A compulsory examination in pathology: redundant or necessary?

Jan G. van den Tweel · Claude Cuvelier · Anthony J. Freemont

In this issue Lehr et al. describe the compulsory examination used by the Swiss Society of Pathology to assess senior residents, and thereby assure the professional competence of its future qualified members [1]. With this examination, Switzerland is, with Britain, one of the few European countries with a comprehensive examination (lasting several days) that tests the full range of theoretical and practical competencies required of a medical specialist-pathologist.

There is considerable variation across Europe in the way that the final competencies of pathology trainees are assessed [2]. The reason for this variation is the fact that European countries are all entirely autonomous with regard to training, licensing and the issuing of specialty diplomas in postgraduate medical education. For example, in pathology six countries do not require any form of testing at all at the end of specialty training. In the remaining 26 there is considerable heterogeneity of testing [2], with autopsy competency tested in 11, gross specimen examination and sampling in 9 and cytology in 18. No exact data about the duration of these examinations are known.

Harmonization of training and the assessment of its effectiveness in producing competent specialists has proven to be very difficult because very few countries are willing to give up their autonomy to decide on the competencies of their medical specialists, to be acquired during residency training. This is in stark contrast to many countries where obligatory specialty examinations, sometimes with considerable failure rates, are the norm. Examples include the North American specialty boards and the examinations of the British Royal Colleges [3, 4]. For the Royal College of Pathologists, examinations are one of the principal benchmarks by which trainees are judged to have reached professional competence. The British examinations are still copied in one form or another by their old colonies (e.g. Australia, Canada, many African countries). When one of us (JGvdT) was an external examiner in Zimbabwe in the 90's it was much more difficult to become a pathologist there (or indeed a specialist in any medical discipline) than in the Netherlands and many other European countries. The same applies e.g. to Tanzania where, to progress further in the specialty, residents have to pass a general pathology examination already after 6 months of training.

To tackle this diversity in training and testing in 1997 the European Board of Pathology (EBP) of the European Union of Medical Specialists (UEMS), introduced an annual voluntary examination for senior pathology residents, based upon a similar examination successfully introduced by the European Board of Urology. Although introduction of the examination was supported by a large majority of the members of EBP, due to the lack of any consequence of failing, and poor support by senior pathologists, the test never really got off the ground and is currently taken by only a handful of people, mainly those from outside the EU hoping to

increase their prospect of finding work as pathologist in Europe. The only exception is Malta where since 2011 the UEMS examinations are officially recognized for all medical specialisms.

With support of a grant from the EU, the European Association of Pathology Chairs and Program Directors (EAPCP) developed a voluntary progress test (EUROPALS) [5], comparable to the American RISE (Resident In Service Examination). The latter test is given for all medical specialties in the USA and is for pathology a good outcome predictor for the American Board Examination [6]. This EUROPALS test had a high participation rate and is now, thanks to the support of the European Society of Pathology being developed as an official progress test, not only for residents but also for specialised pathologists and subspecialists.

The relevant question here of course is why trainee medical specialists, including in pathology, in so many countries in Europe are not thoroughly tested at the end of their training. This is relevant in view of the results of the American and British examinations, showing that a proportion of advanced residents do not have the core competencies, as defined by senior members of the profession, considered necessary for practicing safely. As there is no suggestion that the training in the UK or USA is substandard, the question is relevant whether introduction of similar assessments across Europe would demonstrate lacunar competencies in some of the examined residents. That is not to suggest that trainees across Europe might be less competent than their North American or UK homologues, merely that as the experience in the e.g. USA and UK indicates, assessment stimulates learning. Creating a knowledgeable, thoughtful and competent pool of specialists is surely the fundamental goal of any postgraduate medical training programme.

Historical milestones in renal pathology

Jan J. Weening · J. Charles Jennette

Received: 11 April 2012 / Revised: 10 May 2012 / Accepted: 11 May 2012 / Published online: 3 June 2012

Introduction

The history of renal pathology can be divided into two eras: one starting with the invention of the microscope and its application to renal tissue; the second with the introduction of the renal biopsy, which coincided with the development of electron microscopy and immunofluorescence microscopy that allowed the analysis of pathological changes in great detail with an eye for pathogenesis and pathophysiology. These two eras started in 1650 and 1950, respectively; an interval of no less than three centuries during which clinicians and pathologists struggled with a lack of clear understanding of the causes and evolution of renal disease. In concordance with the design of this series on the history of pathology, we focus primarily on the history of renal pathology before 1970.

The early phase

Renal histology

The origins of renal pathology can be traced back to the earliest descriptions of the microanatomy of the kidney by Marcello Malpighi in the year 1666 [1]. Based on his observations with the newly developed microscope, Malpighi (1628–1694; Fig. 1) hypothesized that the formation of urine took place in the kidneys through a filtering mechanism between blood and renal tubules [1]. Malpighi had studied medicine in Bologna and was professor in medicine first in Pisa and then at his alma mater and at the academy of Messina where he published his microscopic observations of various organs including the kidney. Before his illuminating studies, the relation between the kidney and the excretion of urine had been unclear and a subject of wild speculation as was true for renal function and disease in general.

The microscope was a new device at that time used by only a handful of researchers including Malpighi, Antoni van Leeuwenhoek, and Robert Hooke. Hooke had made an improved version of the instrument that was used by his Italian colleague. In combination with a talent for drawing and a sharp inventive mind, Malpighi was able to make giant strides forward, notwithstanding opposition from many colleagues at the time.

In spite of the seminal contributions of Malpighi based on the use of the microscope, his findings were completely overlooked by Giovanni Battista Morgagni who is regarded as the father of pathological anatomy. Morgagni was born in 1682 and lived and worked immediately after Malpighi, who had died in 1694. Morgagni was an anatomist and clinician and related postmortem findings to his clinical observations. He performed over 600 autopsies that form the basis for his major work *De Sedibus et causis morborum per anatomem indagatis* that was published in 1761 (Fig. 2) and had many reprints throughout Europe [2]. However, a complete understanding of the various diseases described in this book including those of the kidneys failed because of a lack of microscopic analysis, which Morgagni refused to rely on as an important tool.

Malpighi's work was taken to a higher level by William Bowman, an English physician (1816–1892) who would later become a renowned ophthalmologist but devoted his early scientific life to the study of anatomy and physiology of the human body. One of his major contributions was the description of the components of the proximal part of the nephron with the periglomerular capsule (later named after him) as it is connected to the proximal tubule allowing the escape of filtrate produced by the glomerular capillary network (Figs. 3 and 4) [3].

Clinical nephrology

During the time of Bowman's early work, Richard Bright (1789–1858) together with John Bostock in England, Pierre Francois Rayer in France, and Friedrich Theodor von Frerichs in Germany studied patients with kidney diseases in great detail by correlating clinical symptoms and chemical derangements in blood and urine [4–7]. Pathology was limited to macroscopy and its contribution to diagnosis was therefore limited. Edema (dropsy as it was termed by Bright), hypertension, hematuria, oliguria, albuminuria, and uremia were quite well described but the underlying processes remained obscure. We now know that these symptoms can be caused by primary or secondary renal disease, affecting the glomeruli, the tubules, or the interstitium based on many different underlying events, which can only be recognized by microscopic analysis. The philosophy held at that time, however, was that in disease, functional alterations led to visible changes, and the latter, being secondary, were considered of less importance.

Richard Bright described three main macroscopic appearances of the diseased kidneys and tried to classify renal diseases accordingly [4] but admitted that he did not know whether these were mere stages of one disease or the faces of many different diseases from acute inflammatory to degenerative to sclerotic. Carl von Rokitansky, the famous pathologist from Vienna (1809–1878), took this to an extreme and used no less than eight classes of renal disease in albuminuric patients, one of which was renal amyloidosis [8]. Clearly, until microscopic analysis was applied to the pathological diagnosis of patients with various clinical syndromes, a rational classification of renal diseases was impossible.

Renal pathology (1850–1900)

The contribution of pathology was on its way, but it took many steps to achieve a level of refinement necessary to understand what is really going on in diseased renal tissues allowing a precise diagnosis of renal disease. Microscopic evaluation of renal tissue was facilitated by a number of technical advances in the mid nineteenth century. In 1837, Gabriel Valentin, a Swiss–German professor of physiology at Bern University, developed the technique of making thin tissue slides. Valentin described renal histology in patients who had died from massive proteinuria [9]. He observed no changes in the corpora Malpighia, but extensive accumulation of a grayish substance in the tubules soon to be recognized as fat, which subsequently led to the term lipoid nephrosis. In 1854 as a result of the invention of aniline dyes, more stains became available in addition to carmine, the only tissue stain that could be used until that year. Edwin Klebs, a pathologist who had worked with Virchow in Berlin, but had moved on to Switzerland and later to the US, introduced paraffin embedding in 1869 and used his improved histologic preparations to study renal

disease. He coined the term glomerulonephritis in his pathology textbook [10].

The field then expanded quickly and from different sources evidence accumulated that pathological changes varied considerably between patients with similar "classes" of kidney disease. Based on microscopic analysis, several renal diseases were specifically identified including post-scarlatina glomerulonephritis, renal amyloidosis, and nephrosclerosis.

Cellular pathology

Important for the unraveling of tissue injury was the concept of cellular injury. The view of the cell as the basic unit of structure and function in the human body was first reported by Robert Remak [11], a Polish Jewish scientist, based on his observations that cell division led to cell renewal. In 1858 after first opposing this view, Rudolph Virchow applied it to his concept of cellular pathology [12], although he did not acknowledge the seminal work of Remak. The concept of cellular pathology was as valid for the kidney as for any other organ, but it took over a hundred years to unravel the characteristics of the variously differentiated cells of the nephron and their role in renal pathology.

Cellular physiology

Friedrich Henle (1809–1885) carefully dissected the microanatomy of the kidney (and many other organs) and discovered the tubular segment named after him as the loop of Henle [13]. He studied medicine at Heidelberg and Bonn, worked in anatomy in Berlin, and then became professor of anatomy in Zürich, Switzerland (Fig. 5). From there he went to Heidelberg to teach pathology, anatomy, and physiology. From Heidelberg, he published the *Handbuch der systematischen Anatomie des Menschen* [14], based on his concept that pathology and physiology were branches of one science. The cellular diversity of the tubular compartment became evident, ready to be unraveled by physiologists over the next century, starting with Carl Ludwig (1816–1895) and Claude Bernard (1813–1878), followed by Homer Smith (1895–1962), A. Newton Richards (1876–1966), Carl Gottschalk (1922–1997), and many others. Crucial for their studies were the contributions of chemists, among whom we can mention Donald van Slyke (1883–1971) and Lawrence Henderson (1878–1942), who developed techniques to allow microanalysis of plasma and urine.

Friedrich Theodor von Frerichs (professor of medicine at Berlin, 1819–1885) was perhaps the first to try to integrate clinical findings with microscopic analysis. This was taken further by his successor Friedrich von Mueller (Marburg, 1858–1941), and then by Volhard and Fahr [15].

Renal pathology (1900–1950)

Theodor Fahr (1877–1945) was the first modern renal pathologist, documenting pathological changes in renal tissue with an exact eye for detail and relating these with the internist Franz Volhard to clinical expression of renal disease [15]. Fahr had trained in Giessen and received further training in Hamburg and Paris, where he worked with Ilya Metchnikoff, who in 1908 received the Nobel Prize for his work on phagocytosis. Fahr was made chairman of the institute of pathology at Hamburg University-Eppendorf in 1924 (Fig. 6).

The fruitful collaboration with Franz Volhard who worked at the university of Frankfurt-am-Main resulted in many publications, including the seminal *Die Bright'sche Nierenkrankenheit, Klinik, Pathologie und Atlas* (1914) [15] and his volume on the kidney in the series on pathological anatomy by Henke and Lubarsch [16].

In their classification of Bright'sche Nierenkrankenheiten, Fahr and Volhard classified renal disease into three major syndromes: the degenerative diseases (nephrosis), inflammatory diseases (nephritides), and chronic nephrosclerosis. Because of a lack of ultrastructural detail (the electron microscopy was not invented until 50 years later) and limited by only a superficial insight in renal inflammatory processes, the authors failed to recognize the glomerulus as the origin of proteinuria in patients with the nephrotic syndrome and placed too much emphasis on tubular reabsorption patterns coined lipoid nephrosis. However, by removing much of the confusion and controversies created by the publications of Bright and Morgagni, this new classification based on the combination of pathology and clinical expression of disease was a major improvement and became widely accepted.

Sir Arthur Ellis (1883–1966) published one of the earliest clinicopathologic studies of glomerular disease based on observations of the clinical courses of 600 patients with Bright's disease in the London Hospital including *postmortem* histological observations in 200 patients [17]. Ellis began his career in Toronto as a clinical chemist, trained in pathology at Western Reserve University in Cleveland, and eventually became a renowned professor of medicine at the University of London and Oxford before being knighted in 1953 for his contributions to the study of kidney disease. His multidisciplinary background in clinical chemistry, pathology, and internal medicine provided a unique perspective for making clinicopathologic correlations. He correlated clinical features, associated conditions (e.g., pharyngitis), blood and urine laboratory results, and histologic findings to propose two types of nephritis. Type I nephritis had an abrupt acute onset, often following an infection, with many but not all patients recovering. Type II nephritis had a more insidious onset characterized by edema and severe proteinuria. He described and illustrated with photomicrographs distinct patterns of glomerular injury that correlated with the clinical course, including glomerular hypercellularity with numerous neutrophils in

Fig. 6 Theodor Fahr as the director of the Institute of Pathology at the University of Hamburg. From Historical Archives of the University Hospital Hamburg-Eppendorf, Institute of Medical History, University Hamburg, Germany

acute type I nephritis, fibrinoid necrosis, and crescents in severe type I nephritis and focal and nodular sclerosis in type II nephritis.

Further insight in the etiology and pathogenesis of renal disease was hampered by the fact that only autopsy material was available for analysis, mostly revealing no more than the endpoint of diseases, obscuring their kinetics and evolution. In addition, more knowledge was required in the field of genetics, cell biology, and immunology before renal diseases could be understood by pathologists and nephrologists as they are today. An important step forward was the introduction of experimental pathology. In a similar way as animal autopsies had preceded the precise study of the human body, laboratory animal experimentation allowed the early twentieth century scientist to induce renal disease and study its evolution over time. It permitted modulation of disease and the study of clinical symptoms. Several experimental models of renal disease were thus developed, preparing the field for a rational interpretation of renal biopsies in man.

Experimental renal pathology

Experimental renal pathology has contributed immensely to the understanding of renal disease for over a hundred years. In 1888, Theodor Tuffier (Paris, 1857–1929) studied the effects of partial renal ablation on renal structure and function [18]. This model would be explored in detail by many investigators in the last quarter of the twentieth century, documenting the role of intracapillary hypertension, glomerular cellular injury, and accelerating loss of nephrons, as a model for progressive renal disease [19–21].

A major impetus for the understanding of renal disease was derived from studies on infection and immunity. Infectious diseases had been by far the most important threat to health and society for ages and still were around the turn of the nineteenth to twentieth century. As of the nineteenth century, clinical and experimental works successfully started to reveal the basis of infection and immunity. Around 1900, the immune response was recognized as having a dark side causing disease by inflammation, anaphylaxis, allergy, and autoimmune reactions.

These early advances in immunology received much attention, were honored with Nobel prizes, and had their immediate impact on the renal field as on every other part of medicine. The Institut Pasteur in Paris was one of the centers of research in this field. It was there that Theodor Fahr worked with Metchnikoff and where kidney disease was studied in laboratory animals exposed to anaphylactic substances [22–24].

Also at Pasteur's Institute, W. Lindemann in 1900 developed a model of autoimmune glomerulonephritis by injecting rabbits with heterologous antiserum raised in guinea pigs against rabbit kidney [25]. This model was studied in depth by M. Masugi in 1933 [26] and was important in the new era that started in 1950. Between 1950 and 1960, *serum sickness-like glomerulonephritis* was identified as the first immune-mediated disease of the kidney caused by deposition of circulating immune complexes, a characteristic phenomenon in chronic infectious diseases and autoimmune diseases [27, 28].

The modern era

Renal pathology (1950–1970)

Three centuries had passed since Malpighi first observed the complex microanatomy of the renal glomerulus. Three centuries later, the almost simultaneous development of techniques to safely obtain renal tissue from a patient by means of a percutaneous needle biopsy and to analyze the tissue not only by light microscopy but also by electron microscopy and immunofluorescence microscopy suddenly provided the structural basis for diagnosis of the many different inflammatory and non-inflammatory, acute and chronic, relapsing and remitting, proteinuric and hematuric, hypertensive and non-hypertensive, and all other renal diseases that had been impossible to classify in an orderly fashion thus far. Within five decades, many questions were going to be answered, although several enigmas still remain today.

The renal needle biopsy was first used for clinical diagnosis of patients by Nils Alwall from Lund, Sweden in 1944. Alwall was successful in obtaining renal tissue by an aspiration technique from his first 13 patients but when 1 of them died from complications, he decided to no longer pursue the technique and did not publish his work until 1952 [29]. His efforts were continued by Paul Iversen and Claus Brun from Copenhagen who published their first series of renal biopsies in 1951 [30] and by Robert Kark from Chicago.

Robert M. Kark (Fig. 7), originally from Cape Town, a renowned rugby player while a medical student at Guy's Hospital, London, had developed an interest in nutrition during a fellowship at Harvard. In World War II, he used this expertise in nutrition to help develop K-rations and foiled a sabotage attempt on a plane to be used by Winston Churchill. Following the war, he became an expert on kidney disease at Rush-Presbyterian-St Luke's Medical Center in Chicago. Kark, who had met Iversen at a congress in Copenhagen in 1950, developed together with Muehrcke and Franklin a technique using the Vim Silverman needle (a cutting needle instead of an aspiration needle) in prone patients which proved to be much more successful than Alwall's procedure [31]. In collaboration with one of the first modern pathologists to specialize in renal pathology, Conrad Pirani, the Chicago group exploited the new development effectively, published widely, and established the Chicago unit as a teaching center for this new technique [31, 32]. The pathology world was at first skeptical, or should we

Fig. 7 Robert M. Kark who with Robert Muehrcke and renal pathologist Conrad Pirani pioneered the use of the renal biopsy in patient care. From Images from the History of Medicine

say hostile, to the idea of a tiny renal biopsy on which a full diagnosis was supposed to be made ("the smaller the biopsy, the more they want to know" is a frequently heard complaint in the practice of pathology). But several pathologists took up the challenge and successfully collaborated with nephrologists to advance the field of nephropathology.

Immunofluorescence microscopy as a technique to detect tissue-bound immune deposits had been developed by Coons and Kaplan in 1950 [33]. In 1955, Mellors first applied the technique to renal tissue [34]. Many renal diseases, particularly the various forms of glomerulonephritis, are antibody- and immune complex-mediated and the newly developed technique allowed for the first time observation of immune reactants that were contributing to the pathogenesis of many different forms of glomerulonephritis [35]. During the 1960s, Frank Dixon, Fred Germuth, and Robert McCluskey integrated the new knowledge about the pathogenesis of immune complex-mediated glomerulonephritis into concepts of diagnostic renal pathology.

Electron microscopy was new in the field as well and the first observations of ultrastructural changes in glomerular disease were published in 1957 [36].

The fenestrated endothelium, the multiple-layered glomerular basement membrane, the mesangium, and the intricate structure of the arborizing and interdigitating podocytes were discovered by thrilled pathologists staring through the binoculars of the first generation of electron microscopes [36, 37] (Fig. 8). Conrad Pirani in Chicago, Ramzi Cotran from Boston and Jacob Churg and Edith Grishman in New York were early pioneers in applying electron microscopy to renal biopsy diagnosis.

With the advent of the renal biopsy, and the application of better histology methods and electron microscopy, the understanding of the histopathology of renal disease developed rapidly at many centers around the world. During the 1950s, the Renal Association in London had monthly meetings at the Ciba Foundation where frequent discussions of renal biopsy findings and clinical correlations were discussed. This presaged the 1961 CIBA Foundation Symposium on Renal Biopsy in London, which was a landmark event in the maturation of the field of renal pathology. The session was chaired by Arnold Rich and pioneering renal pathologists who attended included A. Bergstrand (Sweden), R. Habib (France), R.H. Heptinstall (UK), R.B. Jennings (USA), H.Z. Movat (Canada), and C.L. Pirani (USA) [38]. Knowledge of renal pathology advanced to the stage that comprehensive textbooks became available to provide guidance to nephrologists and pathologists involved in the care of patients with kidney disease. Preeminent among these was Robert H. Heptinstall's (Fig. 9) *Pathology of the Kidney*, first published in 1966 [39], which has cataloged the progression of knowledge in nephropathology through seven editions [40]. Robert H. Heptinstall began his medical career in London as a surgeon, but after World War II he trained as a pathologist. As a young pathologist at St. Mary's in London he collaborated with the renowned internist George Pickering on clinicopathologic studies of hypertensive

nephropathy, which was the beginning of a lifelong focus on renal pathology. With radiologist John Hodson, he worked on the pathogenesis of reflux nephropathy. In 1954 he did a fellowship at Johns Hopkins with Arnold Rich and Fred Germuth studying immune complex glomerulonephritis and in 1959 with Harry Goldblatt in Cleveland. He moved permanently to USA in 1960, briefly at Washington University in St. Louis and then at Johns Hopkins for the remainder of his illustrious career. At Hopkins he continued his research on hypertensive nephropathy and also studied pyelonephritis. His lasting legacy to renal pathology is the textbook that he first published in 1966 [39]. Several valuable books on renal pathology had been published already but his was the first to emphasize observations in renal biopsies rather than autopsies. The first edition primarily covered findings by light microscopy and electron microscopy, but the second edition in 1974 included immunofluorescence microscopy observations as well as a chapter by Robert McCluskey specifically devoted to immunologic mechanisms of renal disease [41]. These books by Heptinstall heralded the current era in renal pathology.

Renal pathology (1970 onward)

In the 1970s, the relatively few pioneers of renal pathology passed the baton to eager younger renal pathologists too numerous to name. Between 1970 and 2010, etiology, pathogenesis, clinicopathological correlations, and classification were established for renal diseases as diverse as lupus nephritis [42, 43], post-infectious glomerulonephritis [44], multiple forms of membranoproliferative glomerulonephritis [45], anti-GBM disease [46, 47], membranous glomerulopathy [48–50], IgA nephropathy [51–53], ANCA-associated vasculitis and glomerulonephritis [54–56], focal segmental glomerulosclerosis and other podocytopathies [57–59], hereditary renal diseases [47], hemolytic uremic syndrome [60], tubulointerstitial disease [61], renal injury in the kidney transplant patient [62], and many others (Table 1). Today's renal pathologists continue to build on the strong foundation laid by the pioneers of renal pathology to advance our knowledge of the pathology and pathogenesis of kidney diseases and to use this to improve the management of patients.

Perspective

In the almost 100 years since the pioneering clinicopathologic studies of Volhard the internist and Fahr the pathologist, tremendous advances have been made in our understanding

Table 1 Time table of seminal discoveries in renal pathology

1666	The glomerulus	[1]
1842	The nephron	[3]
1827	Clinical renal syndromes	[4]
1914	First renal histopathology classification	[15]
1900–1950	Experimental autoimmune glomerulonephritis	[25, 26]
1950–1960	Renal biopsy	[29–32]
1950–1970	Immunofluorescence microscopy, electron microscopy	[33–37]
1960–present	Immune complex diseases, anti-GBM, lupus nephritis, post-infectious GN, IgAN	[27, 28, 42–47, 51]
1975–present	Focal segmental glomerulosclerosis	[19–21, 58, 59]
1980–present	ANCA disease	[54–56]
1980–present	Membranous glomerulopathy pathogenesis	[48–50]
1990–2009	Hemolytic uremic syndrome	[60]
1990–present	Podocyte pathobiology	[57, 59]
1990–present	Classification of diseases of the transplanted kidney	[62]

of the pathology and pathophysiology of kidney disease and the care of patients with kidney disease. These advances have come as a result of intense collaboration between nephrologists and nephropathologists and have been facilitated by sharing new knowledge disseminated through national and international scientific societies, journals, and annual congresses in the field of pathology and nephrology. Advances in renal pathology also have been fostered in particular by the vitality of the Renal Pathology Society, which is international, and the Nephropathology Working Group of the European Society of Pathology. International collaborative efforts to benefit from advances in nephropathology have not been confined to economically well-off countries but also have been extended to the developing countries through the International Society of Nephrology [63]. Reviewing the history of renal pathology reveals how an entire field can only advance by the contributions of many, through implementing new technical developments, and fostered by the fortune of economic prosperity.

REVIEW AND PERSPECTIVES

Interpretation of needle biopsies of the kidney for investigation of renal masses

Benoît Lhermitte · Laurence de Leval

Received: 1 February 2012 / Revised: 17 April 2012 / Accepted: 18 May 2012 / Published online: 8 June 2012

Abstract The development of new therapeutic options for renal tumors has lead to the need of a pretherapeutic diagnosis for an increasing proportion of patients presenting with a renal mass. This need is particularly important for a small, incidentally discovered renal mass (less than 4 cm) as it can be a benign lesion in a significant percentage of cases. Recent studies have shown that needle biopsy is an accurate and safe method allowing for a precise histopathological diagnosis of the mass in most cases. The aims of the biopsy are (1) to assess the benign or malignant nature of the lesion, (2) to assess the primary or secondary nature of the lesion, and (3), in case of a primary malignancy, to determine histological prognostic factors, such as the tumor type. This review, based on the most recent literature and our own experience, is intended to provide a practical approach to the diagnosis, relying on appropriate morphologic assessment and the use of immunohistochemistry.

Keywords Kidney · Tumor · Core biopsy · Renal cell carcinoma · Immunohistochemistry

Introduction

In the past, complete surgical resection (radical nephrectomy) without preoperative histological assessment has long been considered the gold standard for the management of renal masses, as indeed the majority of solid renal tumors are malignant primaries for which surgical management allows optimal staging and treatment. In that context, core needle biopsies were mostly restricted to situations where the indication of surgery was questionable, i.e., in cases of high suspicion of a benign tumor, metastasis, lymphoma, or abscess [1]. Other factors reported to compound preoperative biopsies included an overestimated risk of noncontributive samples, tumor dissemination along the needle track, and hemorrhagic complications [2].

For the past few years, the number of biopsies for renal masses has virtually exploded. The increased use of cross-sectional imaging for other pathologies has lead to the discovery of renal masses, especially of small size, without radiological criteria allowing to determine the nature of the tumor. Nowadays, more than half of all renal tumors are incidentally detected [3]. Moreover, a significant minority (between 15 and 35 %) of these small renal masses, by definition less than 4 cm, consist of benign lesions which do not require surgical removal [4–7]. At the same time, new therapeutic options including partial nephrectomy, imaging-guided ablative therapy (using radiofrequency ablation, high intensity focused ultrasound, or cryotherapy), active surveillance, or systemic neoadjuvant therapy have emerged for the treatment of renal cell carcinoma [8, 9]. In these cases (with the exception of partial nephrectomy), these new therapeutic options require pretherapeutic pathological diagnosis. Moreover, the diagnostic accuracy of the biopsy has increased in the last decade [10], as a result of both the improvement in biopsy techniques and the development of immunohistochemistry panels allowing the identification of almost all tumor subtypes and the newly described entities.

There are currently numerous conditions for which the indication of a biopsy can be discussed: (1) the discovery of a small renal mass because it can correspond to a benign lesion for which a partial or radical nephrectomy would not

be required; (2) in metastatic patients eligible for a systemic therapy with no previous pathology documentation, in order to select therapy by classifying the tumor; (3) a previous history of extrarenal malignancy raising the differential diagnosis of a metastasis or when suspecting lymphoma; (4) a mass associated with a febrile urinary tract infection, in this situation the differential diagnosis includes renal abscess or an inflammatory pseudotumor such as xanthogranulomatous pyelonephritis

Therefore, the aim of a pretherapeutic biopsy is to determine (1) the benign or malignant nature of the lesion, (2) the primary or secondary nature of a malignant lesion, and (3) the tumor type. Lesions that are mostly cystic are currently not an indication for pretherapeutic biopsy because of the difficulty to obtain representative samples of the lesion. The prognosis of cystic lesions can be determined to some extent by appropriate imaging modalities (mainly ultrasound, CT scan, and MRI) using Bosniak's classification [11].

This review is intended to provide a practical approach to the diagnosis of renal core biopsies performed for investigating kidney masses. It is based on the most recent literature concerning the subject and on our own experience.

Technical considerations and diagnostic accuracy

Biopsies are generally performed by the radiologist under US or helical CT guidance, with the patient in prone position under local anesthesia. CT is performed immediately after needle removal to exclude postbiopsy complications. The recommendation is to use 18-gauge (G) needles (yielding 1.7×0.1-cm cores) and to obtain at least two cores in the periphery of the tumor and in nonnecrotic areas [12]. In a prospective ex vivo study conducted on nephrectomy specimens, aimed to compare the yield of 14-, 18-, and 20-G core needle biopsies, Breda et al. [13] found that three biopsies with 14- and 18-G needles allowed to obtain an adequate diagnosis of solid renal masses in 94 and 97 % of the cases, respectively, while the yield of 20-G needles was significantly inferior (81 %). Although fine needle aspiration is not the topic of this review, it is worth mentioning that in some centers, smear preparations are examined extemporaneously to verify the adequacy of the sample. Others use it as a diagnostic tool, with an accuracy close to that of needle biopsies, especially in conjunction with immunocytology [16].

The samples are fixed in formalin and submitted as one core per cassette for standard processing and paraffin embedding. In our institution, sections from three levels are stained with hematoxylin and eosin for histopathological evaluation, and four additional sections per level are kept unstained for special stains and/or immunohistochemistry.

When an adequate sample is obtained, the ability to distinguish benign from malignant lesions is excellent and almost reaches 100 % of the cases. Indeed, in an in vivo study, all oncocytomas were well identified [14]. The ability to determine the histological subtype of renal cell carcinoma (RCC) is excellent, especially when adding adequate immunostain with an accuracy of 90 % overall and 99 % among the four most common subtypes [15].

Interpretation

Renal cell tumors are currently classified according to the World Health Organization (WHO) system which defines tumor entities based on their pathological features, clinical behavior, and genetic alterations (Table 1) [17]. The histopathological diagnosis primarily relies on the examination of routinely stained sections, by taking into account (1) the cytologic features of the tumor cells (i.e., clear, eosinophilic, chromophobic, oncocytic, spindle cells), and (2) the tumor architecture (i.e., solid, acinar, papillary). Assessment of the growth pattern and associated stroma may be of interest for the identification of some renal cell tumor entities and also in the differential diagnosis with non-renal cell tumors.

Clear cell tumors

Clear cell renal cell carcinoma

Clear cell renal cell carcinoma (CCRCC), by far the commonest malignant renal epithelial neoplasm, represents approximately 60 % of renal cortical tumors. Importantly, however, all clear cell lesions are not clear cell renal cell carcinomas, and clear cell renal cell carcinoma is not in fact always composed of clear cells, a reason why some authors advocate the designation "conventional" renal cell carcinoma. Nevertheless, the recommended nomenclature according to the WHO classification remains "clear cell" renal cell carcinoma [17].

In typical cases, the biopsy shows a proliferation of clear cells, possibly admixed with an eosinophilic granular cell component, with a solid or acinar architecture. A prominent delicate and branching vascularization network is characteristic and almost always observed. Secondary changes such as focal fibrosis or hyalinization, geographic necrosis, and focal hemorrhage are frequent. When typical features are observed, the diagnosis is straightforward by morphology and additional ancillary techniques are usually not necessary (Fig. 1). When facing unusual morphology (predominantly granular eosinophilic component or predominantly papillary architecture), immunohistochemistry is helpful to confirm the diagnosis.

Table 1 Classification of renal cell tumors (adapted from the WHO histological classification of tumors of the kidney, 2004)

Renal cell tumors
Clear cell renal cell carcinoma
Multilocular clear cell renal cell carcinoma
Papillary renal cell carcinoma
Type I
Type II
Chromophobe renal cell carcinoma
Carcinoma of the collecting ducts of Bellini
Renal medullary carcinoma
Xp11 translocation carcinomas
Carcinoma associated with neuroblastoma
Mucinous tubular and spindle cell carcinoma
Renal cell carcinoma, unclassified
Papillary adenoma[a]
Oncocytoma[a]
Tumors recently described, not yet listed in the WHO classification
Clear cell papillary renal cell carcinoma
Clear cell carcinoma with leiomyomatous stroma
Oncocytic type papillary carcinoma
Metanephric tumors
Nephroblastic tumors
Mesenchymal tumors
Mixed mesenchymal and epithelial tumors
Neuroendocrine tumors
Hematopoietic and lymphoid tumors
Germ cell tumors
Metastatic tumors

[a] Benign lesions

CCRCC expresses pan-cytokeratins (for example those recognized by the AE1/AE3 cocktail), epithelial membrane antigen (EMA), vimentin, and CD10 in a membranous distribution. Alpha-methyl CoA racemase (AMACR) expression is detected in up to 68 % but usually more focally than in papillary carcinoma. Cytokeratin 7 (CK7) expression is weak and focal. Less than 10 % of the cases show focal positivity for CD117 while the majority of cases are negative. HMB-45 is negative. Antibodies raised against carbonic anhydrase IX (CA-IX), a membranous enzyme acting to regulate both intracellular and extracellular pH and whose expression is induced by hypoxie, have been recently characterized and found of interest for diagnostic purposes. The majority (>85 %) of CCRCC strongly express CA-IX [18, 19]. Importantly, only a membranous pattern is characteristic for clear cell RCC, while cytoplasmic staining is not specific and often observed focally with preferential distribution around necrotic areas in other nonclear cell renal cell neoplasms.

Nuclear grading as per the Fuhrman grading system should be assigned because it is one of the most important prognostic factors in organ-confined carcinoma [20] and because some authors advocate that in elderly and unfit patients, low-grade carcinoma can be initially observed or ablated rather than operated on, while the former treatments are not appropriate for high-grade RCC [7]. However, the concordance is low (less than 50 %) between the grades assessed on paired biopsies and surgical specimens, reflecting intratumor heterogeneity [21]. Alternatively, several authors have advocated to combine lower grades (1 and 2) and higher grades (3 and 4) into a two-tier grading system, which has been shown to reduce the discrepancies between pre- and postsurgical grade assessments [21].

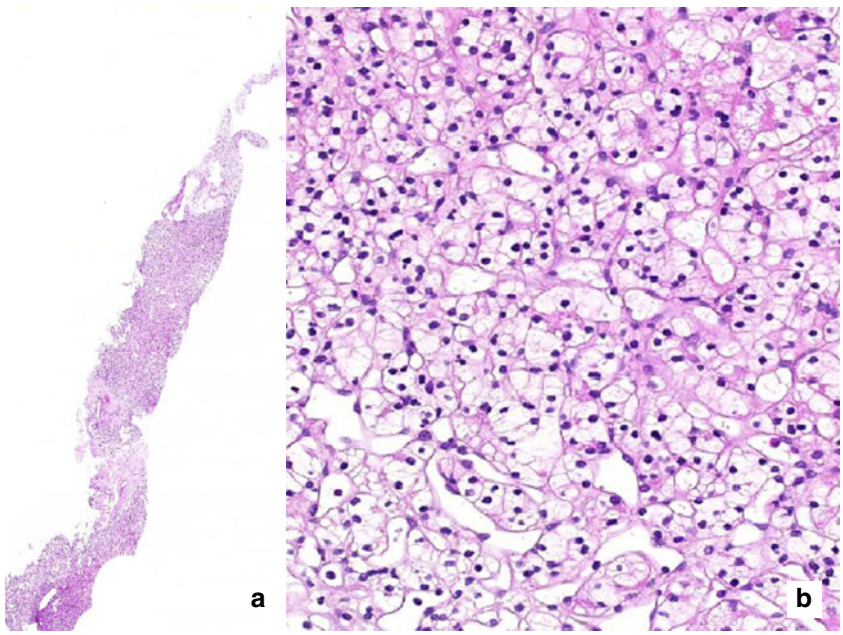

Fig. 1 Core biopsy of a clear cell RCC. Low magnification shows a solid epithelial proliferation (**a**, hematoxylin and eosin, ×2). Higher magnification shows a proliferation of large polygonal cells with clear or finely granular cytoplasm, with round hyperchromatic nuclei (**b**, hematoxylin and eosin, original magnification ×12). In such a case, no ancillary techniques are necessary to confirm the diagnosis

Differential diagnosis

Clear cell RCC can be confused with a variety of other benign or malignant lesions composed of clear cells (Table 2) [22]. In case of diagnostic problems, immunohistochemistry is a helpful adjunct to careful morphologic evaluation to distinguish between the several diagnostic possibilities (Table 3).

Chromophobe renal cell carcinoma Chromophobe carcinoma is generally composed of an admixture of clear and eosinophilic cells. The cellular contours are sharply delineated with thick membranes accounting for a pseudovegetal aspect. In the clear cells, the nuclei are characteristically wrinkled. Vascularization is less prominent than in CCRCC. The immunohistochemical profile differs from that of CCRCC since chromophobe carcinoma usually does not diffusely express vimentin, CD10, or CA-IX, while conversely CK7 and CD117 are both diffusely expressed.

Clear cell papillary renal cell carcinoma Clear cell papillary renal cell carcinoma, first described in the setting of end-stage kidney diseases, may also occur in the absence of impaired renal function. The few cases with documented clinical follow-up suggest an indolent course. These tumors are usually well circumscribed, encapsulated, and unilateral and measure less than 5 cm. In typical cases, there is a delicate papillary architecture with thin fibrovascular septa lined by a single layer of clear cell. The nuclei, generally relatively bland, are arranged in a linear fashion, centrally, or in the upper pole of the cytoplasm. Purely solid forms do exist as well, with a cord-like or trabeculated pattern, reminiscent of that of sex-cord neoplasms. The immunohistochemical profile is quite characteristic, and the distinguishing features from CCRCC are a strong and diffuse CK7 expression and usual negativity for CD10 [23, 24].

Leiomyomatous renal cell carcinoma Recently, a few cases of renal cell carcinoma with angioleiomyoma-like stroma have been described [24, 25]. These tumors which appear to run an indolent clinical course are composed of nests, cords, and sheets of epithelial clear cells, with low nuclear grade. This epithelial proliferation is dissociated by a stroma featuring mature smooth muscle appearance. The differential diagnosis includes not only CCRCC with fibrohyalinized stroma but also angiomyolipoma and sarcomatoid CCRCC with sarcomatoid component. Unlike CCRCC, the epithelial component of leiomyomatous RCC expresses CK7 and high molecular weight CK, and the stroma shows smooth muscle cell differentiation evidenced by positivity for smooth muscle actin and desmin. Leiomyomatous RCC is negative for melanocytic markers, at variance with angiomyolipoma, and the absence of significant atypia in the stromal component distinguishes it from sarcomatoid carcinoma (Fig. 2).

Table 2 Differential diagnosis of clear cell renal cell carcinoma

Malignant neoplasms
Chromophobe renal cell carcinoma
Clear cell papillary renal cell carcinoma
Clear cell carcinoma with leiomyomatous component
Translocation renal cell carcinoma
Benign lesions
Angiomyolipoma
Histiocytic infiltrates
Adrenocortical tissue

Translocation-associated renal carcinomas The presence of a mixed alveolar/papillary architecture, an admixture of large clear and eosinophilic cells, and calcifications, especially in a young patient, are features suggestive for a translocation carcinoma. Translocation carcinomas are commonly negative for all epithelial markers, although focal positivity may be observed, especially for EMA. CA-IX, CD10, and vimentin can be expressed, like AMACR, Melan-A, and human melanoma black-45 (HMB45). As discussed below, the diagnosis can be immunohistochemically proven by the nuclear positivity of transcription factor E3 (TFE3) or transcription factor EB (TFEB) or by fluorescence in situ hybridization (FISH) assays [26].

Angiomyolipoma with epithelioid component Angiomyolipomas are composed of variable combinations of spindle or epithelioid smooth muscle cells sometimes with clear cytoplasm, adipose tissue, and abnormal thick-walled blood vessels. In the presence of abnormal vessels or fat, the diagnosis is usually straightforward but in the presence of a fat-poor lesion with prominent epithelioid clear cell component; it can be confused with clear cell RCC. Immunohistochemistry is useful in this setting since the epithelioid cells of angiomyolipoma do not express any epithelial markers, CA-IX, CD10, or AMACR, while smooth muscle actin, desmin, HMB45, and Melan-A will be at least focally positive.

Histiocytic infiltrates Inflammatory lesions or pseudotumors with a high macrophage content can be present on biopsies as clear cell-rich lesions, which may be mistaken as CCRCC. Careful evaluation of the cytologic features will show xanthomatous rather than granular cytoplasm and consistently low-grade nuclear features. Another hint is the frequent admixture of other inflammatory cells and the presence of preserved normal or atrophic renal structures, while conversely carcinoma infiltrates in a pushing and destructive manner. In

Table 3 Immunohistochemistry for the differential diagnosis of RCC with clear cell features

	VIM	PanCK	CK7	CA-IX	CD10	AMACR	CD117
Clear cell RCC	++	+	−/+	++	++	+/− or −	−
Chromophobe RCC	−	++	++ or −	−	−	−	++
Translocation RCC	++	−	−	−	−/+	+/− or −	−
Leiomyomatous RCC	++	++	++	ND	ND	ND	ND
Clear cell papillary RCC	++	++	++	ND	−	ND	−

ND not determined, *RCC* renal cell carcinoma, *VIM* vimentin, ++ strong positivity in >75 % of tumor cells, + moderate positivity in >75 % of tumor cells, +/− positivity in 50–75 % of tumor cells, −/+ positivity in <50 % of tumor cells, − absence of significant expression

cases of doubt, a limited immunohistochemistry panel with antibodies directed against CD68 and cytokeratins can solve the differential diagnosis (Fig. 3).

Adrenocortical tissue Adrenocortical tissue—either normal or neoplastic and benign or malignant—may be misinterpreted as CCRCC. Biopsy sampling of adrenocortical tissue is more likely to occur when dealing with an upper pole lesion, but one has to be aware of the possibility of renal–adrenal fusion or ectopic adrenal tissue as well. Compared to CCRCC, adrenocortical cells have a more granular cytoplasm and are arranged in a trabecular or nested rather than acinar pattern. Upon immunostaining, adrenocortical tissue lacks expression of EMA or CA-IX and conversely is positive for inhibin, calretinin, synaptophysin, and Melan-A. In a minority of cases, CKAE1-AE3 and CD10 may be positive [22, 27].

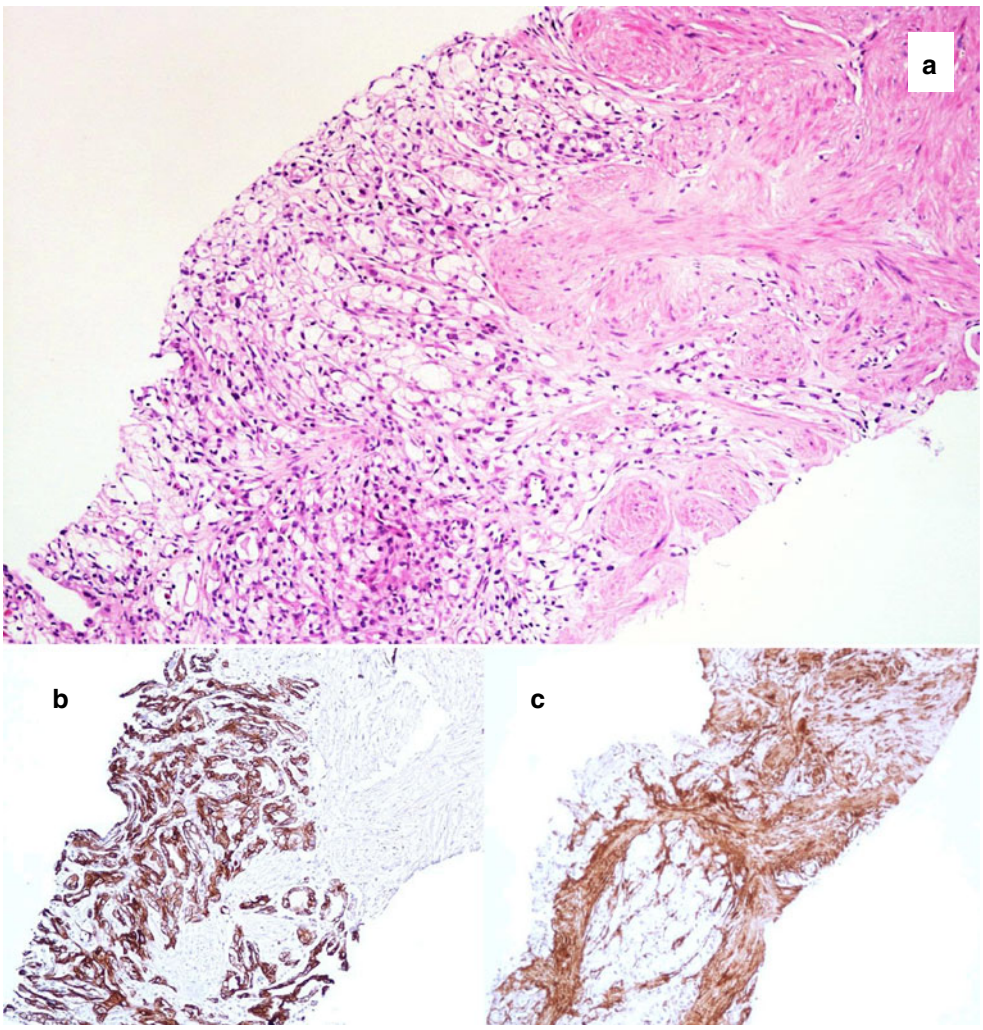

Fig. 2 Core biopsy of a leiomyomatous RCC showing a tubuloacinar clear cell epithelial component admixed with a leiomyomatous component (**a**, hematoxylin and eosin, original magnification ×20). Intense and diffuse expression of CK7 in the epithelial component (**b**, immunoperoxidase, ×10). Intense expression of actin in the leiomyomatous component (**c**, immunoperoxidase, ×10)

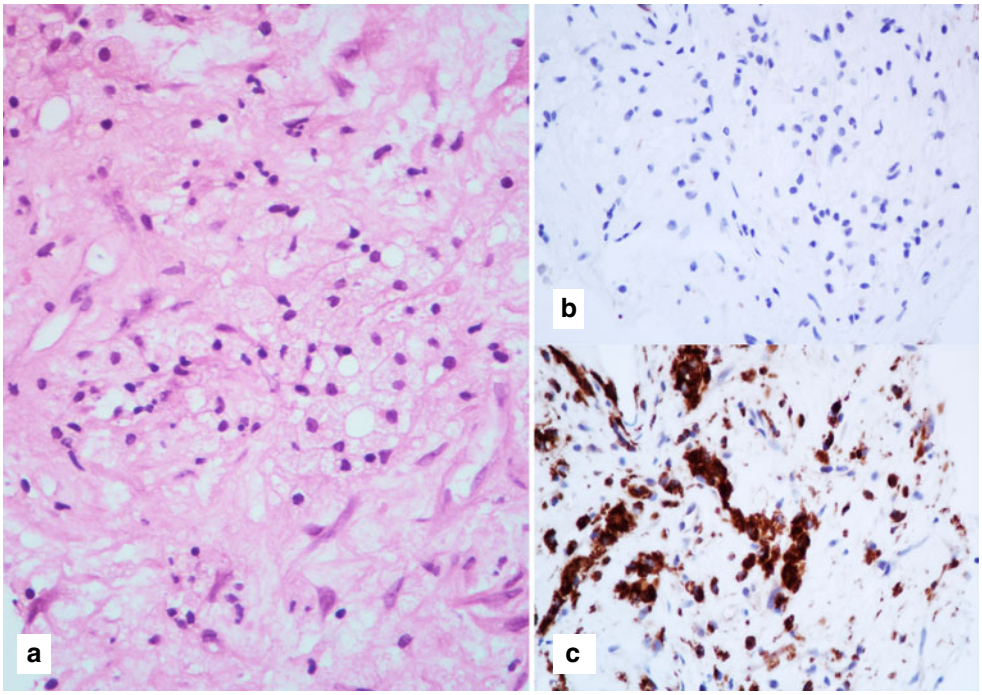

Fig. 3 Xanthogranulomatous pyelonephritis with pseudoglandular architecture of the foamy histiocytic infiltrate (**a**, hematoxylin and eosin, original magnification ×20). Negativity of the pan-keratine AE1/AE3 (**b**, immunoperoxidase, ×20) and expression of CD68 (**c**, immunoperoxidase, ×20)

Eosinophilic cell tumors

Chromophobe cell carcinoma and oncocytoma

Chromophobe renal cell carcinoma and oncocytoma account for the majority of eosinophilic renal cell tumors. The distinction is clinically of paramount importance, given distinct managerial consequences. The differential diagnosis which may be difficult due to overlap in morphological features is greatly aided by the use of ancillary techniques.

