises from prevalence of the new clone cells (70%) with maintenance of preceding clones at the levels of 20% and 10% (Avtandilov G.G., 1984, 2004).

The conclusion: The results of tumor cells computer ploidometry give proof for the law of stepped staging benign, border and malignant tumours development, due to initial following DNA mass increase in nuclei per one unit of ploidity.

P130

Problems during Tissue Microarrays process

Stephanos Miliadis, Mattheos Bobos, Ioannis Kostopoulos

Department of Pathology, Aristotle University of Thessaloniki, Greece

Objectives: Tissue microarray (TMA) is a procedure which reduces the cost of immunohistochemical or molecular methods of archival tissue blocks. Protocols have been described elsewhere, but problems often occur during the procedure.

Methods and results: The quality and the temperature of the paraffin were substantial for the success of the process. Covering the back side of the cassette with paraffin, induced its strength. Not recently prepared, and not properly stored blocks, were sensitive. The recipient blocks constructed, contained about 120 to 250 cores each, at least five cores per case. Clefs and "actiniformed" paraffin breakings were observed, leading sometimes to block destruction. Setting the cores of the same type of tissue in the same line, according to the hardness of each tissue was also helpful. A "multi-zoned" core was constructed when thin tissue block was punched, constituting of multiple small cores of the tissue. Before sectioning, incubation of the recipient blocks was done, for 50 minutes in 37°C and in three sessions, to flatten the surface. A thin layer of wet paraffin covered the surface of the recipient block, after sectioning, so it could be stored and re-used for a long period, preventing the oxidation of the tissues and DNA destruction.

Discussion: TMA is a useful and a cost-effective procedure which contributes to the development of a Pathology Laboratory. New technologies and ideas can improve it

Computer-supported quality control in DNA flowcytometry analysis

Nick van Rodijnen^{1,2}, Erik Postma², Sjack Hoop and Marius Nap¹
¹Atrium medical center Heerlen, ²IKAT, University of Maastricht, The Netherlands

Automation of the ploidy analysis of DNA histograms may contribute to the reliability of the final classification. We present an algorithm that models a flowcytometry dataset and maps all individual DNA histograms onto a standardised neutral interpretation axis (NIX), after a linearity check and diploid G0/G1 peak analysis. The NIX mapping corrects for drifting. A number of pre-defined classification characteristics are counted to arrive at a ploidy classification. We applied the algorithm to 833 manually labelled DNA histograms, which may contain errors due to inconsistent labelling. The algorithm rejected 4% (33 cases) of the DNA histograms because of non-linearity, in 0,4% (3 cases) of the histograms the diploid G0/G1 peak was detected incorrectly. 11% (94 cases) with a skewed diploid G0/G1 peak could not be analysed. In 701 cases an automatic classification could be given, with on-screen inspection for acceptance or rejection. In 635 / 701 cases two evaluators accepted the automatic label suggestion. The kappa value of the two evaluators with the automated classification label is resp. 0.9186 and 0.9458. NIX mapping allows for automated quality control of the manual ploidy labelling.

Thymidine Phosphorylase expression in breast cancer: The prognostic significance, its association with angiogenesis, extracellular matrix components, and clinicopathological features

Antigony Mitselou¹, Elli Ioachim², Constantina Damala², Elena Tsanou², Michael Doukas², Theodore Vougiouklakis¹, Niki Agnantis².
 Departments of ¹Forensic Pathology, ²Pathology, Medical School, University of Ioannina, Greece.

Thymidine Phosphorylase (TP), also known as platelet-derived endothelial cell growth factor (PD-ECGF), is an enzyme that catalyzes the reversible dephosphorylation of thymidine, deoxyur-

idine and their analogs. TP also promotes angiogenesis. We examined the TP expression using immunohistochemistry in paraffin-embedded formalin-fixed tissue of 91 invasive breast carcinomas. The cytoplasmic thymidine phosphorylase, nuclear and stroma was estimated semi-quantitatively. Cytoplasmic high TP expression was found in 33 cases (36.3%) of carcinomas, high nuclear expression was seen in 2 cases (2.2%) and 22 cases (24.2%) expressed strongly immunostaining in stroma. A statistical significant relationship between TP cytoplasmic and TP nuclear expression was found ($p=0.03$), as well as between TP stroma expression and TP nuclear expression ($p<0.0001$). No correlation was found between TP cytoplasmic expression and grade of the tumor, type of tumor, size, lymph node involvement and hormonal (PR and GR) status. Statistical correlation between TP stroma expression and MIB-1 ($p=0.014$) and PCNA ($p=0.044$) was found. Regarding the correlation between TP and extracellular components we found association between TP tumor expression with tenascin ($p=0.002$). A statistical significant relationship between overall survival (OS) and TP tumor expression was found ($p=0.018$). In conclusion, our findings suggest that TP has little effect on tumor angiogenesis of breast carcinoma.

P133

Immunohistochemical detection of mismatch repair proteins hMLH1, hMLS2 and hMSH6 in familial breast cancer and correlation with clinicopathological parameters.

Arkoumani E¹, Stefanou D¹, Batistatou A¹, Briasoulis E¹, Kontostolis E³ and Agnantis NJ¹.

¹Department of Pathology, ²Department of Medical Oncology, ³Department of Obstetrics and Gynaecology, University of Ioannina, Medical School, Greece.

Defects in mismatch repair genes are associated with a variety of cancers. However, it is not yet understood whether clinical parameters influence the MMR status. In the present study 30 cases of familial breast cancer were examined for the expression of hMLH1, hMLS2 and hMSH6 using the monoclonal antibodies MLH1, MSH2 and MSH6 (BIOCARE MED-Menarini Diagnostics). We found loss of expression of MLH1 in 8/30 (26%), of MSH2 in 4/30 (13%) and of MSH6 in 13/30 (43,3%) of the cases examined. Three carcinomas (10%) were negative for both MLH1 and MSH2 and seven (23,3%) were negative for both MLH1 and MSH6, showing a strong correlation between the expression of these proteins. Statistical analysis revealed that there is a positive correlation between reduced expression of these proteins, tumor size and estrogen status, but no correlation with lymph node status. Our data suggest that the impaired expression of MMR proteins can be used as a prognostic factor.

P134

EGFR and phosphorylated EGFR expression in HER-2 overexpressing breast carcinomas

Batistatou A., Stefanou D., Arkoumani E, Simou N., Agnantis N.J. Department of Pathology, University of Ioannina Medical School, Greece

Her-2/neu overexpression is an important prognostic parameter in breast cancer patients and a determinant of targeted therapy. Interactions between Her-2/neu and other members of the EGFR family have been implicated in trastuzumab resistance. In the present study we have analyzed the immunohistochemical expression of EGFR and phosphorylated EGFR (monoclonal antibodies anti-EGFR, 31G7 and anti-phospho-EGFR, Y1086, ZYMED Labs) in 51 HER-2/neu overexpressing breast tumors (score 2+ and 3+, Herceptest, DAKO) and investigated potential correlations with clinicopathological parameters and hormone receptor status. Fourteen and 16 out of

51 cases were positive for EGFR and phosphorylated EGFR (27.5% and 31.4% respectively). EGFR expression was inversely correlated with estrogen and progesterone receptor status and positively correlated with phosphorylated EGFR expression. Our data contribute to the further characterization of the EGF receptor tyrosine kinase family and identification of its role in breast carcinogenesis.

The missing kiss of life: Analysis of mutation and protein expression of the metastasis-suppressor gene KISS1 in early breast cancer.

L. Kostadima¹, G. Pentheroudakis¹, L. Dova², I. Georgiou³, V. Malamou-Mitsi⁴, G. Vartholomatos², G. Fountzilias⁶, N. Kolaitis², M. Ntemou⁵, N. Pavlidis¹.

¹Dept. of Medical Oncology, ²Lab of Hematology-Molecular Biology Unit, ³Dept. of Obstetrics and Gynaecology-Genetics Unit, ⁴Dept. of Pathology, Ioannina University Hospital, ⁵Dept. of Pathology, Ioannina General Hospital, ⁶Medical School, Aristotle University of Thessaloniki, Greece

Metastasis-suppressor genes have emerged as molecular hallmarks for clonal evolution of malignancies towards systemic dissemination. We studied tissue expression of KISS1 protein by immunohistochemistry and screened the relevant gene for mutations in 50 women with stage II/III early breast cancer. DNA was extracted for PCR of exons III, IVa, IVb of KISS1 gene, mutation screening with Single Strand Conformational Polymorphism (SSCP) and sequencing of aberrant bands. SSCP was also performed in peripheral blood lymphocyte DNA of 50 healthy controls. An aberrant exon IVa SSCP band was found in 30 patients, but none of 50 controls. The band was sequenced and found to harbor the 242 C to G base substitution, resulting in a proline to arginine switch at codon 81 (P81R) and alteration of the KISS1 tertiary structure. Immunorexpression of KISS1 protein was weak to moderate in the majority of tumours. The observation of a loss-of-function KISS1 gene mutation in more than half of patients with high-risk early breast cancer may shed light in the complex pathway of metastatic dissemination and pave the way for development of new targeted therapeutic approaches.

P136

VEGF and BCL-2 in serum at breast cancer in comparison with CEA and CA15-3. Which factor can detect the recurrence earlier?

R. Iosifiduo, G. Galaktiduo, F. Patakiouta, A. Bousouleagas
Anticancer Hospital, Theagenio, Thessalokini

The purpose of our study is to examine if the expression of VEGF and bcl-2 in serum can detect the recurrence much earlier of CEA and CA15-3 in women with breast cancer. 200 patients with breast cancer stage I and II are enrolled in this study. The age of the patients was 59,65±11,65 years. 102 patients had mastectomy with axillary node dissection and 98 had quadrectomy and axillary node dissection. All had supplementary therapy. 14 patients had recurrence of the disease 18 months after the surgical therapy. Serum VEGF and bcl-2 was measured pre-operative, post-operative one and two years after the surgical treatment with ELISA and CEA and CA15-3 every 4 months until the two years with RIA. The results were analysed with statistical methods (ROC curves and Pearson). ROC curves shows that bcl-2 can detect the recurrence pre-operative (p=0,066), post-operative (p=0,037) and the second year (p=0,029) and VEGF post-operative (p=0,003). CEA and CA15-3 can detect the recurrence 20 (p=0,098) and 8 months (p=0,045) after the surgical treatment. There is no statistical relation between these factors with the size of the

tumor, the histological type and the lymph node status (Pearson). The tumor markers VEGF and bcl-2 can detect the recurrence of the disease much earlier of CEA and CA15-3 and the clinical appearance and so they can be used in the follow-up of the patients. Bcl-2 marker is the most significant as can detect the recurrence in the most measurements.

P137

Deregulation of annexin I expression in invasive breast carcinomas
Tsanou E¹, Damala K¹, Peschos D², Stefanou D¹ and Agnantis N.J¹.
Department of Pathology-Cytology¹ and Forensic Medicine²,
Medical School, University of Ioannina, 45110 Greece

Annexins are calcium-dependent binding proteins, implicated in regulation of membrane trafficking, cellular adhesion and metastatic cascade. **Aims:** To demonstrate immunohistochemically the patterns of annexin I expression in breast cancer and to establish any relationship with clinicopathological features and proteins correlated with the prognosis of breast cancer, especially anti-oxidant proteins (MnSOD) and growth factors (VEGF).

Material-Method: Annexin I immunohistochemical expression was studied in 86 cases of breast cancer. We estimated both the percentage of positive cancer cells and the intensity of immunostaining. Staining of >10% of tumor cells was considered to be positive for the expression of annexin I.

Results: 49 cases (57%) showed increased Annexin I expression compared to normal ductal structures. Annexin I expression was correlated to tumor size (p=0.05), strong immunopositivity for VEGF (p=0.049) and MnSOD (p=0.03). Patients with positive lymph nodes exhibited strong intensity for annexin I (p=0.039).

Conclusions: Up-regulation of annexin I is correlated with advanced T stage, while close association was observed between annexin I and VEGF and MnSOD. We can postulate based on the correlation with the above mentioned proteins the implication of annexin I in early phase carcinogenesis in breast cancer.

P138

Clinicopathologic and prognostic significance of the blood and lymphatic microvessel density in invasive breast carcinoma

¹Nomikos A, ²Mylona E, ²Giannopoulou I, ¹Athanassiadou S, ³Markaki S, ³Keramopoulos A, ¹Nakopoulou L.
Pathology Departments of ¹Attikon Hospital, ²Medical School and ³Alexandra Hospital

Our aim was to investigate the blood and lymphatic vascular density (BVD and LVD, respectively) in invasive breast carcinomas. Immunohistochemistry was applied on paraffin-embedded sections from 146 patients with invasive breast carcinomas to detect blood and lymphatic vessels. Vessel density was evaluated by image analysis. Both BVD and LVD correlated positively with histological grade (p=0.066 and p=0.056 respectively) and inversely with ER (p=0.031 and p=0.056 respectively) and bcl-2 (p=0.013 and p=0.031 respectively). Moreover, BVD correlated positively with topoIIa and LVD with c-erbB2 (p=0.031 and p=0.058). Neither BVD nor LVD correlated with any of the VEGFs. BVD exerted unfavorable impact on both overall and disease-free survival of the patients (p=0.018 and p=0.040 respectively) and specifically of patients with tumor size 2-5cm (p=0,0002 and p=0,0049 respectively). Moreover, intratumoral BVD was recognized to be an independent, unfavorable predictor of overall survival (p=0.051). In the present study BVD and LVD were related to tumors of aggressive phenotype. High BVD may be an unfavorable prognostic indicator for long-term survival in breast cancer.

P139

The effect of the different matrix metalloproteinase (MMP)-9 protein localizations and intensity of expression on the tumor phenotype and prognosis of the patients with invasive breast carcinomas.

¹Magkou C, ¹Nomikos A, ²Mylona E, ²Alexandrou P, ²Liapis G, ¹Nakopoulou L,
Pathology Departments of ¹Attikon Hospital and ²Medical School

We Immunohistochemically investigated the expression of MMP-9 and its clinicopathological and prognostic value in 174 invasive breast carcinomas. MMP-9 was detected in the cytoplasm of the malignant cells and the peritumoral fibroblasts. Moderate cytoplasmic expression of MMP-9 was inversely associated with Ki67 and topoisomerase II α ($p=0.034$ and $p=0.004$ respectively), whereas intensively stained cases were found to demonstrate shorter overall and disease-free survival in ER-positive ($p=0.022$ and $p=0.066$), c-erbB-2 negative ($p=0.0031$ and $p=0.0005$ respectively) and LN-negative ($p=0.0106$ and $p=0.0146$ respectively) patients. Fibroblastic MMP-9 was more frequently observed in c-erbB-2 positive samples ($p=0.043$) and in tumors of higher histological grade ($p=0.07$), exerting unfavorable impact on both overall ($p=0.0203$) and disease-free survival ($p=0.0274$) of the patients. Concluding, moderate cytoplasmic expression of MMP-9 was related to tumors of low proliferative potential, while the high expression exerted unfavorable impact on the prognosis of ER(+), c-erbB2(-) and LN(-) patients. Stromal MMP-9 was associated with tumors of aggressive phenotype, affecting negatively both overall and disease-free survival of the patients.

P140

Immunohistochemical profile of papillary breast tumors using cytokeratins

KIZIRIDOU A., ANESTAKIS D., LAMBROPOULOU M., DESTOUNI C., BOUSOULEGAS A., TOLIOU T.
Pathology and Surgery Department, Theagenion Anticancer Hospital, Thessaloniki

Objective: Papillary tumors of the breast often cause differential diagnosis problems despite the well-described histological features. Sometimes there are difficulties in diagnosing a papilloma (PL) versus a papillary ductal carcinoma in situ (DCIS). This study examines the cytokeratin (CK) profile of these tumors, that may contribute to the correct diagnosis.

Materials and methods: We studied archival tissue of 30 papillary lesions of the breast (15 papillomas and 15 papillary ductal carcinomas in situ) using immunohistochemical method (Biotin-Streptavidin/HRP) by an automated staining machine. We used three monoclonal antibodies against cytokeratins [High molecular weight CK-CK1,5,10,14 (DAKO-Dilution 1:600) (clone 34 β E12), CK-14 (Novocastra-Dilution 1:20) and CK5/CK6 (DAKO, Dilution 1:100)]. Staining intensity was graded 1+(weak) to 3+++ (strong) and was evaluated in luminal and myoepithelial cells.

Results: As far as CK5/6, 8/15 papillomas expressed strong reactivity, 2/15 moderate and 5/15 weak intensity. DCIS 10/15 were negative and 5/15 showed weak positivity. CK14 was expressed in 10/15 papillomas with strong, 4/15 with moderate and 1/15 weak reaction. DCIS was 8/15 negative, 4/15 weak to moderate and 3/15 weak reaction respectively. CK34 β E12 was expressed in 8/15 papillomas with strong, 6/15 with moderate and 1/15 with weak reaction. DCIS was 10/15 weak, 2/15 moderate and 2/15 weak reaction, 1/15 was negative.

Conclusions: 1) The CKs could help besides to morphology, in differential diagnosis of papillary breast tumors. 2) It seems that CK 14 is more specific for papillomas especially when combined with

CK 5/6. 3) CK 34 β E12 is less useful, because of the lower detection rate in papillomas.

P141

Adenomyoepithelioma: an unusual neoplasm of the breast

Sibel Bektas, Burak Bahadır, Banu D. Gun,
Sacide Colak, Sukru O. Ozdamar
Zonguldak Karaelmas University, School of Medicine,
Department of Pathology, Turkey

Adenomyoepithelioma is characterized by proliferation of both epithelial and myoepithelial cells. The consultation material of total mastectomy and axillary lymph node dissection from a 34-year-old female were evaluated. Microscopic examination of the 6,5 cm well-circumscribed tumor revealed rounded tubules lined by both epithelial and myoepithelial cells in a myxomatous stroma. More prominent myoepithelial hyperplasia caused obliteration of some of the tubular lumens. Obvious smooth muscle differentiation was also noted. Immunohistochemically, myoepithelial cells and cells with smooth muscle differentiation exhibited vimentin and smooth muscle actin; myoepithelial cells were also reactive for S-100 protein and epithelial membrane antigen. Luminal epithelial cells revealed positive reaction for epithelial membrane antigen and pan-cytokeratin (AE1/AE3), but displayed only focal staining with carcinoembryonic antigen. Differential diagnosis of adenomyoepithelioma from its malignant counterpart and usual mammary carcinoma may occasionally be challenging. Moreover, although considered an indolent neoplasm but with a potential risk for recurrence and sometimes metastasis, adenomyoepithelioma of the breast requires long-term follow-up.

P142

Metaplastic breast carcinomas: report of 16 cases with emphasis on histopathological findings, hormone status and c-erb-B2 expression.

Kiziridou¹ A., Dimitriadis¹ I., Valeri R., Patakiouta F¹., Toliou I T.
Pathology¹ Department, "Theagenion" Anticancer Hospital,
Thessaloniki, Greece.

Objective: Metaplastic breast carcinomas is a rare cancer, consisting of a heterogeneous group of neoplasms, accounting for less than 1 % of all invasive mammary carcinomas. These tumors can be subclassified into different types, each of them usually causes problems in the differential diagnosis of breast neoplasms. The aim of this study is to refer 16 new cases of metaplastic carcinomas, emphasizing to histopathological findings, oestrogen (ER) and progesterone (PR) receptors and c-erb-B2 oncoprotein expression.

Materials and Methods: The slides of 16 metaplastic breast carcinomas from the files of our Department, (2001 to 2005) were revised and classified according to WHO classification.

Results: The frequency of different subtypes was: 7 of squamous type, 6 of spindle cell type, 2 of matrix producing type and 1 with choriocarcinomatous elements. Immunohistochemically the epithelial cells expressed Cytokeratins antibodies (CK7 or CK AE1/AE3) and occasionally EMA or CEA. The metaplastic elements expressed different antibodies as S-100, Vimentin, SMA.

Conclusions: 1) Metaplastic carcinomas, assume a broad spectrum of phenotypes. 2) Immunohistochemistry is a useful tool in differential diagnosis. 3) They usually don't express oestrogen and progesterone receptors. 4) Sometimes they express c-erb-B2 oncoprotein.

Immunohistochemical and FISH study of EGFR protein expression and gene amplification in 153 invasive breast carcinomas.

T. Koletsa, I. Kostopoulos, V. Kotoula, E. Nenopoulou, C. Papadimitriou.
Department of Pathology, Aristotle University Medical School, Thessaloniki, Greece

EGFR gene amplification, mutations at the genomic level and protein over-expression are among the parameters that are currently tested as potentially predictive markers for EGFR inhibitors. However, it is still not clear whether EGFR gene amplification leads to over-expression of the EGFR protein, such as the case with HER2. In this study we evaluated EGFR gene and protein status in breast cancer. A total of 153 breast carcinomas were examined. Immunohistochemical (IHC) analysis with two different antibodies (EGFR-PharmDX and EGFR-31G7) and Fluorescence In Situ Hybridization (FISH) for EGFR was performed on tissue arrays. Immunopositivity with EGFR PharmDX was observed in 18/153 (11,76%) and in 26/153 (16,99%) cases with EGFR-31G7 ($p = ns$). Lobular carcinomas and grade I tumors were negative for EGFR IHC. Amplification of the EGFR gene was not observed, while 23/128 cases (17,96%) exhibited polysomy of chromosome 7. Only 4 out of these 23 cases were positive with EGFR IHC. Thus, in line with recent reports in other tumor systems, EGFR protein (over) expression does not seem to be related to EGFR gene copy numbers in breast carcinomas, and can not be predicted by assessing this parameter.

Herstatin is associated with the status of HER expression and activation in breast cancer.

T. Koletsa, A. Boutis*, I. Kostopoulos, B. Christoforidou*, Th. Toliou*, C.S. Papadimitriou, V. Kotoula.
Department of Pathology, Aristotle University Medical School, and *Theageneion Cancer Hospital, Thessaloniki, Greece

Herstatin (HST) is a truncated protein produced by alternative splicing from the HER2 gene and serves as a natural endogenous inhibitor of HER receptor dimers. In this study, we investigated HST expression along with HER related parameters in 70 infiltrative breast carcinomas and matched non-cancerous tissues (MNTCs). HST immunopositivity was demonstrated in 27/70 (39%) tumor and 11/70 (16%) MNTCs. Relative expression of HST mRNA positively correlated with relative HER2 ($p < 0.001$) and HER3 ($p = 0.018$) expression, tended to be higher in tumors than MNTCs ($p = 0.022$), but did not correlate with HST protein presence. The latter was associated with cytoplasmic localization of pHER2-Y1248 ($p = 0.006$), non-membranous HER3 ($p = 0.003$) and nuclear localization of pAKT/PKB-S473 ($p = 0.045$). EGFR phosphorylation correlated positively with HER2 immunostaining in HST negative tumors ($p < 0.001$) but not in HST positive ones. Patients with HER2 3+ / HST positive tumors responded better to trastuzumab ($p = 0.010$). In conclusion, HST is expressed in a subset of breast carcinomas in association with HER2. This protein may affect the activation of HER2/EGFR dependent pathways by interfering with the expression of HER3. HST may prove useful as an adjuvant marker for the prediction of response to HER2 targeting treatments.

Image analysis of digitized mammograms and correlation with histopathology

G. Giannakopoulou¹, S. Golemati², D. Koulocheri¹, A. Tsakiri¹, J. Stoitsis², A. Nonni¹, F. Zagouri¹, K. S. Nikita², G. C. Zografos¹, and J. Bramis¹

¹Breast Unit of Hippokraton General Hospital of Athens (1st Propaedeutic Surgery Clinic of Medical School, University of Athens, Radiology Department, Pathology Department of Medical School, University of Athens, Greece) ²Department of Electrical and Computer Engineering, National Technical University of Athens, Greece

Purpose: To correlate breast tissue histology with image texture features, in an attempt to investigate the validity of texture analysis techniques and their potential application in clinical practice.

Materials and methods: 33 patients with non-palpable breast lesions, including masses and microcalcifications, underwent stereotactic directional vacuum-assisted breast biopsies. Tissue samples were subsequently sent for histological examination. Regions of interest (ROIs), corresponding to suspect lesions, were defined and outlined by a radiologist on the digitized mammograms. Texture analysis of the selected ROIs was performed using first-order mathematical descriptors estimated from the normalized gray-level histograms of the image ROIs. These included minimal, maximal, median, and mean gray-levels, standard deviation of gray levels, coefficient of variation, and gray-level skewness, kurtosis, entropy, and energy. The fractal dimension was also estimated.

Results: Compared to the 21 benign cases, the histograms of the 12 malignant cases had a significantly (Student's t-test, $p < 0.05$) higher gray-level skewness and kurtosis. Gray-level skewness characterizes the deviation of the distribution from a symmetrical reference one. Benign lesions had negative values for skewness (-0.05 ± 0.33) corresponding to a left-skew distribution, whereas malignant lesions had positive values (9.81 ± 13.80) corresponding to skewness to the right. Kurtosis is related to the steepness of the distribution and its values were -0.67 ± 0.86 for benign and 34.09 ± 56.52 for malignant cases.

Discussion/Conclusion: Estimation of mathematical descriptors of digitized mammograms provides a quantitative operator-independent assessment of breast lesion type and may be helpful as an additional parameter in differential diagnosis of breast lesions.

Invasive cystic hypersecretory carcinoma of the breast.

A 2 case report.

Apostolikas N., Papaevangelou M., Psychoyiou H., Patereli A., Koniaris E.

Dept. of Pathology of the Hellenic Anticancer Institute, 'St.Savvas' Hospital, Athens, Greece.

The Invasive Cystic Hypersecretory Carcinoma (I. C. H. C.), first described by Rosen in 1984, is a very rare entity of a breast adenocarcinoma. We present the clinical and pathological features of 2 cases of I.C.H.C. and review the literature. The patients were females aged 54 and 52 years. Both tumors were located in the left breast. The presenting symptom was a palpable mass. U/S, FNA and mammography were positive for malignancy in both cases. Gross pathology: the tumors measured 2.5cm and 5.5cm respectively, and were distinct from the surrounding parenchyma. The interesting gross feature was the presence of numerous cysts surrounding the main bulk of both tumors but also within the main lesion itself in the

second case. The cysts measured up to 0.4cm and the secretion was mucinous or gelatinous. Microscopy: the invasive part of the tumors was a high grade Non Otherwise Specified ductal carcinoma, surrounded by an widely spread intraductal component, which had all the typical characteristics of a cystic hypersecretory carcinoma (CHC). Especially in the second case the background of the invasive carcinoma showed a wide spectrum of pathologic lesions ranging from cystic hypersecretory hyperplasia (CHH) to atypical CHH and CHC. The first patient was treated with lumpectomy and excision of 12 auxiliary lymph nodes which had no metastases. The second patient had a modified radical mastectomy and 7/27 positive lymph nodes. The expressions of estrogen and progesterone receptors, c-erb-B2, p53, ki-67, CEA, SMA and PAS-Alcian blue are discussed. Only 13 cases have been reported so far in the literature. We add two more cases in order to contribute to the correct diagnosis of a poorly recognized histological entity. More over it seems that the accurate recognition of a CHC may prevent and avoid the development of an ICHC.

²Breast Unit, 1st Surgical Dep., Medical School of Athens, Greece

The designation lobular neoplasia(LN) includes atypical lobular hyperplasia and lobular carcinoma in situ. Even if these lesions have no prognostic significance, they constitute a precursor lesion of subsequent invasive breast carcinoma(BC). Estrogen(ER) play a significant role in promoting the development and progression of BCs. We evaluated the ER-a, and ER-b status in patients with LN. Tissue specimens were taken from 30 patients with LN. Adjacent normal breast tissues were estimated serving as controls. A standard immunohistochemical procedure, using monoclonal antibodies to ER-a, and ER-b was applied. Both the estrogen receptors were expressed in all the samples. There was no statistically significant difference in the percentage of ER-a expression between LN (Med65%,SD0,18) and normal tissue samples(Med60%,SD 0,18, Mann Whitney U test, p=0.438). Interestingly, ER-b expression was significantly decreased in LN samples (Med70%,SD0,17) in comparison to normal tissue samples (Med85%,SD0,09, Mann Whitney U test, p<0.01). Our results and especially the decrease of ER-b receptors in LN may have a potential role in the determination of women, predisposition for breast carcinoma development.

P148

Vacuum-assisted breast biopsy of microcalcifications: Correlation between mammographic images and histological findings.

D. Koulocheri, G. Giannakopoulou, A. Tsakiri, A. Nonni, F. Zagouri, G. Philippakis, N. Pararas, G.C. Zografos, J. Bramis
Breast Unit, 1st Surgical Depart., Medical School of Athens, Greece

The purpose of our study is to correlate between the histological findings of microcalcifications in breast tissue using the vacuum-assisted 11G biopsy (MammotomeR) device and the mammographic estimation according to the BI-RADS of the American College of Radiology. 190 mammograms of patients with microcalcifications were diagnosed by two independent radiologists and classified using the BI-RADS categories. The patients were biopsied using the MammotomeR device in combination with the stereotactic Fischer's table. Histological examinations were

performed and their findings were classified in 3 categories; benign lesions, atypia (ADH, ALH) and malignancies (in situ and invasive carcinoma). 61/190 mammographic images were classified as BI-RADS 3 and 129/190 as BI-RADS 4. We statistically evaluated the histological findings to the BI-RADS classification and our results are: for BI-RADS 3, 49/61 cases were benign lesions (80,32%), 11/61 were atypia (18,03%) and 1/61 were malignant lesions(1,64%). For BI-RADS 4, 93/129 cases were benign lesions (72,10%), 12/129 were atypia (9,30%) and 24/129 were malignant lesions (18,60%). According to our results, the radiological estimation was successfully made for microcalcifications in conformity with the BI-RADS categories and their histopathology.

Breast Metastasis from Uterine Leiomyosarcoma Diagnosed by Fine Needle Aspiration (FNA). A Case Report

Lina Pappa¹, Nektaria Zagorianakou¹, Evangelia Kitsiou², Maria Bafa¹, Evdoxia Sintou-Mantela¹ and Vassiliki Malamou-Mitsi¹.

Department of Cytology¹, University Hospital of Ioannina, Greece
Department of Pathology², General Hospital "G. Hatzikosta", Ioannina, Greece.

Background: Leiomyosarcomas of the breast are a rare subgroup of primary breast sarcomas. Even more rare is breast metastasis of an extra-mammary leiomyosarcoma. Only four cases have been published up to now in the literature.

Case: We report a case of breast metastatic leiomyosarcoma occurred in a 58-year-old woman with a prior history of uterine leiomyosarcoma, resected 18 months earlier. The breast mass was palpable and a fine needle aspiration performed by a Cytologist. The microscopic examination showed cellular smears composed of loosely structured clusters and tissue fragments of spindle-shaped and polygonal or rounded malignant cells in disorderly arrangement. The tumor cells were medium or large-sized with basophilic cytoplasm and enlarged, irregular, hyperchromatic nuclei with nucleoli. Tumor giant cells and multinucleation were also present. The morphological features along with immunocytochemical positivity for desmin, muscle-specific actin and vimentin put the diagnosis of a metastatic leiomyosarcoma.

Conclusion: FNA cytology can be a reliable method for the diagnosis of a leiomyosarcoma. The morphologic criteria in combination with the clinical history and the immunocytochemical findings can put a definitive diagnosis and avoid additional painful and time consuming diagnostic procedures for the appropriate patient's further clinical management.

The assessment of sensitivity, specificity and positive predictive value of the mammographic evaluation of non-palpable lesions of the breast using the breast imaging reporting & data system (BI-RADS) in an anticancer institute

H. Trihia¹, H. Kajanis², O. Tzaida¹, D. Kondylis³, P. Arapantoni-Dadiotis¹.

¹Departments of Pathology, ²Radiology and ³Surgery, Metaxa Cancer Hospital, Piraeus, Greece

Objective: The purpose of the study was to assess the usefulness of the BI-RADS application in the evaluation of the mammographic findings of non-palpable lesions of the breast in our hospital.

Material and Methods: We retrospectively evaluated 165 non-palpable mammographically detected lesions, on which surgical biopsy was performed. Each lesion was classified according to BI-RADS descriptors for masses (margins and shape) and calcifications (morphology and distribution) and was categorized by the BI-RADS

final assessment categories as category 2 ('benign'), category 3 ('probably benign'), category 4 ('suspicious') and category 5 ('highly suggestive of malignancy'). Mammographic and pathologic findings were reviewed.

Results: Carcinoma was present in 58 of the 165 lesions (35.7%). 38 of them presented as stellate lesions, with- or without calcifications and 19 as pure calcifications. A single case which was categorized mammographically as BIRADS 3 lesion, presented as a relatively well defined lesion. For the 165 lesions subject to biopsy, BI-RADS final assessment categories were 'category 2' in 22 lesions (13.3%), 'category 3' in 63 lesions (38.1%), 'category 4' in 50 (30.3%) lesions and 'category 5' in 30 lesions (18.1%). Carcinoma was present in all 30 'category 5' lesions (100%) compared with 27 of 50 'category 4' lesions (54%) and in one of the 63 'category 3' lesions (1.58%). Of the carcinomatous lesions, 51 (87.9%) were infiltrative of which 9 microinvasive (15.3%) and 7 (12%) were in situ. Of the infiltrative carcinomas, four were of low grade and six multicentric. Precancerous lesions, in the form of atypical ductal hyperplasia were present in 9 (5.45%) of the 165 lesions, six in 'category 3' lesions and three in 'category 4' lesions. Foci of LN/LCIS (incidental finding) were present in 6 cases, four in 'category 3' lesions and two in 'category 4' lesions. The sensitivity of the mammographic evaluation was 98.3% and specificity 82.3%. Positive predictive value for 'category 5' was 100%, 'category 4' 64% and 'category 3' 98.4%. The false positive rate was 31% and false negative rate 1.72%.

Conclusion: The standardized terminology of the BI-RADS lexicon allows quantification of the likelihood of carcinoma in non-palpable breast lesions. By providing a common language, BI-RADS facilitates communication between radiologists, referring clinicians and women undergoing mammography. In our study BI-RADS categories '4' and '5' were useful predictors of the relative likelihood of malignancy and confirms that spiculated margins, irregular shape and pleomorphic calcifications have a higher propability of malignancy.

P151

Occult breast carcinoma presenting with axillary lymph node metastases- three cases report.

Tzaida O, Trihia H, Simoulis A, Kondylis D*, Arapantoni-Dadioti P. Pathology Department, METAXA Cancer Hospital, Piraeus, Greece
*Surgery Department, METAXA Cancer Hospital, Piraeus, Greece

Background: Breast carcinoma presenting with axillary metastases and no apparent primary tumor in the breast is an uncommon form of Stage II disease. Fewer than 1% of patients diagnosed with breast cancer initially present with axillary lymphadenopathy as the only clinical manifestation of their disease. We present three such cases of occult Ca and we discuss the issues of evaluation and management of patients.

Material and Methods: Three postmenopausal female patients presenting with a palpable axillary mass and normal findings at physical examination, mammography and ultrasound of both breasts, were reported to our hospital between 1979 and 2001. Lymph node mass biopsy revealed a metastatic adenocarcinoma of presumed primary breast origin based on histological tumor phenotype. One patient underwent total mastectomy and in the two others breast conserving surgery combined with lymph node dissection was performed. All patients received hormone therapy and breast radiation as well as adjuvant systemic therapy.

Results: In the patient subjected to total mastectomy and in one of the two cases with partial mastectomy, despite a thorough pathologic examination, no primary tumor was found. These two patients were free of disease at 18 and 7 years follow-up, respectively. In the third patient microscopic examination revealed the presence of in situ Ca, comedo type, without an infiltrating component. The histological and immunohistochemical characteristics of the breast tumor were entirely compatible with the ipsilateral axillary metastasis. Immunohistochemical study also revealed a tumor phenotype indicative of an aggressive biologic course. Despite receiving several types of

systemic therapy, plus radiation, plus total excision of the rest of the breast this patient presented inflammatory breast disease, two local recurrences, cervical lymphadenopathy and lung metastases at 3, 10 and 30 months follow-up.

Conclusions: Despite a careful and extensive pathologic examination, in some cases of occult breast Ca, a primary tumor remains undetected. The examination of lymph node metastasis is sufficient and reliable to confirm the tumor origin, to suspect the biologic potential of the disease and to plan the most appropriate patient management.

P152

Analysis of known and novel TP53 gene mutations in breast cancer patients from the region of Epirus, Greece

Chr. Zachariou, V.D. Malamou-Mitsi and N.J. Agnantis
Department of Pathology, Molecular Pathology Unit,
University of Ioannina, Ioannina, Greece

Alterations of p53 gene are probably the most common genetic abnormalities in human malignancies. In breast cancer, the majority of mutations is located in the conserved DNA-binding domain of p53 (exons 5-8) and has been reported to be associated with more aggressive disease and worse overall survival. As direct sequencing of the entire gene is a time-consuming and laborious procedure, several pre-screening methods have been developed. Among them, Denaturing Gradient Gel Electrophoresis (DGGE) appears to be more sensitive, nearly 100%. We used a PCR and GC-clamped DGGE assay, followed by sequencing, to investigate the presence of point mutations within exons 5-8 of p53 gene, in DNA samples from 60 breast cancer patients, from the region of Epirus, Greece. Out of the 60 cases analyzed, 12 (20%) seemed to be carriers of a p53 alteration [7 in exon 6, 2 in exon 7, 2 in exon 8 and 1 in exon 5]. Samples that produced a variant DGGE-pattern were sequenced and carefully examined. In all but one (inadequate sample) cases, sequence alterations were identified by sequencing. Base changes were searched for and validated in the IARC TP53 Mutation Database. Of these, two point mutations [g.13418T>A (p.Y220N) and g.13270delG] and one silent polymorphism [g.13399A>G (p.R213R)] have not been previously reported in breast cancer. Our data indicate that PCR-DGGE assay is an efficient and highly sensitive prescreening approach for p53 mutation detection in DNA samples of breast cancer patients.

P153

Trophoblast expression of EGFR in preeclampsia - a tissue micro-array study

Staribratova D*, Bruder Elizabeth**

*Department of Pathology, Plovdiv Medical University, Bulgaria,
**Institute of Pathology, Kantonspital Basel, Switzerland

Placental pathology in preeclampsia and in pregnancies with intrauterine growth retardation are associated with changes of EGFR expression of the villous trophoblast. The present study is aiming at establishing the EGFR expression of the trophoblast in preeclampsia and intrauterine growth retardation in comparison with normal pregnancies. Tissue micro-array study including 30 placentas from preeclamptic cases, 30 - with intrauterine growth retarded fetuses и 30 normal control placentas are semi-quantitatively examined for EGFR expression of the trophoblast. Positive immuno-expression of EGFR is established in the cytoplasm on the membranes of syncytiotrophoblast, as well as in cytotrophoblast. Comparing the immunopositivity of EGFR in the trophoblast from normal pregnancies, the groups with preeclampsia and retarded fetuses exhibit statistically significant lower expression of EGFR (P < 0.05). There is no correlation between the expression of the growth factor and clinical data such as fetal weight and Apgar score (P >

0.01). The established lower expression of EGFR in the trophoblast from pregnancies complicated with preeclampsia and intrauterine growth retardation can be discussed in the context of the pathologic 'switch' in normal placental development.

P154

Structural Patterns of the placenta remodelling in cases of IUGR

Olga S. Reshetnikova, Olga V. Kononenko, Inna M. Goryanikova, Sergiy A. Morozov

Department of Pathologic Anatomy, Lugansk State Medical University, 1, kv 50-let Oborony Luganska, 91045, Lugansk, Ukraine, State Medical University of Lugansk, Ukraine

Placental insufficiency is an important factor of the fetal intrauterine growth restriction (IUGR). To confirm the relation between placental morphology changes and fetal IUGR 20 placentas from the late medical abortions because of psychotherapeutic reasons in cases of IUGR at 20-25 weeks of gestation (wg) were compared with 20 placentas at the same wg but without fetal IUGR. All material was divided into four groups, including 10 placentas at 20-22wg and 10 - at 23-25wg both in cases of IUGR, which were studied with corresponding 10 (20-22wg) and 10 (23-25wg) controls. Volume fractions (vf) of the major placental components were determined from 5mmk paraffin sections. The results have shown that both placental and fetal weights in IUGR groups were smaller than in controls. The poor vascularisation and immaturity of the villous tree were found in many cases of IUGR. The thickness of placental membrane increased from 10.74±0.09 at 20-22wg and 10.92±0.09 at 23-25wg in controls to 11.62±0.1 and 11.87±0.12mmk, p<0.05 correspondingly. The tendency of the decrease of fetal vessels vf and increase of the interstitium vf in cases of IUGR at 20-22wg has reached the significant level at 23-25 wg: correspondingly - 9.38±1.31 and 58.56±1.98 vs 14.38±2.48 and 52.07±2.75%, p<0.05 in controls. Conclusions: the histopathological changes in placentas and the increased thickness of placental membrane might represent an important factor in the pathogenesis.

P155

Ultrastructural peculiarities of the villous membrane under hypoxia conditions

Olga S. Reshetnikova, Ganna E. Mylovydova, Inna M. Goryanikova, Sergiy A. Morozov.

Department of Pathologic Anatomy, Lugansk State Medical University, 1, kv 50-let Oborony Luganska, 91045, Lugansk, Ukraine, Laboratory of Pathomorphology, Institute of General and Urgent Surgery of Academy of Medical Sciences of Ukraine, 1, vyizd Balakireva, Kharkiv, 61018, Ukraine

The electron microscopic investigation of placenta under hypoxia condition caused by maternal iron-deficiency anaemia and EPH-gestosis was carried. Electronograms from 30 placentas, including 10 cases of EPH-gestosis, 10-maternal anaemia and 10-uncomplicated pregnancy (controls) were studied stereometrically by point count method at magnification X 5600. Pathological ultrastructure's alterations of a placental barrier, including a damage of microvilli, thickening of basal membranes both of epithelium and endothelium, a stromal fibrosis were found. Compensatory proliferations of cytotrophoblast in cases of EPH-gestosis and in anaemia group; as well as hyperaemia of foetal vessels in EPH-gestosis group were seen too. The increase of the syncytiotrophoblast volume fraction (VF) in anaemia group (35,71±0,66 vs. 32,19±0,26 % in controls), as well as cytotrophoblast, epithelium and endothelium basal membranes VF's both in anaemia (A) and gestosis(G) groups had registered (correspondingly: A- 2,76±0,04; 3,52±0,02; 0,57±0,06; G- 1,05±0,03; 4,76±0,03; 0,74±0,04 vs. 0,76±0,04; 3,04±0,01; 0,38±0,12% in controls, P<0,05). The capillary lumen increased to 14,70±0,26% in

gestosis group (13,5±0,21% VF in controls, P<0,05). Pathological changes of a placental barrier could be a structural basis of a placental insufficiency. It was suggested that the process of ultrastructural remodelling of the placental membrane may compensate for different pathologies at the terminal parts of the villous chorion, which is essential base of the morphological correction of a placental insufficiency.

P156

Exaggerated placental site lesion of the cervix

Simona Stolnicu¹, Francisco Nogales², Irina Timar¹, Lucian Puscasu³

¹Department of Pathology, University of Medicine, Targu Mures, Romania, ²University of Granada Medical School, Spain,

³Department of Obstetrics and Gynaecology 1, University of Medicine, Targu Mures, Romania

Exaggerated placental site is a nonmolar miscellaneous trophoblastic lesion included by World Health Organization in the classification of the gestational trophoblastic disease. Its location is exceptional in the cervix. We report the case of a 55 year old non-menopausal patient admitted for vaginal bleeding and irregular menses for two months. Menarche occurred at 14, she was gesta 6, para 4, aborta 2 and the last normal pregnancy occurred 15 years ago. She did not receive any hormonal therapy in the last two months. Because of massive methorrhagia, an emergency simple total hysterectomy was performed. Macroscopy revealed a 20 mm red, ill-defined plaque lesion in the ectocervix, extended to the outer cervical stroma. Microscopically, the superficial cervical stroma at the squamocolumnar junction was infiltrated by cords and small sheets of intermediate (extravillous) mono/and multinucleated trophoblastic cells. These cells were large, polygonal or spindle shaped, had abundant eosinophilic cytoplasm and atypical, hyperchromatic nuclei and were located mainly perivascular- or intravascularly. Mitotic activity was absent. Immunohistochemically, they were invariably positive for Cytokeratin 18, CD10, hPL, but were only focally positive for hCG and Placental Alkaline Phosphatase. Ki-67 and Inhibin were negative. There was a massive hemorrhagic infiltration of the stroma, but no necrosis. The neighbouring endocervical glands showed a focal Arias-Stella phenomenon. No chorionic villi were found. In the corpus uteri, endometrial glands of the spongiosa layer were voluminous with epithelial and intraluminal secretion and were associated with dense decidualized compacta, stromal oedema and a well-developed spiral arterial system. Exaggerated placental site nodules must be differentiated from placental site trophoblastic tumor, and other trophoblastic lesions, invasive nonkeratinizing high grade squamous carcinoma, cervical blue nevi, atypical mesenchymal cells of the type associated with vaginal polyps and other mesenchymal lesions. This is a normal physiological process that can occur many years after a normal pregnancy and that does not require any specific treatment. Serum β-hCG analysis 2 month after the surgery was negative. This case is particularly relevant because of the age of the patient (who still had at 55 years old regular menses) and the most unusual cervical localization of the lesion.

P157

Vaginal non-DES related clear cell adenocarcinoma in a 77 years-old woman. Cytological and histopathological findings.

Makri S., Athanasiou E., Papanikolaou A.,

Hadzibougias J., Konstandoulas M.

Department of Midwifery, School of Health and Medical Care, Technological Educational Institution of Thessaloniki.

A 77-old woman visited a physician for vaginal bleeding. Vaginal examination showed a small-sized bleeding tumor protruding from the vaginal wall. Vaginal smear sampling revealed malignant

cells resemble those of an adenocarcinoma with ball and glandular like growth patterns. Then, followed excision of the tumor and the histological diagnosis was clear cell adenocarcinoma of the vagina. Grossly, the tumor was mostly exophytic, approximately 1cm in size and superficially invasive. Microscopically, the tumor was composed of microcysts, solid areas and papillary formations. The predominant cell type was honail-shaped cells and scattered cells with Müllerian differentiation and moderate nuclear atypia. There was no data of prenatal exposure to DES or related nonsteroid estrogens. The age distribution of all patients with CCAC showed two distinct peaks: at mean age of 23 and 71 years respectively including cases in which DES exposure had been excluded. The bimodal age distribution suggests a carcinogenesis-promoting role of menarche and menopause and/or the existence of a subpopulation with genetic risk factors or exogenous risk factors other than exposure to DES. Despite that cytologic examinations are informative in 65% of CCAC, in our case was diagnostic.

P158

EGFR (HER-1), c-erbB2 and c-Kit expression of uterine sarcomas.

Kiziridou A., Dimitriadis I., Fotiou Ch., Kartsionis Ch., Toliou T. Pathology Department, "Theagenion" Anticancer Hospital, Thessaloniki, Greece.

Objective: Uterine sarcomas are rare tumors characterized by their resistance to traditional treatment. The tyrosine kinase receptors family has been recognized of particular importance in many human malignancies. The role of c-kit oncoprotein in gastrointestinal tumors is also encouraging the use of these data in other tumors.

Methods: Formalin-fixed, paraffin embedded archival tissues from 8 carcinosarcomas and 5 endometrial stromal sarcomas from 13 patients surgically resected or biopsy specimens were examined immunohistochemically using EGFR(HER-1), c-erb-B2(HER-2) and c-kit(CD117).

Results: EGFR(HER-1) was positive in 3 of the 5 (60%) endometrial stromal sarcomas, but only in stromal elements of 2/8(25%) carcinosarcomas. HER-2 was negative in all mesenchymal elements of the tumors. C-kit(CD117) immunorexpression was positively expressed in 4/5(80%) of stromal sarcomas and in 3/8(37,5%) of carcinosarcomas.

Conclusion: Our findings suggest the possible role of new therapeutic approachment using monoclonal antibodies in uterine sarcomas treatment. Further studies with greater number of cases and clinical studies are needed to investigate this prospect.

P159

Tubular dysgerminoma of the ovary – a case report.

Jolanta Kupryjańczyk
Department of Molecular Pathology, Institute of Oncology and Department of Pathology, Bródnowski Hospital and II-nd Faculty of Medicine, Medical University, Warsaw, Poland.

A 27 y.o. female was diagnosed in 1988 with ovarian tumor. She underwent left salpingo-oophorectomy and a hysterectomy. A primary diagnosis of juvenile granulosa cell tumor was changed to androblastoma. Because of the diagnosis and FIGO IA disease the patient was left for observation. One year later the patient appeared with massive and disseminated recurrence and she died 15 months after the primary surgery. The ovarian tumor measured 27 cm in the largest diameter; it was solid and cystic, with haemorrhagic necrosis. Microscopically, it presented with sharply demarcated islands and nests of cells, similar to those observed in insular carcinoids. Peripheral palisading was seen. Uni- and multilayered cysts were a

marked component of the tumor. There were also tubules of varying sizes, either hollow ones lined by a single layer of cells or solid. Lymphocytic infiltrate was sparse. Cytologically, the majority of cells - either infiltrating singly or in nests or forming cysts and tubules were compatible with cells in dysgerminoma. The germ cell nature of the cells was confirmed by diffuse positive nuclear staining for OCT4 antibody. This is the first report of tubular dysgerminoma of the ovary (consultation by Dr Robert E. Scully is gratefully acknowledged).

P160

Benign Brenner tumor of the ovary with unusual large size. A case report with immunohistochemical analysis.

F. Karasavvidou, G. Kalodimos, D. Pappa, E. Tziastoudi, Ch. Galani, E. Kostopoulou, G. Koukoulis.
Department of Pathology, University Hospital, Larissa, Greece.

We report a case of benign Brenner tumor of the left ovary that occurred in a 59-year-old woman. The patient presented with uterine bleeding. Clinically an abdominal mass was palpable. A CT scan displayed a left solid adnexal mass. Surgical excision of the mass and total hysterectomy was performed. Grossly, the tumor was 18 cm in maximal dimension with lobulated outline and solid, firm, gray-white, fibromatous cut surface. Microscopically, the tumor was characterized by sharply demarcated nests of epithelial cells within an abundant fibrous stroma. Immunohistochemical examination showed: the epithelial nests were positive for the cytokeratin 7 and p63 and negative for cytokeratin 20 and thrombomoduline. The stromal cells were positive for progesterone and negative for estrogen receptors. On the basis of the histological findings the diagnoses of benign Brenner tumor was made. This represents a case of unusually large Brenner tumor, which can be considered one of the largest ever documented in the literature.

P161

CHFR gene analysis in ovarian carcinomas.

Agnieszka H. Ludwig¹, Mateusz Bujko², Jolanta Kupryjańczyk¹
¹Department of Molecular Pathology, ²Department of Molecular Biology, The Maria Skłodowska-Curie Memorial Cancer Center, Institute of Oncology, ul. Roentgena 5, Warsaw 02-781, Poland.

CHFR is a mitotic checkpoint protein that under mitotic stress (caused also by taxanes) delays progression into mitosis. The cells with defective *CHFR* gene would be more vulnerable to taxane treatment. We looked for *CHFR* gene (605209) alterations and its promoter hypermethylation in 48 ovarian carcinomas either sensitive or resistant to taxane treatment. We used single-strand conformation polymorphism analysis, sequencing and methylation specific polymerase chain reaction. Neither mutations in the *CHFR* gene nor hypermethylation of its promoter region were found. A novel single nucleotide polymorphism (Val154Val) was identified in exon 5 of alternatively spliced transcript. Our results indicate that *CHFR* gene status cannot serve as a molecular predictor of ovarian cancer sensitivity to taxanes. (supported by the KBN grant 601/PO5/2004/27).

P162

Predictive factors in ovarian carcinomas from patients treated with taxanes

J. Kupryjańczyk^{1,5}, I. Ziolkowska-Seta², T. Szymanska¹, R. Mądry⁴, A. Timorek⁶, E. Kraszewska³, A. Rembiszewska¹, J. Markowska⁴, J. Stelmachow⁶, M. Bidzinski²
¹Dpt Mol Pathol, ²Dpt Gynecol Oncol, ³Dpt Biostatistics, Inst Oncol, Warsaw; ⁴Chair Oncol, Med Uni, Poznań; ⁵Dpt Pathol, ⁶Dpt Gynecol Oncol, Bródnowski Hospit, II-nd Faculty of Med, Med Uni, Warsaw; Poland

We aimed to evaluate clinical significance of TP53, BCL-2 and BAX expression in ovarian cancer patients uniformly treated with taxanes and platinum compounds. Immunohistochemical analysis was performed on archival samples from 196 ovarian carcinomas FIGO stage IIB-IV; the results were analyzed by the Cox and logistic regression models. Statistical analyses were performed in the whole tumor group, and separately in the TP53-negative and TP53-positive group. Similarly to the results previously obtained for patients treated with platinum-based regimens (Br J Cancer 2003), complete remission was negatively influenced by high BAX expression in all patients group (OR 0.5; $p=0.05$; 95% CI for OR [0.25, 1.02]) and by BCL2 expression in the TP53(-) group only (OR 0.27; $p=0.05$; 95% CI for OR [0.07, 1.04]). Our results confirm that binomial TP53 status divides ovarian carcinomas into two biologically distinct groups. BCL-2 and BAX expressions have predictive value in ovarian cancer patients treated with taxanes and platinum-compounds (supported by the KBN grant 601/POS/2004/27).

P163

RCAS1 expression in endometrial cancer: correlation with clinicopathological variables

Zannis Voulgaris¹, Stamatios Theocharis², Alexandros Rodolakis¹, Sonia Markaki³, Theocharis Papageorgiou¹, Georgios Vlachos¹, Emmanuel Diakomanolis¹, Aristidis Antsaklis¹, First Department of Obstetrics and Gynecology¹, Department of Forensic Medicine and Toxicology², University of Athens; Department of Pathology³, Alexandra Hospital, Athens, Greece

The tumor associated antigen "receptor-binding cancer antigen expressed on SiSo cells" (RCAS1) inhibits the growth of receptor expressing cells and induces apoptosis. RCAS1 protein expression was examined immunohistochemically in paraffin embedded tissue sections of 48 endometrial cancer cases and was correlated with clinico-pathological parameters. RCAS1 positivity, overexpression (positivity in more than 50% of tumor cells), and intensity of staining (mild, moderate, intense) were correlated with the clinicopathological variables: patients' age, FIGO stage, tumor histological type, grade, and proliferative capacity (Ki-67 labeling index). RCAS1 protein positivity was noted in all of the examined cases, while it was overexpressed in 33 out of 48 cases (71%). RCAS1 protein overexpression was statistically significantly correlated with tumor histological grade ($p=0.003$) and FIGO stage ($p=0.022$), but not with patients' age, tumor histological type and proliferative capacity. The intensity of staining for RCAS1 protein was not correlated with any of the examined clinico-pathological variables. RCAS1 protein is widely expressed in endo-metrial cancer cases and its overexpression is correlated with important clinicopathological variables for patients' management. Further molecular and clinical studies are required in order to delineate the significance of RCAS1 protein participation in endometrial neoplasia.

P164

pKDR expression in endometrial cancer cells related to HIF1 α /VEGF factors.

A. Giatromanolaki¹, Ch. Charalampidis¹, M.I. Koukourakis², E. Sivridis¹,
¹Department of Pathology, ²Department of Radiotherapy / Oncology, Democritus University of Thrace Medical School, Alexandroupolis - Greece

Vascular endothelial growth factor (VEGF) is a potent angiogenic factor for many malignant neoplasms exerting its function through activation of specific membrane receptors, i.e. KDR/flk-1, residing in

endothelial cells. Using a novel monoclonal antibody, recognizing the activated (phosphorylated) form of the KDR receptor (pKDR), we assessed the expression of pKDR in normal and malignant endometrium. A strong and consistent cytoplasmic and nuclear pKDR expression was noted in the normally cycling endometrium, including epithelial, stromal and endothelial cells, suggesting a role in the normal menstrual cycle. Approximately one third of the 70 endometrioid adenocarcinomas analyzed exhibited an intense cytoplasmic and nuclear pKDR expression in both cancer cells and peritumoral vessels. It was noted that such pKDR reactivity in cancer cells was related directly to VEGF, VEGF/KDR complexes and HIF1 α (hypoxia inducible factor 1 α) expression. Furthermore, pKDR expression was significantly associated with poor prognosis. It is concluded that the VEGF/KDR pathway is activated in both normally cycling and malignant endometrium, suggestive of an important role in the biology of this tissue.

P165

Loss of FOXP1 is a common event in early endometrial cancer: relationship with estrogen receptors and HIF1 α expression.

A. Giatromanolaki¹, Ch. Charalampidis¹, M.I. Koukourakis², E. Sivridis¹,
¹Department of Pathology, ²Department of Radiotherapy / Oncology, Democritus University of Thrace Medical School, Alexandroupolis - Greece

The FOXP1 gene has an important role in cellular transformation, differentiation and proliferation. We studied the expression of FOXP1 in normal and malignant endometrial phases. Normal endometrial cycle showed a predominantly nuclear FOXP1 expression during the proliferate phase, and during the secretory phase of the cycle. Loss of nuclear expression was the most striking event in endometrial adenocarcinomas. Tumors with an exclusively weak cytoplasmic expression of FOXP1 were linked with deep myometrial invasion and hypoxia - inducible factors 1 α (HIF-1 α) expression. On the other hand, the presence of nuclear FOXP1 expression was significantly linked with ER- α reactivity. Survival analysis did not reveal significant differences among patients grouped by FOXP1 expression, presumably due to the high curability of stage I disease. This study provides evidence on pathways to be investigated to elucidate the interplay between FOXP1, ER- α and HIF-1 α in hormone dependent cancers.

P166

Rare primary neoplasms of the female pelvic cavity: report of two cases of transitional cell carcinoma

Kamina S., Zioga C., Batistatou A., Doukas M., Balasi E., Tzioras S., Agnantis N.J.,
Department of Pathology, University of Ioannina Medical School, Ioannina, Greece

Transitional cell carcinoma is rare in the female genital tract. Extremely rare is also the primary peritoneal transitional cell carcinoma. Herein, we describe the clinical, histopathologic and immunohistochemical features of two such cases of transitional cell carcinoma. The first case refers to a 53-year-old woman with transitional cell carcinoma of the endometrial cavity, invading more than half of the myometrium. The second case refers to a 75-year-old woman with multiple tumor nodules in the peritoneal cavity. Microscopically, they had the appearance of transitional cell carcinoma, grade 2. Neoplastic cells were noted invading the surface and the cortical stroma of the right ovary, which contained a large mature cystic teratoma. In both cases upon immunohistochemical examination, the neoplastic cells were Ca125 and cytokeratin 7

positive, cytokeratin 13 and 20 negative. In addition, in both women cystoscopy revealed no abnormalities. Based on the morphologic and immunohistochemical features the diagnosis of primary transitional cell carcinoma of the endometrium and the peritoneal cavity, respectively, was made. Transitional cell carcinoma is a rare, distinct subtype of gynaecological malignancy, which has morphologic features of urothelial differentiation, but retains a müllerian immunoprofile.

P167

Prognostic value of cell proliferation, growth and differentiation regulatory proteins in early stage cervical carcinoma

Neli Basheska, Genghis Yashar, Katerina Kubelka-Sabit, Irina Prodanova

Department of Histopathology and Clinical Cytology, Institute of Radiotherapy and Oncology, Medical Faculty, Skopje, Republic of Macedonia

Objectives: The aim of this study was to evaluate the immunohistochemical histochemical expression of cell proliferation, growth, and differentiation regulatory proteins in early stage cervical carcinoma and to assess their prognostic value by exploring their relationships to various clinicopathological characteristics (age, lymph node involvement, tumor diameter, depth of invasion, thickness of uninvolved cervical stroma, histotype, grade, lymphovascular space invasion, inflammatory infiltrate), human papillomavirus (HPV) status and influence on disease-free survival.

Methods: This retrospective study comprised 83 patients, all subjected to radical hysterectomy with bilateral pelvic lymphadenectomy for early stage cervical carcinoma and postoperative irradiation therapy. Expression of Ki-67, c-erbB-2, EGFR protein, as well as estrogen and progesterone receptors was evaluated by immunohistochemistry using avidinbiotin-peroxidase complex method. The results were assessed semiquantitatively in the surface area, center and invasive front of each tumor as the percentage of the immunostained cells and/or intensity of immunostaining for each protein. The presence of HPV was assessed by conventional in situ hybridization (ISH) technique and catalyzed reporter deposition signal amplification ISH using mixed biotinylated probes to identify types 6/11, 16/18 and 31/33 or 31/33/51. **RESULTS:** In our case series, 73 (88%) patients had a tumor limited to the uterine cervix less than 4 cm in diameter (pT1b1), while 10 (12%) patients had larger neoplasms belonging to pT1b2 category. Pelvic lymph node involvement was found in 20 (24%) patients. During the follow-up period (range, 65-181, mean, 121 months) recurrences were observed in 9 patients. The 5-, 10- and 15-year disease-free survival rate was 92.7%, 90.8% and 86.6%, respectively. Important predictive indicators of recurrence in the univariate analysis were pelvic lymph node involvement ($P=0.0008$), tumor diameter ($P=0.035$), depth of stromal invasion ($P=0.029$), histological type ($P=0.0009$), grade of differentiation ($P=0.056$), HPV DNA presence ($P=0.056$), HPV type ($P=0.043$), as well as Ki-67 ($P=0.031$), and EGFR protein ($P=0.0066$) expression in the tumor's invasive front. Among these variables, however, the histological type, HPV DNA presence, Ki-67 and EGFR protein expression were identified as independent significant prognostic factors for disease-free survival in multivariate analysis using Cox regression model.

Conclusions: The invasive front of carcinomas proved to be the most important area for the evaluation of prognostic significance of the expression of cell proliferation, growth, and differentiation regulatory proteins. In addition to the detection of HPV presence and morphological parameters, the evaluation of Ki-67 and EGFR protein expression may provide additional prognostic information in patients with early stage cervical carcinomas.

P168

CD57 is a reliable marker for monitoring natural killer cells in pregnancy. A morphologic and immunohistochemical study in endometrial and decidual paraffin embedded tissues of 88 women with recurrent miscarriage: Correlation with immunotherapy results

Athanasioiu E., Danihel L.¹, Bobos M.², Papanikolaou A.³, Hatzibugias D.², Hainoglou D., Kiriazaki A., Hatzibugias I. Department of Midwifery, School of Health and Medical Care, Technological Educational Institution of Thessaloniki

¹Department of Pathology, Komenius University of Bratislava, ²Department of Pathology, Aristotle University of Thessaloniki,

³Department of Pathology, Hippokratio General Hospital of Thessaloniki

The role of NK cells in early pregnancy is still unknown and controversial. At the time of implantation the endometrium is populated by lymphocytes expressing antigens characteristic of Large Granular Lymphocytes which correspond to a minor population of NK cells and is due to contact with fetal antigens. In anembyonic and recurrent spontaneous abortions NK cytotoxicity was increased. Women with recurrent miscarriage represent a heterogeneous group and no single pathology can underlie all cases. The aim of our study was to investigate the presence, distribution and immunohistochemical profile of lymphocytic population and NK cells in endometrium and deciduas of 88 women with recurrent abortions. Furthermore we try to correlate the presence of NK cells with the immunotherapy results.

Material and methods: Endometrial and decidual paraffin embedded tissues were collected from 88 women with recurrent miscarriage (number of miscarriages $n=1-4$) in first trimester and of 10 women with elective termination of first-trimester pregnancy. The monoclonal antibodies CD19, CD20, CD45RO, CD4, CD8, CD57 and CD16 were performed by an immunohistochemical method in order to investigate the immunological lymphocytic profile of endometrium and deciduas. The immunotherapy included prezone, aspirin, flaxyparin, anti-lymphocytic serum and vaccinate from the futher(male) serum.

Results: The predominal lymphocytic population expressed in all cases of recurrent abortions was CD56+, CD16-cells. The number of these cells was slightly increased in recurrent abortions than in cases of elective termination of first-trimester pregnancy. CD56+ cells infiltrated the deciduas and the endometrium and invaded the endometrial glands. More lymphocytes were CD4+ than CD8+ and few cells expressed B-cell antigens (CD19, CD20). A subpopulation expressed CD57 positivity (26/88) and infiltrated the endometrium and invaded the endometrial glands, such as CD56+ cells done Fourteen women tried a new pregnancy, 6 were positive for CD57 cells and 5 of them received immunotherapy resulting in live birth except one woman who aborted again. One woman did not received immunotherapy and aborted too. The rest 8 women did not expressed CD57 cells and gained live birth in all cases without any treatment.

Conclusions: NK lymphocytes that express CD56 and especially CD57 antigen seem to play a crucial role in pathogenesis of recurrent miscarriage as they are not found in increased numbers in normal pregnancies. Women with recurrent miscarriage who expressed CD56 and CD57 in deciduas and endometrium seemed to benefit by immunotherapy and lead in successful pregnancies. This evidence indicate that CD57 revealed a subpopulation of NK cells responsible for a subset of miscarriages and could be a specific marker for this group. Farther studies including larger number of cases and more markers needed to investigate the pathogenesis of recurrent miscarriages and find new therapeutics goals.

Pallister-Killian syndrome: A chromosomal abnormality with great variability of the fetal phenotype

P.Ctena-Agapitou, E.Agapitos, P.Dimou, C.Tsarपालis, E.Patsouris
Department of Pathology, Medical School, University of Athens

The first prenatal diagnosis of Pallister-Killian syndrome (PKS) was reported by Gilgenkrantz et al in 1985. This report was referring to about 60 prenatal cases, but both sonographic and cytogenetic diagnosis were difficult. Although ultrasound anomalies such as congenital diaphragmatic hernia, polyhydramnios and rhizomelic micromelia in association with fetal overgrowth are very suggestive of the syndrome, they are inconstant and they may even be absent. The mosaic distribution of the supernumerary isochromosome 12p greatly increases these difficulties. No prenatal cytogenetic technique is sensitive enough to ensure prenatal diagnosis and false-negative results have been described on fetal blood, chorionic villi and amniocentesis. In this study we report a prenatal case of PKS which illustrates great variability of the fetal phenotype. A pregnant woman of 25 years old was referred to our hospital at the 22 week of gestation with the symptoms of polyhydramnios and suspected rhizomelic micromelia in routine ultrasound examination. Fetal chromosome analysis was performed using fibroblasts obtained by amniocentesis and mosaicism of 47XY and isochromosome of 12p were diagnosed. The mother vaginally delivered a male fetus who died just after the delivery. Autopsy findings included rhizomelic micromelia, narrow and angulated palate and skin fibroblastic polyp at the left small finger of 0.5 cm in diameter. Micrognathia, flattened nose and low-set ears were also noted. Pallister-Killian syndrome is a clinically recognized syndrome, usually due to a tissue-limited mosaicism for a supernumerary 12p isochromosome (i(12p)). Premeiotic mitotic error may be the most likely mechanism for i(12p) formation which is maternally inherited. A quite wide spectrum of associated congenital malformations including diaphragmatic hernia, rhizomelic micromelia, mental retardation, cleft palate, pigmentary skin changes and physiognomy alterations have been reported in Pallister-Killian syndrome. Since diaphragmatic hernia and acral hypoplasia can be also found in Fryns syndrome, the differential diagnosis between the two conditions depends on the demonstration of the 12p isochromosome by FISH. Our case did not appear diaphragmatic hernia which is the most common skeletal malformation. Instead of cleft palate, our patient had narrow and angulated palate with minor facial signs and there was an additional minor feature: a skin fibroblastic polyp of the left small finger. Primary cultures of skin fibroblasts obtained by amniocentesis revealed an extra metacentric chromosome i(12p). In reviewing the 63 reported cases of PKS, Doray et al attempt to determine ultrasound indicators of the syndrome and to define a cytogenetic strategy. In cases where ultrasound indicators are present, they proposed first to perform chorionic villus of placental sampling and then amniocentesis when the first cytogenetic result is normal. Fetal blood sampling is the least indicated method because of the low frequency of the isochromosome in lymphocytes. In this cytogenetic strategy fluorescent in situ hybridization (FISH) and especially interphase FISH on non-cultured cells increases the probability of identifying the isochromosome. The analysis of cord blood lymphocytes revealed only 0.5% incidence of tetrasomy of 12p. The incidence of tetrasomy was 8.0% for the placental chorionic villi, 48.0% for the fibroblasts obtained from the umbilical cord and 70.0% for the skin fibroblasts. Thus the diagnosis of PKS is confirmed by mosaicism of i(12p) with the abnormal karyotype expression limited in lymphocytes but marked in skin fibroblasts.

P170

Immunohistochemical expression and prognostic significance of the biological markers bcl-2, p53, mdm-2 and Ki-67 in early stages of invasive cervical carcinomas

Irina Prodanova, Katerina Kubelka-Sabit,
Genghis Yashar, Neli Basheska
Department of Histopathology and Clinical Cytology,
Institute of Radiotherapy and Oncology, Medical Faculty, Skopje,
Republic of Macedonia

Objectives: The objectives of this study were the evaluation of the immunohistochemical expression of apoptosis regulating proteins (bcl-2, mdm-2 and p53 protein) in correlation with proliferation (Ki-67), human papillomavirus (HPV) infection and other histopathological and clinical parameters in early stage cervical carcinomas and estimation of their prognostic significance.

Methods: The subject of this study was a series of 83 surgically treated patients with cervical carcinoma confined to the uterine cervix, who subsequently received complete radiotherapy. The presence of HPV DNA in the neoplasm was determined by the conventional method of in situ hybridization (ISH) and catalyzed reporter deposition signal amplification ISH using mixed biotinylated probes to identify types 6/11, 16/18 and 31/33 or 31/33/51. The immunohistochemical expression of the biological markers was semiquantitatively evaluated as the percentage of immunostained cells in the three compartments of the neoplasm: the surface, the middle layer and the invasive front.

Results: 73 patients had a tumor confined to the uterine cervix less than 4 cm in diameter (pT1b1) and the other 10 had larger neoplasms that belong to the pT1b2 category. Regional lymph node involvement was found in 20 (24%) of the patients. During the clinical followup (mean, 120.7, range 4.4-181 months) a relapse was diagnosed in 9 (10.8%) patients, 6 of which (7.2%) died of the disease. The expected 5-, 10- and 15- year overall survival was 94.4%, 92.7% and 92.7%, and disease-free survival was 92.7%, 90.8% and 86.6%, respectively. The results of the univariate analysis indicate that significant predictive indicators for recurrence are: lymphonodal status, maximal tumor diameter, depth of stromal invasion, histological type, HPV DNA presence and type, and the immunohistochemical expression of bcl-2, mdm-2 and Ki-67 in the invasive front of the neoplasm. In the multivariate analysis, histological type, HPV DNA presence and the expression of Ki-67 in the invasive front have been selected as the most significant independent prognostic parameters (P=0.0024). The value of the prognostic index (PI), calculated using the Cox regression model, provided the basis on which the patients were classified into two distinct risk groups with significantly different disease-free survival period (P=0.0009).

Conclusions: The results indicate that the invasive front of the neoplasms proved to be the most important area for the evaluation of immunohistochemical expression of biological markers. The prognostic index as an indicator of the patient's place in the prognostic spectrum enables the identification of the risk group of patients in whom, due to a higher risk of relapse, better results are to be expected with the application of more aggressive therapy.