Chromophobe RCC (Fig. 4a–d) is composed of clear, eosinophilic, or an admixture of clear and eosinophilic territories. Compared to the classical clear cell variant, in the eosinophilic variant, the cells are generally smaller, with regular and small nuclei, sometimes binucleated, often with a perinuclear halo. The stroma can be focally abundant and fibroedematous. Oncocytomas (Fig. 4e–h) are composed of cells with abundant eosinophilic cytoplasm without sharp delineation of the cell borders. The nuclei are round or with smooth contours and may show atypias, in the form of large irregular hyperchromatic bizarre nuclei. Another characteristic feature of the oncocytoma is the presence of a focally abundant fibroedematous stroma, but this finding is not specific [28].

The expression of CK7 (Fig. 4c, g) is the most discriminant available marker for the differential diagnosis (Table 4), usually intense and diffuse in chromophobe renal cell carcinoma while negative or very focal—in single cells or small clusters of cells—in 95 % of oncocytomas. However, up to 20 % of chromophobe carcinomas lack CK7 expression; hence, negativity of CK7 does not exclude this diagnosis. CD117 (Fig. 4d, h) is another useful marker showing a diffuse cytoplasmic expression with peripheral accentuation in chromophobe renal cell carcinoma while being more often only focally expressed in oncocytoma (essentially in the cytoplasm without membrane reinforcement) [29, 30]. CD10 and AMACR are usually negative in both entities, and expression of vimentin is variable, negative in chromophobe RCC, and possibly focally positive in a large proportion of oncocytomas [31]. CA-IX can be positive in perinecrotic areas of a chromophobe RCC and is consistently negative in oncocytoma. Hale's colloidal iron staining, traditionally recommended as a marker for chromophobe carcinoma, is now obsolete because of technical and interpretation issues.

Clinicians may be doubtful when a diagnosis of oncocytoma is rendered on a biopsy because of the possibility of a hybrid oncocytic/chromophobe tumor of which the potentially malignant component would not have been sampled. However, except in Birt–Hogg–Dubé syndrome or in the setting of renal oncocytomatosis, hybrid tumors appear exceedingly rare, less than 2 % of oncocytoma and chromophobe RCC and do not justify a surgical management for all oncocytoma diagnosed on needles. Moreover, the behavior of these mixed neoplasms seems to be indolent [32].

Differential diagnosis

Other renal cell neoplasms less commonly presenting as eosinophilic cell lesions include a subset of CCRCC (discussed above) and papillary renal cell carcinomas (type II and oncocytic) which may comprise solid areas mimicking oncocytoma [33, 34]. In our institution, when dealing with

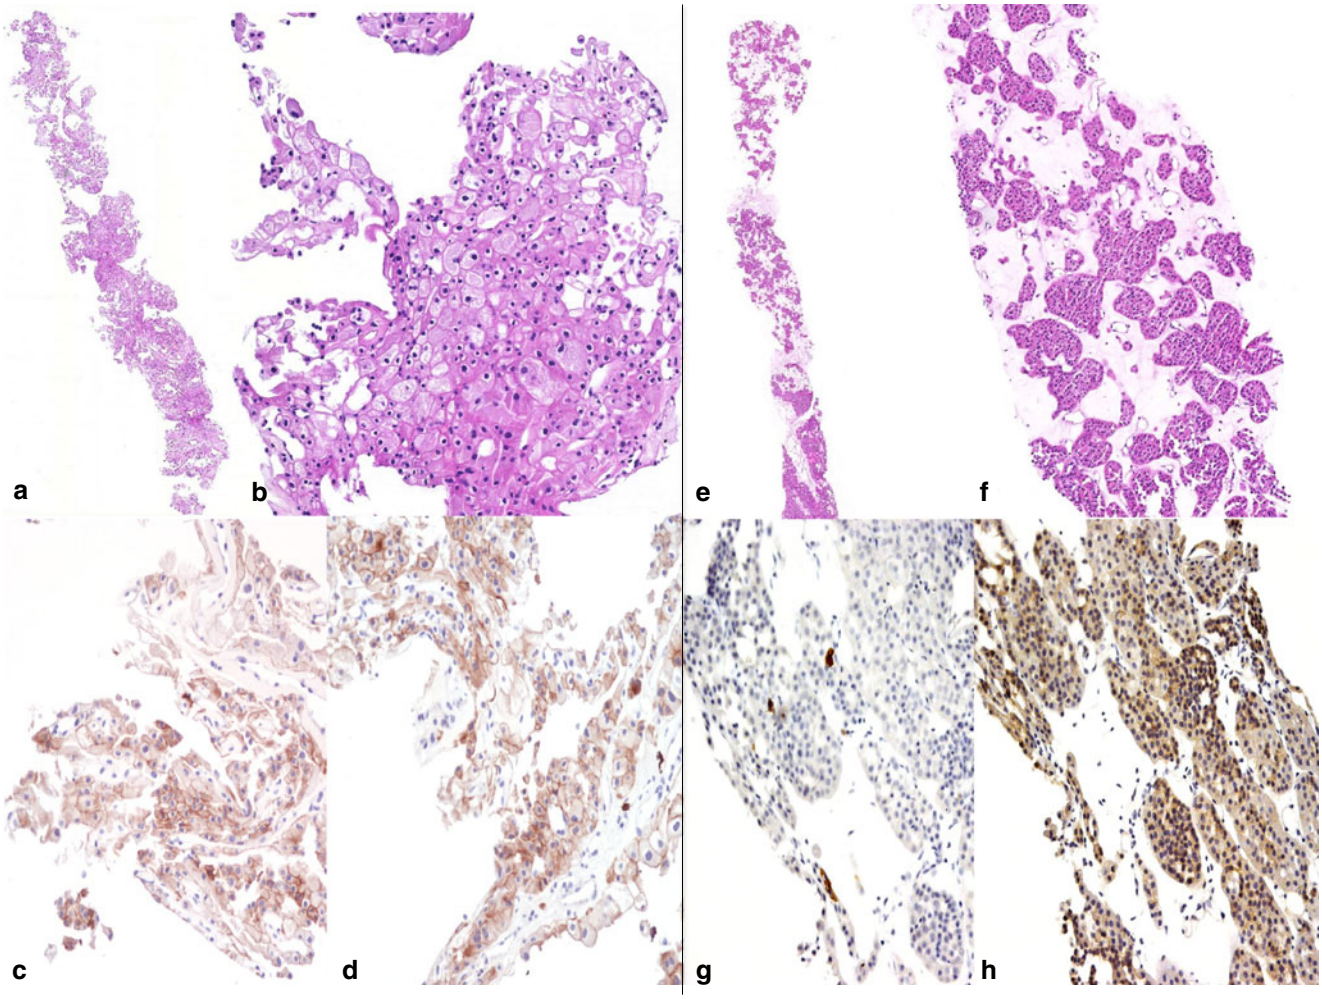

Fig. 4 Chromophobe RCC, mixed clear cell, and eosinophilic type (**a**–**d**). The tumor is composed of large cells with abundant cytoplasm, sharp delineation of the cell borders, and wrinkled nuclei or perinuclear halo. (**a**, **b**, hematoxylin and eosin, original magnification ×2 and ×10). Diffuse expression of CK7 (**c**, immunoperoxidase ×20) and diffuse and intense membranous and cytoplasmic expression of CD117 (**d**, immunoperoxidase ×20). Oncocytoma (**e**–**h**). Core biopsy comprising nests of eosinophilic cells with regular nuclei disposed in an abundant fibroedematous stroma (**e**, **f**, hematoxylin and eosin, original magnifications ×2 and ×20). Positivity of isolated or small cluster of cells for CK7 (**g**, immunoperoxidase ×20). Cytoplasmic expression of CD117 without membranous enhancement (**h**, immunoperoxidase ×20)

small specimen, eosinophilic cell tumors are systematically immunostained for vimentin, CD10, AMACR, CD117, and CK7 (Table 4). In addition, PS100 may be added to the panel as the possibility of metastatic melanoma should also always be borne in mind. If angiomyolipoma is suspected, expression of actin, desmin, HMB45, and Melan-A is also assessed. Exceptional examples of sarcomatoid carcinoma may exhibit rhabdoid features and present as an eosinophilic cell tumor (Fig. 5).

Papillary tumors

A variety of primary renal neoplasms or metastases may show a focal or extensive papillary pattern (Table 5). Once

Papillary type II RCC	++	+ or +/−	−	+	++	−
Papillary oncocytic RCC	++	+ or +/−	−	ND	++	−

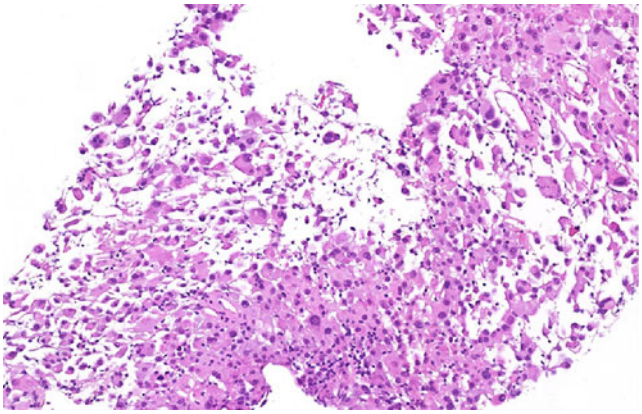

Fig. 5 Rhabdoid RCC. Sarcomatoid component presenting as rhabdoid tumor (hematoxylin and eosin ×20). Expression of CK and INI1 (not shown)

papillary pattern is recognized, morphological analysis should assess the cytoplasmic features (eosinophilic, basophilic, or clear cell), the nuclear grade, the number of layer of cells lining the papilla, and the presence of foamy histiocytes (Fig. 6). In case of a carcinoma featuring a papillary architecture, immunohistochemistry may suggest the renal cell derivation by the positivity of AMACR and CK7. Vimentin and CD10 are generally at least focally positive. If these markers are lacking, metastatic, urothelial, or collecting duct carcinoma should be considered (discussed later). Even in the absence of a clear papillary architecture, the presence of foamy histiocytes is suggestive for papillary RCC. This diagnosis should also be entertained when dealing with an eosinophilic cell lesion, even of solid architecture (see above). Metanephric adenoma, a rare benign entity, must also be considered in the differential diagnosis of papillary neoplasms.

Papillary renal cell carcinoma

Papillary RCC comprises type I, type II, and the oncocytic variant. It is of interest to determine the subgroup of the papillary carcinoma because their prognoses are different. The type I and oncocytic variants are considered low-grade malignant neoplasm while type II is overall more aggressive with a prognosis similar to or worse than that of a clear cell RCC.

Papillary carcinoma, type I This entity features a typical and homogeneous morphology characterized by a delicate papillary architecture lined by a single layer of basophilic cells, with low nuclear grade (Fuhrman 1 or 2). Accumulation of foamy histiocytes in the vascular cores is virtually constant. Necrosis and cholesterol clefts may be abundant. AMACR, CK7, vimentin, and CD10 are almost always expressed (Table 4). Some tumors show a prominent tubular architecture with only minimal papillary pattern, which may be the only component sampled on biopsy. The presence of foamy macrophages is helpful to distinguish this tumor type from the others of tubular architecture (Fig. 7).

Papillary carcinoma, type II Papillary carcinoma type II is a heterogeneous group of tumors with respect to their morphology, immunophenotype, molecular features, and prognosis. Expression of CK7 is not as systematic as in type I but AMACR is usually expressed. In general, the papillae are lined by one or several layers of eosinophilic cells. Fuhrman nuclear grade is higher than in type I (generally 3 or 4), and macrophages are less numerous. Necrosis and cholesterol deposits are frequent.

Oncocytic papillary renal cell carcinoma Oncocytic papillary renal cell carcinoma, formerly included in the group of type II carcinomas, was recently individualized because of its more indolent behavior. It consists of a proliferation of oncocytic cell with round nuclei and large nucleoli. At variance with papillary carcinoma type II, the papillae are mostly lined by a single layer of tumor cells. Foamy macrophages are more frequent than in papillary type II RCC. In all, the oncocytic type of papillary RCC is best described as a tumor resembling papillary type I with oncocytic cells [33].

Microphthalmia-associated transcription factor family–TFE3 translocation-associated renal carcinomas Translocation renal cell carcinoma comprises a group of neoplasms characterized by translocation involving genes encoding transcription factors of the microphthalmia-associated transcription factor family, TFE3, or less frequently TFEB, with various gene partners. The most frequent translocations

involve *TFE3* with *alveolar soft part sarcoma locus* or *papillary renal cell carcinoma*. First described in pediatric population, translocation RCC also occurs in adults accounting for 1 to 4 % of RCCs. Translocation RCC is often

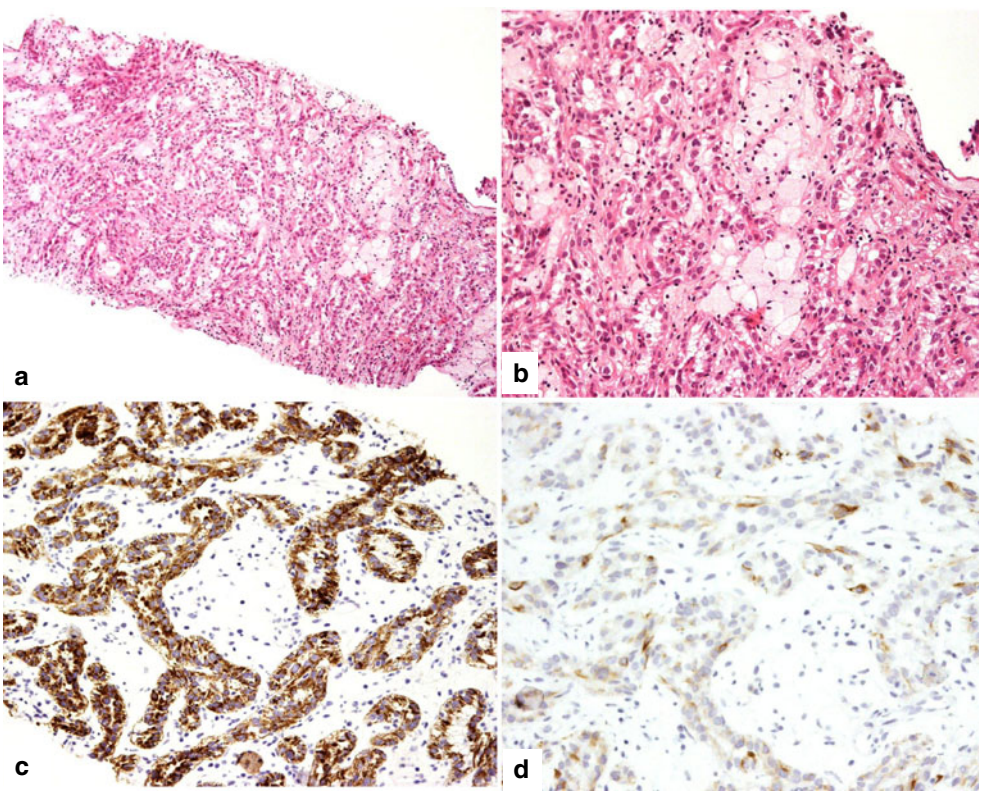

Fig. 7 Papillary RCC probably of type I with prominent tubular architecture (**a**, hematoxylin and eosin ×4). The presence of foamy histiocytes is a useful hint to the diagnosis (**b**, hematoxylin and eosin ×20). The typical immunohistochemical profile includes diffuse and strong expression of AMACR (**c**, immunoperoxidase ×20) and expression of CK7, which was focal in this case (**d**, immunoperoxidase ×20)

present with advanced disease and distant metastasis and carries a dismal prognosis.

Characteristic features of translocation carcinomas include the presence of a mixed alveolar/papillary architecture with an admixture of large clear and eosinophilic cells, the presence of calcifications, and high nuclear grade. Upon immunohistochemistry, translocation carcinomas are usually negative for keratin expression, and hence the diagnosis should always be entertained in front of a keratin-negative renal tumor. EMA can be focally positive, and there is a variable expression of vimentin, AMACR, Melan-A, and HMB45. The diagnosis is definitely proven by the demonstration of TFE3 or TFEB expression [26] and/or by evidencing the gene rearrangement by FISH assay [35].

Metanephric adenoma Metanephric adenoma is a rare benign neoplasm composed of small primitive cells resembling early metanephric tubular differentiation. Histologic features encompass small acini, papillary, and glomeruloid structures composed of monotonous cells with small nuclei and minimal blue cytoplasm. The stroma is often hyalinized and may be abundant. Mitoses are rare or absent. The papillary component may resemble type 1 papillary RCC but the nuclei are smaller, the cytoplasm is less abundant, and CK7 is usually less diffusely positive than in papillary carcinoma type 1. AMACR is positive in both entities. WT1 is helpful, showing often diffuse nuclear positivity in metanephric adenoma [36].

Tumors comprising a spindle cell component

High-grade spindle cell component

When facing a cytologically high-grade spindle cell component, the first diagnosis to consider is a sarcomatoid carcinoma. The probability of finding a sarcomatoid component in small renal masses is low and increases with the tumor size. The identification of sarcomatoid carcinoma is often supported by the presence of an admixed cytologically high-grade epithelial component. In case of proliferations composed exclusively of spindle cells, immunohistochemistry for demonstration of keratin and/or EMA expression is usually useful.

A large variety of primary or secondary sarcomas may involve the kidney. One of the most frequently encountered is synovial sarcoma. Kidney synovial sarcoma is a highly cellular tumor in which tumor cells form short, intersecting fascicles dissecting the native renal parenchyma. This spindle cell solid component is often admixed with cysts of different size lined by hobnail cells. EMA and cytokeratins can be focally positive in the spindle cells and in the cells lining the cyst. The diagnosis is definitely established by the demonstration of *SYT-SSX* fusion at the genetic level or demonstration of the fusion transcript by molecular studies [37].

Low-grade spindle cell lesions

Angiomyolipoma is the most common primary renal tumor with a low-grade spindle cell component. Expression of HMB45 and Melan-A in addition to smooth muscle actin and desmin is characteristic. Other entities in the differential diagnosis include clear cell carcinoma with leiomyomatous stroma (discussed above) and mucinous tubular and spindle cell carcinoma. The latter consists of low-grade epithelial cells in the form of elongated tubules and spindle cells, separated by variable amounts of mucinous stroma. CK7 and AMACR are usually positive. CD10 is negative [38].

Tumors with an infiltrative pattern and desmoplasia

Desmoplasia is not a feature of most renal cell carcinomas, which tend to grow in a pushing manner. An infiltrative pattern of growth between residual glomeruli or tubules brings up the differential diagnoses of collecting duct carcinoma, the very rare renal medullary carcinoma, urothelial carcinoma, and metastasis. In this setting, PAX2 and PAX8 transcription factors represent two potentially useful markers for the demonstration of renal cell derivation.

Collecting duct carcinoma and renal medullary carcinoma

Collecting duct carcinoma is extremely rare (less than 1 % of renal malignancies). It comprises a tubular or tubulopapillary infiltrative growth with a desmoplastic and often inflammatory stroma. Solid, cord-like features may be encountered. In case of prominent papillary architecture, papillary renal cell carcinoma may be suspected but the latter usually lacks desmoplasia.

Renal medullary carcinoma is a very rare entity occurring almost exclusively in young patients with sickled cell trait, viewed by some authors as an aggressive form of collecting duct carcinoma. Intratumoral inflammatory infiltrates, mostly neutrophils, are a constant finding and sickle red blood cell may be recognized. Recent data suggest consistent loss of INI-1 expression in these tumors [39].

Urothelial carcinoma

Invasive urothelial carcinoma in the kidney usually manifests as high-grade carcinoma, poorly differentiated, or with glandular differentiation. Immunohistochemistry is helpful to demonstrate the expression of CK7, CK20, CK5/6, and p63. The latter is very useful for distinguishing from collecting duct carcinoma [40]. Conversely, urothelial carcinoma lacks CD10 and other renal cell markers [30] (Fig. 8).

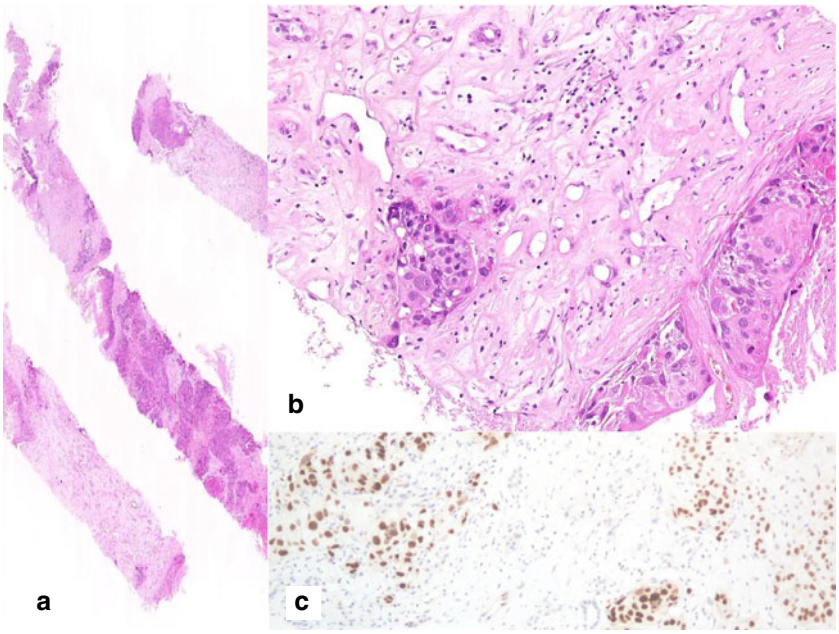

Fig. 8 Invasive high-grade urothelial carcinoma (**a**, hematoxylin and eosin ×2). This field illustrates nests of atypical cells, desmoplastic fibrous stroma, and residual atrophic renal tubules (**b**, hematoxylin and eosin ×10). Immunohistochemical profile includes nuclear expression of P63 (**c**, immunoperoxidase ×10)

Metastatic carcinoma

The possibility of metastasis should be considered whenever a renal neoplasm appears unclassifiable as a primary lesion, i.e., any lesion not showing the classical morphologic features of a renal carcinoma (glandular architecture, desmoplasia, absence of clear cell, etc.) and immunohistochemical expression of classic renal markers (Table 6). It is of importance to stress that AMACR has no specificity for renal primaries and it is expressed in many adenocarcinomas of other origins, for example prostatic, gastric, or colorectal [41, 42]. The most common primary sites are lung, breast, skin

Table 6 Commonly used markers for diagnostic immunohistochemistry: expression in normal kidney and in primary renal and extrarenal tumors

	Normal kidney	Primary renal tumors	Extrarenal tumors
Vimentin	Vessels	Clear cell RCC Papillary RCC	Carcinoma of endometrium, thyroid, and adrenal cortex
Pan-CK	Tubules and glomeruli	All types of RCC except translocation carcinoma	Carcinoma
CK7	Tubules and glomeruli	Papillary RCC Chromophobe RCC Leiomyomatous RCC Clear Cell papillary RCC may be focal in clear cell RCC	Variety of (adeno)carcinoma (breast, lung…)
AMACR	Epithelial cells of the renal tubules	Papillary RCC Clear cell and translocation RCC	Prostate, lung, colon, stomach, ovary, breast, endometrium, gallbladder, neuroendocrine carcinomas
CA IX	Not expressed	Clear cell RCC Collecting duct carcinoma	Endometrium, stomach, cervix, breast, lung, liver, brain tumors, neuroendocrine carcinomas, mesothelioma
CD10	Podocytes, proximal tubular cell brush borders	Typical in clear cell, papillary, and translocation RCC; can be expressed in other renal epithelial neoplasm	Various neoplasms of epithelial, stromal, or hematopoietic derivation
CD117	ND	Chromophobe RCC Oncocytoma	Gastrointestinal stromal tumor, seminoma
PAX2 and PAX8	Podocytes Distal tubular cells Lymphoid cells	All types of primary RCC, decreased in high grade, negative in sarcomatoid carcinoma	Lymphoma, nephrogenic adenoma, thyroid follicular cell neoplasm
RCC	Proximal tubular cell brush borders	Clear cell RCC Papillary RCC	Adrenocortical tumors, breast and colon carcinoma, embryonal carcinoma, parathyroid tumors,

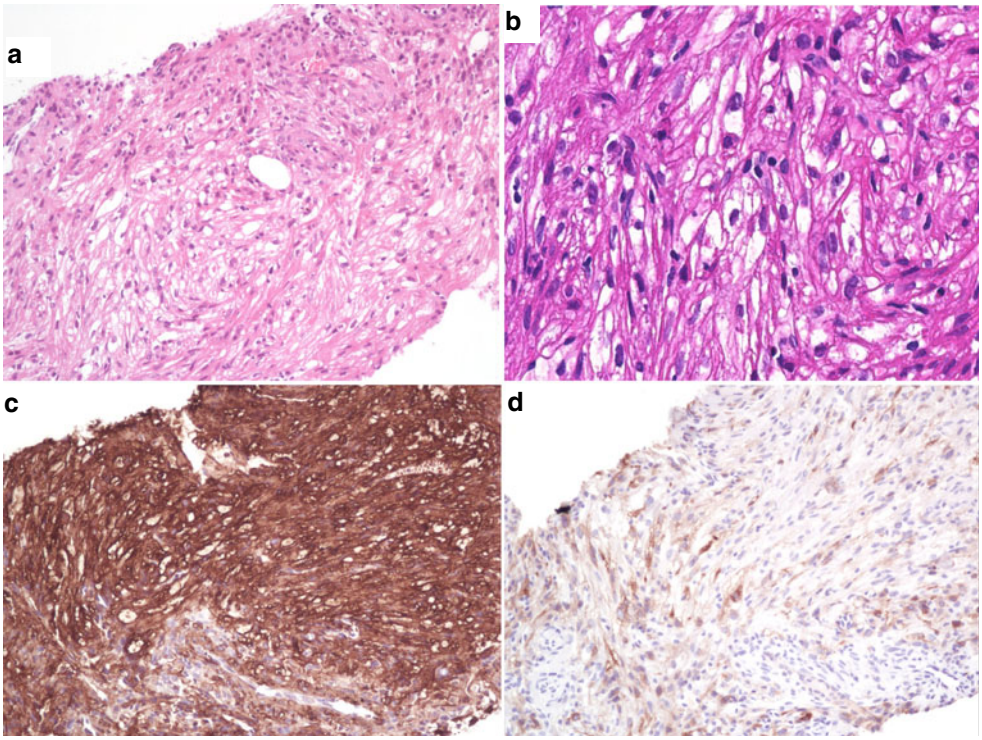

Fig. 9 Epithelioid angiomyolipoma. Proliferation of plump and spindle clear cells arranged in fascicle (**a**, hematoxylin and eosin ×20 and **b**, hematoxylin and eosin ×40). Immunohistochemical profile includes intense expression of actin (**c**, immunoperoxidase ×20) and partial expression of Melan-A (**d**, immunoperoxidase ×20)

(malignant melanoma), contralateral kidney, gastrointestinal tract, ovary, and testis [43]. Renal metastases appear commonly in the late stages of evolution whereas renal metastasis as the initial manifestation of the primary is highly unusual.

Angiomyolipoma

Angiomyolipoma is a benign neoplasm that belongs to the perivascular epithelioid cell (PEC)-oma family of tumors. Its classical triphasic pattern associating variable amounts of adipose tissue, spindle or epithelioid smooth muscle cells, and abnormal thick-walled blood vessels is usually easily recognized histologically and often largely suspected radiologically because of the presence of adipose tissue. When the triphasic pattern is well represented, ancillary techniques are not necessary, but in case of diagnostic doubt, the immunohistochemical pattern is characteristic, with the epithelioid or spindle cells expressing muscular marker (alpha-actin and less frequently desmin) and some melanocytic markers as HMB45 and Melan-A [44]. PEComas are benign, and a simple surveillance can be recommended if the lesion is asymptomatic and small. Large tumors have to be removed because of the rare but real hemorrhagic risk.

Epithelioid angiomyolipoma of the kidney is a rare disease, closely related to classic, triphasic angiomyolipoma and considered as a potentially malignant neoplasm [45]. The epithelioid component is composed of large globulous or plump spindle cells with clear or eosinophilic cytoplasm and voluminous nuclei, similar to those of soft tissue PEComas (Fig. 9). Epithelioid angiomyolipoma can be confused with clear cell RCC or with melanoma, but negativity of cytokeratin and PS100 and positivity of smooth muscle markers (actin and desmin) and HMB45 and/or Melan-A are diagnostic. The minimal amount of epithelioid component required to define angiomyolipoma as epithelioid, and so to suspect the lesion as potentially malignant, however, is not well defined. In our practice, epithelioid features in angiomyolipomas, when present, are systematically mentioned in the pathology report with a note suggesting that surgical removal would be performed.

The nondiagnostic biopsy

Normal renal tissue and fibrous or fibroinflammatory tissue

The proportion of biopsies composed of normal renal tissue or sampling only fibrous or fibroinflammatory tissue varies between 5 and 10 % in published series. Importantly, a diagnosis of malignancy is eventually rendered in more than half of the patients who undergo nephrectomy or repeat biopsies, advocating the need for a second biopsy in case of a nonconclusive biopsy [21]. A final diagnosis of scar or pyelonephritis should strictly correlate with clinical and radiological settings.

Necrotic tissue

Although biopsies are performed under imaging guidance in order to be directed to viable areas, in rare cases, biopsies

may exclusively sample necrotic tissue, raising the differential diagnosis of the underlying process as neoplastic versus inflammatory. Immunohistochemistry can be helpful, as the immunoreactivity of carcinomatous cells for CK or EMA is usually conserved, even when necrotic.

Concluding remarks

A good morphological analysis in conjunction with the appropriate use of an immunohistochemical panel can lead to a precise diagnosis for a vast majority of the renal masses sampled by core biopsy. This is now of importance because of the need of pretherapeutic diagnosis in an increasing number of situations. Nevertheless, definitive tumor typing is not always possible, for example in the case of cytologically low-grade neoplasms with clear cell features or in the case of eosinophilic cell proliferations. In those situations, it is important to state whether the renal cell origin of the lesion can be confirmed and to mention the nuclear grade. Deferring the definitive diagnosis to the examination of the surgical material appears as a reasonable option without impending appropriate management of the patient.

Cytogenetic studies, like FISH or comparative genomic hybridization (CGH) array, can determine changes known to be specifically or preferentially associated with each tumor type. For example, deletion of 3p is characteristic of CCRCC, hyperploidy is characteristic for papillary RCC, and hypoploidy for chromophobe RCC. This kind of ancillary techniques is currently not routinely performed, with the exception of *TFE3* break-apart FISH assays for the identification of translocation RCC. Nevertheless, FISH and CGH array have been proven to be feasible on biopsy samples and could be considered as an option in the future to improve the accuracy of biopsy diagnosis [46, 47].

REVIEW AND PERSPECTIVES

Teratoma with somatic-type malignant components of the testis. A review and an update

Gregor Mikuz · Maurizio Colecchia

Received: 3 March 2012 / Revised: 26 April 2012 / Accepted: 10 May 2012 / Published online: 24 May 2012

Abstract Malignant transformation of germ cell tumors into somatic malignancy is uncommon. Its presentation differs from series to series, with 43 % of adult cases identified within the primary tumors and the remainder at the time of relapse or in the metastasis. Patients with stage I disease enjoy an excellent prognosis; whereas in metastatic sites when not completely resectable, the somatic type malignancies suffer a dismal prognosis. Radical surgery is significant for the prospects of cure and is standard chemotherapy for germ cell tumors; a transformation-oriented treatment can be effective for these patients. A deeper understanding of the biology of this phenomenon is essential for clinicians involved in such malignancies in order to permit a better control of the disease.

Keywords Germ cell · Teratoma · Somatic-type malignancy · Sarcoma

Introduction and historical review

Testicular tumors are of great interest to the pathologist because nearly all of them are of germ cell origin, with a potential for differentiation in many directions. Moreover, these potentially deadly tumors are highly responsive to therapy and more than 90 % can be completely cured. Among this great morphological variety of different subtypes of germ cell malignancies, teratomas can show a partial transformation into a malignant somatic-type tumor component (MSC) [1–3]. However, due to the small number of published clinic pathological studies, our knowledge about these tumors is very limited [4–10].

According to Ewing [11], it was St. Donat who in 1696, for the first time, identified a testicular tumor with the morphological features of teratomas, consisting of a rudimentary skull and embryonic eyes. As reported by Kaufmann [12], Wilms recognized the tendency of single tissue elements in teratomas to predominate over others, and described carcinomatous and sarcomatous tissue in so called "embrioid tumors".

Friedman and Moore [13] reviewed 922 testicular tumors observed at the Armed Forces Institute of Pathology and noted a few teratomas in which carcinoma, rhabdomyosarcoma, or neuroblastoma developed; but they did not report detailed pathological findings and left out certain clinical details of these cases. Finally, Mostofi and Price in the fascicle 8 of the second series of the AFIP Atlas of Tumor Pathology recognized the existence of teratomas with malignant transformation. The clinical information concerning the behavior of the disease was, however, extremely scarce [14].

In the 2004 edition of the WHO Classification of Tumors, this entity was classified as "teratoma with somatic-type malignancy," which was defined as "a teratoma containing a malignant component of a type typically encountered in other organs and tissues, e.g. sarcomas and carcinomas" [15]. It occurs in 3–6 % of patients with metastatic germ cell tumor (GCT). Further analyses have subsequently been

reported, however, each one covering a small number of patients [5, 7, 10].

Teratoma with a malignant somatic component (TMSC) affects mainly young males (aged 20–40), but sporadic cases in the pediatric population have been reported with clinical–pathological features similar to those occurring in adults [16]. Clinical follow ups have shown that compared with teratomas without somatic type malignancies, these tumors in metastatic sites have poor prognosis if not completely resectable. The extent of the disease at onset and consequently, the feasibility of a radical surgical extirpation have been identified as the strongest prognostic parameters for durable remissions [3, 8–10].

Histopathology

For an accurate diagnosis of TMSC located in the testis as well as in the metastases, the pathologist has to assess the degree of atypia in the somatic components and whether the tumor is growing in an expansive way. Davey and Ulbright [17] found cellular atypia of epithelial and mesenchymal elements in teromatous metastases of patients treated with cisplatin-based chemotherapy for nonseminomatous GCTs. The follow-up, however, did not show significant differences compared to patients without significant atypia. The authors thus concluded that only the expansive growth of the somatic malignant proliferation is a significant feature for the diagnosis of a TMSC.

The amount of malignant somatic tissue required for the diagnosis of TSMC is still a controversial issue. Ulbright and Roth [18] suggested that the somatic malignancy is clinically important only if it fills a field of view at low magnification (4× lens). More clinicopathological study including adequate follow-ups is needed to find out whether or not this threshold is reliable.

A variety of somatic malignancies in GCT can occur in neoplasms of gonads, as well as in germinal extragonadal tumors of the mediastinum [19] and intracranial cavity [20]. The somatic neoplasia may be sarcomas of any type [2, 3, 5, 7, 8, 10, 21–26]. The most common were the rhabdomyosarcoma, followed by leiomyosarcoma, myxoid liposarcoma, chondrosarcoma, glioblastoma multiforme, epithelioid hemangioendothelioma, malignant peripheral nerve sheath tumor [5, 7, 10], but also adenocarcinoma or squamous cell carcinoma [27]. Other frequently reported somatic malignancies are nephroblastoma [10, 28, 29], carcinoids [30], and hematologic malignancies. In a series of 40 TMSC observed by one of the authors (MC), rhabdomyosarcoma was observed in 11 cases (27.5 %) [10]. Angiosarcoma has also been described as a primary tumor in the testis as well as in the metastases from testicular GCT [31].

Primitive neuroectodermal tumors (PNETs) are also likely to be a very frequent somatic malignancy arising in teratoma [9, 10, 32–37]. PNETs are sometimes incorrectly reported as immature teratoma [38], an inappropriate diagnosis that can be a source of confusion for clinicians. In the WHO 2004 classification (15), the terms “immature” and “mature” teratoma were abolished because they are clinically irrelevant. Moreover, the *epitheton ornans* “immature” was often mistaken for “malignant” or for a somatic-type malignancy.

Neuroectodermal components may resemble neuroblastoma, medulloepithelioma, peripheral neuroepithelioma, or ependymoblastoma sometimes with mixed differentiation and different immunophenotype. Most are cytokeratin positive [15] and variably stain with synaptophysin, S100 protein, GFAP, Hu, Nb 84, HBA.71, and SOX-2 (personal observation). PNETs occurring in metastatic sites are probably associated with worse prognosis (see below).

Nephroblastoma (Wilms tumor), like teratomas, are an uncommon finding in the testis (Fig. 1), while the occurrence in retroperitoneal teratoma [39] or in distant metastases is far more frequent [40]. A case has been reported arising inside an undescended testis [41]. The nephroblastoma is generally composed of mixture of tubules, blastema, and stromal elements (Fig. 2) and the immunohistochemical finding of a diffuse WT1 stain is sometimes absent. The myogenin and desmin expressions detected rhabdomyomatous differentiation inside the tumor: the skeletal muscle differentiation is apparently due to loss of function of WT1 gene [28].

Carcinomas are less often associated with GCTs of the testis, which is not really surprising, since the number of soft tissue components in teratoma usually exceeds that of the

Fig. 1 Nephroblastoma in teratoma of the testis: macroscopic features of huge enlargement of the right testis with a scrotal cutaneous fistula: at the gross inspection the testis showed a gr. 860 *gray–tan* partially cystic mass with necrosis and hemorragia; the largest diameter of the tumor was 8 cm

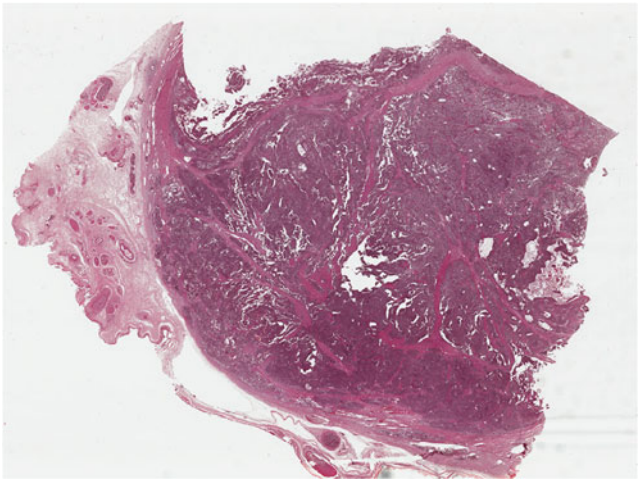

Fig. 2 Nephroblastoma in teratoma of the testis: microscopically, the nephroblastoma appearance of this tumor is easily detectable at low magnification and it is composed of mixtures of tubules, blastema and stromal elements (EE, 4×)

epithelial one. Adenocarcinomas, squamous carcinomas, and neuroendocrine carcinomas are the most frequently reported histological types [2, 3, 8, 9, 42]. These tumors stain for cytokeratins, EMA and sometimes CEA. Stains for PLAP, AFP, and HCG and OCT 3/4 are negative. Recently, a papillary renal cell-like carcinoma has been described in a retroperitoneal metastasis [43]. As in the kidney, the tumor cells positively stained with cytokeratin 7 and alpha-methyl acyl CoA racemase.

Organoid structures mimicking intestine or bronchus are commonly encountered in teratomas. As is the case for normal organs, neuroendocrine cells producing all kinds of hormones (gastrin, bombesin, somatostatin, etc.) are also scattered among the columnar epithelia [44, 45] in these organoid structures. Obviously, testicular carcinoids can arise from these cells and must be classified as MTSC. In case remnants of a germ cell tumor cannot be detected, carcinoids should be diagnosed as a distinct entity. Of the 80 well-documented cases of testicular carcinoid observed, 19 (24 %) were associated with teratoma [45]. They account for 0.2–1 % of all tumors of the testis in various statistics. Tumor cells are immunoreactive for the classical neuroendocrine markers (neuron-specific enolase, chromogranin A, synaptophysin) as well as for the specific peptide hormones produced by carcinoids (gastrin, serotonin, etc.). A small number of patients developed a typical "flash syndrome" [45].

Comparison of testicular and ovarian teratomas

Teratomas arise in the ovaries far more frequently than in the testis. Cystic teratomas account for 10–20 % of all ovarian neoplasms [46]. They are the most common ovarian germ cell tumor and also the most common ovarian neoplasm in patients younger than 20 years. They are bilateral in 8–14 % of cases. In its pure form, the cystic teratoma of the ovary is always benign, but in approximately 0.2–2 % of cases, it can undergo malignant transformation. That means this phenomenon occurs less often than in testicular teratomas. The female patients are mostly menopausal with a median age of 52.5 years (range, 29–77), thus are consistently older than diseased men. Since the single tissue components of ovarian and testicular teratomas differ slightly (Fig. 3) [47] the histology of the MTSC also differs. The dermoid cyst, extremely rare in the testis, is the most frequent ovarian teratoma. Consequently, the squamous carcinoma accounts for more than half of all somatic malignancies reported [48, 49]. Thyroid tissue is a frequent finding in benign teratoma of the ovaries but not existing in the testis, thus also thyroid cancer, generally called "struma maligna ovarii", has been described many times in the ovaries [50]. Carcinoid seems to be described as frequently as in the testis [51]. Extremely rare in the ovaries and never observed in the testis are one amelanotic malignant melanoma [52], a chordoma [53], and two glioblastomas [54].

Genetics and histogenesis

Chromosomal abnormalities typically associated with germ cell tumors, the isochromosome i(12p), were identified in the majority of the cases of TMSC [9] (Fig. 4). Such aberrations were described in the germ cell component as well in

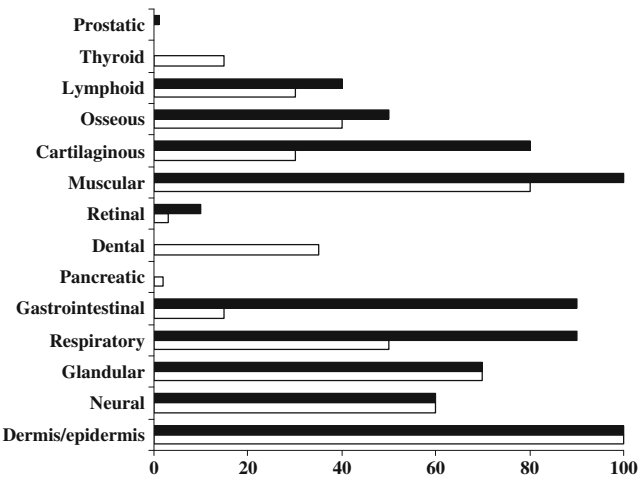

Fig. 3 Frequency of differentiated tissue in teratomas of the testis (*black bars*) and ovary (*white bars*). Respiratory, gastrointestinal, and soft tissue (muscular, osseous, cartilaginous) is more frequent in the testicular than in ovarian teratomas. Thyroid and pancreatic tissue, rather common in teratoma of the ovaries, is not encountered in testicular teratomas (modified after Damjanov [47])

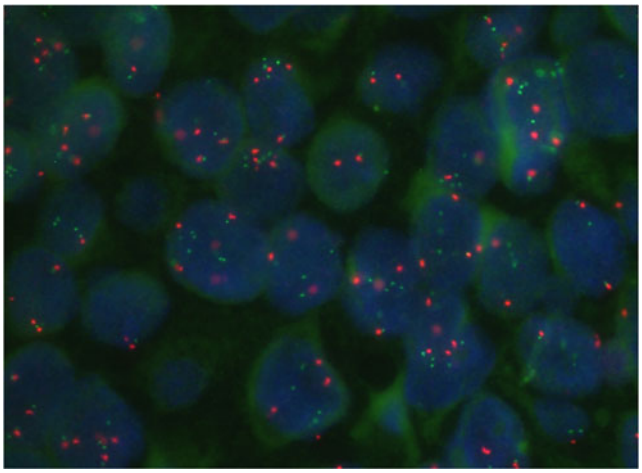

Fig. 4 Two-color FISH performed on teratoma with somatic malignant component occurring in a retroperitoneal lymph node. Overrepresentation of the peritelomeric region (12p13) of the short arm of chromosome 12 (*green*) relative to centromeric region of chromosome 12 (*red*)

the somatic malignancies [9]. Moreover, the typical aberration can also be found in the metastases of such tumors [55].

In a case of teratoma with angiosarcomatous component, the isochromosome 12p overrepresentations were consistently found in the primary germ cell tumor components, metastatic teratoma, and angiosarcoma. The results indicated a clonal origin of the tumors, which supports the conclusion that angiosarcoma, as well as the teratomas, arose from the testicular germ cell tumors sharing epithelioid features and a clonal origin with the other components of the germ cell tumor [42].

In some cases, additionally, chromosomal rearrangements or translocations characteristic of the somatic tumors in their conventional locations were detected [9]. Loss of heterozygosity was observed by Emerson et al. [28] at 11p13, the locus of WT1 inactivation in patients genetically predisposed to nephroblastoma, and may be an important genetic mechanism in nephroblastematous differentiation of GCTs. Loss of heterozygosity was found in four loci, and the same pattern of allelic loss was demonstrated at all four loci in all of the different components (nephroblastoma, mature and immature teratoma, and rhabdomyosarcoma) of the primary tumor and in the metastasis of teratomas, which strongly support the germ cell tumor origin of the nephroblastoma component.

What are actually the original mechanisms of the development of TMSC is still a matter of debate. Two possible explanations have been postulated by Ulbright et al. [3]: a partial differentiation of totipotential germ cells with concomitant malignant transformation or a new tumor arising from differentiated teratomatous elements [6, 8, 10, 29]. The atypical cells of the intratubular germ cell neoplasia (IGCN) cells seem to have a striking phenotypic similarity to embryonic stem cells [56]. Many cancers have been proposed as having originated from tissue-specific stem cells [so-called "cancer stem cells"]. Testicular IGCN may be a very good example of a cancer stem cell with exceptional features due to the retention of embryonic pluripotency. These cells possess a high resistance to exogenous and endogenous agents and are usually not targeted by cytotoxic chemotherapy [57].

Prognosis

Provided the malignant tumor is limited to the testis, the prognosis is not negatively affected [2, 9, 10]. In metastatic sites, the somatic type malignancies have a dismal prognosis if not completely resectable [9, 10, 58]. The presence of MSC in postchemotherapy retroperitoneal lymph node dissection specimens, reported by Little [6], showed a disease-specific survival of 68 % for various sarcomas at a mean follow-up of 2.5 years. Malagon et al. [7] reported only a 20 % survival at a mean of 1.5 years in either testicular TMSC or in their metastases. Comiter et al. [8] described a survival rate of 52 % with a median follow-up of 4 years for TMSC and a much poorer prognosis with a survival of 25 % after 3.5 years mean follow-up in patients showing rhabdomiosarcomatous tumor. Colecchia et al. [10] reported a stage-specific survival of 100 % for stage I, 87.5 % for stage II tumors, and 53 % for stage III patients and the overall survival after a long follow-up (mean 37 months) of 12 stage I patients compared to 28 stages II–III patients showed significant difference (p value<0.0139) [10] (Fig. 5).

GCT-oriented therapy combined with timely surgery seemed to be adequately effective both in first line (64 % of major responses in our series) and in salvage therapy [45]. Therapy designed for the specific type of somatic neoplasm may also be helpful [58].

The histological features of the somatic component do not have any impact on the prognosis. The occurrence of PNET in a stage I tumor seems not to be an unfavorable

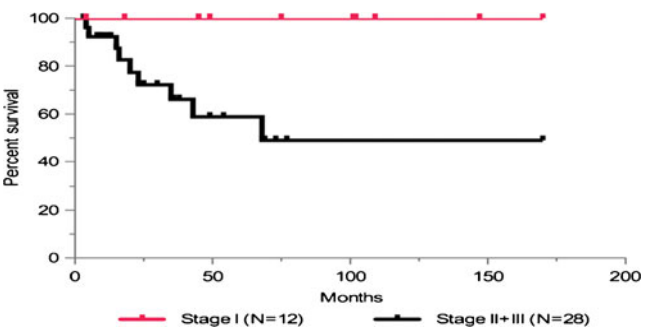

Fig. 5 Stage-specific survival in 40 TMSC followed at the Istituto Nazionale dei Tumori di Milano: the difference among 12 stage I and 28 stages II–III was statistically significant (p value 0.0139)

prognostic factor: these stage I tumors had similar long survival as tumors with other histologies [10], while PNETs occurring in metastatic sites are probably associated with a worse prognosis [34]. In a study from Indiana University, the authors claim that all patients with clinical stage I disease and primitive neuroectodermal tumor in the orchiectomy specimen should initially undergo retroperitoneal lymph node dissection. Of the patients who initially underwent a lymphadenectomy, 89 % had no evidence of disease, whereas the number of disease-free patients without surgery is significantly lower (50 %) [32].

In conclusion, patients who could undergo a radical excision of metastases had a better outcome compared with patients who did not receive a radical extirpation and the strongest prognosticator of a long survival remains tumor burden and the consequent feasibility to perform radical disease removal.

Conclusions and perspectives

Malignant transformation of germ cell tumors into somatic malignancy is uncommon [2, 3, 8, 15, 46]. To establish the therapy based on a wide surgical approach, the correct diagnosis is very important in primary testicular tumors as well as in the metastases. The incidence of intratesticular vs. metastatic occurrence differs in different series, with 43 % of adult cases identified within the primary tumors and the remaining ones at the time of relapse or in the metastasis [29]. The morphology of the teratoma (mature vs. immature teratomas) does not have any impact on the risk of TMSC development [59]. Conventional cytogenetics has been used to demonstrate germ cell origin of these somatic malignancies arising in germ cell tumors [60], but to clarify the biology of TMSC; further studies at molecular level are needed. In addition, new chemotherapies with integration of somatic malignancy tailored therapies and GCT-oriented regimens are necessary to provide a higher rate of cure.

Conflict of interest statement We declare that we have no conflict of interest.

Co-expression of VEGF and CA9 in ovarian high-grade serous carcinoma and relationship to survival

Abstract Poor prognosis in ovarian high-grade serous carcinoma (HGSC) is largely related to resistance to chemotherapy. Tumour hypoxia is known to be associated with chemotherapy resistance. Stabilisation of hypoxia-inducible factor-1α upregulates the expression of downstream genes such as carbonic anhydrase 9 (CA9) and vascular endothelial growth factor (VEGF). This study was undertaken to analyse the hypoxia profile as indicated by the co-expression of VEGF and CA9 and its correlation with survival. VEGF and CA9 expressions were examined in tissue microarray of 97 cases of ovarian high-grade serous carcinoma using immunohistochemistry. High expression of either VEGF or CA9, individually, was associated with decreased overall survival (p=0.006 and p=0.05 respectively). Combined high expression of both markers, to give a 'hypoxia profile', was associated with chemotherapy resistance (p=0.036) and showed worse overall survival with a significant p value (p=0.001). Using multivariate analysis, hypoxia profile was an independent prognostic factor for overall survival (p=0.028). The combined high expression CA9 and VEGF phenotype, described as high hypoxia profile group, was significantly associated with increased resistance to chemotherapy and poor overall survival. This group may benefit from combined targeted therapy for effective response in ovarian HGSC.

Introduction

Ovarian high-grade serous carcinomas (HGSC) are the most common type of ovarian epithelial carcinomas and have the worst prognosis [1]. The 5-year survival rate is only 30 %, mainly due to chemotherapy resistance [2]. Tumour cells that manage to survive within a cluster of over 1 mm^3 undergo a state of hypoxia that necessitates activation of alternative survival pathways. One of the significant alternative pathways is a bypass of the mitochondrial oxidative phosphorylation, using glycolysis instead. On the other hand, the growth of solid tumours depends, at least partly, on establishing new blood supply to facilitate oxygen delivery through the process of angiogenesis; the latter involving production of vascular endothelial growth factor (VEGF), a potent angiogenic factor [3]. However, angiogenesis results in the development of an irregular, chaotic and fragile vascular network leading to further tumour hypoxia and necrosis [4]. Genes that facilitate anaerobic metabolism of glucose and genes that regulate vascularity such as VEGF are described as hypoxia-inducible genes and are regulated by the hypoxia inducible factor-1-α (HIF-1α) [4, 5]. Hypoxia-induced transcription is mediated through promoters of VEGF and carbonic anhydrase 9 (CA9) and controlled by HIF-1 pathway [6].

This state of hypoxia creates an acidic tumour microenvironment which is mainly due to accumulations of lactic acid, a by-product of glycolysis. The reversible hydration of carbon dioxide to carbonic acid, catalysed by carbonic anhydrases [7, 8] contributes further to the acidity of the tumour microenvironment. Tumour cells that succeed in

establishing themselves in an acidic hypoxic environment tend to be aggressive and capable of metastasis. Moreover, tumour hypoxia has been linked with chemotherapy and radiotherapy resistance as well as metastasis and poor clinical outcome [9, 10]. Some chemotherapy agents, such as mitoxantrone, doxorubicin and daunorubicin are weak alkalis and as such are inhibited by the acidic tumour microenvironment. On the other hand, cyclophosphamide, 5-fluorouracil and chlorambucil are weak acids and therefore they are enhanced by the tumour acidity. Hence, tumour microenvironment acidity may act as a significant barrier to tumour response to chemotherapy. The interruption of the previously described pathway of oxygen homeostasis and the reversal of an acidotic microenvironment seems to be a promising therapeutic target to enhance the efficacy of existing chemotherapies [11].

CA9 is a stable transmembrane zinc metalloenzyme. Overexpression of CA9, as a potential marker of hypoxia, has been reported in solid tumours with significant association between high levels of CA9 and unfavourable clinical outcome of several epithelial cancers such as breast, cervical and non-small cell [12–14]. Recently, a significant correlation between high level of co-expression of VEGF and CA9 and poor prognosis was reported in nasopharyngeal carcinoma and upper gastrointestinal adenocarcinoma [15, 16]. A treatment approach that targets hypoxic cells may indeed be important. Data concerning hypoxia in ovarian cancer are limited and mainly performed on cell lines. Effect of hypoxia in ovarian cancer and specifically in high-grade serous carcinoma has not been studied in depth except for the occasional report [17]. The current study was undertaken with the aim to assess the co-expression of CA9 and VEGF and its correlation with clinicopathological variables and survival, in ovarian high-grade serous carcinoma. We hypothesise that the combined increased expression of VEGF and CA9 is significantly correlated with disease outcome.

Materials and methods

Patient cohort and clinicopathological variables

Archival paraffin-embedded tissue blocks from 97 patients (range 36–85, mean 62 years) and with HGSC diagnosed between January 1, 1991 and December 31, 2007, were used. HGSC was defined as ovarian serous carcinomas with high nuclear grade (grades 2 and 3) showing complex branching papillary pattern, highly pleomorphic nuclei and brisk mitotic activity. Only cases treated initially with surgery with available follow-up data were included in this study. Sixteen percent of patients presented with International Federation of Gynaecology and Obstetrics (FIGO) stage 1, 18 % stage 2, 57 % stage 3 and 9 % stage 4. All patients were treated with surgery in an attempt to achieve optimal debulking (where residual tumour was either absent or less than 2 cm) with or without chemotherapy. The reporting of this study adheres to the RECIST guidelines [18]. Information on disease FIGO stage and presence or absence of residual macroscopic disease after surgery, date of recurrence and tumour-related death was collected from records when available (Table 1). According to the Gynaecological Oncology Group criteria, data on response to chemotherapy were categorised as resistant if recurred within 6 months of starting treatment or otherwise classified as responsive to chemotherapy [19].

Overall survival and progression-free survival

Five-year overall survival (OS) and progression-free survival (PFS) were available for calculation. OS was calculated from the date of surgery to August 2009 when any remaining survivors were censored. OS data were available for 97 patients (mean 37 months) with 65 % died within 5 years of diagnosis. Post-operative deaths were excluded. PFS was defined from the date of commencing surgical treatment until the date when recurrence was confirmed clinically; 70 % of cases recurred within 5 years of starting treatment (mean 30 months)

Table 1 Patient and tumour characteristics

Age (n=97) mean (range, year)	62 (36–85)
FIGO stage (n=97)	
Stage 1	16 (16 %)
Stage 2	17 (18 %)
Stage 3	55 (57 %)
Stage 4	9 (9 %)
Residual disease (n=94)	
More than 2 cm	35 (37 %)
Less than 2 cm or none	59 (63 %)
Recurrence within 5 years (n=82), mean 30 months	
Recurrence within 5 years	57 (70 %)
No recurrence within 5 years	25 (30 %)
Overall survival within 5 years (n=97), mean 37 months	
Dead within 5 years	63 (65 %)
Alive after 5 years	33 (35 %)
Type of chemotherapy (n=96)	
Platinum based chemotherapy	88 %
Response to chemotherapy (n=84)*	
Resistant	15 (18 %)
Responsive	69 (82 %)

*As defined by the Gynaecological Oncology Group

All cases were subsequently reviewed by a specialist gynaecological pathologist (SD) to ensure accuracy of histologic type and grade. To build tissue microarray (TMA) blocks, for each of the 97 patients, one 0.6 mm core was used. The validity of this technique has been repeatedly enforced by publications, especially in ovarian tumours where analysis of immunohistochemical markers in one core matched the staining pattern of a whole section in more than 90 % of the time [20, 21]. TMAs were constructed first as outlined by Kononen et al. [22] using Beecher Instruments' microarrayer.

Immunohistochemisty

A prediluted rabbit anti-human VEGF antibody was used (SP28, Abcam, Cambridge, UK) and A rabbit polyclonal antibody to CA9 (Abcam 15086, Cambridge, UK). Renal tissue was used as positive control as recommended by the manufacturer. Fresh 4-μm sections were prepared from each TMA block and placed on poly-L-lysine-coated glass slides for VEGF and CA9 immunohistochemistry to be performed, bearing in mind that it has been demonstrated that many proteins retain their antigenicity for more than 60 years [23]. Optimization of the staining was done on ovarian cancer spare using a range of dilutions and incubation times. For each of the antibodies, the dilution and incubation time that produced the best results with minimal background staining were chosen. Briefly, slides were dewaxed in xylene (2× 10 min) and rehydrated in three grades of ethanol (99, 90 and then 70 %) for 1 min each. Endogenous peroxidase activity was blocked by immersing the slides in a 0.03 % solution of H_2O_2 in methanol for 25 min. Heat-induced epitope retrieval was done using an 800-W rotary microwave oven. Slides were cooled and rinsed with Tris-buffered saline (TBS; Dako, Ely, Cambridgeshire, UK) for10 min. To reduce nonspecific adsorption of antibodies to tissue, the slides were incubated with normal swine serum (Dako) diluted 1:20 in TBS for 10 min. The test sections were then left to incubate with the prediluted rabbit anti-VEGF antibody (SP28, Abcam) and CA9 (1:1,000 dilution) accordingly for 1 h at room temperature. Negative control slides in which the primary antibody was omitted were included in all the assays.

Evaluation of the staining

High-resolution digital images at ×20 magnification of the immunohistochemically stained TMA were obtained (Nanozoomer, Hamamatsu Photonics) and assessed. Only tumour cells in individual cores were assessed using *H* scoring [24]. The *H* score value, for each marker, ranged from 0–300, calculated as the sum of the products of percentage of positive cells multiplied by staining intensity graded from 1+ to 3+. All cores were assessed by two of the authors (EW, SD) independently, both of whom were blind to the clinical and pathologic variables of the case. When there was non-concordance in assessment, cases were discussed using a double-headed microscope and a consensus was reached. Determination of the optimal cut-off points for the markers, based on OS, was assessed using X-tile Bioinformatics Software, version 3.6.1, 2003–2005 (Yale University, USA) [25]. X-tile is a bioinformatics tool that allows users to find out population cut-off points based on marker expression. The *H* score cut-off points between high and low expression groups were 100 and 80 for VEGF and CA9, respectively.

Statistical analysis

The statistical software package SPSS Version 16, (SPSS Inc., Chicago, IL, USA) was used to analyse for correlations between CA9 and VEGF expression and clinicopathological parameters, using Pearson's χ^2 test. Survival analysis, comparing protein expression and OS, was calculated using the Kaplan–Meier method and the statistical significance of the difference between the survival curves of evaluated groups was assessed using the log rank test. Multivariate analysis was performed using Cox regression. In all cases, a p value of <0.05 was taken as indicator of statistical significance.

Results

A significant association between the expression of each of the studied markers (VEGF and CA9) and survival was identified in isolation and when combined together as hypoxia profile which correlated significantly with response to chemotherapy. Moreover, the combined high expressions of high CA9 and VEGF were significantly associated with OS and this remained significant in multivariate analysis.

Marker expression

Granular cytoplasmic staining for VEGF and CA9 (Fig. 1a, b, c and d) was seen in tumour cells. Both markers showed weak occasional staining of the inflammatory cells. Unlike CA9, VEGF also stained endothelial cells; 94 and 86 cases were available for VEGF and CA9 assessment respectively. A total of 39 cases (41 %) and 55 cases (59 %) showed low expression (≤100) and high expression (>100) of VEGF expression, respectively. Nineteen cases (22 %) and 67 cases (78 %) showed low expression (≤80) and high expression (>80) of CA9 expression, respectively. Using Spearman's rank correlation coefficient, there was a significant correlation between CA9 and VEGF ($p=0.007$), albeit with a weak positive correlation coefficient of 0.287.

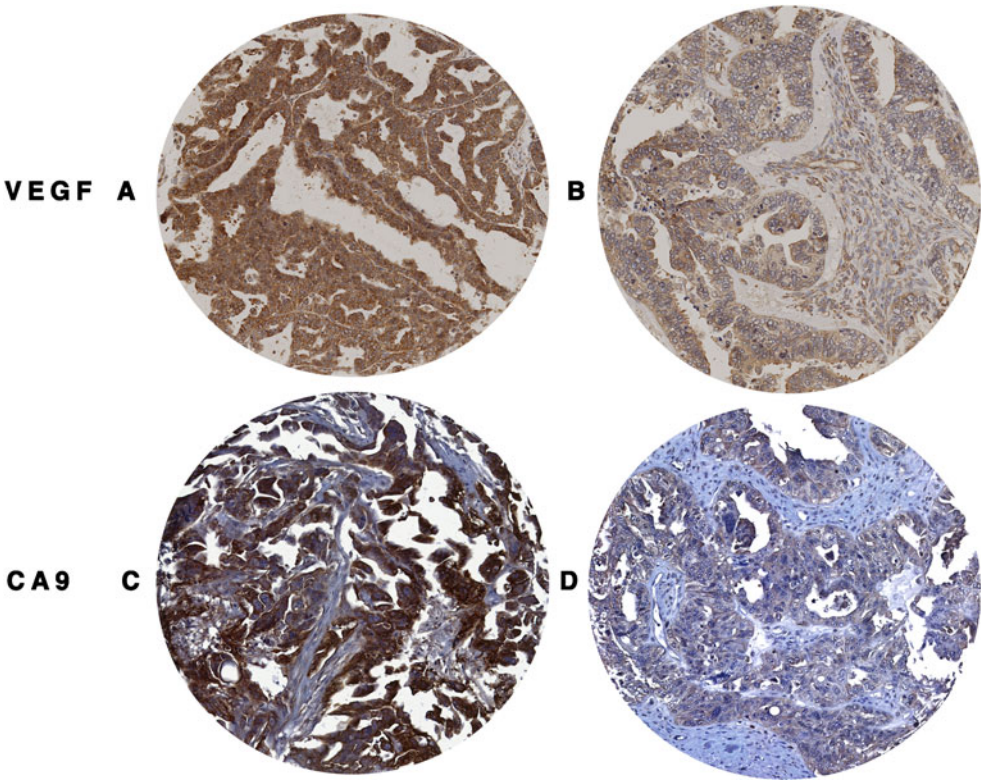

Fig. 1 Photomicrograph showing cytoplasmic staining with high (**a**) and low (**b**) expression of VEGF and high (**c**) and low (**d**) expression of CA9 (×20)

Correlation with clinicopathological variables

All tumours were of the same morphological type of HGSC and by definition they were all of high grade. The correlation between the expression of each marker, VEGF and CA9, with tumour FIGO stage and response to chemotherapy was analysed using Pearson χ^2 statistical test.

High expression of VEGF and tumour FIGO stage (p=0.05) was associated with advanced stage. An average of 66 % of cases in FIGO stages 3 and 4 disease and 45 % cases in FIGO stages 1 and 2 disease showed high expression of VEGF. On the other hand, there was no significant correlation between CA9 and tumour FIGO stage.

VEGF expression was inversely correlated with response to chemotherapy (p=0.039) with 27 % and 6 % of cases in the high and low VEGF expression groups, respectively, being resistant to chemotherapy. On the other hand, there was no significant correlation between CA9 and response to chemotherapy.

Correlation overall survival and progression-free survival

Ninety-four cases stained for VEGF and 86 cases stained for CA9 had follow-up data for survival and were available for assessment. High expressions of VEGF and CA9 were significantly associated with poor OS. In contrast, there was no significant correlation between any of the markers and PFS. Patients with a high VEGF expression had a mean OS of 34 months, in contrast to 46 months for those with a low expression (log rank 7.5, p=0.006, 95 %CI 31.7=54.3; Fig. 2a).

CA9 expression was also significantly associated with OS (Log Rank test 3.8, p=0.051, 95 %CI 29-60.9) with a mean survival of 37 months in the high expression group and 47 months in the low expression group (Fig. 2b).

Combined expressions of VEGF and CA9

The co-expression of VEGF and CA9 was incorporated into a single prognostic marker (hypoxia profile). A total of 86 cases with OS data and available expressions of both VEGF and CA9 were available for assessment and were categorised into 4 possible combinations; low VEGF, low CA9 (LL; n=14, 16 %), low VEGF, high CA9 (LH; n=23, 27 %), high VEGF, low CA9 (HL; n=5, 6 %) and high VEGF, high CA9 (HH; n=44, 51 %). When all four combination groups were analysed, there was a significant correlation with OS (logrank 10.02, p=0.018, 95 %CI 29–60.9), but not with PFS (Table 2, Fig. 2c).

In order to further interrogate the effect of co-expression of high VEGF and high CA9, the cases were re-categorised as high hypoxia profile group (HH group) and low hypoxia profile group showing other combination of co-expression of VEGF and CA9 (LH, HL and LL). The correlations of both groups with OS and PFS were analysed. The analysis demonstrated that the high hypoxia profile group had

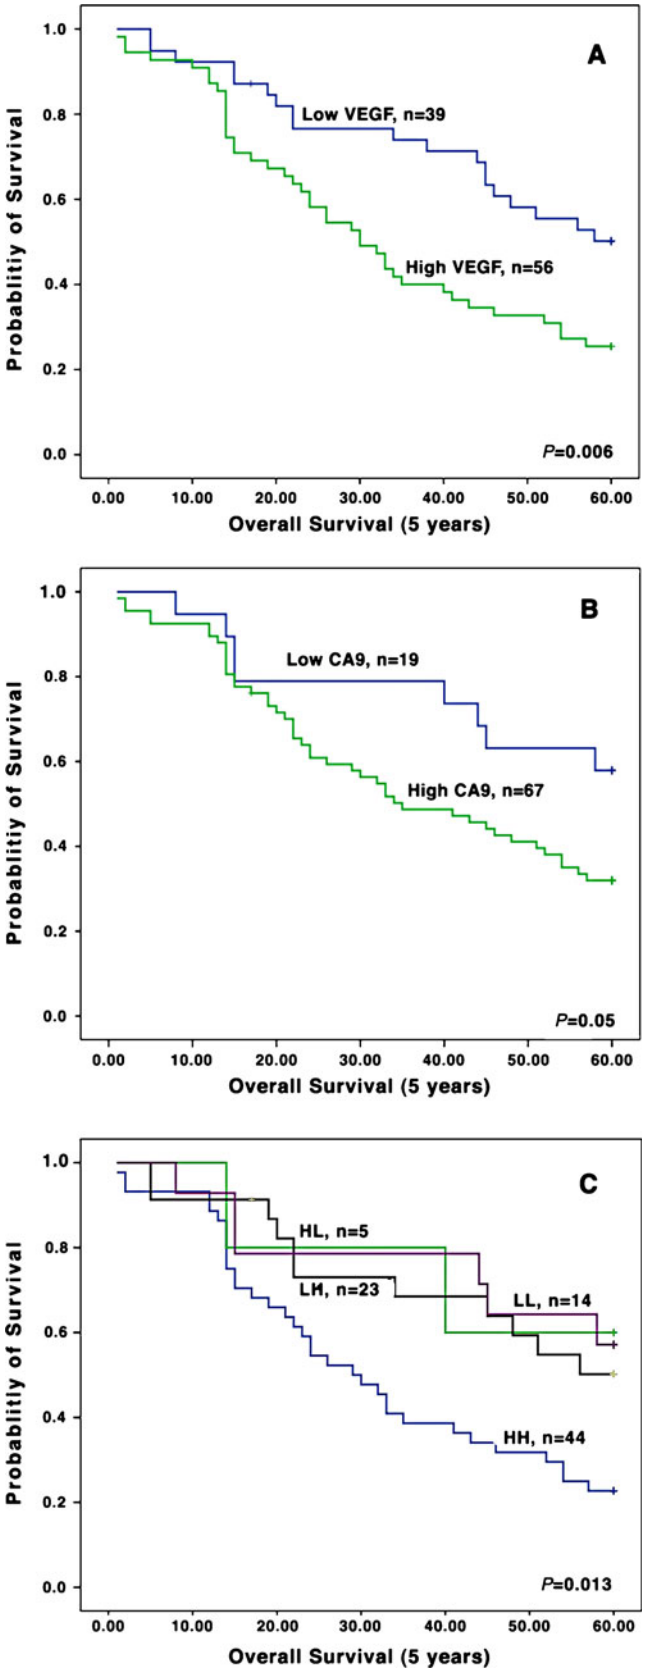

Fig. 2 Kaplan–Meier survival stratified for VEGF (**a**), CA9 (**b**) and co-expression of VEGF and CA9 (**c**) (*blue line* HH, *black line* LH, *green line* HL and *purple line* LL) in cases of ovarian HGSC

Table 2 Univariate analysis of various combinations of CA9 and VEGF expressions in association with OS and PFS

	LL (n=14)	LH (n=23)	HL (n=5)	HH (n=44)	Logrank	p value
OS	48	45	47	33	10.02	0.018
PFS	43	36	37	24	6.6	0.085

LL low VEGF/low CA9); *LH* low VEGF/high CA9; *HL* high VEGF/low CA9; *HH* high VEGF/high CA9

significantly shorter period of OS (logrank 11.2; p=0.001, 95 %CI 29–60.9) when compared with the low hypoxia profile group, with mean survival of 33 and 47, respectively. There was no significant correlation between the two groups and PFS.

When the analysis of each marker, individually, was extended to include tumour FIGO stage and residual disease, the two most important independent prognostic markers in ovarian cancer, using Cox regression multivariate analysis, VEGF, but not CA9, appeared to be an independent prognostic factor (p=0.05, 95 % CI 1.01–3.08). Interestingly, using multivariate analysis revealed that categorising tumours as high and low hypoxia profile groups is an independent prognostic factor with a high significant correlation with survival (p=0.028, 95 % 0.28–0.93; Table 3). Moreover, using Pearson χ^2, the hypoxia profile was significantly correlated with response to chemotherapy (p=0.036) with 28 % and 9 % of the high and low hypoxia profile groups respectively, being resistant to chemotherapy.

Discussion

Cancer growth, spread and chemotherapy resistance are promoted by hypoxic microenvironment which affects several genes through stabilisation of HIF-1α. The latter triggers the promoters of CA9 and VEGF, contributing to the extracellular acidity and neovascular formation [4, 5]. A small number of reports have examined the combined

Table 3 Cox Regression Multivariate model for tumour FIGO stage, residual disease and the co-expression of VEGF and CA9 into high risk and low risk groups

	p value	Exp(B)	95 % CI EXP(B)	
			Lower	Upper
FIGO stage	0.000	2.4	1.5	3.8
Residual disease	0.332	0.833	0.6	1.2
High vs low hypoxia profile groups of VEGF and CA9 co-expression	0.028	0.513	0.3	0.9

expression of CA9 and VEGF in various tumours [15, 16, 26], but this has not, to our knowledge, been conducted in ovarian cancer. In the current study, the combined high expression CA9 and VEGF phenotype, described as high hypoxia profile group, showed significant positive correlation with resistance to chemotherapy and poor OS using multivariate analysis, suggesting that this phenotype may have a useful role in stratifying ovarian cancer for prognostic and therapeutic purposes.

High expression of VEGF is associated with poor disease outcome in various tumours such as breast and ovarian epithelial cancer [27, 28]. In the present study, and consistent with our previous work [20], VEGF expression inversely correlated with OS of ovarian HGSC and that VEGF is an independent prognostic factor for overall survival. However, there was no significant correlation between VEGF expression and PFS.

Hypoxia may lead to enhanced tumour progression potential and resistance to chemotherapy [6]. However, ovarian tumours may reach a significantly large size with expected hypoxic environment albeit the tumour is still confined to the ovary as FIGO stage 1. Therefore, it would be naive to assume that hypoxia is directly correlated with mere tumour growth and spread. This may explain the lack of significant correlation between the expression of CA9 and tumour FIGO stage in the current study. There are no published reports on the correlation between CA9 and ovarian HGSC for comparison; whereas, in agreement with other publications [27], VEGF showed a significant correlation with FIGO stage.

To date, the reports on the correlation between the expression of CA9 and survival in cancer are controversial. Studies on cervical, endometrial and nasopharyngeal carcinomas showed that increased CA9 expression correlated with poor outcome [16, 29]. Conversely, studies on renal clear cell carcinoma [26] and colorectal cancer [30] have suggested that low expression of CA9 was associated with poor prognosis. Few studies on the role of hypoxia in ovarian cancer have been published. In a study by Birner et al. of 102 ovarian cancers, 50 borderline ovarian tumours and 20 benign ovarian tumours with follow-up period ranging between 1 and 130 months showed no correlation between the expression of HIF-1 and overall survival [31]. In the current study, high expression of CA9 was associated with poor overall survival. The main differences between the Birner et al. study and the current one is that they used HIF-1 rather than CA9 and also had a different study design to the current work, where the authors used a variety of ovarian tumour types of variable cell of origin and prognosis.

Under hypoxic conditions, upregulation of HIF-1α results in increased expression of VEGF and CA9, leading to increased angiogenesis and enhanced survival of tumour cells facilitated by a switch to anaerobic metabolism [32]. Few studies have examined the combined effect of CA9 and VEGF. The co-expression of these two markers as being more accurate in predicting prognosis than each marker individually has been reported in nasopharyngeal carcinoma [15] but in intestinal-type adenocarcinoma of upper gastrointestinal tract, only CA9 was an independent prognostic factor for survival [16]. In contrast, Phuoc et al. reported inverse correlation between CA9 and VEGF in clear cell renal cell carcinoma [26]. Moreover, Jubb et al. reported on a diverse cohort of human tumours exhibited VEGF expression in the absence of markers of hypoxia such as CA9 except in renal tumours where correlation between the expressions of both markers was demonstrated [33]. To our knowledge, the combined effect of CA9 and VEGF has not been studied in ovarian HGSC tissue samples. Our results showed significant correlation between the co-expression of VEGF and CA9 and survival in other tumours. To study the combined expression of VEGF and CA9, initially we classified cases into four possible combinations of high and low expression of both markers. These categories are significantly associated with OS and the correlation remained significant when the assessment extended to multivariate analysis. This finding was confirmed with significant results when cases re-classified into two groups of high hypoxia profile (showing high expression of VEGF and CA9) and low hypoxia profile showing other variable combination of both markers' expression. In this study, we propose to define a model of combined expression of VEGF and CA9 to stratify disease outcome as high and low hypoxia profile groups. The high hypoxia profile group showed a positive correlation with chemotherapy resistance and inverse correlation with disease outcome. Whilst the literature varies in the published data on the combined effect of VEGF and CA9, it seems that there is an agreement that studying both makers together is more meaningful than each marker separately. Our study has several limitations. First, whilst we tested 97 cases, this is still considered as a limited sample size and some of the associations were marginally significant. Validation of the results on a larger series would be favourable. Second, it would be beneficial to include other markers of hypoxia. Further, in vitro analysis and tissue molecular testing would be more informative to explain the role VEGF and CA9.

The data presented here indicate that CA9 and VEGF are expressed in epithelial ovarian cancer and the combined effect of the two markers should be evaluated as potential clinically useful markers and target molecules. Targeting both CA9 and VEGF may be more effective than inhibiting either of these proteins in isolation. It may be used in combination with chemotherapy or as a maintenance therapy.

In conclusion, HGSC has a poor prognosis, in part due to limited treatment options. In this study, we analysed the co-expression of VEGF and CA9 in HGSC and demonstrated that cases showing a high expression of VEGF combined with a high expression of CA9 had poor overall survival and were resistant to chemotherapy. This finding stayed significant with multivariate analysis and showed that combined high expression of VEGF and CA9 is an independent prognostic factor of overall survival. Although requiring validation, the findings of this study open the field for further development of targeted therapy in the form of a combined anti-CA9 and anti-VEGF approach that may improve survival of patients with this disease.

Conflict of interest The authors declare they have no conflict of interest.

Abstract Ischemic-type biliary lesions (ITBL) belong to a group of biliary disorders that are regarded as the major complication in patients with orthotopic liver transplantation (OLT). We performed histological evaluation of donor common bile ducts received during OLT to find morphological clues to the pathomechanisms of ITBL. We investigated 93 grafts of 92 patients (recipients: mean age, 56.5 years; underlying disease: hepatocellular carcinoma (n=45), alcoholic cirrhosis (n=16), viral hepatitis with cirrhosis (n=9), retransplantations (n=9), others (n=14); donors: mean age, 53.2 years). Donor common bile ducts were received after recirculation of the hepatic artery prior to biliary end-to-end anastomosis and routinely processed. Statistical evaluation was performed by chi-square analysis and multivariate analysis using a logistic regression model. With regard to ITBL (observed in 19.4 %), the following phenomena were found to be statistically relevant: necrosis of the bile duct wall, arteriolonecrosis, vascular lesions (such as subintimal edema), and intramural bleeding (P<0.001, P<0.001, P=0.029, and P=0.031, respectively). In logistic regression analysis, arteriolonecrosis was the only parameter with significance (P=0.001). Based on these results on the morphology of the donor common bile duct, we conclude that these phenomena of vascular damage, reflecting microangiopathy, play a major role in the pathogenesis of ITBL.

Introduction

Ischemic-type biliary lesions (ITBL) belong to a large group of different biliary disorders that generally are regarded to be the major complication in patients with orthotopic liver transplantation (OLT). Of all liver transplant recipients, 10 to 40 % develop biliary complications which are associated with mortality rates of up to 15 %. There is a variety of disorders that can occur after OLT, the most common being bile leakage and bile duct strictures. Bile duct strictures are grouped into anastomotic biliary stricture and non-anastomotic biliary strictures. Anastomotic biliary strictures are isolated strictures at the site of the bile duct anastomosis. They result mainly from surgical technique and local ischemia, leading to fibrotic scarring of the anastomosis [1, 2]. Non-anastomotic biliary strictures are heterogeneous in origin. They were first described in OLT associated with hepatic artery thrombosis (HAT) causing ischemia. As a result, typical cholangiographic features such as biliary strictures, dilations, and intraductal cast formations could be observed. Therefore, this complication has been

designated as ischemic cholangitis or ischemic biliary lesion (IBL) [3, 4]. About 20 years ago, several authors described non-anastomotic biliary strictures in patients not fulfilling all the aforementioned criteria [5–7]. They suggested this complication to be related to preservation injury and to occur due to ischemia. Thus, the term ischemic-type biliary complication and later "ITBL" was established [1, 5, 8]. The reported incidence of ITBL differs greatly between respective series, ranging up to 26 %. Mortality rates also differ markedly between studies. In many cases, sequelae (cholestasis and cholangitis) require repeated interventional (that is endoscopic or surgical) treatment. It is generally estimated that up to 50 % of patients either die or need retransplantation (re-LTX) [1, 9, 10]. This underlines the need for comprising knowledge on causes and mechanisms of the disease.

The exact pathogenesis of ITBL is not known. It has been shown by various authors that ischemic injury as well as damage of the peribiliary vascular plexus could play a major role [1, 3, 4, 11]. Besides, several immunological factors such as chemokine motif C-C receptors are suggested to be relevant parameters [1, 2, 12]. Finally, bile salt toxicity has been considered to be a potential factor in the pathogenesis of bile duct injury [2, 13]. Based on the idea that morphological evaluation of the bile ducts might contribute to insight into the pathomechanisms of ITBL, we systematically investigated the donor bile ducts of patients with OLT. Histological changes were studied and evaluated by applying several scores. Statistical analysis was subsequently performed with regard to features associated with ITBL.

Table 1 Summary of patient data

Characteristics	Number
Grafts	93
Total number of patients	92
Mean recipient age (range, years)	56.5 (25–73)
Recipient male/female ratio	75:18 (~4:1)
Indication, *n* (%)	
HCC, total number	45 (48.4 %)
HCC combined with viral hepatitis	25 (26.9 %)
HCC combined with C2 toxic cirrhosis	13 (14 %)
Alcoholic cirrhosis without HCC	16 (17.2 %)
Viral-induced cirrhosis	9 (9.7 %)
PSC	4 (4.3 %)
PBC	3 (3.2 %)
Others	7 (7.5 %)
Re-LTX, total number	9 (9.7 %)
PNF	5 (5.4 %)
ITBL	3 (3.2 %)
HAT	1 (1.1 %)
Mean donor age (range, years)	53.2 (18–87)
Donor male/female ratio	45:47 (~1:1)
Cause of brain death, *n* (%)	
Intracerebral bleeding	25 (26.9 %)
Subarachnoid bleeding	22 (23.7 %)
Trauma	16 (17.2 %)
Hypoxia	10 (10.7 %)
Infarction	7 (7.5 %)
Others	13 (14 %)

Materials and methods

Patient data

We included 93 grafts of 92 patients who underwent OLT between November 2006 and September 2011 at our center. Patient characteristics are summarized in Table 1. Inclusion criteria for evaluation were (a) recipients ABO-compatible according to the donor; (b) survival of the recipients for more than 3 months; (c) graft survival for more than 3 months, except occurrence of ITBL in the first 3 months; and (d) tissue specimens of the donor bile ducts for histological evaluation available. Re-LTX was not a criterion of exclusion. Thus, we have included nine grafts of eight patients with re-LTX. In this cohort, four re-LTXs were performed due to primary nonfunction (PNF) of the graft; furthermore, there were three patients who underwent re-LTX because of ITBL in the first graft.

Cold ischemia time was 639±152 min. The tissue specimens were taken during the transplantation. Organ retrieval was performed according to the protocol of the Deutsche Stiftung für Organtransplantation. The liver was generally removed without dissecting the supplying vessels. Aortic flush perfusion was performed used histidine–tryptophan–ketoglutarate (HTK) solution. After retrieval, the cystic duct was ligated and the bile ducts were rinsed with HTK solution. Then, the dissected graft was shipped and prepared for transplantation in ice water. Transplantation was performed using the piggyback technique. Following caval anastomosis, blood supply to the graft was reestablished by the portal vein first in 79 cases and by synchronous—arterial and portal—recirculation in 14 cases. After portal and arterial recirculation of the graft, the biliary anastomosis was performed. Abundant donor bile duct was dissected in order to avoid kinking and submitted for routine assessment (see below). The length of the duct being excised ranged between 2 and 58 mm (median value, 12.8±3.9 mm).

In order to avoid additional surgical injuries and ischemia after recirculation, clamping of the bile duct was omitted at all times. Biliary end-to-end anastomosis was performed in all instances using 6×0 resorbable monofile running suture. A drain (diameter, 1.5 mm) was placed through the cystic

duct of the recipient into the duct and guided cephalad over the anastomosis in order to visualize the biliary system routinely after 3 weeks and in case of complications. The drain was removed after the third week following transplantation. Before the removal of the drain, the biliary tree was visualized by a contrast X-ray.

Histological evaluation

The tissue specimens were paraffin-embedded and further processed for routine diagnosis. For morphological analysis, the bile duct segments were cut in sections which measured between 2 and 4 mm; furthermore, the sections were completely embedded and prepared for histology. The 4-μm sectioned slides were routinely stained by hematoxylin and eosin and by Elastica–van Gieson reaction and Goldner's trichrome staining as special stains. All slides were evaluated by an Olympus microscope [type CX21, Olympus, Hamburg, Germany] by one investigator (TH) who was blinded to the clinical data with special regard to ITBL. Photographs were taken by a Zeiss microscope [type Axiophot, Zeiss, Jena, Germany; Olympus digital camera].

Analysis of the histomorphology of the bile ducts revealed several typical features. For the evaluation of the ducts, we then determined the details of the respective features as follows:

1. Mucosal loss, which was defined by the absence of the epithelial lining, leading to denuded subepithelial stroma (Fig. 1). This feature was subdivided into three categories depending on the severity of the lesion (0, no epithelial loss; 1, ≤50 % of the bile duct with absent epithelial lining; 2, epithelial loss in >50 % of the bile duct).
2. Bleeding: Mural bleeding was characterized by erythrocyte extravasation into the bile duct wall (Fig. 2). Three categories were determined for evaluation (0, no bleeding; 1, ≤50 % of the bile duct wall with bleeding; 2, hemorrhage in >50 % of the bile duct).
3. Thrombi: In several cases, we found hyaline thrombi in small intramural vessels (Fig. 3). This feature was scored in two categories (0, no thrombi; 1, occurrence of thrombi).
4. Vascular lesions: In this heterogeneous group, we summarized all pathological alterations of the small arteries and arterioles of the bile duct wall except necrosis. The most common finding was subendothelial edema (Fig. 4); in addition, loss of endothelial cells occurred as well. Moreover, initial necrotic change of the vessels was subsumed under this feature (e.g., loss of some vital cells either in the intima). The scoring was performed

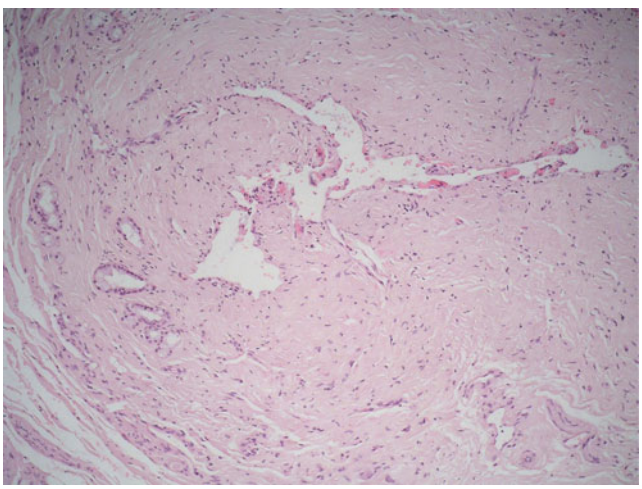

Fig. 1 Bile duct demonstrating mucosal loss >50 %; there is no necrosis and only mild inflammation (HE, original magnification × 100)

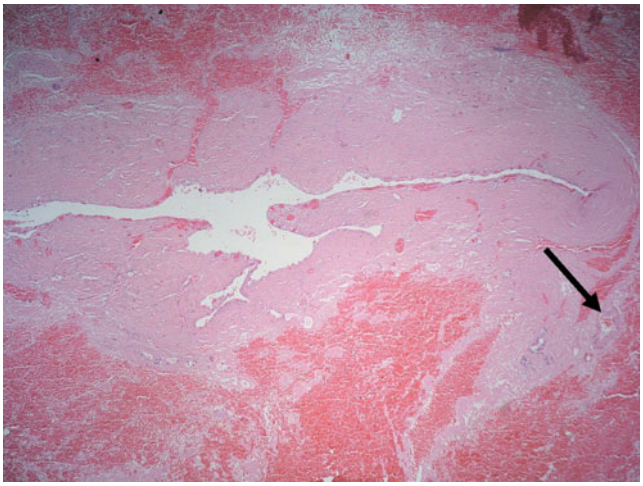

Fig. 2 Overview of a bile duct with massive intramural bleeding (score 2); furthermore, there is complete mucosal loss and necrosis of the bile duct wall, but no significant inflammation; *arrow* shows a necrotic arteriole (HE, magnification × 50)

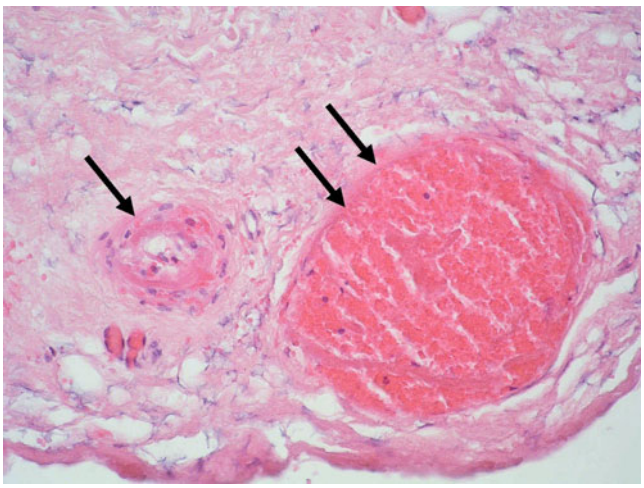

Fig. 3 Detailed view shows two vessels with hyaline thrombi (*two arrows*), on the left side (*one arrow*) also revealing vessel damage (HE, magnification × 250)

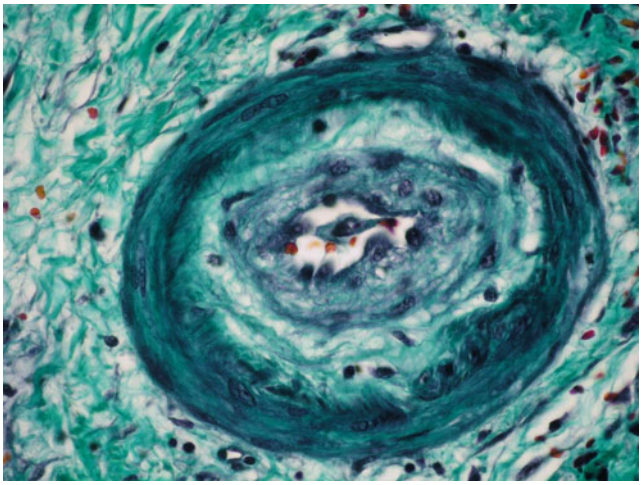

Fig. 4 Detailed view of an arteriole reveals prominent subintimal edema (Goldner reaction, magnification × 800)

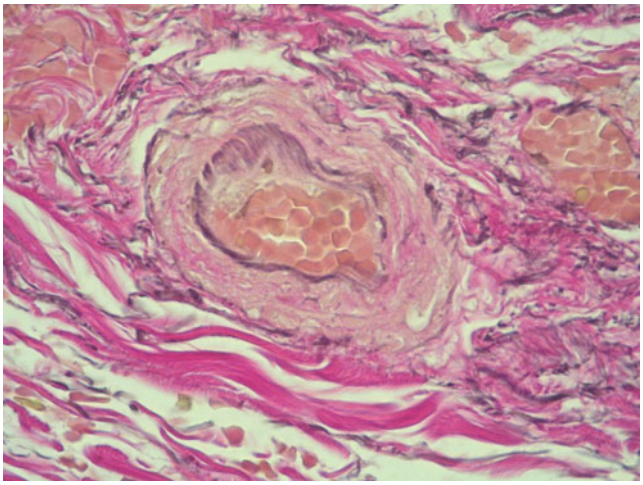

Fig. 6 Detailed view from the same patient as in Fig. 5 demonstrating an arteriole without viable cells. This patient developed ITBL (EVG reaction, magnification × 800)

according to the number of damaged vessels (0, no vascular lesion; 1, ≤50 % of vessels changed; 2, >50 % of vessels damaged).