P171

Female genital actinomycosis: a review of 24 cases

Katerina Kubelka-Sabit, Irina Prodanova,
Genghis Yashar, Gjorgji Zografski, Neli Basheska
Department of Histopathology and Clinical Cytology,
Institute of Radiotherapy and Oncology, Medical Faculty, Skopje,
Republic of Macedonia

Objectives: The aim of this retrospective study was to present the clinical characteristics of the patients with female genital actinomycosis in correlation with the histopathological findings. Actinomycosis is a relatively rare chronic granulomatous inflammatory disease caused by the bacteria *Actinomyces israelii*, a normal commensal of the gastrointestinal and genital tract. The abdominal form of the disease is rare, however the incidence of the female genital and pelvic actinomycosis is rising, especially among the intrauterine device (IUD) users (8-20%).

Methods: According to the computer database at our department, 965 cases of endometritis, 6,313 cases of cervicitis and 584 cases of pelvic inflammatory disease (PID) were diagnosed in a 15 year period (1991-2005). However, only 21 (2.2%) cases of endometrial, 1 (0.02%) cervical actinomycosis and 2 (0.3%) cases of pelvic actinomycosis were identified in this period. Explorative curettage was performed in 21 patients due to prolonged uterine bleeding and extirpation of an IUD was done in 19 of them. One patient had a biopsy taken for a suspicion of cervical neoplasm, consecutively diagnosed as endometrial adenocarcinoma. In the PID group, one patient with a previous history of tubal pregnancy underwent a transabdominal biopsy for a paravesical tumor, two weeks after extirpation of an IUD. The last patient had no IUD and was surgically treated with hysterectomy and bilateral adnexectomy for a suspicion of malignant ovarian tumor. The biopsy, curettage and operative materials were formalin fixed, routinely processed and paraffin embedded. 4_ thin sections were cut and slides were stained using standard hematoxyllin-eosin staining procedure.

Results: The mean age of the patients was 52.3 ranging from 41 to 68. Macroscopically visible sulfur granules were not identified in any of the cases of disease confined to the uterus. However microscopically, in all the 22 biopsy and curettage materials, elements of chronic granulomatous endometritis and/or cervicitis were seen, together with branching filaments of Actinomyces. In the paravesical tumor, abscesses filled with necrotic debris and scattered Actinomyces colonies were found. Macroscopically visible sulfur granules were identified only in the operative material, where a rough necrotic grayish-yellow area was seen on the serosal surface on the left side and posterior wall of the uterine corpus, measuring 4 × 3 cm. A left tubo-ovarian abscess measuring 4 × 3 × 3 cm was also found. On sectioning, several small and large abscesses filled with puss were present. The histological examination confirmed multiple actinomycotic abscesses in the ovary, paraovarian region and the external third of the left lateral uterine wall.

Conclusions: Female genital actinomycosis is a rare and obscure granulomatous disease. It is most prevalent in IUD carriers and easily diagnosed when confined to the uterus. However, the pelvic actinomycosis is often misdiagnosed, simulating malignant pelvic or ovarian tumor. Therefore, unnecessary surgical interventions can be avoided with a careful examination of these patients and a timely identification of the disease.

Synchronous endometrioid carcinoma of the uterine corpus and ovary: A case report

Vasilakaki Th, Grammatoglou X, Glava C, Katsamagkou E, Zizi-Serbetzoglou A
Department of Pathology, Tzaneion General Hospital of Piraeus, Piraeus, Greece

Synchronous endometrioid carcinoma of the uterine corpus and ovary is an uncommon but well recognized event. Diagnosis as either separate independent primary or as metastatic tumors requires careful consideration of a number of gross and histological features. These features illustrate the criteria helpful in distinguishing independent primaries from metastatic carcinomas which have a different therapeutic implication. The possible link between fertility drugs and carcinogenesis still remains controversial. We report a case of a 52 year old woman who came to our hospital with cystic left ovarian mass (8cm). Hysterectomy and bilateral salpingo-oophorectomy were carried out. Histological examination showed well differentiated endometrioid endometrial cancer. Endometrial tumor was intra-mucosal without myometrial or vascular invasion and was associated with atypical complex hyperplasia. The woman had not been previously treated with ovulation induction drugs. She was free of recurrence 20 months after surgery. Patients with synchronous endometrioid tumors of the endometrium and ovary are generally younger than reported for

either endometrial adenocarcinomas or ovarian epithelial adenocarcinomas. They tend to be low grade and early stage and are frequently associated with endometriosis. The prognosis of endometrioid type carcinomas is better than other histological types of carcinoma.

P173

Clinicopathological study of Bcl-2 immunohistochemical expression in endometrioid adenocarcinoma

Bobos M¹, Kalogiannidis I², Papanikolaou A², Makedos A², Makedos G², Nenopoulou E¹

¹Departments of Pathology, and ²Obstetrics and Gynecology, Aristotle University Medical School, Thessaloniki, Greece

Objective: The Bcl-2, an anti-apoptotic protein, plays a central role in apoptosis, acting as an inhibitor of the apoptotic process. The aim of our study was to evaluate the expression of Bcl-2 in endometrioid adenocarcinoma and its clinicopathological significance.

Methods: 78 patients with endometrioid adenocarcinoma were included in the study. The median follow-up time was 43 months. Immunohistochemical analysis for Bcl-2 antigen was performed on formalin-fixed, paraffin embedded tissues of 74 patients.

Results: The median age of the women was 65 years. The cancer related survival was significant correlated with advanced FIGO stage (P=0.0025) and metastatic disease (P=0.0005). Disease free survival was closely associated with tumor diameter (P=0.04), risk factor (P=0.035) and tumor depth (P<0.013), while the most important correlations were associated with metastatic status (P=0.007), FIGO stage (P<0.001) and tumor differentiation (P<0.001). Bcl-2 immunoreactivity was detected in 24/74 (32%) cases of histologic grade 1 and 2, P=0.028. Lack of Bcl-2 expression was directly correlated with high risk patients (9/38), P=0.001.

Conclusions: Bcl-2 is an early event in endometrioid adenocarcinoma. The anti-apoptotic effect of the Bcl-2 is limited in advance stage carcinomas as well in high risk patients.

P174

p53 overexpression and prognostic impact in endometrial carcinoma of endometrioid subtype

Kalogiannidis I¹, Papanikolaou A¹, Bobos M², Nenopoulou E², Aplianitis I³, Makedos G¹.

¹Department of Obstetrics and Gynecology and ²Pathology, Aristotle University Medical School, Thessaloniki, Greece,

³Department of Pathology, Hippokraton Hospital, Thessaloniki, Greece

Objective: Overexpression of p53 in endometrial carcinoma has been reported to correlate with the unfavourable clinicopathologic features and poor prognosis. The aim of the study was to investigate the p53 overexpression and its prognostic significance in patients with endometrial cancer.

Methods: Immunohistochemistry for p53 expression was performed on paraffin embedded material of 71 surgically treated patients with endometrial carcinoma of endometrioid histologic subtype. The evaluation of staining was performed using a relative rank scale from 0 to 2. The 2+ was considered as overexpression. The median follow-up time was 43 months.

Results: The median age of the women was 65 years (range 35-80). Thirty seven of the 71 cases (52%) stained positive for p53, while overexpression of p53 was detected in 20/71 cases (28%). p53 overexpression was significant correlated with unfavourable tumor differentiation (P=0.028) and positive nodal status (P=0.032), while with the overall survival and disease free survival was insignificant (P=NS).

Conclusion: According to our data p53 overexpression is more commonly found in low differentiated tumors and retroperitoneal disease.

P175

Uterine sarcomas and carcinosarcomas: Immunohistochemical study with docus on potential therapeutic targets

Sotiropoulou M, Papaspyrou I, Theocharidou D, Klapsinou I, Markoulis P, Sdrenia P, Markaki S. Histopathology Department, Alexandra General Hospital, Athens, Greece

Background: Carcinosarcomas and pure high grade sarcomas of the uterus are highly aggressive tumors and therapeutic tools are of limited value. The aim of this study was to determine the expression of proteins Her-1 (EGFR) and Her2/neu (cerbB-2), known to be targeted by therapeutic agents, in these neoplasms.

Material and methods: Parafin-embedded archival tissue from 16 carcinosarcomas, 21 leiomyosarcomas, 10 stromal sarcomas and 1 mixed heterologous sarcoma was used for immunohistochemical analysis. All hematoxylin-eosin stained sections were reviewed to confirm the pathologic diagnosis. Sections were stained with monoclonal antibodies against EGFR (clone 31G7, Zymed)and Her-2 (clone CB11, BioGenex). Unequivocal staining of at least 5% tumor cells was considered positive.

Results: EGFR stained in mesenchymal component of 12/16 (75%) and in epithelial component of 6/16 (37,5%) of carcinosarcomas and in 17/32 (53%) of pure sarcomas. Her-2 displayed strong positive membrane staining (+++) in the epithelial component of 2/16 of the carcinosarcomas while stromal component was negative (- or +) in each case. The 30/32 of pure sarcomas were negative in Her-2 (- or +) while 2 of them were, focally, mild positive (++).

Conclusions: Since optimal treatment of carcinosarcomas and high grade uterine sarcomas remains unknown, novel therapeutic approaches need to be investigated. The expression of EGFR in high percentage of pure uterine sarcomas could be used for target treatment. The different expression between epithelial and mesenchymal components in carcinosarcomas must be examined with caution since only one of the tumor's components expresses this marker. Her-2 is a poor therapeutic target for sarcomas and carcinosarcomas because only a small proportion of epithelial component expresses the protein.

P176

Vaginal non-DES related clear cell adenocarcinoma in a 77 years-old woman. Cytological and histopathological findings.

Makri S., Athanasiou E., Papanikolaou A., Hadzibougias J., Konstandoulas M. Department of Midwifery, School of Health and Medical Care, Technological Educational Institution of Thessaloniki.

A 77-old woman visited a physician for vaginal bleeding. Vaginal examination showed a small-sized bleeding tumor protruding from the vaginal wall. Vaginal smear sampling revealed malignant cells resemble those of an adenocarcinoma with ball and glandular like growth patterns. Then, followed excision of the tumor and the histological diagnosis was clear cell adenocarcinoma of the vagina. Grossly, the tumor was mostly exophytic, approximately 1cm in size and superficially invasive. Microscopically, the tumor was composed of microcysts, solid areas and papillary formations. The predominant cell type was honail-shaped cells and scattered cells with Müllerian differentiation and moderate nuclear atypia. There was no data of prenatal exposure to DES or related nonsteroid estrogens. The age distribution of all patients with CCAC showed two distinct peaks: at mean age of 23 and 71 years respectively including cases in which

DES exposure had been excluded. The bimodal age distribution suggests a carcinogenesis-promoting role of menarche and menopause and/or the existence of a subpopulation with genetic risk factors or exogenous risk factors other than exposure to DES. Despite that cytologic examinations are informative in 65% of CCAC, in our case was diagnostic.

P176B

Histologic findings in 619 laparoscopically removed ovarian cysts

Vassiliki Tziortzioti, Leonidas Papadopoulos, Dimitrios Mathiopoulos, George J. Vlahos, Dimitrios Mavrelou, Dimitrios Tziortziotis LITO Maternity Hospital, Athens

The frequency of laparoscopic removal of ovarian cysts is continuously rising over the recent years. We have registered the histologic findings in 619 laparoscopically removed ovarian cysts over the three-year period 2003-2005. Patient age ranged from 15 to 71 years. The cysts measured from 2 to 22 cm in greatest diameter. Frozen section was performed when judged necessary by the clinician.

The vast majority (427/69%) were identified as endometriotic cysts. Moreover, we had a case (0.1%) of atypical endometriosis, a case (0.1%) of atypical proliferative endometrioid tumor developing in an endometriotic cyst, a case (0.1%) of endometrioid adenocarcinoma developing in an endometriotic cyst, and a case (0.1%) of clear cell adenocarcinoma developing in an endometriotic cyst.

The benign non neoplastic diseases observed were 17 (3%) parovarian cysts, 9 (1.5%) hemorrhagic corpus luteum cysts, 3 (0.5%) follicle cysts, and one (0.1%) massive ovarian edema.

The benign neoplasms observed were 65 (10.5%) benign cystic teratomas (dermoid cysts), 50 (8%) serous cystadenomas, and 17 (3%) mucinous cystadenomas.

The atypical proliferative and malignant tumors observed, besides those associated with endometriosis mentioned above, were 20 (3.2%) atypical proliferative serous tumors, 3 (0.5%) atypical proliferative mucinous tumors endocervical – like, one (0.1%) atypical proliferative mucinous tumor gastrointestinal type, one (0.1%) atypical proliferative serous tumor with microinvasion, and one (0.1%) atypical proliferative mucinous tumor endocervical – like with foci of non invasive micropapillary serous carcinoma.

P177

Papillary carcinoma of the thyroid associated with systemic sarcoidosis

Moroz EA, Rotin DL, Pavlovskaya AI, Ermilova VD Department of the Human Pathology of NN Blokhin Cancer Research Center, Kashirskoye Shosse 24, 115478 Moscow, Russia

Introduction: Sarcoidosis is a systemic chronic granulomatous disease of unknown etiology most commonly affecting young females. The disease was described by Beck in 1899. Thyroid involvement is extremely rare in systemic sarcoidosis and was originally described in 1938. Papillary carcinoma of the thyroid gland also occurs more frequently in female. We described a case of coincidence of both those diseases in male patient.

Objective: (Case report): A 53-year-old male presented with dyspnoea, weight loss and cough. Clinically, no data of tuberculosis and multiple lung metastases were obtained. Transbronchial biopsy of lung lesions was performed in order to exclude the possibility of unknown co-existent disease. FNA of the nodule in thyroid suspected papillary carcinoma.

Methods: The paraffin blocks obtained after the lung biopsy and thyroidectomy were routinely processed, sliced and stained with HE, PAS and van Gieson.

Results: Histologically in thyroid specimens were observed the sarcoid granulomas and papillary adenocarcinoma. Similar granulomas were also found in lung biopsy. The finding of granulomas in the thyroid and lung allowed us to interpret the clinical manifestations of our patient leading to the diagnosis of sarcoidosis.

Conclusions: The thyroid cancer co-incidence in systemic sarcoidosis is supposed to be secondary to immunological abnormalities associated with the latter disease.

P178B

Papillary thyroid carcinoma (PTC) in an 11-years old female child. Cytological and histopathological findings

Makri S., Athanasiou E., Hadzibougias J.
Department of Midwifery, School of Health and Medical Care, Technological Educational Institution of Thessaloniki.

We presented a rare case of PTC in an 11-years old female child who was diagnosed on FNAC. The child presented with a well-defined nodule, measuring about 2cm in diameter, in the right lobe. FNAC of the thyroid nodule revealed clusters of malignant cells and papillary fronds with scanty thick colloid in the background. The thyroid hormonal profile was within normal limits. The child was subjected to total thyroidectomy with regional lymphadenectomy. The diagnosis of PTC was confirmed on histological examination of right lobe nodule but scattered neoplasti foci were found in the left lobe too. Metastases were found in all regional lymph nodes. The child is on regular follow up with hormonal supplementation of thyroxine and no evidence of any complication till date after 6 years of surgery. PTC is a very rare neoplasm in childhood but seems to have an excellent prognosis.

P179

Immunohistochemical investigation of angiogenic factors in parathyroid proliferative lesions

Theodore Brousalis, Sofia Tseleni-Balafouta, Thomas G. Papathomas, Aphrodite Nonni, Georgia E. Thomopoulou, Andreas C. Lazaris, George Agrogiannis, Efstratios S. Patsouris
1st Department of Pathology, Medical School, National and Kapodistrian University of Athens, Mikras Asias 75, 11527 Athens, Greece

Endoglin (CD105) is a proliferation-associated and hypoxiainducible protein abundantly expressed in angiogenic endothelial cells. VEGF induces angiogenesis and VEGF-R2 is a tyrosine kinase receptor expressed early in development by endothelial cell precursors. The aim of the present study was to examine whether immunohistochemical expression of CD105, VEGF and VEGF-R2 may be useful in distinguishing between parathyroid hyperplasia and neoplasia as well as to elucidate, to some extent, the mechanism of neovascularization in proliferative lesions of the parathyroid gland. Tissue specimens were taken from 38 patients with primary hyperparathyroidism (HPT) (17 adenomas and 21 primary hyperplasias) and from 30 patients with secondary HPT. Ten parathyroid glands served as normal controls. In a standard immunohistochemical procedure, monoclonal antibodies to endoglin, VEGF and VEGF-R2 were applied to detect angiogenic endothelial cells. Immunostaining was estimated by image analysis and statistical analysis was subsequently performed. Positive CD105 immunoreaction was significantly increased in parathyroid adenomas by comparison with primary hyperplasias ($p=0.033$) and with secondary hyperplasias ($p=0.033$). When parathyroid adenomas, primary hyperplasia and secondary hyperplasia specimens were comparatively evaluated, VEGF immunoreaction was much more common in adenomas ($p=0.018$). In addition, no significant association emerged between VEGF expression and CD105 immunostaining. In samples with secondary hyperplasia, VEGF-

R2 immunoreactivity was positively linked with VEGF expression ($p=0.038$). This study shows increased angiogenesis in parathyroid adenomas compared with parathyroid hyperplastic lesions. The positive correlation seen between VEGF expression and VEGF-R2 suggests that both may have an important influence on the course of secondary hyperplasias, while the lack of correlation between CD105 and VEGF expression suggests that VEGF, on its own, is not likely to be the primary proangiogenic factor in parathyroid tissue.

P180

Hyalinizing trabecular adenoma.

Gerasimidou D, Karayannopoulou G, Hytioglou P, Gamvros O, Papadimitriou CS.
Department of Pathology, Aristotle University Medical School, Thessaloniki, Greece.

Hyalinizing trabecular adenoma (HTA) of the thyroid gland is an uncommon benign follicular neoplasm, which shares some of the histopathologic features of papillary carcinoma; therefore, the true nature of HTA has been a subject of controversy. We present two cases of HTA, which occurred in women of 23 and 51 years of age, respectively. Both tumors were composed of polygonal or cylindrical neoplastic cells, arranged in trabeculae, compact clusters and follicles. The cells contained oval or round nuclei, which in some areas exhibited intranuclear pseudoinclusions and grooves, as well as nuclear overlapping. Hyalinizing septa of fibroconnective tissue were present among the trabeculae. Both tumors contained calcifications, which in the first one had the appearance of psammoma bodies. Both tumors were surrounded by a fibrous capsule. No invasion of the capsule or vessels was observed. Immunohistochemical stains showed both tumors to be positive for thyroglobulin, and negative for calcitonin and chromogranin. Immunopositivity for cyto 19 was present in many cells of the first case, and only rare cells of the second case. Staining for Ki-67/mib-1 showed strong membranous positivity only in the second case. Our findings suggest that HTA may show heterogeneity in the expression of various immunohistochemical markers. Results from large series of cases will be necessary to appreciate the full spectrum of these tumors.

P181

Relative expression of EGFR and its auto-inhibitor p55 mRNAs in thyroid carcinomas.

E. Charalambous¹, G. Karayannopoulou¹, T. Koletsis¹, C. Mitsiades³, N. Mitsiades³, S. Tseleni-Balafouta², C.S. Papadimitriou¹, V. Kotoula¹
¹Dept. of Pathology, Aristotle University Medical School, Thessaloniki, and ²Dept. of Pathology, University of Athens, Athens, Greece; ³Dept. of Medical Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA, USA.

EGFR-p55, a truncated EGFR protein, is an endogenous EGFR inhibitor that is derived from an alternatively spliced EGFR mRNA (variant 3 [v3]). The aim of this study was to investigate the expression of EGFRv3 in carcinomas with established EGFR pathway activation. Relative quantification for non-spliced EGFR (EGFRns) and for EGFRv3 mRNA targets was applied in samples from 6 anaplastic (ATC) and 12 papillary (PTC) thyroid carcinomas, 12 matched non-cancerous tissues (MNCT), and 11 thyroid carcinoma cell lines (TCL) that were tested to be resistant to targeted EGFR inhibition. In comparison to MNCTs, the expression of EGFRns mRNA was not higher in TCLs, PTCs and ATCs. EGFRv3 transcripts were identified in 42/43 (97%) samples. Relative expression of EGFRv3 vs EGFRns was at least 1 log order higher in TCLs and carcinomas ($p=.003$),

especially in PTCs ($p=.005$), than in MNCTs. In conclusion, while EGFR is not overexpressed, production of its endogenous auto-inhibitor EGFRv3 seems to be upregulated in thyroid cancer in comparison to MNCTs.

P182

EGFR phosphorylation and downstream effector activation in thyroid carcinomas.

G. Karayannopoulou¹, T. Koletsis¹, I. Pliakos¹, C. Mitsiades³, N. Mitsiades³, S. Tseleni-Balafouta², C.S. Papadimitriou¹, V. Kotoula¹

¹Dept. of Pathology, Aristotle University Medical School, Thessaloniki, and ²Dept. of Pathology, University of Athens, Athens, Greece; ³Dept. of Medical Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA, USA.

The aim of this study was to investigate the expression and activation status of the EGFR pathway and its downstream effector pAKT/PKB-S473 in thyroid carcinomas in comparison to matched non-cancerous tissues (MNCTs). Immunohisto-chemistry for EGFR membranous localization, pEGFR-Y992, pEGFR-Y1068, pEGFR-Y1173, pAkt-S473 and pAsk1-S83 (pAkt dependent) was performed on 104 thyroid carcinomas and 92 MNCTs. EGFR scores 2+/3+, and positivity for pEGFR-Y992, pEGFR-Y1068 were similar in tumors and MNCTs. Strong positivity for pEGFR-Y1173, cytoplasmic pAkt and pAsk1 were significantly more frequent in tumors than in MNCTs ($p=.001$, $p=.001$ and $p<.0001$, respectively). However, none of these parameters correlated with tumor aggressiveness or clinical outcome. These data show that EGFR activation is present in MNCTs and carcinomas. Specific patterns of EGFR phosphorylation and differences in the activation of EGFR downstream effectors are encountered in carcinomas, which, however, are not associated with disease aggressiveness.

P183

Relationship between: thrombospondin-1, angiogenic factor (VEGF), microvessel density (CD31), tumor suppressor gene (p53), proliferation marker (Ki-67), and anti-apoptotic marker (bcl-2) in thyroid pathologies.

Antigony Mitselou¹, Dimitrios Peschos¹, Pavlos Dallas¹, Niki Agnantis², Theodore Vougiouklakis¹.

¹Department of Forensic Pathology ²Department of Pathology, Medical School, University of Ioannina, Greece .

Thrombospondin (TSP) is a multifunctional extracellular matrix protein that affects tumor growth, modulation and angiogenesis. TSP is expressed in various cell types under physiological and pathological states including wound healing, angiogenesis and neoplasia. Vascular endothelial growth factor (VEGF) is an angiogenic factor which play crucial role in neovascularization and CD31 is a marker to determine the microvascular density of the tumors. The tumor suppressor gene p53 is involved in the regulation of angiogenesis and the antiapoptotic marker bcl-2 seems to provide the necessary signal to increase the state of VEGF.

Tissue specimens were obtained from the archives of the Department of Forensic Pathology, University Hospital of Ioannina. The cases consisted of 50 carcinomas, 30 adenomas and 40 hyperplastic disorders of thyroid gland. Immunohistochemistry was performed in paraffin-embedded formalin-fixed tissue, with streptavidin-biotin method, using antibodies against TPS-1, VEGF, CD31, p53, Ki-67, and bcl-2. Statistical analysis was performing using the SPSS for windows (version 6.0) statistical package.

Results: Normal thyroid tissues showed immunostaining for TSP-1 confined to the interfollicular stroma, and to the vasculature endothelium. A similar degree of reactivity was found in hyperplastic

lesions and adenomas. TSP-1 was strongly expressed in papillary carcinomas with a desmoplastic stroma, but weak to moderate in cancer epithelium. VEGF was observed intensively in epithelial cells of the tumors, a statistically significant correlation between TSP-1 and VEGF ($p=0.022$) was found. No statistical significant correlation between TSP-1 expression and p53 protein and Ki-67 proliferating marker was found. Statistical inverse correlation between bcl-2 and TSP-1 ($p=0.044$) was found.

In conclusion, these results suggest that in papillary carcinomas, the expression of TSP-1 restricted to the stroma, might be act as protective effects against tumor progression. In addition, TSP-1 expression could be plays an important role in cancer cell growth.

P184

The expression of E-cadherin is preferentially reduced compared with that of syndecan-1 in thyroid pathologies.

Antigony Mitselou¹, Dimitrios Peschos¹, Elli Ioachim², Konstantinos Charalabopoulos³, Theodore Vougiouklakis¹, Niki Agnantis²

Departments of ¹Forensic Pathology, ²Pathology, ³Clinical and Experimental Physiology, Medical School, University of Ioannina, Greece.

Cadherins and syndecans are transmembrane glycoproteins implicated in cell-cell and cell-matrix adhesion. Impairment of E-cadherin and syndecan-1 play an important role in the acquisition of invasive and metastatic proprieties by neoplastic epithelial cells. The purpose of this study was to elucidate the role and alterations of syndecan-1 expression in comparison with those of E-cadherin in normal and pathological thyroid glands. A total of 55 carcinomas, 40 adenomas, 40 cases of hyperplastic disorders and 20 cases of normal thyroid gland tissue, retrieved from our archives. The staining, intensity and distribution of syndecan-1 and E-cadherin in sequential sections were examined and semiquantified. Immunostaining of syndecan-1 and E-cadherin was strong in normal follicular cells. No significant changes were observed in either molecule in hyperplastic disorders compared with adenomas. A significant reduction in expression of both proteins was seen in well-differentiated carcinomas as compared with normal epithelium ($p=0.0001$ and $p=0.032$, respectively). Similarly, there was significant reduction of syndecan-1 and E-cadherin in poorly differentiated and anaplastic carcinomas compared with the well-differentiated carcinomas (syndecan-1, $p=0.0037$; E-cadherin $p=0.075$). In conclusion, decreased syndecan-1 and E-cadherin expression with decreasing cellular differentiation may be involved in the complex mechanism of thyroid lesions.

P185

Cell cycle associated markers (cyclins A, B1, D1, E) expression in papillary carcinomas and microcarcinomas of the thyroid gland

Antigony Mitselou¹, Dimitrios Peschos¹, Pavlos Dallas¹, Theodore Vougiouklakis¹, Niki Agnantis².

Departments of ¹Forensic Pathology and ²Pathology Medical School, University of Ioannina- Greece.

The aim of this study was to determine the cell-cycle cyclins by immunohistochemistry in papillary carcinomas (PCs) and papillary microcarcinomas (PMCs) of thyroid gland. Tissue specimens were obtained from our archives. The cases consisted of 14 primary conventional PCs, 42 PMCs, 5 cases of normal thyroid gland, and 5 cases of hyperplastic lesions. Immunohistochemistry was performed in paraffin-embedded, formalin-fixed tissue, using antibodies against cyclin A, B1, D1, E, and proliferation marker KI-67. Statistical analysis was performed using the SPSS for windows (version 6.0) statistical package. Cyclin E expression was found in 89.7% of PCs and 30.95% of PMCs. Cyclin D1 was evident in the nuclei of cancer cells of 92.85% PCs, and 42.85% in PMCs. No statistical correlation

between these groups was found. Cyclin A expression was seen in 49.98% of PC and 21.42% of PMCs. Cyclin B1 was found in 35.74% cases of PCs and 11.90% of PMCs. Statistical analysis revealed that cyclin D1 and cyclin E significantly higher in PMCs >5mm than PMCs <5mm ($p < 0.00024$). There was no significant difference between cyclin A and B1 in PCs and PMCs. In conclusion these results suggest that cyclin D1 and cyclin E, rather than cyclin A and cyclin B1 might be contribute significantly to aggressive character of thyroid microcarcinomas. Further studies will be necessary to clarify the role of these cell-cycle regulators in growth and aggressiveness of papillary carcinomas and microcarcinomas.

P186

HBME-1, cytokeratin 19, high molecular weight keratin 34BE12 and MIB-1 in thyroid lesions

H.P. Kourea, A. Liava, C.E. Vagianos¹, C.D. Scopa
Departments of Pathology and ¹Surgery,
University of Patras Medical School, Patras, Greece

Incompletely developed nuclear features of papillary thyroid carcinoma (PTC) can be observed in nodular goiter (NG), follicular adenoma (FA) and follicular carcinoma (FC). Tumors have also been classified as well differentiated tumors of uncertain malignant potential (WDT-UMP) and well differentiated carcinomas not otherwise specified (WDCa, NOS). To distinguish the above tumors, the use of immunohistochemistry for HBME-1, CK19, 34BE12 and MIB-1 was studied in paraffin sections of 107 thyroid lesions (48 PTC, 26 FA, 13 FC, 3 WDT-UMP, 1 WDCa, NOS) and 16 NG. The immunoreactivity was interpreted as 0, 1+ & 2+ if observed in 0, <20% or ≥20% of the cells, respectively. HBME-1 and CK19 2+ expression was noted in 88% (42/48) & 90% (43/48) PTC, 100% (3/3) & 67% (2/3) WDT-UMP, 100% (1/1) WDCa, 6% (1/16) & 38% (6/16) NG, 27% (7/26) & 15% (4/26) FA, 31% (4/13) & 38% (5/13) FC, respectively. Foci of CK19 highlighted even minor nuclear enlargement or clearing. 34BE12 was negative in most lesions of all types while MIB-1 was noted in <1% of cells in all lesions studied. HBME-1 is useful in differentiating PTC from questionable FA and FC and highlights the proximity of PTC with WDT-UMP and WDCa. CK19 is less specific. 34BE12 and MIB-1 do not exhibit diagnostic value.

P187

FNA application in cytological examination of the thyroid goiter.

Sopta J.*, Havelka M.*, Tatic S.*, Markovic LJ.***, Mijucic V.***, Radojevic S.*, Glumac S.*

* Institute of Pathology, School of Medicine, Belgrade

** Institute of Pathophysiology, School of Medicine, Belgrade

***National cancer center, Belgrade

Introduction: FNA is very useful method in cytological diagnosing of different lesion in the thyroid gland, among them is benign goiter.

Material and methods: In the period of 2 years cytologically was analyzed 600 aspirates from the thyroid lesions. We analyzed: sex distribution, age distribution, correlation between clinical and cytological diagnoses and goiter classification in accordance with cytological characteristics.

Results: From 600 analyzed aspirates 414 cases (69%) were diagnosed as goiter. This lesion was five times frequent in females than males (348 women, 66 men). X^2 test confirmed high significance for arising goiter ($X^2=192,08$; $p < 0,005$) in females. In our examination the most patients were old between 41 and 50 years. The least patients (6) were younger than 20. The youngest patient was 13, and the oldest 78 years old. Statistically was confirmed high significance for arising goiter ($X^2=494,30$; $p < 0,005$) according to the ages of life. From 414 cytological confirmed goiters 222 had clinical diagnosis "nodular goiter", 127 "diffuse goiter", Our conclusions are: 84% of

cytological diagnosed goiters had the some clinical diagnosis, in only 1,5% of all patients clinically tumor was suspected. We confirmed high correlation between clinical and cytological diagnosis.

Conclusion: FNA permits a substantial reduction or even elimination of other diagnostic procedure, such as imaging, with consequent saving in time and money. Furthermore, benign cystic lesion may be cured by FNA (a diagnostic and unexpected therapeutic value of FNA).

P188

Fine needle aspiration diagnosis of hyperplastic and neoplastic follicular nodules of thyroid. A computerized nuclear morphometric study.

Zaxou K, Nenopoulou E, Zaraboukas T, Vrettou E, Karkavelas G, Papadimitriou CS
Department of Pathology, Aristotle University Medical School, Thessaloniki, Greece

Objective: Fine needle aspiration of the thyroid is limited in differentiating hyperplastic nodular goiters from follicular neoplasms and in separating follicular adenomas from follicular carcinomas. To determine the value of computerized interactive morphometry in the preoperative prediction of malignancy in fine needle aspirates of follicular lesions of thyroid, we studied the morphometric parameters of nuclear area, perimeter, diameter, short axis, long axis, axis ratio, form Ar, form Pe, Form NCI, contour ratio, and nuclear roundness. **Study design:** We measured samples from FNA aspirates obtained from 22 hyperplastic nodules, 22 follicular adenomas and 22 follicular carcinomas and follicular variant of papillary carcinomas, all of which were subsequently confirmed by histological examination.

Results: The mean values of nuclear area, perimeter, diameter, short axis and long axis were significantly different (p less than 0,009) between the adenoma and carcinoma cases as well as between adenomas and hyperplastic nodules. No differences were found for the axis ratio, form Ar, form Pe, form NCI, Contour and nuclear roundness.

Conclusion: Computerized nuclear morphometry can be considered a helpful ancillary tool for the preoperative differential diagnosis of follicular lesions of the thyroid.

Adrenocortical tumors with the neuroendocrine IHC and EM features

Rotin DL, Smirnova EA, Moroz EA

Department of Human Pathology, NN Blokhin Cancer Research Center, Kashirskoye Shosse 24, 115478 Moscow, Russia

Introduction: Medullary features in adrenocortical tumor cells were originally described by Eranko и Hanninen in 1960. These features include immunohistochemical and EM neuroendocrine appearance. Sometimes it could lead pathologist away from the correct diagnosis.

Objective: We investigated and evaluated different "medullary" immunohistochemical and ultrastructural features in group of adrenocortical tumors clinically mimicking pheochromocytoma and compared these proprieties with control group of pheochromocytomas.

Methods: We investigated expression of Melan A, Chromogranin A, Synaptophysin, CD 56, NSE, Vimentin and Citokeratins in "simulating a pheochromocytoma" 10 adrenal cortical tumors (5-adenomas and 5 – carcinomas) and in 5 pheochromocytomas. EM was performed in all 15 cases.

Results: All adrenocortical tumors – both adenomas and carcinomas, were Melan A - positive and Chromogranin A - negative. The features of the neuroendocrine differentiation, including expression of other neuroendocrine IHC markers (NSE,

CD 56 and Synaptophysin) and ultrastructurely - defined adrenalin-type neurosecretory granules were seen in different degree and variable combinations in all cases of this group. All pheochromocytomas were positive to all neuroendocrine markers and negative to Melan A.

Conclusion: Positive expression of Melan A and negative reaction with chromogranin A are supposed to be most reliable markers in differential diagnosis between medullary and cortical origination of the tumor. Any other features of the neuroendocrine differentiation (including IHC and EM) are not occurred to play a useful role in the differential diagnosis.

P190

Galectin-3 expression in functioning and silent corticotroph adenomas of the pituitary gland

Theodore Argyrakos, Eleni Thodou, George Kontogeorgos
Department of Pathology, G. Gennimatas General
Hospital of Athens, Hellas

Galectin-3 (Gal-3) belongs to the family of carbohydrate-binding proteins with high affinity for β -galactoside and it is involved in many biological processes including cell growth, cell adhesion, apoptosis and metastasis. We have recently studied immunohistochemically the expression of Gal-3 in 30 corticotroph pituitary adenomas (19 functioning and 11 silent). Antigen retrieval was achieved by 3-minute pressure boiling in citrate buffer solution. The independent variables t-test was used for comparing the mean percentages of Gal-3 in the two different subgroups. Eighteen of the functioning corticotroph adenomas (94.73%) expressed Gal-3 with a cytoplasmic and focally membranous distribution. The mean percentage of Gal-3 positive adenoma cells was 77%. Among the silent corticotroph adenomas 9 (81.81%) were negative for Gal-3, while two of the remaining adenomas expressed Gal-3 in 15% and 80% of their tumour cells respectively (mean percentage: 8.72%). The statistical differences between functioning and silent adenomas were highly significant ($p=0.001$). Gal-3 is expressed in the substantial majority of functioning corticotroph adenomas of the pituitary gland, whereas the majority of silent adenomas are negative or express focally Gal-3. We conclude that these observations can be proved helpful in distinguishing silent corticotroph adenomas of the pituitary gland.

P191

Bilateral adrenal and extra-adrenal pheochromocytomas: Related or look-alikes?

¹Esther Korpershoek, ¹Bart-Jeroen Petri, ¹Francien H. van Nederveen, ¹Winand N.M. Dinjens, ²Albert A. Verhofstad, ³Wouter W. de Herder, ⁴Sonja Schmid, ⁴Aurel Perren, ⁴Paul Komminoth, ¹Ronald R. de Krijger

¹Department of Pathology, Josephine Nefkens Institute, Erasmus MC, University Medical Center Rotterdam, Rotterdam, The Netherlands ²Department of Pathology, ³Departments of Pathology,

Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands ³Department of Internal Medicine, Erasmus MC, University Medical Center Rotterdam, Rotterdam, The Netherlands

⁴Department of Pathology, University Hospital Zurich, Zurich, Switzerland

Pheochromocytomas (PCC) are rare tumors that arise from chromaffin tissue in the adrenal medulla, but can also occur in the abdomen outside the adrenals and are then called extra-adrenal PCC.

Up to 25% of adrenal and extra-adrenal PCC are caused by germline mutations in RET, VHL, SDHB, or SDHD, but little is known about the contribution of these genes in bilateral and extra-adrenal PCC.

We have performed mutation analysis on tumor DNA of 32 patients with bilateral PCC and 27 patients with extra-adrenal PCC for RET (exon 10, 11 and 16) and the entire coding region of VHL, SDHB, and SDHD. When alterations were found, sequence analysis was performed to identify the mutation.

Eighteen RET and two VHL germline mutations were found in the patients with bilateral adrenal PCC. In extra-adrenal PCC one novel SDHB germline and one novel somatic SDHB mutation were observed. In addition, two SDHD germline mutations were found in extra-adrenal PCC.

Because only RET and VHL mutations were found in patients with bilateral PCC, and SDHB and SDHD mutations were only seen in patients with extra-adrenal PCC, we conclude that different mechanisms are involved in the pathogenesis of these groups of tumors. Therefore, it should be considered that patients with bilateral adrenal PCC will be tested first for RET or VHL mutations, and patients with extra-adrenal PCC should be examined first for SDHB or SDHD mutations.

P192

Array CGH Analysis in sporadic benign pheochromocytomas

Francien H. van Nederveen¹, Esther Korpershoek¹, Ronald J. deLeeuw², Wan L. Lam², Winand N.M. Dinjens¹ and Ronald R. de Krijger¹

¹Department of Pathology, Josephine Nefkens Institute, Erasmus MC, University Medical Center Rotterdam, Rotterdam, The Netherlands,

²Department of Cancer Genetics and Developmental Biology, British Columbia Cancer Research Centre, Vancouver, Canada

Pheochromocytomas (PCC) are neuro-endocrine tumours usually arising in the adrenal medulla. There are 4 important candidate genes that are involved in PCC tumorigenesis: RET causing multiple endocrine neoplasia type 2; VHL causing Von Hippel-Lindau disease; and SDHB/SDHD, causing the so-called pheochromocytoma-paranglioma syndrome. Together, germ line mutations in one of these four genes account for up to 25% of PCC patients, but the pathogenesis of the remaining 75%, truly sporadic, PCC is still largely unknown. We selected a group of 42 benign PCC, with a negative family history for PCC or relevant cancer syndromes, and isolated DNA from fresh frozen tumour tissue. Benign PCC were defined as those tumours that did not show evidence of metastasis within an average follow-up period of 4 years. 17 patients were lost to follow-up. Tiling high-resolution comparative genomic hybridisation (CGH) micro-arrays were used for genome-wide analysis. The most striking loss concerned the short arm of chromosome 1, in 65% of all PCC analysed. We could not detect a smallest region of minimal loss of 1p, in contrast to our earlier studies on a different group of tumours, and in contrast to previously published studies of others. The second most frequent loss was found on the long arm of chromosome 3, comprising 40% of all PCC. Additional losses were detected at high frequency on the short arm of chromosome 17 (43%), and the long arms of chromosome 21 (35%) and 22 (48%). Interestingly, we could separate a subgroup of 7 PCC that did not have loss of 1p, but instead showed distinct partial losses of chromosomes 3 and 11. This pattern has previously been reported to be associated with VHL-disease related PCC. From these results we conclude that: 1) truly sporadic benign PCC can be separated into 2 distinct groups, based on their genomic aberrations, one group displaying loss of 1p, 3q, 17p, 21q, 22q, and another group characterized by a so-called "VHL-pattern" of chromosomes 3 and 11 loss; 2) in addition to previously described chromosomal regions

(1p, 3q, 17p) further analysis for their role in PCC tumorigenesis of 21q and 22q appears warranted.

P193

Human pheochromocytoma with prominent piecemeal degranulation of endocrine granules

The aim of the study was the evaluation of pheochromocytoma patients using different morphological techniques and correlation of those results with clinical presentation of the disease. We studied 18 cases (6 women and 12 men) of adrenal pheochromocytoma. The patients age ranged from 37 to 62 yrs (mean 48 yrs). All patients had typical clinical syndromes related to pheochromocytoma with paroxysmal hypertension without response to pharmacological treatment. The hypertensive crises continue from several minutes up to one hour, and breaks between attacks were longer than 7 days. The raises in blood pressure were accompanied by sweating, skin as well as abdominal manifestations. All other neuroendocrine tumors as well as other causes of hypertension were excluded in those patients. In all cases before surgery the diagnosis was confirmed by total urinary free catecholamines level (in all patients over 1000 nmol/24hrs). In all cases adrenal tumors were surgically removed and tissue samples were processed for routine histology, immunohistochemistry and routine transmission electron microscopy (TEM). In all cases histo-pathological studies confirmed diagnosis of pheochromocytoma. Moreover using tissue specimens the immunohistochemical studies for p53, Ki67 and PCNA were done. Ultrastructural studies in TEM revealed well matured cells with typical features of cytoplasm arrangement. In TEM we focused on studies on activity of nuclei, secretory activity as well as interaction between pheochromocytoma cells infiltrating adrenal cortex with normal cortical cells. There were found differences in the ultrastructure of nuclei between cases. In two cases, the vast majority of cells in tumor mass had enlarged nuclei with enlarged nucleoli. And the nuclear membrane had irregular shape. In some of such cell nuclei expressions of p53 and PCNA as well as Ki67 were observed. Moreover, in all patients using TEM technique we evaluated interaction between tumor cells and the normal adrenal gland, as well as relation of tumor tissue to the vasculature. There were found areas of insertion of tumor cells into vascular lumen, and some of those cells were expelling their content directly to the blood stream. In studied material we found a direct release of neuroendocrine granules into blood vessels or indirectly through the endothelial calls. Sporadically, the tumor cells were also degranulating directly into extracellular space, especially in the areas of adrenal cortex invasion. In such area in cells of zona fasciculata we observed high number of tubulo-vesicular mitochondria characteristic for cell producing cortisol. In this studies we confirmed piecemeal degranulation of pheochromocytoma cells into tumor capillaries. It could be responsible for uncontrolled high elevations of blood pressure in our patients. Second important finding of this study was that adrenal cortex cells that had a contact with tumor cells contained numerous tubulo-vesicular mitochondria. It verify their high activity for cortisol synthesis.

P194

Mutational analysis of the *BRAF* gene in human adrenocortical carcinomas

S. Tseleni-Balafouta¹, E. Sozopoulos¹, H. Litsiou¹, G. Voutsinas², G. Fanourakis¹, N. Mitsiades³, K. Mitsiades³, E. Patsouris¹
¹Department of Pathology, Medical School, University of Athens,
²Laboratory of Environmental Mutagenesis and Carcinogenesis, Institute of Biology, NCSR 'Demokritos', Athens, Greece,
³Dana Farber Cancer Institute, Harvard Medical School, Boston, MA, USA

Activating mutations in the *BRAF* gene are present in several types of human malignancies. It has been proposed that ,Braf is important for cAMP-mediated signaling pathways regulating proliferation, in response to cell-specific trophic hormones that activate adenylate cyclase. Angiotensin II and ACTH activate adenylate cyclase in adrenocortical cells, so the latter could be targets for *BRAF* mutations that would lead to tumorigenesis (adrenocortical carcinoma). We thus evaluated the presence of *BRAF*, *KRAS* and *NRAS* mutations in adrenal carcinomas (30 tumor specimens and 2 cell lines) by DNA sequencing. 5 mutations were found in 4 of 30 tumor specimens: Two *BRAF* substitutions (G463E, V600E), a *KRAS* substitution (G12C), and two *NRAS* substitutions (V8A and L16N). No mutations were found in the 2 adrenocortical cell lines. These data suggest that activating *BRAF* mutations occur in a small subset of human adrenocortical carcinomas supporting a role for Ras/Raf-mediated signaling, and suggest that inhibitors of this pathway may provide clinical benefit for some patients with this malignancy.

P195

Histologic and immunohistochemical findings in hyperinsulinemic hypoglycemia in pediatric patients

Diclehan Orhan*, Saniye Ekinçi**, Zuhal Akçören*, Arbay Çiftçi**, Gülsev Kale*
 Hacettepe University Faculty of Medicine, İhsan Doğramacı Children's Hospital, Division of Pediatric Pathology, Ankara, Turkey, ** Hacettepe University Faculty of Medicine, Department of Pediatric Surgery, Ankara, Turkey

Pancreas from 8 children with idiopathic hyperinsulinemic hypoglycemia was evaluated histopathologically using immunohistochemical staining. The patients ranged from newborn to 3 years in age. Hematoxylin and eosin stained sections were evaluated for the presence or absence of islet cell dysplasia and the distribution of islet cells. Immunohistochemical staining for insulin, glucagons, somatostatin, pancreatic polypeptide and neuron specific enolase was performed. In 2 cases, intraoperative frozen sections were examined. All patients were diagnosed as nesidioblastosis. Islet cell dysplasia was observed in every case. Immunohistochemical staining revealed the the extent of islet cell proliferation. Scattered insulin-positive islet cells were seen easily with immunostaining. As islet cell dysplasia was observed in all cases, performing intraoperative frozen section evaluation was found to be beneficial to direct the extent of pancreatectomy as was the case in our 2 patients. We conclude that immunohistochemical analysis is useful to identify the small intralobular islet cell aggregates and scattered islet cells.

Carcinoid tumors of the jejunum and ileum

Doinita Radulescu¹, Simona Stolnicu²
¹Department of Pathology, University of Medicine, Iasi, Romania
²Department of Pathology, University of Medicine, Targu Mures, Romania

The purpose of this study was to describe the clinical, pathological and immunohistochemical characteristics of jejunoileal carcinoid tumors and to evaluate the predicting factors of behaviour and prognosis. Ten cases of ileal and two cases of jejunal carcinoids were retrospectively studied with emphasis on clinical, pathologic, immunohistochemical and prognostic features. Our cases involved 10 men and 2 women, with mean ages of 52 years old. Only one patient presented a carcinoid syndrome. In 2 cases, tumours were multiple, in 10 were transmurally invasive and in 3 cases presented regional lymph node metastases. Tumoral cells were disposed in solid nests, in rosette type and glandular-like structures. Most tumor

cells were intensely argyrophilic-, Chromogranin- and Serotonin-positive. Survival was negatively correlated with distant metastases at the time of surgery, tumour multiplicity, mitotic rate and depth of invasion. Jejunoileal carcinoid tumors have generally a relatively high rate of transmural invasion and aggressive clinical behaviour, differing from those occurring in other sites of the gut in that they are often at an advanced stage at the time of presentation, as we also observed in the reported cases. Other pathologic characteristics are that they are usually insular and argentaffin, with a high rate of Chromogranin and Serotonin positivity and these features differentiated the presented jejunoileal carcinoids from other gastrointestinal carcinoids.

P197

Primary Clear cell Sarcoma of the Small Intestine: The Diagnostic Difficulties of a visceral case

Parasi A, Karakosta A, Sotiriou E, Mennonna R, Karayannis M, Pantoula P
Department of Pathology General Hospital of Nikaia-Piraeus
«Agios Panteleimon» Greece

A rare case of clear cell sarcoma, arising primarily in the small intestine of a 48 year old man is described. Microscopically, a circumferential tumor, focally ulcerated, diffusely infiltrating the intestinal wall and the mesentery without lymph node metastases was found. The neoplasm consisted of nests and fascicles of ovoid to spindle-shaped cells with slightly eosinophilic and rarely clear cytoplasm, vesicular uniform nuclei with prominent nucleoli and marked mitotic activity. Immunohistochemically, the tumor cells stained only for Vimentin and S-100 protein. HMB-45, MELAN-A, MART-1 were negative, as well as Keratins, EMA, CD117, CD34, CD1a, CD99, Synaptophysin, Chromogranin, Neurofilaments, SMA, Desmin and Myogenin. Five years later, a liver metastasis with similar histological features was found. Clear cell sarcoma and Malignant Melanoma are immunohistochemically indistinguishable, but the cytologic uniformity and the distinctive infiltrative growth pattern of our tumor, in combination with the localized for several years disease, allowed the exclusion of a metastatic melanoma. Primary clear cell sarcomas arising in the GI tract, although very rare, are increasingly recognized and show an aggressive behavior. They are rarely negative to Melanoma antigens, demonstrating only the characteristic (12;22) translocation, which confirms the diagnosis.

P198

EGFR profiling in cancer of unknown primary (CUP): Gene mutation, amplification, regulation and tissue protein expression in fifty cases.

L. Dova¹, G. Pentheroudakis², I. Georgiou³, V. Malamou-Mitsi⁴, G. Vartholomatos¹, G. Fountzilias⁵, N. Kolaitis¹, E. Kitsiou⁶, N. Pavlidis².

¹Hematological Laboratory-Molecular Biology Unit, ²Dept. of Medical Oncology, ³Dept. of Obstetrics and Gynaecology-Genetics Unit, ⁴Dept. of Pathology, Ioannina University Hospital, ⁵Medical School, Aristotle University of Thessaloniki, ⁶Dept. of Pathology, Ioannina General Hospital, Greece.

EGFR signaling contributes to malignant transformation and survival. We studied known markers of EGFR activation in 50 patients with CUP. Tumor sections were stained for EGFR protein by IHC. PCR amplification, SSCP and direct sequencing were used to study EGFR intron 1 (CA) repeat length as well as exon 18,19,21 activating mutations and amplification. 37 tumors (74%) expressed EGFR protein but only 6 (12%) strongly. In intron 1, we detected five alleles with 16 to 20 CA repeats, allele 16 being the most common. All samples were heterozygous, the commonest genotype being 16/18

dinucleotides. Five samples had three intron-1 alleles and were associated with EGFR overexpression in 40% of cases. When a 16-CA allele was present, the length of the other allele was inversely correlated to EGFR expression (p=0.04). There was no evidence of exon 18,19,21 amplification. Two mutations were detected: Exon 21 [2508C>T, a silent polymorphism (R836R)] and exon 19 [G>A (IVS19+24G>A) resulting in aberrant mRNA splicing]. Neither EGFR expression nor CA repeats length were prognostic factors. Our data provide evidence for lack of contribution of EGFR in the development of CUP and lack of benefit from EGFR modulation.

P199

Serous cystadenoma of the pancreas in a child

Liviu Niculescu¹, Rafira Catu¹, Amelia Petrescu²
¹“Grigore Alexandrescu” Children Hospital, Bucharest, Romania,
²“Prof. Dr. Th. Burghel” Hospital, Bucharest, Romania

Pancreatic tumors and cyst are very rare in children. When encountered they can present a diagnostic and therapeutic challenge to the pediatric surgeon. The aim of this work is to report a new case of 12 years old girl with a short history of epigastric pain, vomiting and local discomfort. Sonography and computed tomography showed a pancreatic head mass. The surgeons decided to remove the tumour. Macroscopically examination carried out the removed tumour showed a 3,8 /1,2/ 2,5 cm multiloculated mass, small cystic cavities filled with a serous “clear” and haemorrhagic fluid.

Material and methods: Fragments of the tumour were fixed in formaldehyde 10 %, included in paraffin and the sections were stained with H.E, V.G. and immunohistochemically: EMA, Muc 1, low molecular weight keratin.

Results: The histological examination revealed multiple small cysts lined by cuboidal cells; myoepithelial cells were also present beneath this epithelium surrounded by prominent vascularized connective tissue. Immunohistochemically: EMA, low molecular weight keratin, Muc 1 positive reaction.

Conclusions: These findings plead for the diagnosis of serous cystadenoma of the pancreas.

P200

Inflammatory Myofibroblastic tumor arising in hyperplastic polyp of the stomach

Orlowska J¹, Zakrzewska K², Albinski J³
Histopathology Laboratory of the Department of Gastroenterology, Medical Center for Postgraduate Education¹, Department of Pathology², Department of Surgery of the Upper Gastrointestinal Tract³, Oncology Center, WARSAW, POLAND

Inflammatory Myofibroblastic Tumor (IMT) is a lesion reported mainly in lungs, mesentery and omentum. Only 50 stomach IMTs were described in a period of 1970 - 2006. The following case is, to our knowledge, the first one in which the stomach IMT has grown on the ground of gastric Hyperplastic Polyp.

A 67-year-old man was admitted to the Dept. of Gastroenterology with one year history of fatigue and postprandial abdominal pain. Low hematocrit (26%) and RBC (3,82), and highly increased ESR (144) were disclosed. Gastroscopy revealed a large polypoid tumor of the stomach. In biopsy specimens only fragments of hyperplastic polyp were found. However, a total gastrectomy with regional lymphadenectomy D2 was performed. An ulcerated, fragile, polycyclic tumor measuring 6,5x 5,0x 2,5cm localized in the body and antrum was found. Microscopically it was mostly composed of interlacing fascicles of elongated spindle-shaped fibroblasts / myofibroblasts weakly positive for desmin and SMA, and strongly positive for vimentin; CD117, CD34, S-100 and CKAE1/3 were negative. They were localized inside the structures typical for hyperplastic polyp. The diagnosis of IMF inside hyperplastic polyp

was established. The surgical margins and all lymph nodes were free from the tumor. Long term follow-up is recommended because of the risk of IMT local recurrence.

P201

Immunohistochemical expression and prognostic significance of DCC (deleted in colon cancer), p53 protein and proliferative marker Ki-67 in colorectal cancer patients

Genghis Yashar¹, Neli Basheska¹, Irina Prodanova¹, Katerina Kubelka-Sabit¹, Aleksandar Dimovski², Ana-Marija Stefanovska², George Zografski¹

¹Department of Histopathology and Clinical Cytology, Institute of Radiotherapy and Oncology, Medical Faculty, Skopje, Republic of Macedonia, ²Center for Genetic Engineering and New Technologies, Macedonian Academy of Sciences and Arts, Skopje, Republic of Macedonia.

Objectives: The objective of this study was to evaluate the immunohistochemical expression of Deleted in colon cancer (DCC), p53 protein and proliferating index Ki-67 in correlation with various clinico-pathological (age, sex, tumor status, lymph node involvement, localization, tumor diameter, grade of differentiation, histological type) and biomolecular parameters (loss of heterozygosity of the long arm of chromosome 18 and microsatellite instability) in colorectal cancer patients. In addition, the prognostic significance of their influence on overall survival (OS) was also estimated.

Methods: A retrospective analysis of 100 patients with colorectal cancer who underwent large bowel resection with regional lymphadenectomy was conducted in the period between 1995 and 2000. All the patients were in stage II and stage III of the disease according to the postoperative TNM classification of UICC (1997) guidelines. The immunohistochemical expression of protein products of the DCC, p53 tumor suppressor genes and Ki-67 proliferating index were semi-quantitatively evaluated. Biomolecular analyses for the loss of heterozygosity of the chromosome 18q and microsatellite instability were performed with the Polymerase chain reaction (PCR) technique.

Results: In our case series, 57 (57%) patients were in stage II, and the remaining 43 (43%) patients in stage III of the disease. During the follow-up period (mean 53, range 5-97 months), 41(41%) patients died of the disease. The expected 5-year OS rate was 58.6%. In the univariate analysis, tumor status, lymph node involvement, sex, age, tumor grade, p53 protein expression and Ki-67 proliferating index were parameters with prognostic significance related to OS ($p < 0.05$). Among these variables, in the multivariate analysis the tumor status and Ki-67 proliferating index were selected as independent and significant prognostic factors related to OS ($p = 0.0019$). According to the value of the prognostic index (PI) defined by Cox regression model, the patients were categorized in two distinct risk groups. The 5-year OS rate of the low- and high-risk group patients was 65.0% vs. 29.4% ($p = 0.001$). The 5-year OS for stage II was 71.1% vs. 40.0% ($p = 0.05$) and for stage III of the disease it was 54.8% vs. 25.0% ($p = 0.03$), respectively.

Conclusions: These data indicate that defining prognostic groups in each stage of the disease allow an exact and objective selection of colorectal cancer patients with different death risk. Therefore, the prognostic index (PI) as an indicator of the patient's place in the prognostic spectrum could be a sound basis for an appropriate planning.

P202

Pseudomyxoma Peritonei

Papaevangelou Maria MD, Koniaris E. MD, Gazalidou Maria MD, Papathanasaki Antigoni MD, Biteli Maria MD, Apostolikas N. MD Dept. of pathology, Hellenic Anticancer Institute, 'St. Savvas' Hospital, Athens Greece

Pseudomyxoma peritonei is a rare condition which is referred to a widespread mucin accumulation within the peritoneal cavity. Microscopically it is composed of extracellular mucin accumulation and well-differentiated tumor cells, fibrosis, hyperemia, and mesothelial reaction. It usually affects the ovaries, their involvement is usually bilateral and represents secondary deposits from appendiceal neoplasms. However synchronous, similar tumors to the ovary, adenocarcinomas, are not rare and the pathologist confronts a difficult differential diagnosis. We present such a case and we review the literature.

Keywords: pseudomyxoma peritonei, secondary deposits, adenocarcinoma of the ovary.

P203

Signet ring cell adenocarcinoma of the colon or primary linitis plastica of the colon. A case report.

Apostolikas N., Koniaris E., Papaevangelou M. Dept. of Pathology, Hellenic Anticancer Institute, 'St. Savvas' Hospital, 171 Alexandras Av., 11522, Athens Greece.

Our aim is to report a rare case of signet ring cell adenocarcinoma of the colon (SRCA) or primary linitis plastica of the colon and review the literature. SRCA is an uncommon type of colorectal cancer with an incidence rate varying from 0.1% to 2.6% of all large bowel cancers. A 73 year old patient who had been operated on an adenocarcinoma of the kidney, admitted to the hospital again two months later, because of a mild constipation and weight loss. After colonoscopy and biopsy an adenocarcinoma of the left colon was diagnosed. The patient underwent a left colectomy. The received specimen had 10.6cm length and a narrowed lumen up to 1.3cm with a widespread neoplastic thickening of the intestinal wall (maximum diameter 8.4cm) was found. Histological examination revealed a tumor which grew in a diffuse fashion without any glandular formation, consisted of sheets or files of typical signet-ring cells. The tumor infiltrated diffusely under the mucosa, disseminating into the pericolic fat as well. No metastases developed in the five excised lymph nodes and no peritoneal dissemination was found (stage B2 Astler and Coller) The immunohistochemistry showed that the tumor was mainly negative in CK7 and positive in CK20. Metastases from stomach were excluded. Only 15 cases have been reported in the literature during the last ten years.

P204

Immunohistochemical evaluation of the EGFR expression in advanced metastatic colorectal cancer using two commercially available antibodies.

Arapantoni-Dadioti P.¹, Valavanis C.^{1,2}, Karampola M.¹, Vecchini G.¹, Iakovidou J.¹.

Technical assistance: Kontogianni H., Charalabidou A.

¹Dept. of Pathology – ²Molecular Pathology Unit, METAXA Cancer Hospital, Piraeus, Greece

Background and objective: Colorectal carcinoma is one of the most common malignancies worldwide and manifests a high mortality, especially at late stages of the disease. Currently available therapeutic strategies have a modest effect on overall survival of patients with advanced and/or metastatic disease. Recently, targeted therapy drugs, such as EGFR inhibitors, are in use for the management of advanced-stage colorectal cancer. It is well known that the dysregulation of the epidermal growth factor receptor (EGFR) signal transduction pathway is involved in colon cancer development and progression, and overexpression of the receptor confers a poor prognosis. Thus targeting the EGFR has become a rational approach for the treatment of colorectal carcinoma. In this context we investigated the expression of

EGFR in advanced/metastatic colorectal cancer using two different antibodies against EGFR and compared the incidence, the cellular distribution and the intensity of its expression as given by the two antibodies.

Methods: In this study, 121 archival specimens of metastatic colorectal cancer were analysed immunohistochemically, using two different antibodies against EGFR, the mouse monoclonal anti-human EGFR clone 2-18C9 of the EGFR pharmDx kit (DAKO) and clone 31G7 (Zymed). Immunostaining was evaluated as membranous, and the intensity of the immunostaining was graded 0 (negative), 1+ (weak), 2+ (moderate) and 3+ (strong).

Results and conclusions: Overall, 34.7 % of the adenocarcinoma cases had membranous EGFR reactivity; 9.1 % of the tumors had 3+ reactivity in 3-30% of the neoplastic cells, 17.4% of them displayed 2+ reactivity and 8.3% exhibited 1+ in the same tumor cell percentage. EGFR expression in colorectal carcinomas seems to correlate with differentiation grade. However, there were no associations with Dukes' stage, site, patient age or gender.

There was high concordance (92%) in evaluating EGFR expression between the two antibodies used in this study, with no differences in the incidence, the cellular distribution and the intensity of EGFR expression.

P205

Liver cell proliferation in renal transplant and immunocompetent patients with HCV infection.

K. Giaslaktiotis¹, P. Aleksandrou¹, M. Psichogiou², G. Nikolopoulos², J. Boletis³, J. Delladetsima¹.
¹Dept of Pathology, Laiko Hospital, ²Dept of Hygiene and Epidemiology, Athens University, ³Transplantation Center, Laiko Hospital, 75 Mikras Asias, 115 27 Athens, Greece.

Liver cell proliferation in HCV infection is still unclear and available data are controversial. In the present study hepatocellular proliferation was assessed in liver biopsies of HCV infected renal transplant (RT) and immunocompetent (IC) patients (pts) and was correlated with hepatitis grade and stage, viremia, genotype and age. Liver biopsies from 58 RT recipients and 46 from ICpts were examined histologically. Hepatocyte proliferation was assessed by immunohistochemical detection of Ki67, while the proliferation activity index (PAI) was defined by the mean number of positive hepatocellular nuclei per 10 high power fields. Serum HCV RNA levels and HCV genotype were also determined. In ICpts PAI was 14.7 in minimal (6 cases), 25.6 in mild (32 cases) and 52.7 in moderate (8 cases) hepatitis. In RTpts PAI was 9.9 in minimal (42 cases), 19.7 in mild (14 cases) and 84 in moderate (2 cases) hepatitis. In ICpts, PAI correlated with lobular activity ($p < 0.01$). Mean PAI was significantly higher in ICpts (mean 28.9IC vs 14.8RT, $|z| = 0$), especially in the mild hepatitis group ($p < 0.01$) and in all three grades of lobular activity (minimal, $p < 0.01$), mild, $p < 0.05$ moderate, $p < 0.05$). No correlation was observed between PAI and hepatitis stage, HCV genotype, serum HCV RNA and age. Hepatocellular proliferation in HCV infected ICpts is closely related to necroinflammatory activity. The deficient proliferation in RTpts may be related to immunosuppressive therapy.

P206

Hereditary non-polyposis colorectal cancer (Lynch syndrome) - A case report.

Tzaida O.¹, Valavanis C.^{1,2}, Britsou M.¹, Vogiatzis P.¹, Akrivos T.³, Arapantoni-Dadioti P.¹
¹Pathology Department, ²Molecular Pathology Unit, ³Department of Gynecology, METAXA Cancer Hospital, Piraeus, Greece.

Background: Hereditary non-polyposis colorectal cancer (HNPCC, Lynch syndrome) is an autosomal dominant disorder, characterized by the development of colorectal carcinoma, endometrial carcinoma and a range of other malignancies including neoplasms of renal pelvis/ureter, stomach, small bowel, ovary, brain, hepatobiliary tract and sebaceous glands. The proposed revised criteria by International Collaborative Group on HNPCC, referred as Amsterdam Criteria II (ACII), concern a set of clinical, pathological and genetic features appropriate to diagnose HNPCC syndrome. Germline mutations in the DNA mismatch repair (MMR) genes particularly MLH1, MSH2 and MSH6 underline this disorder. A characteristic such case of HNPCC is presented.

Case description: A female patient 65 years old with a family cancer history of her first degree relatives (mother and sister with endometrial cancer) was admitted to our hospital complaining for vaginal bleeding during last year. A preoperative diagnostic endometrial biopsy was performed. The thorough clinical and laboratory patient investigation, including CT and colonoscopic studies, revealed a bulky tumor located in the sigmoid as well as two smaller polypoid growths of the transverse colon. The patient underwent a total hysterectomy as well as a resection of the sigmoid with excision of the colonic polyps.

Pathologic findings: The histological examination of the surgical specimens revealed: villous adenomas of the transverse colon, a moderately differentiated adenocarcinoma of the sigmoid with a mucinous component and adenomatous remnants at the tumor margin, classified as Dukes C, T2N2 Ca, a moderately differentiated endometrial adenocarcinoma of the endometrioid type invading the endometrium, as well as two occult, microscopical foci of sex cord-stromal ovarian neoplasms (Sertoli type). An immunohistochemical analysis of the MMR gene products was performed.

Results: Based on the former, accumulated pathologic-immunohistochemical features and on the family history, the patient was considered to fulfill ACII criteria as a HNPCC case, and was advised to further genetic counseling and mutation investigation.

P207

Immunohistochemical expression of syndecan-1 protein in gastric cancer

Antonia Charchanti¹, Ann C. Goussia², Eufemia Balasi², Catherine Zioga², George Fountzilias³, Panagiotis Kanavaros¹, Niki J. Agnantis², Maria Bai²
 Departments of ¹Anatomy-Histology-Embryology and ²Pathology, Medical School, University of Ioannina, 45110, Ioannina, Greece
 Department of ³Medical Oncology, Medical School, Aristotle's University of Thessaloniki, Thessaloniki, Greece

Syndecan-1 (SDC-1) is a transmembrane heparan sulfate proteoglycan, that binds to various extracellular matrix components, mitogenic and growth factors via its heparan sulfate chains. In the present study, we analyzed the immunohistochemical expression of SDC-1 in 103 cases of gastric adenocarcinomas. SDC-1 expression was observed in both neoplastic and stromal cells. Strong neoplastic and stromal staining (>50% of cells) was found in 16.3% and 4.8% of the cases respectively, moderate (10-50% of cells) in 24% and 21.2% of the cases, respectively and weak (<10% of cells) in 59.6% and 74% of the cases, respectively. SDC-1 expression in neoplastic cells lower in more invasive cases (mucosa/submucosa vs muscularis propria/serosa/perigastric fat, $p = 0.034$) and in cases with lymph vessel invasion ($p = 0.035$). Low stromal SDC-1 expression was correlated with histologic type (intestinal vs diffuse/mixed, $p = 0.04$), histologic grade (I vs II/III, $p = 0.04$) and with greater tumor size ($p = 0.026$). It is concluded that low epithelial and stromal SDC-1 expression are associated with unfavorable histopathological parameters in gastric carcinomas.

P208

The potential role of activated stellate cells in liver biopsies with hepatitis C compared with hepatitis C/diabetes mellitus.

AC Tsamandas, V Zolota, A Liava, D Dimitropoulou, C Gogos, CD Scopu. University of Patras Medical School, Patras, Greece
Hepatitis C virus (HCV) infection is a major cause of chronic liver disease. Steatosis is a common finding both in HCV and diabetes mellitus (DM). Activated liver stellate cells (ASC- α SMA+ cells) are a major factor responsible for fibrosis and progression to chronic liver disease. This study investigates the presence of ASC in liver biopsies from patients with HCV alone and in patients with HCV/DM. Fifty liver biopsies (HCV-35 and HCV/DM-15) were immunostained with the anti- α SMA antibody. Results were expressed as %(+ cells and correlated with degree of steatosis, inflammation and fibrosis. The mean \pm SD value, in HCV/DM and HCV patients was: for steatosis 1.1 \pm 0.4 and 0.5 \pm 0.2 ($p=0.01$), for inflammation 1.9 \pm 0.3 and 1.5 \pm 0.2 ($p=0.03$), for fibrosis 2.8 \pm 0.2 and 1.6 \pm 0.1 ($p<0.0001$). The mean % ASC for all zones was 1.3 for HCV/DM and 1.2 for HCV ($p=0.39$). However, when both diagnostic groups were combined, a significant % of ASC was observed in periportal areas and portal tracts for fibrosis stages >2 vs stages ≤ 2 ($p<0.0001$). In addition, a statistically significant increase in %ASC was observed in zone 1 for HCV/DM group (mean 1.5) compared to HCV group (mean 1.2) regardless of fibrosis stage ($p=0.02$). This study suggests that in patients with HCV or HCV/DM, activated stellate cells are predominantly located in periportal areas and correlate with advanced fibrosis stages (>2). Periportal stellate cell activation is significantly increased in the HCV/DM group compared to HCV group.

P209

Report of two rare cases of hepatoid adenocarcinoma with gastric and gallbladder localization.

Gakiopoulou H., Liapis G., Givalos N., Agrogiannis G., Patsouris E, Delladetsima I.
Department of Pathology, Medical Faculty, National Kapodistrian University of Athens & Department of Pathology, Laikon Hospital, 75 Mikras Asias, 11527, Athens, Greece

Hepatoid adenocarcinoma (HAC) is a rare variant of adenocarcinoma associated with hepatic differentiation in both morphological and functional terms. Although it was first described as a specific type of primary gastric cancer, HAC has recently been reported in various anatomic locations. We present two rare cases of HAC observed the first in the stomach and the second in the gallbladder. The later constitutes a very rare localization since a thorough research of the literature has revealed only six previously reported cases.

Histologically, within a conventional gallbladder adenocarcinoma and a gastric adenocarcinoma with enteroblastic features, areas of hepatoid differentiation were observed composed of eosinophilic or clear cells arranged in a trabecular, nested or rosettoïd pattern. Bile plugs were additionally noticed in the gallbladder HAC. Immunohistochemistry in the hepatoid areas demonstrated HepPar 1 reactivity (strong and diffuse in the gallbladder and focal in the gastric HAC), polyclonal CEA positivity with a canalicular pattern of expression and AFP immunoreactivity (strong and diffuse in the gastric but faint and focal in the gallbladder HAC). Based on the histological and immunohistochemical findings, these cases were diagnosed as adenocarcinomas with hepatoid differentiation. Knowledge of this rare histologic variant is important in the differential diagnosis from metastatic hepatocellular carcinoma.

P210

Prognostic and therapeutic implications of Replication Protein A (RPA) immunohistochemical expression for colon cancer patients

Givalos N², Agrogiannis G¹, Gakiopoulou H¹, Konstantinidou AE¹, Skliri M¹, Lelouda M¹, Kouraklis G², Karatzas G², Patsouris E¹
¹Department of Pathology & ²Department of Surgery, Medical Faculty, National Kapodistrian University of Athens, 75 Mikras Asias, 11527, Athens, Greece

Replication protein A (RPA), a component of the origin recognition complex, is required for stabilization of single stranded DNA at early and later stages of DNA replication being thus critical for eukaryotic DNA replication. Moreover, RPA is involved in DNA recombination and repair. This protein is present in cells as a heterotrimeric complex consisting of three subunits which, in order of decreasing size, have been designated as RPA1 (70kDa), RPA2 (32kDa), and RPA3(14kDa). The aim of the present study was to investigate for the first time the value of RPA1 and RPA2 proteins, as prognostic indicators and possible therapeutic targets in colon cancer patients. RPA1 and RPA2 protein expression was analyzed in a series of 130 colon cancer resection specimens in relation to conventional clinicopathological parameters and patients' survival. Immunohistochemistry (ABC-HRP method) was performed using monoclonal antibodies (Oncogene, NA13 and NA 18, respectively). For statistical analysis the following tests were used: Spearman's rho, Kruskal Wallis, Mann-Whitney U, Wilcoxon Signed Ranks. Survival analysis was univariate (Log-Rank test) and multivariate (Cox regression model).

Statistical significant positive associations emerged between: a) RPA1 and RPA2 protein expressions ($p=0.0001$), b) RPA1 and RPA2 labeling indices (LIs) and advanced stage of the disease ($p=0.001$ and $p=0.003$ respectively), c) RPA1 and RPA2 LIs and the presence of lymph node metastasis ($p=0.002$ and $p=0.004$ respectively), d) RPA1 LI and the number of infiltrated lymph nodes ($p=0.021$), e) RPA2 LI and histological grade of carcinomas ($p=0.05$). Moreover, a statistical significant higher RPA1 LI was observed in the metastatic sites compared to the original ones ($p=0.012$). RPA1 and RPA2 protein expression associated with adverse patients' outcome in both univariate (Log Rank test: $p<0.00001$ and $p<0.00001$ respectively) and multivariate (Cox model: $p=0.092$ and $p=0.0001$ respectively) statistical analysis. Statistical significant differences according to the expression of RPA1 and RPA2 proteins were also noticed in the survival of stage B ($p<0.00001$ and $p=0.0016$ respectively) and stage C ($p=0.0029$ and $p=0.0079$ respectively) patients. In conclusion, RPA1 and RPA2 proteins appear to be useful prognostic indicators in colon cancer patients and attractive targets for regulation by tumor suppressors or other proteins involved in the control of cell proliferation.

P211

Hepatocellular adenoma with telangiectatic changes, focal hemorrhagic necrosis and heavy lipofuscin - like pigment deposition in a 45 year old male.

K. Giaslaktiotis, D. Hatzianastasiou, G. Liapis, K. Kokkori, J.K. Delladetsima
Department of Pathology, Laiko General Hospital, 75 Mikras Asias, 115 27 Athens, Greece.

Heavily pigmented hepatocellular adenoma in men without a history of steroid use is very rare, while a pigmented subtype with telangiectatic changes has not been reported. A 49-year-old man, with no previous steroid use, presented with a hepatic mass, discovered incidentally. A limited hepatic resection was performed. On macroscopic examination, the lesion measured 9cm in diameter with a well limited contour, congestive areas and focal hemorrhagic necroses. Histologically the lesion consisted of hepatocytes arranged in one to two cell thick plates, mildly pleomorphic, densely loaded with coarse granules of iron negative brown pigment. No mitoses were identified, while the reticulin network was preserved. Of note were extensive areas with peliod changes. Dissecting fibrous septa thick walled arterial branches and dilated

veins were also present, but the absence of reactive bile ductules excluded focal nodular hyperplasia. CD34 immunohistochemical staining was focally positive. Based on the histopathologic findings, the changes were in keeping with a hepatocellular adenoma. Two years after resection the patient is free of relapse.

P212

Heterotopic mesenteric ossification

Chatziagianni E., Katafygiotis P., Bouza E., Kyratzis G, Mahera H. Department of Pathology & B'Surgical Department, General Hospital of Attikis "KAT" Greece

We present a case of a 42 year old male patient who was admitted to our Hospital with bowel obstruction apparently due to symphysis from a previous colectomy for a malignancy. The specimen, we received in the Pathology Department consisted of two pieces of bowel specimen joined firmly with lots of symphysis, while in the surrounding fatty tissue there were several whitish-yellowish hard, firm areas ill defined, resembling fat necrosis. The histologic findings showed that these areas contained foci of bone while the rest there were foci of fat necrosis, fibrosis, hemorrhagic and inflammatory changes. Subsequently the patient had a normal recovery, but six months later re- admitted, for recurrent bowel obstruction with the same lesion as previously mentioned. Our diagnosis was heterotopic mesenteric ossification which is a rare entity occurring mainly in young or middle aged males up to the age of 72. The size of the tumor ranges between 3,5cm up to 20cm. It occurs mostly in association with trauma, infection, or chemotherapy while the main aetiologic factors have not yet been clarified.

P213

Immunohistochemical expression of syndecan-1 protein in gastric cancer

Heat Shock Protein (HSP)-27, -70 and -90 expression in gastric cancer: correlation with clinicopathological variables

Costantinos Giaginis¹, Stella Daskalopoulou^{1,2}, Olga Nousia¹, Ioannis Sfiniadakis^{1,3}, Gregorios Kouraklis², Stamatios Theocharis¹
Depts of Forensic Medicine-Toxicology¹ and Propaedeutic Surgery², University of Athens; Dept of Pathology³, Naval Hospital; Athens, Greece

Heat Shock Proteins (HSPs) are crucial for the maintenance of cell integrity in normal and malignant cell growth. In the present study HSP-27, -70 and -90 expression was examined immunohistochemically on paraffin embedded gastric cancer tissue sections obtained from 56 patients. HSP-27, -70 and -90 positivity, overexpression (positivity in more than the mean percentage value) and intensity of staining (mild, moderate, intense) were correlated with patients' age, gender and TNM stage, tumor histological type, grade and proliferative capacity (Ki-67 labeling index). HSPs were abundantly expressed in gastric cancer cases examined. HSP-27 overexpression was statistically significantly correlated with tumor size (T, p=0,008) and the presence of nodular metastasis (N, p=0,049). HSP-90 intensity of staining was statistically significantly correlated with tumor histological type (p=0,004). No correlation was noted between either HSP-70 protein positivity, or overexpression, or intensity of staining and the clinicopathological variables examined. Our findings verify that HSPs are widely expressed in gastric cancer suggesting participation of these proteins in gastric carcinogenesis.

P215

Granular cell tumors of the sigmoid and rectum.

Papaevangelou M.¹, Koniaris E.¹, Papathanasaki A.¹, Gazalidou M.¹, Biteli M.¹, Tsamakidis K.²
¹Dept. of Pathology of the Hellenic Anticancer Institute, 'St. Savvas' Hospital, Athens, Greece.
²Dept. of Gastroenterology of the Hellenic Anticancer Institute, 'St. Savvas' Hospital, Athens, Greece.

Granular cell (Abrikossoff's) tumors are uncommon in the gastrointestinal tract and are quite rare in the colon and the rectum. To date 64 cases of granular cell tumors of the colon have been reported in the literature. We present a 56-year old patient admitted to our hospital for further evaluation because of blood in his stool. The endoscopic examination revealed a spherical non-pedunculated polyp with smooth surface, measured 2x2cm, located in the sigmoid (50cm from the anal sphincter). Another polyp with similar endoscopic features, measured 0.8x0.8cm, was also found 5cm from the anal sphincter and both tumors were resected by endoscopic loop. Endoscopic examination of the entire colon up to the caecum did not reveal any other lesions. The histological examination disclosed two submucosal tumors consisted of large tumor cells with abundant granular cytoplasm and small round nuclei. The tumors cells expressed S-100 protein, Neuron Specific Enolase, Period Acid Schiff and Vinmentin but were negative for Smooth Muscle Actin, Desmin and CD117.

Granular cell tumors are rare in the gastrointestinal tract and the pathologist must be aware of this. They can be misinterpreted to indicate a possible malignancy on a biopsy. The therapeutic approach, since granular cell tumors are usually benign must be conservative and in multiple tumors a strict endoscopic follow-up is suggested.

P216

B-raf mutations and Microsatellite Instability analysis in sporadic Basal Cell Carcinomas.

Angeliki I. Stamatelli, Angelica A. Saetta, Kiriaki G. Aroni, Fanie L. Gigelou, Efstratios S. Patsouris
Department of Pathology, Medical School,
National and Kapodistrian University of Athens, Greece

Alterations of BRAF have been linked with colorectal cancers exhibiting microsatellite instability (MSI). Our aim was to investigate the role of BRAF in basal cell carcinomas (BCC) in correlation with the presence of MSI. 75 BCCs were screened for mutations in the kinase domain of BRAF gene by single-strand conformation polymorphism (SSCP) analysis followed by DNA sequencing. The presence of MSI was based on the analysis of two mononucleotide markers: BAT25, BAT26. Four additional markers were analysed in cases where matched normal tissue was available: BAT40, D2S123, D5S346 and D17S250. The repetitive sequences within the known target genes, TGF- β receptor type II (TGF- β RII), hMSH3 and hMSH6 were also analysed. A mutation in BRAF gene exon 15 was detected in one case, which was classified as microsatellite stable. MSI was found in 8% of the tumours investigated. TGF- β RII frameshift mutations were identified in four cases. Four BCCs carried hMSH3 mutations, one of which was scored as microsatellite unstable. There were no alterations in hMSH6. According to our results the investigated BRAF gene does not appear to be a significant target for mutations in BCCs. The implication of the MAP kinase ERK signalling pathway in the pathogenesis of BCC mandates further evaluation.

P217

A low cost strategy for detection of hereditary nonpolyposis colorectal cancer (HNPCC)

H. Bouzourene, L. Taminelli, C Monnerat, W. Seelentag,
D. Sandmeier, S Andrejevic, M Matter, F Bosman, J Benhattar
Institute of Pathology, Lausanne, Switzerland

The detection of microsatellite instability (MSI) in colorectal cancer (CRC) allows to detect HNPCC but it also appears that MSI cancers respond differently to chemotherapy than cancers with chromosomal instability. The purpose of this study was to develop a strategy for HNPCC detection with the highest sensitivity and the lowest cost. In 148 CRC, expression of MLH1, MSH2, MSH6 protein was analyzed, MSI was tested by PCR and methylation of MLH1 promoter was examined. MSI-H was detected in 14.2 % CRC. MSI-H tumors were right located, were of mucinous typer or have a high number of tumor infiltrating lymphocytes. Twenty of 21 MSI-H cancers showed loss of expression of MLH1, MSH2, or MSH6 genes. Out of 15 tumors immunohistochemically MLH1 silent, 3 tumors did not present methylation of the MLH1 promoter. We propose the following algorithm for HNPCC cases detection: 1/ selection of MSI searching would be based on CRC morphology and immunohistochemical analysis might represent the first step in MSI detection. 2/ in cases of abnormal expression of MLH1 protein, MLH1 methylation detection should be required and represent the second step. 3/ in non methylated MLH1 cases and in MSH2, MSH6 immunohistochemically negative cases further molecular analysis should be performed for the detection of HNPCC.

P218

Hepatocellular carcinoma in patients who underwent partial hepatectomy: prognostic factors and therapeutic implications

AC Tsamandras, V Zolota, N Pagoni, A Liava, T Petsas, C Karatza, CD Scopa. University of Patras Medical School, Patras Greece.

In this study the gross and pathologic features of 76 hepatocellular carcinomas (HCC), were investigated and correlated with features of invasive growth and disease-free survival. The study included 76 HCCs removed, by partial hepatectomy, from equal number of patients. In these tumors, several gross and microscopic features were assessed, graded and correlated with disease-free survival. HCCs begin as small, well-differentiated tumors that have an increased proliferation rate and neoangiogenesis. Vascular invasion, is the strongest predictor of disease recurrence, (95%CI: 1.42-16-p<0.001) and is significantly correlated with the number of tumor nodules (included in the specimen), major diameter of the tumors, worst grade and apoptosis/mitosis (A/M) ratio. In the absence of vascular invasion, the size of the largest tumor nodule (p=0.006), the A/M (p=0.03) and the number of neoplastic nodules (p=0.04) were independent predictors of disease-free survival. Tumors with A/M ratio >3 displayed higher disease-free survival compared to those with A/M ratio <3 (p<0.01). From the 8 cases with A/M ratio >6, none developed recurrence 5 years after hepatectomy. In conclusion, this study showed that, in humans, the prognosis of HCC depends on several biological factors. Aggressive biological behavior (vascular invasion and recurrence) correlated significantly with: a) alterations in the apoptosis/mitosis ratio and b) architectural and cellular alterations.

P219

Characteristics of colorectal cancers with or without DNA polymerase epsilon mutations.

Collan Y, Zhou Q, Elzagheid A, Sundstrom J,
Talvinen K, Pospiech H, Syvaola J
Department of Pathology, University of Turku, Kiinamyllynkatu 10,
FI-20520 Turku, and Departments of Biochemistry, Universities
of Oulu, and Joensuu, Finland

In an earlier study Zavrides et al. (Pol J Pathol, 56, 4, 179-185, 2005) demonstrated that bcl-2 positivity in colorectal cancer was associated with stage of the disease, and improved prognosis. They also showed that bcl-2 expression and Ki-67 index showed an association. We decided to compare our material of 16 colorectal cancers with (N=5) or without (N=11) DNA polymerase epsilon mutations with their findings. The mutations were associated with the second largest subunit of the DNA polymerase epsilon. 3 changes consisted of AATT deletions in intron 18, and 2 of cases showing several single nucleotide transitions in different locations of the gene, and suggesting an amino acid change (tyrosine – histidine) in the protein product of exon 17.

In our material significant or nearly significant associations were found between Ki-67 index, and the location of neoplasms (right side/left side), bcl-2 index, and Her-2 index. Higher p53 positivity was associated with more advanced stage, Her-2 staining index, but also with higher bcl-2 index. The tumors with mutations had higher Ki-67 index than the nonmutated tumors. Especially the two cases showing point mutations had high Ki-67 indices.

The study suggests that DNA polymerase epsilon mutations have a potential to influence the biological behavior of colorectal cancer. The mutations found may be a reflection of general genomic instability in the studied neoplasms.

P220

Malakoplakia of the colon associated with colonic adenocarcinoma, diagnosed in colonic biopsies.

F. Karasavvidou^a, SP. Potamianos^b, S. Barbanis^a, E. Stathakisa,
E. Tziastoudi^a, AN. Kapsoritakis^b, G. Koukoulis^a
Departments of Pathology^a and Gastroenterology^b,
University Hospital, Larissa, Greece.

Malakoplakia is an uncommon form of chronic inflammation caused by chronic infections and characterized by accumulation of distinct macrophages. Malakoplakia typically involves the urinary tract. It has also been found in various sites such as the gastrointestinal tract, pancreas, liver, lymph nodes, skin, respiratory tract, adrenal gland, vagina and brain.

We present a case of a 64 year old man who referred to our hospital with cachexia and radiologic evidence of metastatic tumor in the liver. Colonoscopy revealed a large malignant-appearing polypoid mass of the ascending colon and multiple distinct polyps throughout the rest of the colon.

Biopsies of the ascending colon mass confirmed the diagnosis of adenocarcinoma. Histological examination of one of the other polyps revealed malakoplakia characterized by aggregates of granular histiocytes with Michaelis – Gutmann bodies, confirmed histochemically with periodic acid-Schiff and von Kossa stains.

This is one of few cases diagnosed on endoscopic sample. Most of the reported cases were found in surgical specimens.

In addition the endoscopic appearance is unusual. There are no reports of malakoplakia mimicking multiple colonic polyposis.

P221

The relationship between expression of c-erbB-2 protein and clinicopathological factors in gastric carcinomas and prognostic significance of c-erbB-2 overexpression

Hakan H. Ozgur, Aysenur A Igdem, Elife Sahan, Nusret Erdogan
Taksim Training and Research Hospital, Pathology Department, 34433, Istanbul, Turkiye.

The c-erbB-2 or HER-2/neu oncogene is a member of the tyrosine kinase oncogene family, and encodes a transmembrane glycoprotein of 185 kDa. It is expressed in a variety of human adenocarcinomas. Expression of c-erbB-2 protein in breast cancer has been reported to be associated with poor prognosis. The overexpression of c-erbB-2 protein has been reported to take place in gastric carcinomas. We wanted to investigate the frequency and clinical significance of c-erbB-2 protein expression in gastric carcinoma. In this retrospective study formaline-fixed, paraffin-embedded tissue sections were prepared from gastrectomy specimens from 61 patients with gastric carcinoma. We investigated the relationships between expression of c-erbB-2 oncoprotein and clinicopathologic characteristics of tumours. In this study, correlations of c-erbB-2 protein expression with prognostic outcomes in 46 of 61 gastric adenocarcinomas was evaluated. There was a correlation between the immunohistochemical score for c-erbB-2 protein and the degree of histological differentiation of gastric carcinoma ($p=0.006$). Kaplan-Meier analysis (log-rank statistics) revealed a significant association of increasing positive expression of c-erbB-2 with shorter disease-free survival ($p=0.042$). We concluded that positivity with c-erbB-2 in gastric carcinomas, especially intestinal type carcinomas was specific. We have reported that 9 of the 61 gastric carcinomas showed expression of c-erbB-2 protein and we evaluated that c-erbB-2 protein is a useful prognostic indicator in gastric carcinoma.

P222

Promoter Hypermethylation of RassF1A, DAP kinase, E-cadherin and hMLH1 genes in sporadic colon carcinomas

F.L. Gigelou, A.A. Saetta, P.I. Papanastasiou, M.S. Karlou, A. I. Stamatelli, E.A. El-Habr, N.V. Michalopoulos, N. Kavantzias, P.A. Korkolopoulou, E. S. Patsouris
Department of Pathology, Medical School,
The National and Kapodistrian University of Athens, Greece

The aberrant methylation of promoter CpG islands is considered as an important mechanism of inactivation of tumor-related genes. In order to investigate its clinicopathological significance in colon tumorigenesis, we examined the methylation status of DAP kinase, RassF1A, E-cadherin and hMLH1 genes in 86 tumor specimens from Greek patients with sporadic colon cancer. We performed Methylation Specific - PCR and sequencing. The MSI status of these tumor specimens was also evaluated. Hypermethylation of the promoters of RassF1A, DAP kinase, E-cadherin and hMLH1 genes was detected in 22%, 17%, 16% and 8% of the examined cases, respectively. In 11 out of 86 tumors simultaneous promoter hypermethylation of at least 2 genes was found. 13% of the hypermethylated samples were classified as MSI positive. No RassF1A promoter hypermethylation was observed in MSI positive tumors. Abnormal patterns of methylation are commonly observed in various genes during tumorigenesis. The examined genes seem to contribute to colon carcinogenesis even though they exhibited moderate levels of epigenetic aberration.

P223

Expression of Bax protein in gastric carcinomas. A clinicopathological and immunohistochemical study.

Anagnostopoulos G, Stefanou D, Arkoumani E, Chalkley L, Tsianos E, Agnantis NJ.
Department of Pathology and Gastroenterology,
University of Ioannina, Medical School, Greece.

Bax plays a key role in apoptosis by accelerating cell death. Bax protein suppression is an early event in gastric tumorigenesis. In the present study we immunohistochemically analyzed Bax protein expression in 47 cases of gastric cancer and correlated its expression with clinicopathological parameters. Positive staining for Bax protein was found in 20 (42.4%) of the 47 adenocarcinomas examined. Negative Bax protein expression was correlated with lymph node metastasis and degree of differentiation. Multivariate analysis showed that the only variable with an impact on survival was Bax protein expression ($p<0.05$). Kaplan-Meier curves showed that the 5-year survival was 36.8% in cases with positive Bax protein expression compared with 16 % in negative cases. Negative Bax expression in gastric cancer is associated with de-differentiation, lymph node metastases, and poor clinical prognosis. Therefore, Bax protein expression might play an important role in the development and phenotypic differentiation of gastric carcinomas and tumor progression.

P224

Expression of a-SMA, MMP-2, MMP-9, TIMP-1, TIMP-2 and TGF β in chronic viral liver diseases.

both of Medical School, Aristotle University of Thessaloniki, Greece

Liver fibrosis is a common result of chronic hepatic injury of diverse causes. It is a complex biophysical phenomenon, with reversible and irreversible stage. In order for the liver fibrosis to be developed, an imbalance between fibrogenesis and fibrolysis is necessary to exist, which is characterized by the deposition of extracellular matrix from fibrogenic cells. The aim of our study was to compare the expression of a-SMA, MMP-2, MMP-9, TIMP-1, TIMP-2 and TGF β in chronic hepatitis B and hepatitis C and the probable correlation with the progression of the disease. We studied 82 cases of chronic hepatitis of different stages histologically and immunohistochemically, using monoclonal antibodies for the above factors. Our results showed: 1)

Statistically significant correlation of the fibrosis stage to the expression percentage of a) a-SMA ($R=0.82$, $P<0.001$), b) TIMP-1 ($R=0.54$, $P<0.001$) and c) TGF β ($R=0.55$, $P<0.001$). 2) Statistically significant correlation of the expression percentage of a-SMA to the expression percentage of a) TIMP-1 ($R=0.46$, $P<0.001$) and b) TGF β ($R=0.57$, $P<0.001$). Our findings suggest that immunohistochemical stains for a-SMA, TIMP-1 and TGF β may be helpful in assessing the progress of liver fibrosis in chronic hepatitis.

P225

Alternative mediators of apoptosis in toxic induced liver injury

Eleonora Codorean, C. Tanase, C. Iosif, E. Raducan,
D. Popescu, V. Barca

National Institute of Pathology "Victor Babes" Bucharest,
Romania

TNF- α is a key cytokine triggering apoptosis of liver cells and may mediate it through alternative pathway involving cathepsin B, an apoptotic noncaspase mediator acting as a dominant execution protease in a mitochondrial pathway. Aim of the study is to evaluate the potential modulation of the toxic liver injury by cathepsin B specific inhibitors. Wistar rats were intoxicated with alcohol, with or without pretreatment of a cathepsin B inhibitor. After dosing fragments of the liver were routinely prepared for histological/immunohistochemical analysis (TNF- α receptor) and to evaluate DNA fragmentation by pulsed field gel electrophoresis. The incidence of TNF- α positive cells was higher compared to cells undergoing apoptosis in liver of the rat receiving cathepsin B inhibitor. The features were associated with lower liver morphological changes – reduced area with hepatocyte injury, minimal necrotic area and absence of fibrotic area. DNA fragmentation level, a sensitive indicator of apoptosis were also decreased in synergic action of alcohol and cathepsin B inhibitor compared to alcohol intoxication. Conclusion: the results may indicate that the alcoholic liver injury was reduced in presence of cathepsin B inhibitor. This lysosomal enzyme may play a pivotal role in TNF- α induced apoptosis and might be a potential new pharmacological target in therapy of ethanol induced liver diseases.

Background: In a wide variety of inflammatory liver diseases, TNF- α has been implicated as a key cytokine triggering apoptosis through TNF- α receptor expressed by liver cells. The start point of the study was the recent observation that TNF- α might mediate apoptosis through alternative pathway involving cathepsin B, a lysosomal cysteine protease, representing an apoptotic noncaspase mediator acting as a dominant execution protease in programmed cell death by an alternative mitochondrial pathway.

Aims of the study is to evaluate the potential modulation of the liver toxic injury by cathepsin B specific inhibitors.

Material and methods: Male Wistar rats were intoxicated with alcohol, with or without pretreatment of a cathepsin B inhibitor. After 2 - 4h the rats were sacrificed and fragments of the liver routinely prepared for histological/ immunohistochemical analysis and to evaluate DNA fragmentation by pulsed field gel electrophoresis.

Results: TNF- α expressing cells and incidence of apoptosis were compared in intoxicated liver with or without cathepsin B inhibitor and in control lot. The incidence of TNF- α positive cells was higher than the cells undergoing apoptosis in liver of the rat receiving cathepsin B inhibitor, associated with lower morphological changes – reduced area with hepatocyte injury, minimal necrotic area and absence of fibrotic area. DNA fragmentation values, a sensitive indicator of apoptosis were also decreased in synergic action of alcohol and cathepsin B inhibitor compared to alcohol intoxication.

Conclusion: Our preliminary results indicate that the alcoholic liver injury was reduced in presence of cathepsin B inhibitor suggesting that a cathepsin B may play a pivotal role in TNF- α induced hepatocyte apoptosis and might be a potential new pharmacological target for inhibiting TNF- α mediated toxic liver injury.

Gastrointestinal dialysis related amyloidosis: Severe complications in two patients under long term hemodialysis.

K. Giaslaktiotis¹, D. Stamatiadis², J. Bokos³,
J.N. Boletis⁴, J.K. Delladetsima¹

¹Department of Pathology, ²Department of Nephrology, ³Department of Surgery, ⁴Renal Transplantation Unit, Laikon General Hospital, Mikrasias 75, 115 27 Athens, Greece.

Dialysis related amyloidosis (DRA) is a disabling complication of end stage renal failure, associated with beta-2-microglobulin amyloid deposition principally in the osteoarticular system, while complications related to gastrointestinal involvement are rarely reported. We report two cases of gastrointestinal DRA with fatal outcome presented with ileus and acute colonic perforation respectively. Patients' age was 64 and 57 years; time from initiation of hemodialysis was 19 and 20 years respectively; the former patient presented with intestinal pseudoobstruction and the latter with acute abdomen. Clinical evidence of preexistent osteoarticular involvement was present only in the latter. In both patients amyloid depositions were found predominantly in the outer muscular layer and blood vessels. Both patients died of sepsis after sigmoid colon resection. Intermittent ileus, as well as spontaneous bowel perforation, even in the absence of osteoarticular manifestations, should raise suspicion of underlying gastrointestinal amyloidosis in long term hemodialysis patients.

P227

Chemoradiation In Scc Of Esophagus.

B. Mofid, H.R. Mirzaei

Shahid Beheshti University of Medical Sciences-Tehran-Iran.

Purpose: Esophageal cancer ranks among the ten most common cancers worldwide, with high prevalence in Iran. Previously surgery or radiotherapy alone was choice of treatment but they were not effective. Today number of patients receiving definitive chemo radiation has been increasing worldwide. Therefore it is important for evaluate response rate and tolerance patients to chemo radiation.

Material and method: This study is Quasi experimental clinical trial. Patients were evaluated with S.c.c of the esophageal and treated with chemo radiation without metastases, with P.S between 0-2 and adequate organ function (Kidney, liver, bone marrow). Patients were treated with two protocols: a) Cisplatin 40 mg/m weekly plus 50-60 Gyb Cisplatin 75mg/m day 1 and 5-Fu 1000mg/m day 1-4 in weeks 1, 5,9,13 and concomitant RT 50 GY.

Results: There were 39 patients who received definitive chemo radiation during the period: 1377-1382 in radiation oncology department of Shohada Tajrish hospital. 30 patients matched the recruitment Criteria. The characteristics of the 30 patient were: 23 male and 7 female, median age 65 years (range, 35-75 years). One patient suffered neutropenic fever and there were two treatment related death including sepsis in one patient and uncertain causes on death in another. Of 30 patients, 23(76.6%) achieved complete response.

Conclusion: Chemo radiation has low complication and high efficacy. Other studies for confirmation of these results are recommended.

P228

Colorectal carcinoma incidence in patients under age 30

Simona Stolnicu¹, Doinița Rădulescu²

¹Department of Pathology, University of Medicine Targu Mures

²Department of Pathology, University of Medicine, Iasi

The aim of the study is to find colorectal carcinoma incidence in patients under age 30 and to describe the distributions depending on localization, histological type and stage, comparing to older patients. The study was performed between January 1995 and December 2005, on 257 patients with invasive adenocarcinoma. We found 7 patients under age 30, representing 2,72 % of all invasive cancer. The youngest patient was 21 years old. There were no reliable differences between older and younger patients considering localization, histological type and stage of the disease. The 5-years survival is the same in both categories of patients, strategy of the therapeutical approach. Its application is helpful in the identification of patients with unfavorable prognostic characteristics who require a modified and more aggressive therapy.

P230

Immune – effective reactance in Helicobacter pylori infected children, teenagers and young people

Kakabadze Yulia, Kakabadze Sergei
Republic Pathologoanatomic Bureau, Vladikavkas, Russia

Immune-effective reactance was estimated on biopsies from 294 patients with Helicobacter pylori (HP) gastritis according to Sydney system. Within the limits of age group hyporeactions is represented by the variants with prevalence of immune reactance with equality immune and effective reactance and with absence of effective reactance at significant prevalence of the latter. Adequate reactance is represent with variants with low, average and high degree in decreasing frequency. Hyperreactance is represented mainly with variants with equality of immune and effective reactance and with prevalence of immune reactance. In an age of observations group among variants of immune – effective hyporeactance the share of variants with prevalence of immune reactance gradually accrues. Such dynamics is characteristic also for variants with immune – effective hyperreactance. Among variants with adequate immune – effective reactance the share of variants with an average and high degree also gradually accrues. On the generalized data of hyporeactance and hyperreactance, triple prevalence of active follicles above inactive is characteristic and at adequate reactance – double. The received results on differentiated immune – effective reactance at HP – gastritis allow to estimate anti-HP resistance more objectively and show the positive tendency of its increase from children to youth.

VEGF Polymorphisms and VEGF gene expression status and angiogenic activity in Gastric Cancer Development, Prognosis and Survival

N. Tzanakis¹, M. Gazouli², Ch. Gakiopoulou³,
V. Atsaves³, Z. Christoni⁴, A.C. Lazaris³, P. Karakitsos⁴,
E. Patsouris³, N. Nikiteas³

¹4th Surgical Department, “Attikon” Hospital, University of Athens;
²Department of Biology, School of Medicine, University of Athens;
³1st Department of Pathology, School of Medicine, University of Athens;
⁴Department of Histology-Embryology, School of Medicine, University of Athens; 52nd Surgical Department, “Laiko” Hospital, University of Athens, Athens, Greece

Angiogenesis plays an important role in growth, progression and metastasis of tumors. VEGF overexpression has been associated with advanced stage and poor survival in several cancers. In the present study, we evaluated the association of functional single nucleotide polymorphisms (SNPs) of VEGF gene as well as VEGF expression status and angiogenic activity, with gastric cancer development, prognosis, and survival in a case-control study of 100 gastric cancer Greek patients. Included in the study were four SNPs (-2578C/A, -1154G/A, -634G/C, and +936C/T) in the VEGF gene. The

genotyping was performed with PCR-RFLP techniques. The VEGF expression status was evaluated with immunohistochemistry. Tumor vasculature was highlighted using the anti-CD105 MoAb technique. Our results revealed a marginally significant association of the 634CC genotype ($p=0.042$) with increased risk for gastric cancer development. None of the rest of the examined polymorphisms or haplotypes conferred any gastric cancer susceptibility. A strong association between the -2578AA ($p=0.025$), -634CC ($p=0.013$), +936CT ($p=0.028$), +936TT ($p=0.0001$) genotypes and a larger tumor size was observed, while the 2578AA and -634CC genotypes were strongly correlated to poor differentiation ($p=0.01$) and advanced stage of disease ($p=0.039$), respectively. In addition, our results indicated that metastatic disease frequency was more accentuated among the +936TT carriers ($p=0.0035$). Interestingly, carrying the -634CC genotype was associated with decreased overall survival rates (46.67%). VEGF overexpression was observed in 36% cases and was accompanied with high vascularization. No significant association was observed between VEGF protein production and VEGF gene polymorphisms. However, a strong correlation between the VEGF overexpression and lymph node metastasis was observed ($p=0.028$). Furthermore, overexpression of VEGF was related with poor survival. The present study suggests that VEGF polymorphisms may contribute to gastric tumor characteristics and confirms the association between VEGF overexpression and poor survival in gastric cancer. These observations, however, require further confirmation in a larger multi-ethnic study.

P232

The potential role of activated stellate cells in liver biopsies with hepatitis C compared with hepatitis C/diabetes mellitus.

AC Tsamandas, V Zolota, A Liava, D Dimitropoulou, C Gogos, CD Scopa. University of Patras Medical School, Patras, Greece

Hepatitis C virus (HCV) infection is a major cause of chronic liver disease. Steatosis is a common finding both in HCV and diabetes mellitus (DM). Activated liver stellate cells (ASC- α SMA+ cells) are a major factor responsible for fibrosis and progression to chronic liver disease. This study investigates the presence of ASC in liver biopsies from patients with HCV alone and in patients with HCV/DM. Fifty liver biopsies (HCV-35 and HCV/DM-15) were immunostained with the anti- α SMA antibody. Results were expressed as % (+) cells and correlated with degree of steatosis, inflammation and fibrosis. The mean \pm SD value, in HCV/DM and HCV patients was: for steatosis 1.1 \pm 0.4 and 0.5 \pm 0.2 ($p=0.01$), for inflammation 1.9 \pm 0.3 and 1.5 \pm 0.2 ($p=0.03$), for fibrosis 2.8 \pm 0.2 and 1.6 \pm 0.1 ($p<0.0001$). The mean %ASC for all zones was 1.3 for HCV/DM and 1.2 for HCV ($p=0.39$). However, when both diagnostic groups were combined, a significant % of ASC was observed in periportal areas and portal tracts for fibrosis stages >2 vs stages ≤ 2 ($p<0.0001$). In addition, a statistically significant increase in %ASC was observed in zone 1 for HCV/DM group (mean 1.5) compared to HCV group (mean 1.2) regardless of fibrosis stage ($p=0.02$). This study suggests that in patients with HCV or HCV/DM, activated stellate cells are predominantly located in periportal areas and correlate with advanced fibrosis stages (>2). Periportal stellate cell activation is significantly increased in the HCV/DM group compared to HCV group.

Eosinophilic esophagitis: Report of 3 cases

Bobos M¹, Televantou D¹, Akriviadis E²,
Mavropoulou S, Leontidis C, Hytiroglou P¹.
Departments of Pathology¹ and Internal Medicine²,
Aristotle University Medical School, Thessaloniki, Greece

Eosinophilic esophagitis (EE) is a chronic inflammatory disorder of the esophagus with a growing incidence over the recent years. The characteristic histologic finding is the increased number of mucosal eosinophils (>20) per high power field (eos/hpf). We present 3 cases of EE in young men. The first patient presented with acute dysphagia. On endoscopy, there was vertical furrowing of the lower two thirds of the esophageal mucosa and granularity of the upper third. Biopsies revealed many eosinophils (mean eos/hpf: 30) in the esophageal squamous epithelium. The second patient complained for heartburn, retrosternal discomfort and dysphagia. Endoscopic examination showed vertical furrows and rings in the proximal esophageal mucosa. Biopsies revealed a dense eosinophilic infiltration of the epithelium (mean eos/hpf: 114) with several eosinophilic micro-abscesses. The third patient presented with food impaction and occasional gastroesophageal reflux. Endoscopy showed whitish color of the mucosa, furrows and rings. On histologic examination, there were numerous intramucosal eosinophils (mean eos/hpf: 57). After appropriate treatment, the patients were asymptomatic without signs of recurrence. Both clinicians and pathologists should be aware of the typical features of EE, in order to be able to recognize this entity in the appropriate setting.

P234

An unusual multifocal leiomyosarcoma of the small and the large intestine

Vasilakaki Th, Glava C, Petrakopoulou N, Grammatoglou X, Zizi-Serbetzoglou A

Department of Pathology, Tzaneion General Hospital of Piraeus, Piraeus, Greece

Malignant tumors of the small bowel are rare and account for less than 2% of the total gastrointestinal malignancy. Leiomyosarcoma accounts for less than 15% of the cases with diverse presentation and high incidence of metastasis. In this case we report an unusual presentation of multifocal leiomyosarcoma in the large intestine (descending part of the duodenum). A 71-year-old man came to our hospital complaining about intense pain in the right hypochondrium. Clinical examination showed hepatomegaly. Ultrasound imaging of the superior abdomen showed multiple nodules in the liver with mixed echogenicity. Abdominal computed tomography revealed a small bowel mass in close proximity to the head of the pancreas expanding towards the liver. There was para-aortic lymph nodes enlargement and thrombosis of the inferior cava vein. Gastroscopy performed showed a diffusely reddish region, an edema in the descending tract of the duodenum in close proximity to the Vater's ampulla and biopsies were taken. Also colonoscopy was performed and two lumps one in correspondence to the caecum and the other in the descending colon were observed and biopsied. Histological examination of the specimens showed a spindle cell tumor with morphologic and immunohistochemical features (the tumor was positive for alpha-smooth muscle actin and desmin but negative for CD34, CD117, S-100 protein and cytokeratins) compatible with leiomyosarcoma. Neoplastic cells demonstrated prominent cellular atypia, a mitotic rate >10 mitoses/10 high power fields and high expression of the cell proliferation marker Ki67. The majority of leiomyosarcomas grow extraluminally but infrequently tumor can grow both extra and intraluminally. Tumor size varies from 1 to 20 cm and in more than 3/4th of patients tumor is >5 cm. The most common route of metastasis is hematogenous and common sites are liver and lungs. The most frequent site of leiomyosarcoma in the small bowel is jejunum, followed by ileum and duodenum. Surgical resection is the mainstay of treatment in these tumors. Unfortunately leiomyosarcomas are notoriously radioresistant and attempts at using adjunctive radiotherapy and chemotherapy have failed

P235

Expression of syndecan-1 in colorectal carcinomas: its association with angiogenesis, extracellular matrix components, clinicopathological features, and prognostic significance

Antigony Mitselou¹, Elli Ioachim², Melli Machera², Ioannis Nesseris², Eufemia Balassi², Michael Doukas², Theodore Vougiouklakis¹, Niki Agnantis²

¹Department of Forensic Pathology, ²Department of Pathology, Medical School, University of Ioannina, Greece

Syndecan-1 is a transmembrane heparan sulphate proteoglycan, which regulates cell-to-cell or cell-to-extracellular interactions and may influence malignant cell behavior.

Tumor development in the large bowel is associated with loss of normal epithelial adhesion and altered patterns of expression of cell adhesion molecules, possibly including syndecan-1. To evaluate changes in syndecan-1 we studied 97 colorectal carcinomas by immunohistochemistry. The staining intensity and distribution was examined, semi-quantified and compared with vascular endothelial growth factor (VEGF), tenascin, fibronectin, collagen IV, laminin, and clinicopathological features.

Strong staining of syndecan-1 was observed in 52 cases (74.2%), moderate in 20 cases (20.6%), and weak in 5 cases (5.2%) of colorectal carcinomas. The expression of syndecan-1 was positively correlated with VEGF of the tumor (p=0.001) and VEGF of the vessels (p=0.007).

The relationship between syndecan-1 expression, clinicopathological parameters, and extracellular matrix components, collagen IV, fibronectin, laminin was not significant. A borderline statistical significance between syndecan-1 expression and tenascin was observed (p=0.053).

In conclusion, our results indicate that disruption of cell-matrix adhesion is critical in colorectal carcinogenesis, and angiogenesis might be plays a significant role in the tumor-stromal microenvironment in cancer. Further studies with a large number of patients are needed to clarify the influence of syndecan-1 in colorectal carcinomas.

P236

Unusual presentation of choriocarcinoma. A case report

Eufemia Balassi¹, Elli Ioachim¹, Antigony Mitselou², Vasilios Nousias³, Costas Nikolaides⁴, Nicholas Pavlidis⁴, Angelos Kappas³, Vasiliki Malamou-Mitsi¹

Departments of ¹Pathology, ²Forensic Pathology, ³Surgery,

⁴Internal Medicine - University Hospital of Ioannina. Greece.

We report a case of primary choriocarcinoma of the ascendant colon in a 60-year-old woman. The patient consulted a physician because of fever and abdominal pain. On admission at hospital, ultrasonography (US) showed an obscure mass in the right lower quadrant of the abdomen measuring 9x5x7 cm with neovascularisation. The patient underwent resection of about 26 cm of ileum and 22 cm of colon with an end-to-end anastomosis, part of bowel mesentery. A mass was found proximal to ileocaecal valve, in the large bowel. The tumour was 6.5x3.5x3.5 cm in size. Microscopic examination, revealed a proliferation of tumour cells that was composed of two distinctive elements, poor differentiated adenocarcinoma and cytotrophoblasts having eosinophilic cytoplasm and round vesicular nuclear. Numerous mitoses are present as well giant multinucleated cells. Immunohistochemical staining revealed that the tumour cells were positive for EMA, CEA, cytoker 19, cytoker 20 (in some cells), CA19-9, strongly positively for human chorionic gonadotrophin (β -hCG), and negative for cytoker 7. This case of mixed tumor in gastrointestinal tract, suggest that unexpected trophoblastic differ-

entiation may result from aberrant differentiation of locally proliferating cells, so called retrodifferentiation from adenocarcinoma cells, rather than originating in ectopic germ cells or in foci of embryonic totipotent cells.

P237

Expression of syndecan-1 in colorectal carcinomas: its association with angiogenesis, extracellular matrix components, clinicopathological features, and prognostic significance

P238

Expression of the anti-angiogenic factor Thrombospondin-1 in colorectal carcinomas: its association with angiogenesis, extracellular matrix components, clinicopathological features and prognostic significance.

Antigony Mitselou¹, Elli Ioachim², Melli Machera², Ioannis Pamelos², Nafsika Simou², Evangelia Lampri², Theodore Vougiouklakis¹, Niki Agnantis²

¹Department of Forensic Pathology, ²Department of Pathology, Medical School, University of Ioannina, Greece.

Thrombospondin-1 (TSP-1) is a multifunctional platelet and extracellular matrix protein that is involved in angiogenesis. Under certain pathological conditions, e.g. malignant tumors, high concentrations of TSP-1 work as an angiogenic agonist. Angiogenesis, the process leading to the formation of new blood vessels from a preexisting vascular network, is necessary from tumor growth, invasion, and metastasis.

Surgical specimens of primary colorectal carcinomas ($n=87$) were selected from the archives of the Department of Pathology at

University Hospital of Ioannina. The specimens were fixed in 10% neutral buffered formaldehyde and embedded in paraffin. Immunohistochemical staining was performed by the streptavidin-biotin method. The antibodies used are anti VEGF, anti CD34, anti p53, anti tenascin, anti fibronectin, anti collagen IV.

To extrapolate the correlation of TSP-1 with tumor neovascularization we examined the relationship of TSP-1 with microvessel density (CD34) and with angiogenesis (VEGF). The tumor TPS-1, the stroma TPS-1 and the vessel TPS-1 were estimated semi-quantitatively. Strong cytoplasmic expression of TSP-1 protein was detected in 14 cases (16.1%) of tumor cells, strong expression in stroma was observed in 24 cases (27.6%), and 18 cases (20.7%) expressed strongly in vessels. Positive relationship between TSP-1 cytoplasmic and TSP-1 stroma ($p=0.0001$) was found, as well as between TSP-1 stroma and Tsp-1 vessels ($p<0.0001$). The level of TSP-1 stroma expression increased in histological grade ($p=0.041$) and histological type ($p=0.001$) of the tumor. The relationship of TSP-1 vessel and VEGF vessel of the tumor was statistically significant ($p=0.06$). Positive relationship between TSP-1 stroma with tenascin and fibronectin ($p=0.053$ and $p=0.063$, respectively) was observed.

In conclusion, as a modulator of angiogenesis, TSP-1 is expressed in colorectal carcinomas and is likely to contribute to the extensive neovascularization and spread of these tumors.

P239

Expression patterns of cyclins D1, E, cyclin dependent kinase inhibitors p21 Waf1/Cip1, p27 Kip1, in colorectal carcinoma. Correlation with other cell cycle regulators (pRb, p53, Ki-67 and PCNA), and clinicopathological parameters.

Antigony Mitselou¹, Elli Ioachim², Melli Machera², Pamelos Ioannis², Nafsika Simou², Evangelia Lampri², Theodore Vougiouklakis¹, Niki Agnantis²

¹Department of Forensic Pathology, ²Department of Pathology, Medical School, University of Ioannina, Greece.

Aberrations in the cell cycle regulators are common features of many tumors and several have been shown to have prognostic significance in colorectal cancer. The expression patterns of cyclins D1 and E, as well as cyclin dependent kinase inhibitors p21, p27 and their relationship with other cell cycle checkpoint proteins (p53, pRb, Ki-67 and PCNA) were investigated in colorectal cancer in order to ascertain co-regulation and influence on tumor behavior or survival.

The molecular markers were analyzed immunohistochemically using the monoclonal antibodies against cyclin D1, cyclin E, p21, p27, p53, pRb, MIB-1 and PC10, in colorectal cancer tissue from 97 patients. Data were analyzed statistically using the SPSS software program.

Overexpression of cyclin D1, E, and p21 was seen in 5.9%, 30%, and 7.2% of the cases respectively. We observed increased levels of cyclin D1 ($p=0.0001$), and p21 protein ($p=0.03$) in tumors with mucous differentiation. Overexpression of cyclin D1 was correlated with tumor stage ($p=0.03$), the lymph node involvement ($p=0.02$) and p21 protein expression ($p<0.0001$).

Cyclin E was found positively correlated with p21 protein expression ($p=0.014$), as well as with cell proliferation labeling index as measured by PCNA ($p=0.011$) and Ki-67 score ($p=0.07$). The prognostic significance of cyclin D1, E, p21, p27 in determining the risk of recurrence and overall survival with both univariate and multivariate methods of analysis showed no statistically significant differences.

In conclusion, these findings suggests that, the levels of cell cycle regulators studied, do not seems to have a prognostic value, in terms of predicting the risk of early recurrence and overall survival in patients with colorectal carcinoma.

P240

Expression of PTEN, MVD and Caspase-3 and their clinicopathological significance in primary gastric cancer

Zizi-Serbetzoglou A, Glava C, Grammatoglou X, Petrakopoulou N, Katsamagou E, Vasilakaki Th.
Department of Pathology, Tzaneion General Hospital of Piraeus, Piraeus, Greece

Introduction: Gastric cancer is one of the commonest malignancies in the world. In patients with gastric cancer the natural disease process consists of carcinogenesis, metastasis and eventual death. The aim of this study was to detect the relation of PTEN, MVD and Caspase-3 and metastasis of gastric cancer.

Materials and methods: We examined the immunohistochemical expression of PTEN, MVD and Caspase-3 protein, in formalin-fixed paraffin embedded tissue sections, taken from 75 cases of total or subtotal gastrectomy for gastric cancer, in primary gastric cancer and adjacent non- tumor mucosa.

Results: PTEN was positively expressed in the nuclei of adjacent epithelial cells and neoplastic cells of gastric cancer in 79,5% and 52,9% of tumor respectively ($p < 0,05$). There was no correlation between PTEN and microvessel density (MVD). There was a significant association between PTEN expression and invasive depth, metastasis, growth pattern and Lauren's classification ($p < 0,05$). Neoplastic cells showed less frequent immunoreactivity to Caspase-3 than epithelial cells of adjacent gastric mucosa (30%, 60,4% $p < 0,05$). Furthermore, Caspase-3 expression was dependent of PTEN expression in primary gastric cancer ($p < 0,05$).

Conclusion: The down-regulated expression of PTEN and Caspase-3 played an important role in tumorigenesis of the gastric cancer.

P241

Glomus tumor of the stomach. A case report

Vasilakaki Th¹, Zizi – Serbetzoglou A¹, Zisis D², Grammatoglou X¹, Nikolaidou ME¹

¹Department of Pathology, ²Department of Gastroenterology, Tzaneion General Hospital of Piraeus, Piraeus, Greece

Glomus tumors are usually benign neoplasms that arise from modified smooth muscle cells of the glomus body. They usually occur in the dermis or subcutis of the extremities. Rare cases have been reported in the visceral location, most often in the stomach. Since glomus tumors are essentially benign and are amenable to conservative excision, it is important to separate them preoperatively from more aggressive gastric neoplasms. We report a case of a 75-year-old man who came to our hospital with gastrointestinal bleeding and epigastric pain. Endoscopic examination revealed an ulcer (1cm) at the lesser curvature, near the antrum, that was biopsied and the diagnosis of glomus tumor was made. The patient underwent an operation and under the ulcer a submucosal tumor 2x1,8cm was observed which was extending to the serosa. Histologically, the tumor was composed of typical glomus cells arranged in a predominantly solid pattern with low mitotic activity. There was no indication of atypia in these cells. Immunohistochemically, the tumor cells were positive for alpha-smooth-muscle Actin and Vimentin, but were negative for CD34, CD117, L26, B, T, Chromogranin, Desmin and S-100 protein. The expression of the cell proliferation marker Ki67 was low. Gastric glomus tumors are rare, benign and normally solitary lesions in the antrum of pyloric region and they have a good overall prognosis, but a small unpredictable potential for malignant behaviour exists. Although rare, glomus tumor should be in the differential diagnosis among other gastric lesions, such as carcinoid tumor, epithelioid GIST, lymphoma and adenocarcinoma. Treatment is local excision.

P242

Cavernous Hemangioma of the Thyroid: a case report with review of the literature

Valavanis C.^{1,2}, Gavresea Th.¹, Konstantoudakis S.¹, Petridis N.³, Vecchini G.¹

¹Dept. of Pathology – ²Molecular Pathology Unit, ³Dept. of Otorhinolaryncology, METAXA Cancer Hospital, Piraeus, Greece

Cavernous hemangioma of the thyroid gland is an extremely rare pathologic entity. It is considered a developmental malformation resulting from the inability of angioblastic mesenchyma to form complete blood vessels. We report a case of cavernous hemangioma of the thyroid gland in a euthyroid 74 year old woman with catching episodes for 3 months. The scan revealed a cold nodule in the middle portion of the right lobe of the thyroid gland and the organ was removed for histopathological examination. The microscopic examination showed lesions of nodule goiter associated with chronic non specific thyroiditis. Focally, a small cavernous hemangioma measuring 0.6 x 0.5 cm was recognized. The lesion was poorly circumscribed and composed of dilated thin-walled blood vessels. The vessels were lined by flattened CD34 positive endothelial cells and were congested with blood. Secondary hemangioma of the thyroid after fine needle aspiration was excluded according to the clinical history of the patient. A review of the relevant literature is presented.

P243

Type 1 neurofibromatosis (von Recklinghausen's disease) associated with multiple GISTs of the small bowel and a rectal adenocarcinoma. A case report and review of the literature.

I. Evangelou, N. Alevizopoulos, G. Kanellis, K. Dimosthenous, C. Meristoudis, C. Petraki
Department of Pathology, Evangelismos Hospital, Athens, Greece.

Type 1 neurofibromatosis, (NF-1) or von Recklinghausen's disease is an autosomal dominant disorder, presenting with multiple neurofibromas throughout the body. Gastrointestinal stromal tumours (GISTs) and endocrine tumours are other rare gastrointestinal manifestations of NF-1. Furthermore, the association of NF-1 with several non-endocrine tumours of different organs has been also reported. We present a 70 years old man with multiple cutaneous tumours of the upper extremities and the trunk and an established diagnosis of rectal cancer post a six month history of rectal blood loss. A rectosigmoid resection was performed and during the surgery multiple solid tumours were found in the small intestinal wall. Two of them, as well as two of the cutaneous solid tumours were resected. The histological and immunohistochemical study revealed: i) a moderately differentiated, p T3N2 rectal adenocarcinoma, ii) GISTs of low malignant potential of the small bowel and iii) cutaneous neurofibromas. The imaging tests revealed no colon cancer metastatic disease. The patient underwent adjuvant chemotherapy and is still alive, with no evidence of disease relapse, one year post surgery. Reviewing the relevant literature thoroughly, we did not find a match of our case that combined NF-1, multiple GISTs of the small bowel and rectal adenocarcinoma.

P244

Comparative Analysis of Small Bowel Biopsies and Serological Markers in the Diagnosis of Celiac Disease

Maria Sajin, M. Craiu, M. Iordachescu, Alina Stanescu
IOMC - "Alfred Russescu" Hospital, Bucharest, Romania

This study is focused on the morphological and serological aspect of the intestinal mucosa in patients sensitive to gluten, hospitalized in the last 7 years.

Methods: Intestinal biopsies, in children aged between 1,3 - 8 years. 117 cases were analyzed serological (positive IgA anti-endomysial antibodies), morphologically (HE, histochemical coloring) and IHC (L B, LT with possible subtypes).

Results: The lesions counted according to the Marsh score were: • 47 Marsh I infiltrating lesions but positive coeliac serology is only for 41 patients; • 18 Marsh II infiltrating lesions with enlarged crypts and infiltrated with lymphocytes, with positive coeliac serology; • 15 Marsh IIIa destructive lesions with partial villi atrophy (VA) and hyperplastic crypts / HPC but positive coeliac serology is only for 12 patients; • 19 Marsh IIIb destructive lesions with subtotal VA, widened HPC containing immature epithelial cells with a higher growth rate and influx of inflammatory cells but positive coeliac serology is only for 16 patients; • 28 Marsh IIIc hyperplastic lesions but positive coeliac serology is only for 27 patients. The IHC tests have indicated the prevalence of T lymphocytes (CD3, CD4, CD8, $\gamma\delta$) This study is presented in order to illustrate the absence of concordance between serology and the intestinal microscopically aspects of the coeliac disease.

P245

Nuclear Morphometric Analysis in Gastrointestinal Stromal Tumors: A Preliminary Study.

Sukru O. Ozdamar*, Sibel Bektas*, Sevim E. Ozdamar**, Gokhan Gedikoglu***, Banu D. Gun*, Burak Bahadir*
Departments of Pathology; Zonguldak Karaelmas University School of Medicine*, Hacettepe University School of Medicine***, Department of Neurology, Hacettepe University School of Medicine**, Turkey

Gastrointestinal stromal tumors (GISTs) are considered a specialized group of mesenchymal neoplasm. In this study, the histomorphologic and immunohistochemical features of GISTs are compared with nuclear morphometric results. Morphometric nuclear parameters such as mean area, mean roundness factor, mean formellipse, mean length and mean perimeter were evaluated in a total of 22 GISTs, 9 benign and 13 with malignant potential. Results were compared with tumor behavior and size, the presence of necrosis, mitotic index, and immunohistochemical expressions of p53 and proliferating cell nuclear antigen (PCNA). No correlation has been found between morphometric features and GISTs' behavior, tumor size, index of PCNA and p53 expressions ($p>0.05$). However we found that tumor necrosis were correlated with mean nuclear roundness factor, mean nuclear formellipse, mean nuclear length and mean nuclear perimeter ($p<0.05$). Mitotic index were also correlated with mean nuclear roundness factor and mean nuclear formellipse ($p<0.05$). The relative concordance of the results and general histomorphologic and clinical data exhibited the importance of nuclear morphometric analysis.

P246

Alternative mediators of apoptosis in toxic induced liver injury

Eleonora Codorean, C. Tanase, C. Iosif, E. Raducan, D. Popescu, V. Barca
National Institute of Pathology "Victor Babes" Bucharest, Romania

TNF- α is a key cytokine triggering apoptosis of liver cells and may mediate it through alternative pathway involving cathepsin B, an apoptotic noncaspase mediator acting as a dominant execution protease in a mitochondrial pathway. **Aim** of the study is to evaluate the potential modulation of the toxic liver injury by cathepsin B specific inhibitors. Wistar rats were intoxicated with alcohol, with or without pretreatment of a cathepsin B inhibitor. After dosing fragments of the liver were routinely prepared for histological/immunohistochemical analysis (TNF- α receptor) and to evaluate DNA fragmentation by puls field gel electrophoresis. The incidence of TNF- α positive cells was higher compared to cells undergoing

apoptosis in liver of the rat receiving cathepsin B inhibitor. The feature were associated with lower liver morphological changes – reduced area with hepatocyte injury, minimal necrotic area and absence of fibrotic area. DNA fragmentation level, a sensitive indicator of apoptosis were also decreased in synergic action of alcohol and cathepsin B inhibitor compared to alcohol intoxication.

Conclusion: the results may indicate that the alcoholic liver injury was reduced in presence of cathepsin B inhibitor. This lysosomal enzyme may play a pivotal role in TNF- α induced apoptosis and might be a potential new pharmacological target in therapy of ethanol induced liver diseases.

Background: In a wide variety of inflammatory liver diseases, TNF- α has been implicated as a key cytokine triggering apoptosis through TNF- α receptor expressed by liver cells. The start point of the study was the recent observation that TNF- α might mediate apoptosis through alternative pathway involving cathepsin B, a lysosomal cysteine protease, representing an apoptotic noncaspase mediator acting as a dominant execution protease in programed cell death by an alternative mitochondrial pathway.

Aims of the study is to evaluate the potential modulation of the liver toxic injury by cathepsin B specific inhibitors.

Material and methods: Male Wistar rats were intoxicated with alcohol, with or without pretreatment of a cathepsin B inhibitor. After 2 - 4h the rats were sacrificed and fragments of the liver routinely prepared for histological/ immunohistochemical analysis and to evaluate DNA fragmentation by puls field gel electrophoresis.

Results: TNF- α expressing cells and incidence of apoptosis were compared in intoxicated liver with or without cathepsin B inhibitor and in control lot. The incidence of TNF- α positive cells was higher than the cells undergoing apoptosis in liver of the rat receiving cathepsin B inhibitor, associated with lower morphological changes – reduced area with hepatocyte injury, minimal necrotic area and absence of fibrotic area. DNA fragmentation values, a sensitive indicator of apoptosis were also decreased in synergic action of alcohol and cathepsin B inhibitor compared to alcohol intoxication.

Conclusion: Our preliminary results indicate that the alcoholic liver injury was reduced in presence of cat B inhibitor suggesting that a cat B may play a pivotal role in TNF- α induced hepatocyte apoptosis and might be a potential new pharmacological target for inhibiting TNF- α mediated toxic liver injury.

P246B

Neonatal menetrier disease

Identification of a novel age-related subtype

A.E. Konstantinidou, A. Nonni, G. Morphopoulos, E. Tsekoura, I. Thymara, E. Patsouris
Dept. Pathology, Medical Faculty, National University of Athens B'Neonatal Intensity Care Unit, Agia Sofia Children's Hospital, Athens, Greece

Menetrier disease (MD), a rare hypertrophic gastropathy, has been described in adult and pediatric patients. Both pediatric and adult types of the disease share similar histological and clinical features, while a specific pattern of transforming growth factor- α (TGF- α) overexpression has been described in both adults and children with MD. Despite these similarities, pediatric MD is a transient condition, frequently associated with cytomegalovirus gastric infection, whereas adult MD is more chronic and may require gastrectomy. In early infancy, MD has only rarely been reported. In this article, on the occasion of two new neonatal cases, we describe the clinical, laboratory and pathological data available for all the reported cases in early infancy. In addition, we describe an abnormal pattern of TGF- α and EGFR immunohistochemical localization and expression in the gastric mucosa of 4 infants with MD diagnosed in our department. From the comparative examination of the total of neonatal cases (n=9), we are led to presume that neonatal MD may represent a

separate subtype of the disease with a fatal clinical outcome. We also suggest that MD should not be considered a specific disease, but rather a reaction of the gastric mucosa to various insults, mediated by TGF- α and EGFR activation.

P246C

Potential involvement of PTEN expression in resistance to anti-HER2 targeted therapies in pancreatic ductal adenocarcinoma: A combined chromogenic in situ hybridization and immunohistochemistry analysis based on tissue microarrays

E Tsiambas¹, A Karameris¹, D Tiniakou², P Karakitsos², Ch Kittas²
¹Department of Pathology, 417 VA (NIMTS) Hospital, Athens, Greece, ²Lab of Histology & Embryology, Medical School, National and Kapodestrian University of Athens, Greece.

Background: Although HER2/neu overexpression is observed in different proportions in pancreatic ductal adenocarcinomas (PDAC), the specific mechanisms of gene deregulation and chemo resistance to novel targeted therapeutic agents remain under investigation. Our aim was to identify HER2/neu gene alterations in PDAC correlating them to its protein levels and also to PTEN suppressor gene expression, which normally opposes the activation of PI3K-Akt-mTOR signaling pathway.

Materials and Methods: Using tissue microarray technology, fifty (n=50) paraffin embedded tissue samples of histologically confirmed primary PDACs were cored at a diameter of 2mm and re embedded into the final recipient block. Ten (n=10) samples of normal epithelia, adjacent to cancerous tissue were used as normal control group. Immunohistochemistry was performed by the use of anti-HER2/neu monoclonal antibody (TAB 250) and anti-PTEN polyclonal antibody. Chromogenic in situ hybridization was applied based on the use of HER2/neu gene and 17 centromeric probes, respectively. Protein expression levels were evaluated using an image analysis system. SPSS (chi square test and interrater kappa) was performed for statistical analysis.

Results: HER2/neu protein over expression was observed in 10/50 (20%) correlated only to grade (p=0.019). Low levels or loss of PTEN protein expression were observed in 17/50 (34%) cases associated to grade and stage (p=0.044 and p=0.02, respectively) Gene analysis identified 8/50 (16%) HER2/neu low-level gene amplified cases. Chromosome 17 analysis detected aneuploidy in 19/50 (38%) cases. Simultaneous HER2/neu overexpression and reduced PTEN expression was observed in 7 cases, whereas six of them demonstrated HER2/neu gene amplification (overall 95% CI kappa=0.12). Concerning control group, HER2/neu protein overexpression was identified in one case, whereas two cases demonstrated low-level PTEN protein expression.

Conclusions: Our results indicate that a subset of PDAC is characterized by simultaneous HER2/neu over- and PTEN reduced expression including sporadic cases of HER2/neu gene amplification. Because, on binding to the HER2/neu receptor, monoclonal antibodies, such as trastuzumab, stabilize and activate PTEN, frequently loss of its expression in PDAC maybe influence the efficacy of targeted therapeutic strategies, especially in the cases of gene amplification, which are associated to response to those agents, earning survival benefit regarding breast cancer.

P247

The value of agnors index in the typing of basal cell carcinomas and prediction of recurrence

Doinita Radulescu¹, Simona Stolnicu², Claudia Costea¹
¹ Department of Pathology, University of Medicine, Iasi, Romania
² Department of Pathology, University of Medicine, Targu Mures, Romania

Basal cell carcinoma (BCC) is the most common cutaneous cancer in humans and its incidence increases with age and exposure to ultraviolet rays. Although generally presents a relatively benign course, in classic form of BCC (BCC1), some cases show aggressive behaviour (BCC2). In order to identify reliable prognostic indicators that correlate with outcome, we investigated Nucleolar Organizer Regions (AgNORs) and their correlation with tumor aggressiveness. We selected 35 cases of BCC2 from a total 149 cases of BCCs using the following criteria: nuclear pleomorphism, high mitotic index, absence of cellular peripheral palisading, hyaline fibrosing stroma and irregular spiky pattern of invasion. BCC2 samples showed statistically significant higher counts of AgNORs than did BCC1, a finding that in many other malignancies is linked to a more activated state of neoplastic cells. Our results suggest that the increase of proliferative activity, evaluated by AgNOR index may represent an important step in the acquisition of the aggressive phenotype in human BCCs. Evaluation of AgNOR in BCC may be helpful in selecting patients with high risk for recurrence (BCC2), who could benefit from additional therapies and closer follow-up, in order to improve the quality of life and to prolong the overall survival.

P248

Spindle and epithelioid cell nevus (Spitz Nevus)

Doinita Radulescu, S. Dumitriu
 Department of Pathology,
 University of Medicine and Pharmacy, Iassy, Romania.

12 cases with spindle and epithelioid cell nevus occurred in children were analyzed clinically and morphologically. The results indicate that Spitz nevus is composed of cells resembling those of a malignant melanoma. There are some morphological aspects such as: discontinuous junctional proliferation, the sparse mitotic activity, the process of maturation of the cells with increasing depth, considered as valuable marks for the benign character of this type of tumor.

P249

Histological control of excised tissue edges in the operative treatment of basal cell carcinomas of the eyelid

Claudia Costea¹, Doinita Radulescu², Simona Stolnicu³, L. Popa²
¹“Sf.Treime” Hospital, Iasi, Romania, ²Department of Pathology, University of Medicine, Iasi, Romania, ³ Department of Pathology, University of Medicine, Tg.Mures, Romania

Surgical treatment of Basal Cell Carcinoma generally aims at primary and radical excision of the lesion. The curability of Basal Cell Carcinoma is particularly good, because the risk of metastasis is extremely low. There is a relation between the clinical diameter of the tumor and a safe margin that can guarantee long-term radical excision. The edges of 250 basal-cell carcinoma specimens were evaluated histologically to assess subclinical extension and to ensure radical excision. This procedure is considerably simpler and faster than the standard method of microscopically controlled surgery. Since this procedure is simple, it can be routinely used for all primary basal cell carcinoma and thus eliminates recurrence, which usually results in considerably longer defects. With this method, no recurrences of lesions, excised were observed, during a 4 ½ year observation.

P250

Clinical and histopathologic aspects in anorectal malignant melanoma

Simona Stolnicu¹, Doinița Rădulescu², Simona Mocan¹
¹Department of Pathology, University of Medicine Targu Mures
²Department of Pathology, University of Medicine, Iasi

We present 3 cases of anorectal malignant melanoma developed in the inferior portion of rectum. In two cases, endoscopic examination relived a large exophytic, brown tumor mass. In one case, the gross appearance was of a small polypoid lesion, 1 centimetre in diameter, with the head of the polyp pigmented. Microscopic examination showed sheets of atypical spindle cells, with granular material in the cytoplasm, positive with Masson Fontana staining. All 3 tumors present an in situ component identified both in the squamous and cylindrical epithelium, covering the tumors. The spindle cells expressed HMB-45. Anorectal malignant melanoma is a very rare tumor, with a long term evolution, discovered late because frequently is asymptomatic.

P251

E-cadherin/catenin complex and dysadherin expression in benign and malignant melanocytic lesions.

Panelos J.D.¹, Batistatou A.¹, Zioga C.¹, Nakanishi Y.², Hirohashi S.², Charalabopoulos K.³, Agnantis N.J.¹
Departments of ¹Pathology and ³Physiology, Clinical Unit, University of Ioannina Medical School, Greece, ²Pathology Division, National Cancer Center Research Institute, Tokyo, Japan.

Adhesion molecules are believed to play an important role in melanocytic tumor progression. To gain detailed insight in this allocated role we examined the immunohistochemical expression of E-cadherin, the associated proteins α - and β -catenin, and the recently discovered dysadherin, in compound and dermal nevi, Spitz nevi, blue nevi and cutaneous melanomas. We noted changes in E-cadherin expression in the majority of benign and malignant melanocytic lesions. These alterations were more pronounced in melanomas and were correlated with reduction of β -catenin expression. Interestingly, in benign melanocytic lesions preserved expression of β -catenin was demonstrated. α -catenin immunostaining was not detected in our material. Increased dysadherin expression was noted primarily in melanomas, but there was no significant inverse correlation with E-cadherin expression. Our findings indicate that changes in the expression of E-cadherin, β -catenin and dysadherin occur in melanocytic lesions, probably reflecting the various stages of their progression.

P252

The effect of polarized-infrared light on secondary skin wound healing. An experimental study.

Koniaris E.¹, Papaevangelou M.¹, Athanasiou A.², Iordanou P.³
¹Dept. of Pathology, Hellenic Anticancer Institute, 'St. Savvas' Hospital, 171 Alexandras Av., 11522, Athens, Greece, ²Dept. of Plastic Surgery, Hellenic Anticancer Institute, 'St. Savvas' Hospital, 171 Alexandras Av., 11522, Athens, Greece, ³Assistant Professor, Nursing TEI of Athens, Greece.

The purpose of our experiment is to investigate the association between the polarized infrared light and the secondary skin wound healing. For this purpose 40 Wistar mice were used. All of them had the same skin wound and they were divided into two groups. The first one was named experiment group and all those mice were treated with polarized infrared light (480-3400nm for 5 min) while the others, named control group, were not. Samples from the skin of the mice that were sacrificed on the 5th, 10th, 15th and 20th day were taken. Those preparations were formalin embedded, paraffin treated, and then stained for Haematoxylin-Eosin (HE), Vascular Endothelial Growth Factor antibody (VEGF), Smooth Muscle Actin- α (SMA- α) and Vimentin (Vim). Our histological findings support the evidence that the polarized infrared light promotes, especially in the initial phase, the process of secondary wound healing. In fact the experiment group mice were found to have a quicker response to the healing process, as it was demonstrated that they developed much faster granulation tissue, and early maturation of the newly formed capillary network from the first days. Moreover the transformation of

myofibroblasts, forming collagen bundles parallel to the surface, and the re-epithelialization of the surface of the wound were faster in the experiment group mice.

P253

Aggressive Digital Papillary Adenocarcinoma. Report of two cases.

K. Revelos³, P. Kitsanta¹, E. Keramidis², G. Miller², S.K. Suvarna¹
Departments of ¹Histopathology and ²Plastic Surgery, Sheffield Teaching Hospitals, NHS Trust, Sheffield, U.K and ³Pathology Department, 251 Hellenic Air Force General Hospital, Athens, Greece.

Aggressive Digital Papillary Adenocarcinoma (ADPAca) and aggressive digital papillary adenoma (ADPA) are rare sweat gland tumours. There are only 75 published cases in the literature. The tumours typically involved the dermis and subcutaneous tissue of fingers, toes, and/or the adjacent skin of the palms and soles. They presented as a solitary, asymptomatic, gradually enlarging area of swelling or cystic mass. Histologically, the tumours were not well circumscribed, were composed of nodules of tubuloalveolar and ductular structures with areas of papillary projections into cystic spaces separated by fibrocollagenous stroma. Focally, the glandular spaces contained eosinophilic, amorphous material. Single or double layers of cuboidal or columnar cells lined the glands and cystic lumens. The mitotic rate was low. ADPAca was previously differentiated from ADPA by its glandular differentiation, necrosis, mitotic rate, cytologic atypia and invasion of soft tissue, bone and blood vessels but now all lesions are regarded as malignant. They are locally aggressive with 50% of local recurrence and can give metastasis in 14% of cases. The treatment is wide excision or amputation at the appropriate level. We report two cases of this rare neoplasm.

P254

Malignant eccrine spiradenoma; an exceedingly rare tumor. Report of a case and comparison with a benign eccrine spiradenoma.

George Apostolou, Ismini Vassilaki, Syrou Alexandra, Helen Mahera
General Hospital of Attikis "KAT", Department of Pathology

Malignant eccrine spiradenoma (MES) is an exceedingly rare tumor of the skin appendages, that apparently arises (malignant transformation) within a long-standing solitary lesion of benign eccrine spiradenoma (BES). We report a case of MES that occurred in a 46-year-old woman on the skin of the left antebrium, four years ago. The removed part of the skin and soft tissue was fixed in 10% buffered formalin and routinely processed for microscopic examination. The paraffin-embedded tissues were investigated by means of histopathology using hematoxylin and eosin stain and immunohistochemistry. The tumor consisted of two circumscribed nodules. Two distinct components were seen: typical benign eccrine spiradenoma and carcinoma, with areas of transitions. Tumor cells were atypical with a high mitotic rate and penetration through the capsule into the adjacent stroma. The epithelial nature of the tumor cells was demonstrated by positivity for epithelial membrane antigen (EMA) and CAM5.2. To confirm the clinicopathological entity of MES, it is important to compare MES and BES.

P255

Kaposi's sarcoma(NON AIDS)as unique skin lesion

M. Mastora, D. Petrakis, A. Ntemou*, F. Koutsouka, E. Nanos, H. Papathanasiou, H. Liapis, S. Stefanaki*, N Akritidis
Department of Internal Medicine, Department of Pathology*, General Hospital, "G. Hatzikosta" Ioannina, Greece.

Aim of this study is to signalize the existence of the relation between NON AIDS Kaposi's sarcoma and other malignancy, but mainly to signalize the difficult diagnostically problem that primary disease, without biopsy, represents.

Material and methods: Our material is composed by 6 patients, 5 men and 1 woman, between 67 and 90 years. All of them were admitted to our institution, because of skin lesions, for examination and treatment. Complete clinical, laboratory controls and biopsy of skin lesion were accomplished.

Results: The specimen of the skin lesion confirmed the diagnosis of Kaposi's sarcoma to all the cases. The clinical and laboratory findings were compatible with malignant haematological disease in 3 of the patients. In these, skin lesion was extended. In the other 3 patients (3 men), Kaposi's sarcoma was primary, manifested with located, at the limbs, skin lesion.

The ablation of the skin lesion and the histological examination has shown vascular slits and structures mixed with fascicles of spindle cells, extravasated erythrocytes and PAS positive globules.

Conclusion: The NON AIDS Kaposi's sarcoma is present also in our country. Skin biopsy is imposed in unique skin lesions. The sensitivity about this disease contributes to precocious diagnosis and treatment.