5. Arteriolonecrosis was defined by complete loss of vital cells in the wall of arterioles and small arteries which commonly were arranged around the bile duct wall (Figs. 5, 6, and 7). One characteristic finding was degeneration of the collagen in the vessels leading to fibrinoid necrosis (Fig. 7). Arteriolonecrosis was scored in the same way as described under no. 4.
6. Duct necrosis: Bile duct necrosis exhibited loss of vital cells in the mural stroma. Although it was commonly accompanied by mucosal loss, the loss of epithelial lining alone was not interpreted as bile duct necrosis. Typically, bile duct necrosis was more pronounced at the inner mural layer and the avital areas showed scattered cells with karyolysis or no cellular remnant at all (Fig. 8). Bile duct necrosis was evaluated with respect to the damaged circumference of the duct as follows: 0, no necrosis; 1, ≤25 % of the bile duct wall necrotic; 2, >25 and ≤50 % of the bile duct wall necrotic; 3, >50 and ≤75 % of the bile duct wall necrotic; 4, >75 % of the bile duct wall necrotic).
7. Inflammation: Occurrence of leukocytes in the bile duct wall was evaluated as inflammation independent of the predominant cell type (lymphocytes or granulocytes; Fig. 9). Inflammation was scored according to the number of leukocytes in high-power field (HPF; 0.159 mm^2): 0, no inflammation; 1, at least one HPF with more than 10 leukocytes; 2, at least one HPF with more than 50 leukocytes.

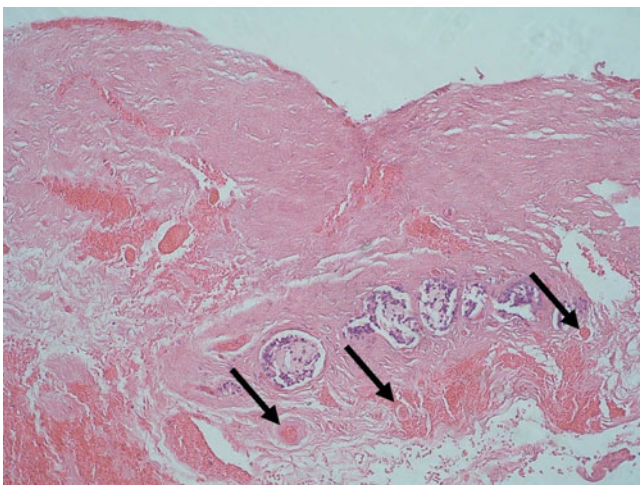

Fig. 5 Bile duct with mural necrosis and small necrotic arterioles (*arrows*, magnification × 100)

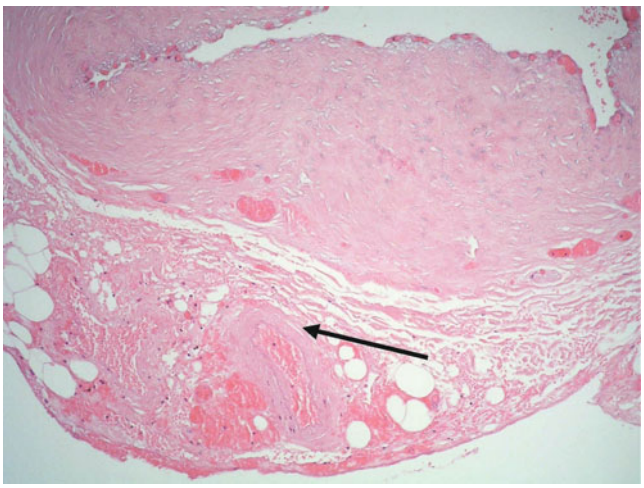

Fig. 7 Bile duct with mural necrosis and an arteriole showing necrosis (*arrow*). In this patient, ITBL was observed as well (HE, magnification × 100)

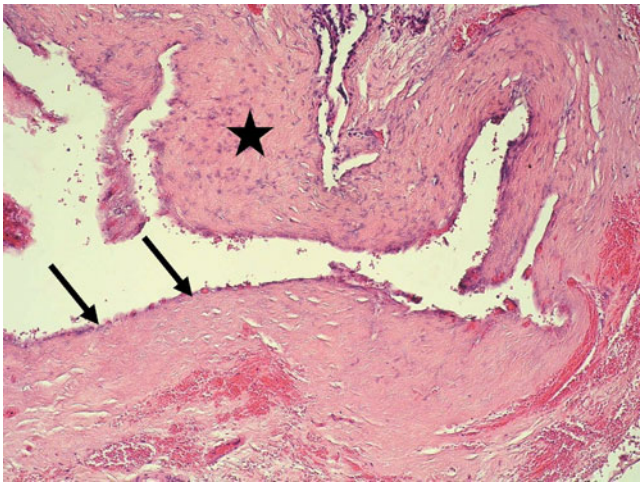

Fig. 8 View of a necrotic bile duct (ITBL patient): *arrows* show complete loss of viable stromal cells, while in the neighbourhood (*asterisk*) some intact tissue is visible (HE, magnification × 100)

Diagnosis of ITBL

Clinical symptoms of biliary obstruction including increased levels of bilirubin, alkaline phosphatase, and γ-glutamyl transferase led to the diagnostic procedure. Diagnosis of ITBL was confirmed by either endoscopic retrograde cholangiography or percutaneous transhepatic cholangiography showing typical signs of segmental or diffuse intrahepatic or extrahepatic strictures or destructive lesions of the biliary tree. HAT, ABO incompatibility, biliary anastomotic stricture, and/or chronic ductopenic rejection were always excluded prior to establishing the diagnosis of ITBL.

Statistical analysis

Chi-square analysis was performed to compare the association between the above-mentioned morphological features and the occurrence of ITBL. All statistical calculations were performed in IBM SPSS Statistics 19 [SPSS Inc., Chicago, IL, USA]. Multivariate analysis was carried out using a logistic regression model. *P* values of <0.05 were considered to be statistically significant.

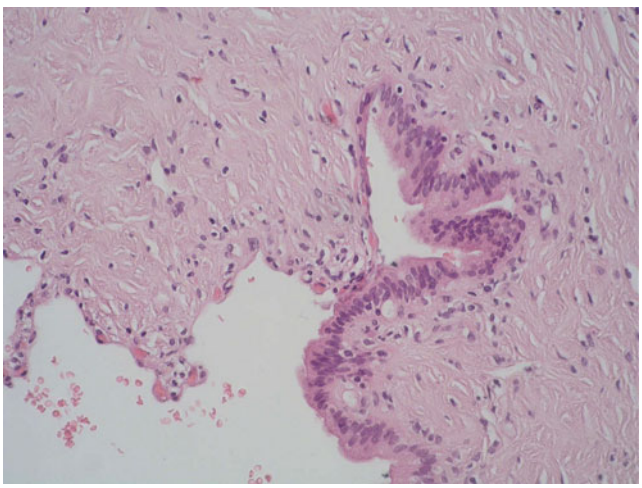

Fig. 9 Typical mild inflammation of a bile duct is presented, most of the cells comprising lymphocytes (HE, magnification × 250)

Results

In the present cohort, 18 patients (19.4 % of all cases examined) developed ITBL (mean age, 55.3 years; 15 male patients, 3 female patients). Underlying diseases were as follows: HCC combined with viral hepatitis (n=5), HCC combined with alcoholic cirrhosis (n=3), cryptogenic cirrhosis (n=3), one of them combined with HCC, combined HBV/HDV hepatitis with cirrhosis (n=2), C2 toxic cirrhosis (n=2), and others (n=3). It needs to be stressed that patients with re-LTX were not demonstrable in this specific group. In particular, none of the three patients who were retransplanted due to ITBL could be found in this cohort (i.e., they did not develop ITBL for a second time). The length of the bile duct segments was not significantly different between ITBL and non-ITBL patients (*P* value=0.202, respectively).

The results of the histological evaluation are summarized in Table 2. Mucosal loss was found in the vast majority of the tissue specimens investigated; only one case revealed a complete epithelial lining. Interestingly, only a very few cases showed bile extravasation into the mural stroma. Bile incrustations were not found. In 16.1 %, we found mucosal loss <50 %, while in 82.8 %, we observed severe damage with >50 % of epithelial lining being lost. Statistical analysis revealed no significant association between mucosal loss and later development of ITBL (*P* value=0.341).

Like mucosal loss, bleeding of the duct wall was a very common finding with 93.5 % of cases being affected. While minor bleeding (score 1) was often encountered (73.1 %), severe mural hemorrhage was observed in 19 recipients. Interestingly, comparison between all patients with bleeding (score 1 or 2) and without bleeding led to no statistically relevant result, while score 2 hemorrhage compared to score 1 and 0 showed a significant association with respect to the development of ITBL (*P* value=0.031).

Hyaline thrombi were found in 26.3 % of cases examined. Mostly, they were found in small capillaries in the mural wall. Larger vessels did not demonstrate relevant amounts of thrombi. There was no statistically significant difference for the patients with thrombosis or without thrombosis concerning establishment of ITBL (*P* value=0.061).

Vascular lesions could be demonstrated in 74.2 % of all grafts. The majority showed lesions in <50 % of vessels (n=60; 64.5 %). Applying chi-square analysis, we did not find relevant association with ITBL (*P* value=0.071). However, by comparison of the group without any vessel damage (score 0)

Table 2 Influence of histological parameters on occurrence of ITBL

with the combined group of score 1 and score 2 cases, we found statistical relevance (P value=0.029).

One of the most conspicuous results was the detection of necrotic arterioles and small arteries. A total percentage of 42.9 % of cases revealed this feature, which was prominent in 8.6 %. Statistical analysis established a highly significant correlation between the detection of arteriolonecrosis and the development of ITBL (P value<0.001).

Bile duct necrosis was a further common observation. Forty-three cases demonstrated a necrosis of the stromal layer. Approximately half of this cohort (n=25) revealed <25 % of the circumference damaged, while lesions were more pronounced (with lesion of more than 50 %) in about one fifth (n=8). Statistical evaluation of this score revealed a very close association with ITBL (P value<0.001).

Finally, inflammation was observed in 84.9 % of evaluated subjects. Most commonly, inflammation was only mild (score 1; 76.3 %). In eight cases, inflammation was pronounced, especially in the non-ITBL group. Inflammation in general was found in 89 % of the non-ITBL patients, but in a less percentage of ITBL patients (approximately 67 %). Further analysis demonstrated a statistically significant association (P value=0.016).

Based on these findings, we performed stepwise logistic regression analysis with regard to ITBL as endpoint. Arteriolonecrosis (independent on score 1 or 2) was the only parameter predictive for the development of ITBL (P value=0.001; odds ratio, 0.09; confidence interval, 0.03–0.36).

Discussion

ITBL comprises one of the most troublesome complications after OLT. Several risk factors are discussed to be major parameters for the development of ITBL. Among them, ischemic injury, immunological abnormalities, and bile salt toxicity appear to have the most important influence [1, 2]. We investigated the morphology of the donor bile ducts received during OLT in order to give some insights in the pathomechanism of this important disorder. Among the variety of abnormalities, we evaluated damage to the vasculature, first of all arteriolonecrosis, in combination with mural necrosis to be relevant for further development of ITBL. This confirms the previous concept of microangiopathy as the leading phenomenon in the pathogenesis of ITBL.

Evidence for a critical role of bile salt toxicity in the pathogenesis of ischemia/reperfusion injury of liver grafts has gradually emerged in the last years [2]. Bile salts have potent detergent properties towards biliary epithelial cells. Normally, the toxic effects of bile salts are prevented by complex formation (mixed micelles) with phospholipids. However, the formation of mixed micelles is impaired after OLT, since restoration of biliary secretion of phospholipids may recover more slowly compared to secretion of toxic bile salts [1, 2, 13]. It has been generally recommended to carefully rinse the bile ducts with preservation solution in order to remove residual bile salts [1, 13]. In our study, we observed mucosal loss in nearly all patients tested. There was no statistically significant difference between ITBL and non-ITBL patients. Based on these morphological findings, conclusions concerning a possible influence of bile salts cannot be made.

We found inflammatory infiltrates in about 85 % of evaluated cases. Most interestingly, inflammation in general was

found in 89 % of the non-ITBL patients, but in a less percentage of ITBL patients (approximately 67 %). This difference was statistically significant. Further investigation is needed to elucidate whether inflammation might serve as a protective factor in the pathogenesis of ITBL.

Injury of the peribiliary vascular plexus is believed to play a central role in the pathogenesis of ITBL. Preservation injury has been suggested to result in increased arterial resistance and may cause circulatory disturbances in small capillaries [6]. The crucial role of the vasculature has also been elucidated by clinical studies of Heidenhain et al. [10] and Moench et al. [4]. These authors demonstrated that use of high-pressure aortal perfusion resulted in a significantly lower number of ITBL cases. Since in IBL thrombosis is described as a central factor leading to vessel damage [1], we firstly analyzed the vasculature of the donor bile ducts for the occurrence of thrombi. However, on the basis of histological evaluation, we did not find a statistically significant difference between ITBL and non-ITBL patients. Thus, clotting of the peribiliary vascular plexus probably does not play a role in the pathogenesis of ITBL.

In one of the very early studies of ITBL, Sanchez-Urdazpal [5] and colleagues considered that bile duct strictures could represent injury of the microvasculature and mentioned arteriolar necrosis as one possible cause. In fact, arteriolonecrosis was the most conspicuous finding of our morphological study. We detected this feature in 42.9 % of all cases. Moreover, by statistical analysis, we could establish a significant association with ITBL: while about 83 % of the ITBL patients revealed arteriolonecrosis, we detected this phenomenon in only 32 % of the non-ITBL group (P value<0.001). The central role of arteriolonecrosis for the development of ITBL is additionally confirmed by our further statistical approach revealing that, in logistic regression analysis, only arteriolonecrosis could serve as a predictive factor. There were further lesions of the vasculature in the bile duct wall, with subendothelial or subintimal edema being the most common form. These were collected in the group of vascular lesions, which were observed in about 74 % of all cases. Interestingly, we also found statistical significance between ITBL and non-ITBL patients for this feature. Finally, we suggest strong intramural bleeding or hemorrhage to be further parameters that may be interpreted in this context of a multifactorial vascular damage, since we have found this phenomenon as a statistically significant parameter with regard to ITBL.

We believe that the vascular lesions can be attributed to hypoxic damage on the endothelial cells leading to subintimal edema and subsequently causing arteriolonecrosis. Following erythrocyte extravasation through damaged vessels, intramural hemorrhage might also reflect this pathway. In summary, these histological data of human donor bile duct contribute to the view that (hypoxic) injury of the microvasculature is crucial for the development of ITBL. We suggest that this type of microangiopathy plays a central role in the pathogenesis of ITBL.

Due to the close similarities with IBL, bile duct necrosis has also been supposed to be of major importance for ITBL [1, 5, 6]. In accordance, we demonstrated in this study a statistically relevant association between mural necrosis and ITBL. Since we found a close relationship between patients with arteriolonecrosis and patients with mural necrosis (P<0.001; data not shown in the "Results" section), both features might be closely associated according to the pathomechanism. Therefore, the necrosis of the bile duct wall is most likely caused by microangiopathy. In previous studies, it has been proposed to reclassify diffuse bile duct damage after OLT. Especially, it was considered that IBL and ITBL belong to the same group of ischemic biliary injuries, on one hand with IBL reflecting a macroangiopathic form due to thrombosis and/or stenosis of large vessels (first of all, the hepatic artery) and on the other hand with ITBL representing the microangiopathic variant of ischemic disease [12]. The results of our morphological study are in line with this pathogenetic model. We have summarized our results in a flowchart model for the possible pathogenetic steps leading to ITBL (Fig. 10). In previous studies, it became clear that several donor parameters such as donor age and cold ischemia time are significant risk factors for the development of ITBL [4, 10]. In our morphological study, the length of the bile duct segments did not have any significant influence for the development of ITBL. Based on the presented results, a thorough analysis of the clinical data

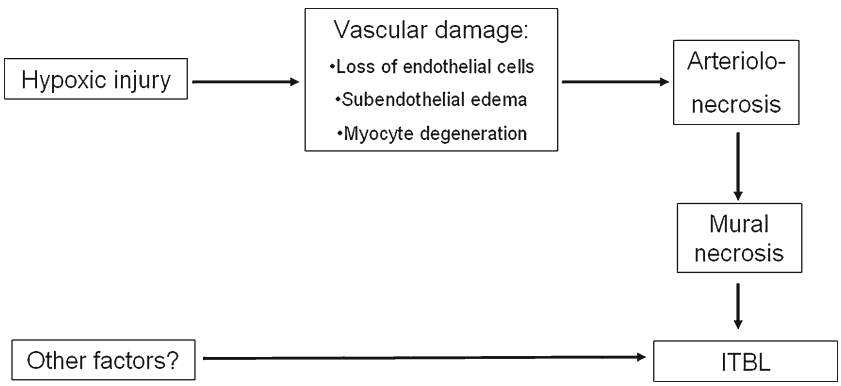

Fig. 10 Flowchart summarizes the pathogenetic model of ITBL as revealed by previous data and results of the present study

with respect to the histological features (arteriolonecrosis in particular) and ITBL will be performed.

Considering our data, it remains unresolved why a distinct percentage of ITBL patients (17 %) did not show arteriolonecrosis and/or mural necrosis (in particular with two patients missing both features). Two possible reasons might explain this discrepancy. First, as reflected by multifocal and discontinuous affection of the biliary tree, the angiopathy could be variably pronounced depending on the specific site of bile duct. In other words, the missing detection of the above-named features could be due to a "sampling error," since the ischemic damage might occur in more peripherally localized (i.e., intrahepatic) bile duct segments. Second, as already considered in previous studies, there might be forms of ITBL which are influenced by as yet unknown immunological factors [2, 12]. In those forms, vessel damage might be less well developed, thus leading to a rather bland morphology. Possibly, innate alloimmunity such as toll-like receptor-triggered signaling pathways could be involved in these pathomechanisms [14].

In summary, this is the first morphological study on bile ducts received during LTX. Our findings confirm the previous view that damage to the microvasculature is associated with an increased risk for the development of ITBL. In order to elucidate the possible causes of hypoxic injury, further analysis of the clinical data of the donor (such as the donor age, cause of death, and cold ischemia time) should be performed and correlated with the respective histopathological findings.

Conflict of interest We declare that we have no conflict of interest.

Abstract FGFR1 is a receptor tyrosine kinase of which the ligands belong to the fibroblast growth factor family. To evaluate the significance of FGFR1 in lung cancer, we analysed tumours by immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH). Tissue microarrays were constructed containing 380 lung cancer samples including squamous cell carcinomas (SCC), adenocarcinomas (ADC), non-small cell lung cancer not otherwise specified, metastases, neuroendocrine tumours, large cell lung cancer and small cell lung cancer. FGFR1 expression was analysed by IHC and scored semi-quantitatively by a four-tier approach (0, 1, 2, 3). Using dual-colour interphase FISH with probes specific for the locus on 8p12 and the centromere of chromosome 8 (CEN8), copy numbers of FGFR1 were determined. High expression of FGFR1 was associated with increased FGFR1 gene copy numbers in squamous cell carcinoma ($p<0.001$). The FGFR1 locus was equally affected by copy number losses and gains. The higher FGFR1 gene copy numbers in SCC compared to ADC did not reach statistical significance. High copy number amplification of FGFR1 was a very rare event, the FGFR1/CEN8 signal ratio reaching a maximum value of 2.75. There were no significant associations between FGFR1 and clinicopathological parameters. Fibroblast growth factor signalling represents an interesting therapeutic target in lung cancer. However, the pathways are complex with potential oncogenic and anti-oncogenic activities. Our data may help to define criteria for selecting patients that may benefit from these new therapeutic options.

Introduction

Lung cancer is the leading cause for cancer-associated mortality in the USA and Germany [1, 2] and ranks first in worldwide cancer incidence (16.5 %) and mortality (22.5 %) in males [3]. Fibroblast growth factors and their receptors have diverse and important physiological roles in the mammalian organism including the regulation of angiogenesis, wound repair, as well as phosphate homeostasis [4, 5]. Specifically, the FGFR family consists of four members in which

mutations have been described not only in developmental disorders like achondroplasia and thanatophoric dysplasias but also several cancer types. For instance, nucleotide exchange mutations have been reported for FGFR2 in endometrial carcinomas and for FGFR3 in urothelial carcinomas. In contrast, FGFR1 seems to be preferentially affected by focal amplifications [6].

In lung cancer, FGFR1 was found to be amplified using large-scale single nucleotide polymorphism arrays [7]. We were involved in a recent publication demonstrating FGFR1 amplification and overexpression as a frequent event in lung squamous cell carcinoma [8]. This non-small-cell lung cancer (NSCLC) subtype thus far has not been subjected to targeted therapy, which, however, is probably going to change in the near future [9, 10].

In this study, we aimed to further evaluate FGFR1 gene copy numbers and protein expression in lung cancer and their potential association with clinicopathological parameters.

Material and methods

Tumour collective

The materials of this study originated from resections from the lung of 380 patients who underwent a surgical intervention at the thoracic surgery department at the Central Clinic Bad Berka between January 1999 and December 2002. The case series consisted of squamous cell carcinomas (n=194), adenocarcinomas (n=83), non-small cell lung carcinomas not otherwise specified (NOS) (n=47), large cell lung cancer (n=7), small cell lung cancer (n=10), metastases (n=29) and other neuroendocrine tumours consisting of carcinoids of the lung (n=10) (Table 1).

TMA construction

We constructed two tissue microarrays (TMAs) by using 1-mm punches from formalin-fixed, paraffin-embedded tumour specimens using standard procedure [11] and instrumentation (Beecher Instruments, Microarray Technology, Sun Prairie, WI, USA).

Immunohistochemistry

We analysed FGFR1 expression by performing immunohistochemistry using a FGFR1 antibody (Abcam ab71928) and standard procedures (antibody dilution, 1:250) with antigen retrieval (30-min steamer using a citrate buffer of pH 6,1) and a commercially available detection system [11].

High expression was defined as strong FGFR1 staining of the cell membrane or the cytoplasm. Expression levels were first scored semi-quantitatively by a four-tier approach (Fig. 1a). Later, it was reduced to the three subgroups no expression (immunohistochemistry (IHC)-score 0), low expression (IHC score 1+) and high expression (IHC score 2+ and 3+) (Table 1). For statistical analysis, the subgroups were finally dichotomized into IHC negative (IHC scores 0 or 1+) and IHC positive (IHC scores 2+ and 3+).

Fluorescence in situ hybridization

To determine the gene copy number of FGFR1, dual-colour fluorescence in situ hybridization (FISH) was performed on the lung cancer TMAs. Therefore, a Zytolight SPEC FGFR1/CEN8 Dual Color Probe (ZytoVision GmbH, Bremerhaven, Germany) was used to detect the FGFR1 gene on chromosome 8p12 as green signal and the centromeric region/alpha-satellite of chromosome 8 as a red signal. FISH was performed according to the manufacturer's instructions. Examples of representative FISH results are shown in Fig. 1b. For the analysis, 20 nuclei per case were analysed. Since there are as yet no standard criteria for the definition of FISH positivity, different cut-off values, i.e. FGFR1 signals≥ 2/3/3.5/4 per cell, were defined and submitted to the statistical analysis.

Statistical analysis

Fisher's exact test, Pearson correlation coefficient or Kruskal–Wallis test were used to test the correlation between the parameters as indicated. The p values <0.05 were considered significant. All calculations were performed on a PC using SPSS (version 18, Munich, Germany). For overall survival, all deaths were counted as events; patients who were alive in 2010 were censored at time of last observation. Differences in survival were tested for statistical significance with the log rank test.

Clinicopathological parameters were available for 324 cases (289 for the nodal stage, 323 for primary tumour (pT) category and 324 for grading); follow-up data could be obtained for 256 patients. Because of the small sample size, we excluded small cell lung cancer (SCLC), metastases (MTS) and neuroendocrine tumours (NET) from the statistical analysis while LCLC samples were combined with NSCLC-NOS (n=54)

Results

Immunohistochemistry

FGFR1 expression was scored semi-quantitatively by using a four-tier approach (Fig. 1a). In total, 320 samples were successfully analysed by immunohistochemistry (Table 1). In general, the IHC scores were similar for adenocarcinoma

Table 1 Tumour collective—clinicopathological and experimental data

	Parameter	SCC	ADC	NSCLC-NOS	LCLC	SCLC	MET	NET

(ADC) and squamous cell carcinomas (SCC) while the higher score in NSCLC-NOS was not statistically significant (Fig. 2). Similarly, high expression of FGFR1 (scores 2+3) were not correlated to the clinicopathological parameters sex (p=0.689), age (p=0.206), pT stage (p=0.557), nodal stage (p=0.450) or grading (p=0.187). Overall, increased FGFR1 expression levels correlated with FGFR1 gene copy number, notably in lung squamous cell carcinomas, but there were also discordant cases (Fig. 3).

Fluorescence in situ hybridization

FISH data could be analysed for 260 tumour samples (Table 1). Significant differences in FGFR1 signal numbers between squamous cell carcinomas and adenocarcinomas were not found (Fig. 4). However, the analysis suggested that FGFR1 gene copy number increases are more frequent in lung SCC cases. Therefore, we specifically analysed those cases with gene copy number equal or above 4, a threshold that has been previously used to define FGFR1 amplifications [8]. We found that 14 out of 133 SCC cases (10.5 %) showed ≥4 copies of the FGFR1 gene on chromosome 8p12 while the frequency was considerably lower for lung ADC (3 out of 64 cases, 4.7 %). This difference, however, failed to reach statistical significance (Fig. 5). Similarly, there was no significant association between increased FGFR1 gene copy number (≥4) and any clinicopathological parameter (sex, p=0.57; age, p=0.247; pT stage, p=0.685; pathological nodal (pN) stage, p=0.602; grading, p=0.947).

In addition to the analysis of FGFR1 alone, we also evaluated the ratio between the signals of the locus-specific probe and centromere 8. Within the subgroup of cases with FGFR1 gene copies ≥4, all tumours showed a locus-specific gene copy number increase with ratio values above 1 (range, 1.14 to 2.75). We found almost equal numbers of cases with ratio values below 1 (n=117) suggesting a FGFR1 deletion and those with ratio values above 1 (n=143) indicative of a regional FGFR1 gene copy number gain. Within the subgroup of cases with reduced FGFR1 gene copies, there were also no significant associations with clinicopathological parameters or survival.

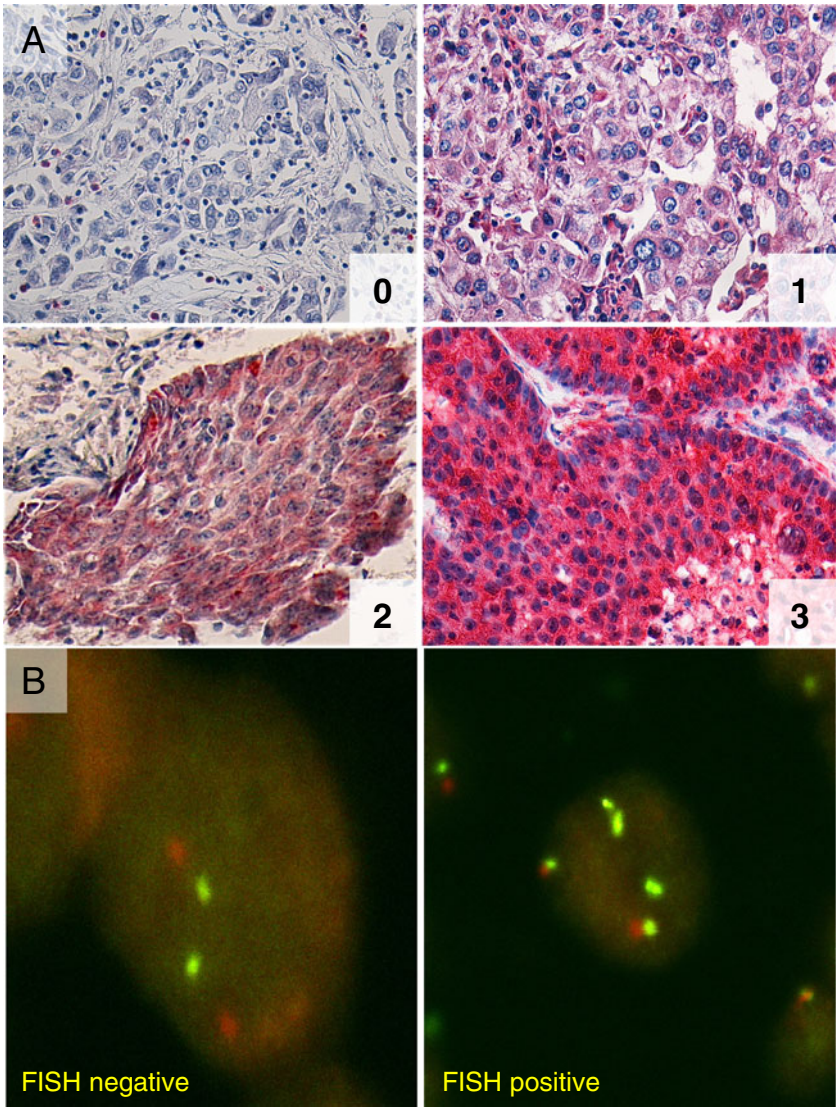

Fig. 1 **a** Immunohistochemical detection of FGFR1 and scoring of protein expression by a four-tier system: *0* no expression, *1* low, *2* moderate, *3* strong expression (magnification, ×630). **b** Representative examples of the dual-colour FISH analysis for FGFR1 (*green signals*) and CEN8 (*red signals*)

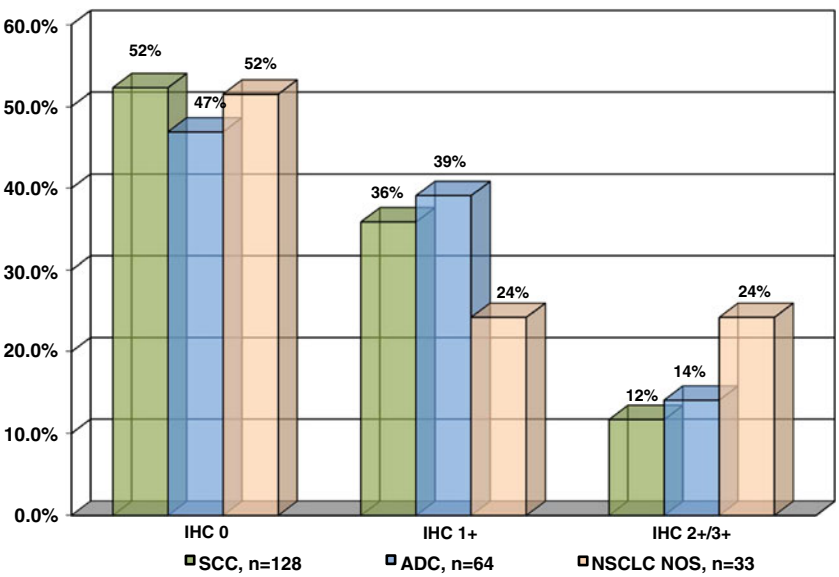

Fig. 2 FGFR1 protein expression in different lung cancer subtypes revealed no significant differences

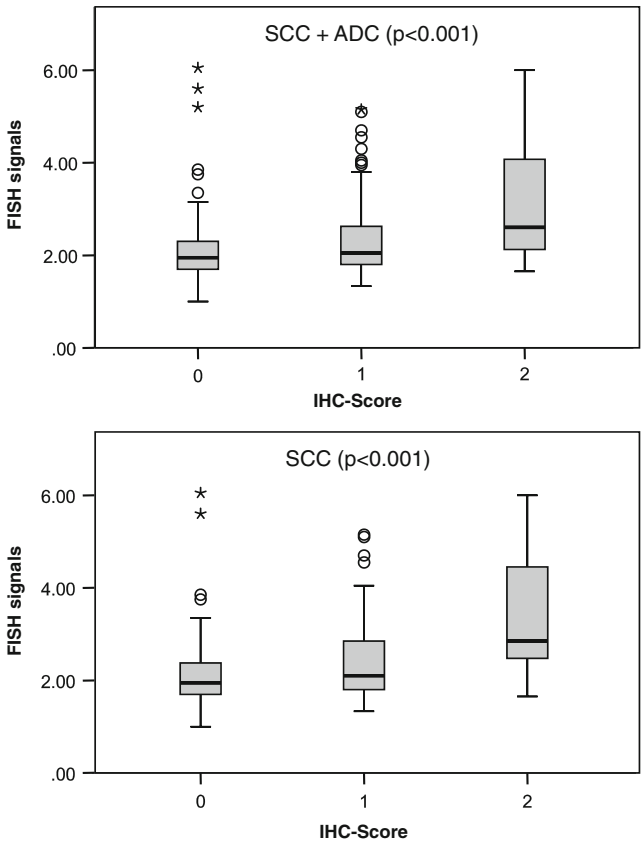

Fig. 3 Boxplot analysis for the correlation between FGFR1 gene copy numbers and protein expression indicated significant associations for lung SCC and ADC which was mainly due to the subgroup of SCC

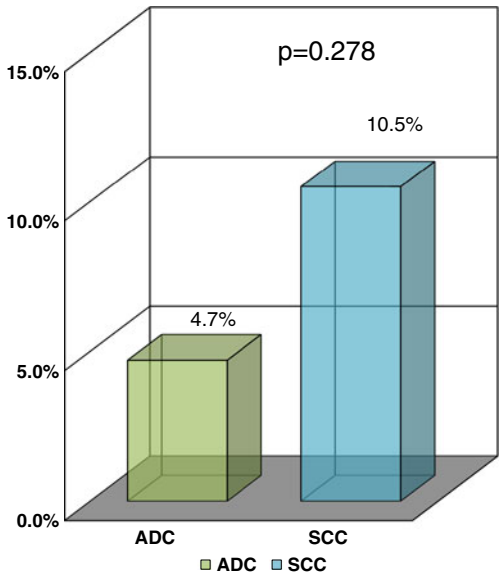

Fig. 5 FGFR1 amplification (≥4 FISH signals) was more frequent in lung SCC than ADC, however without reaching statistical significance

Survival analysis

In our case series, we observed significant correlations between clinicopathological parameters and patient survival. In the 5-year-survival analysis, ADC patients with grade 2 or 3 tumours showed a significantly shorter survival than patients with a grade 1 lung ADC ($p<0.05$). Similarly, ADC patients without lymph node metastasis ($n=39$) had a significantly higher 5-year survival than patients with lymph node metastases ($p<0.0001$); only about 15 % of the patients with pN1, pN2 or pN3 stages survived 60 months while more than 60 % of the patients with pN0 were alive after 5 years. For patients with SCC, we did not observe significant differences in 5-year survival according to the lymph node status or tumour grade. After 30 months of follow-up, 65 % of the patients with ADC and 45 % of SCC patients were still alive. After 5 years, the survival rates for ADC and SCC patients were 35 and 30 %, respectively. The pT stage did not correlate significantly with survival (SCC, $p=0.178$; ADC, $p=0.145$), but there was a trend towards a better survival of patients with T1/T2 tumours compared to those with a T3/T4 tumour stage.

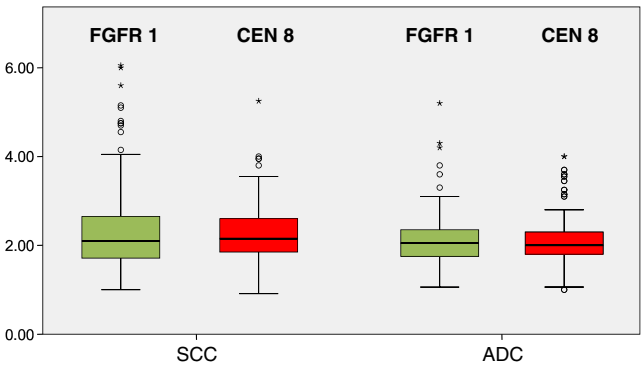

Fig. 4 Comparison of FISH signals indicated more SCC cases with higher FGFR1 copy numbers than ADC, however without reaching a statistical significant difference

FGFR1 expression or gene copy number alterations, in general, did not show any significant association with survival. However, there are some interesting trends when analysing overall survival in relation to different signal frequencies of the FGFR1 gene (Fig. 6). Specifically, with FGFR1 signal numbers above 3, the curves for lung SCC start to split. Patients with FGFR1 copy number increases carried a worse prognosis with survival curves being almost identical when comparing absolute FGFR1 signals (≥4 signals, Fig. 6d) and FGFR1/CEN8 ratio values (≥1.5, data not shown). In contrast, the few lung ADC with FGFR1 signals ≥4 ($n=3$) showed a better survival than the amplified squamous cell carcinoma patients. Due to the small number of cases, these differences did not reach statistical significance.

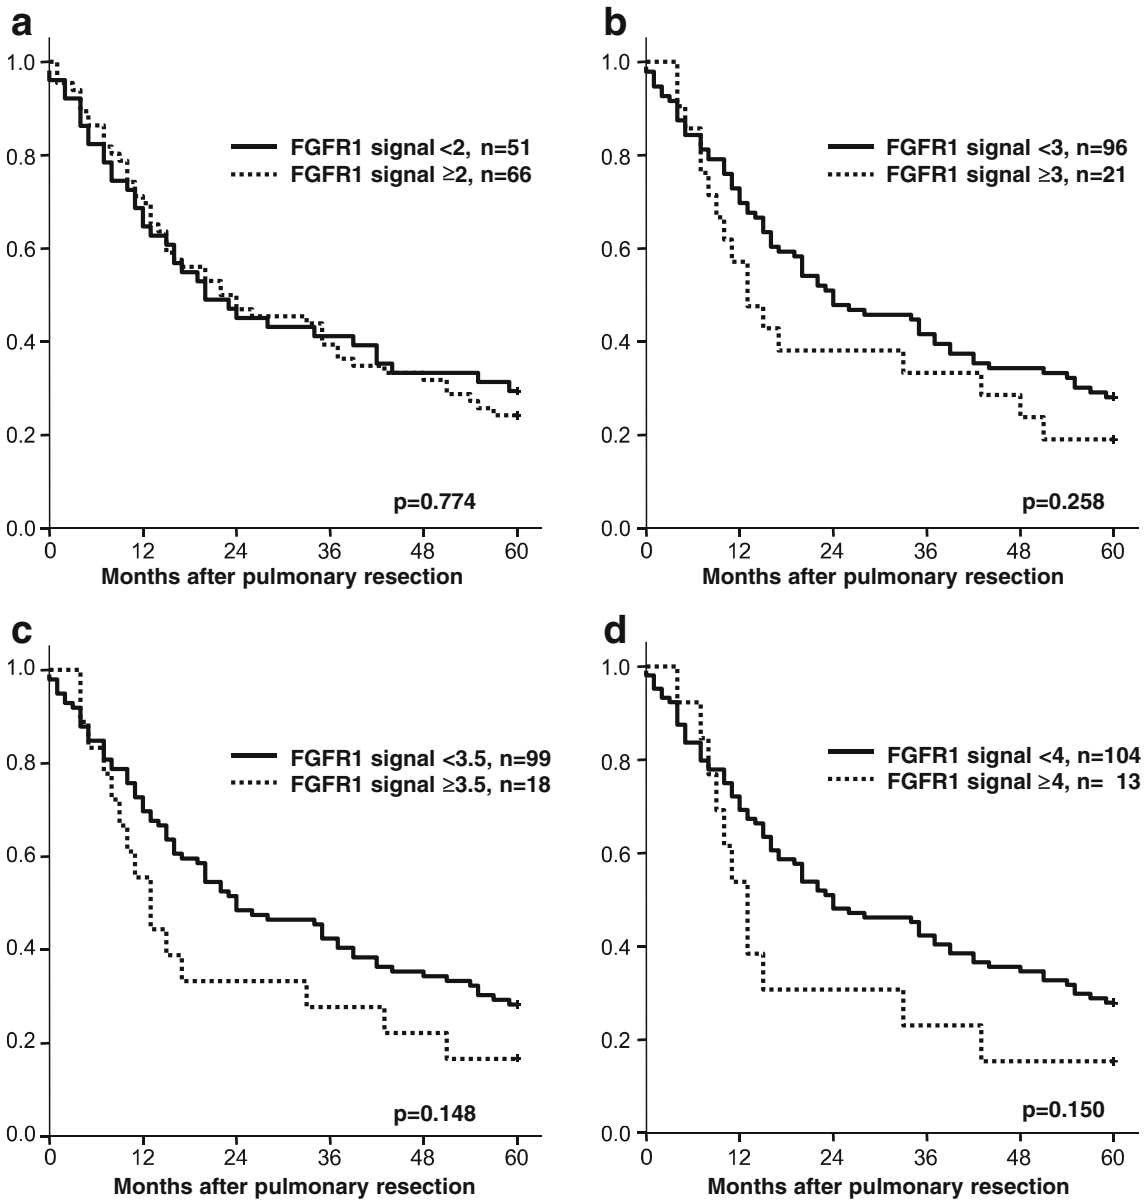

Fig. 6 Survival analysis of lung SCC according to different FGFR1 gene copy number cut-off values suggested a worse prognosis of cases with increased gene copy numbers, however without reaching statistical significance

Discussion

FGFR1 and its signalling pathway seem to be of key importance in tumour progression and survival [12, 13]. The genomic region of FGFR1 is located on chromosome 8p12, and frequent and focal amplifications at this region are described in several publications for different tumours. Breast cancer showed an amplification frequency of 10 % [14]. With lower frequency, bladder cancer [15], ovarian carcinoma [16] and rhabdomyosarcoma [17] also showed amplifications at chromosome 8p12. Alterations in the FGFR gene family have also been found for different tumour subgroups like bladder cancer, breast cancer, endometrium cancer and gastric cancer [4, 18–20].

To evaluate the amplification frequency of FGFR1 in human lung cancer specimens, we performed FISH on tissue microarrays to compare in particular lung SCC and ADC. Earlier publications suggested a significant difference in the amplification frequency in these two tumour subgroups [8, 21]. In principle, our analysis showed a similar percentage of 10 % of SCC cases with increased FGFR1 gene copies (≥4 signals) as shown by Weiss et al. [8]. The same study also reported on an independent case series of SCC harbouring ≥4 FGFR1 gene copies in 22 % of cases. This

number seems to be exaggerated; at least, it was not consistent with our data. In addition, we could also not confirm the statistical significant difference between lung SCC and ADC which may be due to the slightly lower number of cases that were analysed in our study.

Another possibility may be the lack of standardized criteria for defining FGFR1 amplification. In this regard, the study of Weiss et al. is helpful because it introduced a new threshold for defining FGFR1 amplifications. However, considerable heterogeneity exists in the assessment and terminology of gene amplifications. For HER2, it was traditionally defined as a gene to reference ratio above 2.0, and this cut-off value has achieved major practical relevance in selecting patients for targeted therapy. However, there are also other parameters like clusters of gene signals in 10 % of tumour cells or signal copy numbers >6 [22]. Other cut-off values may need to be defined for distinct genes. For FGFR1, Weiss et al. not only introduced the ≥4 threshold but also used the term low-level amplification for cases with ≥2 but <4 signals and high-level amplification for those with ≥9 signals. We did not find cases with high-level amplification. The maximum number of FGFR1 signals in our study was 6.05 (mean of signals per tumour cell). In fact, most carcinomas showed only a modest increase of the FGFR1 gene copies. However, a limitation of our study is that we analysed only one core punch biopsy per tumour resection specimen. Thus, we cannot make any statements on the heterogeneity of FGFR1 gene copy numbers within a single tumour.

A first follow-up study after the report of Weiss et al. reported that increased copy number status of FGFR1 in lung SCC correlated significantly with the parameters gender (females, 13.8 %, vs. males, 39.4 %), smoking status (never smoker, 4.2 %, vs. smokers, 40.8 %) and pathological subtypes (squamous cell carcinoma, 41.5 %, vs. non-squamous cell carcinoma, 40.8 %), but not with age, grade and lymph node status [21]. Significance for the smoking status was also reported earlier by Behrens et al. using FGFR1 IHC expression analysis [23].

It is interesting to analyse whether the FGFR1 gene copy number increase is due to chromosome 8 polysomy or a regional FGFR1 amplification. In the cases with a FGFR1 gene copy number increase ≥4, the ratio values FGFR1/CEN8 were all greater than 1 suggesting a regional copy number increase. However, the ratio values varied only between 1.14 and 2.75 indicating that local, high copy number amplifications with the generation of double minutes or homogenously staining region as reported for the myc oncogenes do not affect the FGFR1 locus or at least represent a very rare event that was not detectable in our collective. This view is supported by our conventional comparative genomic hybridization (CGH) data (Fig. 7, [24–30]). The FISH-positive case of Fig. 1b seems to be representative for the few lung carcinomas with FGFR1 amplifications. SCC is the lung cancer subtype with the highest DNA content [24]. Thus, polyploidy leading to chromosome 8 polysomy probably also contributes to the increase of FGFR1 gene copy numbers in SCC compared to lung ADC.

It is important to take note of the difference between absolute and relative gene copy numbers. CGH detects relative copy number changes. In case of triploid carcinomas, two copies of the FGFR1 gene would be interpreted as a deletion. In contrast, FISH detects absolute gene copy numbers which may be transformed into relative copy numbers by calculating ratio values between two distinct chromosomal probes. Our FISH ratio analysis confirmed the previous CGH findings that chromosome 8p is affected not only by DNA gains but also DNA losses. CGH as well as LOH data actually suggested that 8p deletions may be a marker for tumour progression and metastasis in lung cancer [28, 29]. Interestingly, one metastasis suppressor gene for hepatocellular carcinoma has been identified on chromosome 8p12 [31]. Furthermore, mutations of the Werner syndrome gene WRN at 8p12 may cause premature ageing and is associated with a predisposition to cancer [32].

Thus, it is not surprising that we could not find any association between FGFR1 protein expression or copy number gains and clinicopathological parameters indicative for tumour progression. Similar observations were made in a recent study using FISH and IHC [21] as well as an earlier protein expression study [23]. However, this statement may

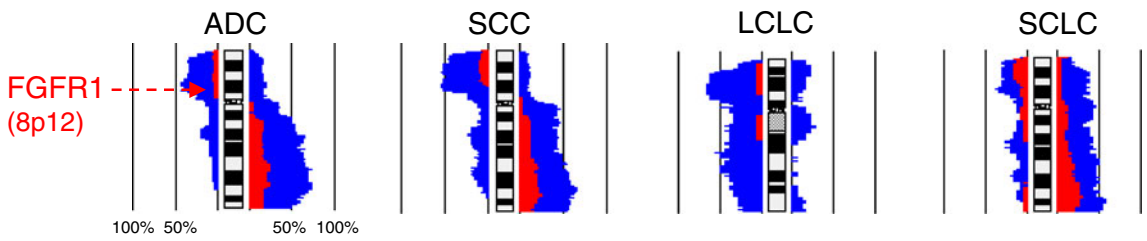

Fig. 7 DNA imbalances of lung cancer subtypes according to conventional comparative genomic hybridization/CGH (compiled from data of Petersen I in Travis et al. 2004, [30]). Cases with DNA gains were represented by the histogram on the *right side* of the chromosome ideogram, cases with DNA loss on the *left side*. The data indicated that 8p deletions are at least as frequent as DNA gains with pronounced gains (indicated by the *red colour*) as putative correlates of an amplification being undetectable in the NSCLC subtypes

need to be reassessed after the analysis of larger tumour collectives. At least, our survival analysis using different cut-off values for FGFR1 copy number gains suggested a trend towards worse prognosis in case of gene copy number increase (Fig. 6). A similar trend was observed by Sasaki et al. [21]; however, the authors also failed to confirm a significant difference in their case series of 100 lung SCC. Furthermore, it is noteworthy that increased FGFR1 expression has been associated with cancer cell survival and chemotherapy resistance [33, 34]. Several studies reported elevated levels of FGFR1 protein in NSCLC [35, 36]. The highest FGFR1 expression was found in lung SCC [37].

Following the study of Weiss et al., FGFR1 analysis of lung SCC has achieved considerable interest because of its potential use as a drug target [6, 8, 10]. The results of the clinical trials are eagerly awaited, and it is far too early to make final judgements on the importance of FGFR1 targeting in lung cancer. However, it must be stated that the fibroblast growth factor (FGF) signalling is quite complex with a high number of ligands and receptors. Furthermore, FGF and their receptors may not only have oncogenic functions but may also act as tumour suppressors in a tissue-dependent manner which has specifically been reported for FGFR2 [4]. Thus, it is fair to assume that targeting of FGFR1 alone will not bring a major breakthrough in the treatment of the majority of lung cancer patients.

Acknowledgments We thank Barbara Bergholz, Christiane Geier and other colleagues from the institute of pathology for technical assistance. In addition, we are indebted to Piere Rogalla and Sven Hauke from ZytoVision GmbH for providing the FGFR1/CEN8 dual-colour FISH probes in the context of the BMBF project for molecular sarcoma diagnosis (FKZ 0315509).

Abstract Previous studies have shown that pulmonary sclerosing hemangioma is a tumor derived from primitive respiratory epithelium, but its character and the differentiation status of the two cell types (polygonal and cuboidal) composing the lesion are still controversial. We hypothesize that the polygonal cells are immature compared with cuboidal cells and have higher proliferative activity. To further study this question, we examined the expression of β-catenin, Axin, and C-myc by immunostaining in 45 primary sclerosing hemangioma (PSH) specimens. The two cell types were captured by laser capture microdissection from 28 PSH specimens, and total RNA was extracted. Messenger RNA (mRNA) expression of Axin and C-myc was examined by reverse transcription polymerase chain reaction (RT-PCR). By immunostaining, β-catenin was predominantly strongly expressed on the cell membrane of cuboidal cells, while in polygonal cells, β-catenin was predominantly expressed in the cytoplasm and significantly decreased on cell membranes. Axin was expressed in cuboidal cells in 93 % of our 45 cases, but only expressed in 18 % of these in polygonal cells. C-myc expression in polygonal cells was significantly stronger than in cuboidal cells ($P<0.05$). RT-PCR showed that the expression level of Axin mRNA in cuboidal cells was significantly higher than in polygonal cells ($P<0.05$), and expression level of C-myc mRNA in polygonal cells was significantly higher than in cuboidal cells ($P<0.05$).The two PHS cell types have distinct expression of β-catenin, Axin, and C-myc, suggesting that their differentiation status may be different. The higher expression of C-myc in polygonal cells suggests that these cells might have higher proliferative activity.

Introduction

Pulmonary sclerosing hemangioma (PSH) is a rare pulmonary tumor first described by Liebow and Hubbel [1]. Its histogenesis and nature have been controversial for decades, and the pathogenesis of PSH remains unclear [2–7]. In the 1981 WHO classification of lung tumors, PSH was accepted as tumor-like lesion. However, recent studies have revealed that PSH is a true tumor rather than a hamartoma [8, 9]. Therefore, in the 1999 and 2004 WHO classifications of lung tumors, PSH was categorized as a miscellaneous tumor. It consists mainly of two types of cells: polygonal cells in the solid areas and the interstitium of papillary areas and cuboidal cells on the surface of papillary areas or in various lacunar spaces. The two cell types are significantly different in histological pattern, cellular morphology, and immunophenotype. Histologically, the cuboidal cells look like type II pneumocytes, but the polygonal cells are significantly different from pneumocytes. Literature reports and our previous study indicate that they have the same cellular origin [8, 9], and both originate from primitive respiratory epithelium [10–12]. Therefore, the use of the term pneumocytoma was recommended. The question arises as to what might be

the nature of the difference between the two types of cells. Our working hypothesis is that they are in a different differentiation status, the cuboidal cells being more mature than the polygonal cells. If the polygonal cells are in an immature status, they might be in an active state of proliferation. Although most scholars believe that the tumor is benign, there are reports of lymph node metastasis [13, 14], pleural dissemination [15], and metastatic spread to the stomach [16]. These findings have prompted us to study the differentiation status of the two types of cells and the clinical behavior of PSH.

The Wnt signaling pathway is a conserved signaling pathway, which plays a key role in embryonic development, and is involved in the regulation of cell growth, migration, and differentiation. Activation of Wnt signaling has been proven to be involved in the development of many tumors [17]. β-Catenin, Axin, and C-myc are major factors of Wnt signaling pathway, their abnormal expression having been detected in many tumors [17–19]. In nonsmall cell lung cancer, the activation of Wnt signaling has been found, as well as aberrant expression of β-catenin, Axin, and C-myc. In contrast, in mature epithelial cells, the Wnt signaling pathway is not activated. Dacic et al. found in PSH genetic changes similar to those in bronchioloalveolar carcinoma (BAC) [20]. This supports the notion that PSH may have mechanisms of tumorigenesis in common with BAC. Therefore, to further analyze the character of PSH and differentiation status of two types of cells, the above factors were chosen, and the expression was examined in PSH by immunochemical staining and reverse transcription polymerase chain reaction (RT-PCR).

Materials and methods

Patients and specimens

We collected 45 cases of PSH from The First Affiliated Hospital of China Medical University from 1990 to 2009. The patients with PSH included 11 men and 34 women. The age of the patients ranged from 26–66 years (average, 45 years). Most of the 45 patients exhibited no symptoms before operation and were diagnosed during routine examinations; a few patients had clinical symptoms including chest pain, blood-tinged sputum, and persistent coughing. In all cases, a peripheral round, solitary, well-circumscribed, and highly dense nodule was found by chest radiographs and computed tomography scans. The tumor mass diameters ranged from 0.6 to 5.0 cm. Of the 45 patients, 31 underwent wedge resection; the other 14 underwent lobectomy. In six cases, intraoperative frozen biopsy failed to exclude bronchioloalveolar carcinoma or acinar adenocarcinoma; as a consequence, the patients underwent lymph node dissection, but no lymph node metastases were found. Postoperative follow-up was obtained for 24 patients and ranged from 6 to 64 months (mean follow up, 25 months).

Immunohistochemical staining

All the resected specimens were fixed with 10 % neutral-buffered formalin and embedded in paraffin. Tissue blocks were cut into 4-μm sections, which were deparaffinized in xylene, rehydrated with graded alcohols, and immunostained with anti-Axin (rabbit polyclonal antibody, Santa, USA), anti-β-catenin, and anti-C-myc (mouse monoclonal antibody, Santa, USA).

Sections were stained with a streptavidin-peroxidase system (KIT-9720, ultrasensitive TM S-P, MaiXin, China). The chromogen used was diaminobenzidine tetrahydrochloride substrate (DAB kit, MaiXin, China), and the sections were slightly counterstained with hematoxylin, dehydrated, and mounted. As negative control, the primary antibody was replaced with phosphate-buffered saline. In each section, five random high power fields were observed, and 100 cells were counted in each field. The proportion of immunopositive cells was categorized as follows: 0, <5 %; 1, ≥5 to <25 %; 2, ≥25 to <50 %; and 3, ≥50 %. The staining intensity was categorized by relative intensity as follows: 0, no positivity; 1, weak; 2, moderate; and 3, strong. A final immunoreactivity score of each section was obtained by multiplying the two individual scores: (−), <2; (+), ≥2 to <4; (++), ≥4 to <7; (+++), ≥7. To obtain final statistical results, (−) was considered as negative, and (+)–(+++) were considered as positive. The location of β-catenin staining was on the membrane and/or cytoplasm and even nuclear. When more than 90 % of the tumor cells stained for β-catenin on the cell membrane, the case was defined as normal membranous expression. When fewer than 90 % of the tumor cells stained for membranous expression, and/or more than 10 % of the tumor cells stained for β-catenin in the cytoplasm or nuclear, the case was defined as abnormal expression. The location of Axin and C-myc staining was in the cytoplasm.

Laser capture target cells

The 28 specimens were cut into 6-μm serial sections, laid on a thin polyethylene foil slide, deparaffinized, and stained with laser capture microdissection (LCM) Staining Kit (AM1935, Ambion, USA). Then, the cuboidal and polygonal cells were separately captured by LCM (LEICA LMD6000, Leica, Germany). More than 10,000 cells were captured from each specimen.

Reverse transcription polymerase chain reaction

The total RNA of the captured cells was extracted with RNAqueous-Micro Kit (AM1931, Ambion, USA); RNA

quantity and quality was determined by OD at 260 and 280 nm on a NanoDrop® ND-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA).The RNA concentration ranged from 60 to 120 ng/μl, the value of A_{260}/A_{280} ranged from 1.8 to 2.0. RT-PCR was performed using an EasyRT-PCR kit (TransGen Biotech, China), according to the manufacturer's instruction. The sequences of the primers and PCR conditions are listed in Table 1. After electrophoresis on 1.5 % agar gel, the bands of PCR products were visualized using BioImaging Systems (UVP, CA, USA). The grayscale of PCR products was measured. The relative messenger RNA (mRNA) expression levels were normalized relative to the amount of β-actin mRNA.

Statistical analysis

All statistical calculations were performed by SPSS version 13.0 for Windows software (SPSS Inc, Chicago, IL, USA). The chi-square test was used to analyze the results of immunohistochemical staining. The *t* test was used to compare data from the RT-PCR. $P<0.05$ were considered statistically significant

Results

Histological features and follow-up

Histologically, all cases exhibited the following features: solid (Fig. 1a), papillary (Fig. 1b), hemorrhagic (Fig. 1c), and sclerotic (Fig. 1d) areas were noted, and the lesions were composed entirely of polygonal and cuboidal cells. The two types of cells were significantly different in histological pattern and morphological phenotype (Fig. 1) .The cuboidal cells were arranged in a tight monolayer, had dense chromatin, and looked like type II pneumocytes, while polygonal cells were distributed in interstitial locations and displayed abundant clear to eosinophilic cytoplasm with centrally located nuclei. In addition, the polygonal cells occasionally demonstrated moderate to severe cellular atypia, notably nuclear pleomorphism, but typically with rare mitotic activity.

In the period of follow-up, no patient died from the tumor, but one patent developed acinar adenocarcinoma in the same lung lobe 56 months after the wedge resection, while another patient developed a recurrence 26 months after the wedge resection.

Imunohistochemical staining of β-catenin, Axin, and C-myc in PSH

By imunohistochemical staining β-catenin was found in cuboidal cells in all 45 PSH specimens, and clear and consistent expression on the membrane and weak expression in the cytoplasm was seen. In polygonal cells, β-catenin was predominantly expressed in cytoplasm; the expression levels on the membrane were significantly decreased, with even a lack of expression in some cases (Fig. 2). In 8.9 % (4/45) of PSH specimens, β-catenin expression was not detected in polygonal cells; in the remaining cases, expression could be detected in cytoplasm of polygonal cells, within 24.4 % (11/45) of PSH specimens strong expression (+++) in cytoplasm and expression in the nuclei of few cells (Table 2).

In 93.3 % (42/45) of PSH specimens, Axin was expressed in cuboidal cells, while in only 17.8 % (8/45) of PSH specimens, Axin expression was detected in polygonal cells. Axin expression was much stronger in cuboidal cells than in polygonal cells ($P<0.05$).

In 84.4 % (38/45) of PSH specimens, C-myc was expressed in polygonal cells, while in 20 %(9/45) of PSH specimens, C-myc was expressed in cuboidal cells. The expression level in polygonal cells was significantly higher than that in cuboidal cells ($P<0.05$; Fig. 3 and Table 2).

The mRNA expression of Axin and C-myc in two types of cells of PSH

By RT-PCR, the mean relative expression level of Axin mRNA in cuboidal cells was 0.26±0.05 and in polygonal cells was 0.85±0.09.The expression level of Axin in cuboidal cells was significantly higher than that in polygonal cells ($P<0.05$). The mean relative expression level of C-myc was 0.23±0.04 in cuboidal cells and 0.91±0.08 in polygonal cells, and the expression level in polygonal cells was significantly higher than in cuboidal cells ($P<0.05$, Fig. 4).

Discussion

Pulmonary sclerosing hemangioma (PSH) is an uncommon lung tumor, considered to be a particular type of epithelial tumor [10–12]. Histologically, PSH consists mainly of two types of cells: polygonal cells and cuboidal cells. The polygonal cells are located in the solid areas and interstitium of papillary areas, while the cuboidal cells are located on the surface of papillary areas and in various lacunar spaces or in the solid region with cells in clusters or in an adenoidal pattern. PSH has been considered as a hamartoma for several years. In a previous study, we performed clonality analysis using the X-linked androgen receptor and phosphoglycerate kinase gene polymorphisms, and the results revealed that this tumor is a true neoplasm rather than a tumor-like lesion [9]. However, the biological behavior of this tumor and differentiation status of the two types of cells is still controversial [10, 11, 13–16]. The cuboidal and polygonal cells significantly differ in histological pattern, cellular morphology, and even immunophenotype, but our

Table 2 Expression of β-catenin, Axin, and C-myc in two types of cells of PSH (*cyto*cytoplasm positive; *mem* membrane positive)

Antibodies	*n*	Cuboidal cells				Polygonal cells			
		−	+	++	+++	−	+	++	+++
β-Catenin	45	0	0	0	45 (mem)	4	16 (Cyto)	14 (Cyto)	11 (Cyto)
Axin	45	3	5	10	27	37	8	0	0
C-myc	45	36	9	0	0	7	10	13	15

previous study indicated that they have the same origin [9–11]. So far, there are several reports of lymph node metastases, and in cases of lymph node metastasis, the lymph node metastases consisted mainly of polygonal cells [13, 14]. This suggested that the two cell types might have different differentiation status and proliferative activity. We also had performed P53 mutation analysis in the two types of cells, and a sense mutation of the P53 gene was detected in polygonal cells [21]. Therefore, we deemed it necessary to further characterize this tumor and determine the differentiation of the two cell types.

The Wnt signaling pathway is involved in the regulation of cell growth, migration, and differentiation of lung tissue and other tissues, and many papers have reported abnormal activation of the Wnt signaling pathway in nonsmall cell lung cancer [17, 18]. Therefore, in order to further analyze the biological nature of PSH, we examined the expression of β-catenin, Axin, and C-myc in these lesions.

β-Catenin is a central factor in the Wnt signaling pathway. In normal tissue, Wnt signaling is not activated, β-catenin acting mainly as epithelial adhesion molecule localized in the epithelial cell membrane. Upon activation of Wnt signaling, β-catenin accumulates in the cytoplasm, releasing β-catenin, which might reach the nucleus as transcription factor, causing transcription of C-myc and other genes that promotes cell proliferation [17, 18]. Naoki et al. [22] reported a case of familial adenomatous polyposis patient who also developed PSH; aberrant nuclear and cytoplasmic expression of β-catenin was detected in the PSH. Therefore, abnormal Wnt signaling may be involved in this tumor. By immunohistochemical staining, we found strong β-catenin expression on cell membranes of cuboidal cells, but in polygonal cells, membrane expression was significantly decreased or even lacking, while aberrant cytoplasmic and even nuclear expression was detected. Anani et al. [23] found in invasive mesotheliomas more frequent cytoplasmic and nuclear staining and reduced membranous staining with β-catenin than in normal or reactive mesothelium, which showed distinct membranous β-catenin staining. The expression of β-catenin in both cell types supports that they both display epithelial differentiation, but at different levels of maturity. In this concept, cuboidal cells are mature as normal epithelium, but polygonal cells are poorly differentiated with an activated state of the Wnt signaling pathway. Some PSHs are located peripherally adjacent to the pleura even with pleural dissemination, which could cause pleural thickening or pleural fibrosis, which might lead to confusion with primary pleural tumors such as solitary fibrous tumor (SFT) [24]. SFT also expresses β-catenin in the cytoplasm and even in nuclei [25]. However, in tumor cells of SFT, membranous expression was never seen, and CD34 and TTF-1 staining are useful to distinguish between the two tumors.

As a negative regulator of Wnt pathway in normal tissue, Axin can form a complex with β-catenin, causing β-catenin degradation, thus avoiding activation of the Wnt signaling pathway. Axin is expressed in normal bronchial epithelium,

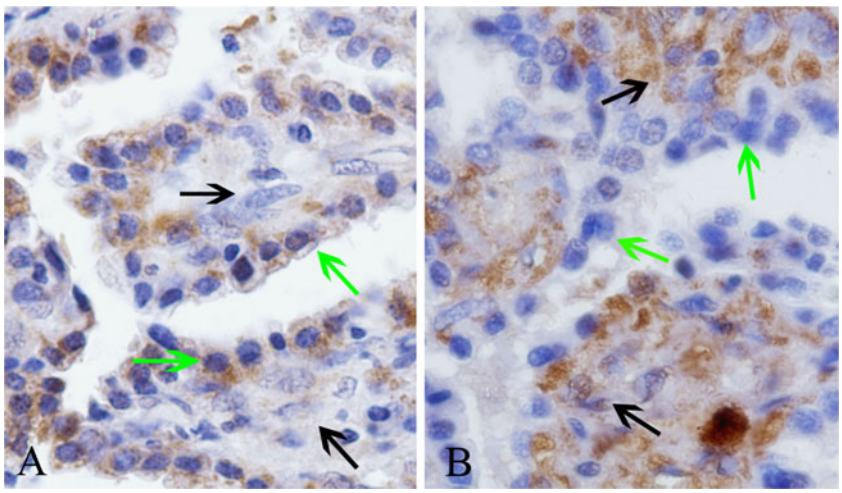

Fig. 3 Imunohistochemical staining of Axin and C-myc in PSH. **a** Axin strongly stains the cytoplasm in cuboidal cells (*green arrow*), but weakly stains few polygonal cells (*black arrow*); **b** expression of C-myc in polygonal cells (*black arrow*) is significantly higher than in cuboidal cells (*green arrow*)

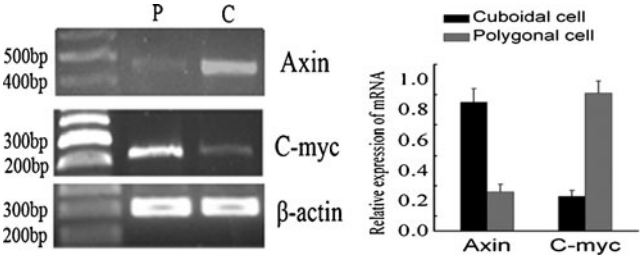

Fig. 4 The mRNA expression of Axin and C-myc in two types of cells (*P* polygonal cells; *C* cuboidal cells). The expression level of Axin in cuboidal cells is significantly higher in polygonal cells ($P<0.05$), while the expression level of C-myc in polygonal cells is significantly higher than in cuboidal cells ($P<0.05$)

but in lung cancer, expression of Axin was significantly decreased [18, 26]. By immunohistochemistry and RT-PCR, we found that expression of Axin is strong in cuboidal cells of PSH, but significantly reduced in polygonal cells, suggesting that compared with the cuboidal cells, polygonal cells might be in a poorly differentiated status. C-myc is an effector of the Wnt signaling pathway and can regulate cell growth and differentiation [17, 19]. Chiba et al [27] found in two cases of PSH that C-myc expression is significantly higher in the tumor cells than in the surrounding lymphocytes using flow cytometry, and C-myc protein and mRNA expression are significantly higher in polygonal cells than in cuboidal cells. The higher C-myc expression prompted us to consider polygonal cells to be immature and in a relatively active proliferative state.

The prevailing opinion was that PSH is a benign tumor, but because of more reports of lymph node metastasis, the notion has emerged that PSH might be a tumor with low malignant potential. Dacic et al. [20] proposed that PSH has the same origin and a similar molecular pathogenesis as bronchioloalveolar carcinoma, with PSH having a biological behavior similar to BAC. Liu et al. [28] recently reported a case of coexistence of PSH and primary adenocarcinoma in the same nodule of lung. This result also suggested that the two tumor types maybe closely related. In our follow-up studies, we found no tumor-related death, but one case with postoperative recurrence, and another case in which a lung adenocarcinoma had developed. The tumor recurrence demonstrated that PSH might be a tumor with low malignant potential and should be further followed up. For the case that developed adenocarcinoma, it was not clear whether the adenocarcinoma was related to the PSH. Bae et al. [16] recently reported a case with metastatic spread to stomach. This finding suggested that PSH has a capacity for distant metastasis. Therefore, to further elucidate the clinical behavior of this tumor, we need to collect more information and carry out longer follow-up.

In conclusion, we found higher β-catenin membrane expression, Axin expression, and lower level C-myc expression in cuboidal cells, suggesting that cuboidal cells are relatively mature. In polygonal cells, membranous expression of β-catenin was significantly reduced with aberrant expression in cytoplasm, and even in nuclei, Axin expression was reduced and C-myc expression level was significantly higher. These results suggest that polygonal cells are poorly differentiated and have high proliferative activity.

Acknowledgments All lung tissue samples were obtained from The First Affiliated Hospital of China Medical University. The study was conducted according to the regulations of the institutional review boards at China Medical University

Abstract While surgery is the usual treatment for localized well-differentiated and dedifferentiated liposarcomas (WDLPS/DDLPS), the therapeutic options for patients with advanced disease are limited. The classical antimitotic treatments are most often inefficient. The establishment of genetically characterized cell lines is therefore crucial for providing in vitro models for novel targeted therapies. We have used spectral karyotyping, fluorescence in situ hybridization with whole chromosome painting and locus-specific probes, and array-comparative genomic hybridization to identify the chromosomal and molecular alterations of a novel cell line established from a recurring sclerosing WDLPS. The karyotype was hypertriploid and showed multiple structural anomalies. All cells retained the presence of a giant marker chromosome that had been previously identified in the primary cell cultures. This giant chromosome contained high-level amplification of chromosomal regions 12q13-21 and lacked the alpha-satellite centromeric sequences associated with WDLPS/DDLPS. The 12q amplicon was large, containing 370 amplified genes. The DNA copy

number ranged from 3 to 57. The highest levels of amplification were observed at 12q14.3 for *GNS*, *WIF1*, and *HMGA2*. We analyzed the mRNA expression status by real-time reverse transcription polymerase chain reaction for six genes from this amplicon: *MDM2*, *HMGA2*, *CDK4*, *TSPAN31*, *WIF1*, and *YEATS4*. mRNA overexpression was correlated with genomic amplification. A second amplicon originating from 10p11-14 was also present in the giant marker chromosome. The 10p amplicon contained 62 genes, including oncogenes such as *MLLT10*, previously described in chimeric fusion with *MLL* in leukemias, *NEBL*, and *BMI1*.

Introduction

Well-differentiated and dedifferentiated liposarcomas (WDLPS/DDLPS) are the most frequent sarcomas in adults [1–3]. Histologically, WDLPS are made up of mature adipocytes, atypical cells, and lipoblasts. They are considered as tumors of intermediate malignancy because they demonstrate a high rate of recurrence but rarely metastasize. When mature adipocytes are prominent within a WDLPS, the main differential diagnosis is deep-seated lipoma or intramuscular lipoma. In approximately 10 % of cases, a poorly differentiated component is present and the tumor is classified as DDLPS [3, 4]. Most often, the transition between well-differentiated and non-lipogenic areas is abrupt. Difficulties for diagnosing DDLPS arise when the poorly differentiated component predominates. The distinction between DDLPS and poorly differentiated tumors can be hard in such cases.

Molecular cytogenetic analyses are valuable ancillary tools for correct recognition of WDLPS and DDLPS. Indeed, both are characterized by the presence of giant marker or ring chromosomes, containing amplification of the 12q14-15 chromosomal region [5]. The amplified 12q14-15 region consistently contains the *MDM2* gene, located at 12q15, and co-amplification may involve several other genes, including *HMGA2* (12q14.3), *CDK4*, *SAS/TSPAN31* (12q14.1), *YEATS4* [6–8], *CPM* [9], and *FRS2* [10] (12q15).

During the last decade, genomic studies have consistently improved the characterization of WDLPS/DDLPS. However, many points still need to be clarified concerning the biology, pathogenesis, and clinical management of these tumors. First, the mechanism of generation of the large marker chromosomes containing the amplified regions remains obscure. Numerous chromosomal regions have been described to be variably co-amplified with the 12q14-15 amplicon [5, 6, 8, 9, 11–22]. Moreover, the marker chromosomes present unusual centromere alterations that suggest a peculiar way of formation [15, 23]. Second, while surgery with or without radiotherapy is the usual treatment for localized WDLPS/DDLPS, the therapeutic options for patients with advanced disease are very limited. The classical antimitotic treatments such as doxorubicin or ifosfamide show low response rates [24]. Therefore, there is an urgent need for novel targeted therapies against WDLPS/DDLPS. Several strategies such as those targeting P53 or the JUN/JUNK pathways are currently studied [20, 25]. However, the lack of model systems impairs the development of new treatments. Indeed, WDLPS/DDLPS are difficult to grow in vitro. Most primary cultures do not provide enough material for extensive genomic and pharmacological studies. To our knowledge, only a few human cell lines, such as LS141, DDLS [26], FU-DDLS-1 [27], LS14 [28], LPS695, LP6 [29], GOT3 [30], 93449, and 94778 [6, 15], have been described as arising from WDLPS/DDLPS. We report here the molecular and cytogenetic characterization of a novel WDLPS cell line designated 95T1000.

Materials and methods

Clinical information and histological analysis

A 43-year-old man without significant medical history presented in 1990 with a swollen thigh. The tumor was located within the adductor muscles. Histologically, the surgical specimen showed two components: a sclerosing WDLPS zone without any necrotic area or mitotic activity and a cellular dedifferentiated area containing short spindle cells organized in a cartwheel pattern. Tumor cells of the dedifferentiated area presented hyperchromatic irregular nuclei, with low mitotic activity. Zones of tumor necrosis were present. Transition between WDLPS and poorly differentiated zones was abrupt. The diagnosis was sclerosing WDLPS with dedifferentiated zones of grade II malignancy. The metastatic workup, including a chest computed tomography scan, was negative. Surgery was considered as R0 [31] and adjuvant radiotherapy (50 Gy) was delivered.

A local recurrence presented in October 1995. The tumor measured 14×7.5 cm and was macroscopically well-delineated. Histologically, the tumor presented the features of a sclerosing WDLPS without any necrotic area or mitotic activity (Fig. 1a). Preoperative radiotherapy (45 Gy) was delivered. Immunohistochemistry showed strong expression of MDM2 protein (Fig. 1b). A second grade I sclerosing WDLPS recurrence presented in October 1997. The diagnosis of sclerosing WDLPS was established according to the World Health Organization Classification of Tumors [1, 32].

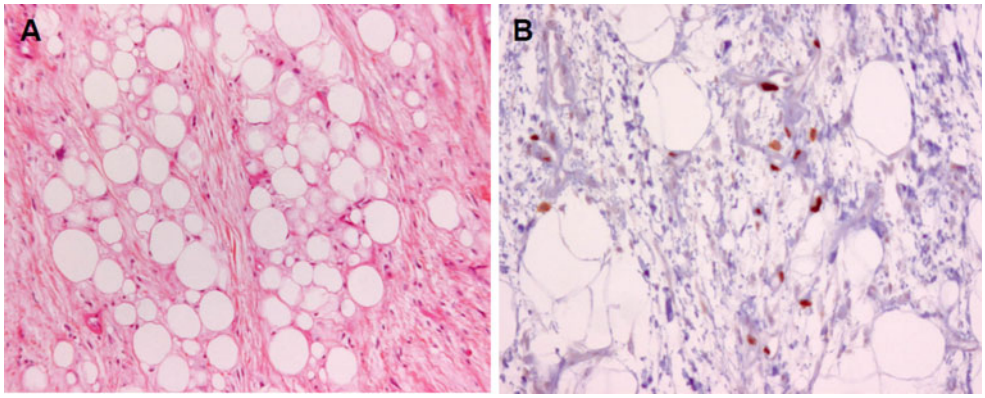

Fig. 1 Histological features and anti-MDM2 immunohistochemical staining of the 95T1000 well-differentiated liposarcoma. **a** Histological features of well-differentiated liposarcoma of the sclerosing subtype, characterized by adipocytic cells admixed with thick fibrous septa containing spindle cells with nuclear atypia (haematoxylin–eosin, magnification ×100). **b** Strong nuclear imunohistochemical staining of spindle cells with anti-MDM2 antibody (magnification ×200)

Establishment of the cell line and molecular cytogenetic analysis

Fresh tumor material from the first recurrence in 1995 was reserved for cell culture and cytogenetic analysis following surgical excision. Tumor tissue was disaggregated and cells from short-term cultures (10 days) were used for metaphase chromosome preparations according to established procedures [33]. Meanwhile, tumor cells were maintained in culture in RPMI 1640 medium (Gibco BRL, Life Technologies, Grand Island, NY, USA) supplemented with 10 % fetal calf serum (Gibco). Karyotype analyses of the 95T1000 cells were performed at passages 4, 10, 12, 31, 34, 54, 59, 60, 61, 69, and 80 (P80). Metaphase cells were analyzed by reverse banding using heat and Giemsa (RHG).

Spectral karyotyping (SKY) was performed on metaphases from P80 according to the manufacturer's instructions (Applied Spectral Imaging, Carlsbad, CA, USA) and as previously published [34, 35]. Fluorescence in situ hybridization (FISH) analyses were performed on metaphase and interphase cells. The FISH probes used for our study are listed in Table 1. Bacterial artificial chromosomes (BAC) clones from the Roswell Park Cancer Institute library were selected according to their location in the University of California Santa Cruz genome browser (http://genome.ucsc.edu/) and obtained from the Children's Hospital Oakland Research Institute (http://bacpac.chori.org/). Microscopic analysis was performed using a DM6000B microscope (Leica Microsystems, Wetzlar, Germany). FISH images were processed using the ISIS software (MetaSystems, Altussheim, Germany). Whole chromosome painting (WCP) probes and pan-alpha satellite probes were used according to supplier's recommendations (MetaSystems, Altussheim, Germany and QBIOgene, Illkirch, France, respectively). Preliminary FISH data using 12q probes have been published in Italiano et al. (case #16) [6].

Array-comparative genomic hybridization analyses

DNA was extracted using Qiagen Blood and Tissue DNeasy Kit (Doncaster, Victoria, Australia) following the manufacturer's instructions. Array-comparative genomic hybridization (aCGH) analysis was performed on 95T1000 and normal female reference DNA (Promega, Madison, WI, USA) using Affymetrix 250K *Nsp1* SNP microarrays (nominal average resolution, 1–5 kb), according to manufacturer's instructions (Affimetrix, Santa Clara, CA, USA). Copy number analysis of the 250K *Nsp* data was initially processed using Affymetrix Genotyping Console (GTC3.0.1) and subsequently analyzed using the Partek suite of software (St. Louis, MO, USA) as previously described [36]. Copy number information was derived after normalizing to the control reference DNA, and chromosome gains and losses were expressed as estimated relative copy number (ECN). The Partek segmentation algorithm used a minimum of one feature per region, a P value threshold of <0.00001, a signal-to-noise ratio of 0.3, and an expected range of 0.3 (Table S1).

Real-time quantitative RT-PCR

Real-time quantitative RT-PCR (qRT-PCR) was used to determine the expression levels of *GLI1*, *DDIT3*, *CDK4*, *TSPAN31*, *MDM2*, *YEATS4*, *WIF1*, *HMGA2*, *CDKN2A (p16INK4a* and *p14ARF)*, *CCND1*, and *RB1*. Total RNA was extracted from the 95T1000 cells (P57) and from short-term cultures of normal adipose tissue using

Trizol™ (Invitrogen, Carlsbad, CA) according to the manufacturer's protocol. The RNA samples were treated with DNA-free™ (Applied Biosystems, Foster City, CA). The quality of RNA was evaluated using the 2100 BioAnalyser and RNA 6000 Nano Kit (Agilent Technologies, Santa Clara, CA). One microgram of total RNA was reverse-transcribed into cDNA using the High Capacity cDNA Reverse Transcription Kit (Applied Biosystems). Each quantitative PCR (Q-PCR) experiment was performed twice using either fluorescein amidite dye for *MDM2*, *CDK4*, *DDIT3*, *YEATS4*, *HMGA2* (exons 1–2), *HMGA2* (exons 3–4), *HMGA2* (exons 4–5), *TSPAN31*, *GLI1*, *WIF1*, *p14ARF*, *CCND1*, *RB1*, or SYBRGreen dye for *p16INK4a* according to the manufacturer's protocols (ABI PRISM 7500 Detection System, Applied Biosystems). *RPLP0* was used as endogenous control for normalization [37]. qRT-PCR was performed using the TaqMan gene expression assays (Applied Biosystems) (Table S2) as described in Italiano et al. [6]. The primers used for SYBRGreen experiments are described in Supplementary Table S3. The comparative threshold cycle method was used to achieve relative quantification of gene expression [6].

Results

Conventional and spectral karyotype: hypertriploid genome containing giant marker chromosomes

Cytogenetic analysis of the primary culture of the 95T1000 WDLPS showed a near-diploid karyotype. The number of chromosomes ranged from 45 to 49 after 10 days of culture. One or two giant marker chromosomes were observed in metaphase cells (Fig. 2a). Several structural abnormalities that were not identifiable by conventional banding techniques were also observed. At P80, the karyotype was hypertriploid; the number of chromosomes ranged from 62 to 89, with a modal number of 79. We observed one or two giant marker chromosomes apparently similar to those observed in the primary culture. In addition, several structural and numerical abnormalities were observed (Fig. 2b). These anomalies were too complex to be correctly interpreted by means of conventional cytogenetics and were characterized by SKY analysis that showed a variety of clonal and non-clonal aberrations (Fig. 2c). Both intra- and inter-chromosomal anomalies were observed. The extremities of

the giant markers had variable origins: they were most frequently composed of sequences from chromosome 14 and intermittently from chromosomes 1, 5, 6, and 11 (Fig. 2d and Table S4). The SKY method was not appropriate to identify the central region of the giant markers because the dyes were too closely intermixed for providing an interpretable pattern. The co-amplification of sequences from chromosomes 10 and 12 that constitutes the core of these giant markers was eventually identified by aCGH and complementary FISH analyses (see below).

Among abnormally sized chromosomes apparently composed of unique chromosome material, aberrant chromosomes 1, 2, 3, 4, 7, 10, 11, 12, 13, 16, 18, 20, 21, and 22 were frequently observed. In addition to the marker chromosomes with 10p-12q amplification mentioned above, 15 recurrent derivative chromosomes showing inter-chromosomal rearrangements were identified (Table 2 and Fig. S1). The derivative chromosomes A, F, H, J, and O were sometimes duplicated. Most derivative chromosomes were made up of two to three different chromosomes while the derivative B and C resulted from more complex rearrangements. Evidence for chromosomal instability was suggested by the heterogeneous presence of various derivative chromosomes within the different metaphase cells analyzed (Table 2), as well as variation in the number of giant markers (Table S4).

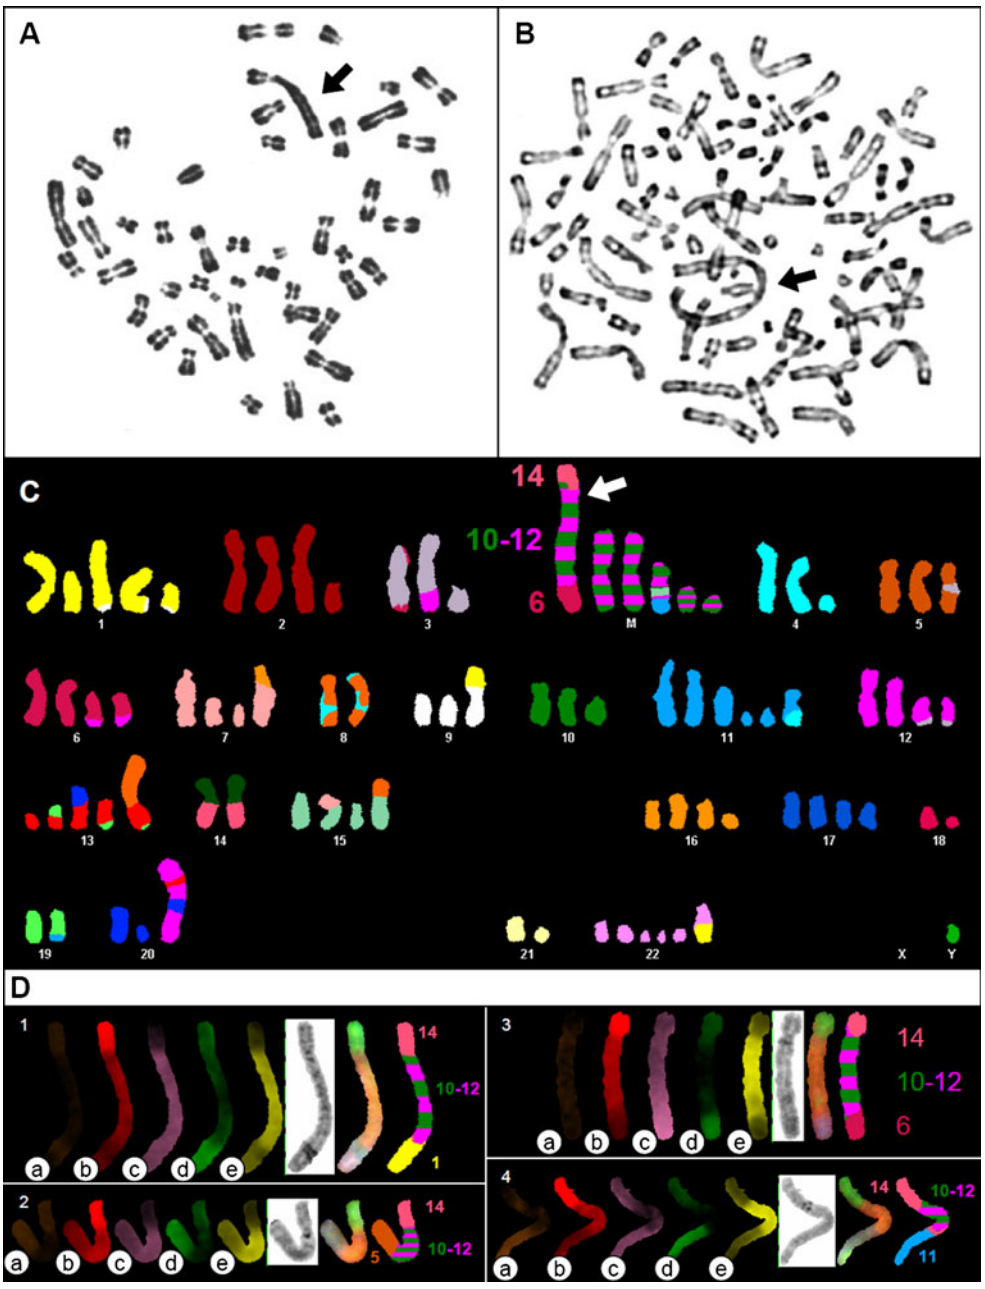

Fig. 2 Chromosomal analysis. **a** Representative RHG-banded near-diploid metaphase cell of the primary culture containing 47 chromosomes. The *arrow* indicates the supernumerary giant marker. **b** Representative RHG-banded metaphase cell at passage 80 (P80) containing 83 chromosomes including the giant marker chromosome (*arrow*). **c** False-colored SKY of a hypertriploid metaphase cell at P80. Complex numerical and structural abnormalities are observed. The *arrow* indicates the giant marker. The zebra pattern is deduced from complementary FISH analysis with whole chromosome painting and locus-specific probes and corresponds to co-amplified sequences from chromosomes 10 and 12. This co-amplification was also observed on additional marker chromosomes (*M*). **d** Individual dye spectra, inverted DAPI, SKY spectrum, and SKY false color of representative large markers selected from four metaphase cells (D1 to D4) (out of the ten metaphase cells analyzed). Each dye spectrum is identified by a lower case letter: *a*, *b*, *c*, *d*, and *e*

Amplification of 10p and 12q detected by array-comparative genomic hybridization

The detailed aCGH profile of losses, gains, and amplifications was identified across the genome (Fig. 3a and Supplementary Table S1). The most significant imbalances were represented by high-level amplification of chromosomes 10 and 12 (ECN higher than 10). The 10p-amplified regions spanned approximately 27 Mb from 10p14 to 10p11.21 and were composed of four distinct amplicons: a large one of 5.4 Mb from 10p14 to 10p12.2, two small ones (10p12.1/0.8 and 10p11.22/1 Mb), and an isolated focal amplification (31 ECN) of 0.2 Mb at 10p11.21 (Fig. 3b). A total of 45 segments showing various levels of gain and amplification (from 6 to 55 ECN) and sizes (from 30 kb to 0.7 Mb; average, 0.5 Mb) were identified (Table 3). Overall, these segments included 62 amplified genes.

The amplified regions from the long arm of chromosome 12 spanned 82 Mb from 12q12 to 12q24.21 (Fig. 3c) and consisted of 67 independent amplified segments; the size of which ranged from 70 kb to 2.4 Mb (average, 0.4 Mb; total size, 27.8 Mb). The ECN ranged from 3 to 57 (average, 18) (Table 3). Overall, these segments contained 370 amplified genes including *CDK4*, *TSPAN31* (12q14.1), *GNS*, *WIF1*, *HMGA2* (12q14.3), *MDM2*, *CPM YEATS4*, and *FRS2* (12q15). In contrast, *GLI1* and *DDIT3* (12q13.3) were not amplified (Fig. 3c).

No losses were observed except for a 1.3-Mb segment at 20p13 and a 3.4-Mb segment at 20q13.32-q13.33. On the proximal side of the 20q13-deleted segment, a moderate gain (4 ECN) of 16 Mb was observed. Chromosomes 4, 13, and 17 showed similar profiles characterized by moderate gain of long segments (from 3 to 7 ECN) across the full chromosome length (Table 3, S1).