P256

Causes and histopathological findings of leukocytoclastic vasculitis. A retrospective study of 12 cases.

Raptis L¹, Stefanaki S², Mastora M¹, Gizas N¹, Gousis C¹, Demou A², Kitsiou E², Akritidis N¹

¹Internal Medicine Clinic and ²Pathology Department of General Hospital 'G Hatzikosta', Ioannina, Greece.

Introduction: Leukocytoclastic vasculitis (LCV) is a histopathologic term commonly used to denote a small-vessel vasculitis. LCV could be a manifestation of many diseases such as collagen vascular disease, HIV, Hepatitis C.

Aim: The scope of this study to present the causes of leukocytoclastic vasculitis in a five-year retrospective study and their histopathological findings.

Material and methods: A total of 12 patients (F/M 7/5) with a mean age 57,5 years participated in a retrospective study during the years 2003-2005. All patients had palpable purpura of the body and extremities, with lesions 1-3 mm in diameter. Skin biopsy was performed in all patients.

Results: There was a positive exposure to drugs such as antibiotics (beta-lactam) (60%), cumarin treatment (10%) and viral infections (30%). A skin biopsy sample revealed the presence of perivascular infiltration of polymorphonuclear leukocytes with formation of nuclear dust (leukocytoclasia), extravasation of erythrocytes, and fibrinoid necrosis of the vessel walls.

Conclusion: In our study, drugs especially antibiotics caused leukocytoclastic vasculitis in 60%. The second most frequent causes were viral infections in 30%.

Malignant eccrine spiradenoma of the breast: a case report

Eufemia Balassi¹, Catherine Zioga¹, Ann C. Goussia¹, Sevasti Kamina¹, Emmanuel Kontostolis², Dimitrios Stefanou¹
Departments of Pathology¹ and Obstetrics-Gynaecology²,
Medical School, University of Ioannina, 45110 Ioannina, Greece

Eccrine spiradenoma is a generally benign skin appendage neoplasm. Malignant cases are very rare. We describe a case of malignant eccrine spiradenoma that occurred in the breast of a 71-

year-old woman. The patient presented with a breast mass and was scheduled for surgical excision of the lesion and intraoperative frozen section. The surgical specimen was consisted of breast tissue covered by a piece of skin. Sectioning revealed a cutaneous encapsulated tumor 4 cm of maximal diameter and several small satellite nodules. Histology of the frozen section from the main lesion showed an almost solid proliferation of epithelioid cells with nuclear pleomorphism and occasional mitotic figures. At the permanent sections of the main and satellite lesions, lobules of monomorphic large cells with oval, pleomorphic nuclei and numerous mitoses surrounded by a delicate reticulin network were observed. Ductular structures as well as areas with small, dark basaloid cells were rarely identified. Histology of the axillary lymph nodes showed an extensive metastatic involvement. Immunohistochemically, pancytokeratin, keratin 8 and ER were expressed in most neoplastic cells. Focal reactivity of CEA was observed in ductal luminal cells. A diagnosis of a malignant eccrine spiradenoma was performed. The patient underwent radiotherapy and chemotherapy with tamoxifen.

P258

Perianal paget's disease

Pazarli E., Katsiki E., Dermitzogloy A., Kakoylidis D., Kafanas. A.
Department of Pathology & Dermatology, General Hospital of Serres, Serres, Greece.

Aim: Extramammary Paget's disease (EMPD) with perianal region localization presents a very rare condition with variable clinical appearance and difficulties in differential diagnosis. We report two cases of extramammary Paget's disease (EMPD) both involving the perianal region with successful surgical treatment.

It may be associated with an underlying carcinoma of the rectum, which may exist simultaneously with the diagnosis of Paget's disease or may appear later.

Due to the rarity of EMPD we review the medical literature.

Material-Method-Results: 1st case: A 37 year old man presented with an erythematous, scaly and pruriginous exanthema in the perianal region. In a period of two years, the exanthema became an ulcerated white plaque with irregular margins about 7cm in diameter. Topical treatment was performed without success. The following step taken was a skin biopsy for histology. The results of the histological examination were typical findings of Paget's disease. After this, the patient was screened for an underlying malignancy. The colonoscopy and the gastroscopy were negative. A broad surgical excision of the affected skin was performed. The patient has been well until now and is in follow up every 6 months.

2nd case: A 68 year-old man has been complaining for pruritus in the perianal region for the last 5 years. At the first examination, the exanthema was erythematous, scaly, with irregular borders and ulcerated. It was located in and around the anus (3cm). The lesion did not respond to topical treatment. So, skin biopsy was taken and histological examination showed typical findings of Paget's disease.

Conclusions: Patients with persistent chronic pruriginous and eczematous lesion in the perianal region that weren't treated with various topical medications for some time, have to be biopsied for histological examination.

In cases of perianal Paget disease it is necessary to evaluate the rectum and anus to determine if the lesion is a manifestation of underlying rectal or anal adenocarcinoma.

The wide local surgical excision is the primary treatment and a long term follow-up is necessary because of the frequent recurrences and the possibility of development of malignancy in the future.

Gallbladder metastatic melanoma mimicking acute cholecystitis.

Koletsis T¹, Dokmetzioglou G², Pappas D¹, Pliakos G²,
Maganaris A³, Bobos M¹, Nenopoulou¹

¹Department of Pathology, ²3rd Department of Surgery, Medical School, Aristotle University, ³Department of Otolaryngology, Theagenion Hospital, Thessaloniki, Greece

Both primary and metastatic melanoma of the gallbladder are rare. Although it is known that metastatic malignant melanoma can occur in every organ of the body, gallbladder involvement in the absence of disseminated disease is rare. We present a case of metastatic melanoma of the gallbladder that mimicking acute cholecystitis. A 84-year-old woman presented clinically with obstructive cholecystitis and cholecystectomy was performed. When the specimen sectioned a polypoid mass was found to be attached to the mucosa. Morphological and immunohistochemical findings confirmed the diagnosis of malignant melanoma. Medical history of the patient revealed a skin lesion that was locally excised 6 years ago and was proved to be malignant melanoma. So, this case was considered as a solitary metastasis. The patient was re-examined a year after the cholecystectomy and was found to be free of any recurrence. Surgical excision remains the treatment of choice for isolated metastasis of malignant melanoma. Complementary chemotherapy and immunotherapy is still being examined in such cases.

P260

Mucosal melanomas

Zioga C., Kamina S., Dimou S., Goussia A., Simou N., Agnantis N.J.
Department of Pathology, University Hospital of Ioannina, Greece

Primary mucosal melanoma arising from the melanocytes located in the epithelia or the dispersed regional melanocytes are extremely rare. They develop in areas that have no sun exposure and definitive risk factors have not been identified. Due to their rarity, mucosal melanomas have not been adequately characterized and significant questions have been raised regarding their pathogenesis and behavior patterns, rendering further studies necessary. During the last decade we have diagnosed six mucosal melanomas: two located at the nasal diaphragm, one at the outer urethral canal, two at the vagina and one at the colon. All six cases occurred in relatively old patients (>70 yrs old), four women and two men. Herein, we describe the macroscopic and microscopic features (gross appearance, size, presence of ulceration, cell morphology, number of mitoses, presence of neoplastic emboli, immunophenotype of cells) of these neoplasms, as well as provide evidence for a rich vascular network (immunohistochemical study). All the above data are correlated with the therapeutic efforts and patient prognosis.

Dissecting the pathologist's brain: mental processes that lead to pathological diagnoses

Received: 19 January 2006 / Accepted: 19 January 2006 / Published online: 21 March 2006
© Springer-Verlag 2006

On the interest of morphology

The specificity of the discipline of pathological anatomy is the study of seats and causes of diseases through morphological interpretation at a macroscopical and microscopical level. Such interpretation and categorization of visible features are being effected through mental processes, which are still poorly understood, despite their interest.

First of all their study might allow to reach a more sound, objective and motivated selection of residents and applicants to the discipline. We know very little about the characteristics which will make a good pathologist, but tests devised for assessing visual memory [17] might help in the selection. We do not even know, for instance, if gender makes any difference and if women are better fit for this speciality than men or vice versa. Indeed, recent evidence shows that women perform better in some forms of memory [14], and this might have to be taken in consideration. In addition, again for the recruitment, we might find ways to better motivate students and applicants.

The second reason why this study is important is to improve reproducibility in pathological classifications and diagnoses because we might thus be able to select and focus our attention on those specific steps of the mental process that are more prone to affect reproducibility.

Other medicine specialists involved in morphological interpretation such as radiologist have already been pursuing an analysis of the process leading to interpretation of images. Following the percouse of perception and decision making during morphological interpretation, they concluded that long decision times work against perfor-

mance [18]. It is worth mentioning that this might apply as well to cytological reading of pap smears.

The third reason, which makes an analysis worthwhile, is that we might find a way to improve the image of pathology. Morphology is presently regarded as being too subjective, not being based on numbers, and we have to acknowledge that its ranking among scientific disciplines is not high despite the legacy of morphological sciences to medicine and their great impact on the process of medical evolution.

Sources

The feasibility of such study is presently linked to indirect information because no studies were so far specifically addressed to clarify the process leading pathologists to formulate diagnoses. As a result, we have to derive suggestions and information from various alternative sources.

One source is philosophy and psychology. Since Aristotle, from the very beginning of philosophy, human beings have been trying to understand how form is interpreted. In the nineteenth century, mainly German psychologists and philosophers worked on the "Gestalt theorie," the theory of the form, and they have been trying to establish laws whereby people can understand the forms [23]. For instance, Wertheimer's seventh law establishes the principle that the past experience addresses to the correct interpretation [24]. A clarifying example comes from Kanizsa's figure (Fig. 1), indicating that our mind does not only consider what is present but what is missing as well [7]. This applies so well to the interpretation of histopathological slides: what you do not see has to be taken into consideration, and what is missing is sometimes more important than what you actually see in the microscopic figure.

A considerable source of information are art critics, which have been trying to understand how people look at pictures and perceive art. What are the mental mechanisms that make us appreciate a masterpiece? Martin Kemp has

Lecture presented at the XXth Congress of the European Society of Pathology held in Paris on September 4, 2005.

Fig. 1 Kanizsa's triangle

been publishing about this subject [9], and in recent times, Semir Zeki, a neurophysiologist, has been trying to explore the relationship between art and the brain from a neurophysiological point of view [25]. He came out with a very interesting theory which might apply as well to the interpretation of histological slides or of pathological lesions in general: the theory of multistage integration of visual consciousness. Visual brain does not process images as a whole, but through several multistage processing systems. Each system is specialized in a given attribute such as colour or motion or form and so on, working either in parallel or in sequence, finally leading to the interpretation (diagnosis). Support to this theory comes from neurophysiological investigations, which, in recent times, have been providing very important information, especially through functional magnetic resonance images (fMRIs) showing for instance that in right-handed people observing faces rather than objects, it is the medial temporal lobe which is involved and activated [8].

Category-specific breakdowns provide some information: already in the past, it was known that ischaemic infarcts in the medial temporal region of the right hemisphere cause a failure in the rapid recognition of familiar faces [13], and that patients with bilateral insult to the medial temporal lobe cannot transform present experience into future conscious recollection. Radiologists have been trying to understand how [4] expert radiologists process X-ray images, and it appears that they process such images in the way that we all process faces: by quickly devoting processing resources to features that distinguish one stimulus from another [16]. Such process is likely to apply as well to the morphological interpretation of histological slides.

Analysis of the mental process

When trying to analyse the mental processes leading to interpretation of images in pathology, we have to select and analyse different and sequential steps. Four steps can be

identified in sequence: (1) to look, (2) to see, (3) to recognize and (4) to understand.

The first step, that of looking, is easily understood because of course, the stimulus goes from the eye to the calcarine sulcus in the occipital lobe.

Thereafter, the stimulus is transferred to other areas devoted to the interpretation of colour, form and faces, mainly located in the fusiform area and in the medial temporal lobe [25].

The second step, that of seeing, is deeply intermingled with the understanding process.

The art critic Martin Kemp observed that "content and recognition are inextricably involved in all our visual acts, since in no occasion you have seeing without meaning, without recollecting" [9]. So let us consider the step of seeing together with that of recognizing. A good example is the following. In 1609, a British astronomer, Thomas Harriot, looked at the moon with his telescope. What he saw and what he described was a sphere, dark and bright areas being separated by an irregular line. He gave no other information or interpretation. A few weeks later Galileo Galilei looked at the moon with his telescope, and what he saw and described in his book *Sidereus Nuncius* (Star Announcement) were mountains and valleys and seas and craters and so on. He saw an irregular line and he could interpret it. Why? Most probably because Galileo had been growing in the atmosphere of Italian Renaissance at the time when the laws of perspective had been discovered and applied to paintings, so he could understand what the irregularities meant and he could interpret them [10].

The process of seeing and that of recognition are strictly linked to the fusiform gyrus, as shown by fMRI, and confirmative evidence comes from the observation that such nucleus is selectively activated by faces [8].

Specifically, if we analyse the diagnostic process of pathological interpretation, we can subdivide different sequences: first of all, a visual search of the image, then interpretation of the perceived information and finally, a combination of the collected information. Such process has been analysed and experimentally investigated by Tiersma and coworkers [22]. The experiment was carried out using a helmet endowed with a beam that could follow the direction of the eye and the gazing in different points so that such a scan eye tracking system was enabling the visualisation of the eye points of gaze of a subject and thus provided the possibilities to create computerised graphic representations of scanning patterns.

This study indicates that the well-known (almost obvious) fact that experienced pathologists reach diagnoses (i.e. categorization of the lesions) in a shorter time is related to their focusing on the most significant areas. Moreover, these processes (searching, focusing and moving) constitute the unconscious phase, to be followed and completed by the final, conscious stage of diagnosis. We have to conclude that the diagnostic process is not just a sequence of three steps (search, interpretation and association), but such steps have to be repeated several times back and forth, again and again, till the process reaches the conscious state. We have to conclude that while making a pathological

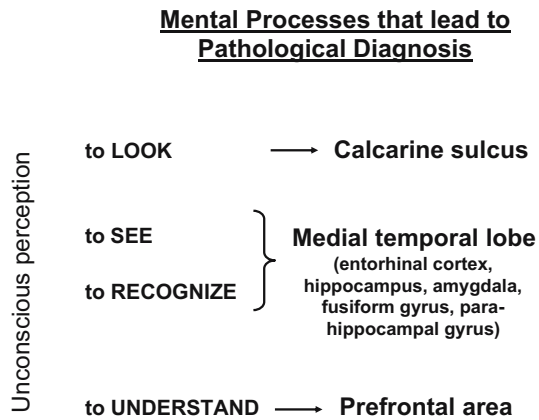

Fig. 2 Mental processes that lead to pathological diagnosis

diagnosis, we experience first an unconscious stage and then a conscious state. The unconscious stage is fast and laborious: in a few seconds, the eye goes here and there, interpreting the different areas and images. Thereafter, the process reaches consciousness, and the diagnosis is made. Such sequence had already been investigated by radiologist who described the steps of visual scanning, pattern recognition and decision making as the sequence of events taking place during pulmonary nodule detection [11]. They also concluded on the influence of expertise on X-ray image processing [16].

Following the analysis of the unconscious steps of looking, seeing and recognizing, we have to take into consideration the last step, the conscious one, that of understanding. This stage is most probably linked to the pre-frontal area, as shown by the recent observation by fMRI that when people look at an image, at a painting for instance, and then reach the conclusion that they like it, the pre-frontal area is selectively activated [2]. We have to conclude that the process of looking is linked to the calcarine sulcus, that of seeing and recognizing to the medial temporal lobe, to hippocampus and amygdala, fusiform gyrus and parahippocampus gyrus, and that finally, when pathologists reach the diagnosis, it is the pre-frontal area that is selectively involved (Fig. 2).

Components which make up a good pathologist

Fig. 3 Components which make up a good pathologist

On the complexity of pathology

We have to acknowledge that the analytical processes leading to the interpretation of pathological images are not comprehensive of the whole complexity of pathology. The processes relate to pattern recognition, which represents a basic part of pathology, but not the whole of it. Let us now consider the factors that seem essential for forming a good pathologist. Good sight is important, but “we see what we know” [5], so culture is important. Knowledge of previous discoveries and observations is fundamental in our discipline, but knowledge is to remember [19]. Memory and experience are extremely important in pathology. Now, what exactly is memory? The study of memory and of its different forms was conducted by several philosophers and psychologists, but mainly, I’m referring to a philosopher, Henry Bergson, whose main contribution was related to the unravelling of the different types of memory. He lived and worked in Paris, at the beginning of the twentieth century, in the same town and at the same time when Marcel Proust, who was a relative of Bergson, was engaged in the *Recherche du Temps Perdu*. According to Bergson, we can subdivide a memory by repetition, and that of recollection/recording via intensity, via affection [1]. This represents a common experience for pathologists, who can remember cases they observed years before, because they were so impressed and interested so that every single particular is vividly remembered.

From a neurophysiological point of view, during the memorizing process, by repetition, the area of hippocampus is directly stimulated, while in the process, via intensity, the hippocampus is indirectly stimulated through the area of the amygdala [21].

However, not everything is known about memory and its mechanism. A recent study shows that if you give a stimulus, its performance deteriorates during the day, but if you have a short nap, then the performance improves, and after a good sleep, it improves again and again till it reaches a plateau [15]. Our experience as pathologists teaches us something else. Sometimes, not only memory is consoli-

Fig. 4 Freude an der Morphologie

dated, but even recollection is enhanced by sleep. We look at a peculiar case and we cannot give a proper interpretation, then we go back home, and the day after, the solution immediately is obvious. Moreover, a recent observation indicates that some neurones in the medial temporal lobe are selectively activated by strikingly different pictures of given objects, and it cannot be excluded that single neurones are dedicated to a given face or image [20]. Such observations indicate that we are far from having a complete and well-assessed knowledge of the extremely complex and fascinating process of memory, a process of fundamental importance in the process of diagnosis of pathological lesions.

Besides good sight, culture, memory and experience, of course, technique is important for pathologists, and of course, a school which gives a method, a system.

But a list of the different components of the characteristics which make up a good pathologist would not be complete without taking into consideration a special and dedicated ability, a gift or a knack, what John Azzopardi used to call “*oculus patologicus*,” the pathological eye, the ability to select and recognize morphological subtleties (Fig. 3). This was also the opinion of a German-Swiss pathologist, Paul Ernst, who subdivided his students into three groups: the great majority unable to see what is shown, then a relatively small, but valuable group, able to see and understand what is shown, and then a minute minority, who can even see what is not shown [3].

On the essence of pathology

The priming factor, the most important component for making up a good pathologist, is still failing to our search, but we should agree that among the different factors, three characteristics are really essential for forming a good pathologist: the “eye,” the experience and finally, the school. These are clearly the pillars that make up a good pathologist. When I presented these three alternatives to colleagues collected at the *Meeting along the way to Santiago* (May 2004) and asked the colleagues’ opinion, the audience divided into three groups. Some people said that the school is the most important factor, somebody else said that the eye, sort of an inborn ability, is the most valuable one and then, of course, experience is fundamental.

The only dissenting opinion was expressed by Francisco Gonzalez-Crussi, a prominent pathologist, author of several scientific papers and a successful writer of rather hectic books such as *On the nature of things erotic* [6]. He came out with the observation that “Love,” love for pathology is the priming factor. This opinion has merits and reasons because in fact, memory is stimulated, motivated by interest, by affection, by love. What is the eye, if not a total dedication to morphology, faith in morphology. Finally, the school, in its ultimate essence, is nothing but

the transfer of an interest, the transfer of a passion, the transfer through generations of a small flame, the tantalizing but vital flame of curiosity. However, while searching for a proper term to indicate dedicated interest and passion, the English term “love” seems inappropriate, being perhaps too abused and uncommitted. A better term is the one proposed by Karl Lennert [12]: he used the term “*freude an der morphologie*,” enjoyment for morphology. Such inspiring German expression is inextricably linked to Schiller’s *Hymn to Joy* and of course, to the music from Beethoven’s *9th Symphony*.

So let us conclude that by dissecting a pathologist’s brain, ultimately, what you find is a dedicated heart (Fig. 4).

Acknowledgements My sincere thanks go to all curious and inspiring friends and colleagues who have been sharing my interests, furnished suggestions and helped to enlighten this multifaceted search.

Personalized medicine and development of targeted therapies: the upcoming challenge for diagnostic molecular pathology. A review

Received: 4 July 2005 / Accepted: 20 September 2005 / Published online: 22 April 2006
© Springer-Verlag 2006

Abstract Due to continuous technical developments and new insights into the high complexity of many diseases, molecular pathology is a rapidly growing field gaining center stage in the clinical management of tumors as well as in the pharmaceutical development of new anti-cancer drugs. The application of novel compounds in clinical trials has revealed promising results; however, the current diagnostic procedures available for determining which patients will primarily benefit from rational tumor therapy are insufficient. To read a patient's tissue as "deeply" as possible, in the future, gaining information on the morphology and on genetic, proteomic, and epigenetic alterations will be the upcoming task of surgical pathologists experienced in molecular diagnostics to provide the clinicians with information relevant for an individualized medicine. Among the different high-throughput technologies, DNA microarrays are now the first array approach close to enter routine diagnostics. Technically advanced and well-established microarray platforms can nowadays be evaluated by distinct bioinformatic tools capable of identifying both novel genes associated with disease development and clusters of genes predicting clinical outcome of an individual tumor. The automatic, highly parallel analysis of proteins and complex proteins lysates for early detection of cancers such as breast, prostate and ovary as proteomic patterns in the serum also appears at the horizon. In addition, an improved analysis of tumor samples via antibody or reverse-phase protein arrays is likely to provide the pathologist in the future with

information about activated oncogenic signaling pathways and other cell functions, such as drug response or the potential to metastasize. While expression microarrays and proteomic analysis rely on relatively unstable material incompatible with paraffin-embedded tissue samples, an investigation of DNA methylation using specialized high-throughput platforms has revealed the potential of being used in future diagnostics. Each of these approaches on its own might not suffice to extract all information required for an efficient individualized diagnostics. Therefore, a "multiplex approach" combining the different biological levels DNA, RNA, and protein, may be necessary to functionally classify malignant tumors. This appears to become a major challenge for diagnostic pathologists.

Keywords Review · Molecular pathology · Targeted therapy

Introduction

Standard diagnostic procedures for human tumors are currently based on a combination of histopathology and immunohistology closely connected with clinical data. This strategy, in most cases, provides precise information on dignity, tissue origin, tumor type, stage, and grade as well as information on the completeness of surgical tumor removal. Up to now, these data comprise the most relevant information on a patient's prognosis and are a rational basis for therapy design. As the diversity of alterations in tumor cells is not completely mirrored by tumor cell morphology, pathologists and clinicians often observe that two patients harboring the "same" type of tumor in a seemingly "identical" stage show different clinical outcome with respect to survival and, in particular, with respect to therapy response. To improve this unsatisfactory situation, a patient-specific disease prediction based on tissue examination by pathologists would be extremely helpful.

During recent years, many molecular markers and marker patterns ("signatures") have been disclosed which, at least, partially predict prognosis and therapeutic

effectiveness. Considering the fact that cell function is controlled by a complex network of functionally active signaling pathways, it is unlikely that expression analysis of a single or a small number of proteins will precisely predict the clinical outcome of an individual tumor. Hanahan and Weinberg (2000) have described six essential alterations in cancer cells that are common to most human tumors: self-sufficiency in growth signals, insensitivity to growth-inhibitory signals, evasion of apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis. However, each of these alterations is achieved by different modifications in signal transduction, gene or protein expression, protein modification, and localization. Thus, a different and improved characterization of malignant tumors as compared to current standard diagnostics is required to reflect the multitude of genetic, proteomic, and metabolomic alterations typical for malignant cells. Several newly developed high-throughput technologies, such as DNA microarrays, protein and antibody arrays, proteome technologies such as mass spectroscopy MALDI-TOF, metabolomic analyses, methylation arrays, reverse-phase protein microarrays (RPs), etc., provide the technical platforms for this approach and will gain more interest in the future. By integrating these technologies into standard diagnostic procedures, future molecular pathology will be able to dramatically increase the relevance of tissue-based examinations. Pathology will play a crucial role in therapy design and, by providing molecular diagnostic approaches, also in therapy adjustment and selection of effective drugs.

In this review, we will describe genomic, proteomic, and epigenomic approaches which have been shown recently to improve diagnostics and prognosis. We will focus on DNA microarrays as the most advanced technology in this field and suggest the development of an integrated approach for future diagnostic molecular pathology.

Genomics—DNA microarrays

Technology

The generation of gene expression profiles from cultured cells and tissue samples is nowadays a well-established method. In the majority of experiments, DNA fragments specific for individual genes on activated glass surfaces are used [13, 62]. RNA is prepared from the biological material to be analyzed, reverse transcribed into cDNA, labeled with fluorescent dyes, and hybridized to the array. The hybridization signals are detected by a laser scanner, the images are normalized in various ways, and the relative expression levels obtained for individual genes are further clustered into groups of genes with similar or identical expression patterns.

DNA microarrays consist of thousands of DNA elements (10,000–80,000 or even more) robotically tethered to a solid surface, e.g., coated glass slide, silicon, or nylon. The DNA sequences are either oligonucleotides or cDNA and represent different genes of interest. Each

gene is usually represented by more than one feature to increase the specificity of the analysis. The cDNA clones are often selected from public databases, amplified from cDNA libraries, and purified before spotting. Oligonucleotides (20–80 bp) are alternatively chemically synthesized and spotted or may be directly synthesized on the array surface. In addition to sequences representing known genes, sequences representing expressed sequence tags (EST) coding for genes of unknown function can also be spotted on the solid surface, offering the potential of investigating new marker genes.

The target DNA usually is a cDNA derived from tumor cell mRNA which is amplified and simultaneously labeled by reverse transcriptase-polymerase chain reaction (PCR). The RNA is prepared from rapidly processed cell cultures or fresh frozen tissue. Novel fixation techniques and preparation methods are currently tested which might also allow in the future the use of RNA prepared from paraffin-embedded tissues to be utilized in diverse microarray experiments [28, 30, 54]. Target DNA, of course, can also be prepared from genomic DNA fragments. For labeling, fluorescent dyes are used nowadays. The expression intensity of each gene is determined after hybridization of the target DNA to the immobilized array DNA.

The hybridization signal generated on each spot reflects the expression of the corresponding gene. The quantification of the signals is performed using special software which allows to correct for spot integrity and for technical deviations during array production and hybridization and to interpret the signal intensity. For this purpose, cDNA of normal tissue or any other reference cDNA has to be introduced. The final results provide a genetic expression profile indicating overexpression, underexpression, no change, or complete absence for each gene in the tissue samples to be compared to each other (for review, see [52]).

Bioinformatics

The enormous amount of data obtained not only from each high-throughput experiment but also from data documentation, data processing, and data interpretation is a unique challenge requiring close cooperation between pathologists and bioinformatic specialists. Therefore, methods and bioinformatic tools have been developed for the extraction of complex information, the evaluation via statistical methods, and the translation of molecular information into clinically relevant data. cDNA microarrays today have been used for a variety of different objectives. To choose the method of statistical analysis that is appropriate for each study, it is helpful to distinguish different types of array analysis. Simon et al. [72] have distinguished three different types of study objectives: “class discovery” (find a new class), “class comparison” (find differences between two predefined classes), and “class prediction” (find a predictive gene set for a certain predefined class). For each type of study, different statistical strategies for evaluation should be used. According to Simon et al., using methods incompatible with the goal and the design of the

study is one of the most common errors in the analysis of microarray data.

Several methods for data analysis and interpretation have been developed, which can be separated into two classes: supervised and unsupervised methods [11]. A supervised approach means that some external information such as tumor grading or patients' survival define the relevant classes before the analysis; this method is used for "class prediction" and "class comparison" studies.

In contrast, for "class discovery" studies, an unsupervised approach is used, which defines different groups of tumors exclusively according to their gene expression profiles without using external information. An unsupervised classification detects similarities in gene expression profiles. For this purpose, the hierarchical clustering [24] combined with a graphic presentation is an excellent tool (Fig. 1). K-means or self-organizing maps are further examples of unsupervised methods frequently used in microarray analyses [79, 82]. It is important to note that cluster analysis should not be used for class prediction and class comparison studies.

Especially for "class prediction" studies, supervised approaches should be applied. The supervised algorithm establishes a model on the training set of samples, which assigns gene sets with a defined expression profile to predefined groups of tumor samples. After the class prediction algorithm has been trained, it can be used to

predict the class of new samples. To assess the error rate (e.g., percentage of incorrectly classified tumors), a crossvalidation approach is often used. In this approach, the available data sets are split repeatedly into a training set and a test set. The algorithm is then trained on the training set and applied to the test set, and correct and false predictions are counted. A special type of cross-validation is the leave-one-out strategy, where just one sample is omitted from the training set (training on $n-1$). This one sample is then used as the test set. This procedure is repeated n times, each time using another sample as a test set. This approach achieves maximal efficiency of training yet requires high computational resources.

Such sample classification can be helpful to identify the set of genes that discriminates between predefined groups of patients with good or poor survival, e.g., estrogen receptor (ER) positivity or ER negativity. This approach has been described to discriminate, e.g., between tumor entities like different solid tumors [78], subgroups of acute myeloid leukemia and acute lymphocytic leukaemia [31], diffuse large B-cell lymphomas, between early- and late-stage ovarian carcinomas [52], and breast carcinomas with or without the potency to metastasize [85].

In a critical commentary, Simon, Radmacher, Dobbin, and McShane [72] already worried that "many investigators are not experienced in the analytical steps needed to convert thousands of noisy data points into reliable and

Fig. 1 Hierarchical clustering analysis exemplified for Topotecan-resistant (*R*) and Topotecan-sensitive (*S*) cell lines. All cell lines resistant to Topotecan (*left panel*) and all cell lines sensitive to Topotecan (*right panel*) express a unique set of genes. Each *row* in the cluster indicates the expression profile of a specific gene across all 19 cell lines. Each *column* indicates the individual cell line in which the gene is expressed. *Red, green, and black squares* indicate that expression of the gene is greater than, less than, or equal to the median level of expression across all cell lines, respectively. The *scale bar* reflects the fold increase (*red*) or decrease (*green*) for any given gene relative to the median level of expression across all samples

interpretable biological information". Furthermore, the molecular profiles are often relatively unstable due to tumour heterogeneity and platform specificity. The authors listed a number of prerequisites necessary to avoid misinterpretation of the data. In particular, the issue of class prediction is discussed as it includes derivation of classifiers, which predict prognosis, response to therapy, potential to metastasize, and many more. In a very recent publication by Michiels et al. [53], several of the most prominent classifiers were doubted. The authors concluded that the list of genes included in a molecular signature largely depends on the constitution and size of the training sets used and even claimed that a majority of the published classifiers are not significant. A comprehensive overview is also given by Scharpf et al. [67], suggesting several methodological approaches and illustrating the associated software to generate interpretable, robust, and less platform-dependent results.

A relatively new unsupervised approach to analyze array data is provided by linear independent component analysis (ICA) [37, 48, 49]. In contrast to cluster analysis methods, which assume that each gene belongs to just one cluster, ICA is based on the idea of a combinatorial control which is more realistic from a biological point of view. Gene expression levels are described as linear functions of common hidden variables which are (in the ideal case) related to distinct biological causes of variation such as transcriptional regulators or responses to treatments. Thus, ICA-based results show increased biological relevance and might describe new biological links previously undetected by clustering methods. An interesting study was conducted on endometrial carcinomas and benign endometrial samples [66]. The authors compared the power of ICA to other established methods and thereby detected (a) an improved separation of benign and malignant groups, (b) a characteristic expression pattern corresponding to the histological classification, and (c) a novel pattern of coregulated genes related to fatty acid metabolism which are clinically associated with endometrial carcinoma. Thus, a careful examination of histopathologically well-characterized tumor material via high-throughput methods and sophisticated bioinformatic approaches might even unravel novel disease mechanisms during such advanced diagnostic schemes.

Application of DNA microarrays

The application of high-throughput cDNA and oligonucleotide array technologies and the establishment of gene expression profiles has already revolutionized experimental tumor diagnostics in the last couple of years. With the use of these tools, otherwise indistinguishable tumor subgroups have been identified [2]. In addition, the development of gene signatures enabled prognostic conclusions which could not be drawn using standard histopathological and immunohistochemical methods [35, 84, 85], opening the door for a more comprehensive tumor analysis by diagnostic pathology. In the following, some

examples of microarray applications will be described to demonstrate the wide range of applications where this technique could support and even improve the predictive power of histopathological diagnostics.

Molecular classification and prognosis

Based on hundreds of international studies including thousands of patients, an international classification system for malignant tumors based on conventional histopathology supported by immunohistochemistry has been established, the UICC–TNM system [73]. In general, the TNM system helps to estimate the prognosis of groups of tumors. However, this classical approach with conventional histopathology, analyzing morphological parameters, is not completely sufficient when the prognosis of an individual case shall be predicted. Therefore, the DNA microarray technique is currently under investigation to improve the current classification system by correlating array results with histomorphology and clinical behavior of tumors.

The first step towards a molecular classification was done by Khan et al. [39] who defined expression signatures from cancer cell lines which were indicative for the organ type of origin. A landmark study including gene expression profiling with DNA microarrays as an extension of histopathological classification has shown the possibility to differentiate between AML and ALL and to improve the precision of prognosis prediction [31].

Tumors with similar histological appearance but with different clinical behavior, such as small blue round tumors of childhood, are difficult to classify on a routine microscopical basis. Genetic profiling proved to correctly identify the four subgroups neuroblastoma, rhabdomyosarcoma, Ewings sarcoma, and special types of non-Hodgkin's lymphoma [40] and, thus, can be a valuable help in tumor classification.

The WHO grading system of oligodendrogliomas is somewhat limited due to subjectivity of histopathological evaluation. Gene expression profiling now unraveled two molecularly distinct subgroups which correspond to the morphological grading and, thus, can be applied to provide a more objective tool for grading and prediction of prognosis [89]. This approach may be extended towards other brain tumors where reproducible histological assessment is often difficult, if not impossible.

In a group of 55 breast cancer patients with balanced clinicopathological features, three subclasses of tumors with different 5-year survival could be identified by analyzing mRNA expression of only $\approx 1,000$ candidate genes [7, 8]. In a population-based study, Sotiriou et al. [75] were able to suggest distinct aspects of breast cancer classification and prognosis based on gene signatures. The molecular analysis of pre-invasive vs invasive breast tumors revealed extensive similarities of the genetic alterations [51], suggesting that, in the early stage, the potential for invasive growth is already almost fully developed—an insight which might change the current strategy of early breast cancer treatment.

Further genetic subclassifications of tumor entities with distinct clinical features have been described for breast cancer [60, 74], cutaneous malignant melanoma [10, 86], large B-cell lymphoma [2], and B-cell lymphoma [14], pediatric ALL [92] and acute leukemia with MLL translocation [3], and adenocarcinoma of the lung [9, 26], ovary [57, 69], colon [25], and prostate [21].

Metastatic potential

Up to now, it is impossible to determine precisely whether a tumor which has not developed clinically detectable metastases at the time of diagnosis will metastasize during the following years. This information, however, would be of utmost importance to decide, e.g., whether an adjuvant therapy is necessary or not. The first steps to elucidate the metastasizing potency of an individual tumor have been published by van't Veer et al. [85]. In breast carcinomas with T1/T2, NO at time of diagnosis, the authors defined 70 "predictor genes" whose signature predicts with approximately 80% sensitivity and specificity the chance to set lymph node metastases. A recent study by Wang et al. [88] confirmed these data. This provides a rationale to treat patients with adjuvant therapy or not.

Tissue assignment, primary and occult metastases

In clinical practice, it may happen that a metastasis is found while the primary tumor is unknown or it is unclear whether a certain metastasis is derived from a known primary tumor. Most often, histopathology, in addition to morphological immunophenotyping, can disclose the tissue origin. Nonetheless, gene expression profiling may be of additional help to classify cancer cells according to their tissue of origin [29, 39, 63, 78]. It was shown that the molecular signature of the primary tumor is preserved in its metastases and, thus, allows a clear assignment which gives the necessary information for an adequate treatment. Furthermore, it could be shown that DNA arrays are able to distinguish between lung adenocarcinomas and metastases of extrapulmonary origin [9]. The origin of cancer of unknown primary can be derived from characteristic expression patterns as the tumors often harbor distinct gene expression profiles characteristic for the organ type of origin [83].

Therapy response and drug resistance

Drug resistance remains a major problem during therapy for systemic cancer disease. Due to the high potency to adapt to therapeutical intervention, malignant tumor cells frequently develop escape mechanisms in response to radiation or cytostatic drugs. Although many attempts have been made [45, 46], up to now, reliable and practically applicable techniques to predict a tumor's reaction to drugs or radiation do not exist. The reason for this are multiple

cellular mechanisms such as increased DNA repair, elevated levels of drug transporters, overexpression of detoxifying enzymes, and decreased rates of apoptosis which are often involved in the development of drug resistance. To monitor multiple alterations occurring in tumors being drug insensitive, highly parallel analyses, such as the DNA microarray technique and also proteomic analysis, are required. This opportunity opens new dimensions to predict therapy resistance and sensitivity.

A recent National Institutes of Health study [68] investigated 60 tumor cell lines (NCI60) which have been treated independently with more than 70,000 different agents, one at a time. Among other results, the study linked bioinformatics and chemoinformatics by correlating cellular drug response with transcriptomic information derived from DNA microarrays. The aim was to associate clusters of related drugs with clusters of gene alterations and, thereby, to define drug-gene relationships. This approach may contribute to the establishment of a defined expression database on which an individualized molecular pharmacology of tumor drug response can be established.

By comparing wild-type cell lines with derivatives resistant for thymidilate synthase (TS) inhibitors, Wang et al. [87] were able to identify certain patterns of genetic alterations correlating with TS resistance. The associated gene expression profile was partly tissue dependent, e.g., *YES1* was overexpressed in the epithelial cell lines while it was not upregulated in a lymphoblast cell line. Cisplatin (cDDP) resistance was shown by microarray analysis to be accompanied with altered expression of genes coding for membrane proteins and a glycoprotein hormone subunit [33] not previously known to play any role in cDDP resistance.

In an excellent study by Zembutsu et al. [94], 85 human cancer xenografts were tested with regard to characteristic expression profiles in response to nine anticancer drugs often used in clinical therapy. More than 1,500 genes were identified whose expression profile has correlated in some way with chemosensitivity. The authors identified sets of genes which could partly be associated with chemosensitivity of particular tumor types (colon, breast, non-small cell lung cancer, etc.) to the different drugs applied. To predict the efficacy of adjuvant therapy in esophageal tumors, the DNA microarray technique was applied to 20 cancer specimens with clinically known responses [41]. There were 52 genes identified which were likely to correlate with patients' outcome and possibly with chemosensitivity and chemoresistance. This approach shows some potential to determine drug response in advance. In addition, bone marrow samples from 19 patients with acute lymphoblastic leukemia were investigated with regard to resistance to an ABL tyrosine kinase inhibitor [34]. On the basis of 95 differentially expressed genes, it appeared to be possible to distinguish responder from non-responder. Raponi et al. [65] showed the possibility to detect the pathways modulated by inhibitory drugs in AML elucidating the mechanisms of drug action. Thus, gene expression profiling can be helpful for the pre-treatment assessment of anti-cancer therapy. Although a

vast number of experiments still have to be conducted, it might become possible to predict chemoresistance (Fig. 2) and to avoid non-effective drugs and unnecessary side effects for the patients. The discrimination between responders and non-responders before therapy will further stimulate the development of an individualized therapeutic strategy with a personalized combination of drugs.

Pitfalls of DNA microarray analyses

Numerous studies have shown characteristic expression patterns related to certain aspects of tumor biology. Dozens of genes were associated with prognosis, drug resistance, potential to metastasize, etc.; however, the clinical confirmation of the results is so far only on the way. The clinical application of DNA microarrays will require a high level of reproducibility and reliability of technology, of sample processing, and of analysis. A major obstacle is the still low inter-laboratory and inter-platform reproducibility of microarray data. Several of the reasons underlying this problem were described in 2003 by Tan et al. [80]. A comparison of the three most widely used commercially available platforms revealed significant discordance, which could in part be attributed not only to differences between the types of array but also to the different algorithms used for data evaluation. In 2001, the MIAME standard was already suggested, which includes a predefined set of information for a certain microarray experiment which allows for an independent evaluation of the results and for a conclusion to be drawn [12]. In a more recent publication by the Toxicogenomics Research Consortium, the impact of array type, data handling, image analysis, and experimental protocol onto the reproducibility of microarray analysis between different laboratories was investigated [5]. This study revealed that, like in the earlier reports, the

type of microarray used has by far the largest influence onto the comparability of microarray data. More importantly, the authors conclude that, upon application of a common, commercial microarray platform, standardized experimental image analysis and data processing approaches correlation coefficients up to 0.9 can be achieved between experiments performed in different laboratories.

Thus, careful experimental design and a strict standardization of the whole procedure will be of utmost importance in the future for the reproducibility of microarray experiments. Furthermore, one should keep in mind the fundamental challenges, which have frequently obstructed cancer research during the last decades. These include inter- and intratumor heterogeneity, specimens either extracted, stored, or diagnosed inappropriately, and unexpected changes of cell line properties. These complications are still relevant and may be even accelerated by high-throughput techniques.

Proteomics

The rapid development of proteome technology has lifted tumor diagnostics to a new level. Despite the high relevance of DNA- and RNA-based information discussed above, nucleic acids are several layers of abstraction away from the physiological events that determine disease characteristics. Proteins govern metabolic processes, protein interaction, and posttranslational modifications and are, therefore, the major targets to be included in future molecular pathological approaches (see also review by Hanash [32]). Three fields of application are beginning to emerge: (a) highly sensitive mass spectroscopy coupled to an array-based separation of complex protein lysates (surface enhanced laser desorption time-of-flight, SELDI-TOF) or microdissected tumor samples are used for early

Fig. 2 A possible approach to predict chemosensitivity and/or chemoresistance of clinically relevant tumor samples. The low-density DNA arrays are specially designed to indicate the altered expression profile of sensitivity/resistance associated genes or EST. Different patterns appear to be correlated with sensitivity or resistance of malignant tumors for certain cytostatic drugs

detection and identification of new biomarkers for human tumors [59, 61], (b) a direct mass spectroscopic analysis and the establishment of protein profiles of tumor and normal tissue [14, 76, 91], and (c) the application of protein and antibody arrays for the specific identification of certain proteins and their activated forms in tumors [50, 55, 77].

Although technically advanced screening methods have improved early cancer detection, in some cancer types, such as ovarian carcinoma, new methods which allow easy and routine screening are urgently needed to ameliorate the currently frustrating clinical outcomes. For this purpose, the highly sensitive SELDI-TOF approach appeared as the most promising technological development during recent years. Petricoin et al. [61] reported the identification of serum proteomic patterns using SELDI-TOF and developed a bioinformatic tool to distinguish neoplastic ovarian disease from the normal status. By applying the serum spectra from 50 healthy women and 50 ovarian carcinoma patients as training sets, they proposed a proteomic signature which segregated cancer from non-cancer with a sensitivity of 100% and a specificity of 95%. Yet, these results were severely criticized and the expectations were smoothed in recent publications [4, 17, 96]. Further-

more, this provoked an intense debate about future processes of establishing and proving the reliability of novel technologies [22, 23, 64]. Thus, despite being an exciting new approach, K. Coombes et al. [17] recently stated that the “current state of the art in serum proteome profiling allows considerable room for improvement”.

While serum proteomic analysis is currently tested in the identification of new and early cancer markers, SELDI-TOF has been successfully applied to the characterization of distinct tumor areas carefully dissected by the help of laser capture microdissection. This approach was used to identify markers differentially expressed in prostate cancer cells as compared to prostatic prostate intraepithelial neoplasms (PIN) lesions and normal prostate epithelium [16, 97]. Similar experimental schemes were also developed for a proteomic evaluation of bladder carcinoma [43], colon carcinoma [47], and breast carcinoma [19].

In addition to the direct identification of proteins using mass spectroscopy, antibody arrays and so-called reverse phase protein array approaches have also been developed and applied for the identification of tumor-associated proteins and also their activated phosphorylated derivatives. Nowadays still in a developmental stage, both types

Table 1 Examples of targeted therapy approaches

Drug	Tumor type	Target	Known action	Detection method	Remarks
Trastuzumab	Metastatic breast cancer	HER-2/neu	Rc blocking	IH, FISH, ISH	1
Cetuximab + Irinotecan	Metastatic colorectal cancer	EGFR	Rc blocking/immunologic response	IH, FISH	1
Imatinib Mesylate (Gleevec)	CML, GIST with activated c-kit receptor tyrosine kinase, other sarcomas	Bcr/abl, c-Kit, PDGF-R	Tyrosine kinase inhibitor	IH	1
Bevacizumab (Avastin) (+5FU)	Colorectal cancer	VEGF	Rc blocking	IH	2
G3139 (Genta, Berkley)	Hematologic malignancies and malignant melanoma	Antiapoptotic gene <i>bcl-2</i> in	Bcl-2 antisense oligonucleotide-decreasing Bcl-2 mRNA	Immunophenotyping by IH	2
Bortezomib, Epoxomicin	Multiple myeloma	Proteasome	Proteasome inhibitor		
Gefitinib (Iressa)	Non-small cell lung cancer	Mutated EGFR	Kinase inhibitor	Mutational analyses, immunoblotting	4
Erlotinib (Tarceva)	Non-small cell lung cancer	Mutated EGFR	Kinase inhibitor	Mutational analyses, immunoblotting	4
Rituximab (+ CHOP), Y90-Ibritumomab, I131-Tositumomab	Non-Hodgkin lymphoma	CD20	Lympholytic	Immunophenotyping IH	3
Gemtuzumab-Ozogamicin (calicheamicin)	AML (>60 years)	CD33	Anti-CD33 guided cytotoxic antibiotic, reduction of P-glycoprotein	Immunophenotyping by IH	3
Alemtuzumab (Campath)	B-CLL, T-NHL, osteogenic tumors ^a	CD52	Lympholytic	Immunophenotyping by IH	3
Rapamycin RAD001	Breast, prostate, renal cancer	TOR	Kinase inhibitor		4
BMS 354825	GIST	Kit	Tyrosine kinase inhibitor	IH	4
BAY43-9006	Melanoma	RAF kinase	Kinase inhibitor		4

1 FDA-approved drugs requiring a pretherapeutic diagnostic eligibility test, 2 FDA-approved drugs targeting a specific pathway—no tests available, 3 FDA-approved antibody-targeted therapies for hematologic malignancies guided by immunophenotyping, 4 under development, Rc receptor, IH immunohistochemistry, ISH in situ hybridization, FISH fluorescence in situ hybridization

^aPatent no. EP:03029464.9, V. Krenn, Institute of Pathology (submitted)

of arrays might become valuable alternatives to cDNA or oligoarrays and also for immunohistochemical analyses during daily pathological routine. A major obstacle, among others, for these applications is the broad range of antibody specificity and affinity which complicates detection of defined antibody–antigen interactions [44]. Several studies which used antibody arrays to profile protein patterns in tumor samples derived from hepatocellular carcinomas [81] or breast carcinomas [36, 42] applied verification strategies such as standard immunohistochemistry on tissue microarrays to demonstrate specificity of their platform. An interesting derivative of antibody microarrays are the RPAs. In this case, instead of antibodies, whole protein lysates are spotted onto glass surfaces and distinct proteins are detected via antibodies [58]. This procedure can be combined with laser capture microdissection and each patient set can be applied in miniature dilution curves to improve quantification accuracy and to enlarge the dynamic range. RPAs are generated from frozen tissue samples and, therefore, allow the use of detection antibodies specific for phospho-proteins. This technology was consequently described to compare survival pathway activation as measured by phosphorylated Akt and Erk in normal prostate epithelium, in PIN, and in invasive prostate cancer [58]. In addition, it has been used in pathology for the investigation of the relative expression levels of Bcl-2 and Akt family members in follicular lymphomas [95]. One can anticipate the future implication of these methods in the elucidation of intracellular signaling networks downstream of tyrosine kinase receptors such as HER2 and also emerging from intracellular oncogenes such as RAS during cancer therapy. Many of the substances in the new generation of cancer drugs are designed to interfere with specific molecular targets, which are believed to have a critical role in tumor growth by regulating key signaling

pathways (Table 1; Fig. 3). Yet, this requires the development of optimized protocols and superior detection techniques [27] and the use of reference standards as described recently by Sheehan et al. [70].

Epigenomics

Epigenetic modification of DNA by the addition of a methyl group to cytosine residues in CpG dinucleotides is one of the most important mechanisms of tumor suppressor gene inactivation known today [6, 38]. A DNA-based methylation analysis has several advantages when compared to the RNA-based gene expression analysis. The preparation of DNA suitable for such experiments can be successfully obtained from both frozen and paraffin-embedded tissues. Furthermore, according to current knowledge, methylation of genes is a rather stable modification not prone to produce as many artifacts due to RNA decay as in mRNA expression analysis. Methylation arrays are now consequently designed for the high-throughput analysis of DNA methylation at distinct CpG positions. Furthermore, a real-time PCR-based assay for gene- and methylation-specific detection has recently been developed [18]. For methylation arrays, genomic DNA from the tissue under investigation is treated with sodium bisulphite, resulting in the conversion of unmethylated cytosine residues into uracil [56]. Following this procedure, specific fragments from the regulatory, CpG-containing regions of genes are PCR-amplified using fluorescent-labeled primers. The uracil residues (UpG) are replaced by tyrosine residues (TpG) during PCR amplification. These fragments are then hybridized to their complementary oligonucleotides spotted onto a microarray, which are specific for the originally non-methylated CpG dinucleotide.

Fig. 3 Novel cancer drugs targeting signaling pathways. Several growth-stimulatory signaling pathways are activated in tumors due to tyrosine kinase receptor overexpression (*HER2* and *EGFR*) and mutation (*EGFR* and *KIT*). Inhibition of tumor cell proliferation is expected to occur via inhibition of receptor tyrosine kinases on

tumor cells or on endothelial cells (*VEGFR*). Furthermore, intracellular protein kinases such as bcr/abl and RAF and phosphatidylinositol-related kinases such as mTOR can be targeted by specific inhibitors. Proteins like the antiapoptotic Bcl-2 can also be inhibited to support chemotherapy

The hybridization conditions are designed in a such way that a single mismatch between TpG and CpG variants yields a specific detection signal. Such applications have been used for the identification of CpG island methylation correlated with tumor progression [1] and to evaluate a potential significance for disease-free survival in ovarian carcinoma patients after chemotherapy [90]. In addition, sophisticated technologies (methylation target array) have enabled the detection of CpG island methylation of known tumor suppressor genes such as *WT1*, *BRCA1*, *p16INK4A*, and others in hundreds of tumor samples at the same time [15]. An interesting further development is the combined use of expression and methylation arrays, even in conjunction with an analysis of histone acetylation [71] using the same tissue samples. Such an approach allows the correlation of methylation data with expression data and the identification of functionally relevant genes harboring hypermethylated CpG islands with a higher accuracy [93]. Although a multitude of publications on high-throughput analysis of DNA methylation in tumor tissues already exist, it is evident that this technology has to be further developed to enter routine clinical diagnostic procedures. Nevertheless, it becomes clear that, in the future, a combination of transcriptomic, proteomic, and epigenomic analysis is required to identify the tumor-specific alterations with the highest relevance for prognosis and therapy.

Outlook—an integrated approach in future diagnostics

In recent years, the efforts devoted to unraveling the connection between activated receptor tyrosine kinases, intracellular oncogenes, and distinct intracellular signaling pathways and their role in growth control have uncovered a large number of potential therapeutic target structures. Herceptin and Gleevec targeting the *HER2/neu*, and *BCR/ABL*, *c-KIT*, and *PDGF-R* *oncoproteins*, respectively, are the first designer drugs which are already used with considerable success in the clinic. In the meantime, other drugs which act more or less specifically against a broad range of receptors and signaling components have entered clinical trials (Table 1) [20]. This development is intimately connected with the expectation that tumor therapy can be dramatically improved in the near future. To date, the percentage of patients responding to the new inhibitors is often below 30%. This indicates that the current portfolio of diagnostic methods based on immunohistochemical or DNA analysis (e.g., fluorescence insitu hybridization) of single target molecules is still insufficient. For the identification of those patients who will benefit from novel therapies, special methods capable of detecting the entire spectrum of rate-limiting oncogenic pathways in tumors before and during therapy have to be developed and adapted to routine diagnostic pathology. This will clearly play an increasing role in the future tasks of pathological institutes.

Before transmission and establishment of such an integrated approach into daily routine can occur, extensive research has to be performed to allow a firm prediction on

the activation of a certain pathway in clinical material. In this case, a strategy consisting of a parallel analysis of gene expression and methylation combined with a proteomic analysis of activated signaling pathways and overexpressed proteins will be the method of choice.

The implementation of bioinformatic procedures, which will undergo further standardization together with highly parallel tissue analyses, opens the door for a broad profiling of human cancer tissue, thus improving the possibility to predict the biological behavior of single tumors. Such a “multiplex approach” may help to functionally classify malignant tumors, provided that a “diagnostic algorithm”, beginning with conventional histopathology in combination with immunohistochemistry, provides the basis. This basic evaluation will then be supplemented by specialized disease-specific analyses such as different kinds of microrarrays to predict tumor-associated features including tumor progression, drug response, and metastatic potential, which will have an important impact on tumor prognosis and adequate individual therapy.

The recent technical developments also indicate changing demands for routine pathological diagnostics within the next years. Only a consequent integration of the methods described within this review into pathological diagnostics will guarantee that, in the future, pathology is also the discipline holding the main body of knowledge about disease etiology and disease mechanisms.

However, the demonstration that there exists a real benefit for the patients with, e.g., longer survival times or better response to therapy is still open. Only when well-designed clinical studies prove the progress an implementation of molecular tumor profiling with individualized therapeutic strategies will become accepted to be routinely integrated in diagnosis and treatment of cancer. One major prerequisite for an advantageous way is the interdisciplinary cooperation of basic scientists, clinically oriented physicians, diagnostic pathologists, and clinicians which all must speak the same “language”. They must have an understanding of their partners. The “translation” between different groups of researchers will be one of the most challenging tasks in modern experimental and diagnostic pathology.

Cytokeratin 7/20 and mucin core protein expression in ulcerative colitis-associated colorectal neoplasms

Received: 10 August 2005 / Accepted: 6 March 2006 / Published online: 12 April 2006
© Springer-Verlag 2006

Abstract Different histogenetic pathways have been suggested between ulcerative colitis (UC)-associated neoplasia and sporadic colorectal neoplasia. Little is known about the cytokeratin (CK) and mucin expression in UC-associated neoplasms. To clarify the characteristics of UC-associated colorectal carcinogenesis, we examined the immunohistochemical expression of CK7, CK20, MUC2, MUC5AC and MUC6 in 90 colorectal neoplasms, including 22 UC-associated adenocarcinomas (colitic cancer; CC), ten high-grade dysplasias (HGD) in UC, nine low-grade dysplasias (LGD) in UC, 24 sporadic tubular adenomas (TA) and 25 adenocarcinomas (AC). CK7 was positive in most of UC-associated neoplasms: 59% of CC cases, 80% of HGD and 89% of LGD, respectively, whereas, in non-UC associated neoplasia, 21% of TA and 12% of AC. The frequency of MUC6 expression in UC-associated neoplasia was 32% in CC, 30% in HGD and 44% in LGD, respectively, whereas, in non-UC associated

neoplasia, 4.2% in TA and 0% in AC. MUC5AC expression in UC-associated neoplasia was detectable in 73% of CC, 90% of HGD and 89% of LGD, respectively; in non-UC associated neoplasia 67% in AC and 20% in TA. There were obvious differences in the expression of CK7 and MUC6 between UC-associated neoplasms and sporadic tumors. The incidence of MUC5AC expression in UC-associated neoplasms was also higher than sporadic tumors. *These results suggest that gastric-type mucins play an important role in the initial step of CC-tumorigenesis, and CK7 and gastric-type mucins may be useful in the differential diagnosis between UC-associated neoplasms and sporadic ones.*

Introduction

Ulcerative colitis (UC) is a chronic relapsing inflammatory bowel disease of still unclear etiology. The initial case report of colorectal cancer emerging from UC was first published by Crohn and Rosenberg in 1925 [6]. Since then, it has been well established that long-standing UC predisposes to development of colorectal carcinoma [12]. To date, these cancers are thought to have a distinct histogenetic pathway from that of sporadic colorectal cancers involving precursor stages of low- and high-grade dysplasia (LGD and HGD), respectively. There are some reports of differential gene abnormalities between sporadic colonic and ulcerative colitis (UC) associated neoplasia [1, 2, 9, 18]. Although *p53* alteration occurs rather often with loss of heterozygosity (LOH), a low prevalence of *APC* and *ras* mutations in UC-associated tumors has been described, along with a high LOH frequency of chromosomes 3 and 18 and *p16*, compared to sporadic colorectal cancers [31].

Cytokeratins (CKs) are cytoplasmic structural proteins in normal epithelial cells, and a variable expression has been demonstrated depending on the cellular differentiation [19, 21]. CK20 has been widely applied as a useful

Table 1 Summary of cytokeratin (CK) and mucin expressions in ulcerative colitis-associated neoplasms and sporadic adenoma–carcinoma group

	CK7	MUC6	MUC5AC	MUC2	CK20
Ulcerative colitis-associated neoplasm	29/41(71%) ^a	14/41(34%) ^a	33/41(80%)	37/41(90%)	36/41(88%)
Sporadic adenoma–carcinoma group	8/49(16%) ^b	1/49(2.0%) ^b	21/49(43%)	37/49(76%)	45/49(92%)

marker of colon adenocarcinomas. CK7 is found in the normal epithelium of the lung, cervix, breast, bile ducts and bladder transitional cell epithelium. However, CK7 is essentially absent in the normal gastrointestinal epithelium [22]. CK7 has also been reported to be a possible marker of transient dedifferentiation in the sequence between gastritis, metaplasia, dysplasia and cancer of the stomach [14]. Most recently, we reported the high incidence of CK7-expression in hyperplastic polyps and serrated adenomas of the colon [26]. These colon lesions have been considered to progress through the pathway which is different from the so-called adenoma–carcinoma sequence. There have been many studies about CK7/CK20 expression in sporadic colorectal and other carcinomas; however, the expression in UC-associated colorectal neoplasms has not extensively been evaluated.

On the other hand, initial histochemical studies showed typically changes in the biochemical characteristics of mucin occurring in intestinal disorders [10, 11]. It has been reported that quantity and quality of mucin secretion are affected in inflammatory bowel disease (IBD) [8]. Additionally, the recent identification of several mucin genes [7] and the production of monoclonal antibodies to mucin protein cores has led to the immunohistochemical

localization of several mucin species. More than ten genes encoding distinct mucin proteins have recently been identified by molecular cloning. Among them, MUC5AC, MUC6 and MUC2 are specifically expressed in gastric surface mucous cells, pyloric gland cells and intestinal goblet cells of the mature gastrointestinal tract, respectively [23, 28]. There have been some reports about expression of MUC2 in UC-associated neoplasms, but the results were controversial [13, 24, 29, 30]. Little is known about the expression of the gastric-type mucins in UC-associated intraepithelial neoplasms.

In the present study, we targeted the expression of CK7, CK20, MUC2, MUC5AC and MUC6 in UC-associated colorectal neoplasms as compared to sporadic colon carcinoma, to further investigate colitic cancer carcinogenesis.

Materials and methods

Tissue specimens

The material consisted of 90 paraffin-embedded tissue sections of colorectal neoplasms from 77 patients. The material consisted of 41 UC-associated neoplasms, 24

Fig. 1 Schematic presentation of scoring results of each neoplasm for cytokeratin (CK) and mucin. **a** CK7; **b** CK20; **c** MUC6; **d** MUC5AC; **e** MUC2. *LGD* Low-grade dysplasia, *HGD* high-grade dysplasia, *CC* colitis cancer, *TA* tubular adenoma, *AD* adenocarcinoma

Fig 2 Histological and immunohistochemical (CK7) findings of *LGD* (a,b) and *HGD* (c,d) in ulcerative colitis. Positivity for CK7 is diffuse and cytoplasmic

sporadic adenomas and 25 adenocarcinomas. Of the UC-associated neoplasms, nine were low-grade dysplasia (LGD), ten were high grade dysplasia (HGD), and 22 were colitic cancer (CC). Specimen collection procedures were approved by the ethics committee of our university, and informed consent was obtained from all patients.

Mucin histochemical and immunohistochemical studies

Immunohistochemical staining was carried out with the following monoclonal antibodies (MAbs): CK7 (OV-TL 12/30, 1:50, NovoCastra, UK), CK20 (Ks20.8, 1:50, NovoCastra, UK), MUC2(Ccp58; 1:100, NovoCastra, UK); MUC5AC (CLH2, 1:100, NovoCastra, UK) and MUC6 (CLH5, 1:100, NovoCastra, UK). The standard streptavidin–biotin method of detection was used. Peroxidase binding sites

Fig. 3 Histological and immunohistochemical (CK7) findings of CC. Examples of mucinous adenocarcinoma (a,b) and papillary adenocarcinoma (c,d) are displayed. Positivity for CK7 is diffuse and cytoplasmic

Fig. 4 Comparative demonstration of histology (a), CK7- (b), MUC5AC- (c), and MUC6-expression (d) of *LGD* in ulcerative colitis. MUC6-positivity is confined to the bottom of crypts

were visualized by diaminobenzidine method, and the sections were slightly counterstained with hematoxylin.

The following controls were performed: negative controls: (1) slides run without the primary antibody; (2) careful examination of non-epithelial structures (vessels, muscles and connective tissue); positive controls; inclusion of normal tissues known to express CK7 (bile duct), CK20 and MUC2 (small intestine), MUC5AC (gastric foveolar cells), and MUC6 (pyloric gland cells), respectively.

Scoring of immunostaining and statistical analysis

The extent of positivity for CK7, CK20, MUC2, MUC5AC and MUC6 was scored according to the percentage of neoplastic cells stained: -, no positive cells or essentially none (<5%); 1+, some positive cells (5-30%); 2+, diffuse areas of positive cells (30-60%); 3+, extensive areas of positive cells (>60%). The chi-square test with Yates correction was used for statistical analysis. Differences were considered to be significant at $p < 0.05$. Fisher's test was applied whenever appropriate.

Results

The immunohistochemical results with comparison of the UC-associated neoplasms and the sporadic adenoma–carcinoma group (CA and AD) are summarized in Table 1, and the scoring results of each neoplasm are shown in Fig. 1.

CK7 and CK20 expression

CK7 Typical staining patterns of the various neoplasms are shown in Figs. 2, 3, 4 and 5. CK7 was not expressed in normal colorectal epithelium; however, the hyperplastic epithelium near the colorectal carcinoma occasionally expressed CK7. In CK7 positive colorectal neoplasms, the positivity was generally diffuse and cytoplasmic, and it was expressed without preference within the glandular epithelium of the crypts. There was a significant difference in CK7 expression between the UC-associated neoplasms and the sporadic adenoma–carcinoma group (CA and AD) (Table 1). The vast majority of cases with UC-associated neoplasms were positive for CK7; whereas, a small percentage of cases with sporadic adenomas and adenocarcinomas were CK7-positive (71 vs 16%, $p < 0.01$). CK7 expression was detected in 88% (eight of nine) of LGD and 80% (eight of ten) of HGD and 59% (13 of 22) of CC, while only 21% (five of 24) of sporadic adenomas and 12% (three of 25) of adenocarcinomas were CK7-positive. None of sporadic adenoma–carcinoma group showed 3+, whereas, 39% (16 of 41) of UC-associated neoplasms expressed 3+ (Fig. 1a).

CK20 CK20 was expressed in normal colorectal surface epithelium. The most cases of UC-associated and UC-nonassociated neoplasms were positive for CK20 which are as follows: in 100% (nine of nine) of LGD and 90% (nine of ten) of HGD and 82% (18 of 22) of CC, while 96% (23 of 24) of TA and 88% (22 of 25) of AD, respectively (Fig. 1b). There was no significance in the positive rate of CK20 expression between UC-associated and sporadic adenoma–carcinoma group. However, carcinomas (CC and AD) showed a lower expression than intraepithelial neoplasia (LGD and HGD) and adenomas (TA).

MUC6, MUC5AC and MUC2 expression

MUC6 UC-associated neoplasms showed a significantly increased expression than cases of the sporadic adenoma–carcinoma group (34 vs 2.0%, $p < 0.01$; Table 1). The positive rate of MUC6 in UC-associated neoplasms was in 32% of cases with CC, 30% of HGD and 44% of LGD, respectively (Fig. 1c). In non-UC-associated neoplasms the frequencies were: 4.2% in TA and 0% in AC. Only one case of TA showed a 1+ expression, whereas, all AD cases were negative for MUC6 expression. For the most in UC-associated neoplasms, MUC6 expression was restricted to the bottom of crypts (Fig. 4).

MUC5AC UC-associated neoplasms showed high positive rates of MUC5AC; LGD: 89%, HGD: 90%, CC: 73%. The positive rate of CA was relatively high (67%), but the positive rate of AD was lower (20%) (Fig. 1d). In UC-associated neoplasms, the percentage of neoplastic cells positive for MUC5AC tended to decrease with the severity of dysplasia. However, CC showed higher positivity than sporadic adenocarcinoma (73 vs 20%, $p < 0.01$). The expression pattern of gastric mucins (MUC5AC detected in the upper portion of glands and MUC6 in the bottom of glands) was detected especially in LGD but not detected in CC (Figs. 4, 5 and 6).

MUC2 There was no significant difference in MUC2 expression among all categories, but carcinomas (CC and AD) showed a tendency for lesser expression than compared to cases with dysplasias and adenomas. All cases of LGD, HGD and CA showed MUC2 expression, while the frequency of MUC2 expression was 82% in CC and 52% in AD, respectively (Fig. 1e).

Discussion

Our results showed that CK7 and MUC6 expression was significantly higher in UC-associated neoplasms than sporadic ones. MUC5AC was also detected at a higher level in UC-associated neoplasms.

Expressions of CKs 7 and 20 have been commonly investigated to determine the primary site of the metastatic lesion. Colorectal adenocarcinomas typically express CK20 but not CK7, and this CK7–/CK20+ profile has been used to distinguish colonic adenocarcinoma from

metastatic carcinomas of other origin [15, 17, 20, 27]. Although CK7 is negative in the normal stomach and most gastric carcinomas, it is expressed in fetal stomach and intestinal metaplasia and dysplasia [25]. Kirchner et al. [14] suggested that metaplastic and neoplastic changes in the gastritis-cancer sequence are associated to dedifferentiated epithelial cells which are defined by CK7 expression and those cells exhibited a low proliferation and beta-catenin accumulation similar to stem cells. Most recently, we demonstrated the high incidence of CK7-expression in hyperplastic polyps and serrated adenomas of the colon [26]. In this respect, hyperplastic polyps/serrated adenomas and UC-associated neoplasms show a similar phenotypic expression.

It is well-known that preneoplastic and neoplastic tissues can express fetal-like morphological and phenotypic characteristics. MUC5AC is expressed in embryonic intestine during a limited period with close relation to development of intestinal differentiation [4]. Recently, aberrant expression of gastric-type mucin such as MUC5AC and MUC6 is suggested to play an important role in regeneration of intestinal epithelium [3]. Our group and others suggested that gastric-type mucins play an important role in epithelial regeneration and healing after prior mucosal injury in Crohn's disease in addition to mucosal protection [5, 16]. In studies of expressions of MUC2, MUC5AC and gastric trefoil factor (TFF1) in Crohn's disease and UC, Shaoul et al. have suggested that gastric-type mucins may play an important role in epithelial wound healing after mucosal injury in IBD [24]. Therefore, our results suggested that gastric-type mucins play an important role in the initial step of CC tumorigenesis in the regenerative process against the chronic persistent and relapsing inflammation.

In conclusion, these findings enable us to consider the possibility that gastric differentiation contributes to the development of UC-associated neoplasms. CK7 and gastric-type mucins may be useful in the differential diagnosis between UC-associated neoplasms and sporadic tubular adenomas and adenocarcinomas.

Expression patterns of dysadherin and E-cadherin in lymph node metastases of colorectal carcinoma

Received: 27 November 2005 / Accepted: 3 March 2006 / Published online: 29 March 2006
© Springer-Verlag 2006

Abstract Reduction/loss of E-cadherin is associated with the development and progression of many epithelial tumors, while in a limited number of neoplasms, E-cadherin is re-expressed in metastases. Dysadherin, recently characterized by members of our research team, has an anti-cell–cell adhesion function and downregulates E-cadherin in a posttranscriptional manner. Colorectal cancer (CRC) is one of the most common tumors in the developed world, and lymph node metastases are harbingers of aggressive behavior. The aim of the present study was to examine the dysadherin and E-cadherin expression patterns in lymph node metastases vs primary CRC. Dysadherin and E-cadherin expression was examined immunohistochemically in 78 patients with CRC, Dukes' stage C in the primary tumor and in one lymph node metastasis. Dysadherin was expressed in 42% while E-

cadherin immunoreactivity was reduced in 45% of primary tumors. In lymph nodes, 33 and 81% of metastatic tumors were positive for dysadherin and E-cadherin, respectively. Dysadherin expression was not correlated with E-cadherin expression in the primary tumor with a reverse correlation evident in the lymph node metastases. Our results suggest that different mechanisms govern E-cadherin expression in the primary tumor and the corresponding lymph node metastases.

Keywords Dysadherin · E-cadherin · Colon · Adenocarcinoma · Metastases · Lymph nodes

Introduction

Colorectal cancer (CRC) is one of the most common tumors in the developed world and the second leading cause of death following lung cancer in the United States [29]. The tumor develops in the mucosa, extends locally, invading through the bowel wall into adjacent tissues, and metastasizes through the lymphatics and blood vessels to regional lymph nodes and distant organs. Primary tumor resection with/without postoperative chemotherapy is the standard therapeutic approach of CRC. If the neoplasm has extended through the bowel wall but has not given lymph node metastases (Dukes' stage B), then, the 5-year survival rates for patients is 70–80% [26]. Lymph node metastases or distant metastases through blood vessels (i.e. liver, lung, ovaries) have been shown to be the most significant prognostic factors for patients with CRC. In particular, when the tumor has spread to the lymph nodes (Dukes' stage C), the survival rate drops sharply (5-year survival, 25–50%) [29]. The usual malignant tumor of the large bowel is a well to moderately differentiated adenocarcinoma. Based on histopathological observations, it has been shown that lymph node metastases are most common in tumors with poorly differentiated areas and a highly infiltrative pattern of growth [28]. The cellular and molecular steps required for metastases of neoplastic cells are starting to be elucidated. The metastatic cascade

starts with a downregulation of the epithelial bonds which enables tumor cells to leave epithelial structures, to invade the stroma, to enter the blood stream or the lymphatics, to extravasate, and to colonize the target organs. Interestingly, invasive growth and metastases often recapitulate embryonic development and are greatly influenced by the stromal microenvironment [15]. Thus, carcinoma cells interact bidirectionally with neighboring fibroblasts, endothelial cells, and lymphocytes through growth factors, chemokines, cell adhesion molecules, and extracellular matrix proteases.