Comprehensive structural analysis of amplified 10p and 12q segments within the giant marker chromosomes

The 10p- and 12q-amplified sequences were colocated and intermixed in the central region of the giant marker chromosome as well as in a few other marker chromosomes (B, C, G, J, and O) as shown by FISH analysis with WCP 10 and 12 probes as well as several locus-specific probes, such as RP11-150J3 (*FRMD4A*; 10p13), RP11-177H22 (*MLLT10*; 10p12.31), RP11-269B1 (*NEBL*; 10p12.31), and *MDM2* (12q15) (Fig. 4). Discontinuities in the 10p- and 12q-amplified regions were detected by shifts of amplification levels nearby or within several genes: for instance, BAC clone RP11-34I5 (10p12.31) that contained the 3′ region of *NEBL* did not show an amplified signal in contrast to the high amplification detected for clone RP11-269B1 that contained most part of the *NEBL* gene. A structural rearrangement was also detected in the vicinity of

+ and ++ : one (+) or two (++) derivative chromosome/cell

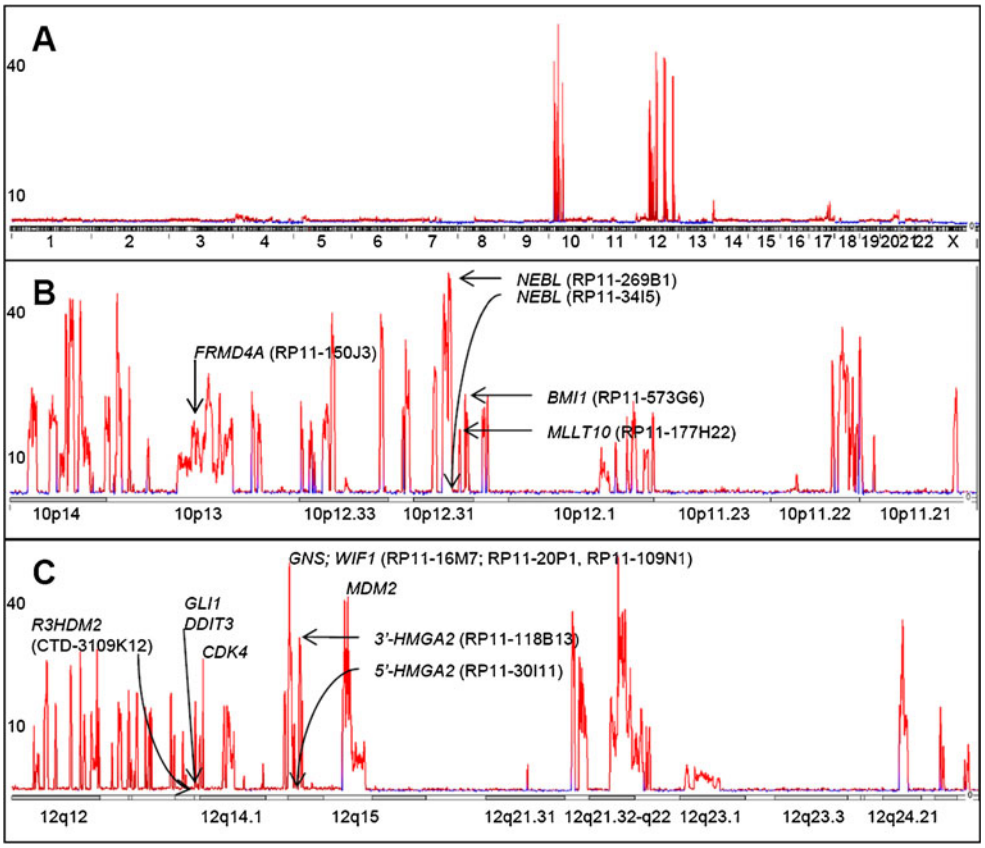

Fig. 3 aCGH profile. **a** Genome-wide copy number alterations in 95T1000 cells. The *x*-axis represents chromosome 1 to chromosome X and from pter to qter. The ECN is on the *y*-axis. The color gradient from *blue* to *red* corresponds to an ECN of 2 (*blue*) to high level of amplification (*red*). Discreet regions of gain are observed on chromosomes 4, 13, 17, and 20 and loss on chromosome 20. Large amplicons and multiple focal amplifications are observed on chromosome 10 p (**b**) and 12 q (**c**). Key genes and loci for which FISH had been performed are noted

HMGA2: while probes containing exons 1 to 5 (RP11-299L9, RP11-23C9, and CTC-782I9) and the telomeric side of the 3′ extremity of *HMGA2* (RP11-118B13) showed highly amplified signals, only a few gained copies were observed with RP11-30I11 probe, located on the centromeric side of the 5′ extremity of *HMGA2* (Fig. 4f). In addition, it is noteworthy that the giant marker did not contain any alpha-satellite sequences, suggesting the presence of an analphoid neocentromere (not shown).

Secondary chromosomal anomalies: complementary FISH analyses

The centromeric probes for chromosomes 3, 7, 9, and 17 showed a signal pattern consistent with the hypertriploid karyotype (Table 1). Four copies of each were identified on normal and abnormal chromosomes, respectively. The probes for chromosome 9 showed not only a pattern consistent with hypertriploidy, but also the presence of structural rearrangements. The *CDKN2A* locus (9p21) was disomic,

Table 3 Characteristics of the chromosome segmental gains/amplifications identified by array-comparative genomic hybridization

Chromosomes	Number of segment(s)	Minimum SL/ECN	Maximum SL/ECN	Average SL/ECN	Amplicon's total length (Mb)	Total size (Mb)
Gains						
4p16.3-q27	8	0.4 Mb/3	20.7 Mb/3	6.2 Mb/3	50	139
13q12.11-q34	4	0.1 Mb/3	3.2 Mb/7	1.6 Mb/6	6.6	96

SL segment length, *ECN* estimated relative copy number

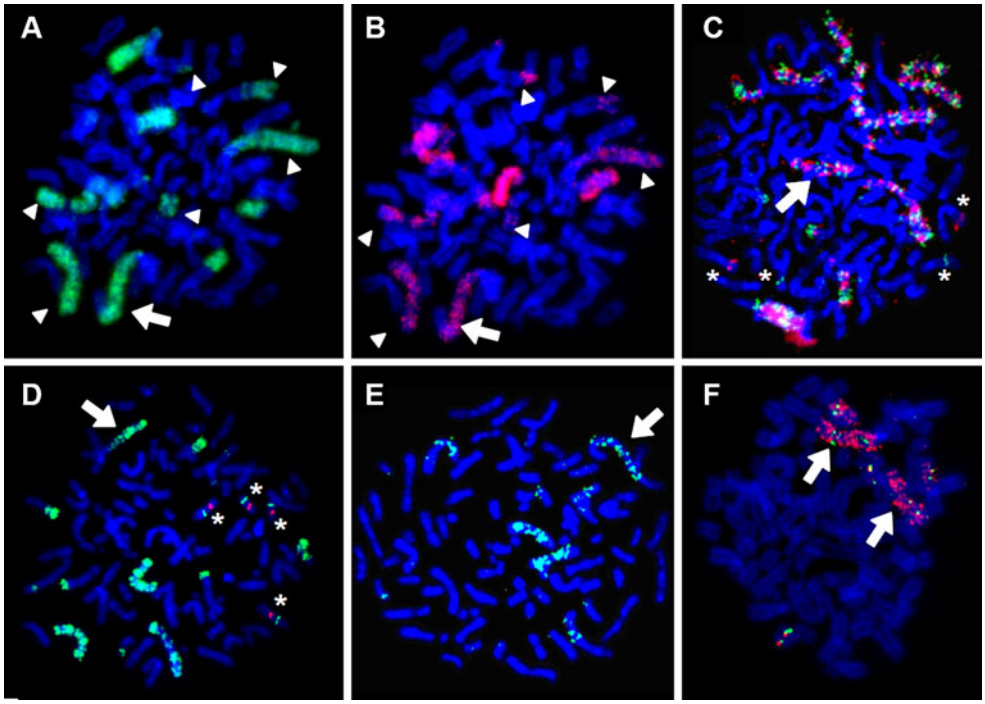

Fig. 4 Characterization of chromosomal imbalances and structural rearrangements by FISH on 95T1000 metaphase cells at passage P80. **a**–**c** Co-amplification of chromosome 10 and 12 regions. Co-localization of both *green* and *red* signals on the central region of the giant marker (*arrow*), as well as several other marker chromosomes (*arrowheads*), using WCP probes for chromosome 10 (**a**) and 12 (**b**). Co-amplification of the *MDM2* (*green*) and RP11-269B1 (*NEBL* 10p12.31) probes (*red*) on the giant marker (*arrow*) and on several other marker chromosomes (**c**). Apparently normal chromosomes 12 and 10 were also identified (*asterisk*). **d** High amplification of *MDM2* (*green signals*) located on one giant marker (*arrow*) and several marker chromosomes. Four apparently normal chromosomes 12 (*asterisk*) identified by centromere 12 (*red signals*) and *MDM2* at their expected position were also observed. **e** Hybridization with the RP11-177H22 probe containing *MLLT10* (10p12.31) shows a high level of amplification on the giant marker (*arrow*) and several marker chromosomes. **f** Hybridization with the dual-colored probes that flanks the 5′ (RP11-30I11-green) and 3′ (RP11-118B13-red) regions of *HMGA2*. High-level amplification of the 3′ region of *HMGA2* on the giant marker and marker chromosomes is observed. In contrast, the 5′ region is not amplified

indicating a relative loss of the 9p21 region since four chromosome 9 centromeres were observed. This loss was not detected by aCGH analysis, presumably because of a low statistical significance value related with the polyploidy of the specimen (Table S1). *MAP3K5* (*ASK1*) (6q23.3) and *JUN* (1p32.1) loci showed no imbalance, in concordance with the aCGH results (Table 1, S1). The *CCND1* gene was duplicated on abnormal derivative chromosomes 11. The interstitial gains of chromosome 13 long arm detected by aCGH were confirmed by FISH analysis, which showed two to six signals per cell for the CTD-2328A22 probe (13q34), while more than ten signals were observed with the RP11-313L9 probe (13q33.3-13q34) (not shown).

qRT-PCR

We have detected strong overexpression of the following genes: *MDM2*, *CDK4*, *YEATS4*, *HMGA2*, *TSPAN31*, and *WIF1* and no overexpression of *GLI1* and *DDIT3* (Table 4). Among the overexpressed genes from 12q region, *WIF1* showed the highest fold change (1,733, in comparison to normal adipose tissue). All the five exons of *HMGA2* showed overexpression (fold change values, 317 for exons 1 and 2 and 65 for exons 3 to 5, respectively). Genes of the RB1 pathway, such as *CCND1*, *CDK4*, *CDKN2A* (*p14ARF* and *p16INK4a*), were overexpressed, whereas *RB1* was not.

Discussion

We describe a novel WDLPS cell line designated 95T1000. This cell line was established spontaneously from primary cultures of a recurring sclerosing WDLPS and contained high-level amplification of the 12q14-15 region located on supernumerary giant marker chromosomes. The patient had received adjuvant radiotherapy following the excision of the primary liposarcoma and also a preoperative dose of 45 Gy prior to the excision of the first recurrent tumor that was used for establishing the cell line. This first recurrence did not present the features of a radiation-induced liposarcoma, since it was histologically similar to the primary tumor and with a near diploid karyotype, including the characteristic

Table 4 Real-time quantitative RT-PCR

Gene (exon)	Genomic locus	Fold change[a]
p14ARF	9p21.3	5.5
p16INK4a	9p21.3	22
TSPAN31	11p15.5	42
CCND1	11q13.2	5
DDIT3	12q13.3	2.5
GLI-1	12q13.3	0.6
CDK4	12q14.1	39
HMGA2 (1–2)	12q14.3	317
HMGA2 (3–4)	12q14.3	64
HMGA2 (4–5)	12q14.3	66
WIF1	12q14.3	1,733
MDM2	12q15	48
YEATS4	12q15	83
RB1	13q14.2	1.2

[a] Values from normal adipose tissue are used as reference

giant markers containing 12q14-15 amplification. It is possible that radiation contributed to the occurrence of several clonal and non-clonal chromosomal alterations seen in addition to the large markers. The giant marker chromosomes were retained along the subcultures and were still present after more than 80 passages.

The 12q14-15 amplification is fully characteristic of WDLPS/DDLPS. It constitutes the genetic hallmark of this group of tumors [5, 9, 10, 13–16, 21, 22, 26, 29, 30, 38–41]. Consequently, detection of 12q amplified genes is widely used for distinguishing WDLPS/DDLPS from other tumors. This detection can be done by FISH [15], Q-PCR [42], or aCGH [4] and indirectly by immunohistochemistry [43, 44]. *MDM2* has early been identified as the main driver gene of the WDLPS/DDLPS amplicon since it is consistently amplified in all cases of WDLPS and DDLPS [10, 43, 45, 46]. The overexpression of MDM2 protein generated by the genomic amplification inactivates TP53. Indeed, MDM2 targets TP53 degradation toward the proteasome and inhibits its P53-mediated transactivation [47]. Pharmaceutical compounds, such as nutlin, are currently being tested for the purpose of blocking the P53 inactivation mediated by MDM2 [48].

Despite its obvious major contribution, the amplification of *MDM2* does not seem to be sufficient by itself to account for the pathogenesis of WDLPS/DDLPS. Other genes from the 12q14-15 region are co-amplified and co-expressed with *MDM2* [7, 10, 49–51]. Similarly, a number of previously described WDLPS/DDLPS cases have identified giant marker chromosomes of comparable size to that in the 95T1000 cell line that also contained amplification of *CDK4* and *HMGA2*. *CDK4* is not consistently amplified in WDLPS/DDLPS. It is amplified only in approximately 85 % of cases [1, 6, 7, 10, 30]. The absence of *CDK4* amplification in WDLPS has been correlated to low-grade lipoma-like tumors of peripheral location and a better outcome [7]. In the present case, although the primary tumor was located peripherally, it had a high potential of recurrence that might be related to *CDK4* amplification and overexpression.

We observed amplification of the 5 exons as well as the 3′ region of *HMGA2* and this amplification resulted in the overexpression of the whole gene. It is noteworthy that the region immediately proximal to the 5′ part of *HMGA2* was not amplified (Fig. 4f). Structural rearrangements of *HMGA2* have initially been described in lipomas where they often consist in breakage within the third intron followed by fusion with various partner genes [52–54]. It was later shown that anomalies of *HMGA2* were not confined to benign adipose tumors since *HMGA2* was recurrently amplified, rearranged, and overexpressed in WDLPS/DDLPS [6, 55–59]. Although various ectopic sequences can be fused to *HMGA2* in WDLPS [56], it does not appear that bona fide fusion genes are present in WDLPS as they often are in lipomas. However, it has been shown that in lipomas as well as in other tumors, overexpression of *HMGA2* is not always generated by fusion genes [60–63]. The overexpression of *HMGA2* is a feature shared by both lipomas and WDLPS, though resulting from distinct events. The exact underlying mechanisms of dysregulation that makes *HMGA2* a central gene in differentiated adipose tumors still remain to be elucidated.

Overall, the size of the 95T1000 12q amplicon was large, comprising 370 genes. This is more than twice the number of amplified 12q genes found in the WDLPS cell line described by Persson et al. [30], but similar to the number observed in 93T449 and 94T778 WDLPS cell lines [23; D.M. Thomas, personal communication]. Among these amplified genes, we have found amplification of *TSPAN31*, *GNS*, *WIF1*, *CPM*, *YEATS4*, and *FRS2* as recurrently described in WDLPS/DDLPS [6, 7, 10, 30].

In addition to the amplification of 12q genes, we have found a high-level amplification of the 10p chromosomal region. The finding of co-amplification of at least one chromosomal region other than 12q14-15 [5, 6, 8, 9, 12–14, 16–22] is a recurrent feature of WDLPS/DDLPS. These "extra-12q14-15" co-amplified regions are variable among patients. The most frequent and most studied are 6q23, 1p32, and 1q23-24. While the amplification of *MAP3K5* at 6q23 and *JUN* at 1p32 has been correlated to the presence of a poorly differentiated component [17, 22, 29, 40, 41], the significance and role of other genomic regions that are co-amplified with 12q14-15 are not elucidated. We have emitted the hypothesis these co-amplified regions might provide

neocentromeric sequences to the giant markers that lack alpha-satellite sequences [15, 23]. The 1q23-24 amplicon [30, 56] has been recently suggested to be associated more frequently with WDLPS/DDLPS lacking *CDK4* amplification [7, 64]. The 10p11-14 region is rarely co-amplified with 12q in WDLPS/DDLPS, only a handful of cases have been described [22, 65]. In the 95T1000 cells, the 10p amplicon contained 62 genes. It was smaller than the 12q amplicon (27 Mb) but reached similar ECN. It also displayed a discontinuous pattern. Among the amplified genes, several of them are of interest because of their oncogenic functions. In particular, we found amplification of the oncogene *MLLT10*. This gene, previously called *AF10* encodes a transcription factor and is a fusion partner of *MLL* in acute leukemias with t(10;11)(p12;q23) [66, 67]. It has also been described to fuse with *PICALM* (11q14.2) in various hematologic malignancies, including acute lymphoblastic and myeloblastic leukemias and diffuse histiocytic lymphomas. In addition, *MLLT10* is a susceptibility locus for meningioma [68]. The *NEBL* gene that codes for nebulette protein highly expressed in cardiac muscle [69] is also amplified in 95T1000 cells. This gene is located closely nearby *MLLT10* and has also been described to be a fusion partner of *MLL* in a case of infant leukemia [70].

Another interesting oncogene contained in the 10p amplicon was *BMI1*. It encodes a polycomb-group protein involved in a multiprotein complex that represses the transcription of developmental genes, such as *Hox* genes. *BMI1* is required for proliferation of both normal and leukemic stem cells [71]. It is expressed in a variety of malignancies such as lymphoma, leukemia, carcinoma, medulloblastoma, as well as glioblastoma and has been shown to be moderately amplified in some cases of mantle cell lymphoma and gained in gliomas [72].

In conclusion, we describe here the genetic features of a novel WDLPS cell line characterized by typical 12q amplification. We provide a comprehensive description of the chromosomal anomalies present in these cells by using a panel of molecular cytogenetics methods. Notably, this cell line harbors an original amplification of the 10p11-14 region. Future studies on genes contained within this region will hopefully shed light on the pathogenesis of WDLPS.

Acknowledgments The authors are grateful to Association pour la Recherche sur le Cancer (ARC 4080 to FP), Institut National du Cancer (projet libre (GENOSTT), and Cancéropôle Provence Alpes Côte d'Azur and Conseil Régional Provence Alpes Côte d'Azur. DMT is the recipient of a Victorian Cancer Agency Clinician Researcher Fellowship.

Conflict of interest We declare that we have no conflict of interest.

Abstract Tissue banks constitute decisive and rate-limiting resource and technology platforms for basic and translational biomedical research, notably in the area of cancer. Thus, it is essential to plan and structure tissue banking and allocate resources according to research needs, but essential requirements are still incompletely defined. The tissue bank of the National Center of Tumor Diseases Heidelberg (NCT) was founded with the intention to provide tissues of optimal quality and to prioritize the realization of research projects. We analysed its structure and prospective project management registration as well as tracking records for all projects of the NCT tissue bank as of its start in 2005 in order to obtain information that may be relevant for tissue bank planning. All project proposals submitted to the NCT tissue bank (n=681) were included in the study. For a detailed evaluation of provided services, only projects that were completed until July 2011 (n=605) were analysed. For these 605 projects, NCT tissue bank provided 769 specific services. In all projects/services, we recorded project leader, type and amount of material provided, type of research (basic/translational), work load of project and project completion. Furthermore, all completed projects were tracked after 90 days according to a standard protocol to determine principal investigators' (PI) satisfaction and quality of the provided material. Until July 2011, 605 projects had been successfully completed as documented by material transfer agreement. Of the projects, 72.7 % addressed basic research, 22.3 % were translational research projects and 3 % concerned epidemiological research; 91 % (n=546) concerned a single PI and the NTC tissue bank. For these projects, 769 specific services were provided. Of these services, 288 concerned providing formalin-fixed and paraffin-embedded (FFPE) tissue (extracts, full size sections), 126 providing fresh frozen materials (including fresh frozen sections), 137 providing tissue microarray (TMA)-based sections and 199 providing immunohistochemical services. Project tracking demonstrated that all projects had started within 90 days after reception of the material by the PIs, and PI satisfaction with provided material exceeded 97 %. Standardized registration and tracking provides valuable structural information for planning and financing of tissue banks and allocation of resources. The high number of completed projects as well as high user satisfaction demonstrates that structuring of tissue banks should be preferably research-oriented and highly efficient. The comparable number of requests for FFPE and fresh frozen tissue as well as TMA-based services underpins the need for a broad approach in terms of methods and material types in order to fulfil research needs.

Introduction

Access to quality-assured and comprehensive biomaterial, especially human tissue samples, represents an essential resource for basic and translational biomedical research and its translation into clinical application [1–4]. Structured tissue banks fulfil essential tasks in guaranteeing good scientific practice in handling and evaluation of human tissues. Therefore, they are a decisive but also limiting resource. Thus, it is essential to plan and structure tissue banking and allocate resources according to research needs, but to date little is known about the actual requirements research tissue banks [5] are facing.

Many recommendations exist about organizational aspects of research biobanks or regarding ethical and legal aspects [6, 7]. Little is known about the necessary resource allocation for research biobanks, the infrastructural and/or organizational requirements including workflow and time lines in tissue bank procedures. Reported information and experience has been derived from biobanks with a low number of projects or refer to single projects [5, 8–10], and therefore useful information about large size respective research tissue biobanks are missing.

The tissue bank of the National Centre for Tumor Diseases (NCT) in Heidelberg, Germany, was founded in 2005 by the University of Heidelberg Medical School and the German Cancer Research Centre (DKFZ) as a section of the NCT [2]. It is a non-profit research tissue bank with a completely evaluated legal, ethical and data protection framework and represents an integral part of the Comprehensive Cancer Centre concept [2]. The NCT tissue bank has installed comprehensive quality management with all procedures documented in a complete quality management handbook and is the first fully accredited (DAkkS, DIN/ISO 17020) research tissue bank [11]. Its main aims are the acquisition, characterization and handling of fresh-frozen and paraffin-embedded human tissues (FFPE) solely for research purposes, the preparation of tissue specimen derivatives, while respecting and promoting good scientific practice and interdisciplinary tumor research of the Heidelberg research community/NCT and its cooperating partners. Since May 2005, the NCT tissue bank has stored fresh frozen tissue samples of more than 20,000 patients and provided access to more than one million FFPE tissue samples. Furthermore, the NCT tissue bank has produced 67 different entity-specific or epidemiological trial-related tissue micro-arrays (TMAs) covering a broad spectrum of neoplastic diseases and corresponding tumor-free tissues. As yet, the NCT tissue bank has supported more than 680 different research projects. In the context of these research projects, more than 769 specific services were provided.

Because of the high number and non-selected type of projects, the standardized project management and the clear separation from clinical diagnostic issues, the NCT tissue bank represents an ideal model of a comprehensive, single-location research tissue bank. In order to generate relevant basic structural information that may support tissue bank planning, implementation, operation and long-term sustainability/financing, we analysed the comprehensive prospective standardized registration and tracking records from all projects that the NCT tissue bank has supported.

We show that structured tissue bank project assessment is a necessary and relevant tool for tissue bank planning and allocation of resources. Our results demonstrate that research-oriented structures and regulation of a tissue bank can be highly efficient and are thus preferable. This is supported by the high project number and the high completion rates as well as the high user satisfaction rates. Furthermore, the important number of FFPE and fresh frozen tissue as well as TMA-based projects argues in favour of a broad spectrum platform approach of a tissue bank in order to fulfil research needs and to achieve maximum efficiency.

Materials and methods

All projects of the NCT tissue bank from its start in Spring 2005 until July 2011 were included in the analyses. The analyses were structured into two different aspects: (a) administrative aspects and (b) practical and scientific aspects.

The following administrative aspects were evaluated:

- Number of project requests to the NCT tissue bank, approved and rejected projects and number of complex projects that required detailed and specific evaluation by the scientific advisory board. A project was defined as a documented singular request for tissue, derivatives or specific analyses, or combinations of these, submitted by a named PI to the NCT tissue bank.
- Affiliation of applying PI.
- Types of research supported. Categories were: clinical and translational research, basic biomedical research and epidemiological research. Categorization of research type followed the mandatory and standardized project description that was provided by every researcher along with the project application. Research projects which were, e.g., biomarker or trial-associated projects were summarized in the category "clinical/translational research" and all research projects dealing, e.g., with functional or animal model-associated human research projects were summarized in the subgroup "basic research". The tissue bank also supports large-scale epidemiological trials; these associated projects were summarized in the subgroup "epidemiological research".
- Partners involved in application. Categories defined were: single applicant, more than one applicant, defined research networks and epidemiological trials.

- Number of projects completed by NCT tissue bank. Completion was defined as transfer of material to applicant and its documentation by countersigning of the material transfer agreement by the PI.

Regarding the practical and scientific aspects, all 769 services that were provided within the 605 projects were analysed. Because some projects generated different services, statistical analyses of the practical and scientific aspects were performed on all services. For example, some projects required FFPE slides and in a second step TMA sections, and in this case two different services were provided for one project and therefore separately evaluated.

The following services were provided by the NCT tissue bank: preparation of FFPE slides, fresh frozen tissue slides or TMA slides. Additionally, preparation of FFPE and fresh frozen tissue samples for extraction methods (e.g. DNA and RNA extraction) and immunohistochemical stains were provided as services. Last but not least, preparation of large scale tissue micro arrays was performed.

The following aspects of the services were evaluated:

- Type of tissue provided. Categories were: fresh frozen tissue, formalin-fixed and paraffin-embedded tissue, tissue-micro-array-slides.
- Type of service provided. Categories were: serial sections, immunohistochemistry, composition of TMAs and itemization of platform services (staff training, cooperations with, e.g., virtual microscopy).
- Project size categorized by number of samples employed: small [<10 samples/slides], medium [11–30 samples/slides] and large [>30 samples/ slides].
- Duration of projects. Categories were long term (>6 months) and short term (<6 months).
- Quality of provided service and satisfaction rate of PI as evaluated from standardized project tracking. To this end, the date of delivery was entered into the electronic calendar of the tissue bank on the day of material transfer. After 90 days, through an automatic reminder, the NCT tissue bank office sent a standard email to the respective PI or contacted him/her directly.

All presented data were submitted to continuous internal and external validation: Internal audits took place three times a year, and all project data were controlled twice annually by the board of the NCT tissue bank. Furthermore, all NCT tissue bank data were externally validated by DAkkS (Deutsche Akkreditierungsstelle) in the successful accreditation review in April 2009 and the external audit in February 2011. Additionally, the NCT tissue bank was twice successfully reviewed internationally as part of the review of the translational research area of the DKFZ in 2008 and 2011.

Results

Administrative aspects

In all, 697 project requests were submitted to the NCT tissue bank from May 2005 until July 2011 (Fig. 1).

Some requests (n=49) could not be decided upon directly by the NCT tissue bank according to its standing orders and therefore had to be reviewed by the advisory board of the NCT tissue bank, which is composed of representatives of all participating institutions of the NCT tissue bank. Of these requests, three were rejected after review by the advisory board for reasons of interference with clinical diagnostic necessities, incomplete project planning/incomplete preliminary work or lack of compliance to NCT tissue bank regulations by the PI. Overall, 13 project requests were withdrawn by the PIs after discussion of the project with the representatives of the NCT tissue bank.

Thus, 681 project requests were accepted and supported by the NCT tissue bank. From Spring 2005 until July 2011, 605 of the 681 supported projects were completed (Fig. 3). For some of the 605 projects, more than one specific service was provided. In total, 769 services emerged from the 605 projects. All 769 services were therefore considered for the evaluation of the practical and scientific aspects.

Regarding the type of research performed, of the 605 projects finished during the observation period, 440 projects (72.7 %) addressed basic biomedical research, 135 (22.3 %) were categorized as clinical and translational research, 21 (3 %) were associated with epidemiological trials (Fig. 2a) and nine (2 %) were others (e.g. re-evaluation of external tissue samples, staff training or virtual microscopy).

Affiliation of the researchers was as follows: In 456 (75 %) projects, researchers held working contracts with the Academic Hospital of the University Heidelberg. In 125 (21 %) projects, researchers were staff members of the DKFZ, a national research institution and 14 (2 %) projects were performed by researchers of the Thoracic Hospital

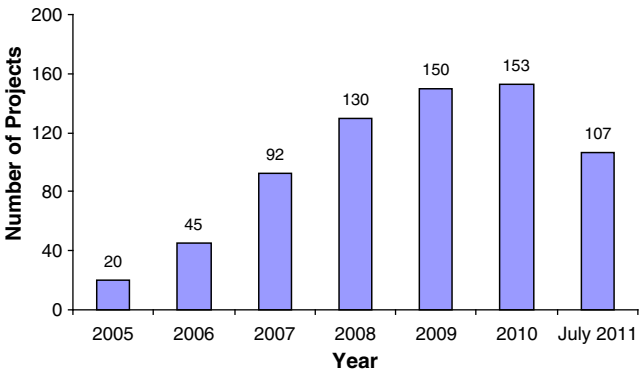

Fig. 1 Since May 2005 and July 2010 in total 697 project requests were sent to the NCT tissue bank

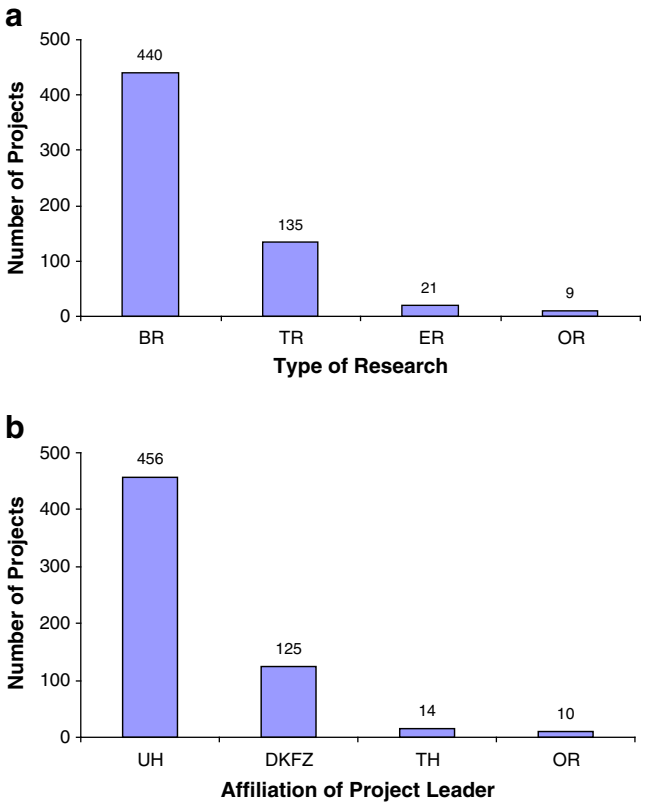

Fig. 2 **a** Type of supported research projects (n=605). TR = Translational and clinical research; BR = Basic biomedical research; ER = Epidemiological studies; OR = Others. **b** Affiliation of project leader (n=605). UH = University Hospital Heidelberg; DKFZ = German Cancer Research Center; TH = Thoracic Hospital Heidelberg; OR = Epidemiological studies

Heidelberg, a closely affiliated hospital. In ten (2 %) projects, the applicants were associated with large-scale epidemiological trials (e.g. ColoCare, DACHS, EPIC) (Fig. 2b).

Regarding the number of applying partners in a given project, 546 (90.2 %) of 605 research projects were single-applicant projects. These projects always consisted of a team of complementary histological and/or clinical partners (according to the standing order of the NCT tissue bank). For the other 9 % (n=56) of the projects, two or more applying cooperation partners were involved.

Practical and scientific aspects

A complete analysis of all 769 provided services that emerged from the 605 projects was performed for evaluation of the practical and scientific aspects.

In 414 services, either tissue samples of paraffin-embedded or fresh frozen tissue samples were requested. Samples of FFPE tissues were requested in 288 services; fresh frozen samples were requested in 126 services. In 137 services, slides of TMAs were requested. In 199 services, immunohistochemical staining was performed by the NCT tissue bank (Fig. 3). Other types of services, like re-evaluation of external tissue samples, staff training or virtual microscopy, were performed additionally in 19 of the 769 services.

Of the services using formalin-fixed and paraffin-embedded tissue samples (n=288), 238 services provided FFPE slides and 50 services provided whole samples or sections for RNA or DNA extraction procedures (Table 1). For all services using FFPE tissues, overall 8,268 blocks were used and 26,862 sections were prepared. On average, 112 sections were provided for each of the 238 FFPE slide projects. Grouping of the projects by effort resulted in the following numbers (Table 2): in 22 FFPE slide services (9.2 %) less than ten slides were provided, in 64 FFPE slide services (26.9 %) 11–30 slides were provided and in 152 services (63.9 %) more than 30 slides per service were provided.

By the 50 services which used FFPE tissue sections for extraction methods (RNA/DNA), in total 1,482 FFPE samples were provided and 2,350 tubes containing ten sections of 10 μm were prepared. The average number of tubes per service was 47.0 (for details, see Table 2).

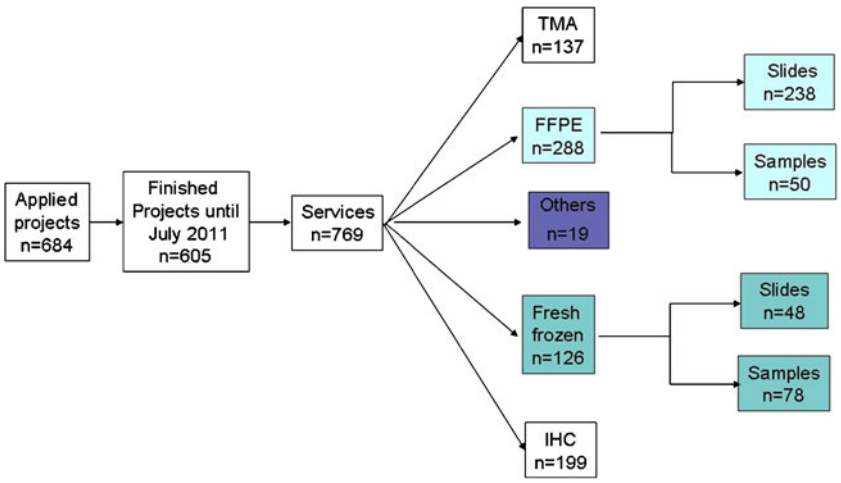

Fig. 3 In total since 2005 till July 2011 the tissue bank has supported 605 projects that generated 769 services. FFPE = Formalin fixed and paraffin embedded tissue; TMA = Tissue-Micro-Array; IHC = Immunohistochemistry

Table 1 Distribution of FFPE tissue and fresh frozen tissue services according to size

	Services (*n*)	Number/count, *n*	< 10	11 to 30	> 30
FFPE (*n*=288)	Samples	50	25	10	15
	Slides	238	22	64	152
Fresh frozen (*n*=126)	Samples	78	39	28	11
	Slides	48	5	18	25

Regarding the fresh frozen tissue sample services (*n*=126), 48 services provided fresh frozen tissue slides for histochemical and/or immunohistochemical analyses. A total of 78 services provided fresh frozen tissue sections for extraction methods (RNA/DNA) (Table 1). For the 48 fresh frozen tissue slide services, in total 264 different tissue probes were used and 2,407 sections were prepared. Thus, on average, 50 fresh frozen slides were provided per service. In detail (Table 3), for five fresh frozen slide services, less than ten slides were provided. For 18 services, 11–30 slides were provided and more than 30 slides per service were provided for 25 services. Looking at the 78 services where whole samples or sections were provided for extraction methods (RNA/DNA), in total 1,822 samples of fresh frozen samples were used. For 39 (50.0 %) services less than ten different fresh frozen samples were used, for 28 (35.9 %) services 11–30 were provided and for 11 (14.1 %) services more than 30 fresh frozen samples per service were provided (Table 3).

About one out of four project applications required TMA sections (*n*=137). In total, 3,056 TMA slides were handed out to researchers, resulting in an average of 22 TMA slides per service.

Furthermore, the NCT tissue bank also represents a technology platform that also provides specific biobanking-related technologies (e.g. virtual microscopy) for research purposes and under specific and limiting conditions operators in registered projects may also be trained in practical aspects of tissue processing (e.g. preparation of a TMA or cryo-sectioning). Therefore, for 19 services specific training of the researcher on tissue bank-based technologies concerning virtual microscopy were performed by the NCT tissue bank.

To qualify the duration of services provided by the NCT tissue bank, we defined long- and short-term services. Services exceeding 6 months in duration, e.g. TMAs for large-scale epidemiological trials or projects requiring large amounts of samples, were defined as long-term services. Services that were finished in less than 6 months were defined as short-term services. In total, 4.7 % services were rated as long-term and 95.3 % as short-term service.

Additionally, all projects supported by the NCT tissue bank were submitted to a standardized project tracking 90 days after the material was transferred to the PI to evaluate the quality of provided service and satisfaction of PI. Until July 2011, from the 605 projects, 412 projects had received their material more than 90 days earlier and therefore the query was sent to the responsible PI. Participation was voluntary and 382 PIs (92.7 %) replied, while 30 researchers (7.3 %) did not respond. A total of 374 responses revealed a positive feedback, six responses were negative, and in two projects the PIs stated that the material had quality limitations but was still useful for the specific analyses of the project**.** Thus, the satisfaction rate exceeded 97.9 % (Fig. 4).

Discussion

Access to quality-assured and comprehensive human tissue samples is essential for basic and translational molecular

Table 2 Description of FFPE slide services (*n*=238) subdivided upon the amount of provided slides and used samples and FFPE sample services (*n*=50) subdivided upon the amount of provided tubes and used samples

Size of FFPE slide service subdivided on slides performed/tubes provided	Services (*n*)	Total number performed slides/tubes	Mean performed slides/tubes	Total number used samples	Mean used samples
FFPE slide services (*n*=238) subdivided upon the amount of provided slides and used samples					
<10	22	170	7.73	100	4.55
11 bis 30	64	1,327	20.73	487	7.61
>30	152	25,365	166.88	7,681	50.53
Total	238	26,862	112.87	8,268	34.74
FFPE sample services (*n*=50) subdivided upon the amount of provided tubes and used samples					
<10	25	109	4.3	101	4.0
11 bis 30	10	186	18.6	154	15.4

Total	78					1,822	50.2

Description of fresh frozen tissue services (n=78) subdivided upon amount of provided samples

cancer research and its translation into clinical application [2–4, 12, 13]. Therefore, structured information about tissue banks, the requests they are facing and their performance is mandatory in order to base tissue bank planning, financing, organization and sustainability on rational data. This can be obtained only from comprehensive, long-standing and structured tissue banks that provide standardized project management and tracking. All these prerequisites are fulfilled from its start for more than 6 years by the NCT tissue bank; thus, we undertook the task to subject these information to a structured and comprehensive analysis. These analyses provided several relevant and, in part, surprising conclusions.

Human tissue for research, especially fresh frozen tissue, is a sparse and rate-limiting resource [14], and therefore adequate use of tissue should and can be enforced via structured project management [12, 15, 16]. Consequently, most of the effort in general focuses on the acquisition, handling and storage of frozen tissue. From its start onwards, the NCT tissue bank included FFPE tissues, their handling and derivatives (including the fabrication of TMAs) into its portfolio and project management. Interestingly, our analyses showed that, for about half of services, FFPE tissues sufficed and for one out of four services TMA sections were sufficient. Only the remaining quarter of projects needed fresh frozen tissue. Consequently, it is necessary to check projects/service applications in a qualitative manner by the tissue bank, whether services may be performed with, e.g., FFPE tissue or even TMAs instead of frozen tissue. Furthermore, this implies that tissue banks should have a broad base of resources and technologies to achieve the highest possible efficiency. As a consequence, tissues with different types of fixation method (e.g. FFPE and cryopreserved) should be accessible, and different types of tissue preparation methods, like sectioning, TMAs and extraction procedures, should be provided [9, 17]. Consequently, tissue banks should not only be managed as tissue resources but also as technology and even training platforms which offer state-of-the-art technology to generate, e.g., derivatives (TMAs, extracts) or analyse tissue data (e.g. digital image analysis) in order to assure qualified and rational use of the sparse human tissue resource [2]. These resources can be increased, for example, by cooperation with large-scale epidemiological studies, which sometimes offer the potential to collect large and well-annotated collectives in a less biased and prospective manner compared to hospital-based approaches. Finally, it points to another relevant role of tissue banks: they can play a central role even as project brokers: for example, human tissues can be further processed by tissue banks, e.g., by preparing TMAs; these TMAs may enable a broad research community to work with a comparably low amount of well-annotated tissues that are of identical quality and even allow correlative analyses between different projects.

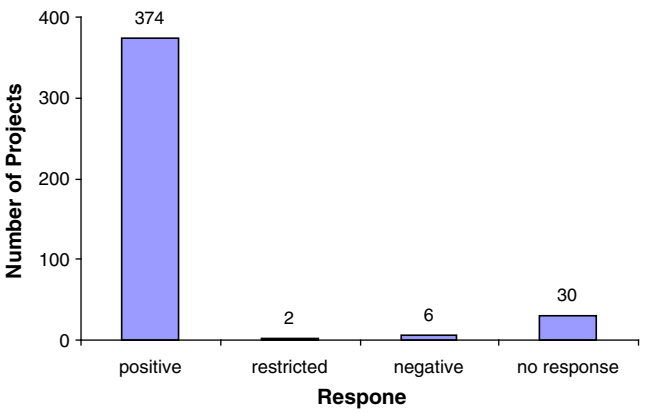

Fig. 4 Tracking request results after 90 days. In total the requests were sent to n=425 service projects

Quality aspects are central for all tissue banks as the quality of research results absolutely depends on the quality of the material used for analyses [16, 18]. To guarantee a consistent level of quality and good scientific practice, it is mandatory for research tissue banks to provide a quality management system [11, 14]. According to this, evaluation of tissue specimens by competent pathologists and a competent performance of tissue entry and exit controls and the reporting of the results is mandatory [3, 11, 19, 20]. In addition, a project-specific evaluation of tissue samples is necessary [14]. This is supported by the NCT tissue bank tracking results which revealed a high user satisfaction (>97 %) and indicated that structured entry and exit controls as well as project-specific processing are highly relevant for maximal efficiency. However, 7 % of project leaders did not respond to the tracking request. This is in part due to the fact that some of the researchers had participated in several projects but did not answer separately for every project or to the researcher having left the Heidelberg research community within the tracking period. Considering these aspects, we feel that the low non-responder rate does not pose a significant bias and does not invalidate our claim of a high satisfaction rate. These analyses are also evidence supporting that research-oriented structuring of tissue banks is highly efficient and superior to primary collection-oriented biobanking.

A regular standardized feedback or monitoring system has several other implications: as mentioned above, it can be used in a continuous manner to improve standard operating procedures that influence tissue/biomaterial quality. It is a valuable tool to discipline PI because it may be used to control whether the provided material has actually been used for the applied research project. Furthermore, data on standardized project tracking are important for the resource allocation of the individual tissue bank, e.g. regarding time efforts, finances and personnel. The NCT tissue bank data show that it takes more than 1–2 years for a tissue bank until it is well accepted within the local research community. Even after 6 years, project numbers of the NCT tissue bank are steadily increasing (see Fig. 1).

Networking of biobanks is a central topic in science politics as well as funding efforts especially when research projects involve many different locations or even different countries [5, 6, 21]. Reflecting the statistical analyses of the NCT tissue bank, however, it can be shown that the majority of projects (90 %) were performed between a single PI and the NCT tissue bank. This does not invalidate the notion of biobank networking and harmonization, but it should be kept in mind that local research projects are the predominant activity of a comprehensive research tissue bank.

The applicability of our analyses has several limitations; first of all, many different types of tissue banks exist worldwide. The NCT tissue bank is a good model for comprehensive, single-location biobanks for research purposes, which certainly represent a significant percentage of all tissue banks. The results of our analysis can be transferred in a modified manner to other academic and non-academic local tissue banks. Some aspects of NCT tissue bank analyses are helpful for constructing (meta-)tissue banks for research networks. For commercial/industry-driven tissue banks, comparable analyses should be performed.

In conclusion, standardized registration and tracking provides valuable structural information for planning and resources allocation (including financing) at the level of the individual tissue bank and for tissue banking in general. High project numbers and completion rates as well as a high user satisfaction rate demonstrate that research-oriented structuring of tissue banks is highly efficient and, in principle, preferable; significant numbers of paraffin and fresh frozen tissue as well as TMA-based projects argue in favour of a broad spectrum platform approach in order to fulfil research needs.

Conflict of interest We declare that we have no conflict of interest.

Abstract About 15 years ago, the Swiss Society of Pathology has developed and implemented a board examination in anatomical pathology. We describe herein the contents covered by this 2-day exam (autopsy pathology, cytology, histopathology, molecular pathology, and basic knowledge about mechanisms of disease) and its exact modalities, sketch a brief history of the exam, and finish with a concise discussion about the possible objectives and

putative benefits weighed against the hardship that it imposes on the candidates.

Keywords Board examination · Training · Anatomical pathology · Quality control

In 1996, the Swiss Society of Pathology (Schweizerische Gesellschaft für Pathologie, SGPath) definitely implemented a national examination to ensure the professional competence of its board members. This exam consists of a 2-day "tour de force" that covers all aspects of the professional activity of an anatomical pathologist. Only senior residents can apply for the exam by writing to the secretary of the president of the board committee, usually 6–12 months in advance, and usually dedicate most of their time to its preparation during their last year of residency. The examination takes place twice a year, sometimes even three times if the number of applicants largely exceeds the capacity of two sessions. Indeed, a maximum of six candidates can be accepted for each exam (seven in rare exceptional situations). The venue of the exam changes each time, according to a rotating system between academic pathology institutions (Basel, Bern, Geneva, Lausanne, and Zürich) and pathology departments in larger cantonal or city hospitals (Baden, Liestal, Lucerne, St. Gall, and Triemli Hospital, Zurich).

The main venue consists of a conference room with six tables on which the candidates find a diagnostic microscope as well as a collection of standard textbooks of diagnostic pathology which can be consulted freely during the slide sessions (Fig. 1). In addition, candidates are free to bring and use their own selection of textbooks for the diagnostic part of the exam, but on-line consultation of web sites is not allowed. In addition, a room with a multihead (three heads minimum) microscope has to be made available by the hosting institution for the discussion of slides between candidates and members of the exam committee. Finally, the institution that hosts the exam must assure that the candidates can examine the unfixed organs of a recent autopsy, usually in the autopsy suite (Fig. 2).

As a rule, the examination begins on a Thursday afternoon at one o'clock and ends the following day around four o'clock. Knowledge in cytopathology is first examined. For 1 hour, ten cases of gynecological and non-gynecological exfoliative and aspiration cytology are rotated between the candidates in such a way that each candidate has at least 4 minutes to examine each slide, with the possible option of reviewing selected slides once again if so wished. The best diagnosis must be chosen among five possible diagnoses in a multiple choice modus. The candidates are free to consult textbooks, just as they would do during their daily diagnostic activity. In addition, two free text questions about cytopathology have to be answered by the candidates, without the help of textbooks.

The second part of the examination covers autopsy pathology. For 3 hours, the candidates have to analyze and describe the pathological findings of three autopsy cases and formulate a final diagnostic conclusion that also integrates the pertinent clinical information. Two of the three autopsy cases are based on collections of slides (10–16 slides of the major organs), accompanied by a description of the macroscopic findings and relevant clinical information, including specific questions raised by the clinicians. For that purpose, all candidates receive one of six identical

Fig. 1 Candidates dispose of high-quality diagnostic microscopes and their proper sets of slides. The use of standard textbooks is permitted during the parts where slides are examined, but prohibited during the theoretical part with multiple choice and open questions (photo taken at the occasion of the exam in September 2011 in Lucerne, in the rooms of the Academy for Medical Training and Simulation)

Fig. 2 Autopsy exam: Candidates are asked to examine the fresh organs of a recent autopsy usually in the autopsy suite of the hosting institute and describe their macroscopic impressions, which are being transcribed by one of the examiners (photo taken at the occasion of the exam in September 2011 in Lucerne, autopsy suite of the Cantonal Institute of Pathology)

sets of slides. The third autopsy case is based on the examination of the fresh organs of a recent autopsy which are to be viewed in the local autopsy suite—along with a copy of the available clinical information and a list of specific questions to be addressed by the autopsy. For practical purposes, each of the six candidates is individually taken to the autopsy suite by two members of the exam committee. The candidate has 20 minutes to examine the organs and dictate his/her observations to one of the committee members (preferentially the one with the most readable handwriting!; Fig. 2) The candidate then returns to the examination room and writes up his/her observations, diagnoses, and final conclusions. For this part of the exam, textbooks can be freely used by the candidates. The autopsy exam terminates the first day of the examination.

The next morning starts at 8 o'clock with a 1 hour exam dedicated to macroscopic pathology. The candidates find a stack of 12 letter size high-quality color photos of "typical" macroscopic presentations of lesions in either surgical resection specimens or organs from autopsies. They have to identify the lesion, either by naming the pathological process/diagnosis (free text) or by selecting their best solution from a list of five possibilities (multiple choice). In addition, the candidates are asked to (a) draw on the illustration of the specimen in which regions they would select tissue blocks for the subsequent histological analysis and (b) indicate which auxiliary tests (i.e., special stains, immunohistochemistry, molecular pathology, other) they would like to perform in order to confirm, and/or to complement their diagnosis.

After a short pause follows a 3-hour period, during which candidates have to examine 24 histological slides and name the correct diagnosis. In the case that they are unable to come to a definite diagnosis, they have to list their differential diagnoses and state the approach they would choose to arrive at a final diagnosis (i.e., special stains, immunohistochemistry, molecular pathology, etc.). As for the cytopathology and the autopsy parts, candidates are free to use textbooks for this period, just as they would do during their daily diagnostic practice.

After the lunch break comes the theoretical part, in which 12 multiple choice and three of four free text questions have to be answered. This part of the exam is primarily intended to test the knowledge of the candidates in terms of pathophysiological concepts and novel techniques as they pertain to diagnostic anatomical pathology, but also in terms of scientific (for example: what do you have to consider when planning a biomarker study) and legal/ethical concepts (i.e., professional secret in clin–path conferences and research projects, use of human tissues for research and teaching, autopsy regulations, certification/accreditation of a diagnostic service, etc.). The candidates are asked to respond to at least three of the four free text questions, the fourth may be ignored. For this part of the examination, the use of textbooks is no longer permitted. This part of the exam also integrates an increasing number of questions related to concepts and techniques of molecular pathology.

The board examination comes to its end with a 15–30 minutes interview of each candidate separately with two members of the exam committee, around a multihead microscope. During this interview, the candidate gets a chance to review some of the cytology and histology slides that he/she had failed to correctly identify during the test, explain his/her initial line of reasoning, and propose a better solution. The members of the committee find this interview particularly helpful in getting a reliable feeling of the background knowledge of the candidates. As the distribution of points from the different parts of the exam shows (Table 1), it becomes apparent that this interview may be particularly helpful in all cases of "shaky" candidates, who have not been able, up to this point, to secure enough points in the preceding parts of the exam for a clear pass. It also gives the members of the committee quite a good idea of where the candidate stands in his/her formation, whether he/she has had so far missed out on certain aspects of his/her training (i.e., the cytology rotation), notions that will eventually help to arrive at a final

Table 1 Algorithm for point assignment for final "pass" score

Time	Test	Consisting of	Points per correct answer	Maximum
1 h	Cytology	10 slides, 2 questions	2 points per case/question	24 points
3 h[a]	Autopsy I	Autopsy, fresh organs	Case-specific distribution	16 points
	Autopsy II	Autopsy, slides	Case-specific distribution	16 points
	Autopsy III	Autopsy, slides	Case-specific distribution	16 points
1 h	Macro	12 specimen images	2 points per case	24 points
3 h	Histology	24 slides[b]	4 points per case	96 points
1 h[a]	Theory I	12 MC questions	2 points per case	24 points
	Theory II	3 free questions[c]	4 points per question	12 points
15–30 min	Interview	Multihead microscope	Individual	12 points
Total				240 points
Points needed to pass (75 %)				180 points

[a]For autopsies I–III combined

[b]The candidates are given 25 slides, of which one may be ignored

[c]The candidates are given four questions, of which one may be ignored

decision, and to council the candidate. Based on the results of the candidates in the different parts of the test, scores are assigned according to a pre-defined algorithm which is presented in Table 1.

Compared to similar tests in the USA and various European countries, the Swiss exam lasts certainly longer (2 days) and covers a wider field (cytology + autopsy + histology + macroscopy + theory). While this may be considered as a disadvantage, adding stress and hardship on the candidates who have to organize their lives (leave of absence, babysitter for children, etc.) and stay overnight in a foreign town, it does make sure that no one fails the exam simply because of bad chance with too few and over-focused questions. In that respect, the exam is designed to prevent false-negative results, i.e., failing a candidate who is competent, and to prevent false-positive results, i.e., allowing an unprepared candidate to pass unnoticed [1].

The questions and cases selected for the exam reflect the constant effort to recreate as closely as possible the real-world situation of the pathologists during their daily work dealing with a wide spectrum of simple, more challenging, and also some quite difficult cases, i.e., when they have to council clinicians about rare diagnoses and novel diagnostic techniques, and not to forget that they should be able to contribute also to academic activities. It is hence not surprising that the last few years have seen a gradual increase of questions that pertain to molecular pathology and its role in predicting the response of novel targeted treatments in an increasing number of malignant tumors. In this respect, the contents of the examination constantly adapt to changes in the postgraduate curriculum in medicine and anatomical pathology, respond for instance to a dwindling number of autopsies on one side, and an increased focus on molecular pathology on the other side. These modifications of the curriculum are currently being discussed and prepared in detail at the level of the respective professional societies and legal instances, and the exam will be modified accordingly.

History The initiative to create a professional exam in anatomical pathology goes back to the decision of the Swiss Society of Pathology (SSPath/SGPath) in the early 1990s. The scheme of the examination was first tested in 1993 with six candidates who participated on a purely voluntary basis (one of the candidates became father on the day of the exam, which was considered a positive omen for the project). In the first few years, unofficial diplomas were handed out to the candidates, stating that the candidates had passed the board examination in anatomical pathology. From 1994 on, the participation at the examination but not its passing became compulsory and only since 1996 did the successful outcome of the exam become compulsory for board certification. This was also the time when the exam was accredited by the Swiss Medical Association, Federatio Medicorum Helveticorum (FMH, the national institution that certifies medical specialties). It was only after intense discussions between members of the SSPath/SGPath and the FMH that this official institution acknowledged and accredited the board examination in anatomical pathology—and at the same time saluted the quality of the exam, its broad spectrum and the initiative of SSPath/SGPath members for mounting this exam. Today, FMH and SSPath/SGPath collaborate harmoniously in the certification of anatomical pathologists. The FMH verifies whether the candidates can document the necessary prerequisites for the board certification (i.e., a rotation through different diagnostic services, log book documenting the required minimum numbers of autopsies, histology and cytology cases, as well as frozen sections, participation in conferences and slide seminars, authorship in scientific publications, etc.). The SSPath/SGPath administers the board examination and issues a certificate of successful participation, without which no board certification will be ultimately issued by the FMH.

During the first years, the candidates also had to realize a frozen section (cutting, staining, and interpreting). In 1999, the cytology part was added to the exam and a few years later the discussion between candidates and examiners at a multi-head microscope. Over the years, failure rates have been low (5–10 %). Candidates who had failed had the chance to take the exam again, usually 6 months or 1 year after the initial exam, and so far everyone who had failed once eventually passed in the next exam for which he/she sat. Even though this has never happened in the history of the exam, the candidates are free to take the exam yet again in case they failed a second time. During the first years of the exam, a large collection of slides had been put together, and even though the collection was quite extensive, covering all aspects of anatomical pathology, candidates eventually realized that some of the cases/questions recurred and started to generate memory protocols that were then passed on to the "next generation" of candidates. This in turn did not escape the members of the exam committee who noticed that many of the more difficult cases were easily answered—if the cases had been used in an exam before. A graphic rendition of points reached in the different parts of the exam underlines this fact, where between 1999 and 2009 there was a steady and statistically significant increment of the points obtained on histological slides, while at the same time results in the autopsy and the cytology parts (which were renewed in every exam) remained at a rather constant level (Fig. 3). When in 2009 the decision was made to no longer reuse slides from the collection, the results obtained on histological slides fell to levels similar to those before the widespread distribution of "exam diagnoses." The simultaneous drop in the results obtained in the theory part of the exam reflects a change in the orientation of theoretical questions, with an increasing emphasis being placed on practical aspects of diagnostic molecular pathology—in agreement with the new spirit of the boards of anatomical pathology set

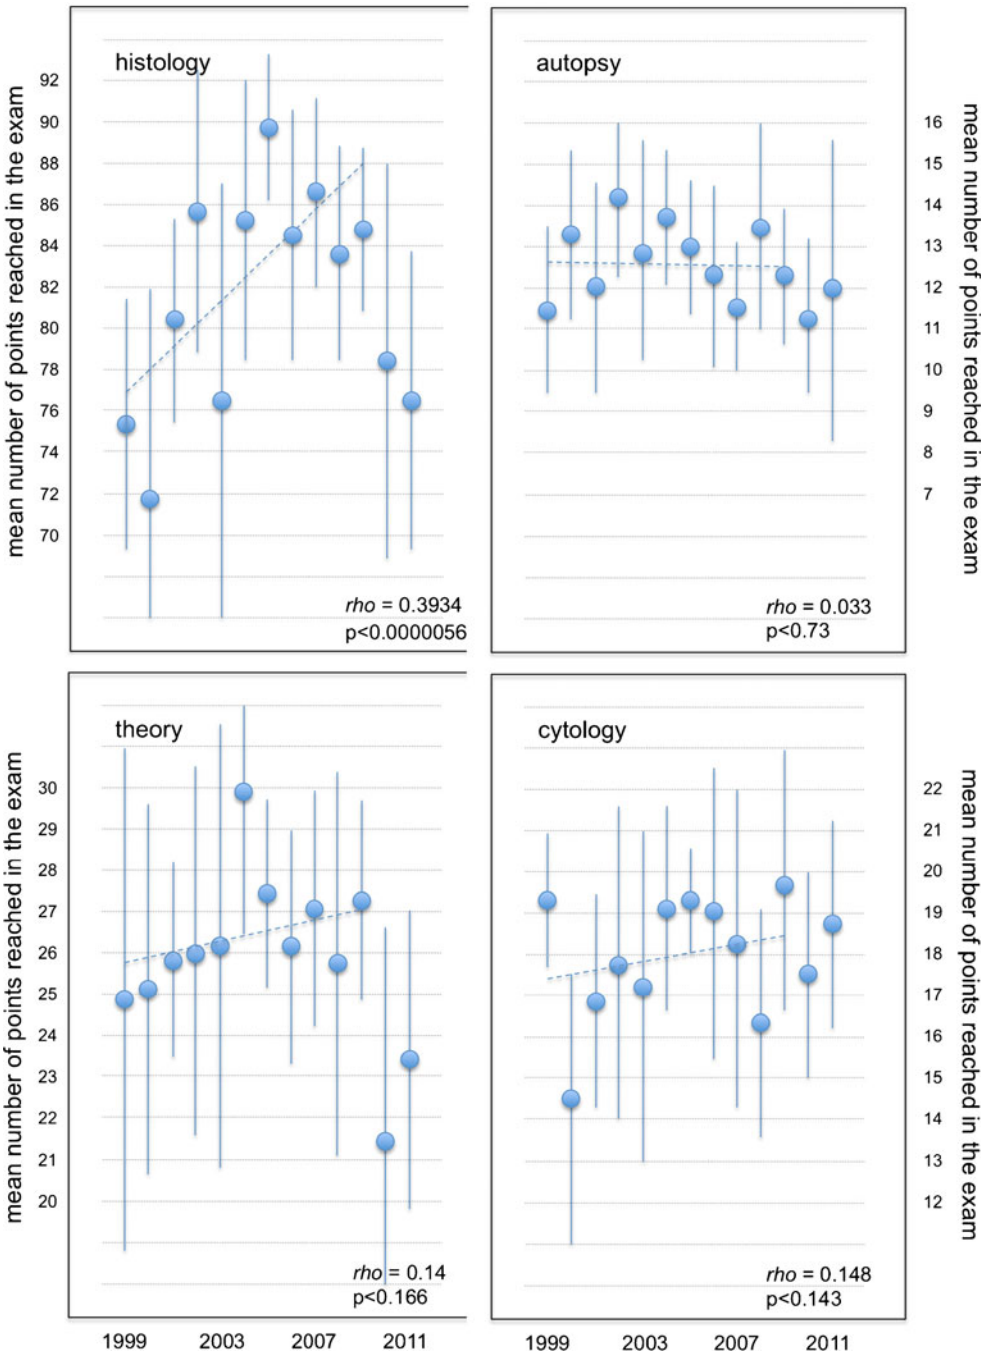

Fig. 3 Graphic rendition of points obtained by the candidates in the different parts of the exam over the past 12 years. Note that there was a significant increase from 1999 to 2009 of the results obtained in the histology part (*upper left panel*), likely due to the "tradition" of diagnoses of exam slides from one generation of candidates to the next. No such trend was observed for those parts where no "old cases" (cytology and autopsy) were being used. Note also that the results returned to "baseline" when the decision was made in 2009 to not reuse slides and theoretical questions from the exam collection that had been used in prior exams

forth by the educational committee of the SSPath/SGPath. Once the revised version of the board prerequisites, in particular the (reduced) number of autopsies, as well as surgical, and cytological cases, and the (increased) number of exams in molecular pathology (FISH and PCR), is accepted by the various instances, an increasing emphasis will be placed on the examination of molecular pathology, no longer limited to questions in the theory part of the exam (knowledge), but also in the practical part of the exam (skills).

Can a 2-day exam predict and verify if the candidates who pass the exam will be good anatomical pathologists? Certainly, it is not possible for such an exam to fully cover all aspects of the multi-faceted and complex nature of our profession. Communication skills, professional attitudes related to patient management, quality control, and error culture, as well as laboratory management, can certainly not be thoroughly tested, to name only a few examples. However, no board examination can claim to reliably test the future performance of medical professionals. In fact, Hamdy and coworkers have concluded from a thorough review of professional exams in various fields of medicine that evidence on predictors of performance in practice beyond residency training is rare

and weak [2]. Consistent with this notion, Cox has rightly stated that testing skills in an exam can at best test the prerequisites for professional performance rather than the performance itself, which includes processes and outputs in one of many practice settings [3]. The SGPath board examination in anatomical pathology tries its best to evaluate the skills and the knowledge of our future professionals. Whether or not the exam in its present design responds to this effort remains speculative. Even though we regularly ask candidates after the exam about their opinions, their mostly positive answers are likely biased by the particular situation in which they find themselves at that very moment, having just been told that the hard work of many months has been rewarded by a piece of paper with the magic word "passed."

End of service exams of professional proficiency are not mandatory in all member countries of the European Union. Based on a survey among members of countries represented in the European Section/Board of Pathology [4], all but six countries offer similar, albeit usually shorter (usually 1 day or less) and less extensive exams (often without autopsy or cytology parts). In six countries, in particular from southern Europe and Scandinavia, no end of service exams are offered. In these countries, the responsibility to verify the proficiency of former residents resides within the program director or the peer group of past and future colleagues.

Other than fulfilling a certain moral obligation towards society to verify the capacity of future professionals in anatomical pathology, the question may indeed be asked whether there is any gain to be derived from taking the exam. Since candidates are very well aware of the fact that the examination tests their knowledge and skills related to the diagnostic routine, they typically prepare for it by going over collections of slides, either alone or in study groups with one or several colleagues, and by reviewing quite a bit more than usual the existing diagnostic literature (i.e., pathology journals and recent textbooks). This preparation may in itself be considered as a clear advantage, and some former candidates have stated that they have never been more "fit" in pathology than during the preparation for the exam.

Acknowledgments The authors of this manuscript have either functioned as presidents and/or elected members of the standing exam committee for periods of usually 4–5 years and/or contributed in a substantial way to the exam and to this manuscript. They would like to acknowledge the excellent assistance and support by the secretaries of the presidents of the exam committee, Ghislaine Perriard and Murielle Barman in Lausanne, Doris Manca in Neuchâtel, as well as Brigitte Terrier in Zürich.

Conflict of interest Neither the presidents nor the elected members of the examination committee are paid for their activities, except for their travel costs to the exam venues, which are reimbursed by the SGPath. The price paid by the candidates for the examination is currently CHF 450.00 (reduced fee of CHF 300.00 for members of the SGPath), which is being used for travel expenses for the examiners, the rental of microscopes, and other expenses linked to the exam.

CASE REPORT

Polymorphic lymphoid proliferations occurring in HIV-positive patients: report of a case responding to HAART

Jenny Buxton · Clifford Leen · John R. Goodlad

Received: 27 March 2012 / Revised: 1 June 2012 / Accepted: 4 June 2012 / Published online: 17 June 2012
© Springer-Verlag 2012

Abstract Epstein–Barr virus (EBV)-associated polymorphic lymphoid proliferations resembling polymorphic post-transplant lymphoproliferative disorders are a rare but recognised complication of the human immunodeficiency virus (HIV). These account for fewer than 5 % of HIV-associated lymphomas, and little information has been published regarding their treatment and outcome. Of the reported cases, many have presented with extranodal disease, not typical of lymphoma. We report the case of a patient presenting with lung infiltrates shown to be the result of an EBV-associated polymorphic lymphoproliferation resembling a polymorphic post-transplant lymphoproliferative disorder. The patient was simultaneously found to be HIV positive and commenced on highly active antiretroviral therapy. Without any specific antineoplastic treatment, the patient recovered completely and within 20 months had no symptoms or radiological evidence of a lymphoproliferative disorder. This illustrates the importance of recognising this uncommon condition in HIV-positive patients and avoiding potentially unnecessary chemotherapy.

Keywords Immunodeficiency-associated lymphoproliferative disorder · Post-transplant lymphoproliferative disorder · Human immunodeficiency virus (HIV) · Epstein–Barr virus (EBV) · Antiretroviral therapy

Introduction

The risk of developing a lymphoproliferative disorder is increased with immunosuppression of any cause, whether congenital, acquired through infection with the human immunodeficiency virus (HIV) or iatrogenic following solid organ transplant, stem cell transplant or immunosuppression for autoimmune disorders [1]. Although the relative risks vary between subtypes and have altered since the introduction of highly active antiretroviral therapy (HAART), the incidence of lymphoma in HIV-positive patients is increased by between 60 and 200 times [2, 3]. In the most recent World Health Organisation classification, HIV associated lymphoproliferations are separated into three groups: (1) lymphomas also occurring in immunocompetent patients such as Burkitt lymphoma, diffuse large B-cell lymphoma, primary central nervous system (CNS) lymphoma and Hodgkin lymphoma; (2) lymphomas more specifically seen in HIV-positive patients, including primary effusion lymphoma, plasmablastic lymphoma and lymphoma arising in human herpes virus 8 (HHV8)-associated multicentric Castleman's disease and (3) lymphoproliferations occurring in HIV but also seen in other immunodeficient states [2]. Clinically aggressive B-cell neoplasms, indistinguishable from those seen in immunocompetent patients, are by far the most common HIV-associated lymphomas [1, 3]. The current case is an example of the third group of much less frequently encountered and rarely reported polymorphic lymphoid proliferations associated with HIV infection.

Clinical history

A 42-year-old Zimbabwean lady presented with a short history of weight loss and general malaise. Two years previously, she had been successfully treated for pulmonary tuberculosis with a standard 6 month course of quadruple therapy resulting in complete resolution of all chest X-ray abnormalities and symptoms. On this occasion, her chest X-ray showed new bilateral nodular interstitial shadowing (Fig. 1), and a high-resolution CT confirmed widespread pulmonary parenchymal nodules. A presumptive diagnosis of miliary TB was made, but the patient's condition continued to deteriorate despite 4 weeks of quadruple anti-tuberculous therapy. It was at this stage she was found to be HIV positive [HIV ribonucleic acid (RNA) 278 481 copies/ml, CD4 count 57 cells/mm^3]. An initial transbronchial lung biopsy proved nondiagnostic, but a subsequent video-assisted thoracoscopic lung biopsy provided the diagnosis of an Epstein–Barr virus (EBV)-associated polymorphic lymphoid proliferation resembling a polymorphic post-transplant lymphoproliferative disorder (PTLD). Staging studies, including repeat CT and bone marrow, showed no other evidence of lymphoma. Serum EBV polymerase chain reaction (PCR) was positive at log 5.68 copies/ml. HAART was commenced with good effect. Within 1 month the $CD4^+$ count had risen to 388 cells/mm^3; the serum EBV PCR titre was undetectable, and the HIV viral load was falling, reaching <40 copies/ml 8 months later. By 20 months the chest X-ray was reported as normal and 4 years after diagnosis the patient remains well with no evidence of a lymphoproliferative disorder. $CD4^+$ count is 472 cells/mm^3, and HIV viral load is <40 copies/ml.

Materials and methods

The lung biopsy consisted of a wedge of tissue measuring 40×20×15 mm. This was fixed in 10 % buffered formalin, paraffin-embedded and 4-μm sections cut for routine haematoxylin and eosin staining in addition to sections for immunohistochemical (IHC) analysis.

Immunohistochemistry

IHC labelling was performed using the automated 'Bondmax' system (Leica Microsystems, Wetzlar, Germany), and the following antibodies were applied to sections: CD20, CD79a, Bcl-2, Epstein–Barr virus nuclear antigen 2 (EBNA 2), latent membrane protein 1 (LMP-1), CD138, kappa and lambda light chains (all DAKO, Cambridgeshire, UK); CD5, CD10, CD23, Bcl-6, HHV8 (Leica Biosystems, Newcastle upon Tyne, UK) and cyclin D1 (Thermo Scientific, Waltham, USA). Antigen retrieval for all antibodies was achieved using ethylenediaminetetraacetic acid with the exception of CD20 for which sodium citrate was used. The presence of Epstein–Barr virus-encoded RNAs (EBERs) was investigated using in situ hybridisation (ISH) on formalin-fixed paraffin-embedded sections with EBERs which were supplied in a kit complete with anti-fluoroscein antibody, RNA negative control probe and EBER probe (Leica Biosystems).

Polymerase chain reaction

DNA was extracted from 10-μm sections of formalin-fixed paraffin-embedded tissue, by incubating overnight with Qiagen lysis buffer (Qiagen, Crawley, UK) and proteinase K. DNA was then purified using the automated 12GC magtration system (Precision System Science, California, USA) and amplified using MasterMix with HotStar Taq polymerase (Qiagen) on a Peltier Thermal Cycler (Genetic Technologies, Miami, USA). The following Identiclone primers were applied: IGH, tubes A-E targeting framework 1, 2 and 3 regions and the diversity and joining regions of the

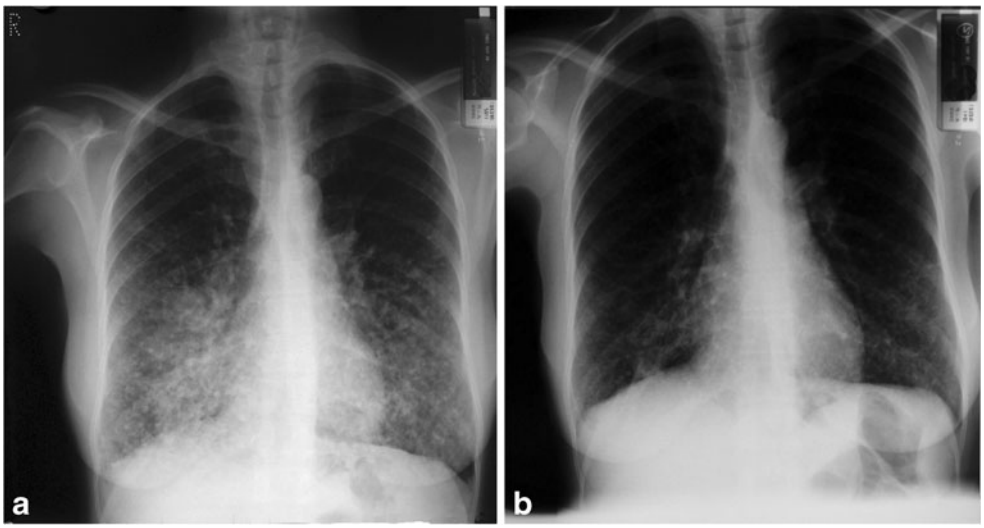

Fig. 1 Chest X-ray appearances before and after treatment with HAART. **a** Nodular interstitial infiltrate seen at presentation. **b** Clearing of lung fields at 12 months

immunoglobulin heavy chain gene; IGK, tubes A and B targeting the variable and joining regions, JK-CK intron and Kde regions of the immunoglobulin Kappa light chain gene and IGL targeting the V lambda and J lambda region of the immunoglobulin lambda light chain gene (Invivoscribe, San Diego, USA). Samples were then processed through a capillary electrophoresis system with laser detection of fluorescently labelled nucleic acids (3130 Genetic Analyser) and results analysed using GeneMapper software (both Applied Biosystems, California, USA).

Results

Haematoxylin and eosin-stained sections showed a dense lymphoid infiltrate forming large interstitial nodules and in places replacing the adjacent lung parenchyma (Fig. 2a). The infiltrate consisted of plasma cells, lymphoplasmacytoid cells, small lymphocytes, scattered immunoblasts, histiocytes and occasional eosinophils (Fig. 2b). In places, the polymorphic infiltrate was seen to surround ill-defined residual germinal centres. Most of the blasts and many of the lymphocytes and lymphoplasmacytoid cells were positive with the B-cell markers CD20 and CD79a (Fig. 2c). They also expressed Bcl-2 but were negative for CD5, CD10, CD23, Bcl-6 and cyclin D1. Immunohistochemistry for LMP-1 and EBNA 2 were negative, but ISH for EBER was positive in a moderate number of small and large lymphocytes (Fig. 2d). Immunohistochemistry for HHV8 was negative. Plasma cells expressed CD79a and CD138. Light chain expression was polytypic (Fig. 2e, f), but a small B-cell clone was demonstrable by PCR (Fig. 3). A diagnosis of EBV-associated polymorphic lymphoid proliferation resembling a polymorphic post-transplant lymphoproliferative disorder was made.

Discussion

Most HIV-associated lymphoproliferations are clinically aggressive monoclonal B-cell lymphomas. These include primary effusion lymphoma, plasmablastic lymphoma and lymphoma arising in HHV8-associated multicentric Castleman's disease, as well as lymphomas similar to those occurring in immunocompetent patients, e.g. Burkitt lymphoma, diffuse large B-cell lymphoma and Hodgkin lymphoma [1, 3]. This case represents an EBV-associated polymorphic lymphoid proliferation resembling those more often encountered in transplant recipients [1, 4–8]. Such lymphoproliferations include early infectious mononucleosis (IM)-like PTLDs and polymorphic PTLDs, entities that show overlapping pathological features and represent closely related points on a continuous spectrum of disease. Effacement of underlying architecture and the presence of clonally rearranged immunoglobulin genes are the two main distinguishing criteria for polymorphic PTLD-like lymphoproliferations [2] and hence this designation was favoured. However, we accept that the architectural effacement was relatively minor and that small clones can rarely be encountered in early IM-like PTLDs [2]. Although polymorphic PTLDs constitute a relatively high proportion of the lymphoid proliferations in transplant patients, they have only rarely been reported in association with HIV infection and there is relatively little information on the response to treatment and prognosis [1, 2, 4–8].

Including the current patient, a total of 17 cases of HIV-associated polymorphic lymphoproliferations have been reported, including both adult and paediatric examples, with an excess of male patients (11 male to 6 female) [1, 4–8]. The majority of cases (11 out of 17) have presented at extranodal sites, including the lung (n=5), parotid gland (n=1), perineum (n=1), skin (n=1), stomach (n=1), terminal ileum (n=1) and CNS (n=1) [1, 4–8]. The histological features described in this case are similar to those described in previous reports, lesions being characterized by a polymorphic infiltrate of B cells showing all stages of maturation from immunoblasts to plasma cells, admixed with relatively numerous T cells. Cytological atypia may also be present, including immunoblasts reminiscent of Reed–Sternberg cells, and areas of necrosis have been reported [1, 4–8]. EBV is usually, but not always, present (13 out of 17 cases), and HHV8 has been identified in 1 of the 12 cases tested to date [1, 4–8].

Although the current case was polyclonal by light chain immunohistochemistry, a small B cell clone was demonstrable, by PCR, against a polyclonal background. Ten of the other 14 cases assessed by PCR and/or Southern blot analysis also showed evidence of a dominant B-cell clone, usually manifesting small peaks or faint positive bands, with only 4 cases being reported as polyclonal or oligoclonal [1, 4–8]. These findings suggest HIV-associated polymorphic lymphoproliferations represent the 'earliest' end of a spectrum

of lymphomas arising in HIV-positive patients. As a consequence of immunosuppression, a dominant clone evidently emerges from a polyclonal, usually EBV-stimulated, chronic lymphoproliferation. They appear to lack oncogene and tumour suppressor gene mutations, unlike most other AIDS-related systemic non-Hodgkin lymphoma, but can evolve into high-grade lymphoma, when they may be seen to have acquired such mutations [1].

Information regarding treatment and outcome for polymorphic HIV-associated lymphoproliferations is very limited. Follow-up details were only available for three of the patients described by Nador and colleagues. One received no treatment and died of disease at 5 months. Two received chemotherapy: one patient dying at 28 months with no evidence of disease and the other remaining alive but with disease recurrence at 7 months. The nature of chemotherapy was not stated in either case [1]. The case of Wang et al. died at 4 months but appeared to receive no treatment and had a concomitant high-grade B-cell lymphoma [7]. The two paediatric cases of Tao et al. had differing outcomes. One responded to a combination of zidovudine (nucleoside analogue reverse transcriptase inhibitor), nelfinavir (protease inhibitor) and intravenous immunoglobulin, and was stable 8 months after presentation, whilst the other received pentamidine, ceftriaxone and nelfinavir, but died of multiorgan failure just 7 weeks after presentation [4]. Kingma et al. also reported a paediatric HIV-associated polymorphic lymphoproliferation this time affecting the CNS. The patient was treated with steroids and antiretroviral therapy (zidovudine and didanosine, reverse transcriptase inhibitor) but subsequently developed cytomegalovirus retinitis and progressive HIV-associated encephalopathy, dying 10 months after diagnosis [6]. Our case, and that described by Fujito and colleagues, provides more encouraging observations. Both patients achieved complete remission following initiation of HAART [albeit the latter also received one course of CHOP-like chemotherapy (cyclophosphamide, doxorubicin, vincristine, prednisolone)] and remained in complete remission at 48 and 20 months, respectively [5]. Although fewer details are given, the case reported by Martin et al. also suggests at least partial resolution with antiretrovirals [8].

The widespread introduction of HAART in the mid-1990s resulted in fewer HIV-positive patients developing lymphoma, although this was not universal for all subtypes [3, 9]. More recently, HAART has also been recognised as a key component of treatment for established cancers in HIV-positive patients. For example, in primary CNS lymphoma, patients treated with HAART plus whole brain irradiation and chemotherapy do significantly better than those given chemo-radiotherapy alone [3, 10]. This certainly holds true for those patients who have a good response to antiretrovirals, with increases in $CD4^+$ counts and reductions in HIV viral load [11], but there is increasing evidence that HAART itself may have a direct antitumour effect independent of its immunomodulatory functions. For instance, in Kaposi's sarcoma, a high rate of complete tumour regression is seen in patients treated either with HAART alone or with HAART in combination with chemotherapy, but complete remission does not consistently correlate with a reduction in HIV viral load or increase in $CD4^+$ count [12].

Conclusion

Although uncommon, polymorphic lymphoproliferations are an important differential diagnosis to consider in HIV-positive patients who present with unusual signs and symptoms, especially those not responsive to antimicrobial treatment. It is imperative to appreciate that, even when dominant clonal B-cell populations are present, there is the potential for complete resolution with antiretroviral treatment alone, and anti-neoplastic chemotherapy may not be appropriate. Our patient achieved a good response to HAART with restoration of $CD4^+$ counts and a reduction in HIV viral load to undetectable levels. Improving immune surveillance certainly appears to be key in reversing EBV-driven lymphoproliferative disorders such as described here, but whether HAART may have additional, more direct antiproliferative effects is also of interest and merits further study.

LETTER TO THE EDITOR

Urothelial carcinoma with abundant myxoid stroma: evidence for mucus production by cancer cells

Magdalena M. Gilg · Birgitta Wimmer · Arthur Ott · Cord Langner

Received: 14 March 2012 / Accepted: 11 May 2012 / Published online: 26 May 2012
© Springer-Verlag 2012

Dear Editor,

Urothelial carcinoma has a propensity for aberrant differentiation, with squamous and glandular being the most common histological variants [1]. Notably, divergent differentiation occurs more frequently in high-grade and high-stage tumours [2]. Recently, urothelial carcinoma with abundant myxoid stroma has been identified as a new histological variant [3]. The origin of stromal mucin, however, is currently unclear.

A 66-year-old male with history of gastric signet ring cell carcinoma presented with haematuria and unspecific lower abdominal pain. Cystoscopy disclosed a polypoid lesion, measuring 3 cm in largest diameter, which extended from the bladder wall into the lumen and was removed by transurethral resection.

Histology revealed non-invasive papillary urothelial low-grade carcinoma with mild architectural and cytologic atypia. Parts of the lesion showed infiltration of the lamina propria by high-grade cancer cells. The most striking morphological feature was an abundant myxoid stroma which covered approximately 30 % of the lesion. Notably, mucin production was evident also in non-invasive cancer areas, as documented by the presence of intercellular mucin leading to a cord-like and ultimately microcystic pattern (Fig. 1a–c). Neoplastic glandular epithelium was not observed. Histochemical stains for Alcian blue and PAS showed positivity of extracellular mucinous material, but reactivity was also observed within the cytoplasm of cancer cells (Fig. 1d–e). Upon immunohistochemistry, the tumour cells were positive for p63, keratin 7 and 20, E-cadherin, MUC1, MUC2 and MUC5AC (Fig. 1f–h). Electron microscopy performed on formalin-fixed, paraffin-embedded material disclosed non-membrane-bound cytoplasmatic globules, consistent with mucus droplets (Fig. 2).

Prominent myxoid stroma has been described as pseudosarcomatous stroma reaction associated with urothelial carcinoma and as sarcomatoid urothelial carcinoma. Recently, Tavora et al. [3] introduced the term "urothelial carcinoma with abundant myxoid stroma" for otherwise typical urothelial tumours showing marked extracellular mucin deposition which should not be confused with primary or secondary adenocarcinoma of the bladder as well as benign lesions, such as cystitis glandularis with intestinal metaplasia, endocervicosis and villous adenomas [3, 4]. Although their series was small and follow-up limited, the authors suggested that this new variant might be less aggressive compared to conventional urothelial carcinoma. Most probably, Cox et al. [5] described the same tumour variant under the name "invasive urothelial carcinoma with chordoid features". Their tumours were similarly characterized by prominent myxoid stroma and intercellular mucin deposition, leading to cord-like epithelial architecture and microcystic pattern, as was also shown for our case.

According to Tavora et al. [3], the origin of mucin is unclear, particularly in the absence of overt glandular epithelium. Our case, however, clearly shows mucin production by otherwise typical urothelial cancer cells in both invasive and non-invasive tumour areas. This finding illustrates the capacity of urothelial cancer cells to show divergent, i.e. aberrant mucinous differentiation. In our opinion,

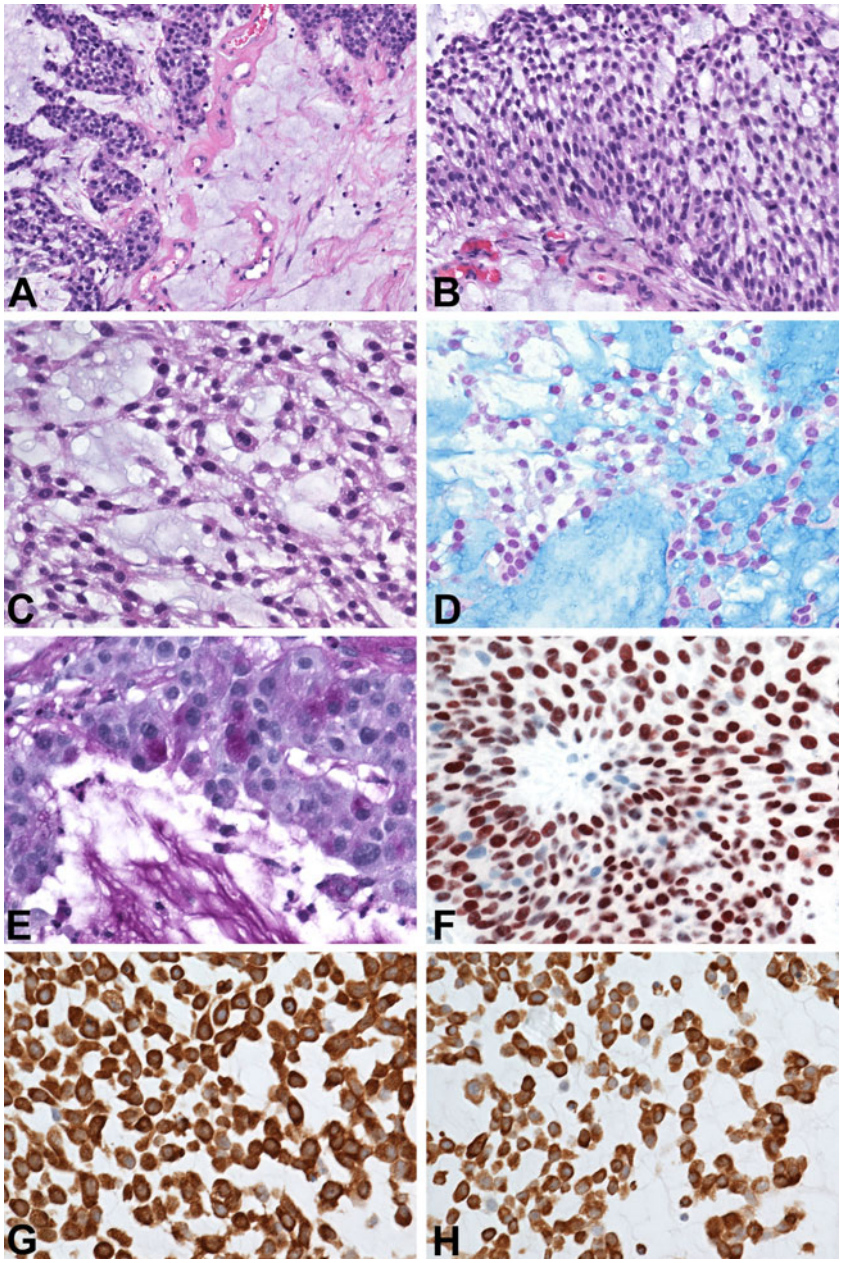

Fig. 1 Urothelial carcinoma with abundant myxoid stroma (**a**); note intercellular mucin deposition in non-invasive tumour areas (**b**), ultimately leading to cord-like epithelial architecture with microcystic pattern (**c**). The mucinous material is Alcian blue positive (**d**). PAS stain shows positivity of mucin but also decorates the cytoplasm of adjacent cancer cells (**e**). The neoplastic cells are positive for p63 (**f**), MUC1 (**g**), and MUC 2 (**h**)

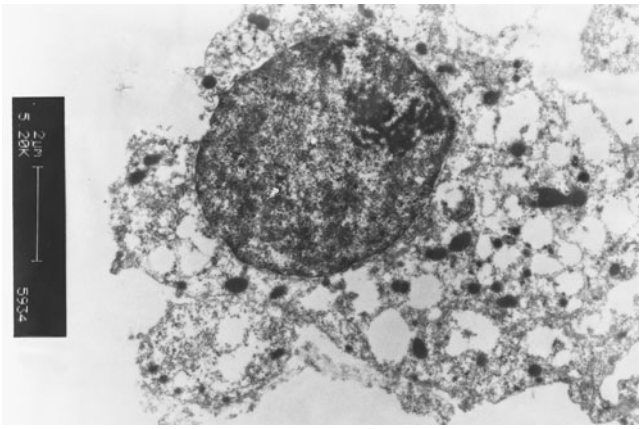

Fig. 2 Electron microscopy performed on formalin-fixed, paraffin-embedded material shows tumour cells with non-membrane-bound cytoplasmatic globules, consistent with mucus droplets (original ×5,200)

the term "mucinous urothelial carcinoma" would better characterize the lesion.

In conclusion, we present a new case of urothelial carcinoma with abundant myxoid stroma and prove the urothelial cancer cells to be the source of mucin. The term "mucinous urothelial carcinoma" might therefore better characterize this peculiar tumour variant.

Conflict of interest We declare that we have no conflict of interest.

Neuroendocrine differentiation does not have independent prognostic value in conservatively treated prostate cancer

Abstract In vitro studies have implicated neuroendocrine differentiation in the development of hormone resistant prostate cancer following administration of androgen blockers. Studies on clinical material are equivocal. We wished to understand the significance of neuroendocrine differentiation in our large and well-characterised cohort of clinically localised prostate cancer, treated conservatively. Immunohistochemical expression of chromogranin-A was assessed semi-quantitatively on tissue samples of 806 patients in a tissue microarray approach. The correlation of expression with 10-year prostate cancer survival was examined. Multivariate analysis including contemporary Gleason score was performed and sub-group analysis of early hormone treated patients was also undertaken. Chromogranin-A expression correlated with high Gleason score (χ^2=28.35, p<0.001) and early prostate cancer death (HR=1.61, 95 %CI=1.15–2.27, p<0.001). In univariate analysis, NE differentiation correlated significantly with outcome (HR=1.61, 95 % CI 1.15-2.27, p<0.001) However in multivariate analysis including Gleason score, chromogranin-A expression was not an independent predictor of survival (HR=0.97, 95 %CI=0.89–1.37, p=0.87). Although chromogranin-A expression was higher in patients with early hormone therapy (χ^2=7.25, p=0.007), there was no association with prostate cancer survival in this sub-group (p=0.083). Determination of neuroendocrine differentiation does not appear to have any bearing on the outcome of prostatic carcinoma and does not add to the established prognostic model.

Introduction

A particular characteristic of carcinoma of the prostate is the inevitable development of an androgen-resistant phenotype in what is, in its initial stages, an exquisitely hormone-sensitive tumour. A mechanism to explain this phenomenon has been proposed which involves up-regulation of the signalling via neuroendocrine cells. Neuroendocrine (NE) cells, which are interspersed among basal cells and luminal epithelial cells, do not possess androgen receptors [1, 2]. Instead, signal transduction is performed with the release of various non-androgenic chemical messengers including chromogranins, bombesin, neuron-specific enolase and synaptophysin. Chromogranin-A, in particular, has been demonstrated to be the best marker of neuroendocrine differentiation [3, 4]. In the normal prostate gland, the cells are thought to be important in normal prostate development and control of secretory functions through autocrine and paracrine signalling mechanisms [5].

Gleason score [6, 7], tumour stage [7] and serum PSA [7] remain the best contemporary markers for prediction of outcome in prostatic carcinoma. However, this is suboptimal

[8, 9] and additional parameters which can improve on projections of mortality would greatly facilitate management of the disease, especially before treatment decisions are made.

Various molecular in vitro studies [10–18] have been able to implicate neuroendocrine signalling mechanisms in the development of hormone resistant prostate cancer but extrapolation to resection specimens and translational material has not yielded conclusive results.

It has been proposed in previous studies [19–24] that quantification of neuroendocrine differentiation in prostatic pre-treatment material might be useful in: (1) identifying aggressive disease which might be less sensitive to androgen deprivation therapy, (2) identifying those tumours that may develop androgen insensitivity more quickly and (3) understanding local signalling mechanisms mediated by neuroendocrine cells.

The Trans-Atlantic Prostate Group was formed to retrospectively investigate the behaviour of clinically localised prostate cancer in patients who had been conservatively treated, together with contemporary Gleason score and baseline PSA. Translational material from this resource remains the largest series of prostate cancers, treated conservatively and with all contemporaneous prognostic information available.

We hypothesised that increasing NE differentiation implies poor prognosis and its assessment could be helpful in deciding on treatment options in localised prostate cancer.

Patients and methods

The details of cohort assembly have been described previously [8]. In brief, patients diagnosed with histologically proven, localised prostate cancer between 1990 and 1996 were identified, by searching through six UK cancer registries. Exclusion criteria were: age older than 76 years; no baseline PSA or baseline PSA>100 ng/ml; invasive carcinoma within 5 years before diagnosis, or hormone treatment before biopsy. Patients were also excluded when they had undergone radical treatment within 6 months of diagnosis (hormonal treament was acceptable), when there was evidence of metastasis or they had died within 6 months of diagnosis. This was a pragmatic method to ensure that patients truly had localised disease. The patients were managed conservatively: approximately a third of patients were managed with early hormone manipulation and the rest were observed until clinically symptomatic. The primary endpoint was defined as death from prostate cancer. Where available, death certificates were reviewed to verify cause of the death and survival outcomes were determined from medical records and cancer registry data. In all, details on 1,656 patients were retrieved and prognostic tables were constructed after 10 years of follow up. Tissue from these cases was also obtained and Gleason scores were re-assessed [25] to modern criteria [26].

Carcinoma which was diagnosed on trans-urethral resection of the prostate (TURP) tissue was microarrayed into 24 wax blocks. Generally, one to three tissue cores of 0.6 mm diameter were taken from each formalin-fixed donor block and were transferred into a new recipient wax block. Sections cut from the tissue microarray (TMA) blocks were immunohistochemically stained for chromogranin-A (BioGenex-clone LK2H10, San Ramon, California) at a dilution of 1/3,000 and then counterstained with haematoxylin. Antigen retrieval was performed by pressure cooking in citrate buffer at pH 6.0 for 30 min. Colon and appendix mucosa served as positive controls, highlighting neuroendocrine cells. The tissue microarray without primary antibody incubation was used as negative control. Chromogranin-A was chosen as a marker of neuroendocrine differentiation as it has been shown to be the most reliable of available immunohistochemical markers [27], it is used extensively in routine histopathology practice, the staining protocol is reliable and it is been used extensively in other studies investigating neuroendocrine differentiation in prostate cancer.