The cadherin family is a group of Ca^{2+} -dependent cell–cell adhesion molecules, which are essential for the induction and maintenance of tissue structures. E-cadherin is present in most epithelial cells and plays a crucial role in the architecture of the epithelial junctions [24]. Reduction/loss of E-cadherin has been associated with the development and progression of many epithelial tumors, by contributing to carcinogenesis, tumor invasion, and metastases [7, 8, 15]. Aberrant E-cadherin expression (heterogeneous, cytoplasmic, or absent) has been detected immunohistochemically in a variety of poorly differentiated, invasive, and metastatic carcinomas, including head and neck carcinoma, gastric adenocarcinoma, lobular breast carcinoma, lung cancer, CRC, prostate adenocarcinoma, pancreatic, and bladder cancer [8, 9, 15, 23, 37, 38]. In CRC, downregulation of E-cadherin has been associated with loss of differentiation, increased likelihood of metastases, and poor prognosis [1, 10–12, 14]. Furthermore, there are less than a handful of studies showing reexpression of E-cadherin in the metastatic lymph nodes [11, 10, 16]. Recently, we have reported the cloning and characterization of dysadherin (HSPCii3, IWU-1, KCT1, PIC), a cell membrane glycoprotein which has an anti-cell–cell adhesion function and downregulates E-cadherin in a posttranscriptional manner [18, 35]. So far, there are only a few reports on the function and expression of dysadherin in human malignancies. This novel cancer-associated protein has been detected in head and neck, gastric, testis, pancreatic, esophageal, thyroid, tongue, and cervical carcinomas and in malignant melanoma and is associated with tumor aggressiveness [2, 21, 24, 25, 27, 30–34, 36]. Recently, Aoki et al. reported that in advanced CRC, dysadherin expression has prognostic significance [1]. The aim of the present study was to examine the dysadherin and E-cadherin expression patterns in lymph node metastases vs primary CRC.

Materials and methods

Seventy-eight formalin-fixed, paraffin-embedded archival tissue blocks of CRC and an equal number of blocks from corresponding lymph node metastases (from the same patients) were included in the current study. They represented an equal number of patients (mean age: 64 years, range: 39–82). Forty-five were male and 33 were female. The patients had no family history of CRC. They had not received chemotherapy or radiation treatment

before surgery. The histopathological stage of tumors in all patients was Dukes C. All tumors were moderately differentiated adenocarcinomas. The middle part and the advancing edge of the tumor were always included in the blocks from the primary tumor.

Immunohistochemistry

We performed immunostaining on formalin-fixed, paraffin-embedded tissue sections using the EnVision System (DAKO) and the monoclonal antibodies: NCC-M53 against dysadherin [1] and E-cadherin (CM170B, Biocare Medical). Briefly, 4- μm thick tissue sections were deparaffinized in xylene; rehydrated through graded concentrations of alcohol and heated in a microwave oven for two cycles of 15 min each at 300 W, in citrate buffer, for antigen retrieval. Endogenous peroxidase activity was blocked with H_2O_2 solution in methanol (0.01 M), for 30 min. After washing with phosphate buffered saline (PBS) for 5 min, the primary antibodies, NCC-M53 (dilution 1:1,000) and CM170B (dilution 1:50), were applied for incubation (30 min at room temperature and overnight at 4°C, respectively). Then, the slides were washed for 10 min with PBS and were visualized with the EnVision system using diaminobenzidine tetrahydrochloride as a chromogen. Finally, all sections were counterstained with hematoxylin. Positive staining of endothelial cells and lymphocytes was used as an internal positive control for dysadherin. As an internal positive control for E-cadherin, positive staining of normal colorectal epithelial cells was used. As a negative control, the first antibody was substituted with normal mouse immunoglobulin of the same class.

Evaluation of the staining

Two pathologists (AB and CDS) performed independently semiquantitative evaluation of the staining. When disagreement arose, slides were reviewed together and a consensus view was obtained. For each sample, at least 1,000 neoplastic cells were counted, and the percentage of the cancer cells with positive membranous immunostaining and the staining intensity were recorded. For the purposes of statistical analysis, as described previously, when more than 50% of tumor cells were stained for dysadherin, the tumor was evaluated as “positive dysadherin expression (Dys(+))” [1]. When less than 50% of tumor cells were stained for dysadherin, the tumor was evaluated as “negative dysadherin expression (Dys(-)).” Regarding E-cadherin, when more than 80% of tumor cells showed complete membranous staining, the tumor was evaluated as “preserved E-cadherin expression (E-cad(+)),” while when less than 80% of tumor cells were positive, the tumor was evaluated as “reduced E-cadherin expression (E-cad(-))” [1].

Statistical analysis

Analyses were conducted in SPSS software version 11.0 (SPSS, Chicago, IL). For comparisons between antibodies' expression with clinicopathological variables, we used the chi-square (χ^2) test. All differences were considered statistically significant if $p < 0.05$. p values are two-tailed.

Results

Dysadherin expression

Dysadherin expression was not detected in non-neoplastic colorectal epithelial cells. Dysadherin immunostaining was mostly observed in the membranes of the neoplastic cells and it was heterogeneous throughout the neoplasm (Fig. 1a,b). In particular, as described, preferential expression in the infiltrative border of tumors in the primary site was detected in some cases [1]. Overall, "positive dysadherin expression" was found in 42% (33 out of 78) of primary tumors. In lymph node metastases, the staining was more homogeneous but was noted in less cases, as only 26 out of 78 (33%) metastatic tumors were "dysadherin positive." In all the positive metastatic cases, primary tumors were positive for dysadherin as well (Table 1).

E-cadherin expression

Expression of E-cadherin was evident at the cell–cell borders of epithelial cells in normal colorectal mucosa. In CRC, the expression patterns varied; i.e., tumors with preserved, homogeneous, heterogeneous, and aberrant/cytoplasmic expression were observed. E-cadherin immunoreactivity was reduced in 45% of cases (35 out of 78) (Fig. 1c). Interestingly, the majority of lymph node

metastases (81%, 63 out of 78) showed preserved expression of E-cadherin (Fig. 1d). All primary tumors with preserved E-cadherin expression retained this expression in the lymph node metastasis. Furthermore, the immunostaining was homogeneous regardless of the E-cadherin staining pattern of the primary tumor.

Dysadherin expression was not correlated with E-cadherin expression in the primary tumor ($p > 0.05$). However, a reverse correlation between dysadherin and E-cadherin expression was evident in the lymph node metastases ($p < 0.05$) (Table 1).

Discussion

In patients with CRC, lymph node metastases are harbingers of aggressive behavior, leading to a sharp drop of 5-year survival rates; thus, the search for new molecules, possibly involved in the metastatic pathway, is of high importance [26, 29]. To metastasize, neoplastic cells must dissociate from the primary tumor, invade the surrounding stroma, enter into the circulation, and extravasate in the target organs where they must grow again into tumors. There is growing evidence that adhesion molecules, in particular, E-cadherin, play pivotal role in this process not only by being downregulated at the primary site and but also by being reexpressed at the metastatic foci [10–12, 14]. Such observations have been made, so far, in invasive ductal and lobular carcinomas, in esophageal and lung carcinomas, and in gastric adenocarcinomas that progress to develop lymph node metastases [4, 5, 20, 22]. Regarding CRC, there are only three published studies, all showing downregulation of E-cadherin expression in the primary tumors simultaneous with upregulation of the same protein in the metastatic foci, although the percentages vary considerably [11, 16, 19].

Fig. 1 **a** Positive dysadherin expression in colon adenocarcinoma (DABX400). **b** Loss of dysadherin expression in the lymph node metastasis of the same tumor. Adjacent lymphocytes serve as internal positive control (DABX400). **c** Reduced E-cadherin expression in colon adenocarcinoma (DABX400). **d** Reexpression of E-cadherin in the lymph node metastasis of the same tumor (DABX400)

Table 1 Results of immunostaining, classified by dysadherin and E-cadherin expression

E-cadherin expression	Dysadherin expression		<i>p</i> -value
	<50%	>50%	
Primary tumor			
Preserved	28	15	<i>p</i> >0.05
Reduced	17	18	
Lymph node metastasis			
Preserved	47	16	<i>p</i> <0.05
Reduced	5	10	

In the present study, we have also observed the same phenomenon, with 55% of primary tumors and 81% of lymph node metastases retaining E-cadherin expression. The significance and pathogenetic mechanisms of this phenomenon are issues under investigation. It has been shown that neoplastic cells with reduced/aberrant E-cadherin expression are far more likely to detach from the tumor mass in response to low shear forces such as those found in the lymphatic vessels or venules. The reexpression of E-cadherin in lymph nodes with *metastases* may play an important role in the growth of the cancer cells in the metastatic foci, offering them a survival advantage [6, 13]. In most studied tumors, loss of E-cadherin expression in the primary site is usually due to epigenetic mechanisms rather than mutations. Thus, it is conceivable that the observed reexpression of E-cadherin could be due to loss of epigenetic inhibition. An alternative hypothesis is that metastases arise from tumor cells that have never lost E-cadherin expression and constitute the focal E-cadherin positive component in an otherwise E-cadherin negative tumor. However, it is evident that metastases can occur irrespective of E-cadherin expression levels; thus, it is conceivable that E-cadherin plays a role in metastases by more than one mechanism [3, 17].

In vitro studies have shown that dysadherin expression facilitates cell motility and metastatic potential of human pancreatic cancer cells [34]. In vivo, dysadherin expression has been studied in colorectal, pancreatic, gastric, esophageal, tongue, and thyroid carcinomas, and in cervical squamous cell carcinomas, testicular neoplasms including lymphomas and cutaneous malignant melanomas [1, 2, 21, 25, 27, 30–34, 36]. In all these cancer types, a general phenomenon is that dysadherin expression seems to reflect tumor aggressiveness, being furthermore, a marker of poor prognosis when considered alone or/and in combination with downregulation of E-cadherin. In most tumors examined, increased dysadherin expression was correlated with reduced/aberrant E-cadherin expression. This does not appear to be the case in CRC where the data presented, herein, and the one in accordance with a previously published report show that there is no correlation between dysadherin and E-cadherin expression in the primary tumors [1]. This finding suggests that other *mechanisms* apart from dysadherin regulation, are implicated in E-cadherin expression/activity both at transcriptional and posttranscriptional level in the primary site. Dysadherin may only partly suppress/regulate the

activity of E-cadherin. Many other factors may also be involved, such as methylation of the promoter region, gene mutation, involvement of snail, sip-1, and slug transcription factors, *ubiquitination* of E-cadherin, tyrosine phosphorylation of β -catenin, and catenin abnormalities, such as absence of α -catenin. In contrast, we report that in metastatic neoplastic deposits, there is a negative association between dysadherin and E-cadherin expression resulting from the decrease of the former and increase of the latter. This observation leads to the hypothesis that different mechanisms *govern E-cadherin expression in the primary tumor and the corresponding lymph node metastasis*. If this is the case, then it is plausible that the increased expression of E-cadherin in the metastatic foci is truly a reexpression, possibly associated with dysadherin downregulation and loss of epigenetic inhibition and does not represent neoplastic clones that have never lost E-cadherin expression.

In conclusion, this is the first report on *dysadherin and E-cadherin expression* in lymph node metastases of CRC. Expression patterns were described and their possible involvement in the metastatic cascade have been discussed. As it is regarded that although the molecular pathways of tumorigenesis may vary among different tumors and the cascade of events required for metastases are similar for all neoplastic cells, it is conceivable that our observations hold true for other metastatic cancers as well. Larger prospective studies, fulfilling many clinicopathological parameters are needed to clarify the important issue of metastatic carcinoma.

Endoglin (CD105) as a prognostic factor in head and neck squamous cell carcinoma

Received: 12 January 2006 / Accepted: 28 February 2006 / Published online: 13 April 2006
© Springer-Verlag 2006

Abstract Endoglin (CD105) is a proliferation-associated protein abundantly expressed in angiogenic endothelial cells. Recent studies revealed that CD105 is intensively expressed in tumor vasculature, whereas intratumoral microvessel density (MVD) determined with the use of antibodies to CD105 has been found to be an important prognostic indicator for the outcome in a number of malignancies. In the current study, we investigated endoglin expression and evaluated MVD in 108 patients with head and neck squamous cell carcinoma. Endoglin was intensively expressed in intratumoral blood vessels, whilst lymphatics were rarely positive for CD105. High microvessel density was associated with a more aggressive tumor phenotype, including advanced clinical stage ($p=0.008$) and the presence of lymph node metastasis at the time of diagnosis ($p=0.02$). When microvessel counts were assessed for their prognostic values (high vs low MVD), there was a statistically significant difference in the overall survival among patients with tumors of the oral cavity and larynx ($p<0.001$) and in the disease-free survival among patients with tumors of the lower lip ($p=0.01$). The prognostic impact of microvessel density was not dependent on clinical stage or lymph node status. The results of the current study suggest that CD105 is a promising target for tumor imaging and prognosis.

Keywords CD105 · Endoglin · D2-40 · Angiogenesis · Head and neck cancer · Oral cancer

Introduction

Angiogenesis is the propelling force for tumor growth and metastatic dissemination in solid neoplasms [9, 11]. This

process is tightly controlled by numerous positive and negative angiogenic factors and their receptors, the interaction of which regulates the cascades enabled in tumor neovascularization [8, 34]. However, the mechanisms underlying this procedure are not yet fully elucidated.

Endoglin (CD105) is a 180-kDa homodimeric transmembrane glycoprotein [8, 13]. It is a receptor for transforming growth factor- β (TGF- β) and modulates TGF- β signaling by interacting with TGF- β receptors I and III [12]. TGF- β acts as a negative regulator for tumor angiogenesis via inhibition of proliferation and migration of endothelial cells and, thus, interrupting the formation of microvessels, whereas CD105 counteracts these actions [8, 12]. A possible explanation for this paradox is the presentation of TGF- β signaling in a non-functional way by this receptor [12, 13]. Endoglin is strongly expressed in blood vessels of tumors, whilst it is absent or weakly expressed in blood vessels of normal tissues [13, 14]. Endoglin is induced by hypoxia [12] and associated with increased endothelial cell proliferation [12, 13] and decreased apoptosis [8]. It is also suggested that endoglin might have a role in tumor lymphangiogenesis [16]; however, its expression on lymphatic vessels has never been examined, so far, in tumor settings.

Intratumoral microvessel density (MVD) determined by antibodies against CD105 was correlated with decreased survival and increased tumor aggressiveness in a number of malignancies, such as breast cancer [7, 18], cutaneous melanoma [29], colon cancer [26, 36, 45], lung cancer [3, 30, 40], gynecological malignancies [4, 35, 38], and renal cancer [6, 44]. It was suggested that CD105 might be the optimal antibody for microvessel's highlight to preclude disturbances caused by the low accuracy of the pan-endothelial markers (CD31, CD34, and von Willebrand factor) used so far [12–14, 36].

Up to date, the prognostic impact of CD105 in tumor angiogenesis for head and neck cancer was examined by a limited number of studies [5, 27, 28, 31]. Thus, we performed immunohistochemical evaluation of CD105 expression in a cohort of patients with head and neck squamous cell carcinoma (HNSCC). Our aim was to

examine the expression pattern of CD105 on tumor blood and lymphatic vessels, to assess the correlation of CD105-determined MVD with tumor aggressiveness and clinical outcome (if any), and to find possible explanations for the role of this molecule in the angiogenic procedure.

Materials and methods

Tissues and clinical parameters

One hundred and eight formalin-fixed, paraffin-embedded archival tissue blocks of head and neck squamous cell carcinoma specimens were included in the current study. There were 81 of the included samples that originated from complete resection material, and 27 were biopsy specimens. We reviewed all hematoxylin slides and selected the best section from each block showing central and peripheral areas of the tumor, avoiding areas with necrosis. Patients' records were reviewed, and clinicopathological characteristics and follow-up data were noted. Staging was established by IUCC system, and grading was performed according to WHO.

Immunohistochemistry

CD105 monostaining

We performed immunostaining on formalin-fixed, paraffin-embedded tissue sections using the EnVision System (DAKO) as described previously [19, 22]. In brief, one 4- μ m-thick section from each paraffin-embedded block was cut. The sections were deparaffinized in xylene and rehydrated through graded concentrations of alcohol. Sections were incubated with Proteinase-K (DAKO) in a humid chamber for 25 min for antigen retrieval. The endogenous peroxidase's activity was blocked with H₂O₂ solution in methanol (0.01 M) for 30 min. After washing with phosphate-buffered saline (PBS) for 5 min, the primary antibody (mouse monoclonal antibody to CD105, clone SN6h, Diagnostic Biosystems, Netherlands, in a dilution 1:20) was incubated overnight at 4°C. Then, the slides were washed for 10 min with PBS. EnVision system (DAKO) was used for visualization of the expression of the antibody. Diaminobezidinetetrahydrochloride (DAB) was used as a chromogen. All sections were then counterstained with hematoxylin.

Double staining (CD105/D2-40)

The expression of endoglin in lymphatic vessels has never been evaluated in HNSCC [9]. Therefore, we contacted double immunostaining with CD105 and the specific lymphatic endothelium marker D2-40 (SIG-730, Signet Laboratories) [10] to investigate the presence of colocalization of the two antibodies [20]. Twenty randomly selected blocks were used as a convenient sample. In

brief, the antibody against CD105 was applied as described above. After the visualization of the expression of endoglin with DAB, sections were washed in PBS for 5 min. Serum block was applied for 5 min and, afterwards, D2-40 (dilution 1:40) was applied for 30 min in a humid chamber at room temperature. Secondary antibody (Multilink, Biogenex, USA) was applied for 20 min, followed by 10 min washing with buffer. Alkaline-phosphatase link was applied for 20 min, and the expression of D2-40 was visualized with Fast-Red (Biogenex, USA) diluted in naphthol phosphate. One drop of levimazole was added to reduce unspecific background staining. All sections were then counterstained with hematoxylin.

Antibody expression

Two observers (PK and DS) without knowledge of the clinical data performed evaluation of the staining. Quantitative analysis of the intratumoral microvessel density was performed as described previously [7, 19, 29, 42]. Three fields with the highest vascular density (hot spots) were identified in each sample using an Olympus BX-51 microscope at $\times 40$ magnification, and vessels were counted using a $\times 200$ magnification. Microvessel density was defined as the number of CD105-positive vessels per optical field (an optical field corresponds to an examination area of 0.7386 mm²). For statistical analyses, the median value of the above measurements was used as a cut-off to separate tumors with high vs low microvessel density, as previously described [2].

Survival and recurrence analysis

The cohort of our patients was divided into two groups regarding the location of the primary tumor. It is well known that squamous cell carcinoma (SCC) of the lower lip is more curable than those of the oral cavity or the larynx [17, 33], and the major problem with this malignancy is local recurrence after surgical removal of the primary tumor. On the other hand, SCC of the oral cavity and larynx are more aggressive. Thus, we performed survival analysis in the subgroup of patients with oral-larynx SCC and recurrence analysis in the subgroup of patients with SCC of the lower lip.

Survival analysis was also stratified over clinical stage, lymph node status, and location. In a sensitivity analysis, we examined whether the influence of MVD on survival differed between complete resections and biopsy samples.

Statistical analysis

Analyses were conducted in SPSS software version 11.0 (SPSS, Chicago, IL, USA). For comparison between MVD with clinicopathological variables, we used chi-square (χ^2) test and Mann-Whitney *U* test, as appropriate [2]. Analyses for survival and recurrence were done using the

Kaplan–Meier method and different subgroups were compared using the log-rank test. Cox regression model was used to determine the importance of different factors. All differences were considered positive if $p < 0.05$. p -values are two-tailed.

Results

Clinicopathologic data

The clinicopathologic characteristics of the patients enrolled in the study are listed in Table 1. The median age of the patients was 64.5 (range 33–98). There were 88 (81%) of the patients who were male and 20 (19%) were female. Twenty-eight patients (26%) presented with lymph node metastasis at the time of diagnosis. A total of 76 of the patients (70%) had cancer classified as initial (I and II) and of 32 (30%) as advanced (III and IV) clinical stage. There were 30 patients (38%) who had histologically high-grade tumors, 39 (36%) who had tumors with moderate differentiation, and with 39 (36%) of the tumors well differentiated (Table 1). A total of 23 (21%) of the tumors was located in the oral cavity, 35 (33%) were located in the larynx, and 50 (46%) were located at the lower lip.

The patients were treated in the Ear Nose Throat (ENT) Department of Ioannina University Hospital from 1998 to 2003. Available follow-up data existed for 93 of the patients. These were followed-up until death or recurrence, respectively, or for at least 24 months. There were 27 of the 58 patients with oral–larynx SCC who were dead at the end

of the follow-up period, and 12 of the 35 patients with lip SCC had experienced local recurrence.

Treatment decision-making was based on clinical stage and on the presence or not of lymph node metastasis at the time of diagnosis [33]. All of the patients with squamous cell carcinoma of the lower lip underwent surgical resection of the tumor, and adjuvant radiotherapy was administered only to two (4%) patients. All patients who presented with lymph node metastasis at diagnosis received neck dissection operation, simultaneously to the primary tumor removal (29). There were 14 (25%) of the patients with oral–larynx squamous cell carcinoma who were given only surgical treatment; 10 (17%) patients with lower-stage (I or II) laryngeal squamous cell carcinoma received only radiotherapy in an attempt of organ preservation (29); 20 (33%) patients underwent surgical treatment and received adjuvant radiotherapy; and, finally, 14 (25%) patients were treated with surgery plus combined adjuvant radiotherapy and chemotherapy.

CD105 expression

Monostaining

It is interesting that CD105 stained intensively intratumoral vessels (Fig. 1a–f); vessels at the adjacent normal mucosa were only rarely expressing endoglin (Fig. 1d), and staining was faint and weak. Neoplastic, inflammatory, mesenchymal, and hematopoietic cells were negative for endoglin.

Double staining (CD105/D2-40)

We observed a distinct expression pattern between CD105 and D2-40. The vast majority of the CD105-positive vessels were negative for D2-40 (Fig. 2a,b). D2-40-positive lymphatics were generally negative for endoglin immunostaining (Fig. 2a,b). Nevertheless, we observed colocalization of both markers in a limited number of small intratumoral vessels (Fig. 2b–d). However, this was a very rare phenomenon across the examined samples.

Evaluation of MVD

Microvessel density varied among tissue samples from 14 to 265 (median 49). Using the median MVD as a cut-off, 53 (49%) tumors were classified in the “high MVD” group and the rest, 55 (51%) tumors, consisted the “low MVD” group.

The correlation of the microvessel density with clinicopathologic parameters is summarized in Table 1. Higher microvessel density was correlated with a more aggressive tumor phenotype, including advanced clinical stage ($\chi^2 p = 0.008$, Mann–Whitney $p < 0.001$), and the presence of lymph node metastasis at the time of diagnosis ($\chi^2 p = 0.02$, Mann–Whitney $p < 0.001$). We did not observe

Table 1 Correlation of clinicopathological characteristics of the patients included in the study with microvessel density

	N patients (%)	Microvessel density		p-value
		High	Low	
Histological grade				
Poorly	30 (28%)	15	15	NS
Moderate	39 (36%)	20	19	
Well	39 (36%)	18	21	
Stage				
I	53 (49%)	18	35	$p = 0.008$
II	23 (21%)	13	10	
III	15 (14%)	9	6

Biopsy	27 (25%)	12	15	

Fig. 1 Microvessels within hot spot areas, in the invasive front of a squamous cell carcinoma of the lower lip (**a, e**), larynx (**b, d**), and tongue (**c, f**). Endothelial cells of intratumoral vessels are intensively

stained with CD105 (**b, d, and f**, magnification $\times 200$; **a, c, and e**, magnification $\times 400$). Notice the weak vessel staining in the normal mucosa adjacent to the neoplasm (**d**, yellow arrow)

Fig. 2 Double immunostaining with CD105 and the specific lymphatic endothelium marker D2-40. The vast majority of the endoglin-positive microvessels are negative for D2-40 (**a, b**). D2-40 positive lymphatic vessels are generally negative for CD105 (**a, b**). Few intratumoral vessels exhibit co-localization of both markers (**b**, yellow arrow; **c, d**) (magnification $\times 400$ for **a, b** and $\times 1,000$ for **c, d**)

any significant association of MVD with age, sex, or differentiation grade. MVD did not depend on the primary tumor's location, did not correlate with treatment modality, and did not differ between biopsy samples and complete resections.

Survival and recurrence analysis

Advanced (III and IV) clinical stage, the presence of lymph node metastasis at the time of diagnosis, and high MVD associated with worse overall survival in patients with oral-larynx squamous cell carcinoma (in all cases, log-rank $p < 0.001$, Fig. 3a-c). The impact of MVD on survival remained significant when the patients were further separated in oral cancer group (log-rank $p = 0.02$) and larynx cancer group (log-rank $p = 0.01$). Stratification over clinical stage and lymph node status revealed that the prognostic significance of MVD was not dependent on these factors (Fig. 3e-h). This last observation was confirmed when stage, lymph node status, and MVD were entered in a multivariate Cox model: all three prognostic factors remained significant (Table 2). Mortality was 2.7-fold higher in patients with high MVD (Cox $p = 0.04$). The significant influence of high MVD on poor outcome was similar between patients with biopsy samples and complete resections.

High MVD was also associated with worse disease-free survival in patients with squamous cell carcinoma of the lower lip (Fig. 3d). The incidence of recurrence in the group of patients with high MVD was significantly higher than the group with low MVD (log-rank $p = 0.02$).

Discussion

The results of the current study suggest a significant association of intratumoral microvessel density (determined with CD105) with poor prognosis in patients with head and neck squamous cell carcinoma. High MVD was an independent predictor of mortality in the subgroup of patients with squamous cell carcinoma of the oral cavity and larynx, with almost the same impact as lymph node status which is, up to date, the most reliable prognostic factor for these patients [33]. We also observed significantly lower disease-free survival in patients with highly vascular lower lip tumors. Our observations support previous findings for the prognostic significance of CD105 in HNSCC [5, 27, 28, 31].

There have been a number of studies evaluating the prognostic significance of microvessel density in head and neck squamous cell carcinoma [1, 15, 23, 24, 32, 37] with conflicting and contradictory results. In all of these reports, investigators used pan-endothelial markers, namely, CD34, CD31, and von Willebrand factor, to highlight microvessels. However, the accuracy of MVD assessment with these markers may not be the best possible, as their sensitivity and specificity are not optimal. All these markers are not always expressed in all intratumoral vessels (low sensitiv-

ity) [36, 43]. Von Willebrand factor can also stain lymphatic vessels [43]; CD31 has been observed in many hematopoietic cells, besides vascular endothelium; and CD34 is additionally expressed by a variety of mesenchymal cells [36, 43]. All these aspects reflect the low specificity of these markers. It must be also mentioned that these pan-endothelial markers stain vessels in tumor and normal tissue with equal intensity. On the other hand, as we observed in the current study, endoglin stained intensively intratumoral vessels with high sensitivity, whereas vessels in non-neoplastic tissue were not or were weakly expressing CD105. This confirms previous observations that endoglin reacts specifically with angiogenic endothelial cells and that its expression declines as we move away from the invasive front of the tumor [39]. Neoplastic, inflammatory, mesenchymal, and hematopoietic cells were not stained with endoglin. These observations have been also reported previously for other solid malignancies [4, 7, 26, 29, 30, 35, 44]. In addition, in our samples, lymphatic vessels were generally negative for endoglin, as confirmed with double staining with the specific lymphatic endothelium marker D2-40. However, we observed a small number of intratumoral vessels that were expressing both of the markers simultaneously. This was not reported previously. Hence, a possible role of endoglin in lymphangiogenesis cannot be excluded, as interactions between angiogenesis and lymphangiogenesis are common in tumors [16].

An increasing amount of studies evaluating MVD with CD105, in various neoplasms, is being published [4, 7, 26, 29, 30, 35, 44]. So far, with no exceptions, in all of these studies, a significant association of high MVD with poor prognosis was observed, and investigators agree that assessment of microvessel counts with endoglin seems to be better than the use of any other pan-endothelial marker. Thus, the use of CD105 offers a feasible solution to one of the major problems in studying angiogenesis in cancer samples: the selection of the optimal endothelial marker [41]. However, we must keep in mind that there are other equally important difficulties. Measuring microvessel density by examining small sections of archival tissue at a single point in time does not necessarily represent the angiogenic status of the tumor. There is also significant inter-observer variability for the identification and selection of the "hot spots". The selection of an unbiased cut-off for separation of tumors with high vs low microvessel density can also be problematic [21, 41]. Therefore, more studies, preferentially prospectively drifted, are needed to confirm the importance of MVD (determined with CD105) as a prognostic factor before it can be incorporated into clinical practice.

Although the importance of CD105 for microvessel staining is adequately supported by enough observational data, little is known about the direct implication of this molecule in the angiogenic procedure. Research is currently focusing on the discovery of the intracellular partners and molecules interacting with endoglin [12]. It was reported that CD105 gene promoter is predominantly active in proliferating endothelial cells, and its activity is induced by hypoxia [12-14, 25]. These aspects suggest that

Fig. 3 **a** Kaplan–Meier curve for the overall survival of the patients with squamous cell carcinoma of the oral cavity and larynx, according to the CD105-determined microvessel density (high MVD vs low MVD). The two curves are significantly different (log-rank $p < 0.001$). **b** Kaplan–Meier curve for the overall survival of the patients with squamous cell carcinoma of the oral cavity and larynx, according to clinical stage (IV + III vs I + II). The two curves are significantly different (log-rank $p < 0.001$). **c** Kaplan–Meier curve for the overall survival of the patients with squamous cell carcinoma of the oral cavity and larynx, according to the lymph node status (N positive vs N negative). The two curves are significantly different

(log-rank $p < 0.001$). **d** Kaplan–Meier curve for the disease-free survival of the patients with squamous cell carcinoma of the lower lip, according to the CD105-determined microvessel density (high MVD vs low MVD). The two curves are significantly different (log-rank $p = 0.02$). **e–h** Kaplan–Meier curves for the overall survival of the patients with squamous cell carcinoma of the oral cavity and larynx, according to the CD105-determined microvessel density (high MVD vs low MVD), stratified over clinical stage (**e**, **f**) and lymph node status (**g**, **h**). The prognostic significance of MVD on survival remains unchanged after stratification

Table 2 Multivariate survival analysis for patients with squamous cell carcinoma of the oral cavity and larynx

	Multivariate Cox		
	Hazard ratio	95% confidence intervals	<i>p</i> -value
Clinical stage (III + IV vs I + II)	2.4	1.3–4.5	<i>p</i> =0.003
Lymph node status (N+ vs N-)	2.9	1.1–8.7	<i>p</i> =0.04
MVD (high vs low)	2.7	1.1–7.5	<i>p</i> =0.04

CD105 gene could be an objective for targeted gene delivery in therapies directed to malignant neoplasms; but these observations must be further confirmed [12].

In conclusion, this study suggests that MVD evaluation with CD105 is a promising prognostic factor for outcome of patients with head and neck squamous cell carcinoma. We suggest that endoglin is a more sensitive and specific marker for microvessel highlight than the pan-endothelial markers currently in use and may represent a novel target for prognostic purposes and for novel therapeutic approaches. Our observations for the prognostic significance of endoglin should be confirmed in larger series of squamous cell carcinoma from the same anatomic location and suspected to the same treatment modalities before the incorporation of CD105 into clinical practice.

Cystic cholangiomas after transplantation of pancreatic islets into the livers of diabetic rats

Received: 18 January 2006 / Accepted: 21 February 2006 / Published online: 7 April 2006
© Springer-Verlag 2006

Abstract Islet transplantation is increasingly used as a therapy for human type 1 diabetes mellitus. In our study, we investigated the effect of the transplantation of a low number ($n=350$) of pancreatic islets into the right liver part on the neighboring portal bile ducts. Male streptozotocin-diabetic Lewis or autoimmune-diabetic BB/Pfd rats ($n=1065$) were subdivided into 11 experimental groups. A few days after low-number islet transplantation, cholangiocytes adjacent to the grafts showed an increase in proliferative activity. During the next 12–24 months, many peri-insular ductules progressed via tumor-like cystic lesions to large cystic cholangiomas, accompanied by a translocation of the insulin receptor into the cytoplasm and an increase in expression of insulin-related signaling proteins (Insulin-receptor-substrate-1, Raf-1, Mek-1). After 24 months, 53% of rats with low-number transplantation exhibited at least one cholangioma >10 mm, significantly outnumbering tumor development in the transplant-free left liver part and in any control group. No cholangiocarcinomas emerged. A graft cell origin of the tumors was excluded by Y chromosome in situ hybridization in cross-gender transplantations. Conclusively, low-number intrahepatic islet transplantation, most likely acting by permanent local hyperinsulinism, leads to prolonged cholangiocellular proliferation in streptozotocin- and in autoimmune-diabetic rats, resulting in the development of benign cystic cholangiomas.

Keywords Insulin · Cholangioma · Islet transplantation

Introduction

Transplantation of islets of Langerhans into the liver is regarded as an ideal therapy for treating human type 1 diabetic patients but clinical success, i.e., achievement of insulin independence, has not been reached for a long time. Recent advances in immunosuppressive regimens, beginning with a glucocorticoid-free therapy established by the Edmonton Group in Canada [51] and improved islet preparation techniques have meanwhile substantially contributed to the excellent long-term metabolic control in transplanted patients [46–49]. More than 750 patients have been treated so far, and further improvement of the immunosuppression protocols to reduce the risk of complications is one of the major future challenges [46, 47].

As a result of the long-term vitality of the islet grafts, the influence of islet hormones on adjacent liver tissue, i.e., hepatocytes, cholangiocytes, and non-parenchymal liver cells, will become a focus of increasing attention in the future. Naturally, detailed long-term morphologic studies on human recipient livers are lacking and most results are obtained in animal models, but there is an increasing number of case studies reporting on alterations in the liver parenchyma surrounding the islet grafts, i.e., focal steatosis in most cases [7, 17, 49, 53]. Focal glycogenosis and steatosis are long known to be induced by islet transplantation in rat animal models [11, 27].

Low-number islet transplantation ($n=450$) is ideal to study the effect of local high insulin levels on the adjacent cells of the downstream liver acinus, as it does not completely compensate hyperglycemia and the persisting mild diabetes thus stimulates the islet grafts to maximally synthesize and secrete insulin. Several studies have shown that these conditions, i.e., combined hyperglycemia and hyperinsulinism, lead to distinct alterations in the metabolism and growth control of the hepatocytes, such as glycogen and lipid accumulation, an altered enzyme expression pattern and increased proliferation and apoptosis

kinetics [11–13, 22]. The hyperinsulinism has induced a translocation of the insulin receptor into the cytoplasm of altered hepatocytes, leading to increased intracellular insulin signaling via the Ras–Raf–MAPKinase pathway as demonstrated by the overexpression of key proteins such as insulin receptor substrate (IRS)-1, Raf-1, and Mek-1 and has also altered signaling via the insulin like growth factor (IGF) 1 axis [21, 50]. This altered liver acinus corresponds, in nearly every aspect, to the preneoplastic clear-cell hepatocellular focus known from chemical hepatocarcinogenesis [4], and indeed, proved to be of preneoplastic nature, as it was shown to progress to advanced stages of preneoplasias and subsequently to hepatocellular adenomas and carcinomas after 6–24 months [13].

It is most likely that the cholangiocytes of the directly adjacent portal bile ducts are also exposed to high local concentrations of islet hormones, in particular, insulin. Cholangiocellular alterations in human islet recipients have not yet been reported, but some authors described cholangiocellular cystic lesions in the liver of streptozotocin (STZ)-diabetic rats that received islet transplants [24, 25, 34]. However, there was substantial disagreement whether islet transplantation or streptozotocin treatment was responsible for their development. On the one hand, besides growth factors such as nerve growth factor, transforming growth factor (TGF) α and hepatocyte growth factor [26, 28, 56], insulin has, indeed, been shown to stimulate cholangiocellular proliferation in vitro [10]. Moreover, there are clear indications that growth factors are also involved in cholangiocellular metabolism and growth control of normal and preneoplastic cholangiocytes in vivo [38, 42]. However, to the best of our knowledge, the influence of insulin on the proliferative activity of bile duct epithelia in vivo has not yet been investigated. On the other hand, streptozotocin that is widely used in islet transplantation studies in rats, to establish diabetes, is genotoxic and has carcinogenic potential [9, 39]. Therefore, it is still not clarified whether insulin after islet transplantation or streptozotocin was

responsible for the development of cholangiocellular lesions.

The aim of this study was, thus, to examine in detail the long-term influence of islet transplantation on the neighboring bile duct epithelia in diabetic rats and to evaluate the influence of streptozotocin in this setting. Moreover, we investigated whether the insulin-related Ras–Raf–MAPKinase pathway and TGF- α action are involved in cholangiocellular proliferation in this model.

Materials and methods

Animals and diabetes induction

Altogether, 1,065 animals were examined in this experiment. We used two different inbred rat strains, i.e., Lewis rats ($n=324$) and a substrain of autoimmune diabetic BB (bio-breeding) rats, the so-called BB-Pfd rats ($n=741$). BB rats become diabetic by an autoimmunological mechanism and serve, similar to the non-obese diabetic (NOD) mouse, as an animal model for human type 1 diabetes [37]. The substrain of BB/Pfd rats is characterized by a high probability of spontaneous reestablishment of the lost self-tolerance to the β -cells [32, 36]. Thus, most of these animals tolerate the transplanted isologous islet grafts without immunosuppressive therapy, whereas, the remaining rats destroy the grafts via the same autoimmunological mechanism, as they have done with their own islets before, and become diabetic again.

With the exception of some female donor animals that were used for the cross-gender transplantation and in situ hybridization, all animals were male. Lewis rats (Harlan Winkelmann, Borcheln, Germany) were subdivided into four experimental groups (L1–L4) and treated according to Table 1. L1–L3 were made diabetic by a single intravenous injection of streptozotocin (80 mg/kg body weight), whereas, L4 stayed normoglycemic as a control Lewis group. BB/Pfd rats that developed the autoimmune diabe-

The Lewis rats were subdivided into four experimental groups (L1–L4). The BB/Pfd rats either developed autoimmune diabetes (BB1–BB3) or were made diabetic by streptozotocin administration (BB4–BB6), similar to the Lewis rats. L4 and BB7 served as untreated and normoglycemic control groups. Blood glucose and body weight are given as mean value±standard error of the mean and were measured by the time of sacrifice

tes were subdivided into three groups (BB1–BB3). BB/Pfd rats that did not develop autoimmune diabetes (approximately 90% of the primary population) served as islet donors and were made diabetic (BB4–BB6) by streptozotocin injection (65 mg/kg body weight) or stayed normoglycemic as a BB/Pfd control group (BB7). All animals were inspected daily. Blood glucose and body weight were measured monthly and also 1 and 3 days after transplantation, immediately before and 2 days after streptozotocin treatment, and immediately before killing. Animals showing a weight loss of more than one third of their individual maximal body weight *post transplantation* were given a subcutaneous insulin implant (Linplant, Linshin Canada, Scarborough, Ontario, Canada) to prevent death by diabetes, a measure that was not necessary in diabetic Lewis rats but has to be done in virtually all diabetic BB/Pfd rats with increasing time to avoid death by diabetic complications. Nevertheless, these animals still stayed diabetic; the hyperglycemia was only ameliorated. Animal treatment was in line with the guidelines of the Society for Laboratory Animal Service (GV-SOLAS) and the strict German Animal Protection Law.

Transplantation procedure

Animals were anesthetized (100 mg/kg ketamin, 4 mg/kg xylazin), and islets of Langerhans, consisting of approxi-

mately 85% β cells, were isolated from 3 to 5 months old nondiabetic donors (littermates in case of the BB/Pfd rats), weighing 250–350 g, and transplanted into the liver via the portal vein, 3 weeks after STZ treatment or onset of the autoimmune diabetes, as described in detail previously [11]. During infusion, the branch supplying the left part of the liver (i.e., left lobe and left part of the middle lobe) was clamped, making sure that the transplants were embolized only into the right part of the livers (i.e., right lobe, right part of the middle lobe, caudate lobe, anterior and posterior papillary processus); the left part served as an intra-individual control. Ischemia for the left part lasted only for about 1 min. L1, BB1, and BB4 received a low number ($n=350$) and L2, BB2, and BB5, a high number of islet grafts ($n=1,000$), respectively. L3 received 350 polystyrene (Latex) particles (Polysciences, Warrington, PA) of about 90–100 μm in size to exclude an influence of ischemia, and the remaining groups (L4, BB3, BB6, and BB7) were not transplanted (Table 1).

Animal killings and 5-bromo-2'-desoxyuridine (BrdU) application

Animals were killed and matched in time-groups between 6 and 24 months after transplantation (Table 2). Some animals of each experimental group received osmotic minipumps (Alzet model 2ML1, Alza, Palo Alto, CA,

USA) filled with 40 mg 5-bromo-2'-desoxyuridine (BrdU; Sigma, Heidelberg, Germany) 7 days before killing. Perfusion fixation and anesthesia was done as described previously [11].

Tissue sampling and processing

After fixation, the livers were removed, cut into sections (about 0.5 mm), and examined with a stereomicroscope. All macroscopic liver lesions and at least ten additional liver slices were embedded in paraffin. Serial sections (2–3 µm) of the liver specimens were stained with hematoxylin and eosin (H&E) and with the periodic acid-Schiff (PAS) reaction. Additional sections were made for immunohistochemistry. Semithin sections were stained according to Richardson [45].

Morphometric analysis

In addition to all lesions larger than 2 mm, six slides of different liver parts were investigated per animal. Cholangiocellular lesions or tumors were only counted if they consisted of foci of proliferating ductules, measuring at least 0.5 mm in diameter and were then subdivided into three groups according to their size: small foci of proliferating ductules measuring 0.5–2 mm, tumor-like lesions and small tumors measuring 2–10 mm, and large (cystic) tumors measuring more than 10 mm in diameter.

Immunohistochemistry

Paraffin sections were incubated with the following primary polyclonal rabbit antibodies: anti-insulin, anti-glucagon, and anti-somatostatin (all Dako, Hamburg, Germany, dilution 1:200). The Anti-CK 7 (Clone OV-TL 12/30, Novocastra, Newcastle upon Tyne, UK, dilution 1:50) and anti-BrdU antibody (Dako, dilution 1:100) were monoclonal. CK 7-immunohistochemistry required protease pretreatment for 10 min. Furthermore, we used anti-insulin receptor (A1314, concentration of 0.5 mg/ml; provided kindly by Dr. J.W. Unger, Department of Anatomy, University of Munich, Germany), anti-IRS-1 (Upstate Biotechnology, New York, dilution: 1:50, polyclonal), anti-Raf-1 (Santa Cruz Biotechnology, Heidelberg, Germany, dilution 1:50, polyclonal), anti-Mek-1 (Santa Cruz Biotechnology, dilution 1:100, polyclonal), anti-TGF-α (Oncogen-Sciences, Cambridge, MA, final concentration, 10 µg/ml, monoclonal) and anti-epidermal growth factor receptor (EGF-R; Biogenex, San Ramon, USA, dilution 1:25, no pretreatment, polyclonal) antibodies. The immunohistochemical reactions of the proteins were assessed semiquantitatively by comparison with the extrafocal liver tissue, in particular, with cholangiocytes of normal portal bile ducts. Details of the staining procedures, including antigen retrieval methods, secondary antibodies, blocking of endogenous peroxidase, counterstaining, and

mounting of the tissue sections were described previously [11, 13, 21].

In situ hybridization

The rat Y chromosome probe was received in the plasmid pUC18 as a kind gift from Dr. Barbara Hoebee [18]. The plasmid was cloned into DH5α *E. coli* and amplified. Plasmid containing colonies were picked for further sequencing. The sequence was confirmed by analyzing the plasmid on an ABI 310 sequencer (Applied Biosystems, Darmstadt, Germany). Injection time was 25 s, using Pop-4 dRhodamine Matrix standard ABI Prism (Perkin Elmer, Weiterstadt, Germany). BLASTN (version 2.2.4) analysis of a 339-bp DNA fragment revealed 95% (281/295) sequence identity to the original *Rattus norvegicus* 91ES8 DNA sequence (gene bank accession number: X80155.1.)

The whole plasmid was then labeled by nick translation with digoxigenin (Kit# 1745816, Roche Diagnostics, Mannheim, Germany) according to the manufacturer's instructions, resulting in a probe size of 100–500 bp at a concentration of ~0.5 µg/ml. The polyclonal rabbit anti-DIG antibody (Code P 5104) was purchased from Dako, Glostrup, Denmark. Deparaffinization, prehybridization, and hybridization was performed according to O'Leary and Blakemore [40]. The hybridization mix consisted of: 10% salmon testes DNA (10 mg/ml), 20% deionized formamide, 10% 50× Denhardt's solution, 10% 20× saline-sodium citrate (SSC), and 50% dextrane sulphate (all purchased from Sigma-Aldrich, Munich, Germany). After hybridization, slides were washed four times for 5 min each with 2× SSC (48°C), four times for 5 min in 0.1× SSC (48°C), then for 15 min in 1× SSC containing 50% deionized formamide at 48°C (high stringency) or room temperature (low stringency), and finally for 5 min in 2× SSC and counterstained with hemalaun. Female and male control liver sections were used in each run. The tumors were only evaluated (high stringency washing) when these control sections gave correct results.

Twenty-six tumors in 15 male recipients of L1 and BB1 were evaluated. The percentage of labeled nuclei in cholangiomas and in 100 surrounding hepatocytes was determined in six animals of BB1 and L1 and given as mean±standard deviation.

Statistical analysis

We determined the percentages of animals in the experimental groups that had developed at least one cholangiocellular lesion of the respective size and compared differences between their right (transplant-bearing) and left (transplant-free) part of the liver for evaluating the effect of the transplantation. The effect of high local intrahepatic insulin levels was additionally tested by comparing the low- and high-number transplantation groups with their respective control groups, i.e., L1 with

L2–L4; L2 with L3 and L4; BB1 with BB2, BB4 and BB7; BB2 with BB3 and BB7; and BB4 with BB5–BB7.

Strain differences and the influence of streptozotocin-induced vs autoimmune diabetes were examined by comparing the low number transplantation groups (L1, BB1, and BB4) and the nondiabetic control groups (L4 and BB7) among each other. The effect of streptozotocin treatment was tested by comparing L3 with L4 and BB6 with BB7. Other differences were not tested. Fisher's exact test was used, and $p < 0.05$ was considered statistically significant.

Results

Body weight and blood glucose

Body weight and blood glucose were inversely correlated (Table 1). As intended by the experimental design, animals treated by streptozotocin administration or developing

spontaneous auto-immune diabetes became hyperglycaemic; in addition, low-number islet transplantation lowered the hyperglycemia, but the animals remained in a mild diabetic state, whereas, high-number islet transplantation established normoglycemia.

Morphology and quantitative analysis

Islet transplants were vital and located within the portal tracts. Already a few days after islet transplantation, small ductular proliferations were noted in each of the low-number groups (Fig. 1a). Exceptionally, formation of single ductules was also observed after high-number transplantation, but most islet grafts in these groups (L2, BB2, BB5) were free of neoductuli (Fig. 1f). These ductules usually had close contact to the islet grafts. Most of the ductular proliferation occurred at the border between the islet graft and the connective tissue of the portal tracts, but there were examples in which the ductules were located

Fig. 1 a–d depict a transplanted islet graft and the surrounding tissue after low-number transplantation in a Lewis rat 7 days after transplantation. The islet is located in a portal tract infiltrated by some lymphocytes, and the adjacent hepatocytes show a clear cytoplasm owing to an increase in glycogen accumulation as a result of the local hyperinsulinism. The bile ducts are intermingled with islet cells, confirmed in insulin immunohistochemistry (b), in which is demonstrated that β -cells partly surround the bile ducts that show a strong immunohistochemical reaction for cytokeratin 7 (c). BrdU-labeling (d) demonstrates proliferative activity of the β -cells as a result of the systemic insulin deficiency and of the hepatocytes, endothelial cells, and the cholangiocytes. As a result of the increased cholangiocellular proliferation, new ductular structures develop that

stay for a while in close contact to the islet grafts. This situation is maintained for weeks and months as shown 13 months after islet transplantation (L1, e). Rarely, similar neo-ductuli also develop after high-number transplantation, but normally, the islet grafts lie quiescent within the portal tracts, as these animals were normoglycemic and the β -cells were only weakly stimulated. As a result of the comparably lower local insulin concentration, no signs of cholangiocellular proliferation were then observed (f, L2, 13 months after transplantation). a–d Serial sections of the same islet graft stained with hematoxylin & eosin stain (a) or with insulin- (b), cytokeratin 7- (c), and BrdU-immunohistochemistry (d); semithin sections stained according to Richardson (e and f). The lower edge of the panels represent 480 μm (a–d), 530 μm (e), and 340 μm (f)

right within the islet grafts and were partly or completely surrounded by islet cells (Fig. 1a–d). In any case, the ductules were lined by a single layer of cuboidal to flat

epithelial cells without any cytologic atypia (Fig. 1a,e). Positive CK 7-immunostaining proved the epithelial origin, thus, excluding vascular proliferations that must have also

Fig. 2 Some of the ductules in the groups with low-number islet transplantation continued to proliferate and gave rise to cholangiomas measuring several millimeters. (a–c) depict a small cholangioma in serial sections that has developed after 14 months in a Lewis rat. The portal tract is located at the left margin. In the PAS reaction (a), the increase in glycogen in some hepatocytes of the surrounding preneoplastic focus is recognizable although most of the cells in this lesion are predominantly characterized by strong lipid accumulation. The close spatial relationship not only to the preneoplastic hepatocellular focus, but also to the islet, is demonstrated in insulin immunohistochemistry: the β -cells are dispersed and intermingled with the cholangioma (b). The epithelial lining is flat in larger cysts and cuboidal in smaller ducts, as highlighted at this low magnification by cytokeratin 7-immunohistochemistry (c). The development in the BB/Pfd rats was very similar. One minor difference was a stronger lymphocytic infiltration of the islet grafts owing to the

disturbed immunological background in these animals (d). These lesions were also composed of smaller ductules and larger cysts (*left margin*). Note also the lipid accumulation in the preneoplastic hepatocytes in this animal. BrdU-labeling showed the proliferative activity of the epithelia lacking cytologic atypia throughout the entire experiment (e). In situ hybridization performed in liver tissue after cross-gender transplantation of female islet grafts into a male recipient always detected Y chromosomes (*arrowheads* in f) in the cells of all investigated tumors, ruling out an origin of transdifferentiated donor cells. PAS reaction (a), insulin- (b), cytokeratin 7- (c and d), and BrdU-immunohistochemistry (e). Y chromosome in situ hybridization (f). (a–c) L1, 14 months after islet transplantation. (d) BB1, 13 months after islet transplantation. (e) BB1, 14 months after transplantation. (f) L1, 13 months after islet transplantation. The lower edge of the panel represents: 800 μm (a–c), 960 μm (d), 480 μm (e), 150 μm (f)

been taken into account after rinsing the blood cells out of the vessels by the perfusion fixation. Some mitoses were seen, and several nuclei stained positive in BrdU-labeling, indicating proliferative activity (Fig. 1d). We did not notice a morphologically conspicuous transdifferentiation of islet cells or hepatocytes into duct-like cells or a proliferation of oval cells, which may have given rise to the ductular formation.

Concurrently, the liver acini of the hepatocytes that drain the hyperinsulinemic blood from the islet grafts in the low number transplantation groups developed into clear-cell foci of altered hepatocytes that often surrounded the ductular lesions which intermingled with the islet grafts (Figs. 2 and 3). All cholangiocellular and hepatocellular alterations did not occur in the left part of the liver and in the control groups that were not islet-transplanted.

In the first 6 months after transplantation, some of the lesions in the low-number transplantation groups (L1, BB1, and BB4) reached a diameter more than 0.5 mm (Table 2). These larger tumor-like lesions were always restricted to the right part of the liver. The lumina of the ductules often extended to small cysts that were still lined by a single layer of monomorphous epithelia. In some lesions, these cysts were separated by small amounts of connective tissue in which we often found islet cells, proven by immunohistochemical evidence of islet hormones within them (Figs. 1d and 2b).

Between 6 and 12 months *post transplantationem*, small lesions <2 mm were also noted in the livers of the control groups, but they were clearly exceeded by ductular proliferation in the low-number transplantation groups in which a considerable number of animals then already carried cystic tumors in their right liver half, measuring up

Fig. 3 After several months, some of the small lesions developed into large cystic tumors that were macroscopically recognizable. In the smaller lesions, the close spatial relationship between the preneoplastic hepatocellular focus and the cholangiocellular lesion was virtually always visible in stereomicroscopy (a–c). The cystic lesion depicted in this unstained liver slice after perfusion fixation (a) measures approximately 1.5 mm and is surrounded by white tissue corresponding to the preneoplastic hepatocellular focus (L1, 9 months after transplantation). **b** depicts a 3 mm large cystic lesion adjacent to white-colored preneoplastic hepatocellular tissue, 13 months after transplantation. **c** In this liver of a BB/Pfd rat 15 months after transplantation, a 4-mm cystic tumor still exhibits close topographical relation to the surrounding white preneoplastic hepatocellular lesion (BB1). **d** shows a 12-mm large cholangioma, 18 months after transplantation (L1). A surrounding hepatocellular preneoplasia is here not visible. In some animals, at the same time multiple large tumors developed occupying nearly the entire right liver part (e, whole liver, L1, 19 months after transplantation). Note that the left part of the liver, in which no islets have been transplanted, is also free of large cystic cholangiomas

to 10 mm in diameter (Table 2). In group L1, tumor formation was strongest: nearly half of the animals showed lesions <2 mm and nearly one-third of them carried cystic tumors measuring 2–10 mm. This was significantly more when compared not only to the left liver part and the other Lewis groups but also when compared with the streptozotocin-diabetic group BB4, which also received a low number of islet grafts. Autoimmune-diabetic BB1 animals showed also more lesions than streptozotocin-diabetic BB4 rats.

At 12–18 months after transplantation, the formation of cystic tumors progressed in all groups but still predominated in the low-number transplantation groups, of which L1 was again that with the strongest progression (Table 2). We also noticed the first tumors measuring more than 10 mm in diameter. These developed exclusively in the

low-number transplantation groups (L1, BB1, BB4) (Fig. 3d,e). Some of these large tumors measured several centimeters, continued to grow so that they sometimes virtually occupied the whole liver, and caused death of some animals owing to rupture of the cysts or to compression of other organs. Histologically, even in these large tumors, the multicystic appearance and the benign cytology were preserved. We did not encounter any epithelial atypia or foci of invasion and even papillary epithelial projections were only focally seen. Positive BrdU-labeling still indicated proliferative activity, in particular, in areas with cuboidal and columnar epithelia or in the rare papillary areas (Fig. 2e). Bile accumulation was found in up to 30% of the larger tumors. Occasionally, we still recognized a close spatial relationship to islet graft remnants and hepatocellular foci of altered hepatocytes

Fig. 4 Cholangiomas showed a translocation of the insulin receptor from the cell membrane into the cytoplasm, resulting in a granular reaction pattern (a). Proteins of the Ras–Raf–MAP-Kinase pathway, i.e., IRS-1 (b), Raf-1 (c), and Mek-1 (d) were moderately to strongly increased in cholangioma cells (upper part of the panels), although the pattern within one lesion was heterogenous and the signal intensity varied from cell to cell, including negative cells. There was no difference in Lewis rats (a–d) or BB rats (example of IRS-1 expression in e) and normal portal bile duct epithelia of extrafocal tissue were always negative (f). Cholangiomas (lower half in g) and extrafocal hepatocytes (upper edge in g) were transforming growth factor (TGF) α -negative but progressed hepatocellular preneoplasias that directly neighbor cholangiomas as depicted in (g), often showed strong TGF- α expression. As most cholangiomas expressed the receptor for TGF- α , i.e., the epidermal growth factor receptor (h), this may constitute an additional costimulatory paracrine stimulus for cholangioma proliferation during the course of the experiment. (a) L1, 13 months after transplantation. (b–d,f) L1, 13 months after transplantation (same animal; b–d serial sections). (e) BB1, 12 months after transplantation. (g) L1, 14 months after transplantation. (h) L1, 18 months after transplantation. Lower edge of each panel represents 203 μ m except in (e) and (g) representing 406 and 810 μ m, respectively

(FAH) or tumors (Fig. 3b,c). In this time period, the high-number transplantation group, BB2, which had developed autoimmune diabetes and was not treated with streptozotocin, also showed a significantly higher number of tumor-like lesions and tumors in their right liver part than in their left liver part and in the control groups BB3 and BB7 (Table 2). At this time-point, vice versa to 6–12 months, the number of small tumors, measuring 2–10 mm was higher in the streptozotocin-treated BB4 when compared with the autoimmune-diabetic BB1. It should also be noted that streptozotocin treatment increased the number of small lesions in BB6 when compared to BB7.

Lewis rats were examined for an additional 6 months to investigate whether some of the apparently benign tumors would transform into carcinomas. We found an increase in the number of lesions and tumors and in tumor size after 18–24 months (Table 2) but malignant transformation still did not occur.

Immunohistochemical expression of insulin-related signaling proteins (IR, IRS-1, Raf-1, Mek-1), TGF- α , and EGF-R

While cholangiocytes of normal portal bile ducts showed no expression or only barely detectable levels of the IR, IRS-1 (Fig. 4f), Raf-1, and Mek-1, the proliferating ducts of the majority of cholangiomas in the low-number transplantation groups L1, BB1, and BB4 revealed a moderate to strong expression of these proteins. The degree of intensity in the individual cell was comparable to the increased expression in hepatocytes of the surrounding preneoplastic hepatocellular focus, but it was more variable and pronounced in the periphery within cholangiocellular lesions. There was no difference between the streptozotocin-induced or spontaneously diabetic animals.

IR-immunohistochemistry revealed a granular cytoplasmic reaction pattern (Fig. 4a) in cholangioma cells suggesting the same translocation of the IR from the cell membrane into the cytoplasm after insulin binding that has formerly been shown for preneoplastic hepatocellular foci [21]. IRS-1, Raf-1, and Mek-1 were noted as an increased cytoplasmic expression in the cholangiomas (Fig. 4b–d), suggesting increased signaling via the insulin-related Ras–Raf–MAPKinase pathway in the cholangiocytes.

Cholangiomas also moderately to strongly expressed the EGF-R (Fig. 4h). TGF- α was not expressed in cholangiomas but in hepatocytes of adjacent preneoplastic hepatocellular lesions (Fig. 4g), suggesting that TGF- α if secreted in a paracrine manner by the hepatocytes may have co-stimulated proliferation of the cholangiomas, in particular, in large tumors that did no longer show insulin dependence.

In situ hybridization

In situ hybridization for the y chromosome in cross-gender transplantations (female islet donors, male recipients) was done to determine whether the tumors originated from

recipient cholangiocytes or from graft cells that have undergone ductular transformation. The mean nuclear labelling index of hepatocytes was $84.8 \pm 8.7\%$ (range, 72–93%) in the hepatocytes of the investigated male L1 and BB1 animals, whereas, female controls showed no hepatocellular nuclear signals. Owing to polyploid sets of chromosomes, some hepatocellular nuclei showed more than one (up to four) signals. If the y chromosome was not in the cut level, no nuclear signal was noted.

Nuclei of cholangiocellular tumor cells showed a mean labeling index of $58.2 \pm 14.9\%$ (range, 35–72%). In cholangiomas, no more than one signal was noted per nucleus (Fig. 2f) which suggests that these cells were diploid and also explains the lower mean value of labeled nuclei when compared to hepatocytes. There was no single tumor that was devoid of y chromosome-containing cells; thus, each investigated tumor was derived from recipient cholangiocytes.

Additionally, two islet grafts were identified and showed no signals in islet cell nuclei, proving their female genetic background.

Discussion

This study indicates that after low-number transplantation of pancreatic islets into the livers of diabetic rats, local hyperinsulinism in combination with hyperglycemia leads to a prolonged proliferation of cholangiocytes that can progress into cystic cholangiomas within months. The important prerequisite was systemic diabetes, i.e., systemic hyperglycemia, which was not fully compensated by the low number of transplanted islets; thus, stimulating the β -cells in the grafts to maximally synthesize and secrete insulin. As a result, only liver acini located downstream of the islets were under the influence of combined hyperglycemia and hyperinsulinism, whereas, the remaining liver tissue (and the other organs) suffered from hypoinsulinism. This particular metabolic situation leads to distinct alterations in the downstream hepatocytes that proved to be of preneoplastic character and developed within 6–24 months into hepatocellular adenomas and carcinomas in streptozotocin-diabetic [11–13, 20–22] and in autoimmune-diabetic rats [16], but not in non-parenchymal liver cells [19]. The hepatocellular alterations can be explained as initially adaptive changes to the local hyperinsulinism, including increased signaling via insulin-related intracellular signaling pathways, such as the activation of the Ras–Raf–MAPKinase pathway [21], which exert strong proliferative effects. It is obvious that cholangiocytes directly adjacent to the islet grafts had to be under the same metabolic condition as the hepatocytes but before this study, it was not known whether this exerted a relevant effect on cholangiocellular growth.

Interestingly, high-number islet transplantation in BB/Pfd rats (BB2) also led to a slight increase in the formation of small islet graft-induced cholangiocellular tumors in the left liver part, but large tumors did not develop. It can be assumed that in these normoglycemic animals, the meta-

bolic situation (comparably lower insulin, normal glucose) downstream of the islet grafts is not such a strong proliferative stimulus for the bile duct epithelia as is the combination of high insulin and high glucose levels after low-number transplantation. We encountered a similar situation regarding the hepatocytes, in which high-number transplantation alone did not suffice to induce tumors, but was a strong co-carcinogenic factor in chemical hepatocarcinogenesis [15].

The close topographical relationship between islets and tumors of any size and the absence of a similar tumor development in the transplant-free left liver part clearly indicates that high insulin levels after islet transplantation are the major cause for cholangiocellular tumorigenesis. This is confirmed by the immunohistochemical results, showing the same translocation of the insulin receptor and overexpression of insulin-related intracellular signaling proteins of the Ras–Raf–MAPKinase pathway as a result of increased insulin action and as it has previously been shown in preneoplastic hepatocellular foci [21]. Nevertheless, it is known that several rat strains have a certain susceptibility to spontaneously developing (usually small) cholangiocellular tumors, and streptozotocin treatment may also be of influence. Thus, we performed several control experiments to evaluate 1) the rate of spontaneous cholangioma development in normoglycemic and diabetic animals, 2) the influence of the rat strain, 3) an implication of the transplantation procedure/embolization per se and 4) most importantly, the influence of the modus of diabetes induction, i.e., streptozotocin treatment.

The absence of increased tumor formation after transplantation of polystyrene particles in L3 excluded the embolization of the portal venule and ischemia as relevant factors, and strain differences have shown to have only a minor, if any, effect (L1 vs BB4, L2 vs BB5, and L4 vs BB7, respectively). Untreated (hypoinsulinemic) diabetes had also no significant influence (BB3 vs BB7).

As streptozotocin is a genotoxic compound of carcinogenic potential in rats [9, 39], it has to be excluded as a relevant contributor to tumor formation in this model. In the late 1970s, some research groups investigated a similar experimental setting of combined streptozotocin treatment or pancreatectomy and islet transplantation [24, 25, 34], but these studies lacked important control groups and investigated only very few animals ($n=10-25$). Thus, there was controversy about the question of whether the cholangiocellular tumors were a result of streptozotocin action as proposed by Feldman et al. [24] and Lorenz et al. [34], or of the islet transplantation as initially favored by Finch et al. [25] which could not be clarified. The present study shows that there is indeed a minor stimulatory influence of streptozotocin on cholangioma formation, as streptozotocin-administered but otherwise untreated rats (BB6) developed significantly more, albeit, only small cholangiocellular lesions than the corresponding completely untreated control animals (BB7) after 12–18 months. However, the very similar rate of cholangioma formation in BB/Pfd animals that became diabetic either spontaneously (BB1) or by streptozotocin administration (BB4)

highlights hyperinsulinism after islet transplantation to be of much more importance than the minor streptozotocin effect.

The occasional intra-insular proliferation of small ductules in early stages as depicted in Fig. 1 and the high proliferative activity of islet cells which has previously been shown to potentially lead to islet hyperplasia and insulinomas in this model [14], raise the possibility that, at least, some of the cystic tumors may have originated from transplanted graft cells, i.e., periductular or intra-insular stem-like cells with a high capacity for differentiation even into liver cells. Such sort of ductular proliferation has been observed in several experimental settings [6, 29, 30, 33, 41, 43, 44], but this was excluded by *in situ* hybridization.

It is interesting that we neither noticed the development of cholangiocarcinomas, as they were induced by a variety of chemical carcinogens [3, 5, 8, 35, 54], nor the malignant transformation of primarily benign cystic tumors, as occasionally reported for human biliary cystadenocarcinoma [31, 57]. Bannasch and coworkers have shown that the administration of the nitrosamine *N*-nitrosomorpholine (NNM) leads to toxic necrosis of the liver parenchyma, followed by (reparative) oval cell proliferation and neoductular proliferation, which developed into mucous cholangiofibrosis [2, 3, 5]. Cholangiomas, morphologically identical to ours, originated from these cholangiofibrotic foci and represented a final benign end-stage of tumor development. Thus, our study is in line with Bannasch's results regarding the benign character of the lesions, but tumor development in our model did not involve oval cell proliferation or the formation of preneoplastic foci of mucous cholangiofibrosis. The existence of this way of tumor development has already been suggested by Bannasch [5] and is now convincingly demonstrated for the first time. Oval cell proliferation in the regenerating liver only takes place when the regenerating capacity of the primary cell population (hepatocytes, cholangiocytes, or both) is blocked or severe injury has occurred, whereas, differentiated cholangiocytes and hepatocytes otherwise undergo self-renewal [23, 52]. As no severe cell injury affected the liver cells in our model, it is plausible that cholangiocellular proliferation is the result of insulin-induced direct proliferation of differentiated bile duct epithelia but required oval cell proliferation in the *N*-nitrosomorpholine model. However, we noticed the development of cholangiocarcinomas originating from benign cholangiomas in a model of co-carcinogenesis, combining the tumorigenic effects of NNM-administration and islet transplantation (unpublished observations). This indicates that islet hormones in the present experimental context need a co-carcinogenic factor to induce malignant cholangiocellular tumors, something that we will investigate in detail in a future study.

Conclusively, we have shown that low-number islet transplantation into streptozotocin- and autoimmune-diabetic rats leads to the development of large cystic cholangiomas, most likely as a result of combined hyperglycemia and increased local insulin action on cholangiocytes of portal bile ducts. This study also

excluded streptozotocin as a relevant co-carcinogenic factor. Although our results were basic research investigating the effect of transplanted pancreatic islets on the cholangiocytes in an animal model, they may also be of interest for clinical islet transplantation. At present, similar findings have not been reported in large animal studies [1] or in human patients, including one study with a long-term follow-up after autologous islet transplantation [55]. Thus, it is possible that cholangioma formation as a consequence of low-number islet transplantation may be exclusive to the rat model. However, in particular, human studies naturally lack a detailed histopathologic examination of the recipient liver tissue, and most patients did not stay in a long-lasting mild diabetic state, which proved to be a prerequisite for tumor development but are either normoglycemic (insulin-independent) or became diabetic again and received exogenous insulin treatment, owing to graft rejection. The question if insulin has any similar substantial effect on the cholangiocytes in humans can, thus, only reliably be answered in a long-term follow-up including detailed histologic investigation of the livers (autopsy cases), in particular, in patients that did not reach normoglycemia by this procedure, and thus, would be prone to high local intrahepatic insulin levels downstream of the remaining islets.

Acknowledgements The authors wish to thank Gabriele Becker, Jörg Bedorf, Danuta Chrobok, Mariana Dombrowski, Mathilde Hau-Liersch, Kirsten Herrmanns, and Uta Schönborn for technical assistance, Yvonne Fischer and Kurt Rüdél for animal care, Thomas Jonczyk-Weber for photographic work, and Bernd Wüsthoff for editing the manuscript. We are indebted to Dr. Chantal Mathieu, University of Leuven, Belgium, for providing us with breeding pairs of the BB/Pfd rats. This work was supported by the Deutsche Forschungsgemeinschaft (grant numbers Do 622/1-3, 1-4, and 1-5).

Molecular analysis of the EGFR-RAS-RAF pathway in pancreatic ductal adenocarcinomas: lack of mutations in the *BRAF* and *EGFR* genes

Received: 24 August 2005 / Accepted: 28 November 2005 / Published online: 6 April 2006
© Springer-Verlag 2006

Abstract The vast majority of tumors of the pancreas are ductal adenocarcinomas. This cancer type has an extremely poor prognosis and in many Western countries, it represents the fifth leading cause of cancer-related death. Pancreatic ductal adenocarcinomas exhibit the highest incidence of activating *KRAS* (Ki-Ras) mutations observed in any human cancer. It was therefore of interest to examine how this pattern would relate to mutations in the *BRAF* and *EGFR* genes, which are involved in the same signaling pathway as *KRAS*. We screened a series of 43 formalin-fixed, paraffin-embedded ductal adenocarcinomas of the pancreas. When DNA was extracted from whole tissue sections, *KRAS* codon 12 mutations were detected in 67% of the tumors. When cancerous ducts were isolated by laser-assisted microdissection, 91% were positive for *KRAS* mutations. Although it did not reach statistical significance, there was a trend in our material that survival after diagnosis varied according to *KRAS* mutation subtype, GTT-positive patients having the best prognosis. No alterations in *BRAF* exons 11 and 15 or in *EGFR* exons 18–21 were detected in *KRAS*-positive or *KRAS*-negative cases. We therefore conclude that the *BRAF* and *EGFR* mutations commonly seen in a variety of human cancers are generally absent from pancreatic ductal adenocarcinomas. Apparently, these tumors depend on no more than one genetic hit in the EGFR-RAS-RAF signaling pathway.

Keywords Pancreatic cancer · Mutation analysis · *KRAS* · *BRAF* · *EGFR*

Introduction

Cancer of the exocrine pancreas is a highly aggressive tumor, which in Western countries—including Norway—represents the fifth leading cause of cancer death [8, 19]. The overall five-year survival rate is less than 5%. Even for the small group of resectable patients, the five-year survival rate remains low, around 20% [37, 46]. Most pancreatic tumors are ductal adenocarcinomas with a mortality rate almost equal to the incidence rate [9], reflecting the very dismal prognosis of the disease.

Some knowledge has been obtained about the etiological factors behind pancreatic cancer [23]. There is an uneven world distribution with five to seven times higher incidence rates in high-risk countries, implying that environmental factors (reaching an old age, smoking, and diet) and ethnicity play a role [26]. An inherited component is estimated to be responsible for up to 10% of the cases. At least seven different germline disorders are known to be associated with increased risk for cancer of the exocrine pancreas [28] and, in addition, familial pancreatic cancer is now recognized as an own entity [5].

As other cancers, pancreatic ductal adenocarcinomas (PDAC) accumulate genetic changes in oncogenes and tumor suppressor genes. Characteristic for these tumors is the activation of the *KRAS* (Ki-Ras) oncogene, a process that occurs by point mutations in codon 12. In fact, 70–100% of the ductal adenocarcinomas exhibit *KRAS*-mutations—the highest frequency of *RAS* alterations known in human neoplasms [16, 38, 44]. Among the tumor suppressor genes, *CDKN2A* (p16) is inactivated in around 95% of the PDACs [41]. High frequencies of inactivation are also observed for *TP53* (p53) and *SMAD4* (DPC4), which are affected in 40–75% and 50–55% of the cases, respectively (see [23]). The genetic changes are thought to follow a specific temporal order where a *KRAS* mutation arises early in pancreatic carcinogenesis. *KRAS*

activation is then succeeded by *CDKN2A* inactivation and subsequently by the loss of the activity of other tumor suppressor genes [15].

The RAS proteins are part of the mitogen-activated protein (MAP)-kinase pathway where the MAP-kinase ERK is activated via receptor tyrosine kinases, RAS, RAF, and MEK proteins. This signaling cascade mediates growth signals from the cell surface to the nucleus and results in complex changes in cell behavior, especially concerning growth and proliferation. Large screening projects have

revealed that pathway members other than the *RAS* genes are also the subjects of frequent point mutations in human tumors. Davies et al. [11] reported cancer-related mutations in the *BRAF* gene in a majority of malignant melanomas (both primary tumors and cell lines) and lower but significant frequencies in other human cancers. More recently, Lynch et al. [29] and Paez et al. [34] demonstrated the presence of mutations in the epithelial growth factor receptor (*EGFR*) gene in a subset of sporadic, nonsmall-cell lung cancers.

The BRAF protein is a target of RAS. Moreover, overexpression of the receptor tyrosine kinase EGFR is generally observed in epithelial tumors including pancreatic ductal adenocarcinomas [21]. Thus, disturbances of the EGFR-RAS-RAF signaling system could be essential for the establishment and maintenance of pancreatic cancer cells. We therefore sought to undertake a careful mutational analysis of *KRAS*, *BRAF*, and *EGFR* in these tumors, using laser microdissection to isolate the cancerous ducts from the surrounding, nonneoplastic fibrous tissue. The *KRAS* mutation detection rate increased significantly in microdissected specimens compared to whole sections. However, *BRAF* or *EGFR* mutations were not observed, neither in the *KRAS*-positive nor in the *KRAS*-negative cases. We suggest that in this part of the MAP-kinase pathway, only one genetic hit is necessary for the development of the malignant phenotype of the highly aggressive PDAC tumors.

Materials and methods

Tissue specimens

Tissue blocks from 51 cases with adenocarcinomas of the pancreas, resected in the period 1996–2003, were obtained from the archives of the Department of Pathology, The Gade Institute, Haukeland University Hospital. All specimens were fixed in 10% buffered formalin and embedded in paraffin. The cases were revised by a pathologist (H. I.) to identify those tumors that were pancreatic ductal adenocarcinomas. The final diagnosis was based on an evaluation of hematoxylin–eosin (HE) and immunohistochemically stained sections and the patients' clinical records, including computerized tomography reports. Histological classification and staging were done according to the tumor, nodes, and metastasis stage classification system [2, 17]. The 43 cases of PDAC are listed in Table 1. Five specimens (#24, 25, 30, 31, and 32) represent intraoperative needle biopsies from unresectable patients, one specimen (#39) was a total pancreatectomy and the rest were surgical specimens from pancreas resections (classical Whipple procedure and modifications). The study was

approved by the Regional Ethics Committee and performed according to the Helsinki declaration.

DNA extraction from whole sections

One representative, formalin-fixed and paraffin-embedded tissue block was selected from each case. Depending on the size of the tumor tissue, one or two 10- μ m sections were cut. The sections were placed in 190 μ l buffer G2 and 10 μ l proteinase K solution of the MagAttract DNA mini M48 Kit (Qiagen GmbH, Hilden, Germany) and dissolved by shaking overnight at 56°C. DNA was then purified by using this kit in combination with a GenoM48 BioRobot system (Qiagen) in accordance with the manufacturer's instructions.

Laser microdissection and DNA extraction

Polyethylene naphthalate membrane-covered glass slides (P.A.L.M. Microlaser Technologies AG, Bernried, Germany) were treated for 30 min with 254 nm UV light. Tissue sections (7 μ m) were placed on the slides and incubated at 70°C for 30 min. Deparaffination and HE staining were performed according to routine procedures but without xylene at the end of the dehydration process. The stained slides were dried at 60°C for at least 1 h. Cancerous ducts were then microdissected using a Zeiss Axiovert 200 inverted microscope equipped with a microlaser system (P.A.L.M. Microlaser Technologies). To achieve better morphology of the uncovered tissue sections, a 70% alcohol solution was dripped on the slides. Parallel, routinely processed HE-stained sections were used as guide for the selection of cancerous ducts.

Two separate samples with a total area of 150,000 to 300,000 μ m² were microdissected from each section, catapulted, and captured in 15–30 μ l digestion buffer (10 mM Tris–HCl, pH 8.3; 1 mM EDTA; 1% Tween 20) that had been placed in the lid of an Eppendorf tube. After spinning the material down into the tube, proteinase K was added to a final concentration of 0.5 μ g/ μ l. The samples were then incubated for 16 h at 55°C, followed by proteinase K inactivation at 99°C for 10 min. One

microliter of this extract was used as template in the subsequent polymerase chain reactions (PCR).

PCR and DNA sequencing

KRAS (exon 1), *BRAF* (exons 11 and 15), and *EGFR* (exons 18–21) were PCR-amplified and screened for mutations by direct sequencing. Primer sequences are given in Table 2. For *EGFR* exons 18 and 21, a visible PCR product was often difficult to obtain after the initial amplification and nested PCR reactions were then performed with internal primer sets. In general, PCR reactions were run in a total volume of 25 μ l with 0.3 μ M of each primer using the AmpliTaq Gold PCR Master Mix (Applied Biosystems, Foster City, CA, USA). Samples were subjected to an initial denaturation at 95°C for 15 min, 40–45 cycles at 95°C for 50 s, annealing (see Table 2 for temperatures) for 50 s, and elongation at 72°C for 1 min, followed by a final elongation step at 72°C for 7 min. PCR products were column-purified by using the QIAquick PCR Purification Kit (Qiagen) or enzymatically treated with ExoSAP-IT (USB, Cleveland, OH, USA). The sequencing primers were identical to the PCR primers and all samples were sequenced in both directions employing the BigDye Terminator Cycle Sequencing Kit, version 1.1 (Applied Biosystems). The sequence reactions were analyzed on an ABI Prism 3100 Genetic Analyzer with Sequencing Analysis software, version 3.7 (Applied Biosystems). DNA extracted from cutaneous malignant melanomas and lung adenocarcinomas served as positive controls for *BRAF* and *EGFR* mutations, respectively.

KRAS and *BRAF* mutations were searched for in all 43 PDAC cases. *EGFR* mutations were screened in ten randomly selected *KRAS*-positive PDACs and in the four *KRAS*-negative cases. *KRAS* was examined in tumor DNA extracted from both whole tissue sections and laser-microdissected material, whereas *BRAF* and *EGFR* were sequenced only in laser-microdissected material.

Statistics

The statistical analyses were performed using the software package Statistica 4.1 (StatSoft, Tulsa, OK, USA). The Product-limit (Kaplan–Meier) Analysis Module was used for comparing the survival times between multiple groups. Survival times vs cumulative proportion surviving, according to breakdown by mutation groups, were plotted.

Results

Clinical material

Of the 51 collected adenocarcinomas from the pancreatic region, 43 cases were classified as PDACs after the reevaluation. The excluded cases were intraductal papillary mucinous neoplasms and ampullary, bile duct, and duode-

nal cancers. Clinicopathologic features of the 43 PDAC cases are shown in Table 1. The mean age of the patients was 66 years (range 35–82 years) and 42% were females. The tumor of case #31 had an anatomical location that involved the pancreatic body and tail, whereas cases #13, 39, and 50 involved the head and body. The remaining 39 tumors were confined to the pancreatic head. The median survival time after diagnosis was 10 months.

KRAS mutation analysis

We initially isolated DNA from whole tissue sections. *KRAS* mutation status was assessed by sequencing and 29 (67%) of the 43 cases were positive. However, PDACs are characterized by a varying and often very high ratio of desmoplastic stroma to tumor cell area. We therefore employed laser microdissection for isolating the cancerous ducts from the surrounding stromal component (Fig. 1). When *KRAS* sequencing was then repeated, 39 (91%) of the cases were positive. Figure 2a,b illustrates the improvement in sensitivity that was achieved from whole tissue sections to laser-microdissected material.

Fig. 1 Example of laser microdissection of a pancreatic ductal adenocarcinoma. A hematoxylin–eosin-stained section (7 mm) is shown before (a) and after (b) dissection. The isolated fragment with cancer cells in ductal arrangement is also shown (c). Scale bar: 200 μ m

Fig. 2 Mutation analysis by direct DNA-sequencing of pancreatic ductal adenocarcinomas. **a, b** Part of the exon 1 sequence (*reverse direction*) of the *KRAS* gene. Codon 12 is *underlined*. For the sequence in subpanel **a**, DNA was extracted from a whole section of the pancreatic tumor. In subpanel **b**, DNA was extracted from laser-microdissected cancerous ducts of a parallel section. Note the improvement of the signal in **b** as compared to **a** (*arrowhead*). See also Fig. 1. **c, d** Example of sequence analysis of the *BRAF* gene. A part of exon 15 is shown (*forward direction*). All analyzed

pancreatic tumors exhibited normal sequence as illustrated in subpanel **c**. Subpanel **d** shows a sample from a malignant melanoma, which contained the hot spot T1799A mutation of codon 600 (*underlined*) and served as positive control. **e, f** Example of sequence analysis of the *EGFR* gene. A part of exon 19 is shown (*forward direction*). All analyzed pancreatic tumors exhibited normal sequence as illustrated in subpanel **e**. Subpanel **f** shows a sample from a lung adenocarcinoma, which contained a deletion mutation in exon 19 and served as positive control

The distribution of different *KRAS* mutations in the material is shown in Fig. 3. The two most common alterations of the wild-type GGT (Gly) codon 12 was GAT (Asp) and GTT (Val), which were observed in 20 (47%) and ten (23%) of the cases, respectively. The mutations CGT (Arg) and GCT (Ala) were observed in six (14%) and one (2%) of the cases, respectively. No codon 13 mutation was detected. Two tumors contained different *KRAS* mutations in the two areas collected for laser microdissection (Table 1). In most tumors, the signal from the normal and mutated base was of comparable strength but in some cases, a complete change in the mutated base was observed, probably due to loss of the wild-type allele (data not shown).

KRAS mutations and patient survival

Data on survival after diagnosis were available for all cases. Univariate survival analyses demonstrated the expected correlation between negative lymph node status, tumor-free resection margin, and age less than 70 years with better prognosis (data not shown). We also examined whether *KRAS* mutation subtype correlated with survival. In our material, there was a trend where GTT-positive patients survived much longer (median 23.5 months) than GAT-positive patients (median 9.5 months), while the latter had a somewhat better prognosis than CGT-positive cases (median 7.5 months) (Fig. 4). The number of patients in each group is small and the differences did not reach

statistical significance, but the tendency is the same as observed by Kawesha et al. [20].

BRAF and *EGFR* mutational analyses

Previously published tumor-associated mutations in these genes are restricted to exons 11 and 15 (*BRAF*) and exons 18–21 (*EGFR*) and we limited our analyses to these exons. No mutations were observed in *KRAS*-negative or *KRAS*-positive samples. DNA samples extracted from malignant

Fig. 3 Distribution of *KRAS* mutations in the material of 43 pancreatic ductal adenocarcinomas. Regions with tumor cells were isolated by laser microdissection and analyzed by direct DNA sequencing. Mutations were only seen in codon 12 (GGT) and are listed as the changed codon

Fig. 4 Kaplan–Meier survival plot for 36 pancreatic adenocarcinomas according to breakdown by *KRAS* mutation subtype. Median survival time was 7.5, 9.5, and 23.5 months for the CGT, GAT, and GTT mutation groups, respectively. The observed survival times are indicated by circles (complete) or crosses (censored observations). The two cases with simultaneous GAT and GTT mutations were not included in the analysis

melanoma (*BRAF*) and nonsmall cell lung cancer (*EGFR*) were included as positive controls (Fig. 2c–f).

Discussion

The large-scale screening of cancer cell lines and primary tumors for somatic mutations has recently become the focus of several research efforts [47]. Enabled by the sequencing of the human genome, systematic analyses of gene families or signaling pathways have resulted in the identification of novel cancer-related mutations, often with a significant frequency in some malignancies. Examples include the discovery of *BRAF* alterations in melanomas and other cancers [11], *PIK3CA* alterations in colon and other cancers [40], and *EGFR* alterations in nonsmall cell lung cancer [29, 34]. These results are important because they extend our knowledge about the genetic changes necessary for cancers to arise, grow, and spread. Moreover, the presence of such mutations opens for molecular treatments tailor-made for the genetic damage that the tumors depend on. The latter concept is exemplified by the occurrence of *EGFR* mutations in adenocarcinomas of the lung and a positive response to gefitinib [29, 34], and by the possible effect of a RAF inhibitor against the most frequent *BRAF* mutation in malignant melanoma [48].

Pancreatic ductal adenocarcinomas are characterized by an extremely bad prognosis with a lack of treatment options for unresectable tumors. Thus, the identification of somatic mutations with a potentially therapeutic link would be an important finding even if the frequency turned out to be low in this cancer form. Ishimura et al. [18] were the first to report a screening for *BRAF* mutations in PDAC. They examined nine *KRAS*-negative and 19 *KRAS*-positive samples and found the common V599E (now denoted

V600E) mutation of *BRAF* exon 15 in two cases. Both were *KRAS*-positive. Calhoun et al. [7] did not observe any *BRAF* mutations among 74 *KRAS*-positive tumors but detected the common exon 15 mutation in three out of nine *KRAS*-negative cases. The latter constituted a distinct subset of pancreatic cancer with a medullary morphology. Loukopoulos et al. [25] examined 22 cell lines and primary tumors without finding *BRAF* mutations. In the present work, we did not observe any *BRAF* mutations among 39 *KRAS*-positive and four *KRAS*-negative cases. Neither did we detect *EGFR* exon 18–21 mutations among the ten *KRAS*-positive and four *KRAS*-negative cases examined. Similarly, Lynch et al. [29] reported that *EGFR* exon 19 and 21 mutations were sought in 40 pancreatic tumors (classification not specified) without any positive findings.

Taken together, we conclude that *BRAF* and *EGFR* mutations are very infrequent in PDACs. This fits with a model where disturbances of several signaling cascades are necessary for cancer development, but where one genetic hit in each pathway is sufficient. In PDAC with its very high frequency of *KRAS* alterations, simultaneous accumulation of other mutations in the MAP-kinase pathway may not give the tumor a growth advantage and are therefore not selected for. That *RAS* and *BRAF* mutations generally are mutually exclusive is well documented by the majority of studies investigating both genes in tumors or tumor cell lines. Examples include malignant melanoma [1, 11], papillary thyroid carcinoma [13], hyperplastic polyps and serrated adenomas of the colon [10, 22], colorectal carcinomas [32, 35], small intestinal adenocarcinomas [6], Barrett’s adenocarcinoma [43], and gallbladder carcinomas [39].

In colorectal cancer, *BRAF* and *KRAS* alterations associate with mismatch repair status [12, 35]. *BRAF* mutations are most frequent in mismatch-repair deficient (microsatellite instable) colorectal tumors, whereas *KRAS* mutations dominate when the mismatch-repair system is proficient. Pancreatic adenocarcinomas exhibiting DNA replication errors are rare and associated with wild-type *KRAS* and longer survival [14, 49]. They may have a ductal phenotype and may be linked to hereditary nonpolyposis colon cancer [30, 49] or their morphologic features may be consistent with medullary carcinoma [14]. Thus, the lack of *BRAF* mutations and very high frequency of *KRAS* mutations in pancreatic ductal adenocarcinomas could reflect the observation that mismatch repair deficiency seems to be of little importance in this tumor type [49]. Significantly shortened telomeres are detected in nearly all pancreatic intraepithelial neoplasias, the postulated precursor lesions for PDACs [45]. PDACs might therefore depend on the shortening of telomere length to disrupt chromosomal integrity, developing a mutator phenotype without impairment of mismatch repair.

Previous studies of *BRAF* [7, 18, 25] and *EGFR* [29] mutations in pancreatic ductal adenocarcinomas and this report all focus on those exons defined as mutational hotspots from initial, high-throughput screening efforts. Accordingly, one cannot exclude that genetic alterations outside exons 11 and 15 in *BRAF* and 18–21 in *EGFR* are

present in PDACs. Screening of the complete genes (and other genes of the MAP-kinase pathway), particularly in *KRAS*-negative tumors, might therefore be justified.

Methods employed in the screening of somatic cancer mutations include single-strand conformational polymorphism, denaturing gradient gel electrophoresis, and denaturing high-performance liquid chromatography. DNA sequencing is now commonly used for screening and serves as a gold standard for confirming and determining the identity of mutations revealed by other methods. However, the limited sensitivity of DNA sequencing is a pitfall because a mutation may remain undetected if normal or stromal cells outnumber the mutated cancer cells in a specimen [31, 33]. The sensitivity is of particular concern in PDAC where the cancerous ducts often constitute only a fraction of a tissue sample. This is illustrated by our results from the *KRAS* mutational analyses where we found 67% positive tumors when the DNA was isolated from whole sections, but 91% positive tumors after the cancerous ducts had been laser-microdissected. Only after an assurance that the analyzed material contains a significant fraction of tumor cells should direct DNA sequencing be recommended in the screening for somatic cancer mutations.

In various studies of PDAC, the number of *KRAS*-positive cases varies from 70 to 100% [4, 16, 36, 38, 44]. The lower estimates may reflect mutation detection techniques that were not sensitive enough and/or the presence of misclassified tumors in the material. In our collected archival material of 51 tumors originally classified as adenocarcinomas of the pancreas, eight cases (16%) were excluded because they had a morphology or site of origin not consistent with PDAC. Although some of the excluded cases also were *KRAS*-positive, the mutation frequency would have dropped from 91% to 82% if these cases had remained in the material (data not shown). We conclude that the true frequency of *KRAS* mutation in PDACs is at least 90%. A factor that may prevent this number from reaching 100% is that some PDACs arise because of germline mutations in tumor suppressor or DNA-repair genes and do not necessarily depend on *KRAS* activation [28, 49].

It is interesting to note that laser microdissection of two different samples from the same tumor led to the identification of different *KRAS* mutations in two cases (Table 1). *KRAS* mutations are likely to be an early event in pancreatic carcinogenesis as they are often seen in pancreatic intraepithelial neoplasia, increasing in frequency with cellular and architectural atypia [24, 27]. These mutations are also present in cancer-associated, morphologically normal duct epithelia, hyperplastic duct lesions, chronic pancreatitis, and in disease-free pancreas, especially at older ages. It is therefore not surprising that two different mutations may be detected in some cases of PDACs [44].

The distribution of *KRAS* mutation subtypes in our material of PDACs was similar to that observed in other series (see, for example, [16, 20]) with GAT (Asp) as the most commonly observed alteration of the wild type codon

12, followed by GTT (Val), and then CGT (Arg) (Fig. 3). A correlation between the presence and absence of *KRAS* mutation and survival is generally not observed [16, 20, 42]. However, the data of Kawesha et al. [20] suggested that mutation subtype could associate with survival because patients with GTT had a longer median survival than those with the GAT mutation, who again did better than those with CGT. We see the same trend in our material (Fig. 4) but these findings need verification in larger series. In this regard, we note that in advanced colorectal cancers, it is the GTT mutation that is associated with the most aggressive biological behavior and reduced survival [3].

In conclusion, *KRAS* remains the only oncogene for which somatic, activating mutations are known to be present at high frequency in PDACs. The absence of *BRAF* and *EGFR* mutations in these tumors supports a model where one mutational hit suffices to activate the MAP-kinase pathway. It is of fundamental importance to identify genetic alterations in pancreatic cancer with a therapeutic potential, but new candidates should preferentially be sought in other pathways.

Acknowledgements We thank Bendik Nordanger for expert technical assistance and Lars A. Akslen, Hanne Puntervoll, and Audny Hellebø for samples of positive control tissue. The study was supported by grants from the Meltzer Foundation, The Norwegian Cancer Society, and Helse Vest.

Trichostatin A enhances the response of chemotherapeutic agents in inhibiting pancreatic cancer cell proliferation

Received: 11 January 2006 / Accepted: 8 February 2006 / Published online: 28 March 2006
© Springer-Verlag 2006

Abstract Pancreatic cancer is an aggressive neoplasia, and standard chemotherapies are by and large ineffective. The purpose of this work was to get a comprehensive preclinical study on the ability of anticancer drug combinations that best inhibit growth of pancreatic adenocarcinoma cells. We evaluated the in vitro growth inhibition of ten pancreatic cancer cell lines to gemcitabine and 5-fluorouracil, newer generation cytotoxic agents (oxaliplatin, irinotecan), targeted therapy (gefitinib) and a histone deacetylase (HDAC) inhibitor (trichostatin A). Cells were treated with the single drug alone and all pairwise drug association. Our results demonstrate that TSA can effectively increase the drug sensitivity of all the cell lines studied. The association of TSA and irinotecan determines an increase in growth inhibition on the highest percentage of cell lines (80%). Our findings may represent an experimental basis for potential clinical application of HDAC inhibitors, in particular in association with drugs used in cancer clinical treatment, supporting the idea that HDAC inhibitors could act as sensitizers for chemotherapy.

Introduction

Pancreatic adenocarcinoma is one of the most aggressive human cancers. Its incidence nearly mirrors its mortality rate with a 5-year survival lower than 5% [16]; at diagnosis, less than 20% of patients are candidates for surgery with curative intent [21]. Standard treatments for advanced disease include radiotherapy and/or chemotherapy regimens. Radiotherapy has been shown to have some utility for regional confined cancers, but is often too toxic for tissues surrounding the neoplasia. Widely used chemotherapeutic regimens include 5-fluorouracil (5-FU) and gemcitabine, a novel nucleoside analogue of cytidine (2',2'-difluorodeoxycytidine; dFdC) (GEM) [10]. However, even gemcitabine, which is now considered the gold standard, has a response rate of less than 20%, although it does provide an improvement in the quality of life [4]. A major cause of treatment failure in pancreatic cancer is believed to be resistance to chemotherapy, which seems to be related to the altered expression of genes such as those involved in the apoptotic pathway [28]. For instance, the *p53* gene, which shows a high rate of mutation in pancreatic cancer [12], has been shown to increase the sensitivity of pancreatic cancer cells to gemcitabine when reintroduced in these cells [5].

It is known that combination of drugs with different mechanisms of action can compensate the lack of functioning of crucial steps for the activity of a specific drug, thus overcoming mechanisms of resistance. Recent clinical studies have investigated the possibility that the association of different drugs may result in more efficient antitumoral action. For example, gemcitabine in combination with 5-fluorouracil, docetaxel, cisplatin, oxaliplatin, or irinotecan has been shown to give a response rate in phase II trials generally slightly higher than gemcitabine alone [10]. However, no randomized phase III trial has yet established a survival clinical benefit for combination therapy compared with gemcitabine alone. Thus, it is important to identify novel drug associations that are more effective than gemcitabine-based treatment for pancreatic cancer.

The new generation compounds oxaliplatin and irinotecan (CPT11) are among the most promising cytotoxic agents available for clinical cancer treatment. Oxaliplatin is a third generation platinum derivative that differs from cisplatin and carboplatin in that it contains a cyclic, bulky group that may confer greater resistance to DNA repair and efficiently prevent DNA replication once oxaliplatin-DNA adducts have been formed [25]. Oxaliplatin demonstrates mild toxicity and good clinical management [2, 6]. CPT11 is a derivative of camptothecin and acts by interfering with the activity of DNA topoisomerase I, which cuts and relegates single-strand DNA. This drug causes the conversion of single-strand DNA breaks into irreversible double-strand breaks, resulting in cell death [13].

Besides the interest into these new generation cytotoxic agents, intense study has recently focused on drugs directed against specific molecular targets. One of the most promising examples is gefitinib (iressa), which specifically inhibits activation of the EGFR. The drug is now in clinical use for lung cancer [23], although it is worth noting that EGF receptor family is overexpressed in pancreatic cancer as compared with normal pancreatic cells [30].

In the last few years, therapeutic interest on histone deacetylase (HDAC) inhibitors has been rapidly increasing and it has been demonstrated that these drugs, including trichostatin A (TSA), induce growth arrest, differentiation, and/or apoptosis in cancer cells [17]. Moreover, it has been recently demonstrated that TSA induces apoptosis and G2-phase cell cycle arrest in pancreatic cancer cell lines by a p53-independent mechanism [8]. Furthermore, HDAC inhibitors display selective toxicity to cancer cell lines [1], reduce growth of neoplastic cells in animal models at nontoxic doses [22, 29], and thus, may represent a new therapeutic approach for cancer treatment [21].

The aim of the present study was to evaluate the efficacy of growth inhibition of chemotherapeutic drugs used for treatment of pancreatic cancer in a panel of pancreatic adenocarcinoma cell lines. The drugs investigated include, in addition to 5-FU and GEM, cytotoxic agents of new generation (oxaliplatin, CPT11), a molecular targeted drug (iressa), and a HDAC inhibitor (TSA), alone and in pairwise combinations. Using this approach, we demonstrate that the association of TSA with GEM, oxaliplatin, iressa, or CPT11 determines a significantly higher growth inhibition compared to other drug combinations. Our findings provide an experimental basis for clinical application of therapies for pancreatic adenocarcinoma that include HDAC inhibitors.

Materials and methods

Cell lines and culture condition

Ten human pancreatic cancer cell lines were investigated, comprising seven cell lines derived from primary cancer (MiaPaca2, PaCa3, PaCa44, Panc1, PT45P1, PSN1, and PC) and three from metastatic cancers (HPAF II, CFPAC1,

and T3M4) (for detailed descriptions of cell lines in terms of mutations commonly found in pancreatic cancer and origin, see [19]).

All cell lines were grown in RPMI 1640 supplemented with 20 mM glutamine, 10% FBS, and 50 µg/ml gentamicin sulfate (BioWhittaker, Italy), and were incubated at standard conditions (37°C with 5% CO₂). Cells were trypsinized, counted, and plated in 96-well cell culture plates (4×10³ cells/well) and cultured for 24 h. Cells were treated for 48 h with drugs at the indicated concentration.

Chemicals

Six drugs were used and included: 5-fluorouracil (Fluorouracil, 5-FU; Teva Pharma), oxaliplatin (Eloxatin; Sanofi), and irinotecan (Campto, CPT11; Aventis); gemcitabine (2',2'-difluorodeoxycytidine dFdC, Gemzar, GEM; Lilly) solutions prepared in sterile water and freshly diluted before each experiment; gefitinib (Iressa; Astra Zeneca) and trichostatin A (TSA; Sigma-Aldrich) were solubilized in DMSO and stored at -80°C until use.

Determination of IC₅₀ values and cell proliferation assay

The IC₅₀ value was defined as the drug concentration that causes 50% growth inhibition compared to controls. IC₅₀ values of each drug in all cell lines were obtained using dose-dependent curves at 48 h. These concentration values were used to test the antiproliferative effect of the various treatments in all cell lines. The proliferation assay was determined by the Crystal Violet method: cells were stained with Crystal Violet (Sigma) and solubilized in 1% sodium dodecyl sulfate in phosphate-buffered saline. The cell proliferation rate was measured photometrically (A₅₉₅). Three independent experiments were performed for each assay condition.

Statistical analyses

The difference between the strongest single treatment against the combined treatment was evaluated using the Welch two-sample *t* test, considering a *P*-value <0.05 as significant.

Results

Determination of IC₅₀ and inhibition of proliferation of pancreatic adenocarcinoma cell lines by single drugs

Ten pancreatic adenocarcinoma cell lines were treated with different concentrations of various individual drugs for 48 h, and the dose-dependent curves were determined (Fig. 1a,b). IC₅₀ values are shown in Table 1. Examination

of dose-dependent curves and their relative IC₅₀ values reveals that the differences in responsiveness among the ten cell lines is much greater after GEM, CPT11, and oxaliplatin treatments compared to 5-FU, iressa, and TSA. Moreover, treatment with GEM, 5-FU, or CPT11 did not lead to a complete inhibition of cell growth in contrast to oxaliplatin, TSA, and iressa, which resulted in near complete inhibition, suggesting the absence of a saturating effect. PSN1 was generally the most sensitive cell line to all drugs tested, while Panc1 was the most resistant. It is interesting to note that the IC₅₀ mean value was significantly lower with GEM or CPT11 when metastatic cell lines were compared with primary cell lines ($p \leq 0.05$). No correlations were found between the sensitivity towards each single drug and the known, principal genetic aberrations in *K-ras*, *p53*, *p16*, and *DPC4* [19].

Inhibition of proliferation of pancreatic adenocarcinoma cell lines by pairwise combined drug treatment

To test whether pairwise combined treatments may increase the growth inhibitory activity of GEM, 5-FU, oxaliplatin, CPT11, iressa, or TSA on pancreatic adenocarcinoma cells, we analyzed cell proliferation using all possible drug combinations at a concentration corresponding to their respective IC₅₀ (Fig. 2). Table 2 reports the increased percentage of cell growth inhibition by pairwise combination relative to that obtained with the single drug giving the higher growth inhibition. The percentages of the combined treatments that determined a significantly increased growth inhibition in each cell line are shown on the right side of the Table 2, while the percentages of cell lines that presented a significant cooperative effect on cell growth inhibition by the indicated combined treatments are reported at the

Fig. 3 Percentage of pancreatic adenocarcinoma cell lines showing increased effect on cell growth inhibition after the indicated combined treatment

bottom of the Table 2. Of particular interest, all drug combinations including TSA gave the highest value of cell growth inhibition. These results demonstrate that TSA is the best partner for all drugs with the exception of 5-FU; the combination of TSA and CPT11 determined the highest growth inhibition in the largest number of cell lines (Fig. 3).

Panc1, the most resistant cell line to single-drug treatments, showed a much stronger sensitivity in the combined treatments; while PSN1, the most sensitive cell line to single-drug treatments, becomes the most resistant cell line to all combined treatments. It is of interest to note that all pairwise combinations were less effective in PaCa3, which contains a functional *p53* gene.

Discussion

To date, few comprehensive preclinical studies have been performed on the ability of anticancer drug combinations to inhibit pancreatic adenocarcinoma cell growth [3, 9, 15, 18].

In this study, we present for the first time a comprehensive analysis on the growth inhibitory effect of five chemotherapeutic agents (GEM, 5-FU, oxaliplatin, iressa, and CPT11) in clinical use, with an inhibitor of HDACs (TSA) on pancreatic adenocarcinoma cell lines.

We are fully aware that our decision to use a wide panel of drugs and cell lines penalized the experimental plan which was necessarily simplified and was unable to answer the question whether the various drug combinations act in an additive or synergistic manner. However, our study presents the characterization of a panel of pancreatic cancer cell lines for their response to the most commonly used chemotherapeutic drugs either alone or in combination that will be useful for further work on the molecular mechanisms of drug action and interaction.

The most significant finding of our study is that TSA, together with GEM, oxaliplatin, iressa or, in particular, with CPT11, determines a significantly higher growth inhibition compared to the other pairwise drug combinations. Moreover, we also demonstrate that drug combinations including TSA determine the highest growth inhibition on the largest number of cell lines. These results demonstrate that TSA is the best partner for all drugs but 5-FU, and that TSA and CPT11 give rise to an optimal anticancer effect on 80% of cell lines studied, suggesting that it may be a promising treatment strategy for pancreatic adenocarcinoma.

Recently, we have shown that TSA induces growth arrest and apoptotic cell death on nine of the pancreatic adenocarcinoma cell lines described in this paper [8]. In addition, we and others previously demonstrated, by gene expression and proteomic profiling, that HDAC inhibition determined the variation of a relatively small number of genes involved in the regulation of proliferation (*p21*, *p19*, *p57*, and *cyclin A* and *B*), signal transduction (*TNF* and *TNFR* superfamily), and apoptosis (*BCL* superfamily) [7, 8, 11, 20, 27]. In particular, an increased ratio between the expression of proapoptotic (*Bim*) and antiapoptotic (*Bcl-xL* and *Bcl-w*) genes was observed [20]. These results suggested the possibility that an inhibitor of HDAC, such as TSA, may sensitize cells without a functional *p53* gene to the effect of current chemotherapeutic agents. Our data demonstrate that TSA can effectively increase the sensitivity of all pancreatic adenocarcinoma cell lines with a nonfunctional *p53* gene to other drugs. It is interesting to note that PaCa3 cells, which are wild type for the *p53* gene, were particularly resistant to all combined treatments, confirming the idea that the *p53* gene status is not relevant for cell sensitization by TSA.

In conclusion, combined treatments of anticancer drugs and the HDAC inhibitor TSA increase drug cytotoxicity in pancreatic adenocarcinoma cells and may open the way for combination therapy with HDAC inhibitors in pancreatic

cancer. In fact, inhibitors of HDAC are already in clinical use for other tumors and do not show apparent toxicity [14, 17, 24, 26].

Acknowledgements We thank Dr. E. Pinton and Dr. A. Sbarufatti (Aventis and Sanofi-Synthelabo) for providing irinotecan and oxaliplatin. Unusual ultrastructural features in microvillous inclusion disease: a report of two cases

Received: 7 December 2005 / Accepted: 13 February 2006 / Published online: 12 April 2006
© Springer-Verlag 2006

Abstract Microvillous Inclusion Disease (MID) is an inherited disorder characterized by intractable diarrhea in infancy. Ultrastructural detection of pathognomonic microvillous inclusions in the enterocytes is essential for diagnosis. The aim of this research is to contribute to the knowledge of MID studying enterocytes and goblet cells (gc). Samples of duodenal mucosa from two young infants with MID (aged 75 days and 3 months, respectively) were studied by light and electron microscopy. Detection in the intestinal villi of immature gc (with microvilli) in one of the cases led us to seek them in control samples. The total number of gc with microvilli (immature) and without microvilli (mature) were counted. In both MID specimens, light microscopy showed atrophy of villi and PAS-positive material in the enterocyte cytoplasm. The ultrastructure of villous enterocytes was characterized by brush-border abnormalities, microvillous inclusions, dense apical granules, and lysosomes. Intermediate structures between microvillous inclusions and lysosomes were also detected within a cell, as were rare microvilli on the lateral membrane of the enterocytes. In one MID specimen, immature gc were also identified in the absorptive

compartment. Only mature gc were observed in the controls. The significance of the latter finding requires further studies.

Introduction

Microvillous inclusion disease (MID), or congenital microvillous atrophy [7], is a serious disorder within the syndrome of intractable diarrhea of infancy [8]. It appears to be transmitted as an autosomal recessive trait [7], although the relevant molecular abnormality has not been identified. A genetic cause is supported by cases described in siblings and by regional clusters of the disease reported in isolated populations [26]. There are two types of MID: congenital or early-onset MID arising in the first postnatal days with severe watery diarrhea accounts for the vast majority of cases; the less common late-onset MID develops after the neonatal period and carries a better prognosis [23]. Infants often die from severe hydro-electrolyte imbalance or from complications secondary to long-term total parenteral nutrition [7, 23]. Today, small bowel transplantation, alone or in combination with liver transplantation, seems to be the only effective treatment for MID and offers prospects of a good quality of life [29].

The main histological features of the disease include diffuse villous atrophy without inflammatory changes and accumulation of periodic acid-Schiff (PAS)-positive material within the apical cytoplasm of enterocytes [7, 8, 22, 23, 31]. The definitive diagnosis of MID rests on distinctive ultrastructural findings: microvillous inclusions (more frequently in villous enterocytes), increased electron-dense secretory granules (preferentially in crypt epithelial cells), and poorly developed brush-border microvilli on the intestinal surface epithelium [3, 7, 22, 23, 31, 33].

Cases with clinical features similar to MID exhibiting abnormal brush-border microvilli but without the charac-

teristic inclusions have been described as intestinal microvillous dystrophy [19, 27]. However, it is unclear whether the two diseases are related.

The pathogenesis of MID is unknown. The postulated cytoskeletal abnormalities involving actin, myosin, and vinculin [4, 5] cause a block in exocytosis, mainly of PAS-positive material related to the brush border. This mechanism correlates well with accumulation of PAS-positive secretory granules in the apical part of the enterocyte cytoplasm [24]. Recently, abnormalities in glycocalyx exocytosis were demonstrated in MID by Phillips et al. (2004) [25] using histochemical and immunohistochemical methods. The pathogenesis of secretory diarrhea seems to be related to abnormalities in the sodium transport system [18].

We describe the transmission electron microscopic features of two cases of MID to provide a further ultrastructural contribution to the knowledge of this rare disease, of which little more than 30 cases have been reported so far in world literature [15]. We investigated both the enterocytes and the goblet cells, which have poorly been studied in MID [3, 8]. The ultrastructural features of MID goblet cells were compared with those of controls.

Patients and methods

Patients

Small intestinal tissue fragments of per-oral mucosal biopsies from two MID patients, aged 75 days and 3 months, respectively, were available.

For the ultrastructural study of goblet cells, only case 1 could be compared with control tissue, as the specimen from case 2 was too small and was entirely needed for diagnostic purposes. Control tissue was represented by mucosal biopsy samples of the small intestine from seven different patients (ranging 3 up to 26 months in age), four of which were histologically normal and three abnormal, respectively. The clinical characteristics of MID patients and controls are summarized in Table 1. Histologically normal specimens were obtained from three infants with failure to thrive, who had no gastrointestinal cause identified (cases 3, 4, and 5) and from one with cystic fibrosis (case 6). The abnormal specimens came from an infant with chronic diarrhea and partial villous atrophy of the mucosa (case 7); one with celiac disease and villous atrophy (case 8); and one with milk protein intolerance with partial villous atrophy (case 9).

All biopsies were performed with fully informed parent consent as part of the routine investigation of patients with gastrointestinal disorders.

Light and transmission electron microscopy

Duodenal biopsy specimens were processed for light and electron microscopy. Specimens for light microscopy were

fixed in 10% buffered formalin, processed according to standard protocols, and embedded in paraffin. Four-micron-thick sections were stained with haematoxylin and eosin (H&E) and PAS.

For electron microscopy, specimens were fixed in 2% glutaraldehyde/2% paraformaldehyde in 0.1 M phosphate buffer for 3 h at 4°C, postfixed in 1% osmium tetroxide in the same buffer solution, dehydrated in graded alcohols, and embedded in an Epon–Araldite mixture. Semi-thin sections (2 µm) were obtained with a MICROM HM 355 microtome (ZEISS, Oberkochen, Germany) and stained with toluidine blue. Thin sections were obtained with an MTX ultramicrotome (RMC, Tucson, AZ, USA), stained with lead citrate and examined with a CM10 transmission electron microscope (Philips, Eindhoven, The Netherlands).

As preliminary observation of the villi in the MID case 1 showed a well-developed microvillous apparatus in the apical part of some goblet cells, to exclude artefacts related to the plane of section, for the purpose of this study, an ultrastructural qualitative study was also performed. Thus, four grids, each containing about four 80-nm-thick serial sections for a total thickness of about 1.3 µm of tissue, were analyzed. Furthermore, as the goblet cells had microvilli in all examined sections, we investigated whether this unusual feature was also present in control specimens. The number of mature (without microvilli) and immature (with microvilli) goblet cells was, thus, counted in the MID case and in all control specimens as well. Only goblet cells with an intact apical cellular membrane (i.e. cells still containing mucous granules) on perfectly longitudinal sections were examined to better examine the ultrastructural details of the apical part of cytoplasm.

Results

Light microscopy

The duodenal biopsies taken at the age of 75 days in case 1 and at 3 months in case 2 showed partial and total villous

atrophy, respectively. PAS stain highlighted the neutral subgroup of mucins of goblet cells and showed abundant PAS-positive material in the apical part of the enterocyte cytoplasm (Fig. 1), likely corresponding to non-excreted material usually employed by the cell metabolic processes for the composition of the microvillous membrane–glycocalyx complex normally seen along the apical surface of the absorptive cells. In case 1, a diffuse lymphoplasmacytic infiltrate was also seen in the lamina propria.

Transmission electron microscopy

Enterocytes

The ultrastructural appearance of villous enterocytes was similar in both specimens. The microvilli were reduced in number and shortened. Large portions of epithelial cell surfaces were completely devoid of microvilli (Fig. 2). Many microvillous inclusions (MIs) of varying size and shape were detected in the apical part of the enterocyte cytoplasm (Fig. 2). They generally contained numerous and not well-oriented microvilli with well-represented filamentous core rootlets. Many voluminous apical lysosomal granules were also evident (Fig. 2). Transitional structures intermediate between MIs and lysosomes, i.e., granules containing few microvilli-like projections, were identified. These three distinct structures (MIs, lysosomes, and transitional granules) were simultaneously present in villous enterocytes whose apical surface was devoid of microvilli (Fig. 3). Small, membrane-bound dense granules (secretory granules) (Fig. 4) of variable shape and size (ranging from 100 to 300 nm), smaller than lysosomes, were also observed. In case 1, rare microvilli with filamentous core rootlet on the lateral membranes of the villous epithelium were also evident (Fig. 5). Crypt enterocytes had normal appearances and exhibited well-formed microvilli.

Goblet cells (case 1)

Goblet cells with an immature aspect were observed in the villi of MID case 1 (Table 2): they contained well-developed microvilli on the whole apical surface of the cell (Fig. 6a and inset of Fig. 6a). One of these cells, as further evidence of its immaturity, also contained few, non-confluent mucous granules and did not exhibit the characteristic goblet appearance (Fig. 6b and inset Fig. 6b). Some small (ranging from 20 to 80 nm in diameter) membrane-bound dense granules, likely a component of the external glycocalyx, were also present among microvilli (inset of Fig. 6a). Mature goblet cells (cells completely devoid of or with scanty peripheral microvilli) were never observed in this specimen (Table 2).

In the controls, we detected only goblet cells with a mature ultrastructural aspect (Table 2). They always showed the expected goblet appearances; their luminal surface was usually smooth and convex, and completely

lacked microvilli or exhibited few peripheral microvilli (Fig. 6c and inset of Fig. 6c).

Discussion

A few more than 30 cases of MID have been reported so far [15]. Two additional MID cases are herein described. Their submicroscopic features did not differ from previous descriptions: enterocytes with severe brush-border changes contained both secretory dense granules and microvillous inclusions. However, two additional ultrastructural features were detected in these cases, which have rarely been reported in MID enterocytes. In addition, an entirely novel finding is the presence of immature goblet cells.

n.d. not done

The first uncommon feature that has been observed in (absorptive) villous enterocytes was the presence of transitional structures intermediate between microvillous inclusions and lysosomes in the apical part of cytoplasm. This finding is in line with a recent paper [28] demonstrating that the lysosomes accumulating into enterocytes derived from the transformation of microvillous inclusions (considered as early endosomes) via transformation into transitional structures (considered as late endosomes). In fact, microvillous inclusions stain with sucrase-isomaltase (SI) but are negative for lysosome specific markers, such as lysosome-associated membrane protein (LAMP), indicating their nature as early endosomes. Late endosomes express both LAMP and SI, whereas, lysosomes are strongly positive for LAMP and weak for SI. These data suggest that MID is caused by increased autophagocytosis of the apical membrane of enterocytes with formation of microvillous inclusion bodies [28].

The second observed feature was the presence of microvilli on the lateral membrane of villous enterocytes, which has previously been described [6, 23]. Lateral membrane microvilli have been also detected in rats after colchicine treatment [21]. According to Phillips and Schmitz (1992) [23], this ultrastructural finding may be ascribed to de novo synthesis of membrane, as the apical membrane is unlikely to migrate to a basolateral position. Recently, Ameen and Salas (2000) [2] hypothesized a role for ERM (ezrin, radixin, and moesin) proteins in this ultrastructural aspect: these proteins mediate the attachment of the actin/villin cores to the apical membrane to organize and stabilize the microvilli [32]. According to these authors, in MID the protein content decreases in the apical area and increases in the basolateral membrane. Croft et al. (2000) [6] reported a case of late-onset MID, where enterocytes were endowed with lateral membrane microvilli, and suggested that their presence may be related to a mild clinical phenotype. Phillips and Schmitz (1992)

[23] also observed a similar ultrastructural feature in early-onset cases and our finding supports this correlation.

The novel ultrastructural finding reported in this paper is the presence in case 1 of immature villous goblet cells characterized by both a well-developed apical brush border and the presence of scarce, non-confluent mucous granules: to our knowledge this finding has never been reported in MID.

The MID cytotype that has been most extensively investigated from an ultrastructural point of view is the enterocyte. Goblet cells have scarcely been studied and are described as cells with normal morphology and distribution [3, 8]. However, in a recent study Kučinskienė et al. (2004) [16] described a decreased number of goblet cells with low mucus secretion in a MID case. The mature goblet cell is characterized by an expanded apical cytoplasmic region containing confluent mucous granules. The luminal surface of the cell exhibits a few microvilli on the periphery of the cytoplasmic membrane, but it is usually smooth and convex over the secretory granules [11, 12, 30]. Similar goblet cells have been detected in villi from both normal and pathological controls, but immature goblet cells like those described in the villi of our MID case 1 have never been reported.

We can rule out that for technical reasons related to the plane of section the goblet cell microvilli observed in our MID case could be those normally localized at the periphery of the apical cell membrane. These cells were studied in serial sections by analysing a total thickness of about 1.3 μm of tissue (the microvilli measure 80–90 nm in diameter [11]) and were detected in all sections. Among the microvilli of immature goblet cells we observed some membrane-bound dense granules whose appearance corresponds with the glycocalyceal bodies found on the apical surface of normal and neoplastic epithelial cells of intestine [13, 17], respiratory tract [1, 9] and oesophagus [20]. Their function and nature are unknown [10, 14].

Even though the theory of a delayed differentiation of goblet cells needs to be confirmed in further MID cases, we hypothesize that the observed changes in these cells may be due to a mechanism of compensation in a severely disrupted absorptive compartment in this disease, as supported by the simultaneous presence in the same case of laterally sided microvilli.

In conclusion, we report the ultrastructural features of enterocytes in two MID cases and describe some morphological aspects of these cells that have been reported in very few of such cases. In addition, we describe for the first time immature goblet cells in MID villi, a finding that warrants further morpho-functional investigation.

Up-regulation of matrix metalloproteinase-2 and membrane-type 1-matrix metalloproteinase were coupled with that of type I procollagen in granulation tissue response after the onset of aortic dissection

Received: 28 February 2005 / Accepted: 18 November 2005 / Published online: 12 April 2006
© Springer-Verlag 2006

Abstract The pathophysiological significance of matrix metalloproteinases (MMPs) in aortic dissection remains poorly understood. The purpose of the present study is to clarify the significance of MMPs in aortic dissection. The activities and distributions of MMP-2, membrane-type 1-MMP (MT1-MMP), and MMP-9 were evaluated by gelatin zymography, immunohistochemistry, and in situ hybridization in 29 patients and seven autopsy cases. To assess if these MMPs are related to a tissue remodeling process, we compared the expression of these MMPs with that of type I procollagen and platelet-derived growth factor receptor β chain (PDGF R β). Patients were divided into three groups based on histological findings: acute, intermediate, and healed groups. The most remarkable changes were observed in the intermediate group, in which MMP-2 activity peaked and tissue expression of mRNAs for MMP-2 and MT1-MMP were observed in spindle-shaped cells in the neointima, organizing thrombus, and the adventitia.

These expression patterns were essentially coupled with those of type I procollagen mRNA and PDGF-R β protein. The association of MMP-2, MT1-MMP, type I procollagen, and PDGF-R β suggests that MMP-2 and MT1-MMP could be involved not only in the degradation of aortic tissue but also in tissue remodeling, which may be associated with the healing process.

Introduction

Aortic dissection is a dynamic disease that may involve any portion of the aorta. Despite significant advances in diagnostic and therapeutic techniques, morbidity and mortality rates remain unsatisfactory. Conversely, the spontaneous closure of the false lumen has been documented in some patients and this event is a favorable prognostic factor [1, 25]. These clinical data suggest the significance of the healing and repair processes in dissections of the aorta.

Tissue remodeling is an essential part of all repair processes involving the degradation and synthesis of the extracellular matrix. Matrix metalloproteinases (MMPs) can degrade various components of the extracellular matrix. Most MMPs are secreted as zymogens that are most likely activated in the extracellular space by other proteases. Membrane-type 1-MMP (MT1-MMP) forms a complex with tissue inhibitor of metalloproteinase-2 (TIMP-2) serving as a cell surface receptor for pro-MMP-2 activation [22], and degrades collagen fibers [20]. Among the MMPs, MMP-2 and MMP-9 have been implicated in the pathogenesis of aortic aneurysms and atherosclerotic plaque [6, 14, 21]. MMP-1, MMP-2, and MMP-9 have been reported to play a role in the development and progression of aortic dissection [10, 12, 15, 23].

Considering the complex mechanisms involved with these matrix-degrading enzymes, we constructed the

present study to examine the gelatinolytic activities of MMP-2 and MMP-9, and in situ distributions of MMP-2, MMP-9, and MT1-MMP, and analyzed their role in aortic dissection. We also evaluated the tissue remodeling processes by examining in situ distributions of type I procollagen, a representative matrix protein, and platelet-derived growth factor receptor beta chain (PDGF-R β), a marker of activated fibroblasts/myofibroblasts [11]. The results reveal the complex significances of MMPs, and we propose that they are not only involved in tissue degradation but also in tissue remodeling after the onset of dissection.

Materials and methods

Patients

Twenty-nine patients with aortic dissection who underwent surgery at Tohoku University Hospital were analyzed in the present study (Tables 1, 2, and 3). To analyze the significance of MMPs after the onset of dissection, the patients were divided into three groups based on the histological findings [26]: acute, intermediate, and healed as described in the “Results” section. A full-thickness specimen oriented in cross-section was obtained from the dissected site adjacent to the entry site (within 3 cm) during surgery and processed for gelatin zymography, immunohistochemistry, and in situ hybridization. Aortic sample sites are listed in Tables 1, 2, and 3. Control specimens of the ascending aorta were obtained 1 to 3 h after death from seven autopsy cases without significant aortic disease (Table 4). To analyze the significance of MMPs at the onset of dissection, specimens from six patients just after the onset of dissection (<24 h, a subgroup of the acute group) were compared with specimens from seven normal individuals obtained during autopsy. A specimen from a macroscopically confirmed nondissected site was also

obtained from the ascending aorta as “nondissected site (<24 h)” in five of six patients who received surgery within 24 h after the onset of a dissection.

The specimens were conventionally processed and stained with hematoxylin–eosin and elastica-Masson’s staining for evaluation by light microscopy. Patients with Marfan’s syndrome, a bicuspid aortic valve, or those undergoing reoperation were excluded from this study. Patients with a traumatic or iatrogenic aortic dissection were also excluded. This study was approved by the Ethical Committee of Tohoku University School of Medicine (#2000-119). Written informed consent was obtained from all patients.

Gelatin zymography

A fresh full-thickness specimen was snap-frozen in liquid nitrogen and stored at -80°C until use. The frozen tissue was homogenized in chilled 0.01 mol/l NaCl containing 0.01 mol/l CaCl_2 , 0.05% Tween 20, 2 mmol/l PMSF, 0.02% NaN_3 , 2% dimethylsulfoxide (DMSO), 2 mol/l urea, and 50 mol/l Tris–Cl at a pH of 7.5. The homogenate was centrifuged at 13,000 rpm for 15 min at 4°C . The supernatant was collected and applied to gelatin zymography. Gelatin zymography was performed as previously described, with minor modifications [13, 17]. Tissue extract containing 7.5 μg of protein was separated on a sodium dodecyl sulfate (SDS) polyacrylamide gel containing 0.8 mg/ml gelatin in a nonreducing condition. Purified MMP-2 and pro-MMP-9 (Yagai, Yamagata, Japan) were used as positive controls. After electrophoresis, the gel was washed three times for 15 min in a washing buffer containing 2.5% Tween 20, 10 mmol CaCl_2 , 1 μmol ZnCl_2 , and 50 mmol Tris–Cl (pH 7.5) to remove SDS. The gel was then incubated with an incubation buffer containing 1% Tween 20, 10 mmol CaCl_2 , 1 μmol ZnCl_2 , and 50 mmol Tris–Cl (pH 7.5) at 37°C for 18 h, and stained with

Coomassie blue R250. The bands for total MMP-2, active MMP-2, and pro-MMP-9 were quantified by densitometry with Image Gauge (FUJI FILM, Tokyo, Japan). A reference sample in each gel was used to normalize scanned bands among the gels. All results are expressed as the average value obtained from repeating the analysis twice. The relative activities of MMPs were expressed in arbitrary units (AU). To determine if the gelatinolytic bands were derived from MMPs, an additional extraction was incubated with EDTA (20 mmol/l) added to the previously described buffer.

Immunohistochemistry

The methods employed during this study were described previously [2, 11]. We used frozen sections that were prefixed with periodate-lysine-4% paraformaldehyde for 16 h at 4°C. The primary antibodies employed were mouse

monoclonal antibodies against human pro-MMP-2 (clone CA4001, IgG1, concentration 4.8 µg/ml) [9], TIMP-2 (67-4H11, IgG1k, 1.3 µg/ml, Fuji Chemical, Takaoka, Japan), pro-MMP-9 (GE213, 20 µg/ml) [16], PDGF-Rβ (61520.11, IgG1, 5 µg/ml, Genzyme, Cambridge, USA), and type I procollagen (PC-5-5, IgG1, 1.3 µg/ml, Takara, Kyoto, Japan). Frozen sections, 6 µm-thick, were incubated with these primary antibodies overnight and processed with a Nichirei Histofine Kit (Nichirei, Tokyo, Japan). Mouse monoclonal antibodies against human MT1-MMP (114-6G6 and 113-5B7, Fuji Chemical, Takaoka, Japan) were also employed. However, these antibodies were unsuccessful in detecting its respective antigen in frozen sections. As a negative control, the primary antibodies were replaced by isotype-matched control antibodies of the same concentration (DAKO, Grostrup, Denmark). All sections were then counterstained with hematoxylin.

In situ hybridization

The methods employed during this study were described previously [18]. We used the following cDNAs: (1) 2,654 bp *HindIII*-*Xba I* fragment of MMP-2 cDNA [9]; (2) 1,242 bp *EcoRI*-*HindIII* fragment of MT1-MMP cDNA [22]; (3) 1,098 bp *EcoRI*-*EcoRI* fragment of type I procollagen cDNA [5]. Digoxigenin-labeled cRNAs were transcribed in vitro as described in the manufacturer's manual (DIG RNA Labeling Kit; Roche Diagnostics, Basel, Switzerland). For in situ hybridization, the specimen was fixed in 4% paraformaldehyde and 0.5% glutaraldehyde overnight, and then embedded in paraffin. The deparaffinized section was treated with 20 µg/ml proteinase-K for 30 min. The hybridization mixture containing 1 µg/ml antisense or sense probes was applied for 16 h at 50°C. After rinsing, alkaline-phosphatase-conjugated anti-digoxigenin antibody was added at a concentration of 1:500 overnight. The chromogen was nitroblue tetrahydrochloride. All sections were then counterstained with methyl green.

Statistical methods

Statistical analysis for the results of gelatin zymography was performed with SPSS 11.5.1J (SPSS Japan, Tokyo, Japan). Differences among groups greater than three were

Fig. 1 An example of gelatin zymography. *Autopsy*, the cadaveric specimen from autopsy case; *nondissected site* (<24 h) the nondissected site just after the onset (<24 h); *acute* the dissected site in the acute group; *intermediate* the dissected site in the intermediate group; *healed* the dissected site in the healed group. The positions of molecular weight standards (MW) are indicated on the left. Purified pro-MMP-9 and MMP-2 commercially available were used as positive controls

analyzed by the Kruskal–Wallis rank test and Scheffe's *F* test. All tests were considered to be significant at $P < 0.05$.

Two observers (MA and HO, with the latter being blind to the clinical data) independently performed semiquantitative analysis for immunohistochemistry and in situ hybridization. The expression of MMPs, PDGF-R β , and type I procollagen were semiquantified as follows: (+), abundant; (\pm), moderate; (-), minimal or absent. If the observers differed in their opinions, the two observers evaluated the microscopic fields and discuss the findings to reach a consensus.

Results

The clinical profiles of 29 patients and seven autopsy cases were shown in Tables 1, 2, 3, and 4. Twenty-nine patients were divided into three groups: acute ($n=11$, day 0–4, fibrin deposition, neutrophil infiltration, and minimal tissue response), intermediate ($n=9$, 13 days–4 months, abundant stromal cell-response and matrix synthesis), and healed ($n=9$, >2 years, sparse stromal cells and dense deposition of matrix) groups.

The mean age (year) \pm standard deviations of patients in acute, intermediate, and healed groups and that of autopsy cases were 61.9 \pm 9.7, 61.9 \pm 12.7, 65.7 \pm 9.2, and 63.7 \pm 10.2, respectively. There was no significant difference with regard to age among these four groups. As for five patients from whom the nondissected site (<24 h) was obtained, their mean age (year) \pm standard deviations were 56.2 \pm 9.7, which is also not different with that of autopsy cases.

Hypertension was present in 10 (91%), four (44%), and nine (100%) patients in the acute, intermediate, and healed groups, respectively. As for patients from whom the nondissected site (<24 h) was obtained, hypertension was present in all patients. Six of the autopsy cases (86%) had a history of hypertension.

Gelatin zymography

Figure 1 shows an example of gelatin zymography. First, we compared MMP levels among the three groups using all

cases. Active MMP-2 was most abundant in the intermediate group (Fig. 2a), while pro-MMP-9 was higher in the acute group (Fig. 2b). The total MMP-2 activity showed no significant differences among different groups. Next, we compared MMP levels between the dissected and non-dissected site just after the onset of dissection (<24 h; a subgroup of the acute group). As shown in Fig. 3a,b, the levels of active MMP-2 and pro-MMP-9 from the dissected sites were higher than the levels from the nondissected sites in those patients who received surgery within 24 h. The MMP levels in the nondissected sites (<24 h) did not differ from the levels found in the cadaveric specimens.

Immunohistochemistry and in situ hybridization

To clarify the in situ distribution, we performed immunohistochemistry and in situ hybridization to detect proteins and mRNAs, respectively. The semiquantitative results of these studies are shown in Table 5.

Fig. 2 Comparison of the activities of MMP-2 (a) and MMP-9 (b) from the dissected sites in different groups (acute, intermediate, and healed groups) by Box-Whisker plots. MMPs-2 and 9 peaked in the intermediate and the acute groups, respectively. The relative activities of MMPs were expressed in arbitrary units (AU)

Fig. 3 Comparison of the activities of MMP-2 (a) and pro-MMP-9 (b) in the patients just after the onset (<24 h) and in the autopsy cases by Box-Whisker plots. The activities in the dissected sites were higher than those in the nondissected sites and in the cadaveric specimens. The relative activities of MMPs were expressed in arbitrary units (AU)

Dissected site in the acute group (>day 4, 11 patients)

As observed with light microscopy, a thin-layered thrombus was attached to the dissected surface (Fig. 4a), where it was infiltrated by neutrophils. These neutrophils abundantly expressed pro-MMP-9 protein (Fig. 4g). Neutrophils infiltrating in the adventitia also expressed pro-MMP-9. Medial spindle-shaped cells constitutively expressed pro-MMP-2 and TIMP-2 proteins (Fig. 4b,e) and moderately expressed mRNAs for MMP-2 and MT1-MMP (Fig. 4c,d). Type I procollagen mRNA was not observed (Fig. 4f).

In the nondissected site (<24 h, five patients), however, no case revealed expression of pro-MMP-9 protein or mRNAs for MMP-2, MT1-MMP, and type I procollagen. Medial spindle-shaped cells constitutively expressed pro-

Type I procollagen mRNA (**f**) was not detected. Pro-MMP-9 protein (**g**, brown) is abundantly positive in neutrophils. **h** Isotype-matched control antibody for pro-MMP-2 is not stained. Scale bar=50 μm

MMP-2 and TIMP-2 proteins as in dissected sites (data not shown). As shown in Fig. 4h, IgG isotype-matched control antibodies showed no specific stains in all patients, confirming the specificity of our results.

*Dissected site in the intermediate group
(day 13–4 months, nine patients)*

The adventitia was markedly thickened (Fig. 5a). Neointima developed on the dissected surface in patients with patent false lumen. In patients with an occluded false lumen, the thrombus in the false lumen was partially organized, showing a proliferation of spindle-shaped cells and deposition of collagen fibers in the peripheral areas (Fig. 6a). Messenger RNAs for MMP-2 (Figs. 5b and 6b) and MT1-MMP (Figs. 5c and 6d), and pro-MMP-2 (Fig. 6c) and TIMP-2 (Figs. 5h and 6e) proteins were abundantly expressed by the spindle-shaped cells in the neointima, organizing thrombus, and adventitia, which were closely coupled with the expression of type I procollagen mRNA (Figs. 5d and 6f) and protein (Figs. 5i and 6g) in the same areas. The spindle-shaped cells in those areas further expressed PDGF-R β protein

(Figs. 5j and 6h). The number of neutrophils expressing pro-MMP-9 protein decreased, and macrophages and multinucleated giant cells in the organizing thrombus were positive for pro-MMP-9 protein (Fig. 6i). As shown in Figs. 5e–g, the sense probes for mRNAs for MMP-2, MT1-MMP, and type I procollagen showed no specific signals in all patients, confirming the specificity of our results.

Dissected site in the healed group (>2 years, nine patients)

Spindle-shaped cells were sparse with dense deposition of collagen fibers in the neointima, organized false lumen, and adventitia (Fig. 7a). The number of cells positive for pro-MMP-2 (Fig. 7b), TIMP-2, type I procollagen (Fig. 7f), and PDGF-R β (Fig. 7g) proteins markedly decreased, and there were few cells expressing pro-MMP-9 protein (Fig. 7h). The cells positive for these substances were primarily localized around vasa vasorum in the adventitia. The number of cells positive for mRNAs for MMP-2 (Fig. 7c), MT1-MMP (Fig. 7d), and type I procollagen (Fig. 7e) also markedly decreased in those areas.

Fig. 5 Morphological results of the dissected site with a thickened adventitia from the intermediate group (day 14). **a** A panoramic view. *M* media; *FL* false lumen; *Ad* adventitia. Higher magnifications of boxed area in **a**, showing abundant expression of MMP-2 mRNA (**b**, dark blue), MT1-MMP mRNA (**c**, dark blue), and type I procollagen mRNA (**d**, dark blue) by the spindle-shaped cells in the adventitia. Note a clear similarity of the expression pattern of MMP-2, MT1-MMP, and type I procollagen mRNAs. Negative controls are shown in sense probe for MMP-2 mRNA (**e**), sense probe for MT1-MMP mRNA (**f**), and sense probe for type I procollagen mRNA (**g**). TIMP-2 protein (**h**, brown), type I procollagen protein (**i**, brown), and PDGF-R β protein (**j**, brown) are abundantly expressed by the spindle-shaped cells in the adventitia were shown. Discussion

The present study was designed to clarify the significance of MMP-2, MT1-MMP, and MMP-9 in aortic dissection. We have revealed two types of distinctive up-regulation of MMPs: MMP-9 in the acute group, and MMP-2 in the intermediate group, the latter coupled with MT1-MMP, TIMP-2, type I procollagen, and PDGF-R β . The gelatinolytic activities and the in situ distribution of these MMPs in these groups were significantly higher than those in the nondissected aorta (<24 h) or the control aorta obtained from autopsy cases.

It is well known that immunohistochemistry for MMP-2 shows constitutive expression of its protein in smooth muscle cells irrespective of its production status [6, 14]. Therefore, in situ hybridization was performed to evaluate the in situ production of MMP-2 as reported previously [18, 19]. To consider the significance of MMPs in various stages after the onset of dissection, we have divided patients into three groups based on the histopathological changes [26] because these changes were related to the time course.

The most pronounced signal of MMP-2 mRNA was observed in the cytoplasm of spindle-shaped cells in the organizing thrombus, neointima, and thickened adventitia in the intermediate group, in which the gelatinolytic activity of MMP-2 was highest. The spindle-shaped cells in the same areas also abundantly expressed MT1-MMP mRNA and TIMP-2 protein in the same pattern. Moreover, such abundant expression of MMP-2, TIMP-2, and MT1-MMP were coupled with those of type I procollagen and PDGF-R β . These quite notable findings required us to consider tissue remodeling because matrix degradation is not only important for tissue degradation, but is also required for deposition of new collagen fibers in the injured vessels [24]. Morphologic findings showed the formation of granulation tissue on the surface of the false lumen in the intermediate group, which later became fibrosis (scar) in the equivalent areas in the healed group. The same findings were also observed in the thickened adventitia. Briefly, matrix synthesis is stimulated and matrix accumulation actually occurs in these areas where MMP-2, TIMP-2, and MT1-MMP are up-regulated. If we focused only on tissue degradation, it would have been difficult to explain these morphological findings. When the simultaneous up-regu-

Fig. 7 Morphological results of the dissected site with scarring adventitia from the healed group (6 years). **a** A panoramic view. *FL* false lumen; *Ad* adventitia. Higher magnifications of *boxed area* in **a**, showing pro-MMP-2 protein (**b**, *brown*, scanty positive in spindle-shaped cells in vasa vasorum), MMP-2 mRNA (**c**, no signal), MT1-MMP mRNA (**d**, no signal), type I procollagen mRNA (**e**, no signal), type I procollagen protein (**f**, no staining), PDGF-R β protein (**g**, *brown*, no staining), and pro-MMP-9 protein (**h**, no staining). Scale bar=50 μ m

lation of MMP-2, TIMP-2, MT1-MMP, type I procollagen, and PDGF-R β are compared with these morphologic changes described above, we have concluded that the up-regulation of these substances is most probably associated with the deposition of new collagen fibers. The spontaneous closure of false lumen is documented as a favorable prognostic factor [1, 25]. In this situation, the dissection may heal, obliterating the false lumen and leaving a linear scar in the outer media. Our data suggested that MMP-2, TIMP-2, and MT1-MMP in the intermediate group are related to the matrix regeneration process, which may be related to the healing process.

As for MMP-9, we observed its more pronounced expression in neutrophils in the acute group. Neutrophils play a role in tissue damage caused during the inflammatory process. The MMP-9 expressed by neutrophils is involved in the digestion of dead tissue that is a step in the tissue repair process [7]. We could consider two possibilities for this observation. First, from our data, it could be interpreted that MMP-9 may contribute to the degradation of the aortic wall in the early stage. This event may be one of the factors that worsen the prognosis of the disease. The other possibility is that MMP-9 activity may be significant in tissue remodeling. However, further study is required to elucidate the significance of MMP-9.

We compared the activities of MMP-2 and MMP-9 in the nondissected sites (<24 h), the dissected sites (<24 h), and the cadaveric specimens by gelatin zymography. The activities of these MMPs in the dissected sites (<24 h) were significantly higher than in the nondissected sites (<24 h) and in the cadaveric specimens. Our data suggested that the up-regulation of MMP-2 and MMP-9 have already been affected by the dissection itself, not indicating higher MMP-2 and MMP-9 before the dissection. Therefore, we have not obtained the data that supports the concept that MMP-2 and MMP-9 are involved in the onset of aortic dissection. However, the possibility remains that the actual MMP-2 and MMP-9 activities in the entry sites may be higher even before the aortic dissection because aortic dissection occurs at the points of presumed greatest hemodynamic stress [8], which can alter the MMPs activity [3, 4]. The present study revealed the distribution of mRNA and/or protein of MMP-2, MT1-MMP, TIMP-2, and type I procollagen. To evaluate the molecular events more precisely, we should explore in situ zymography or double/triple-labeling tissue staining in future studies. Also, our present study covered a rather limited number of patients, and therefore, future studies will require a larger patient cohort to more accurately compare MMP activities in various clinical conditions. In addition, the involvement of additional MMPs, such as MMP-1, MMP-8, and MMP-12 should be evaluated in the future studies.

In conclusion, the present study revealed the complex activities of MMPs and TIMPs, with a role not only in tissue degradation but also in tissue remodeling after the onset of an aortic dissection.

Acknowledgements We are grateful to Dr. Kazuhiko Igarashi (Department of Biomedical Chemistry, Hiroshima University School of Medicine) for his help with the molecular biological techniques, and to Dr. Shoko Miura and Dr. Isao Ohno (Department of Infectious and Respiratory Diseases, Tohoku University Graduate School of Medicine) for their technical guidance on gelatin zymography. Technical assistance from Ms. Fumiko Date is greatly appreciated. The present study was supported by the Japan Foundation of Cardiovascular Research from 2000 to 2002.

Pathological function of prostaglandin E2 receptors in transitional cell carcinoma of the upper urinary tract

Received: 9 September 2005 / Accepted: 11 December 2005 / Published online: 12 April 2006
© Springer-Verlag 2006

Abstract The prostaglandin E2 receptor, EP4 receptor (EP4R), plays an important role in the development of transitional cell carcinoma of the upper urinary tract (TCC-UUT). However, the clinical significance of other EP receptors (EP1R–3R) is not clear. Furthermore, the pathological function of EP receptors in such patients is not understood. In the present study, we examined the expression of EP1R–3R in 101 TCC-UUT tissues by immunohistochemistry. Furthermore, we defined the relationship between cyclooxygenase (COX)-2 and EP receptor expression, proliferation index (PI), microvessel density (MVD), and expression of metalloproteinase-2 (MMP-2), urokinase-type plasminogen activator (uPA), and exon v6 containing CD44 isoform (CD44 v6) by multivariate analysis. The expression of EP1R, EP2R, and EP3R was positive in 20 (19.8%), 26 (25.7%), and 14 (13.9%) tumor samples, respectively. Expression of these receptors was not associated with pathological findings or survival. COX-2 and EP4R were independently associated with MVD and MMP-2, and uPA or PI and MMP-2,

respectively. Other EP receptors were not influenced by any factors. Our results suggest that EP1R–3R play a minimal role in cancer progression in patients with TCC-UUT. On the other hand, EP4R regulates tumor progression via cancer cell proliferation and MMP-2, distinct from COX-2.

Introduction

The clinical and pathological significance of cyclooxygenase (COX)-2 in cancer cells has become increasingly important due to mounting evidence demonstrating that COX-2 plays an important role in carcinogenesis, tumor development, and prognosis in several cancers including transitional cell carcinoma of the urinary bladder [9, 17, 24, 34, 37]. The main function of COX-2 is to convert arachidonic acid to prostaglandins (PGs); PGE2 is the most predominant and active end-product in this COX-2 pathway. PGE2 affects various physiological functions, including cell proliferation, angiogenesis, immune responsiveness, and apoptosis [4, 31, 32]. The role of PGE2 on these physiological activities has important implications for the malignant potential and aggressiveness of cancer cells. Therefore, much attention has focused on the pathological significance of PGE2, and enhanced synthesis of PGE2 and activation of malignant aggressiveness by PGE2 were observed in various cancers [18, 29, 36]. In addition to these cancers, PGE2 pathway was also reported to be associated with malignant aggressiveness in urothelial carcinomas of the bladder [10]. Furthermore, pharmacological and animal studies showed that the major antitumor action of nonsteroidal anti-inflammatory drugs (NSAIDs), which are COX-2 inhibitors, is mediated through the inhibition of PGE2 [11, 38]. The findings support the notion that PGE2 stimulates carcinogenesis and tumor development.

This study was not funded by any commercial organization. It was supported in part by a Grant-in-Aid from the Japanese Society of the Promotion of Science.

The biological activities of PGE2 can be attributed to their specific receptors (EP1 receptor to EP4 receptor; EP1R–EP4R) on target cells [6]. Therefore, one could hypothesize that one or any of the EP receptors may affect carcinogenesis and tumor progression. Indeed, EP receptors are reported to be associated with malignant potential, cancer cell development, and survival in several cancers [2, 5, 14, 15, 26, 30, 35]. In addition, we recently reported that the expression of COX-2 and EP4R was associated with high stage and poor prognosis in patients with transitional cell carcinoma of the upper urinary tract (TCC-UUT) [23]. However, there are no reports on the clinical significance and prognostic influence of EP1R–EP3R in patients with TCC-UUT.

COX-2 and PGE2 appear to influence tumor development and prognosis through a variety of mechanisms [7, 13, 19, 20–22, 27, 28]. For example, COX-2 and PGE2 regulate cancer cell proliferation, angiogenesis, matrix metalloproteinase (MMP)-2, urokinase-type plasminogen activator (uPA), and CD44 in various carcinomas [7, 19–21]. In patients with TCC-UUT, we previously reported that high proliferation index (PI), microvessel density (MVD), and MMP-2 expression were associated with high pT stage and poor prognosis [22], and several other investigators also showed similar trends and results [13, 28]. In contrast, Nakanishi et al. [27] reported that uPA expression was positively associated with tumor stage in patients with TCC-UUT. Furthermore, among CD44 proteins, exon v6 containing CD44 isoforms (CD44 v6)

was associated with malignant potential and tumor invasion in TCC of the urinary tract [12]. Thus, PGE2 might regulate malignant aggressiveness and tumor development through a complex mechanism. However, the relationship between EP receptors and these COX-2/PGE2-related factors in TCC-UUT is not fully understood.

A number of investigators have assessed the potential usefulness of COX-2 inhibitors for the prevention of carcinogenesis and tumor development [1, 3, 25]. However, other investigators speculated that various EP receptor inhibitors can control carcinogenesis and cancer cell development [11, 15]. Therefore, detailed data regarding the independent action of COX-2 and each EP receptor will be required for planning prevention and treatment strategies.

The main objective of the present study was to clarify the clinical and prognostic significance of EP1-3 receptor in patients with TCC-UUT. A secondary objective was to elucidate the interaction between COX-2 or each EP receptor and PI, MVD, and MMP-2, uPA, and CD44 v6 by using multivariate analysis.

Materials and methods

Patients and tissue samples

One hundred and one consecutive patients who were diagnosed with nonmetastatic TCC of the renal pelvis and ureter were reviewed retrospectively. Our study included

72 men and 29 women, ranging in age from 39 to 87 years (median age, 67 years). The clinicopathological features of participating patients are summarized in Table 1. Patients who had received any preoperative therapy were excluded from the study. All histological diagnoses including tumor grade and pT stage were performed using formalin-fixed and paraffin-embedded specimens from radical surgery; staging and grading were assessed in accordance with the 1997 tumor–node–metastasis (TNM) classification. A single pathologist performed all of the pathological examinations. The median follow-up period was 44 months (range, 3–250 months). The study protocol was approved by the Human Ethics Review Committee of the Nagasaki University School of Medicine.

Immunohistochemistry

Sections (5 μm thick) were deparaffinized stepwise in xylene and rehydrated in graded solutions of ethanol. Antigen retrieval was performed at 95°C for 40 min in 0.01 M sodium citrate buffer (pH 6.0). All sections were then immersed in 3% hydrogen peroxide for 30 min to block endogenous peroxidase activity. Primary antibodies were obtained from Cayman Chemical Corporation (Ann Arbor, MI; antihuman EP1R, EP2R, EP3R, and EP4R antibody), American Diagnostica (Greenwich, CT; antihuman uPA antibody), and R&D systems, Inc. (Minneapolis, MN; antihuman CD44 v6 antibody). Sections were incubated with anti-EP1R–4R antibody (1:100), anti-uPA antibody (1:175), or anti-CD44 v6 antibody (1:1,200) at 4°C overnight. Excluding the EP4R, the sections were washed extensively prior to treatment with peroxidase using the labeled polymer method with DAKO EnVision+ Peroxidase (Dako Corporation, Carpinteria, CA) for 60 min after incubation with primary antibody. On the other hand, the sections were then incubated with biotinylated antirabbit IgG for anti-EP4R antibody, followed by incubation with horseradish-peroxidase-conjugated avidin. The peroxidase reaction was visualized with the liquid DAB substrate kit (Zymed Laboratories Inc., San Francisco, CA). Sections were counterstained with hematoxylin, dehydrated stepwise through graded alcohol series, and cleared in xylene before mounting. A consecutive section from each sample processed without the primary antibody was used as a negative control. Positive controls included normal kidney and breast cancer tissue samples stained for EP1R–4R and uPA, respectively. Immunohistochemical staining for Ki-67, CD31, and MMP-2 was performed as described previously [22].

Quantitative analysis and staining interpretation

All analyses of immunohistochemical staining were assessed by light microscopy within the tumor area. For

evaluation of immunohistochemical staining for EP1R–3R, the staining intensity was graded as none, weak, moderate, or strong. Carcinoma cells that showed moderate or strong staining were considered positively stained. EP1R, EP2R, and EP3R expression was considered positive when at least 10.2, 61.2, and 33.1% of cancer cells were judged as positive cells, according to the ratio of positive cells in normal epithelium (this ratio is the upper limit of positive staining ratio in normal epithelium). Evaluation of EP4R expression was performed similar to a previously reported method [23]. Briefly, EP4R expression was considered positive when at least 20.0% of cancer cells were judged as positive cells. Expression of uPA was evaluated based on previously described criteria [27]. The staining intensity was scored from 0 to 3: none, weak, moderate, or strong staining. The extent of positive staining in the tumor area was scored from 0 to 3: none, focal ($\leq 25\%$), regional (25–75%), or diffuse ($>75\%$). These two scores were summed to yield the final score, ranging from 0 to 6. A score of at least 5 was considered positive. CD44 v6 expression was evaluated using the method described by Toma et al. [33]. In brief, tumors with positive staining rates greater than 50% were considered positive. Evaluation of immunohistochemical staining for Ki-67, CD31, and MMP-2 was performed as described previously [22]. For Ki-67 PI and MVD, the median value was considered as the higher group, and those with staining that does not exceed the median value were considered as the lower group for statistical evaluation. Slides were blindly evaluated twice at different times by two investigators who were blinded to the clinical characteristics and survival data.

Statistical analysis

Normality was evaluated by normal distribution and histograms for each variable, and the results were expressed as medians (interquartile range) unless otherwise stated. The Mann–Whitney U test was performed for continuous variables, and χ^2 test was used for categorical comparison of the data. The crude and adjusted effects on grade and immunohistochemical staining, as well as other risk factors, were estimated by logistic regression analysis and were described as odds ratios (OR) with 95% confidence intervals (95% CI), together with the P values. Variables that achieved statistical significance in univariate analysis were subsequently entered into a multivariate analysis model. Cause-specific survival rates were compared with Kaplan–Meier analysis and the log rank test. Variables that achieved statistical significance ($P < 0.05$) in the univariate analysis were subsequently entered into a multivariate analysis using a Cox proportional hazards analysis. All statistical tests were two-sided and significance was defined as $P < 0.05$. All statistical analyses were performed using the statistical package StatView (version 5.0).

Results

Expression and clinical significance of EP1–3 receptors

Representative examples of EP1R, EP2R, and EP3R in cancer cells are shown in Fig. 1a–c, respectively; staining was observed in the cancer cell membrane and cytoplasm. Representative examples of EP1R, EP2R, and EP3R in normal epithelial cells are shown in Fig. 1d–f, respectively. The median rates (range) of strongly or moderately stained normal epithelial cells of EP1R, EP2R, and EP3R were 5.3% (0.5–10.2%), 43.1% (3.8–61.2%), and 24.1% (5.1–33.1%), respectively. Finally, 20 (19.8%), 26 (25.7%), and 14 (13.9%) tumor sections were judged positive for EP1R, EP2R, and EP3R, respectively. This staining was specific

for each EP receptor because it was performed when each antibody was preincubated with human recombinant protein (data not shown). Expression of EP1R, EP2R, and EP3R was not associated with COX-2 expression ($P=0.578$, 0.700 , and 0.426 , respectively). In addition, this expression was not associated with clinicopathological features including pT stage and grade (Table 1) and cause-specific survival (Fig. 2).

Correlation with cancer cell proliferation, angiogenesis, and expression of MMP-2, uPA, and CD44 v6

The PI and MVD in the tumor area were 17.2% (11.2–30.1%) and 43 per high-power field (HPF) (34–63/HPF), respectively. The PI in specimens negative for COX-2

Fig. 1 Representative examples of expression of EP1 receptor (a), EP2 receptor (b), and EP3 receptor (c) in cancer cells, and expression of EP1 receptor (d), EP2 receptor (e), and EP3 receptor (f) in normal epithelium. Expression of all receptors was observed in the cytoplasm and cell membrane. Expression of uPA (g) and CD44 v6 (h) was detected in the cell cytoplasm and cell membrane, respectively (original magnification: $\times 200$)

Fig. 2 Kaplan-Meier curves for cause-specific survival in patients with TCC-UUT according to EP1 receptor expression (a), EP2 receptor expression (b), and EP3 expression (c). Expression of these receptors was not prognostic for cause-specific survival

expression and those positive for COX-2 expression was 14.2% (10.8–25.1%) and 29.1% (15.2–34.7%), respectively, and there was a significant difference between the two groups ($P < 0.001$). Likewise, the PI in tumors positive for EP4R expression (25.8%, 15.2–32.1%) was significantly higher ($P < 0.001$) than that in tumors negative for EP4R (13.2%, 9.7–24.3%). In contrast, no such significant

differences were found in EP1R, EP2R, and EP3R ($P = 0.936$, 0.565, and 0.498, respectively).

The MVD in specimens negative for COX-2, positive for COX-2, negative for EP4R, and positive for EP4R expression was 41/HPF (34–51/HPF), 59/HPF (42–72/HPF), 41/HPF (34–51/HPF), and 55/HPF (39–70/HPF), respectively. The MVD in specimens positive for COX-2 or EP4R was significantly higher ($P < 0.001$) than in specimens negative for COX-2 or EP4R. However, with regard to MVD, there were no significant differences in EP1R, EP2R, and EP3R ($P = 0.946$, 0.664, and 0.170, respectively).

Representative expression of uPA and CD44 v6 is shown in Fig. 1g,h, respectively; uPA was stained mainly in the cell cytoplasm, and CD44 v6 was in the cell membrane. We then investigated the relationship between COX-2 expression or each EP receptor and expression of MMP-2, uPA, or CD44 v6 (Table 2) with the use of univariate analysis. There was a significant correlation between MMP-2 expression and COX-2 or EP4R expression ($P = 0.003$ and < 0.001 , respectively). Likewise, positive staining for uPA was associated with positive expression of COX-2 ($P = 0.014$) and EP4R ($P = 0.023$). However, MMP-2 expression was not associated with EP1R ($P = 0.400$), EP2R ($P = 0.237$), and EP3R ($P = 0.649$), and uPA expression was not associated with them ($P = 0.298$, 0.608, and 0.087, respectively). In contrast, CD44 v6 expression was not associated with the expression of either COX-2 or EP receptors.

To investigate the independent roles of COX-2 or each EP receptor for high cancer cell proliferation, hypervascularity, and high expression of MMP-2, uPA, and CD44 v6, factors selected in the univariate analysis and high grade were included into a multivariate analysis model (Table 2). COX-2 expression was identified as an independent factor for high MVD and positive expression of MMP-2 and uPA (OR 2.84, 95% CI 1.18–6.82, $P = 0.020$; OR 2.70, 95% CI 1.12–3.75, $P = 0.028$; and OR 2.47, 95% CI 1.06–5.76, $P = 0.036$). In contrast, EP4R expression was not an independent factor for high MVD ($P = 0.402$) and uPA expression ($P = 0.068$), but was independently associated with high PI (OR 3.16, 95% CI 1.25–7.98, $P = 0.015$) and MMP-2 expression (OR 3.14, 95% CI 1.24–7.94, $P = 0.016$).

Discussion

In the present study, our results did not demonstrate that EP1R–3R played a significant and important role in tumor development and survival in patients with TCC-UUT. To our knowledge, the clinical and pathological significance of EP1R–EP3R in these patients has not yet been clearly defined. However, we recently demonstrated that EP4R was positively associated with pT stage and grade, and was a useful predictive marker for cause-specific survival in patients with TCC-UUT [23]. Several investigators have assessed the pathological significance of EP1R–EP3R; for example, EP1 receptor may affect carcinogenesis and

^aAdjusted for tumor grade

tumor development in colon cancer [11] and breast cancer [15]. Furthermore, EP2R and EP3R are also associated with malignant aggressiveness in endometrial adenocarcinoma [14] and prostate cancer [5] or lung cancer [35], respectively. From these reports, we hypothesized that, in addition to EP4R, one or some of the EP1R–3R also influence carcinogenesis, malignant aggressiveness, and survival in patients with TCC-UUT. However, contrary to our hypothesis, the expression of EP1R–3R was not significantly associated with clinicopathological features and survival. We speculate that the expression pattern and function of EP receptors may depend on the pathological type and origin of malignant cells. Finally, we speculate that among the EP receptors, only EP4R had clinical and prognostic significance in patients with TCC-UUT.

COX-2 and/or PGE₂ affects the malignant potential of cancer cells through their capacity to regulate several factors [9, 37]. Among such factors, we paid attention to cancer cell proliferation, angiogenesis, and expression of

MMP-2, uPA, and CD44 v6 because they are thought to be associated with malignant aggressiveness in TCC-UUT [12, 13, 22, 27, 28]. Our results demonstrated that COX-2 expression was positively associated with MVD, MMP-2 expression, and uPA expression. Based on these findings, we speculate that COX-2 influences cancer cell development and survival through tumor proliferation, angiogenesis, and MMP-2 in patients with TCC-UUT. Furthermore, our results also demonstrated that EP4R expression was positively associated with cancer cell proliferation and MMP-2 expression. Several factors are thought to be responsible for the pathological mechanism of EP4R in cancers. Asano et al. [2] reported that increased PGE₂ influenced tumor growth and progression via EP4R in human gallbladder carcinoma. Chen and Hugh-Fulford [5] also reported that PGE₂ modulated cell growth via EP4R in human prostate cancer cells (PC-3 cells). Furthermore, Dohadwala et al. [8] reported that signals via EP4R upregulated MMP-2 in non-small-cell lung cancer. In

agreement with our findings, Kinugasa et al. [16] reported that COX-2 inhibitors can prevent tumor invasion via downregulation of MMP-2 in oral cancer cell lines. The present study did not demonstrate a significant correlation between the expression of CD44 v6 and that of COX-2 and EP receptors. However, several investigators reported that CD44 was regulated by COX-2 or PGE2 in cancer cells [7, 8]. To our knowledge, there are no reports regarding the relationship between CD44 v6 and COX-2 or EP receptors in human cancer tissues. In addition, the relationship between COX-2 or EP receptors and standard or other variant isoforms of CD44 in TCC-UUT remains to be elucidated. We speculate that CD44 v6 is not associated with COX-2 or EP receptors in TCC-UUT. In addition, there was no significant correlation between EP1R–3R and these factors. These results support the findings that all EP1R–3R types were not associated with clinicopathological features and survival in patients with TCC-UUT.

The most interesting finding of the present study is that PI and MMP-2 expression was independently influenced by EP4R expression in a multivariate model that included COX-2 expression and grade. These findings suggest that inhibition of COX-2 activity cannot suppress cancer cell proliferation and MMP-2 activity under EP4R-positive conditions. We speculate that regulation of both COX-2 and EP4R can be more effective than that of COX-2 only for prevention of carcinogenesis or treatment in patients with TCC-UUT.

Our results demonstrated that EP1R–EP3R played a minimal role in tumor development and survival in patients with TCC-UUT. Univariate analysis showed that the expression of COX-2 and EP4R was positively associated with PI, MVD, MMP-2 expression, and uPA expression. Furthermore, COX-2 expression was also associated with MVD, MMP-2 expression, and uPA expression in a multivariate analysis model including grade. EP4R was independently associated with PI and MMP-2 expression in similar analysis. Considered collectively, our findings indicate that, in addition to COX-2, targeting EP4R could be therapeutically effective in the control of TCC-UUT progression.

Carbonic anhydrase-related protein VIII increases invasiveness of non-small cell lung adenocarcinoma

Received: 17 October 2005 / Accepted: 28 February 2006 / Published online: 12 April 2006
© Springer-Verlag 2006

Abstract Carbonic anhydrase-related protein VIII (CA-RP VIII) is believed to be an oncofetal antigen and is overexpressed in colorectal and non-small cell lung cancer. However, the pathobiological properties of CA-RP VIII in lung cancer remain unclear. In the present study, we examined ultrastructural changes caused by exogenous CA-RP VIII expression in a well-differentiated lung adenocarcinoma cell line, PC-9. Many vacuoles lined by cilia, sometimes large vacuoles pushing the nuclei to one side, were found in the cytoplasm of CA-RP VIII-expressing PC-9 cells, but not in control PC-9 cells. Moreover, signet-ring cells containing abundant intracytoplasmic mucin were often found among CA-RP VIII-expressing PC-9 cells, but rarely among control PC-9 cells. We subsequently examined CA-RP VIII expression in atypical adenomatous hyperplasia and early-stage lung adenocarcinoma (Stage Ia). Significant expression of CA-RP VIII was observed in invasive lung adenocarcinoma but not in noninvasive adenocarcinoma. Interestingly, CA-RP

VIII was strongly expressed in signet-ring cell cancer and invasive mucinous adenocarcinoma components. CA-RP VIII also appeared to enhance the invasiveness of PC-9 cells in Matrigel invasion assay. The present findings suggest that CA-RP VIII expression in lung adenocarcinoma is related to cancer cell invasion.

Keywords Carbonic anhydrase-related protein · CA-RP VIII · Invasion · Lung cancer · Signet-ring cell

Introduction

The carbonic anhydrases (CA) (EC 4.2.1.1) constitute a family of zinc metalloenzymes that catalyze the reversible hydration of bicarbonate [10]. The human CA gene family includes 12 isozymes that characteristically exhibit carbonic anhydrase activity. In addition, three molecules that have a CA domain are considered CA isoforms and designated carbonic anhydrase-related proteins (CA-RPs) but lack CA activity because of the absence of one or more histidine residues required for binding to the zinc ion, which is critical for CO₂ hydration activity [4]. *CA8* refers to the carbonic anhydrase 8 gene including mRNA. In contrast, CA-RP VIII refers to the corresponding protein.

Although the biological properties of CA-RPs are still unclear, recent experiments including some from our laboratories have clearly indicated that CA-RP VIII without its enzymatic activity is one of oncofetal antigens and abundantly expressed in non-small cell lung cancers and colorectal cancers [1, 7, 8]. Almost all of the advanced adenocarcinomas of the lung express abundant CA-RP VIII, especially at the invasive front [1]. We, therefore, speculated that CA-RP VIII favors cancer invasion.

In the present study, we examined the pathobiological properties of CA-RP VIII in lung adenocarcinoma. Our findings suggest that CA-RP VIII might facilitate cancer cell invasion.

Materials and methods

Cell culture, plasmid, and transfection

Detailed procedures for maintaining PC-9, a well-differentiated adenocarcinoma cell line, and establishment of CA-RP VIII-expressing transfectants harboring pCI-neo (Promega, WI, USA) were previously described [1]. In the present study, we newly generated other CA-RP VIII-expressing transfectants with the use of a pEF1-His (Invitrogen, CA, USA) vector to achieve virus-promoter-free CA-RP VIII expression. Transfection using DOTAP transfection reagents (Boehringer Mannheim GmbH, Mannheim, Germany) and G418 selection were performed as previously described [14]. Cells were cultured in Dulbecco's modified Eagle's medium (Gibco Life Technologies, NY, USA) containing 10% heat-inactivated fetal bovine serum (FBS) and 50- μ g/ml gentamycin (Gibco Life Technologies). In addition, DJM-1, a human skin cancer cell line, was also maintained in our laboratory and used as control experiments for several reverse transcriptase polymerase chain reaction (RT-PCR) experiments.

Reverse transcriptase polymerase chain reaction and real-time PCR

RT-PCR was performed as previously described [16]. Briefly, total cellular RNA was prepared from cell lysates using RNA-zol B (Biotex Laboratory, Houston, Texas). Serial fivefold dilutions were prepared from master lysates and used as a set in RT-PCR. Total RNA of human adult lung tissues was purchased from Chemicon International (Temecula, CA). cDNA synthesis from total RNA and subsequent PCR were performed using an RNA long and accurate (LA) PCR kit (Takara, Ohtsu, Japan). The procedure was performed according to the manufacturer's instructions. The primer sets used in this study were sense 5'-TCCTGATGCTAATGGGGAATACCAG-3' and antisense 5'-CTAAGAGGCTGAGTGGGCCGAAAG-3' for CA-RP VIII, sense 5'-CAGCCTGGGACTGCCCCCTGAT-3' and antisense 5'-CAGGCCCTCCGGGTCCTCTC-3' for matrix metalloproteinase (MMP)-2 [15], sense 5'-GCCATCGCGGAGATTGGGAACC-3' and antisense 5'-CGGGGAACATCCGGTCCACCTC-3' for MMP-9 [15], and sense 5'-TCCACCACCTGTTGCTGTA-3' and antisense 5'-ACCACAGTCCATGCCATCAC-3' for glyceraldehyde-3-phosphate dehydrogenase (G3PDH). We also used primer sets MUC-1 sense primer, 5'-GTA CCA TCA ATG TCC ACG AC-3', MUC-1 antisense primer 5'-CTA CGA TCG GTA CTG CTA GG, MUC-2 sense primer 5'-CCA TGC GTG CCT CTC TGC AA-3' MUC-2 antisense primer 5'-GTG GGT TGG GTG ACA CAC TC-3', MUC-4 sense primer 5'-GCT CTC CAA CAT CCT CCA CG-3', MUC-4 antisense primer 5'-TCA CAC GAC CAC CAT TGA TG-3', MUC-5AC sense primer 5'-TGA TGT GGA CTT TCC ATC CC-3', MUC-5AC antisense primer 5'-TGG TTG TCC TGG ATT TCT GC, MUC-5B sense primer 5'-CTG CGA GAC CGA GGT CAA CAT C-3',

MUC5B antisense primer 5'-TGG GCA GCA GGA GCA CGG ERG-3', MUC-7 sense primer 5'-CTT CTC GTT CAG TGA AGG TCG-3', and MUC-7 antisense primer 5'-TGG AAG CTT AGG CCT ACA GC-3'.

The PCR-amplified products were electrophoretically separated on a 2% agarose gel. To assure reproducibility of results, the RT-PCR amplification was repeated three times using different clones.

Real-time PCR was also carried out by using representative PC-9 and transfectant clones according to the manufacturer's instructions (Applied Biosystem's (ABI) Prism 7000, Foster City, CA). Primer/probes: Set: Hs 00187850-ml (CA8) and Hs 99999905-ml GAPDH were purchased from ABI.

Electron microscopic examination

A fine structural study was performed using the methods described previously [13]. Briefly, cells were centrifuged and fixed in 3% glutaraldehyde and then 1% osmium tetroxide solutions. After dehydration in a graded series of ethanols, specimens were embedded in an epoxy resin (Luveak, Nakalai Tesque, Kyoto, Japan). Ultrathin sections were cut with a Porter-Blum MT2-B ultramicrotome (Sorvall, USA) equipped with a diamond knife (Diatome, Switzerland), doubly stained with uranyl acetate and lead citrate solutions, and observed with a Hitachi H-7100-type electron microscope.

Histochemical analysis of signet ring cells

Cultured cells were settled to remove large cell aggregates for 5 min at room temperature. The supernatant was then centrifuged at 1,000 \times g for 5 min. Sedimented cells in signet-ring cell-rich fractions were smeared on slide glasses, air-dried, fixed with 10% formaldehyde, and

Fig. 1 CA8 mRNA expression in cultured PC-9 cells and transfectants. A well-differentiated adenocarcinoma cell line, PC-9, was transfected with pEF-His- or pCIneo-based CA8 expression vectors, designated pEF-CA8-PC9 and pCI-CA8-PC9, respectively. Semiquantitative RT-PCR using serially-diluted total RNA (indicated by $\times 1$, $\times 5$, and $\times 25$) from each clone revealed that pEF-CA8-PC9 expressed much more CA8 mRNA than pCI-CA8-PC9. Control PC-9 cells did not express CA8 mRNA. G3PDH mRNA expression was monitored as a control. Results are taken from a single experiment representative of three yielding similar results. Notably, these results were reproducible in other pEF-CA8-PC9 and pCI-CA8-PC9 clones. Real-time PCR revealed that a pEF-CA-PC9 and pCI-CA8-PC9 transfectant clone, which was demonstrated in this figure, expressed CA8 mRNA 10.5 and 5.5 times more than control PC9 cells, respectively

finally stained with hematoxylin and periodic acid-Schiff (PAS).

We also prepared the cell clot tissues of cultured cells and stained with PAS. We subsequently counted the percentage of signet-ring in an original PC-9 cell and three independent transfectant clones of pCI-CA8-PC9 or pEF-CA8-PC9 in five $\times 200$ fields. The results were shown in mean and standard deviation of each clone.

Immunohistochemical staining

In the present study, archival tissues comprising atypical adenomatous hyperplasia (AAH) and stage Ia lung adenocarcinoma specimens were immunostained with a monoclonal antibody or control antibody using an automated immunostainer (Ventana, AZ, USA). According to the modified WHO lung tumor classification system, specimens were classified as 1) AAH, 2) bronchioloalveolar cancer (BAC), 3) mixed type adenocarcinoma (MX) with a

predominantly bronchioloalveolar pattern, lepidic growth pattern, and invasive components, and 4) overt MX without bronchioloalveolar pattern. Procedures for preparation of a monoclonal antibody to human CA-RP VIII and immunohistochemical staining were described in detail previously [17]. As anti-CA-RP VIII antibody was of IgM class, we used isotype-matched monoclonal antibody to *Trichosporon beigelii*, a fungus [12]. Previous studies revealed that this control antibody did not react to human lung tissues tested. Based on the number of stained lung atypical epithelial or cancer cells, immunohistochemical staining was semiquantitatively scored as negative (less than 5%), weakly positive (5 to 20%), moderately positive (20 to 80%), or markedly positive (over 80%). The intensity of immunoreactivity of stained tumor cells was also scored, as follows: grade 1, positive but weaker than internal control (alveolar macrophages), grade 2, equal to immunoreactivity in the internal control, or grade 3, much stronger than internal control.

Fig. 2 General ultrastructural features of control PC-9 (a and b), CA-RP VIII-expressing PC-9 cells, pCI-CA8-PC-9 (c), and pEF-CA8-PC9 (d-f). Note the intracytoplasmic vacuoles in CA-RP VIII-expressing transfectants. Interestingly, pEF-CA8-PC-9 contained many more vacuoles than did pCI-CA8-PC-9. These vacuoles were lined on the surface with numerous microvilli and were, therefore, considered intracytoplasmic lumens. Few or no vacuoles were observed in control PC-9 cells. In several pEF-CA8-PC-9 cells, large vacuoles pushed the crescent-shaped nucleus to one side, as in 3 signet-ring cancer cells (f, see also Fig. 3d)

Fig. 3 Cytochemical staining of control PC-9 (a), CA-RP VIII-expressing PC-9 cells, pCI-CA8-PC-9 (b) and pEF-CA8-PC-9 (c and d) in formalin-fixed cell clots. Periodic acid-Schiff staining highlighted cytoplasmic mucin storage in pEF-CA-PC-9 (c and d), did so to a lesser extent in pCI-CA8-PC-9 (b), but did not in control PC-9 cells (a). The cells were also stained with hematoxylin to observe the nuclei. Original magnification: $\times 200$ (a, b, and c), and $\times 400$ (d)

Cell migration and invasion assay

Migration was defined as the ability of cells to penetrate the 8- μ m pore nucleopore polycarbonate membrane insert of a 6.5-mm transwell according to the methods of Holting et al. [3]. Briefly, cells were seeded in the upper compartment of transwell insert at a concentration of 2×10^5 cells/ml serum-free Dulbecco's modified eagles medium (DMEM). Mi-

Table 1 Immunohistochemical staining of atypical adenomatous hyperplasia and lung adenocarcinoma at stage Ia

A: Based on number of immunoreactive cells				
	Negative (<5%)	Weakly (5–20%)	Moderate (20–80%)	Marked (>80%)
AAH	3	0	0	0
BAC	8	2	1	0
MX with BAC pattern	3	4	4	0
Overt MX	0	1	3	4
B: Based on intensity of staining				
	Grade 1	Grade 2	Grade 3	
AAH	2	0	0	
BAC	7	2	0	
MX with BAC pattern	2	5	3	
Overt MX	0	2	6	

Few or no immunoreactive neoplastic cells were found in specimens including one AAH, two BAC, and a MX with BAC pattern. These cases were not included in the Table. In contrast, when we observed positive neoplastic cells, even when they comprised fewer than 5% of cells, we determined the intensity of staining. When the tumor cells exhibited various intensities of staining in a specimen, grade was assigned based on the strongest intensity of staining

gration was induced by 10% fetal calf serum (FCS), which was added to the lower chamber beneath the insert membrane. After 24 h of incubation, the cell of the lower compartment was counted.

The invasiveness of cultured cells was determined using six-well BD BioCoat Matrigel Invasion Chamber Plates (BD Biosciences, CA) according to the manufacturer's protocol. Briefly, 1×10^5 cells were placed in the upper compartment of an invasion chamber. After 24 h of incubation with DMEM containing 10% (lower chamber) or 0% (upper chamber) FCS, the cells on the lower surface of the filter were counted.

Results

Exogenous CA-RP VIII expression enhanced intracytoplasmic vacuole formation in PC-9 cells

We established three PC-9 transfectant clones in which CA-RP VIII was stably expressed under a human elongation factor 1 α promoter. RT-PCR clearly demonstrated that these transfectants, designated pEF-CA8-PC9, expressed abundant *CA8* mRNA compared to the previously established cytomegalovirus promoter-dependent CA-RP VIII-expressing transfectants, designated as pCI-CA8-PC9 (Fig. 1).

Subsequent electron microscopic examination revealed that CA-RP VIII-expressing PC-9 cells contained many vacuoles of various sizes in the cytoplasm. Each vacuole appeared to be lined by numerous microvilli (Fig. 2c–f). Notably, large intracytoplasmic lumens sometimes pushed the nucleus to one side, as found in signet-ring cell cancer (Fig. 2f). Increased numbers of vacuoles were found in pEF-CA8-PC9 clones (Fig. 2d–f) compared with pCI-CA8-PC9 clones (Fig. 2c). In contrast, few or no vacuoles were found in control PC9 cells (Fig. 2a,b).

Signet-ring cells among CA-RP VIII-expressing PC-9 cells

In the process of establishing and maintaining the pEF-CA8-PC9 transfectants, we found that the transfectants loosely aggregated together and often grew sparsely as single cells.

As demonstrated in Fig. 3, scattered CA-RP VIII-expressing cells often exhibited signet-ring cell features, with abundant mucin stores pushing the nucleus to one side. Notably, signet-ring cells were more frequently found among pEF-CA8-PC9 cells (Fig. 3c,d) than among pCI-CA8-PC9 cells (Fig. 3b). The percentage of signet-ring cell in the cell clot of PC-9, pCI-CA8-PC9, and pEF-CA8-PC9 were 0.2, 1.7±0.9, and 3.7±0.08%.

Immunohistochemical staining

Previous studies revealed that almost all of advanced and invasive non-small lung cancer specimens exhibited strong

CA-RP VIII expression, especially at cancer invasion front [1]. In the present study, we attempted to determine when CA-RP VIII was expressed in lung adenocarcinoma. We immunohistochemically examined CA-RP VIII expression in AAH, which is thought to be premalignant for adenocarcinoma and early-stage lung cancer specimens (stage Ia). The results of immunohistochemical staining using a specific antibody to CA-RP VIII are summarized in Table 1, and representative staining is demonstrated in Fig. 4. Alveolar macrophages were stained with monoclonal antibody to CA-RP VIII and were used as an internal control. As previously described [1], no significant staining was observed in alveolar epithelial cells. Little or no CA-RP VIII expression was observed in AAH specimens (Fig. 4a). CA-RP VIII immunoreactivity was barely observed in several BAC specimens (three of eleven; 27%) (Fig. 4b,g).

In contrast, CA-RP VIII expression was observed in eight of eleven (73%) and all of eight MX with BAC pattern and overt MX specimens, respectively (Fig. 4c-e). Notably, invasive lung cancer at an early stage expressed

Fig. 4 Representative immunohistochemical staining of AAH and lung adenocarcinoma stage Ia specimens. CA-RP VIII was minimally expressed in AAH (a) and BAC (b). In contrast, intense staining was observed in lung adenocarcinoma with invasive foci (c, e, and f), especially in signet-ring cancer components (c: immunostaining, d: HE staining) and mucinous adenocarcinoma components (e). The signet-ring cancer cells in figure e exhibited immunoreactivity with anti-cytokeratin 7 and anti-TTF-1 antibodies, but not with anti-cytokeratin 20. This phenotype is consistent with that of signet-ring cell-type mucinous carcinoma [9]. The CA-RP VIII immunoreactivity was also observed in non-mucinous invasive adenocarcinoma (f). CA-RP VIII was minimally expressed in cancer cells with features of mucinous type BAC (g), whereas, infiltrating lymphocytes in alveolar septum strongly expressed CA-RP VIII. Original magnification: ×100 (e, and f), ×200 (a, b, and g), and ×400 (c and d)

Fig. 5 Exogenously-expressed CA-RP VIII increased invasiveness of PC-9 cells. Representative result demonstrates that pEF-CA8-PC-9 cells (indicated by CA-RP VIII expression) had a significant activity compared to original PC-9 cells in Matrigel assay. Mean value and standard deviation (*SD*) of invasion pEF-CA8-PC-9 cells was 160 and 6.48 ($n=4$). By contrast, mean value and *SD* of invasion PC-9 cells were 4 and 1.71 ($n=4$). Notably, these results were reproducible in other pEF-CA8-PC-9 clones

CA-RP VIII in both the central portion of the tumor mass and at the invasive front. No significant staining was observed with isotype-matched control antibody.

Pure signet-ring cell adenocarcinoma of the lung is quite rare, but signet-ring features can occur in various types of pulmonary adenocarcinoma. In the present study, we also examined three lung adenocarcinoma specimens with signet-ring cell components. As shown in Fig. 4c, signet-ring cell cancer cells exhibited strong CA-RP VIII immunoreactivity in all three specimens. Notably, we also found abundant CA-RP VIII expression in invasive mucinous adenocarcinoma. (Fig. 4f). In contrast, BAC of mucinous type expressed little CA-RP VIII (Fig. 4g).

The present immunohistochemical staining suggested that CA-RP VIII expression was related to invasive activity.

Exogenous CA-RP VIII expression enhanced PC-9 adenocarcinoma cell invasion

To test whether exogenously CA-RP VIII-expressing PC-9 cells were more invasive than control PC-9 cells, we performed a Matrigel invasion assay. CA-RP VIII expressing PC-9 cells, but not control cells, exhibited significant invasiveness, as demonstrated in Fig. 5.

However, we did not observe any significant expression of *MMP-2* and *MMP-9* mRNA by RT-PCR (Fig. 6a). Moreover, exogenous CA-RP VIII expression did not alter the *MUC* expressions (Fig. 6b). Further, migration assay demonstrated no significant differences between PC-9 and transfectants (PC-9: $1,100 \pm 100$ cells, pCI-CA8-PC9: $1,000 \pm 200$ cells, pEF-CA8-PC9: $1,100 \pm 100$ cells).

Fig. 6 Exogenously-expressed CA-RP VIII did not alter the *MMP-2*, *MMP-9*, or *MUCs* mRNA expression in PC-9 cells. **a** Representative result of RT-PCR by using independent transfectants was demonstrated. PC-9 and CA-RP VIII expressing PC-9 cells did not express detectable level of *MMP* mRNAs. The expected transcript size of *MMP-2*, *MMP-3*, and *G3PDH* is 300, 400, and 456 bp, respectively. The control transcript bands from a cultured human skin cancer cell, DJM-1, are also demonstrated. **b** There are no significant differences of *MUC* mRNAs expression between PC-9 and CA-RP VIII expressing PC-9 cells. The expected transcript size of *MUC 2, 4, 5AC, 5B, and 7* is 308, 443, 383, 415, and 178 bp, respectively. *MUC1* RT-PCR band may represent carcinoma associated splicing form of *MUC1*, designated as Episialin [6], with 352 bp, whereas, expected size of *MUC1* transcript is 577 bp. **c** The control transcript bands of *MUC4* and *MUC7* from lung tissues were demonstrated

Discussion

In the present study, we demonstrated that exogenously expressed-CA-RP VIII enhanced invasion activity of PC-9 cells in vitro. Further, immunohistochemical staining indicated that CA-RP VIII expression was related to cancer invasiveness. We examined whether CA-RP VIII altered the expression of invasion-related molecules, including c-met, COX-2, and iNOS in PC-9 cells. However, evidence showing that CA-RP VIII directly altered the expression of

such molecules was not obtained; whereas, melanoma cell lines tested expressed these molecules (data not shown). It is well characterized that MMP-2 and -9 play an important role for lung cancer invasion. However, we could not detect any significant *MMP-2* and -9 mRNA expressions in PC-9 and transfectants (Fig. 6). We cannot exclude the possibility that unexamined invasion-related molecules including uncharacterized ones might be responsible for the high degree of invasiveness of CA-RP VIII-expressing PC-9 cells. However, the present findings rather suggest that CA-RP VIII expression might directly facilitate lung cancer cell invasion. As no significant difference of migration activity was found between PC-9 and transfectants, we speculate that CA-RP VIII provide the suitable microenvironment for matrix-degradation in cancer foci. Following experiments to unravel the exact molecular mechanism, by which CA-RP VIII facilitate the cancer invasion, is now undergoing.

One interesting finding of the present study is that CA-RP VIII induced signet-ring cell formation among PC-9 cells. As demonstrated in Fig. 3, CA-RP VIII induced intracytoplasmic vacuole formation, possibly in a dose-dependent manner. Signet-ring cells are typically found in poorly differentiated and dedifferentiated adenocarcinomas and not only in gastric but in other cancers as well. We suspect that CA-RP VIII expression induced dedifferentiation of PC-9, a well-differentiated adenocarcinoma cell line and signet-ring cell formation. Signet-ring cell cancer, which can arise from various organs, is highly invasive. Tsuta et al. reported that primary lung cancer with signet-ring cell cancer exhibited significant tendency toward blood vessel invasion, lymph vessel invasion, and lymph node metastasis [18]. As demonstrated in Fig. 4c, signet-ring cell components exhibited strong staining with anti-CA-RP VIII antibody. Furthermore, mucinous adenocarcinoma with invasion foci expressed CA-RP VIII, while mucinous type BAC without foci of invasion expressed little CA-RP VIII. These findings indicated that CA-RP VIII was not directly related to mucinous cell differentiation but related to invasion. In fact, we examined expression of various members of the mucin family, including MUC1, 4, 5AC, 5B, and 7 but failed to detect any significant difference in expression of these molecules between CA-RP VIII-expressing and control PC-9 cells (Fig. 6b).

The histogenesis of signet-ring cell cancer of the lung remains unclear. It appears that factors other than CA-RP VIII are required for signet-ring cell formation among PC-9 cells as a large number of CA-RP VIII-expressing PC-9 cells remain as non-signet-ring cells. Concerning the histogenesis of signet-ring cell cancer, Kobayashi et al. also demonstrated that high Phosphatidylinositol (PI) 3-kinase activity can convert differentiated cells with polarity to less differentiated cells with signet-ring cell features [5]. More recently, Xu et al. reported that the PI 3-kinase-Rac-p38 MAP kinase pathway is involved in the formation of gastric signet-ring cell cancer [19]. Interestingly, Hirota et al. reported that carbonic anhydrase-related protein could bind inositol 1,4,5-trisphosphate receptor type 1 [2]. PI 3-kinase can enhance inositol 1,4,5-trisphosphate production [11]. These findings togeth-

er suggest that CA-RP VIII might convert PC-9 cells to signet-ring cells by alternating the cross-talk of PI 3-kinase-Rac-p38 MAP kinase and inositol 1,4,5-trisphosphate signal pathway. A study to demonstrate the relationships between CA-RP VIII expression and these signet-ring cell formation-related molecules is now going on.

In conclusion, the present study demonstrated that 1) exogenously expressed CA-RP VIII altered morphology of PC-9 cells, formation of intracytoplasmic lumens and most notably, signet-ring cell formation. 2) CA-RP VIII expression increased the invasiveness of PC-9 cells in vitro without affecting migration activity. 3) CA-RP VIII was also expressed in invasive lung adenocarcinoma at an early stage but barely so in noninvasive adenocarcinoma and AAH specimens.

Deregulation of *HMGA2* in an aggressive angiomyxoma with t(11;12)(q23;q15)

Received: 20 February 2006 / Accepted: 23 February 2006 / Published online: 28 March 2006
© Springer-Verlag 2006

Abstract Aggressive angiomyxoma is a soft-tissue neoplasm with a predilection for the pelvic and perineal regions and a tendency to recur locally. Cytogenetic data on this tumor type are limited to five cases, three of which showed rearrangement of chromosomal bands 12q13–15. Molecular investigation of two of the tumors identified the *HMGA2* gene as the target of the 12q rearrangements. However, the two previously analyzed tumors were different at the molecular level: in one, the rearrangement of 12q13–15 resulted in a fusion product, whereas, in the second case, the breakpoint was telomeric (3') to the *HMGA2*, leaving the gene intact although expressed in its entire length. To shed more light on the pathobiology of aggressive angiomyxoma and to investigate the molecular mechanisms behind the involvement of the *HMGA2* gene in this tumor type (fusion transcript vs deregulated expression), we investigated, cytogenetically and with molecular techniques, one such tumor which presented a t(11;12)(q23;q15) as the sole karyotypic aberration. FISH analyses demonstrated no structural alteration of *HMGA2* at the cytogenetic level; however, expression of the full-length gene was detected molecularly.

Keywords Aggressive angiomyxoma · Cytogenetic *HMGA2*

Introduction

Aggressive angiomyxoma is an infiltrative mesenchymal tumor composed of fibroblasts, myofibroblasts, and numerous thick-walled blood vessels embedded in an abundant myxoid matrix. It occurs in adult women during reproductive years. In addition to its location in the external genitalia of women, cases have also been reported in men, where they occur in the perineal/perianal region [3, 8, 33]. Although the tumor is locally aggressive and prone to recur after surgical removal, metastases are exceedingly rare [10, 20, 23, 34].

Cytogenetic studies have revealed clonal chromosomal abnormalities in five aggressive angiomyxomas. Four tumors had abnormalities involving chromosome 12, including one case with monosomy 12 among other changes [12] and three cases with rearrangements of chromosomal bands 12q13–15 [4, 15, 24]. The fifth tumor showed monosomy of the X chromosome as the sole karyotypic aberration [17]. Molecular investigations of two cases with structural rearrangements of 12q13–15 have identified the high-mobility-group (HMG) protein gene, *HMGA2*, previously known as *HMGIC*, as the target gene [14, 24]. Its involvement differed between the two analyzed tumors, however. The 12q15 rearrangement in an aggressive angiomyxoma with the karyotype 46,XX,der(5)t(5;12)(q31;p11),der(12)inv(12)(p11q15)t(5;12)(q31;p11) resulted in a fusion product containing the first three exons of *HMGA2* followed by a novel 317 bp sequence mapping to 12p11 [14]. The second molecularly examined tumor, with the karyotype 46,XX,t(8;12)(p12;q15), had a breakpoint telomeric (3') of *HMGA2*, leaving the gene intact but deregulated and expressed.

To shed more light on the pathobiology of aggressive angiomyxoma and, in particular, to investigate the molecular mechanisms behind the involvement of the *HMGA2* gene in this tumor type (fusion transcript vs deregulated

expression), we examined using molecular techniques another such tumor which presented a $t(11;12)(q23;q15)$ as the sole karyotypic aberration.

Materials and methods

Tumor

A 44-year-old woman had an 11-cm large tumor in the right labium majus close to the bladder, the urethra, and the vagina. Histologic examination of the operation specimen showed a tumor consistent with the diagnosis aggressive angiomyxoma. The tumor consisted of an abundant amount of myxoid tissue in which were seen bland spindle cells with small round or oval nuclei. Cellularity was low. A vascular component consisting of small and medium-sized vessels was also present (Fig. 1) and, in small areas, microhemorrhages could be seen. Bundles of smooth muscles and variable amounts of collagen were present in the myxoid stroma, especially around vessels. There was an infiltrative growth pattern but no mitotic figures. Necrosis was absent. The resection margins were not microscopically free of tumor, but no recurrence or metastases have been seen after 5 years and 4 months of follow-up.

Cytogenetic investigation

The specimens intended for cytogenetic analysis were mechanically and enzymatically disaggregated and short-

term-cultured according to Mandahl [19]. Chromosome preparations were made and G-banded using Wright stain. The subsequent cytogenetic analysis and karyotypic description followed the recommendations of the ISCN [13]. Because no metaphase spreads were available for fluorescence in situ hybridization (FISH) analysis, interphase nuclei were used to check for possible rearrangement of the *HMGA2* gene. A pool of cosmid clones spanning the *HMGA2* breakpoint region, 142H1, 245E8, and 154F9 containing exons 1–2 and 156A4 and 27E12 containing exons 4–5, was selected [30]. The clones were grown in selective media, and DNA was extracted according to standard methods [28]. DNA probes were directly labeled with Cy3-dCTP (Amersham, Buckinghamshire, UK) and indirectly with Biotin-dUTP (Molecular Probes, Invitrogen, Carlsbad, CA, USA) by nick-translation, and detected with streptavidin-diethylaminocoumarin (DEAC; Invitrogen). The subsequent hybridization conditions as well as the detection procedure were according to standard protocols [16]. The hybridization was analyzed using a CytoVision system (Applied Imaging, Newcastle, UK).

Molecular genetic investigations

Tumor tissue adjacent to that used for cytogenetic analysis and histologic examination had been frozen and stored at -80°C . *HMGA2* transcripts were detected by reverse-transcribed PCR (RT-PCR); the primers used for PCR amplification are listed in Table 1. Total RNA was extracted using Trizol reagent according to the manufacturer's instructions (Invitrogen).

Table 1 Primers used for PCRs of *HMGA2*

Designation	Sequence	Position	Accession number
HMG848F	5'-ACTTCAGCCCAGGGACAA	848–865	U28749
HMG846F	5'-CCACTTCAGCCCAGGGACAACC	846–867	U28749
HMG1021R	5'-GGCCGTTTTTCTCCAGTG	1021–1038	U28749
HMG1169R	5'-TCCCTTCAAAGATCCAAGTCTGC	1169–1193	U28749

Fig. 2 Chromosome banding and FISH analyses of the aggressive angiomyxoma. **a** Partial G-band karyogram illustrating the (11;12)-translocation; normal chromosomes are included to facilitate comparison; *arrows* indicate breakpoint positions. **b** Image of interphase nuclei showing FISH co-localization of the differently labeled probes (clones 142H1, 245E8, and 154F9 containing exons 1–2 in *blue* color and clones 156A4 and 27E12 containing exons 4–5 in *red* color)

cDNA was synthesized using 5 µg of total RNA in 20 µl reaction mixture [50 mM Tris-HCl pH 8.3 (at 25°C), 75 mM KCl, 3 mM MgCl₂, 10 mM dithiothreitol (DTT), 1 mMol each dNTP, 20 U RNase inhibitor (RNA guard, Amersham Biosciences, Piscataway, USA), 0.5 pM random hexamers, and 400 U M-MLV Reverse Transcriptase (Invitrogen)]. The reaction was carried out at 37°C for 60 min, heated for 5 min at 65°C, and then kept at 4°C until analysis. As an internal control, cDNA quality was checked using *ABL1*-specific primers [25].

The PCR amplification was performed using 1 µl of the cDNA as template in 50 µl reaction volume containing 20 mM Tris-HCl pH 8.4 (at 25°C), 50 KCl, 1.25 mM MgCl₂, 0.2 mM of each dNTP, 1 U Platinum *Taq* polymerase (Invitrogen), and 0.5 µM of each of the forward and reverse primers used. The *HMGA2* transcripts were amplified using an initial denaturation for 5 min at 95°C, followed by 35 cycles of 30 s at 95°C, 30 s at 59°C, and 1 min at 72°C and a final extension for 5 min at 72°C. The PCR products were analyzed by electrophoresis through 1.2% agarose gel stained with ethidium bromide.

Results

The G-banding karyotype of the aggressive angiomyxoma was 46,XX,t(11;12)(q23;q15)[16]/46,XX[4] (Fig. 2a). A total of 120 nuclei were analyzed by FISH but showed no rearrangement of the *HMGA2* gene, i.e., signals from the differentially labeled probes co-localized in all analyzed nuclei (Fig. 2b). The breakpoint, therefore, mapped either centromeric to cosmid 154F9 or telomeric to cosmid 154A4. RT-PCR products obtained with primer combinations for exons 1–3 and 1–5 of the *HMGA2* gene showed the presence of two transcripts of 200 and 350 bp, respectively (Fig. 3). The expression of full-length *HMGA2*, i.e., exons 1–5, was, therefore, demonstrated. Transcript of *HMGA2* exons 1–3 was detected using the HMG848F and HMG1021R primer combination, whereas, transcript of *HMGA2* exons 1–5 was detected with the HMG846F and HMG1169R primer combination.

Discussion

Based on the observation that chromosomal bands 12q13–15 are nonrandomly involved in structural abnormalities in aggressive angiomyxoma, they have been found rearranged in three out of five previously analyzed tumors, and that *HMGA2* was the target gene in the only two examined tumors having such rearrangements, we decided to assess the status of *HMGA2* in an aggressive angiomyxoma showing a t(11;12) as the sole karyotypic abnormality. FISH analyses detected no structural alteration of *HMGA2*, but PCR analysis of the gene using a specific primer combination for exons 1–3 and 1–5 revealed that it was expressed with an intact, full-length product. Expression of the entire *HMGA2* gene has been shown to be achieved through alterations affecting 5' regulatory elements or the

Fig. 3 Detection of the *HMGA2* transcript. Total RNA was reversely transcribed and cDNA used as a template in PCR amplification with specific primer combinations; HMG848F and HMG1021R for exons 1–3, lane 3; HMG846F and HMG1169R for exons 1–5, lane 4; chimeric transcript for the *ABL* gene used as an internal control, lane 5; 1 kb DNA ladder, lane 1; 100 bp DNA ladder, lane 2; no RNA in the cDNA, lane 6

3' untranslated region, leading to a stabilized mRNA in uterine leiomyomata and transfected HeLa cells [6, 26, 29].

As we only analyzed interphase nuclei by FISH, we could not determine the exact position of the breakpoint on 12q, whether it was 5' or 3' of the *HMGA2* gene, and, therefore, we could not identify which mechanism led to a stable *HMGA2* mRNA in our sample, i.e., alteration of the 5' regulatory elements or disruption of the 3' untranslated region. However, FISH data on the previously reported aggressive angiomyxoma showing a full-length *HMGA2* transcript placed the breakpoint 3' (telomeric) to *HMGA2* [24]. An alternative activation mechanism for *HMGA2* was reported by Kazmierczak et al. [14] in an aggressive angiomyxoma with *inv(12)(p11.2q15)*; in that tumor, the third exon of *HMGA2* was fused with a 317-bp ectopic sequence from 12p. Apparently, both main molecular mechanisms of *HMGA2* involvement, the generation of a fusion transcript and deregulation of expression, may be operative in aggressive angiomyxoma [14, 24].

This variability in how activation of *HMGA2* is achieved is similar to what has been found in other benign mesenchymal tumors showing involvement of this gene. Both in bone and soft tissue chondromas [9] and uterine leiomyomata [26], the transcriptional activation may occur via alternative mechanisms. It is also noteworthy that some tumors apparently express both full-length and truncated *HMGA2* transcript [9, 32]. In the aggressive angiomyxoma with a *inv(12)(p11q15)* resulting in a *HMGA2* fusion product reported by Kazmierczak et al. [14], the novel sequence was not homologous to any known gene or expressed-sequence tag, and theoretically contributed only seven amino acid residues before the in-frame stop codon, effectively resulting in a truncated HMGA2 protein containing just the three DNA-binding domains.

The *HMGA2* gene encodes a member of the high-mobility group A (HMGA) of small, non-histone, chromatin-associated proteins. These proteins are believed to affect transcription as architectural elements by bending the DNA and by interacting with a large number of other proteins, mainly transcription factors, but also to influence chromatin changes during the cell cycle [27]. The *HMGA2* gene is highly expressed in embryonic tissues but has in adults only been found expressed in kidney, lung, and synovia [7, 11]. It has nevertheless been predicted to play a role in adult tissues as well [27]. Experiments on mice demonstrated the importance of the HMGA2 protein for embryonic cell growth [2, 35]. Recently, Ligon et al. [18] reported an 8-year-old boy with a constitutional de novo chromosomal inversion resulting in disruption of *HMGA2* and aberrant adiposity and somatic overgrowth. This phenotype, particularly with respect to overgrowth and lipogenesis, is strikingly similar to that of murine models expressing truncated *Hmga2* transcripts [2].

HMGA2 has been found rearranged in a variety of solid tumors including lipoma, uterine leiomyoma, chondroma, and pulmonary chondroid hamartoma [1, 9, 22, 26, 29]. It recombines with other chromosomal sites through translocations, insertions, and inversions. The involvement of *HMGA2* in different mesenchymal tumors and the

promiscuous nature of the translocations involving this gene are reminiscent of that of another gene encoding a nuclear scaffold protein associated with neoplasia. The mixed lineage leukemia (*MLL*) gene is rearranged in numerous acute lymphoid and myeloid leukemias in humans and more than 40 different partner genes have been identified [21]. *MLL* contains three motifs located near its amino terminus that are highly homologous to the core AT hook DNA-binding domains of the HMGA2 protein; however, whether the HMGA proteins and *MLL* share any common mechanism of transformation remains to be shown.

Aggressive angiomyxomas are infiltrative tumors with a marked tendency to recur locally. Immunostaining and ultrastructural studies indicate that this neoplasm derives from a primitive mesenchymal cell normally found in the lower female genital tract and capable of myofibroblastic differentiation. Because the most common pattern of behavior of this tumor involves no metastasis, aggressive angiomyxoma has been considered invariably benign [10, 20, 23]. However, two cases of aggressive angiomyxoma with metastasis leading to the patients' death [5, 31] highlight the need to consider it an intermediate tumor with unpredictable and sometimes unfavorable behavior [5]. On the other hand, as *HMGA2* has hitherto only been found to be pathogenetically involved in benign mesenchymal tumors [1, 9, 22, 26, 29], the involvement of the same gene in aggressive angiomyxoma favors its classification as a benign neoplasm. In addition, as normal tissues adjacent to aggressive angiomyxomas are negative for *HMGA2* expression, inappropriate *HMGA2* expression may potentially be useful as a marker of microscopic residual disease using the immunoperoxidase technique with an anti-HMGA2 antibody [20, 23].

Multifocal kaposiform haemangioendothelioma

Received: 7 March 2005 / Accepted: 18 April 2005 / Published online: 5 April 2006
© Springer-Verlag 2006

Abstract Kaposiform haemangioendothelioma (KHE) is a rare, locally aggressive vascular spindle cell proliferation, with resemblance to Kaposi's sarcoma. This tumour usually occurs in skin and retroperitoneum of infants and young children and is often complicated by the Kasabach–Merritt phenomenon (KMP). A 3-year-old boy presented with a right submandibular swelling due to lymphadenopathies, a violaceous skin lesion at the left commissure of the lips, and an ill-defined lesion in the right thyroid lobe. There were some signs of KMP. Histological examination revealed a typical infiltrative multilobular spindle cell proliferation with slit-like vascular spaces in these three localisations. Immunohistochemical stains showed positivity for CD34 and CD31 and many alpha-smooth muscle actin-positive spindle cells around the vascular spaces. There was no Herpes virus type 8 expression. The presented case is unique in two ways. First, thyroid involvement of KHE has never been described in the literature until now. Secondly, and most remarkably, the multifocal presentation in three anatomically distinct and separated localisations is extremely unusual.

Keywords Kaposiform haemangioendothelioma · Kasabach–Merritt phenomenon · Consumptive coagulopathy · Multifocal

Introduction

Kaposiform haemangioendothelioma (KHE) is defined as a locally aggressive vascular neoplasm, characterised by a predominantly Kaposi sarcoma-like fascicular spindle cell growth pattern [17]. The tumour usually occurs in the skin [3, 7, 8, 11, 18, 20] and retroperitoneum [1, 9, 11, 16, 20] of infants and young children, but some adult cases have been described [5, 10]. KHE is often complicated by Kasabach–Merritt phenomenon (KMP), a condition of severe thrombocytopenia and consumptive coagulopathy [1–3, 6, 7, 11, 14, 16, 18–20]. Some cases of KHE are associated with lymphangiomatosis [7, 20]. Unlike juvenile haemangioma, KHE shows no tendency for spontaneous regression [7, 8]. Regional lymph node metastasis is rare, but distant metastasis has not been reported yet [7]. Mortality is mostly due to KMP with life-threatening haemorrhage [7, 14]. We recently encountered a case of KHE with a multifocal presentation and infiltration into the thyroid gland, a hitherto undescribed phenomenon.

Clinical history

A 3-year-old boy presented with three episodes of fever and a right submandibular swelling of 3 cm in diameter, which was due to painless, but firm lymphadenopathies. Since there was no regression of the adenopathies, an excisional biopsy of a right neck lymph node was taken 4 months after the first consultation. Afterwards, the boy was referred to our center. He was in good general condition. Besides the submandibular lymphadenopathies, clinical examination also revealed a slightly elevated violaceous skin lesion as big as a rice-grain, situated left laterally of the mouth (Fig. 1a). There was no thrombocytopenia, but still an elevation of the D-dimer level

(2,007 $\mu\text{g/l}$) (normal values 0–500 $\mu\text{g/l}$), thyroglobulin (43.5 $\mu\text{g/l}$) (normal values 0.0–25.0) and LDH (625 U/l) (normal values 240–480 U/l). Imaging revealed a prominent submandibular lymph node group and adenopathies along the right internal jugular vein (Fig. 1b). Furthermore, a lesion in the right thyroid lobe was seen, but could not further be specified on CT scan. Because of the presence of multiple lesions and the possibility of malignancy, a right hemithyroidectomy and a right lymph node dissection of levels I to IV was performed. Preoperatively, there was no connection between the thyroid lesion and the enlarged lymph nodes. During the same surgery, the skin lesion was excised. After the operation, there was a normalisation of the D-dimers (340 $\mu\text{g/l}$).

Materials and methods

The right thyroid lobe, the right neck dissection specimen and the skin lesion were received fresh. A small part of the lesion in the thyroid and the lymph nodes was snap-frozen in liquid-nitrogen-cooled isopentane. The rest of the specimens were fixed in 6% formalin and processed to paraffin. Five-micrometer thick tissue sections were subjected to haematoxylin and eosin. Immunohistochemical studies were performed on formalin-fixed, paraffin-embedded tissue, using a three-step indirect peroxidase complex method. The following antibodies were used: CD31 (1:50 dilution, monoclonal, Dako, Glostrup, Denmark), CD34 (1:10 dilution, monoclonal, Becton Dickinson, San Jose, USA), α -SMA (1:100 dilution, monoclonal, Dako,

Glostrup, Denmark), HHV-8 (1:20 dilution, Novocastra, Newcastle, UK).

Pathological findings

The right thyroid lobe, measuring $2.2 \times 1.5 \times 1$ cm, contained an ill-defined lesion of $1.3 \times 0.9 \times 1$ cm. The right neck dissection specimen consisted of enlarged lymph nodes along the right jugular vein and next to the right submandibular gland, which was not infiltrated. The skin biopsy measured $0.5 \times 0.5 \times 0.7$ cm.

Histopathological examination of the three resected specimens showed the same picture. The tumour was characterised by an infiltrative multilobular spindle cell proliferation. The infiltrative growth pattern caused destruction of the thyroid parenchyma (Fig. 2a) and the lymph node parenchyma (Fig. 2b). The skin biopsy showed that the tumour was situated in the deeper part of the dermis and in the upper part of the subcutis (Fig. 2c). The tumour consisted of nodules of compact spindle cell fascicles with hardly recognisable interspersed vascular spaces. Thin-walled dilated and probably lymphatic vessels were seen in-between and around the nodules (Fig. 3). The spindle cells did not show cytological atypia or nuclear pleomorphism. Mitotic activity was inconspicuous. Convincing microthrombi were very rare, as well as hyaline globules.

The tumour showed strong positivity for CD34 (Fig. 4) and CD31. Many SMA-positive spindle cells, presumably pericytes, were present around the vascular spaces. A HHV-8 stain was negative.

Fig. 2 **a** A spindle cell proliferation with destructive infiltration of the thyroid (hematoxylin-eosin stain $\times 100$). **b** A vascular spindle cell proliferation involving a lymph node (hematoxylin-eosin stain $\times 100$). **c** A multilobular spindle cell proliferation in dermis and subcutis (hematoxylin-eosin stain $\times 50$)

Fig. 3 Thyroid: a dilated thin-walled vessel encircling a tumour nodule (hematoxylin-eosin stain $\times 100$)

Based on these morphological and immunohistochemical findings, a diagnosis of KHE was made.

Discussion

The term 'Kaposiform haemangioendothelioma' was introduced in 1993 by Zukerberg et al. Ever since, fewer than 100 cases have been reported in the literature [1–11, 14–16, 18–20].

KHE usually occurs in early childhood, and often in the first decade of life. KHE mostly involves the skin and the retroperitoneum. The tumour occurs less commonly in the head and neck region [2, 5–7, 15, 20] and in the deep soft tissue of the extremities and the trunk [7, 20]. Rare cases have been described in the mediastinum [7], thymus (one case) [19] and scrotum (one case) [7]. To our knowledge, we present in this paper the first case involving the thyroid.

KHE is often associated with KMP. In our case, there was an elevation of D-dimers, an important marker of consumptive coagulopathy. Therefore, it seems likely that this child showed some evidence of KMP, although platelet count was normal and fibrin thrombi were rare. Yet the recent study of Lyons et al. mentioned that the number of platelet thrombi does not correlate with the presence of KMP [7]. Moreover, normalisation of D-dimers after

Fig. 4 Thyroid: an infiltrative CD34-positive proliferation between the thyroid follicles ($\times 100$)

resection of the lesions proves that the trigger for consumptive coagulopathy has been removed. This trigger has been thought to be related to unique architectural features that favour turbulent blood flow and platelet activation [7]. Absence or presence of KMP is an important prognostic factor, since life-threatening haemorrhage can cause mortality.

Our case illustrates both the nodules of compressed vessels and the ectatic vascular component of KHE. This biphasic pattern has been described before in the literature [1, 7, 9, 11, 15, 20].

In contrast to juvenile haemangioma, KHE shows no tendency to involute. KHE is a locally aggressive tumour, and distant metastasis is not described to date. When reviewing the literature, we found one case of congenital cutaneous multifocal haemangioendothelioma [4]. This report mentions the case of a newborn having multiple cutaneous lesions with the histopathological picture of KHE. All these lesions were confined to the skin. In the present case, we describe KHE in three anatomically distinct and separate lesions. Moreover, we do not have evidence of congenital disease.

Theoretically, one could consider metastatic and aggressive disease because of the separate locations. However, in our case, just as in all earlier described KHEs, there were no histological features of malignancy. In addition, some benign vascular lesions, like the spindle cell haemangioma, can give rise to multiple lesions in the same general area [13]. Finally, another benign vascular tumor, the retiform haemangioendothelioma, occasionally metastasises to the lymph nodes without systemic spread and without aggressive behaviour [12]. In our case, multifocal presentation seems more likely than metastasis from the right thyroid lobe to contralateral lymph nodes only and not to ipsilateral lymph nodes. Obviously, the patient will be followed very closely and only a long-term follow-up will be to disclose the true biologic behaviour. At present, it seems that KHE can be added to the list of vascular tumours with an occasional multifocal presentation.

Acknowledgement We are grateful to Professor C. D. M. Fletcher, Harvard Medical School, Boston, for confirming the diagnosis.

Unusual aggressive course of a giant cell tumor of soft tissue during immunosuppressive therapy

Received: 29 December 2005 / Accepted: 26 February 2006 / Published online: 5 April 2006
© Springer-Verlag 2006

Abstract Giant cell tumor of soft tissue with low malignant potential (GCT-ST) is a low-grade, primary soft tissue sarcoma with histological and clinical features similar to giant cell tumor of the bone. The main tumor localizations are the extremities, but it may also occur in the head and neck region. GCT-ST shows a recurrence rate of approximately 15%, but it very rarely metastasizes. The risk of cancer development, especially of the skin, is up to fivefold increased in immunosuppressed patients after organ transplantation. The association of sarcomas and immunosuppressive therapy is best known for Kaposi sarcomas, whereas other types of sarcomas are rarely found. We report of a GCT-ST of low malignant potential, which developed under long-term immunosuppression in a patient 12 years after heart transplantation. The tumor presented with an unusual aggressive course and metastatic site: the parotid gland. Therefore, we suggest that in patients with immunosuppression, even low malignant cancerous lesions should be carefully observed, as their local behavior may be aggressive with development of metastasis.

Keywords Sarcomas · Soft tissue · Transplantation pathology

Introduction

The development of various types of malignancies, especially skin cancer, in patients receiving immunosuppression after organ transplantation is well-recognized. These patients have an up to fivefold increased risk of cancer compared with the general population [5, 13], which indicates that the development of de novo malignancies emerges as a serious long-term complication after organ transplantation [6]. The development of sarcomas under immunosuppressive therapy is unequivocally documented for human herpesvirus 8-associated Kaposi sarcomas [8], but the occurrence of other types of sarcomas seems to be rare.

Giant cell tumor of soft tissue with low malignant potential (GCT-ST) is a rare, low-grade soft tissue sarcoma. This tumor seems to be clinically and histologically similar to the giant cell tumor of the bone. GCT-ST can affect patients of all ages but is predominantly seen in middle-aged patients. The main tumor localizations are the extremities, but about 10% of the cases occur in the head and neck region. GCT-ST has a moderate local recurrence rate of approximately 15% and it rarely metastasizes [9].

The development of GCT-ST in association with the application of an immunosuppressive therapy has not been reported to date. We report a case of a GCT-ST with an unusual aggressive biologic behavior in a patient who underwent heart transplantation 12 years before the occurrence of a GCT-ST.

Clinical history

We describe a 73-year-old male patient who presented in 2004 with a palpable, round, solid mass of the subcutaneous tissue, measuring ~10 mm, of the left temporal forehead (Fig. 1). The mass was surgically resected and the histological examination was consistent with a GCT-ST. The patient suffered from various internal disorders and had received heart transplantation 12 years ago. Due to long-term medical treatment with a triple combination of

immunosuppressive drugs (FK-506, prednisone, and azathioprine), precancerous (actinic keratosis) and cancerous lesions (basal cell carcinoma and squamous cell carcinoma) of the skin developed at different sites of the face. An in situ squamous cell carcinoma of the skin was resected in the same region. Seven months later, a GCT-ST occurred in that region.

The patient had two tumor relapses of the GCT-ST after 6 and 11 months. Thirteen months after the first diagnosis of GCT-ST, the patient presented with a painless swelling of the left parotid gland. A contrast-enhanced cranial computed tomography (CT) image showed a 23.5-mm measuring tumor (Fig. 2a,b). Histological examination of the lumpectomy revealed a metastasis of GCT-ST in the parotid gland (Fig. 2c). A subsequently performed whole-

body positron emission tomography/CT imaging for tumor staging could not detect any other suspect lesions.

Materials and methods

Light microscopy and immunohistochemistry

Tumor specimens were reviewed by using hematoxylin and eosin-stained (H&E) slides.

For immunohistochemistry, 4- μ m sections were cut from formalin-fixed (4% buffered formalin) and paraffin-embedded tissue blocks. Immunohistochemistry was performed using the DAKO EnVision+ System peroxidase method with antibodies against CD68 (DAKO, clone PG-M1, dilution 1:1,200), smooth muscle actin (DAKO, clone 1A4, dilution 1:500), Ki-67 (DCS, clone SP6, dilution 1:1,200), and HHV-8 (Novocastra, clone 13B10, dilution 1:50).

In situ hybridization

For the detection of a latent Epstein–Barr virus (EBV) infection by in situ hybridization, sections from paraffin-embedded GCT-ST tumor tissue (primarius) were analyzed.

In brief, slides were dewaxed, rehydrated, and dried at 45°C. Afterwards, they were pretreated with proteinase K for 25 min at 37°C. Two drops of EBV specific fluorescein isothiocyanate (FITC)-labeled RNA oligonucleotide probe [DAKO, Epstein–Barr virus (EBER) PNA Probe/Fluorescein, Code No. Y5200] were added to the tissue section, and slides were covered with coverslips. The hybridization was carried out for 90 min at 55°C. After washing the slides with diethylpyrocarbonate water, oligonucleotide binding was indirectly detected by an anti-FITC antibody conjugated to alkaline phosphatase (DAKO, PNA ISH detection kit, Code No. K5201).

Results

Pathological findings

Primary tumor

The 27×17×10-mm operation specimen grossly consisted of skin and subcutaneous fat tissue. On the cut surface, a 9-mm, brownish red, well-delineated tumor was seen in the subcutaneous tissue.

The histological investigation of the primary tumor specimen showed a multinodular growth pattern with conspicuous fibrous tissue septa in between the cell-rich tumor nodules. The tumor tissue contained a mixture between multinucleated, osteoclast-like giant cells and a mononuclear type of tumor cells (Fig. 1b,c). High mitotic activity was observed within all areas of the tumor (28 mitotic figures per 10 high-power fields). Atypical mitoses or obvious pleomorphism of the tumor cells was absent. The tumor showed a small area of necrosis, measuring less than 0.1 mm, and focally angiectatic spaces reminiscent of aneurysmal bone cyst changes could be detected.

The histopathological findings were consistent with the diagnosis of a marginal, completely resected GCT-ST.

Metastatic tumor

We received a 39×30×25-mm parotid gland resected specimen and six resection margin specimens. On the cut surface of the lumpectomy specimen from the parotid gland, a 17×16×14-mm, extensively necrotic brown to gray tumor was seen (Fig. 2b).

On histopathological investigation, the metastasis of the tumor had extensive central necrosis and hemorrhage. A small rim of vital tumor was seen at the periphery of the

Fig. 3 a The immunohistochemical investigation using CD68 antibodies revealed a positive reaction of multinucleated osteoclast-like giant cells and a few mononuclear tumor cells ($\times 400$). b Staining with smooth muscle actin antibodies showed a positive reaction exclusively with a few mononuclear cells ($\times 400$). c A high proliferation of the GCT-ST was seen in Ki-67-immunohistochemistry (hot spot, $\times 400$)

nodule (Fig. 2c). The histologic features of this tumor tissue were similar to those described for the primary tumor. The tumor was completely resected with clear margins.

Immunohistochemistry

Immunohistochemical analysis of the tumor tissue revealed that all giant cells and a smaller portion of the mononuclear cells (20%) reacted with antibodies against CD68 (Fig. 3a). A positive reaction with antibodies against smooth muscle actin (Fig. 3b) was exclusively detected in some mononuclear tumor cells. The Ki-67 labeling index was approximately 25% (Fig. 3c).

Tumor tissue was additionally stained with antibodies against human herpesvirus 8 (HHV-8) latent nuclear antigen 1 with a negative result.

RNA in situ hybridization

A latent EBV infection could not be detected in tumor specimens of the primary giant cell tumor by RNA in situ hybridization.

Discussion

Long-term complications of solid organ transplantation have assumed increasing importance as short-term patient and graft survival have improved. It is generally recognized that malignancies are more common after organ transplantation than in the overall population. Generally, this increased risk for developing cancer encompasses almost every type of cancer, but a subset of tumor entities bears an extraordinarily high risk to develop during immunosuppressive therapy [13]. Besides malignant melanoma, non-Hodgkin's lymphoma and carcinomas of the kidney, nonmelanotic skin cancers, particularly squamous cell carcinomas, remain the most common malignancies in solid organ transplant recipients. The incidence of skin cancer increases with survival time after transplantation, and it is noteworthy that the biological behavior of these tumors seems to be much more aggressive than in nonimmunosuppressed skin cancer patients [3, 15]. So it seems to be reasonable to assume that (low-) malignant mesenchymal neoplasms like GCT-ST may behave in a similarly more aggressive fashion under immunosuppressive treatment.

There are different mechanisms that may lead to cancer in patients with immunosuppression [12]. Firstly, immunosuppressive agents can directly cause damage to DNA or interfere with the proper function of DNA repair mechanisms. Secondly, a subset of cancer entities is known to be triggered by specific viral infections that are regularly found in patients with immunosuppression. Finally, immune surveillance, which ordinarily prevents the growth

and development of malignancies, is impaired by immunosuppressive drug treatment.

In 1999, Folpe et al. [4] described a subset of malignant giant cells containing soft tissue tumors with low malignant potential. These tumors were termed as "giant cell tumor of low malignant potential." The authors suggested that the term "malignant giant cell tumor" should be restricted to histologically high-grade soft tissue sarcomas. This division was included in the current WHO Classification of Tumors of Soft Tissue and Bone (2002) [9], in which giant cell tumors of soft parts are represented by two entities. The low-malignant end is covered by GCT-ST (i.e., giant cell tumor of low malignant potential) and the high-grade spectrum by the diagnosis of undifferentiated pleomorphic sarcoma with giant cells (i.e., giant cell malignant fibrous histiocytoma or malignant giant cell tumor of soft parts).

The development of soft tissue sarcomas during long-term immunosuppressive therapy is uncommon with the exception of HHV8 associated Kaposi's sarcoma [2] and, to a much lesser extent, EBV-associated leiomyosarcoma [7]. Virus infection, as etiologic background for GCT-ST development, has not been reported to date. Moreover, according to the WHO classification (2002) [9], the etiology of GCT-ST remains completely unclear. EBV-mRNA or HHV8-antigens could not be detected in the tumor tissue of the present GCT-ST, suggesting a lack of association between GCT-ST development and EBV or HHV8-infection.

The metastatic potential of GCT-ST was shown to be very low. Almost 7 years after the definition of the tumor entity by Folpe et al. [4], approximately 70 cases of patients with GCT-ST have been published mainly in three large cohorts [4, 10, 11]. Follow-up data of 53 patients were available, and only three (including the present case) of these patients developed metastasizing disease. A singular distant metastasis of GCT-ST to the parotid gland has not been reported so far, and the spread of other soft tissue sarcomas to this site is extraordinarily rare and is reported sporadically only [1, 14]. Both previously reported patients with metastatic GCT-ST died of tumor after 12 and 13 months, respectively, with widespread pulmonary metastases.

We conclude that patients on chronic immunosuppression have a high risk to develop different (and rare) types of cancer. Even low malignant cancerous lesions should be observed carefully, as their local behavior may be much more aggressive and they might have an enhanced metastatic potential.

Monoallelic deletion of the *p53* gene through chromosomal translocation in a small cell osteosarcoma

Received: 11 January 2006 / Accepted: 21 February 2006 / Published online: 5 April 2006
© Springer-Verlag 2006

Abstract Small cell osteosarcoma is a rare bone tumor of high-grade malignancy that most often arises in the metaphysis of long bones in the second decade of life. Cytogenetic and molecular genetic findings in small cell osteosarcoma are poorly defined. Conventional cytogenetic analysis of a small cell osteosarcoma arising in the proximal tibia of a 9-year-old male revealed a diploid chromosomal complement with complex structural rearrangements involving chromosomes 6, 16, and 17. Immunohistochemical assessment of p53 protein expression revealed nuclear p53 immunoreactivity in approximately 15% of the neoplastic cells. Subsequent fluorescence in situ hybridization (FISH) analyses confirmed loss of the *p53* gene locus on the derivative chromosome 17 homolog and were negative for amplification of the *MDM2*, *CDK4*, *c-MYC*, *HER-2/neu*, *CCND1*, and *COP3* gene loci. To the best of our knowledge, this represents the first demonstration of monoallelic deletion of *p53* in small cell osteosarcoma,

suggesting that *p53* alterations may play an important role in the development of small cell osteosarcoma as well as conventional osteosarcoma.

Keywords Small cell osteosarcoma · *p53* · Cytogenetics · FISH

Introduction

Osteosarcoma is the most common nonhematopoietic primary malignant tumor of bone in children and young adults. The most recent World Health Organization classification recognizes eight separate types: conventional, telangiectatic, small cell, low-grade central, secondary, parosteal, periosteal, and high-grade surface [8]. Small cell osteosarcoma, first described by Sim et al. [22] in 1979, is a rare, usually highly malignant bone tumor that comprises 1.5% of all osteosarcomas. Histologically, small cell osteosarcoma is composed of small cells with round to oval nuclei and finely dispersed chromatin. By definition, tumor osteoid is always present, although variable in amount, and has a fine, lace-like appearance [8, 16, 22]. There is no specific immunophenotype for this tumor. Clinical and radiographic features of small cell osteosarcoma are similar to those of conventional osteosarcoma. Survival data suggest a slightly worse prognosis when compared to conventional osteosarcoma [8]. Cytogenetically, only two cases of small cell osteosarcoma have been previously reported [18, 23]. No consistent chromosomal abnormality has been identified.

In this study, we present detailed cytogenetic and molecular cytogenetic findings of a small cell osteosarcoma. In contrast to most conventional osteosarcomas, the modal chromosome number was stable with a single abnormal clone. The aberrant complement featured complex translocations involving chromosomes 6, 16, and 17 that were further characterized by multiple fluorescence in situ hybridization (FISH) assays. The presence of p53 protein expression was identified immunohistochemically

and a hemizygous deletion of the *p53* gene locus was confirmed by FISH.

Clinical history

A previously healthy 9-year-old male presented with a 6-month history of a limp referable to his right lower extremity, accentuated while running. His mother later noticed a tender mass over the pes anserine region of his right proximal tibia. A plain film radiograph revealed a destructive process in the right proximal tibial metaphysis. MRI displayed a 12-cm intramedullary lesion centered in the metaphysis, with an extraosseous component crossing the growth plate to involve the epiphysis. The knee joint was not involved. An open biopsy was performed, followed by neoadjuvant chemotherapy. A radical local transarticular resection of the proximal tibia was performed and the limb was reconstructed using a tibial rotationplasty technique.

The highly cellular biopsy specimen was composed of small- to medium-sized cells arranged in sheets. Individual cells exhibited fine chromatin, small nucleoli, and scant cytoplasm. Mitoses, some of them atypical, were frequent (greater than 20 mitoses per 10 high-powered fields). Focal areas of necrosis were present as well. Neoplastic osteoid was sparse, in the form of fine eosinophilic material surrounding neoplastic cells, in some areas appearing lace-like (Fig. 1a).

Immunohistochemically, the neoplastic cells were immunoreactive for vimentin and bcl-2 and were negative for cytokeratins (AE1/AE3, CK7, and CK8/18), CD99, chromogranin, neuron-specific enolase, neurofilament, S-100 protein, synaptophysin, leukocyte common antigen, CD34, myogenin, myoglobin, and desmin. The Ki-67 (MIB-1) proliferation-related labeling index was approximately 40%. Based on a previously described classification: (–) no obvious staining; (+) 5% or less of tumor cells positive; (++) 5–50% of tumor cells positive; (+++) more than 50% of tumor cells positive [19], the extent of p53 immunoreactivity was graded as ++ (Fig. 1b). A diagnosis of small cell osteosarcoma was rendered (consultation and confirmation of diagnosis with Dr. K. Krishnan Unni, Mayo Clinic, Rochester, MN, USA).

The resection specimen contained residual tumor with a histology similar to that seen in the biopsy. Post-therapy tumor necrosis was extensive; approximately 10% of viable tumor remained.

Materials and methods

Culturing, harvesting, and slide preparation were performed as previously described [5]. Metaphase cells were banded with Giemsa trypsin and the karyotypes were expressed according to the International System for Human Cytogenetic Nomenclature (ISCN 2005) [12].

Dual-color FISH studies were performed on clonally abnormal metaphase cells in an effort to further characterize the complex anomalies detected by conventional cytogenetics utilizing the LSI p53 (17p13.1) Spectrum Orange-labeled probe with TelVysion 16p Spectrum Green-labeled probe (Vysis, Abbott Molecular, Des Plaines, IL, USA) and the Smith–Magenis (FITC Spectrum)/Miller-Dieker/ILS (Texas Red Spectrum) probe combination which is specific for 17p11.2 (*FLI*) and 17p13.3 (*LIS1*), respectively (Cytocell Technologies, Cambridge, UK). In addition, to determine the presence or absence of various gene amplifications familiar to conventional osteosarcoma, dual-color FISH assays were conducted on cytologic touch preparations of lesional tissue using the following DNA probe sets: PathVysion LSI HER-2 (Spectrum Orange)/Centromere (CEP)17 (Spectrum Green) for *HER-2/neu*, LSI C-MYC (Spectrum Orange)/CEP8 (Spectrum Green) for *c-MYC*, LSI Cyclin D1 (Spectrum Orange)/CEP11 (Spectrum Green) for *CCND1*, bacterial artificial chromosome (BAC) clone RP11-775J10/CEP12 (Spectrum Orange) for *MDM2*, BAC clone RP11-571M6/CEP12 (Spectrum Orange) for *CDK4*, and BAC clone RP11-45M22/CEP17 (Spectrum Orange) for *COPS3*. BAC-derived probes were directly labeled by nick translation with Spectrum Green-dUTP utilizing the manufacturer's protocol (Vysis). BAC clones were obtained from Research Genetics (Huntsville, AL, USA) and other probes were provided by Vysis.

After pretreatment of the slides, the cells and probes were codenatured at 75°C for 1 min and incubated at 37°C overnight using the HYBrite denaturation/hybridization system (Vysis). Posthybridization washing was performed

Fig. 1 **a** Histological appearance of small cell osteosarcoma with inconspicuous osteoid (400×, original); more defined focus of osteoid shown in *inset* (200×, original). **b** Approximately 15% of tumor cell nuclei are immunoreactive for p53 (200×, original)

in 0.4× SSC/0.3% NP-40 at 72°C for 2 min, followed by 2× SSC/0.1% NP-40 at room temperature for 1 min. The slides were air-dried in the dark and counterstained with 4', 6-diamidino-2-phenylindole (DAPI II; Vysis). Hybridization signals were assessed in 100 interphase nuclei or in a minimum of five metaphase cells with strong and well-delineated signals. As a negative control, normal peripheral blood lymphocytes were simultaneously hybridized with these probes. An interphase cell specimen was interpreted as amplification if the ratio of oncogene signals to corresponding centromere signals was greater than 2. Images were acquired using the CytoVision Image Analysis System (Applied Imaging, Santa Clara, CA, USA).

Results

Traditional cytogenetic analysis of the open biopsy specimen revealed complex structural rearrangements involving chromosomes 6, 16, and 17 (Fig. 2). Examination of the resection specimen showed similar karyotypic abnormalities.

Metaphase FISH studies confirmed a translocation between the short arms of chromosomes 16 and 17 observed in GTG-banding analysis (Fig. 3a) and detected monoallelic deletion of the *p53* gene locus on the der(17) (Fig. 3b). The following nomenclature was assigned: 46,XY,der(6)t(6;17)(q27;q21.32),der(16)t(16;17)(p13.3;p13.1),der(17)del(17)(p13.1;p13.1)t(6;17)(q27;q21.32)t(16;17)(p13.3;p13.1) [31].ish der(16)(LIS1+,P53-),der(17)(16pter+,P53-,FLI+). FISH analyses were negative for amplification of the *MDM2*, *CDK4*, *c-MYC*, *HER-2/neu*, *CCND1*, and *COPS3* genes.

Discussion

Small cell osteosarcoma is histologically characterized by a proliferation of small cells associated with osteoid production. Small cell osteosarcoma may be diagnostically confused with other small cell mesenchymal tumors such as Ewing's sarcoma and mesenchymal chondrosarcoma

Fig. 2 Partial GTG-banded karyotype illustrating the complex rearrangement involving chromosomes 6, 16, and 17. Arrows indicate breakpoints

Fig. 3 a Dual-color FISH analysis with a Smith–Magenis probe (17p11.2; green) and a Miller–Dieker/ILS probe (17p13.3; red) confirms the translocation of distal chromosome 17 short arm material to the short arm of one chromosome 16 homolog (arrowhead). Only the proximal probe (green signal) remains on the derivative 17 (arrow) in contrast to normal chromosome 17 homolog (adjacent green and red signals, open arrow). b Dual-color FISH analysis with LSI *p53* (17p13.1; orange) and TelVysion 16p (16pter; green) probes reveals loss of one orange signal on the derivative 17 (arrow) consistent with monoallelic deletion of the *p53* gene. Remaining chromosomes with orange and green signals represent the normal chromosome 17 and 16 homologs, respectively

because of overlapping histological features and/or lack of specific immunohistochemical markers, particularly in small biopsy specimens. In the present case, a diagnosis of small cell osteosarcoma was established on the basis of the presence of lace-like osteoid.

The majority of conventional osteosarcomas are marked by complex chromosomal complements with abundant structural and numerical aberrations and variable modal chromosome numbers [3, 4, 21]. Common structural abnormalities involve 1p11–p13, 1q11–q12, 1q21–q22, 11p14–p15, 14p11–p13, 15p11–p13, 17p, and 19q13. Numerically, gain of chromosome 1 and loss of chromosomes 9, 10, 13, and 17 are frequent [21]. Of the cytogenetic abnormalities observed in the present case,

only one (a translocation involving 16p13.3) has been seen in two other reported cases [3, 4]. Unlike conventional osteosarcoma, cytogenetic abnormalities of small cell osteosarcoma are not well established. Including the present case, only three cases of small cell osteosarcoma have been subjected to cytogenetic analysis [18, 23]. No consistent anomaly has been identified. One small cell osteosarcoma case reportedly exhibited an 11;22 translocation identical to that of Ewing's sarcoma [18], but subsequent studies have failed to repeat this finding [2, 9, 21]. The 13;21 Robertsonian translocation described in two cases of mesenchymal chondrosarcoma [17] has not been seen in small cell osteosarcoma.

The chromosome band 17p13.1 harbors the tumor suppressor gene *p53*, which regulates cell growth, monitors DNA damage, and facilitates DNA repair. Mutations of *p53* are seen in approximately 35% of sporadic osteosarcomas [8]. Deletions of *p53* are common and are believed to be important in the development of osteosarcoma [6, 21]. Overexpression of the *p53* protein is seen in at least one-fourth of osteosarcomas [15, 19]. Wild-type *p53* gene overexpression has been demonstrated to block osteosarcoma cell growth [7]. Shorter event-free survival has been documented in osteosarcomas with *p53* alterations [26]. In the current study, we found that monoallelic deletion of the *p53* gene can occur through chromosomal translocations in small cell osteosarcoma. To the best of our knowledge, this is the first case of osteosarcoma to demonstrate a *p53* monoallelic deletion through chromosomal translocation.

Numerous candidate genes related to tumorigenesis are sited in the breakpoint regions detected in this small cell osteosarcoma. For example, the *ETS* variant gene 4 (*ETV4*), cancer susceptibility candidate 3 (*CASC3*), and breast cancer 1 (*BRCA1*) are located at 17q21. The product of *ETV4* has sequence similarity in a region required for sequence-specific DNA binding by members of the *ETS* oncogene family and may be associated with tumor cell invasion and metastasis by activating promoters of matrix metalloproteinases [11]. The protein coded by *CASC3* is essential for nonsense-mediated mRNA decay, a surveillance mechanism that degrades mRNAs with premature translation termination codons. Expression of this product has been demonstrated in lymph nodes containing metastatic carcinomas of the breast but not in normal lymph nodes or fibroadenomas [25]. *BRCA1* is implicated in the transcriptional regulation of DNA damage-inducible genes that function in cell cycle arrest. It is interesting to note that loss of heterozygosity at the *BRCA1* gene locus has been demonstrated in 21% of sporadic osteosarcomas, suggesting that inactivation of *BRCA1* may play a role in the development and/or progression of sporadic osteosarcoma [24].

Chromosomal band 6q27 is the locus for the programmed cell death 2 (*PDCD2*) and myeloid/lymphoid or mixed lineage leukemia, translocated to, 4 (*MLLT4*) genes. The *PDCD2* gene is the human homolog of *Rp8*, a rat gene associated with programmed cell death in thymocytes. *BCL6*, a known transcriptional repressor, targets *PDCD2* and may regulate apoptosis via this mechanism [1]. *MLLT4* has been described as a "partner gene" to 11q23, a common

locus involved in translocations seen in acute lymphoblastic and myeloid leukemias. Its product shares a motif present in many proteins involved in signal transduction at cell-cell junctions [20]. Whether these or other genes located on 6q27 are involved in the development of small cell osteosarcoma remains to be elucidated.

Gene amplification is an important mechanism for oncogene overexpression in human cancer. Gene amplification is frequent in osteosarcoma. Amplification of *MDM2*, *CDK4*, *GLI*, *CHOP*, *SAS*, *HMGI-C*, *OS-4*, *OS-9*, and *PRIMI* localized to 12q13–q15, amplification of *COPS3* and *PMP22* localized to 17p11.2, and amplification of *c-MYC*, *HER-2/neu*, and *CCND1* localized to 8q24, 17q21, and 11q13, respectively, have been described in osteosarcoma [10, 14, 21, 27, 28]. In addition, amplification has been observed in several chromosomal regions where the target gene has not been identified such as 1q21–q22, 6p12–p21, 8q21–q22, and 19q12–q13 [13, 21]. In the current study, interphase FISH analyses of *MDM2*, *CDK4*, *c-MYC*, *HER-2/neu*, *CCND1*, and *COPS3* were negative for amplification. In contrast, Sjogren et al. [23] described high-level amplification of the *MDM2*, *CDK4*, and *SAS* genes and low-level amplification of the *HMGI-C* gene in association with a giant marker chromosome in a small cell osteosarcoma with mesenchymal chondrosarcoma-like features.

In summary, genetic data are lacking for small cell osteosarcoma. The findings identified in the current case share some similarities with conventional osteosarcoma but are distinctive from those reported for Ewing's sarcoma and mesenchymal chondrosarcoma. Additional studies are needed to determine the frequency of *p53* alterations in small cell osteosarcoma and their possible prognostic significance.

Papillary thyroid carcinoma presenting as a solitary soft tissue arm metastasis in an elderly hyperthyroid patient. Case report and review of the literature

Received: 8 December 2005 / Accepted: 6 March 2006 / Published online: 28 March 2006
© Springer-Verlag 2006

Abstract A case of papillary thyroid carcinoma (PTC) presenting as a solitary metastasis in the right arm muscle is described in an elderly hyperthyroid male patient. A 2-cm nodule in the right bicipites muscle was found to be a papillary carcinoma of thyroid origin and a primary, 3.5-cm tumor was subsequently found in the left lobe of a hyperfunctioning gland due to toxic goiter. Both tumors were well differentiated PTC, follicular variant. No high grade features, nor extrathyroidal spread, nor regional lymph node metastases were found, but histology evidenced

intrathyroidal vascular invasion. After radical surgery and radioiodine therapy, the patient is currently disease-free 4 years after diagnosis. This is the third reported case of PTC manifesting as a single soft tissue metastasis and the first associated with hyperthyroidism. Hematogenous spread of differentiated PTC is rare, although less unusual in PTC follicular variant. Histological vascular invasion, hypervascularity and increased blood flow in the hyperfunctioning thyroid gland might have facilitated the dissemination of malignant tumor cells through the bloodstream. Literature data indicate that PTC in elderly patients is increasing and is often clinically aggressive. Radical surgical and radiometabolic treatments are required also in this age group to improve clinical outcome.

This work was partially supported by grants from the Italian Ministry of Education and University (ex 60% to MP).

Soft tissue metastasis · Hyperthyroidism

Introduction

Differentiated thyroid carcinoma presenting as a solitary distant metastasis is exceptional. Distant metastases are an uncommon event in differentiated thyroid cancer and are generally associated with follicular carcinoma histological type, rather than papillary. In addition, they are generally detected in lung and bone, and, less commonly, in the brain or liver, other sites being exceptional [5, 9, 12, 18, 19]. To our knowledge, papillary thyroid carcinoma (PTC) presenting as an isolated distant metastasis has been previously described in only three reports, in the pleura [14], in the submandibular gland [17] and in the choroid [20].

The reported prevalence of thyroid malignancy in hyperthyroid patients is varying from 1 to 9% of cases [21]. Anyhow, it is a rare occurrence, generally restricted to multinodular thyroid gland with hyperfunctioning nodules, one of them having malignant features of the follicular (possibly oncocytic) carcinoma type [7]. Small (less than 1.5 cm) papillary carcinomas have also been reported as incidental findings in hyperfunctioning thyroid glands resected for untreatable hyperthyroidism [4, 6, 15].

PTC in the elder (>70 years) population is very rare (approximately 7.6%), the median age of patients with PTC being 40 years for females and 44 years for males, with a female to male ratio of 4:1, age >45 years in males representing an adverse prognostic factor [7, 23].

We, herein, report a case of PTC which is unique for its presentation. It manifested, in fact, as a solitary soft tissue metastasis in the right arm, in an elderly patient affected by hyperthyroidism. The combination of these features has not been reported yet in the English Literature.

Clinical history

A 77-year-old male patient underwent surgical biopsy of a solid nodule of approximately 2 cm in size in his right arm, located within the bicipites muscle. This was interpreted at ultrasound scan and magnetic resonance imaging as a suspected soft tissue tumor. Histologically, an epithelial tumor with the morphological features of PTC was found. As a consequence, the thyroid gland was investigated and a 3.5-cm nodule in the left lobe of a multinodular gland was discovered. In addition, the patient revealed that he was treated with tapazole for a toxic goiter that had caused hyperthyroidism of 2-year duration. A fine needle aspiration biopsy of the left thyroid nodule confirmed the suspicion of PTC. Total thyroidectomy with left cervical lymphadenectomy and radical excision of muscle metastasis were performed. Postoperative radioiodine treatment was administered (total dose of 3.7 GBq). At follow-up, total body scintiscan did not reveal any abnormal uptake; at the last check-up, the patient was alive and disease-free 4 years after diagnosis.

Materials and methods

Surgical specimens from both the arm muscle nodule and total thyroidectomy were formalin fixed and paraffin embedded. Sections were stained with hematoxylin and eosin for conventional histology. Serial sections were collected onto poly-L-lysine-coated slides for immunohistochemistry, using a standard manual immunoperoxidase procedure. Heat-induced antigen retrieval procedure was carried out by three 5-min passages in citrate buffer

solution in microwave oven at 650 W. The following monoclonal antibodies were tested in both the primary carcinoma and the metastatic nodule: anti-thyroglobulin monoclonal antibody (DakoCytomation, Glostrup, Denmark, diluted 1/3,000), Galectin-3 (clone 9C4, Novocastra Laboratories, Newcastle, UK, diluted 1/400), HBME-1 (DakoCytomation, diluted 1/500), Cytokeratin 19 (clone b170, Novocastra Laboratories, diluted 1/150), p27 (clone 1B4, Novocastra Laboratories, diluted 1/30) and Ki67 (clone MIB-1, DakoCytomation, diluted 1/100). The immunoreaction was revealed by incubation with an enzyme-labelled polymer pre-conjugated with anti-mouse secondary antibodies (a biotin-free detection system) (Envision System, DakoCytomation), then with 3'-3'-diaminobenzidine-tetrahydrochloride. The sections were counterstained with Mayer's hemalum and mounted.

Results

Muscle nodule The biopsy and excisional surgical specimens of the right arm nodule were whitish irregular samples of 2×0.5 and 5×2 cm, respectively, surrounded by skeletal muscle fibers irregularly dissected by dense fibrotic tissue admixed with the tumor tissue. The tumor nodule had a similar appearance in both specimens, consisting of small follicles and of irregular papillary formations having a thin fibrovascular stalk. The cells lining the follicles or papillae had medium size, eosinophilic cytoplasm, an enlarged, central nucleus with an irregular profile, indentations, longitudinal grooves and occasional cytoplasmic inclusions (Fig. 1).

Thyroid nodule The thyroidectomy specimen measured 6×4 cm in the left and 6×5 cm in the right lobe and had an irregular multinodular profile. On cut surface, the nodules were dark red with hemorrhagic areas. But the largest (3.5 cm diameter) nodule, located in the mid-portion of the left lobe, was roundish, gray-whitish, partially cystic with a smooth profile and a harder consistency of the solid area. Histologically, the multiple thyroid nodules (except for the largest one) were made of follicles of variable size, containing scalloped colloid and lined by cubic and columnar hyperplastic thyrocytes. The major, capsulated nodule showed focal classical papillary areas and pre-

dominant follicular growth with small, and sometimes, large follicles in a fibrotic stroma. The follicles contained scant, dark colloid and were lined by large cuboidal cells with centrally located irregular, clear and ground-glass nuclei with numerous grooves and occasional cytoplasmic inclusions. Papillary formations lined by similar cells were focally seen. No areas of solid growth or of tall cell or columnar cell variant of PTC were seen in the primary, or in the metastatic tumor (Fig. 2a–d). Foci of intrathyroidal vein invasion were observed within the fibrous tissue surrounding the PTC nodule (Fig. 2e,f). The tumor had no extrathyroidal spreading and was staged pT2. No lymph node metastases were found in the lymphadenectomy specimen which contained 15 small lymph nodes.

Both the primary tumor and the metastatic muscular nodule showed diffuse immunoreactivity for thyroglobulin. In addition, tumor cells expressed Galectin-3, HBME-1 and Cytokeratin 19 and had a down-regulation of p27, as reported in papillary carcinoma. Interestingly, this latter marker was uniformly expressed in hyperplastic, hyperfunctioning thyroid cells of toxic nodules surrounding the PTC nodule. The proliferative activity, evaluated by means of MIB-1 immunostaining in areas of highest labeling density was similar in primary and metastatic nodule, i.e. approximately 2%.

Discussion

We reported a case of PTC quite unique for three different reasons: a) the tumor manifested itself as a solitary muscular metastasis in the right arm; b) it affected an elder patient of 77 years; c) the patient suffered from hyperthyroidism due to toxic goiter. We will briefly comment on these issues.

Cancer and hyperthyroidism Scintigraphically highly uptaking follicular carcinomas, responsible for hyperthyroidism symptoms have been reported more commonly than PTC [7]. Occult (generally small) differentiated carcinomas can be encountered in glands resected for toxic multinodular goiter [22]. The present case was somewhat different because the PTC nodule measured 3.5 cm and was not really occult or an incidental finding, but it was considered part of the toxic multiple nodules responsible for the hyperthyroidism developed 2 years earlier. Morphologically, the primary thyroid tumor did not display any special features that could address to possible hyperfunction or to an aggressive behaviour (see below).

Elderly age PTC is classically affecting young adults and in some circumstances, young children heavily exposed to radiation (as that which occurred in the Chernobyl nuclear accident in 1986). It can, however, be diagnosed at any age. The recent study by Vini and coworkers shed new light on the current follow-up of elderly patients affected by differentiated thyroid carcinoma [23]. Between 2 and 12% of differentiated carcinomas occur in individuals older than 65, and the incidence in this age groups seems to be increasing. In such group, the prevalent histological type is PTC showing an unexpected more aggressive behaviour (with locally advanced disease in two-thirds of the cases and distant spread to bone and/or lung in 23% of patients at presentation) and requiring an aggressive therapeutic strategy (total thyroidectomy, lymph node dissection and early radioiodine treatment) [23]. The currently reported patient benefited from radioiodometabolic therapy immediately after radical surgery and is disease-free 4 years after diagnosis.

Fig. 2 a Primary thyroid papillary carcinoma showing a predominant follicular pattern of growth; b, c typical nuclear inclusions and grooves, d, e intrathyroidal vessel invasion, inset (e) is shown at a higher magnification (hematoxylin and eosin, original magnification: a $\times 25$, b $\times 100$, c $\times 400$, d $\times 20$, e $\times 100$)

Type of presentation The present case presented with a single metastasis in the right arm bycapites muscle without any other synchronous (or metachronous after a 4-year follow-up) localization. Such presumable hematogenous spread occurred in a PTC entirely localized within the thyroid, without cervical lymph node metastases but with histologic evidence of intrathyroidal vascular invasion. Distant spread of differentiated thyroid carcinoma is relatively common for follicular carcinoma whose target organs are generally bone and/or lung and possibly liver or brain [7]. Other localizations of follicular carcinoma, including muscle and other soft tissues, are rare and become exceptional when this metastasis is the first and only clinical manifestation of the tumor, as reported in the pelvis, medial rectus muscle or mandible [3, 10, 13]. Another case was described to have soft tissue metastases of a follicular carcinoma, which were, however, synchronous with bony spread [16]. PTC is commonly associated with lymphatic spread to cervical lymph nodes [7, 8]. Distant (hematogenous) metastases (i.e. to lung, bone or liver) are rare, although they appear less exceptional in the follicular variant of PTC [1] that may share some genetic or molecular features with conventional follicular carcinoma of still unknown clinical significance [2]. Only three reports are on record on the exceptional hematogenous dissemination of differentiated PTC to pleura, submandibular gland and choroid at diagnosis [14, 17, 20]. Metachronous unusual metastasis of (differentiated) PTC have been reported in a few sites such as the mandible and choroids [5, 9].

In another anomalous case, during a 9-year follow-up, several metachronous metastases of a classical PTC were removed from unusual locations such as the thoracic wall, both groins and the thigh, the flow cytometry revealing many tetraploid metastatic tumor cells [11]. However, aggressive forms of PTC exist, including tall cell, columnar cell and solid variants [7]. In addition, cases of poorly differentiated thyroid carcinoma with residual PTC component have been described, causing distant metastatic spread and also a fatal outcome [24]. Such tumors are, however, solid patterned neoplasms, with high grade cytological features, necrosis and extrathyroid infiltration. All these features were absent in the presently reported case which was a partially cystic, follicular variant PTC, the only adverse sign being vascular invasion. The latter has recently been shown to correlate positively with hematogenous distant metastasis of PTC at initial diagnosis [8] and has been reported in 20.9% of cases of the follicular variant of PTC [8]. In the present case, the presence of hyperthyroidism may have further increased the vascularization of the thyroid gland and increased the blood flow, possibly facilitating the dissemination of malignant tumor cells through the bloodstream. Finally, in the present case, the immunophenotype, in terms of thyroglobulin production, expression of markers of malignant follicular-derived tumors, i.e. Galectin-3, HMBE- and Cytokeratin 19, p27 down-regulation and Ki 67 proliferative index were all in the expected profile of conventional PTC.

Conclusion

A case of PTC follicular variant unique for its presentation as solitary muscular metastasis in an elderly hyperthyroid patient was reported. The practical interest in this case is that differentiated thyroid carcinoma, although generally clinically indolent, may occasionally develop distant metastases and even manifest itself as a metastatic tumor. Fortunately, the morphological features of PTC are typical enough, even in metastatic deposits, to suggest a possible thyroid origin. Once the primary thyroid lesion has been identified, an aggressive surgical approach on primary and (hopefully) secondary tumors, immediately followed by radiometabolic therapy, is the treatment of choice, especially in elderly patients often affected by more aggressive thyroid tumors.

Esophageal squamous cell carcinoma with entirely intramural growth pattern

Received: 12 January 2006 / Accepted: 3 March 2006 / Published online: 28 March 2006
© Springer-Verlag 2006

Abstract Esophageal cancers are predominantly carcinomas, which are—due to their origin from the epithelial lining—visible by endoluminal view. We report in this study about the rare case of an esophageal squamous cell cancer with an unusual, entirely intramural growth pattern. The diagnosis could only be established postoperatively, because all preoperative biopsies had failed to demonstrate the tumor. The entirely intramural growth pattern of esophageal squamous cell cancer is an exceedingly rare variant, with only one previously reported case. Nevertheless, clinicians, radiologists, and pathologists should be aware of the potential existence of this condition, especially when clinical and imaging results suggest a malignant tumor that cannot be proven on biopsies. Surgical exploration must be considered under these circumstances.

Keywords Esophageal carcinoma · Intramural tumor growth · Intramural growth pattern

Introduction

Esophageal cancers are accounting for approximately 5% of the incidence and 10% of the deaths from cancers of the digestive system (US Cancer Statistics 2004 [4]). They are

predominantly carcinomas, arising from the inner epithelial layer of the esophageal wall. Two histological tumor types are prevailing and are distinguished as different entities [10]: Squamous cell carcinomas, originating from the original squamous cell epithelium in any location (cervical, supracarinal, and infracarinal esophagus) and adenocarcinomas, arising almost exclusively in the distal third, within specialized intestinal metaplasia (Barrett's esophagus).

Advanced tumors of both carcinoma types are usually visible from endoluminal view (e.g., during endoscopic examination/examination of the resection specimen), typically showing polypous and/or ulcerative growth patterns [9]. These characteristics of esophageal cancers with epithelial origin are in contrast to esophageal sarcomas or melanomas, for which a growth pattern underneath an intact epithelium is typical [3]. The majority of esophageal tumors with mesenchymal origin are benign, mainly leiomyomas, and—due to their characteristic submucosal growth pattern—they are also addressed as submucosal tumors [8].

We present in this study a case of an esophageal squamous cell carcinoma arising in the cervical esophagus, exhibiting a very unusual intramural growth pattern. The indication for oncological treatment by means of surgical resection was made without earlier establishment of the diagnosis, which had failed due to repeatedly negative biopsies.

Clinical history

History and diagnostic work-up

A 58-year-old male patient suffering from repeated episodes of dysphagia was admitted to our University hospital in May 2004 with suspicion of malignant tumor growth in the supracarinal esophagus. The patient had a long-lasting history of tobacco (two packs per day for many years) and alcohol abuse (at least 2 l of beer/day). He had not experienced any weight loss, night sweat, or fatigue.

Flexible endoscopy revealed a moderate stenosis of the cervical esophagus, which could be easily surmounted with the instrument. An area of 5 cm below the upper esophageal sphincter, measuring 3 cm in diameter, appeared suspicious for malignancy. However, there was no intraluminal tumor growth. Staining with Lugol's solution did not provide any additional information on potentially suspicious areas. Several biopsies were sampled using a standard biopsy forceps.

Endoscopic ultrasound (EUS) did not reveal unequivocal findings in favor of malignancy. The same was true for the computed tomography (multislice computed tomography, CT) which revealed moderate thickening of the esophageal wall and few enlarged adjacent lymph nodes (Fig. 1a). Furthermore, investigation by the ear, nose, and throat specialist, including laryngoscopy, as well as bronchoscopy (including cytologic evaluation of lavage) did not show any pathological findings.

Confirmation of esophageal neoplasm by means of biopsy failed: histopathologic evaluation of the biopsies revealed normal squamous cell epithelium. There were foci of mucosal hyperplasia, some fibrosis, and moderate infiltration with inflammatory cells, but no tumor cells or atypical or dysplastic cells could be detected in any of the biopsies (not shown).

The case was discussed in the interdisciplinary tumor conference and it was decided to reevaluate the findings after 1 month (June/July 2004): Endoscopy with sampling of biopsies was repeated and the findings were similar to the initial investigation: endoscopic evaluation still raised suspicion of malignant tumor growth in the supracarinal esophagus, but again no tumor cells were found on histopathologic examination. This situation remained unchanged when—after one more month—a second reevaluation was performed (August 2004). Again biopsies were negative.

In addition to endoscopy and EUS, a combined ^{18}F FDG-PET/CT scan was performed, which also indicated a neoplastic lesion. A slightly increased ^{18}F FDG uptake was found in projection on the thickened esophageal wall of the cervical and upper thoracic esophagus (see Fig. 1b). Now it was decided to establish the diagnosis by means of surgical exploration. Other methods (e.g., CT-guided biopsies) were not estimated suitable for tissue sampling in this localization.

Surgery: indication, findings, and procedure

The cervical esophagus was approached through a cervical incision. The aim was to establish the diagnosis intraoperatively by histopathologic examination of frozen sections. In case of confirmation of the cancer diagnosis, it was planned to proceed with limited cervical esophageal “sleeve” resection and reconstruction with interposition of a free jejunal graft. The latter is a procedure that is frequently employed as a limited surgical procedure for cervical esophageal carcinomas at our institution [1, 11].

Surgical exploration revealed tumor infiltration of the cervical esophagus (from close to the upper esophageal sphincter down to the level below the aortic arch). A frozen section was performed, and histopathologic examination established the diagnosis of a squamous cell carcinoma in the esophagus. Further exploration revealed that the extent of tumor growth did not permit a limited surgical procedure. A transhiatal esophagectomy was performed (blunt dissection of the esophagus through the diaphragmatic esophageal hiatus, without thoracotomy). The intestinal passage was restored with gastric pull-up through the anterior mediastinum (retrosternal) and cervical anastomosis.

Histopathologic examination of the surgical specimen

The operation specimen was opened longitudinally, pinned on a cork board, and fixed over night in 4% buffered formaldehyde. Macroscopic examination of the esophagectomy specimen (Fig. 2a) revealed an intact epithelium in the entire esophagus with only slight irregularities of the internal surface near the oral resection margin in an area of 4 cm length (Fig. 2b). The entire esophagus was then cut transversally into 5 mm-thick slices and embedded completely in paraffin blocks (40 slices of esophageal tissue in total). Histopathologic examination based on hematoxylin and eosin stained sections (Fig. 3a,b) revealed a poorly differentiated squamous cell carcinoma with infiltration of all layers of the esophageal wall from the lamina propria mucosae to the adventitia. No evidence of basaloid or adenoid differentiation was found in the tumor tissue. However, the esophageal squamous epithelium was

Fig. 1 Clinical findings in the 58-year-old patient with moderate dysphagia. The CT scan (a) as well as the combined PET/CT scan (b) were in favor of malignant tumor growth in the cervical/supracarinal esophagus, demonstrating a thickened esophageal wall and enlarged adjacent regional lymph nodes (a, arrows) and an increased ^{18}F FDG uptake (b, arrow)

Fig. 2 Macroscopic evaluation of the surgical specimen shows intact squamous epithelium without obvious tumor growth (a). Higher magnification of the area near the oral resection margin, however, displays irregularities of the surface structure (b)

completely intact and no evidence of squamous intraepithelial neoplasia was found. The tumor was located near the oral resection margin. Reconstruction of the tumor size from the histologic slides revealed a maximum diameter of 5 cm. None of altogether eight dissected lymph nodes showed infiltration by tumor cells. No evidence of lymphovascular invasion or perineural invasion was found. The tumor stages according to UICC criteria [12] were pT3, pN0, and cM0. The resection of the tumor was incomplete at the circumferential margin (R1). Histological examination showed no evidence of esophageal diverticula or cysts.

Immunohistological investigations

One representative paraffin block containing squamous cell carcinoma and overlying esophageal squamous epithelium was selected. Serial sections were immunohistochemically

stained using antibodies against p53 (DO-7; dilution 1:200; DAKO, Hamburg, Germany), Cyclin D1 (SP4; dilution 1:50; Dcs-diagnostics; Hamburg; Germany), EGFR (31 G7; dilution 1:60; Cytomed; Baden-Baden; Germany) Cytokeratin 5/6 (D5/16B4; dilution 1:100; DAKO, Hamburg, Germany), and Chromogranin A (DAK-A3; dilution 1:200; DAKO) using an automated stainer (Ventana Benchmark, Tuscon, Arizona, USA). Expression of p53 and EGFR was found in more than 90% of the tumor cells (Fig. 3c). In the overlying squamous epithelium only scattered cells were found to express p53, whereas expression of EGFR was found in all cells (weak staining intensity). Expression of Cyclin D1 was found only in a minority of cells, both in the cancer tissue as well as in the overlying squamous epithelium (less than 25% positive cells).

The light microscopic diagnosis of squamous cell carcinoma was supported by immunohistochemical inves-

Fig. 3 Microscopic investigation of the esophagus. a At low power magnification a transmural infiltration of the esophageal wall by cancer nests is discernible. The overlying squamous epithelium is intact (H&E; $\times 16$). b At higher magnification, cancer nests can be classified as poorly differentiated squamous cell carcinoma. The overlying squamous epithelium shows mild atrophy (H&E; $\times 100$). Cancer cells invading muscle layer of the esophageal wall showing nuclear accumulation of the p53 protein ($\times 200$) (c). Strong expression of cytokeratin 5/6 in the cancer cells and in the overlying esophageal squamous epithelium ($\times 40$) (d)

tigations showing strong expression of cytokeratin 5/6 in all tumor cells (Fig. 3d). No evidence for neuroendocrine differentiation was found using immunostaining against chromogranin A.

Postoperative course and follow-up

The postoperative course was complicated with anastomotic leakage of the anastomosis, which was managed with temporary insertion of a T-tube. After healing of the anastomotic leak, the patient was discharged home 2 months postoperatively with a good swallowing function and in good general condition. Because of the incomplete resection at the circumferential resection margin it was proposed to perform additive radiochemotherapy (60 Gy + 5-FU). But the patient decided to receive this antineoplastic regimen only after a longer recovery period and depending on results of follow-up investigations. During the further course, the patient developed mild dysphagia, due to strictures of his cervical anastomosis. But neither endoscopic findings nor a recently (May 2005) performed CT scan provided clear evidence of tumor recurrence. The patient is in fine general condition, 13 months after surgical resection, and receives further surveillance with CT and endoscopy.

Discussion

The case presented in this study shows an unusual growth pattern of an esophageal squamous cell carcinoma with entirely intramural localization of the tumor cells. Only one similar case has been reported previously: In the paper by McGregor et al. [7], the tumor cells were also located exclusively intramurally and did not invade the overlying epithelium. Quite similar to the observations in our case, the tumor could not be confirmed by endoscopic investigation because of the intact and all in all nonsuspicious appearance of the mucosa. In contrast to our findings, an esophageal cyst was considered as the origin of the tumor in the publication by McGregor et al.

Another case report describes an esophageal squamous cell cancer with a predominantly submucosal growth pattern, however, preoperative diagnosis by means of endoscopic biopsy was feasible in this case [5].

Intramural growth of esophageal squamous cell carcinoma tissue has also been reported as metastasis to the stomach [2, 6]. In a series of 1,200 esophageal squamous cell cancers reported by Ebihara et al. [2], 13 intramural metastases in the stomach were described. Furthermore, the occurrence of intraesophageal metastases with intramural growth that originate from esophageal squamous cell carcinomas is well known [9]. As a consequence, whenever the diagnosis of a primary esophageal intramural squamous cell carcinoma is under consideration, metastatic origin has to be excluded. Furthermore, one must exclude continuous cancer invasion from the anatomical neighborhood. The most important tumors to be considered in this respect are

nonsmall cell lung cancers with squamous differentiation, as well as squamous cell cancers of head and neck. In our case there was no evidence to suggest invasion of the esophageal wall by primary tumor tissue from any of these neighboring locations, as staging with ENT, bronchoscopy, and CT scan had been unremarkable in this respect.

Hypotheses regarding the pathogenesis

Regarding the pathogenesis of intramural squamous cell carcinoma of the esophagus, two different hypotheses may be proposed.

1. The tumor may have originated from squamous epithelium in an esophageal cyst or small diverticulum, like in the case reported by McGregor et al. [7]. Alternatively, squamous cell metaplasia in esophageal glands may be the origin of tumor growth. The fact that we have not been able to find such a lesion in association with the tumor does not rule out this possibility, as it is well known that advanced tumors may destroy preexisting anatomical structures.
2. Cells of a squamous intraepithelial neoplasia may have reached the submucosal layers by intraepithelial spread in a duct of submucosal glands. Subsequently, these cells may have gained capability of infiltrative growth and infiltration of the esophagus may have taken place under an intact epithelium.

Clinical importance

The clinical importance of esophageal cancer with exclusively intramural growth pattern of esophageal squamous cell cancer is demonstrated by the problems in pretherapeutic diagnosis we had experienced. Clinicians and pathologists have to keep this diagnosis in mind, when repeated biopsies remain negative, but clinical findings strongly suggest malignancy. Surgical exploration with excisional biopsy and/or resection must be considered when demonstration of the tumor by means of endoscopic biopsy fails.

Malignant clear-cell myomelanocytic tumor of broad ligament—a case report

Received: 13 October 2005 / Accepted: 19 December 2005 / Published online: 16 March 2006
© Springer-Verlag 2006

Abstract Clear-cell myomelanocytic tumors (CCMT) of the perivascular epithelioid cell tumor (PEComa) family have been recently reported. We report a case involving a 12-year-old girl. The tumor (9 × 7.5 × 7 cm) was a firm, tan–gray mass with heavily dark pigmentation, massive hemorrhage, and necrosis, and was located in the right broad ligament attached to the right ovary. Histologically, the tumor was composed of polygonal cells exhibiting diffuse hemorrhage, multifocal necroses, and vascular invasion. Most of the tumor cells contained melanin pigments with Fontana–Masson positivity and ultrastructurally suspicious, membrane-bound premelanosomes. Immunohistochemical staining was positive against HMB-45 and focally positive for smooth muscle actin. The tumor recurred in the form of multiple conglomerated masses of the right iliac fossa, with the greatest measuring up to 3.8 cm in dimension, within 1 year. Most CCMT are believed to originate from falciform ligament/ligamentum teres. To the best of our knowledge, this case is the first report of CCMT in broad ligament and the second report of PECOMA, NOS in broad ligament. Further study for proper subclassification of the PECOMA family should be validated, not by anatomic site but by clinical behavior.

Introduction

The “perivascular epithelioid cell (PEC)” was first described by Bonetti and colleagues in 1992 and was observed both in “sugar” tumors of the lung and in angiomyolipomas [3]. These PECs are characterized by an epithelioid shape, clear-to-faintly eosinophilic cytoplasm, perivascular location, and a unique coexpression of markers for smooth muscle actin and melanocytes. The PEComa family includes angiomyolipomas; lymphangioliomyomas; and clear-cell “sugar” tumors of the lung, pancreas, and uterus [2, 4, 8, 9]. Clear-cell myomelanocytic tumors (CCMT) of the PEComa family were first described by Folpe et al. in 2000 [7]. These tumors formed and exclusively developed at the falciform ligament or *ligamentum teres* of children or young adults. We encountered a case of CCMT presenting with a striking amount of melanin pigment, an unusual location, and histologically and clinically malignant features in a young girl.

Clinical history

A 12-year-old girl was admitted to the hospital reporting a right adnexal mass, which had been incidentally detected by abdominal sonogram at a local medical clinic. Physical examination revealed a hen-egg-sized, nontender, soft, movable mass at the right lower abdomen. Abdominal sonogram showed a low echogenic 7.6×6.9-cm mass of the right adnexa (Fig. 1). A pelviscopy-assisted right salpingo-oophorectomy was performed. A few newly developed masses with the same morphology were detected at the right iliac fossa within 1 year.

Pathologic findings

An ovoid, firm, gray mass, measuring 9 × 7.5 × 7 cm, was grossly attached to the right ovary and fallopian tube. The external surface was adhesive but unruptured. The cut

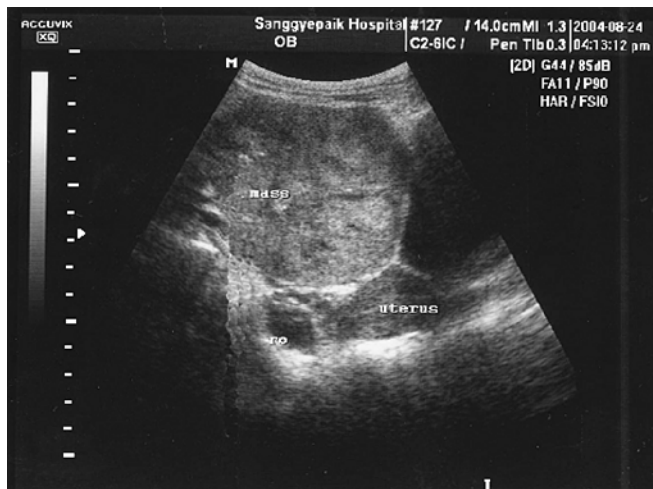

Fig. 1 Abdominal sonogram demonstrates a solid mass at the right broad ligament, which is anteriorly attached to the right ovary (*ro*)

surface was black-colored with diffuse hemorrhage (Fig. 2).

Microscopically, the tumor was circumscribed by a thick capsule, some portion of which was adhesive to the ovarian capsule and tubal serosa. The tumor showed striking vasculature and was composed of uniform, moderate-sized, epithelioid cells with an angiocentric arrangement. Large vessels, as well as small, arcing vessels, subdivided the lesions into coarse packets (Fig. 3a). The tumor cells were oval to elongated in shape, and each showed a single pleomorphic nucleus containing a small but distinct nucleolus. Mitotic figures were occasionally found (4/10 HPFs). The cytoplasm varied from clear to eosinophilic with abundant brownish pigments (Fig. 3b). Angioinvasion and coagulation necrosis were observed (Fig. 3c). Fontana–Masson staining revealed abundant melanin pigment in the tumor cell cytoplasm (Fig. 3d).

Fig. 2 Macroscopic findings reveal a solid mass attached to the ovary and fallopian tube. The cut surface of the mass is dark tan with diffuse hemorrhage

The immunohistochemical profile of the tumor was evaluated on 4- μ m thick, formalin-fixed, deparaffinized sections based on the avidin–biotin–peroxidase complex. The tumor cells were strongly positive for HMB-45 (Immunotech, Marseille, Cedex, France), focally positive for smooth muscle actin (Dakocytomation, Carpinteria, CA, USA), and negative for S-100 protein (Dakocytomation) and pan-cytokeratin (Signet, Dedham, MA, USA) (Fig. 4a–d). The Ki-67 labeling index was low (less than 1%).

Ultrastructurally, the tumor cells had abundant preme-lanosomes with various stages (Fig. 5). A percutaneous needle biopsy specimen from recurred masses revealed morphology similar to the previous mass (Fig. 6).

Discussion

In this report, we describe a case of an unusual epithelioid tumor in the broad ligament, with pathologic and immunohistochemical features entirely compatible with those of a PEComa. PEComas are characterized by an epithelioid appearance, a clear-to-eosinophilic cytoplasm, and an intimate relationship with blood vessels. The cells are consistently immunoreactive to the melanocytic marker HMB-45, variably immunoreactive to smooth muscle actin, and negative for epithelial markers. Since the first description by Bonetti et al. [3], such tumors have been reported in several organs including the uterus, lungs, kidneys, liver, small and large bowel, and prostate.

The uterus is one of the most prevalent sites of involvement. However, so far, only 15 cases have been reported [9]. Uterine PEComa was subclassified into two groups by Vang et al. [10]. The tumors of one group are similar to low-grade endometrial stromal sarcomas with diffuse HMB-45 expression and focal smooth muscle markers. The tumors of the other group are composed of epithelioid cells with less prominent clear-cell features, smaller numbers of which are HMB-45-positive. The latter group exhibits on a morphologic spectrum similar to that of epithelioid smooth muscle tumors, based on the above classification. The predicted clinical course is of uncertain malignant potential.

“CCMT of the falciform ligament/*ligamentum teres*” are a recently recognized addition to the PEComa family, and possess unique histologic, immunohistochemical, and clinical features [2]. They appear to arise exclusively in the abdomens of young patients and show a predilection for the falciform ligament and *ligamentum teres* of the liver. CCMT are characterized by a fascicular and nested proliferation of uniform spindle cells with clear-to-lightly eosinophilic cytoplasm, vesicular nuclei, and small, prominent nucleoli. The gross and ultrastructural findings (numerous stage melanosomes) reported previously [7] revealed more melanocytic features rather than other PEComa groups. Unpublished data has shown the presence of microphthalmia transcription factor (MiTF) in seven cases of CCMT. MiTF is the product of the microphthalmia gene, which encodes a DNA-binding protein, essential for

Fig. 3 **a** Low-power magnification shows a striking vasculature composed of uniform, moderate-sized epithelioid cells with an angiocentric and packet-like arrangement. **b** High-power magnification reveals oval-to-polygonal tumor cells with small but distinct nucleoli and clear cytoplasm, which contain abundant brownish pigment. **c** A conforming tumor embolus is found in a vascular structure. **d** Fontana–Masson special staining reveals abundant intracytoplasmic melanin pigment

melanocyte. These findings provide further evidence of melanocytic character in CCMT. The age predilection and location of CCMT suggest that these tumors arise from the umbilical vessels. The first differential diagnosis of CCMT is clear cell sarcoma (CCS) of tendons and aponeuroses, which can be supported by S-100 protein negativity. By cytogenetic study, CCMT had reported as a translocation between chromosome 3 and 10, but not the translocation (12; 22), of CCS.

A case of a heavily melanotic perivascular epithelioid clear cell tumor of the kidney was recently reported [1]. A large amount of cytoplasmic melanin was reported as a striking feature and the histochemical and immunohistochemical profiles support the extreme melanocytic differ-

entiation. The reported case failed to demonstrate a myoid differentiation or spindle-shaped tumor cells.

The PEComa family is largely composed of an angimyolipoma (AML) and a non-AML group. The non-AML group has been subclassified based on anatomic sites (organ specificity). However, the pathologic classification did not provide any description of biologic behavior. The current and above reported cases are not compatible with the previously described PEComa group.

To the best of our knowledge, this is only the second report in literature of a PEComa arising in the broad ligament, the first being that of a 17-cm-sized pelvic mass in a 51-year-old woman [6]. Histologically, the mass was compatible with a high-grade sarcoma with extensive necrosis and hemorrhage.

Fig. 4 The tumor cells are diffusely and strongly positive for HMB-45 (**a**), focally positive for smooth muscle actin (**b**), negative for S-100 protein (**c**), and negative for pan-cytokeratin (**d**)

Fig. 5 Ultrastructurally, the tumor cells have abundant, membrane-bound premelanosomes (inset)

Fig. 6 The percutaneous needle biopsy from a recurred mass reveals similar morphology composed of polygonal cells with a clear cytoplasm and moderate nuclear atypia

A clinico-pathologic study with comparative genomic hybridization (CGH) analysis for PEComa, not otherwise specified, was done [5]. Five pathologic features of nonbenign cases and benign cases were significantly different; cytologic atypia, necrosis, lymphovascular invasion, size, and significant mitotic activity (more than six

mitoses per 10 HPFs). The presenting case was histologically compatible with the nonbenign group. CGH and DNA ploidy analyses showed a balanced chromosomal profile. Further study for cytogenetic analyses of the PEComa group and definitive assessment for prognostic factors should be validated.

We present a case of a malignant clear-cell myomelanotic tumor of a broad ligament, which we classify as belonging to the PEComa group based on well-developed melanocytic differentiation and the young age of the patient.

CD10+ stromal cells in fibroadenomas and phyllodes tumors of the breast

Received: 26 September 2005 / Accepted: 2 November 2005 / Published online: 21 March 2006
© Springer-Verlag 2006

Sir,

Mammary fibroadenoma (FA) and phyllodes tumor (PT) show a continuum of histologic features, and for this reason, the exact categorization of some lesions can be difficult [1, 5]. Therefore, we found recent reports of differences in CD10 expression between FA, benign PT, and malignant PT to be promising [3, 6]. In the breast pathology, CD10 has been known as a marker of myoepithelium [1], but recently, its expression was also found in stromal cells of fibroepithelial tumors [3, 4, 6]. In a large study of Tse et al. [6], the stroma of FAs was almost always CD10-negative, whereas the stromal cells of PTs, especially in malignant cases, were often CD10-positive. In our practice, we observed CD10 reactivity in several FAs, which is in contrast with previous results [3, 6]. Therefore, we decided to perform a study of CD10 expression in a small series of FA and PT to find out whether CD10 can

help to decide the differential diagnosis between FA and PT, especially in core biopsy specimens offering only a limited amount of tissue.

We examined CD10 expression (56C6, Novocastra, Newcastle upon Tyne, UK) in 20 FAs and 6 PTs. In the FA series, the age of patients ranged from 23 to 57 years (average 39.3), whereas among PTs, the age range was 22–79 years (average 45.2). Five PTs were benign and one was of borderline malignancy [1, 5]. The tumor was considered CD10-positive if there was at least moderate staining in 20% or more stromal cells. CD10 positivity was seen in 12 FAs (60%) and in 4 PTs (67%; Fig. 1a–c). The borderline PT was CD10-negative (Fig. 1d). Subepithelial areas with higher cell density showed often more intense reactivity in both FA and PT.

Our results show that CD10 is frequently positive in both FA and PT (60 and 67%, respectively). Thus, we believe that this antibody cannot assist in the differential diagnosis between FA and PT. Our finding is in contrast with those of Tse et al. [6] and Mechttersheimer et al. [3], who found none or slight CD10 reactivity in FAs (for example, only 1 of 33 FAs was positive in the study of Tse et al.) and increasing positivity in PTs. We suppose that the discrepancy might be explained by different sensitivity of immunohistochemical techniques used in different laboratories. In both FA and PT, the positive cells were often more numerous in subepithelial areas where the cell density is higher, and this finding is similar to that seen in previous studies [3, 6].

In conclusion, our experience indicates that CD10 does not help in differentiation between FA and PT. Further investigations are needed to discover valuable markers that will help in this differential diagnosis.

Dear Editor,

The patient was 47 years old, the diagnosis was made when he was 19, and symptoms began when he was 5. At the age of 37, the patient had a high serum creatinine level and also proteinuria. This makes us believe that there was an important deterioration in the glomerular filtration rate (GFR), because serum creatinine usually rises when GFR falls to at least 50%.

In the report of Schiffmann et al. [1], the age of the patient at the time of the beginning of the TRE is not specified. The autopsy showed acute myocardial infarction associated with coronary stenosis. At a renal level, there are isolated signs of mesangial sclerosis, which do not affect the vascular endothelial cells. The evaluation of the brain showed neuronal commitment, as well as the media and adventitia layers of the blood vessels, which again, did not affect the endothelial cells. In the report, it was suggested that the infused enzyme has limited access to nonvascular endothelial cells and that this may constitute a significant limitation of this therapeutic approach.

I personally believe that the main reason of the bad outcome of the patient is the extremely late beginning of the enzyme replacement therapy (ERT).

At the beginning of the treatment, the patient was close to a chronic renal insufficiency, which, as we well know nowadays, once the point of nonreturn is exceeded, the results of the ERT are not beneficial, as they would be at the early stages [2]. At the same time, we do not have a renal biopsy before the beginning of the ERT. Even though the vascular endothelial cells were clear from Gl3, we cannot know if the ERT reverted the lipid deposits in the interstitial and glomerular cells, which did not show existence of sclerosis.

It would be interesting to count with the latest results of serum creatinine and proteinuria, as the ones published have 10 years and perhaps the renal function was stabilized or could even demonstrate improvements. Although the vascular thrombosis would be accelerated in Fabry disease [3], this patient could have had a polymorphism in the genes of IL-6, eNOS, Factor V, or protein Z, which also adds another vascular risk factor. In conclusion, the ERT with Agalsidasa Beta (Fabrazyme) has clearly demonstrated the removal of Gl3 of endothelial and nonvascular cells [4]. In this report, due to the late beginning of the ERT, I do not believe it is possible to obtain a conclusion on the effectiveness of the enzyme used.

Human T-cell lymphotropic virus type I (HTLV-1) associated myelopathy and Sjögren's syndrome representing pulmonary nodular amyloidosis and multiple bullae: report of an autopsy case

Received: 20 February 2005 / Accepted: 10 June 2005 / Published online: 12 April 2006
© Springer-Verlag 2006

Sir,
T-cell lymphotropic virus type I (HTLV-I), the first human retrovirus, is the causative agent for adult T-cell lymphoma/leukemia (ATL). It has also been reported that the same virus was implicated in the pathogenesis of HTLV-I associated myelopathy/tropical spastic paraparesis (HAM/TSP), HTLV-1 associated bronchopneumopathy (HAB), HTLV-I associated arthropathy, HTLV-I uveitis, and autoimmune diseases such as Sjögren's syndrome (SS) [2, 3]. Thus, HTLV-1 infection contributes to the development of various inflammatory disorders, and the pathogenesis of these inflammatory disorders, which was suspected to be related to the disruption of host immune system, appears to be different from that of ATL.

We experienced an autopsy case of a 59-year-old Japanese non-smoking woman who was found to have both HAM/TSP and SS representing pulmonary nodular amyloidosis and multiple bullae. She was in good health until the late 1980s, when she first noticed obstinate cough. In January 1994, she complained of progressive leg weakness, dysuria, and dyspnea, and she was hospitalized until death. The data of laboratory examination in 1994 was as follows: anti-ATL antibody, >64 titer (cerebrospinal fluid) and >4,096 titer (serum); serum antinuclear antibody (ANA), 80 titer; serum anti-SSA antibody, 16 titer; serum anti-SSB antibody, negative; and serum RA test, positive.

The peripheral white blood cell counts were as follows: 7,100/ μ l in 1994; 3,900/ μ l in 1996; and 8,240/ μ l in 2002. In addition, no apparent ATL-like atypical lymphoid cells were seen. Neither apparent findings of ATL nor monoclonal gammopathy of undetermined significance (MGUS) was seen in the biopsy specimen of bone marrow in 1994. Serum α 1-antitrypsin level was not examined. She noticed dryness of the conjunctiva and mouth, but neither sialography nor biopsy of the minor salivary gland was performed. Chest radiograph showed interstitial pneumonia pattern with some small bullae in both lung fields, but magnetic resonance imaging of the lumbar level was almost normal. These results clinically confirmed the diagnosis of HAM and SS. Conservative therapy was done; however, both neurological and lung functions gradually deteriorated, and chest radiograph and computed tomography revealed increased sizes of multiple cysts through both lungs and a small nodule in right lung (not shown). She finally died of respiratory failure on January 2003. An autopsy was performed 2 h after death. Various organs including both lungs, spinal cord, and submandibular glands were histologically examined in hematoxylin and eosin staining sections. Lung tissues suspected of amyloid deposition were also stained in Congo red with or without KMnO_4 treatment and immunostained with anti-amyloid-A antibody (DakoCytomation, Glostrup, Denmark) and anti-kappa and anti-lambda chains of immunoglobulin (DakoCytomation). Macroscopically, both lungs revealed varying sizes of bullae with some small nodules (Fig. 1), which were found to represent the amyloid deposition histologically. Microscopically, amyloid depositions were also found around the bullae and bronchioles (Fig. 2a), in addition to the nodular deposition with calcification and metaplastic bone formation (Fig. 2b). They were positive for Congo red stain, and the reaction disappeared after KMnO_4 treatment. They were also positive for kappa chain of immunoglobulin, but not for lambda chain nor amyloid-A (Fig. 2c,d), indicating the AL-amyloid. No amyloid deposition was identified in other organs. Organizing pneumonia probably associated with bronchopneumonia and

Fig. 1 Gross appearance of the right lung. The right lung showed multiple bullae formation and a few small nodules of amyloid deposition (*white arrows*). Same findings were also found in the left lung

severe interstitial lymphocytic and plasmacytic infiltration were also found in many portions of both lungs (not shown). Submandibular glands were atrophic with fat infiltration and showed destruction of the glands with lymphocytic infiltration (not shown), and these findings were compatible with SS. The atrophic middle and lower thoracic cords showed symmetric degenerative changes with demyelination accompanied by loss of axons (Fig. 2e). These changes were predominant in the lateral and anterior columns in luxol fast blue stain (inset of Fig. 2e). Mild thickening of the pia mater and sparse infiltration of T lymphocytes ($CD8+ > CD4+$) were also observed (Fig. 2e). These findings of the spinal cord appear to be compatible with those of HAM/TSP with a history of 8 years (inactive-chronic lesion).

This case represented HAM/TSP complicated by SS, nodular amyloidosis, and multiple emphysematous bullae. HAM/TSP has been reported to coexist with various disruptions of the immune system [2]. On the other hand, the pathogenesis of SS has been suspected to be an interaction of genetic, hormonal, and environmental factors. Several viruses, such as Epstein–Barr virus, HTLV-I, human immunodeficiency virus, and human herpesvirus-6, have been suggested as the causative infectious agents of SS and lymphoproliferative disorders [5, 6]. Considering the pathogenesis of the present case, HTLV-I infection was suspected to induce both HAM/TSP and SS. With regard to the lung lesions, the conditions reported in association with HTLV-I infection include HAB and SS [2, 5], and SS has been reported in association with lymphocytic interstitial

Fig. 2 Microscopic findings of the lung (a–d) and spinal cord (e). Amyloid depositions were found around the bullae (*arrow*) and bronchioles (*arrow heads*) (a), in addition to the nodular deposition with calcification and metaplastic bone (b); hematoxylin & eosin stain, original magnification $\times 40$. Amyloid depositions were immunohistochemically positive for kappa chain of immunoglob-

ulin (c) but not for amyloid-A protein (d); immunoperoxidase stain, original magnification $\times 100$. Spinal cord (e) showed monotonous degeneration of the white matter [see also *inset* of (e), Luxol fast blue stain] and thickening of the pia mater. Inflammatory infiltrate is inconspicuous; hematoxylin & eosin stain, original magnification $\times 4$

pneumonia and amyloidosis [4]. Therefore, it is possible to speculate that HTLV-I infection induced SS followed by amyloid deposition as a pulmonary manifestation of SS in the present case. Lymphoplasmacytic infiltration in lungs was most likely to be a lymphoproliferative process associated with SS, although the possible existence of HAB cannot be excluded totally. Amyloidosis is a well-recognized pulmonary complication of SS [4], and there has been one reported case of SS with multiple bullae and pulmonary nodular amyloidosis [1]. They speculated that the narrowing of the airway due to inflammatory cell infiltration and amyloid deposition to the bronchial wall acted as the check-valve mechanism and resulted in multiple bullae formation. The findings of the present case also supported this speculation. In addition, we assume that the destruction of alveolar walls by neutrophilic elastase and matrix metalloproteinases (MMPs) produced by neutrophils and macrophages at the sites of repeating extensive inflammation might also be associated with the formation of multiple bullae, although neutrophilic infiltration was considered to have already disappeared at the time of autopsy. To the best of our knowledge, a case representing HAM/TSP and SS with pulmonary nodular amyloidosis and multiple bullae has never been reported to date, and we believe this report is the first case.

Acknowledgements We thank Dr. M. Kawabata, Department of Pathology, Saitama Prefectural Cardiovascular and Respiratory Center, for valuable discussion in this case and Mr. T. Miyamoto and Mrs. Y. Nomura for their skillful technical assistance.

Warthin's tumour

Received: 20 July 2005 / Accepted: 20 July 2005 / Published online: 12 April 2006
© Springer-Verlag 2006

Dear Editor:

In a recent issue of *Virchows Archiv*, Teymoortash and Werner [8] review the pathogenesis of Warthin's tumour of the parotid gland and conclude that "... it may be classified in the group of tumour-like lesions".

We agree with the aforementioned conclusion, as well as with the assumption that Warthin's tumour may constitute a pathogenetically heterogeneous group of lesions characterized by the growth of oncocytes in a lymphoid stroma [8].

Teymoortash and Werner point out that the oncocytic transformation in Warthin's tumour and in the salivary glands of elderly individuals seems to be related with age-related metabolic deficiencies and may be secondary to damage to the mitochondrial deoxyribonucleic acid (mtDNA) induced by smoking [3]. Furthermore, they identify "oncocytic metaplasia and progressive proliferation of duct epithelium" as the early phase of Warthin's tumour development [8].

From what is known in other tumour and tumour-like models, we think that oncocytic transformation (or metaplasia) plays a pivotal role in the pathogenesis of Warthin's tumour.

The accumulation of mitochondria in the cytoplasm of oncocytic cells may be due to a primary alteration of the mtDNA encoding for mitochondrial enzymes [5], or to mutations in the nuclear DNA encoding for mitochondrial proteins [4, 6]. The most typical mtDNA alteration in oncocytic cells is the presence of a large (about 5 kb) mtDNA deletion that has been detected in oncocytic cells of Hashimoto's thyroiditis and all sorts of oncocytic tumours of the thyroid, as well as in Warthin's tumour, as Teymoortash and Werner emphasize in their review [5–8]. The mitochondria containing deleted and/or mutated mtDNA proliferate more than the "normal" mitochondria, thus leading to a progressive increase in the percentage of abnormal mitochondria in the cells [5, 7].

The mitochondria can accumulate only in cells of tumours that are not actively dividing (i.e., in relatively slow-growing neoplasms); in rapidly growing neoplasms, the division of the cytoplasm of the neoplastic cells prevents the accumulation of the mitochondria. That is the reason why most oncocytic tumours are, like Warthin's tumour and renal oncocytoma, benign or low malignant neoplasms [6, 7].

The mechanism of tumour formation under these circumstances is not yet well understood [7]. It has been advanced that mitochondrial abnormalities block the apoptotic process, increasing the survival of the cells, and/or the deficient mitochondrial function is sensed as a hypoxic stimulus, leading to increased levels of the inducible form of the hypoxic-inducible factor, thus triggering angiogenesis (and proliferation) (for a review, see [1]).

A comparison of a malignant oncocytic tumour with its putative preneoplastic lesion (e.g., an oncocytic variant of PTC arising in the setting of an oncocytic multinodular goiter) discloses frequently the presence of oncogenic mutations in malignant tissues [e.g., in the oncocytic variant of papillary thyroid carcinoma (PTC), RET/PTC rearrangements or BRAF mutations have been detected] [4, 7, 9]. It would be very interesting to find out if the same holds true in rare oncocytic carcinomas arising in pre-existing Warthin's tumours [2].

ANNOUNCEMENTS

4–8 September 2006
Postgraduate Course
Diagnostic Breast Pathology
Department of Pathology
Medical University Graz, Austria

Course Director
Farid Moïnfar, MD (Graz)

Guest faculty
Fattaneh A. Tavassoli, MD (New Haven, USA)

Course Objectives
This intensive course is designed for pathologists in training as well as practicing pathologists. During the course, the participants will review 100 cases dealing with a variety of benign and malignant breast neoplasms and tumor-like lesions. Several common diagnostic problems including papillary neoplasms, intraductal proliferative lesions, variants of ductal and lobular intraepithelial neoplasias, and infiltrating carcinomas are included.

On each day, 20 cases will be extensively discussed by an interactive approach. Particular attention will be paid to the diagnostic criteria with systematic analysis of differential diagnoses. Value and limitations of immunohistochemistry as a diagnostic adjunct will be demonstrated.

Course fee:
Euro 600,- Practicing pathologists
Euro 400,- Pathologists in training

For more information and registration please contact:
Edith Kleinfelchner
Department of Pathology, Medical University Graz

11–13 October 2006
Postgraduate Course
Diagnostic Hepatopathology
Department of Pathology
Medical University Graz, Austria

Course Director
Carolin Lackner, MD (Graz)

Faculty
Helmut Denk, MD, FRCPath (Graz)

Guest faculty
Stefan G. Hübscher, MD (Birmingham)

Course Objectives

The differential diagnosis of chronic hepatitis is a problem frequently encountered in liver pathology. This three day course provides a comprehensive review of the histological features and differential diagnosis of chronic hepatitis in adults; i.e., viral hepatitis, autoimmune hepatitis, overlap syndromes, as well as recurrent chronic hepatitis in the transplanted liver. Liver injury due to drugs, toxins and metabolic disorders and steatohepatitis (ASH/NASH) will also be discussed.

Every day two key lectures, each dealing with a main diagnostic topic will be given. The course covers approx. 50 cases and per day approx. 15–20 cases will be discussed in an interactive approach. Additionally the participants will have ample opportunity for microscopic evaluation of each case.

Course fee:
Euro 400,- (Practicing pathologists)
Euro 280,- (Pathologists in training)