Chromogranin-A expression was analysed in a semi-quantitative manner using a Leica DM2500 microscope (Leica, Germany) at ×200 power. The percentage of epithelial cells expressing chromogranin-A throughout the core was assessed between 0 and 100 % and the intensity of the staining was assessed as follows: 0, no staining; 1, weak; 2, medium; and 3, strong staining. The product of percentage expression and intensity gave a final composite score (CS) between 0 and 300. Staining was restricted to the cytoplasm of epithelial cells only. Scoring was performed by a single pathologist (S.J.) and supervised by a senior pathologist (D.M.B.)

The maximum CS was considered as representative of the tumour. The correlation of CS with demographics and tumour characteristics, including Gleason score, was examined (using the χ^2 test and Fisher's exact test for categorical variables and analysis of variance for numerical variables). The main end points were time to death from prostate cancer. Univariate and multivariate analysis including Gleason score was performed by proportional hazard (Cox) regression analysis. All p values were two sided and 95 % confidence intervals (95 %CIs) were based on normal distribution.

Results

Chromogranin-A expression was analysed in 2483 cores representing 806 patients. Around 60 % of cases were represented by one or two cores. Up to seven cores were taken in three individuals (Fig. 1).

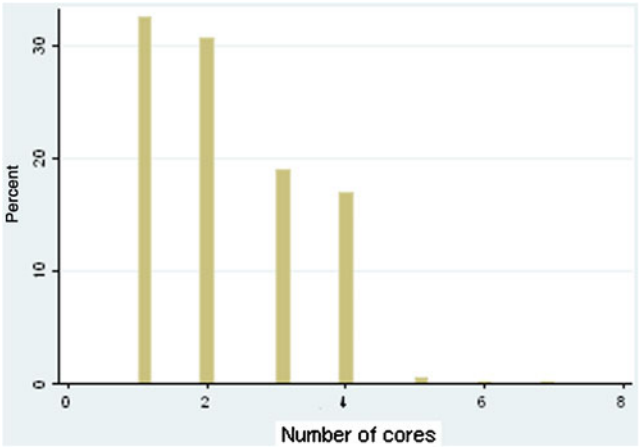

Fig. 1 Histogram showing number of cores per individual

Seventeen percent (133 out of 806) of assessable patient cores demonstrated chromogranin-A expression. On univariate analysis, NE expression significantly correlated with poor outcome (HR=1.61, 95 % CI 1.15-2.27, $p<0.001$; Fig. 2). Furthermore, chromogranin-A expression significantly correlated with higher Gleason score ($p<0.001$; Table 1). However, in multivariate analysis including Gleason score, neuroendocrine differentiation did not have independent prognostic value (HR=0.97, 95 %CI 0.89–0.37, $p=0.87$; Table 2).

Further sub-group analysis was performed on 147 patients who had been given early hormone manipulation therapy (within 6 months of diagnosis). These patients more frequently showed chromogranin-A expression ($\chi^2=7.25$, $p=0.007$) but there was no significant association with prostate cancer deaths ($p=0.083$).

Discussion

NE differentiation in prostatic carcinoma has attracted attention because it may represent an androgen-independent pathway along which tumour cells may progress. Neuroendocrine cells do not possess androgen receptors and are thought to be anti-apoptotic [28, 29]. It is hypothesised that the inevitable development of hormone resistant prostate cancer following the failure of androgen blockade may be due to selection of a neuroendocrine phenotype [30] or the ability for neuroendocrine messengers to bind and activate androgen receptors.

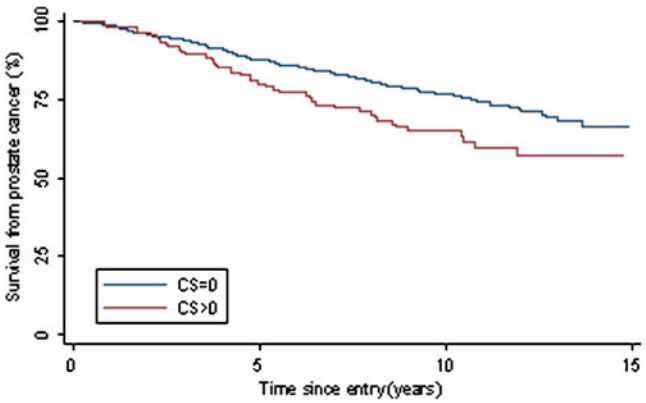

Fig. 2 Kaplan–Meier curves showing composite score (*CS*) with zero cut-off

7	156(78)	43(22)
8-10	139(74)	49(26)

$p<0.001$, $\chi^2=29.80$

Recent translational studies by other groups show divergent findings [19, 31–34]. Cindolo et al. [34] also performed chromogranin-A immunohistochemistry (as well as Ki-67, NeuroD and androgen receptor) on clinically localised prostate cancers using TMAs. Their cohort of 732 patients differed from our study group in that the tissue was derived from radical prostatectomies. Nevertheless the conclusions were broadly similar to ours in that chromogranin-A expression correlated with Gleason score but was not independently predictive of progression. Abrahamsson et al. [19] also studied NE differentiation in a conservatively treated cohort, albeit in smaller numbers (87 patients). In this study, there was no correlation of chromogranin-A either with Gleason score or survival. Allen et al. [31], Tan et al. [32] and Cerovic et al. [33] have also not been able to show association with mortality independent of other variables. Correlation with Gleason score is a consistent feature in all of these studies. There are two notable studies, published in the early 1990s, that have implicated NE differentiation with tumour progression [35, 36]. These studies included small cohorts of patients but the results were sufficient to generate further interest in this field.

The results from our study on conservatively treated, localised prostate cancer does not support this theory. Although univariate analysis of neuroendocrine differentiation correlated

Table 2 Comparison of univariate analysis and multivariate analysis including Gleason score

Variable	Prostate cancer	
	Hazard ratio (95 % CI)	
	Univariate analysis ($N=806$)	Gleason + CG-A ($N=806$)
0 (674)	1 (ref)	1 (ref)
>0 (132)	1.58 (1.15,2.18)	0.97 (0.70, 1.34)

with mortality, multivariate analysis failed to demonstrate significance. We therefore conclude that chromogranin-A as a marker for neuroendocrine differentiation fails to add anything to the prognostic model. Less than 20 % of our cohort had been exposed to hormone manipulation. Although there was correlation with chromogranin-A expression, there was no effect on survival from prostate cancer.

Pure small cell carcinoma was not diagnosed in any of the cores as these cases would have been referred for primary chemotherapy and would not have been included in this conservatively managed cohort.

Despite disappointing clinical data, there is good evidence from basic research to implicate NE mechanisms in the progression of prostate cancer. For example, vasoactive intestinal peptide, a NE transmitter, has been implicated in up-regulation of pro-angiogenic vascular endothelial growth factor [37]. Mechanisms that have been proposed as inducers of NE phenotype include ionising radiation [11], cytokines [12], Epidermal Growth Factor [38] and β-adrenergic agonists [10]. It might be too naive to assume that there is a simple relationship between the degree of NE differentiation and tumour behaviour. It has been described that NE cells secreting chromogranin can be stimulated further with dibutryl cyclic-AMP. This does not result in raised secretion of chromogranin but does cause the production of other NE-specific molecules (bombesin, neuron-specific enolase) [10, 39]. It could be that paracrine stimulation via these messengers is responsible for tumour proliferation independent of chromogranin immuno-expression.

NE differentiation may be more significant in patients that have been subjected to hormone manipulation. In vivo studies on prostate cancer cell lines have shown that NE phenotype is selected for in androgen deprived conditions [14, 30]. Assessment of NE differentiation may still be important in this cohort and numbers of groups have sought to explore whether NE differentiation can be predictive of relapse following hormonal manipulation [40, 41]. Even in this situation, the answer is not clear-cut: Krijnen and colleagues [20] concluded that NE differentiation was a predictor of progressive disease following hormone manipulation. Their work was conducted on localised prostate cancer and TURP chippings. Ahlgren et al. [40] showed an increase in neuroendocrine differentiation following the administration of androgen blockade but this did not translate into increased mortality. Hirano et al. [41] did show higher incidence of NE differentiation in autopsy specimens who had died from hormone refractory prostate cancer compared to living prostate cancer patients currently on hormone manipulation for a shorter duration. They were unable to conclude, however, whether this correlation was secondary to long term hormone manipulation or hormone refractoriness.

Conclusion

In this large series of conservatively treated prostate cancers in which NE differentiation has been assessed, we show that although NE differentiation correlates with higher Gleason score in univariate analysis it has no independent prognostic value in multivariate analysis and therefore does not add to the well-established prognostic models.

We therefore suggest that these tumours are treated by standard methodologies in the absence of small cell differentiation.

Disclosure of conflict of interest We declare that we have no conflict of interest.

Abstract Ovarian high-grade serous carcinoma (HGSC, type 2 ovarian carcinoma) is a poor prognosis cancer with limited therapeutic options. We aimed to investigate the expression pattern and prognostic potential of the metastasis-promoting protein anterior gradient 2 (AGR2) in primary HGSC. Immunohistochemistry was applied to a cohort of 124 primary HGSCs using tissue microarrays. Additionally, in 48 type 1 carcinomas (low-grade serous (LGSC), endometrioid (EC), clear cell (CCC), and mucinous carcinoma (MC)), AGR2 expression was investigated in an exploratory approach. A strong expression of AGR2 was seen in 15 HGSCs (12.1 %) and was significantly linked to shortened overall survival (OS, $p=0.011$) and also for progression-free survival (PFS, $p=0.001$) in the setting of adjuvant platinum-based chemotherapy (CTX). Multivariate survival analysis including age, stage, and residual tumor after surgery revealed that AGR2 expression was an independent prognostic marker for OS ($p=0.001$) and PFS ($p=0.001$) in HGSC. In type 1 carcinomas, AGR2 was significantly increased as compared to HGSC ($p=0.001$) and was seen in subsets of all histological types, low-grade serous LGSC, EC, CCC, and MC. In particular, strong diffuse staining was seen in LGSC and MC. There was no association between AGR2 and estrogen receptor expression in ovarian type 1 or type 2 carcinomas. AGR2 expression identifies highly aggressive HGSC with a compromised prognosis for which novel therapeutic options are needed. Our data strongly support the further evaluation of AGR2 as a therapeutic target and a potential marker for response to platinum-based CTX in this tumor entity.

Introduction

Epithelial ovarian cancer is a heterogeneous group of neoplasms that is constituted of five major histological types, high-grade serous (HGSC), low-grade serous (LGSC), endometrioid (EC), clear cell (CCC), and mucinous carcinoma (MC). HGSC, together with undifferentiated, high-grade endometrioid carcinoma, and cacinosarcoma constitute the so-called type 2 group of ovarian carcinomas whereas LGSC, EC G1-2, CCC, and MC are grouped as type 1 tumors, according to the dualistic model of ovarian carcinogenesis (reviewed in [1]). This theoretical classification, which should not replace the histological terms in widespread use, helps to separate ovarian carcinomas that are often low stage and more slowly progressive and has defined intraovarian precursor lesions (borderline tumors), from the aggressive high-grade tumors. During the last decade, profound differences in molecular profiles, precursor lesions, response to chemotherapy (CTX), and prognosis

have been described for these histological subtypes (reviewed in [2]). HGSC constitutes the major subtype (approximately 70 %) of all ovarian carcinomas. Molecularly, it is characterized by a high rate of genomic instability and p53 alterations [3]. Patient prognosis in general is unfavorable: 75 % of patients are diagnosed in a late stage when the carcinoma has already disseminated in the peritoneal cavity. Radical surgery and adjuvant platinum-based CTX is the standard of care for all ovarian carcinomas to date [4]. However, although 75 % of ovarian cancer patients initially respond to CTX, 75 % of these will relapse and ultimately die of their disease. Novel therapeutic options are therefore needed. The evaluation of novel biomarkers within molecularly and morphologically defined subgroups bears the potential to identify molecules and pathways as targets for a specific cancer therapy.

Anterior gradient protein 2 (AGR2) was first described in *Xenopus laevis* where it plays a role during early neural development [5]. In humans, AGR2 is predominantly found in tissues with mucus-secreting or endocrine cells [6]. It is a member of the protein disulfide isomerase family of endoplasmic reticulum-resident proteins. Although its exact physiological function is not known, AGR2 has been implicated in the folding of proteins as a chaperone protein [6]. It became of interest in cancer research, when a differential expression was found in estrogen receptor (ER)-positive breast cancer cell lines [7]. Since then, elevated AGR2 has been seen in subsets of breast [8–11], prostate [12–14], non-small cell lung [15], pancreatic [16], and hepatic adenocarcinomas [17], in some entities along with an impact on prognosis [8–11, 14]. In breast and prostate adenocarcinoma, AGR2 was under the control of ER or androgen receptor expression [11, 13]. Upregulation of AGR2 enhances classical hallmarks of cancer, such as metastasis, invasion, colony formation, and proliferation (reviewed in [6]).

In ovarian cancer, where ER signaling also has a prognostic implication as we previously showed [18, 19], AGR2 has not yet been investigated in a larger cohort. We therefore determined the expression pattern, the potential prognostic role, and the relationship with ER expression in all major subtypes of ovarian carcinoma.

Methods

Study population This study included 124 patients with primary HGSC who underwent radical surgery between 1991 and 2007 with the aim of total cytoreduction at the Department of Gynecology and Obstetrics (Charité Universitätsmedizin Berlin). Resection specimens were formalin fixed and paraffin embedded for diagnostic purposes at the Institute of Pathology of the Charité. Hematoxylin/eosin (HE)-stained slides were reevaluated according to histology by an experienced gynecopathologist (SDE). Typing as HGSC was performed as suggested by McCluggage taking into account growth pattern, nuclear polymorphism, and mitotic count [20]. As expected from this tumor subtype, most cases were high-stage tumors (Fédération Internationale de Gynécologie et d'Obstétrique (FIGO) stages III–IV, n=110, 88.7 %). Data on residual tumor mass were available for 92 patients (74 %). The majority of patients had been treated with standard adjuvant platinum-based CTX (n=109/114, 95.6 %), and two patients (1.8 %) with FIGO I tumor stage have not received adjuvant CTX. Data on overall survival (OS) were available for all patients. Median OS in patients alive after follow-up was 45.0 months (range 2.5–162.3 months), and 46 patients died during follow-up (37.1 %). Data on progression-free survival (PFS) were available for 111 patients (88.7 %; median PFS in nonprogressive patients 32.1, range 0.5–127.8 months). The distribution of clinicopathological parameters in the study cohort is shown in Table 1. We additionally investigated a group of type 1 carcinomas, consisting of 16 LGSCs, 15 ECs G1-2, 9 CCCs, and 8 MCs.

[a]FIGO I

Immunohistochemistry For tissue microarrays (TMA) construction, representative tumors areas were marked on HE-stained slides by a pathologist, and two to four tissue cores (diameter 1.5 mm) subsequently punched out the respective donor paraffin blocks using a tissue microarrayer (Beecher Instruments, Woodland, WI, USA). Cores from 40 to 60 carcinomas were placed in recipient paraffin blocks. Immunohistochemistry staining of TMA sections was performed according to standard procedures as described earlier [21]. A mouse monoclonal antibody was raised against full-length recombinant AGR2 (clone 1c3, Abnova, GmbH, Heidelberg, Germany) was used in a dilution of 1:50. 3,3′-diaminobenzidine peroxide substrate (DAB^+) was used as a chromogen. Stained slides were scanned and evaluated using the TMA evaluator software from VM Scope GmbH (Berlin, Germany). The percentage of positive tumors cells was scored as 0 (0 %), 1 (0–10 %), 2 (11–50 %), 3 (51–80 %), or 4 (80–100 %), and the staining intensity was scored as 0 (negative), 1 (weak), 2 (moderate), or 3 (strong). The strongest, not necessarily the predominant intensity, was scored. The multiplication of the intensity and percentage scores resulted in an immunoreactivity score (IRS), which ranged from 0 to 12.

Statistical evaluation Statistical analyses were performed with SPSS Statistics 19 (SPSS Inc., Chicago, IL, USA) and GraphPad Prism v.5 (La Jolla, CA, USA). Associations were tested by Fisher's exact, chi-square or Mann–Whitney test, as indicated. Survival analysis was performed using the Kaplan–Meier method or Cox regression for multivariate testing. All p values were calculated two tailed, and p values <0.05 were considered as significant.

Results

Expression pattern of AGR2 in HGSC A significant number of HGSC were completely negative for AGR2 (n=84, 67.7 %). In the remaining carcinomas, staining was either weak to moderate diffuse (Fig. 1a, b) or patchy with groups of positive cells distributed throughout the tumor. Fifteen tumors (12.1 %) revealed groups of strongly stained cells usually constituting 10–50 % of all tumor cells, with two cases revealing 50–80 % of strongly stained cells (Fig. 1c). Staining was strictly cytoplasmic. The use of an IRS yielded one group of completely negative tumors (IRS=0, n=84), one group with intermediate expression (IRS=1–4, n=26), and a high expression group (IRS=6–9, n=14), with the latter group being identical to the group defined simply by strong staining intensity with the exception of a single case with moderate staining in 50–80 % of cells (IRS=6). We therefore decided to continue our subsequent analyses using only staining intensity as a grouping variable. In the diagram (Fig. 1d), the distribution of staining results is displayed. No relevant staining signals were obtained in tumor stroma or inflammatory cells. AGR2 expression was not associated with age, tumor, nodal, or FIGO stage; residual tumor after surgery; or type of CTX (p>0.05, not shown).

Impact of AGR2 expression on patient survival AGR2 expression was subsequently tested for a prognostic effect in HGSC. Kaplan–Meier analysis revealed that patients with AGR2-negative tumors had an OS quite similar to those with AGR2 weakly or moderately expressing carcinomas (Fig. 2a). Only a strong AGR2 expression resulted in a clearly worse OS. The same effect was seen for PFS (Fig. 2b). When we stratified our study cohort into a group of strong AGR2 expression (AGR2 high) and a group of negative, weak, and moderate expression (AGR2 low), patients with AGR2-low carcinomas had a mean survival of 106.17 months as opposed to 47.23 months in patients with AGR2-high carcinomas (p=0.011, Fig. 2c). Mean survival until progression was reduced from 38.71 months in patients with AGR2 low-expressing tumors to 12.38 months in case of a high AGR2 expression (p=0.001, Fig. 2d). A multivariate Cox regression analysis including patient age, FIGO stage, and residual tumor after surgery demonstrated that high AGR2 expression was an independent prognostic marker, both for OS (hazard ratio (HR)=2.60, p=0.023) and PFS (HR=3.89, p=0.001, Table 2).

Correlation with ER expression As a regulation of AGR2 by ER has been reported in breast cancer, the association of AGR2 expression with ER and progesterone receptor (PR) expression was determined on the protein and mRNA level; these data had been determined previously in our study cohort [18, 19]. There was no association of AGR2 expression (high vs. low) with ERα (gene name ESR1) or PR mRNA expression as determined by quantitative reverse transcription polymerase chain reaction, neither on the continuous level (Mann–Whitney test, p=0.438 and p=1.000, respectively) nor with dichotomized ESR1 and PR mRNA expression groups (Fisher's exact test, p=0.320 and p=0.633, respectively). AGR2 expression was also not associated with ER or PR protein expression (Fisher's exact test, p=0.588 and p=0.584, respectively). The use of other cutoffs for AGR2 expression also did not show any association (p>0.05, data not shown).

AGR2 expression in other histological subtypes In an exploratory approach, we analyzed the expression of AGR2 in 16 LGSCs, 8 MCs, 15 G1-2 ECs, and 9 CCCs. Contrarily to HGSC, a strong staining throughout the whole tumor was noted in some LGSC and MC (Fig. 3a, b). AGR2-high expression was found in 15 (12.1 %) of HGSC, in 4 (25 %) of LGSC, in 5 (35.7 %) of EC, in 1 (11.1 %) of CCC, and 5 (62.5 %) of MC (Fig. 3c). No association of

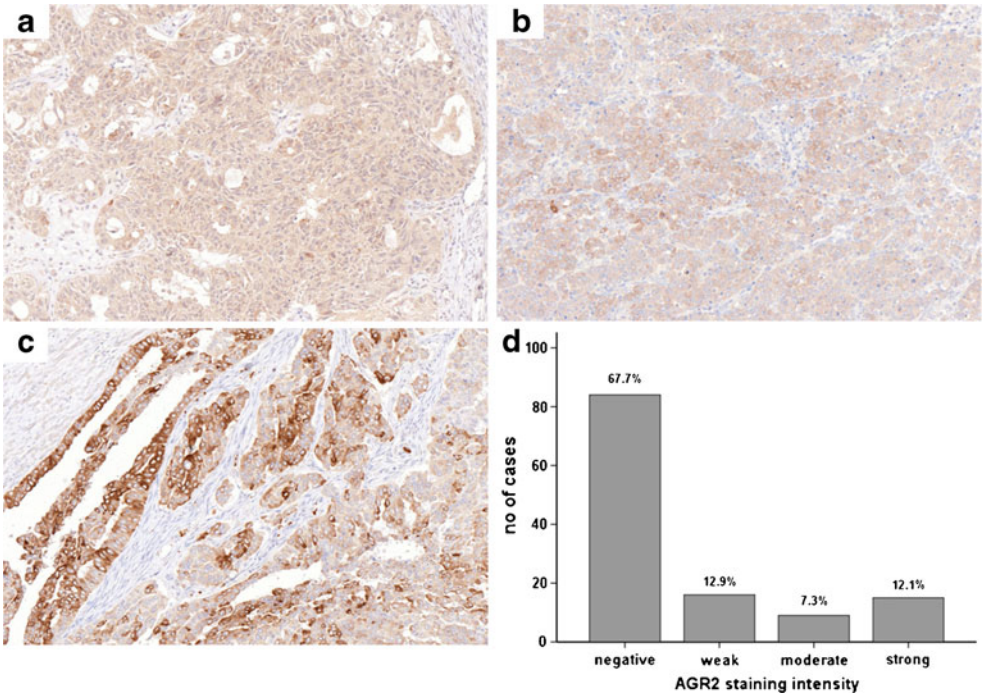

Fig. 1 Expression pattern of AGR2 in HGSC. **a** Solid tumor masses with weak diffuse AGR2 expression, **b** weak to moderate staining, **c** invasive sheets and glands of HGSC with weak background expression of AGR2 and patchy groups of strongly stained tumor cells, and **d** staining intensity groups in HGSC

AGR2 expression with either ER or PR protein or mRNA expression was seen within the histological subtypes of type 1 carcinomas (not shown).

Discussion

In this study, we investigated the expression pattern and the prognostic impact of the metastasis-associated protein AGR2 in HGSC. Strong AGR2 expression was seen in a subset of tumors with exceptionally shortened OS and PFS. The prognostic impact of AGR2 expression was independent of patient age, stage, and residual tumor mass. We further gained evidence that AGR2 is highly expressed in a significant rate of type 1 carcinomas, especially EC, LGSC, and MC.

To our knowledge, this is the first study investigating AGR2 protein expression in a larger cohort of ovarian carcinomas and therefore also the first study to reveal a prognostic significance in HGSC. Elevated AGR2 transcript levels were first detected in ovarian cancer specimens using gene array profiling, especially in the mucinous subtype [22, 23]. Recently, increased AGR2 protein has also been detected in the serum of patients and holds potential as a screening marker [24, 25]. The latter study also provided a preliminary immunohistochemical investigation of AGR2 expression in a group of 15 serous and mucinous carcinomas and found almost all tumors to be positive, whereas in our cohort, a significant proportion of tumors, especially HGSC, were completely negative. Differences in staining protocol and interpretation may account for this. In contrast to AGR2, its ortholog AGR3, which is implicated in growth and metastasis of ER-dependent breast cancers [26], has already been investigated in ovarian carcinoma [27, 28] and, interestingly, was a favorable prognostic factor in HGSC and LGSC. Although in each of those studies including ours less than 10 specimens of MC were evaluated, a consensus on a diffuse expression of AGR2 and/or AGR3 in this histological subtype is evident. Our study additionally shows that also in EC and LGSC, high AGR2 expression is often present and that even CCC may be AGR2 positive, however less frequently. As AGR2 is predominantly found in mucus-secreting or endocrine cells in normal tissue [6], AGR2 expression in ovarian carcinoma may be related to the extent of mucus secretion, which is highest in MC, but also found in subsets of the other histological types. The reasons for the differential expression of AGR2 in ovarian carcinoma subtypes remain to be clarified. Taking together all reports on AGR2/3 expression in ovarian carcinomas, the further evaluation as diagnostic biomarkers and potential therapeutic targets in all histological subtypes is promising; however, due to the rarity of type 1 tumors, these should potentially be investigated in a multicenter setting.

In our study, only HGSC with strong overexpression of AGR2 turned out to constitute a special prognostic subgroup. This is in contrast to the situation in breast cancer, where AGR2 mRNA and protein expression have already been systematically evaluated repeatedly. Here, a clear deterioration of the prognosis was evident even when no more than 1 % of tumor cells were stained, as compared to completely negative cases and patient prognosis declined with a growing rate of

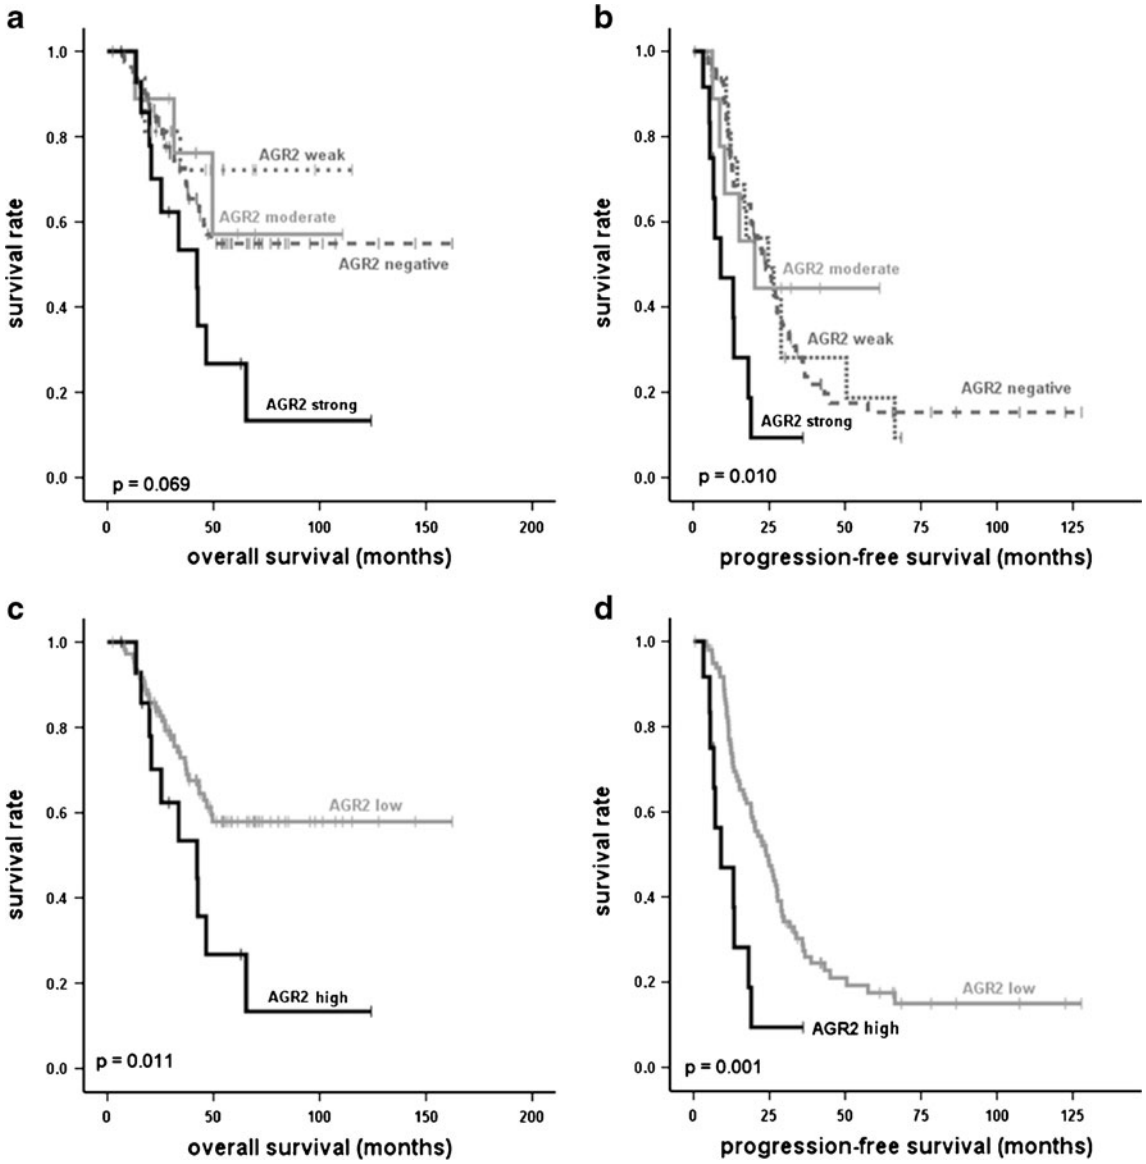

Fig. 2 Survival analysis: OS (**a**) and PFS (**b**) using four groups of AGR2 expression. OS (**c**) and PFS (**d**) after stratifying the cohort into a group with AGR2-low (negative, weak, or moderate staining) and AGR2-high expression (strong staining). *p*: log rank test

positive tumor cells in a dose-dependent manner [8, 9]. Moreover, a clear prognostic impact of AGR2 seemed to be restricted to ER-positive breast cancers [8, 11]. The different impact of AGR2 expression in HGSC and breast cancer might be explained by an apparently differing regulation in both cancer types. In breast cancer, there is a strong association of AGR2 and ER expression [8–10], apparently due to a transcriptional regulation of AGR2 by ER [11]. Although we and others previously showed that a significant subset of ovarian carcinomas including HGSC reveals ER and PR expression [18, 19], we did not find a link between hormone receptor status and AGR2 expression in our cohort. AGR2 therefore plays an ER-independent role in HGSC, similarly to hepatic fibrolamellar and pancreatic adenocarcinoma [16, 17].

Physiological stress seems to constitute an alternative regulatory pathway for induction of AGR2, independently from steroid hormone receptor function. Thus, serum/oxygen depletion [29], UV-induced DNA damage [30], or endoplasmic reticulum-related stress [16] have been found to upregulate AGR2 in various cell culture models. In breast cancer cells, an intact extracellular signal-regulated kinase/mitogen-activated protein kinase pathway was necessary for the upregulation of AGR2 by serum depletion [29]. Alterations are also common in HGSC [3]. Stressful conditions due to reduced blood supply are seen in all solid cancers [31] and might be potential regulators of AGR2 upregulation in HGSC, too.

Our finding of a negative prognostic impact of AGR2 may be explained by its described function in tumor

biology. Cells with the upregulation of AGR2 gain a metastatic, proliferative, and invasive phenotype, which all constitute features of highly aggressive tumors. For instance, transfection of benign rat mammary tumor cells with AGR2 results in the development of lung metastasis after transferral of cells into the mammary fat pad in syngeneic hosts

[16, 32, 33]. An increased proliferative and invasive capacity was seen in breast and pancreatic cancer cells after forced expression of AGR2 [34]. In HGSC, striking individual differences in survival exist, which to date cannot sufficiently be predicted by morphological features or molecular markers. AGR2 might contribute to the aggressiveness of certain ovarian carcinomas, and AGR2 expression might also serve as a prognostic marker. Furthermore, our finding of a significantly shortened survival until disease relapse points to a role of AGR2 in CTX resistance, as PFS in HGSC is largely dependent on response to adjuvant CTX and OS is further dependent on response to second and third line CTX [4]. In pancreatic cancer cells, a direct relationship between AGR2 expression and response to gemcitabine has been established in vitro and in vivo [33]; interestingly, AGR3, which seems to have similar tumor-promoting properties as AGR2, has been implicated with cisplatin resistance in ovarian cancer [27]. In the light of our results, it would be intriguing to functionally investigate the role of AGR2 in CTX response in ovarian HGSC.

In conclusion, we demonstrate that the metastasis-related protein AGR2 is highly expressed in a subset of ovarian HGSC of the ovary that shows a particularly unfavorable prognosis. In HGSC, as opposed to breast cancer, AGR2 expression does not seem to be under transcriptional control of ER. We further show a high expression of AGR2 in subsets of LGSC, EC, CCC, and especially MC. Our data strongly encourage the further evaluation of AGR2 as a therapeutic target molecule and a potential response predictor to platinum-based CTX in this tumor entity.

Acknowledgments We thank Mrs. Petra Wachs for her excellent technical assistance.

Abstract Desmoid-type fibromatosis (DTF) is a rare soft tissue tumor with fibroblastic features affecting two to four individuals per million population per year. Despite its bland microscopic appearance, the tumor behaves aggressively. Although unable to metastasize, DTF tends to recur and local recurrences in anatomically critical sites can be fatal. Tumor-associated macrophages (TAM) play an important role in tumor development through the activation of angiogenesis, particularly in cases of epithelial malignancies. The aim of this study is to investigate the prognostic significance of TAMs and the number of microvessels in DTF. Tumor macrophages (CD163), microvessel density (CD31), and beta-catenin were investigated on 69 primary DTF cases with follow-up information. *CTNNB1* mutations were also studied. High density of tumor macrophages and high number of microvessels were associated with a significantly worse recurrence-free survival (P=0.03 and P=0.007, respectively). There was a significant correlation between microvessel density and CD163 macrophages (P=0.02). Furthermore, combination of high number of tumor macrophages and high microvessel density greatly improved the statistical significance (P=0.000005). Macrophages and microvessels may play an important role in the biologic behavior of DTF. This finding could help in the clinical management of patients with DTF.

Introduction

Desmoid-type fibromatosis (DTF) is a rare, locally invasive soft tissue tumor with fibroblastic–myofibroblastic features. Although unable to metastasize, desmoid-type fibromatoses often recur and they can rarely cause death when they invade or compress a vital structure, such as occurs with tumors in the root of the neck and within the abdomen [1]. There are currently no well-established prognostic factors beyond size, site, and the extent and adequacy of initial excision that can assist in the management of patients, especially in terms of follow-up. The identification of new prognostic factors, particularly ones that are relevant to the biology of DTF, will therefore be of clinical value in the management of these patients.

Many studies have shown that tumor-associated macrophages (TAMs) play an important role in tumor development and progression [2–4]. These macrophages produce cytokines that promote tumor growth, angiogenesis, extracellular matrix breakdown, invasion, and metastases. The

formation of new blood vessels has been correlated with prognosis in different types of tumors [5–10]. In addition, several studies have shown an association between number of TAMs and microvessel density [10–12].

In this study, we evaluated if there is a statistically significant correlation between TAMs, microvessel density, and clinical outcome in DTF.

Material and methods

Tissue samples

Paraffin-embedded samples of 69 specimens from 69 different patients with desmoid-type fibromatosis were obtained from the Tumor Tissue Bank and the Surgical Pathology files of the Hospital de la Santa Creu i Sant Pau, Barcelona, Spain and from the Hospital Clínico Universitario San Carlos, Madrid, Spain. The 69 specimens represent biopsy or resection of the primary disease, and the date of the diagnosis ranged from 1995 to 2009. For 12 cases, material from recurrent lesions was available. Follow-up information was available in 58 cases. Tumors were examined and classified using the histopathological criteria recommended by the World Health Organization. Cases in which patients were diagnosed with familial adenomatous polyposis (FAP) or had a family history of FAP were excluded; therefore, only sporadic desmoid tumors were ultimately evaluated.

Tissue microarray design

Two tissue microarrays (TA88 and TA98) were made using a tissue microarray workstation (Beecher Instruments, Sun Prairie, WI, USA). For each DTF case, a block with viable tumor was chosen. Hyalinized, myxoid, and hypocellular areas were avoided. Only high or moderately cellular areas were chosen. A 0.6-mm tissue core was taken from these areas in each of the blocks and inserted into the TA88 and TA98 tissue microarray blocks. To confirm the presence of the original tumor area, a hematoxylin and eosin section was analyzed.

Immunohistochemical analysis

Slides were cut at 4 μm. Deparaffination and antigen retrieval were done in a PT Link module (DAKO, Glostrup, Denmark) and immunohistochemistry was done in a Dako Autostainer (DAKO, Glostrup, Denmark). The primary antibodies used were CD31 (mouse monoclonal JC70A, prediluted, DAKO), CD163 (mouse monoclonal 10D6, 1/100, Novocastra, CA, USA) and β-catenin (mouse monoclonal β-catenin-1, prediluted, DAKO). Antigen retrieval solution was PT Link High pH. For CD31 and CD163, an additional incubation was done with EnVision Linker mouse (DAKO). Visualization system used was EnVision+FLEX (DAKO). Detection was done with DAB/HRP and hematoxylin as a counter stain. A tumor-associated macrophage identified by CD163 was defined as a cell with abundant cytoplasm, a dendritic pattern, and a round or oval nuclei. Microvessel density was determined by counting the number of CD31-positive microvessels in an entire 0.6-mm core. A microvessel was defined as any endothelial cell or endothelial cell cluster staining positive for CD31. Scoring criteria are shown in Table 1.

CTNNB1 genotyping

Mutations of the beta-catenin gene (*CTNNB1*) were assessed by PCR amplification followed by sequencing analyses. The exon 3 of *CTNNB1* was amplified by PCR using the oligonucleotide primers P3 (5′-GATTTGATGGAGTTGGACATGG-3′) and P4 (5′-TGTTCTTGAGTGAAGGACTGAG-3′). After this first-round amplification, 1 μL of the PCR product was reamplified by nested PCR, using a set of amplimers, P1 (5′-AGTCACTGGCAGCAACAGTC-3′) and P2 (5′-TCTTCCTCAGGATTGCCTT-3′). PCR conditions were as described previously; annealing temperatures were 55 °C for primers P3 and P4 and 52 °C for primers P1 and P2. The PCR products were purified using the exoSAP-IT (USB, Cleveland, OH, USA) and subjected to direct sequencing using ABI PRISM™ big Dye terminator v1.1 cycle sequencing Kit (Applied Biosystems, Foster City, CA, USA). Sequencing fragments were detected by capillary electrophoresis using an automated ABI PRISM 310 Genetic Analyzer (Applied Biosystems).

Statistical analysis

Statistical analysis was done using WinSTAT, a statistics add-in for Microsoft Excel, where the Kaplan–Meier method was used for survival analysis. Analysis of time to recurrence (recurrence-free survival (RFS)) was calculated

Table 1 Scoring criteria for MVD (CD31), macrophages (CD163), and β-catenin

	CD31 (MVD)	CD163 (macrophages)	β-catenin
Score 1	≤9 cells/0.6 mm	≤25 cells/0.6 mm	Negative; nuclear staining in <1 % of tumor cell/0.6 mm
Score 2	>9 cells/0.6 mm	>25 cells/0.6 mm	Positive; nuclear staining in ≥1 % of tumor cell/0.6 mm

from initial surgery for the primary desmoids to the first recurrence. Cox regression analysis was used to study the relationship between survival and the different variables. The following variables were introduced into the analysis: age, sex, tumor location, tumor size, surgical margins status, *CTNNB1* mutations, β-catenin expression, and co-expression of CD163 and CD31 in DTF cases. A value of $P \leq 0.05$ was considered statistically significant.

Results

Cases

A series of 69 paraffin-embedded primary desmoid-type fibromatoses were used for the construction of the tissue microarrays. Clinical details are described in Table 2. There was a slight predominance of female patients, with a female to male ratio of ~1.3:1. The average age of the patients at the time of initial diagnosis was 41 years (ranging from 13 to 94 years). Size was known in 45 cases and ranged from 1 to 27 cm (average, 7 cm). The most common location in this series was superficial trunk (27, 39 %), followed by upper and lower extremities (22, 31 %), neck (10, 15 %), and deep trunk/mesentery (10, 15 %). Information about resection margins was available for 41 patients. Margins were positive in 30 (73 %) tumors and negative in 11 (27 %) tumors. Univariate analysis showed that male patients and an extremity tumor location were significantly associated with an increased propensity for local recurrence ($P=0.02$ and $P=0.0001$, respectively; Table 3).

Expression of CD31 (MVD) and CD163 (TAM) in DTF

In order to investigate microvessel density (MVD) in patients with DTF, a vascular marker (CD31) was used to mark the endothelial cells. There was considerable variation in MVD across the different cases of DTF where it ranged from 0 to 33 per 0.6 mm core (mean, 9; Fig. 1). To quantify the amount of tumor-associated macrophages, we used CD163, a relatively specific marker for macrophages. The staining signal was located in the membrane and cytoplasm but not in the nucleus (Fig. 1). Tumor-associated macrophages ranged from 3 to 84/0.6 mm (mean, 25). There was a significant correlation between microvessel density and CD163-macrophages ($P=0.02$). CD163 and CD31 immunostaining was done on whole tissue sections of selected

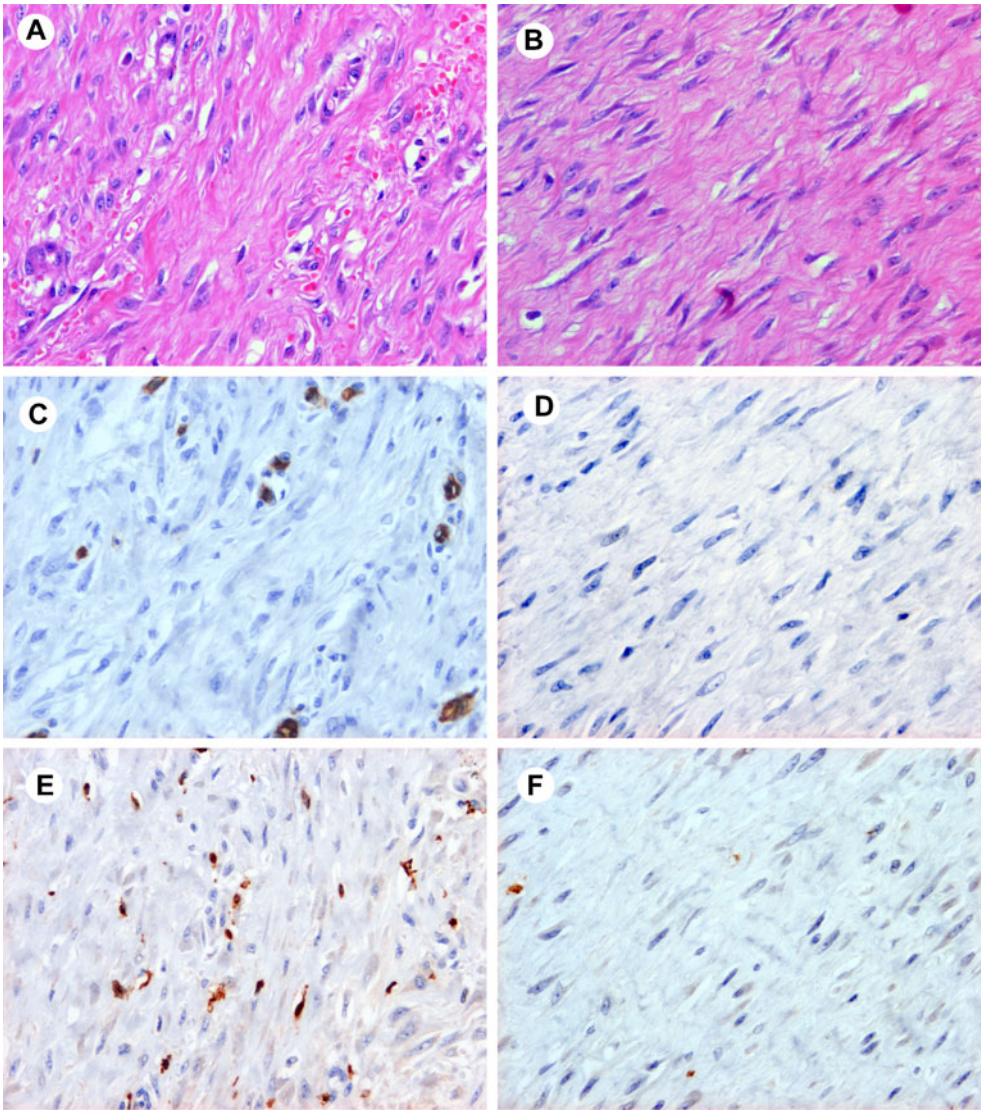

Fig. 1 Representative images showing a DTF case (**a**, H&E) with high MVD (**c**, CD31) and dense infiltrate of macrophages (**e**, CD163). A DTF case (**b**, H&E) with low MVD (**d**, CD31) and sparse infiltrate of macrophages (**f**, CD163)

cases of desmoid-type fibromatosis that showed dense or sparse CD163-positive macrophage infiltrates and high or low microvessel density. There seems to be a high degree of spatial uniformity in the intratumoral macrophage density and in the intratumoral number of microvessels within the high or moderately cellular areas. We next examined the consistency in macrophage infiltrate and MVD by comparing these features in 12 primary DTF and their corresponding recurrent lesions. The presence of TAMs, as measured by CD163 staining, and the level of MVD did not remain stable between primary and recurrent lesions (data not shown).

Prognosis of TAMs and MVD in DTF

Cases were stratified based on whether they displayed greater or less than the mean MVD and TAMs. RFS was used as an endpoint measurement for Kaplan–Meier analysis. Patients with high MVD (>9 microvessels/0.6 mm) had a higher probability to recur than patients with low MVD (n=54, P=0.007; Fig. 2a). Also, patients with DTF showing dense CD163-positive macrophages (>25/0.6 mm) had worse recurrence-free survival than patients with low macrophage infiltrate (n=52, P=0.03; Fig. 2b). Furthermore, the 12 cases that had high MVD and dense macrophage infiltrate showed a very strong correlation with poor patient outcome compared to the 38 cases that had either singly high MVD or dense macrophage infiltrate, or low for both (P=0.000005; Fig. 2c). In the multivariate analysis incorporating age, sex, tumor location, tumor size, surgical margins status, *CTNNB1* mutations, β-catenin expression, and co-expression of CD163 and CD31, the presence of high MVD and dense macrophage infiltrate was selected as the feature most predictive of recurrence (P=0.008).

CTNNB1 mutations and nuclear expression of B-catenin

Mutational information was available in 47 patients. A mutation in exon 3 of the *CTNNB1* gene was identified in

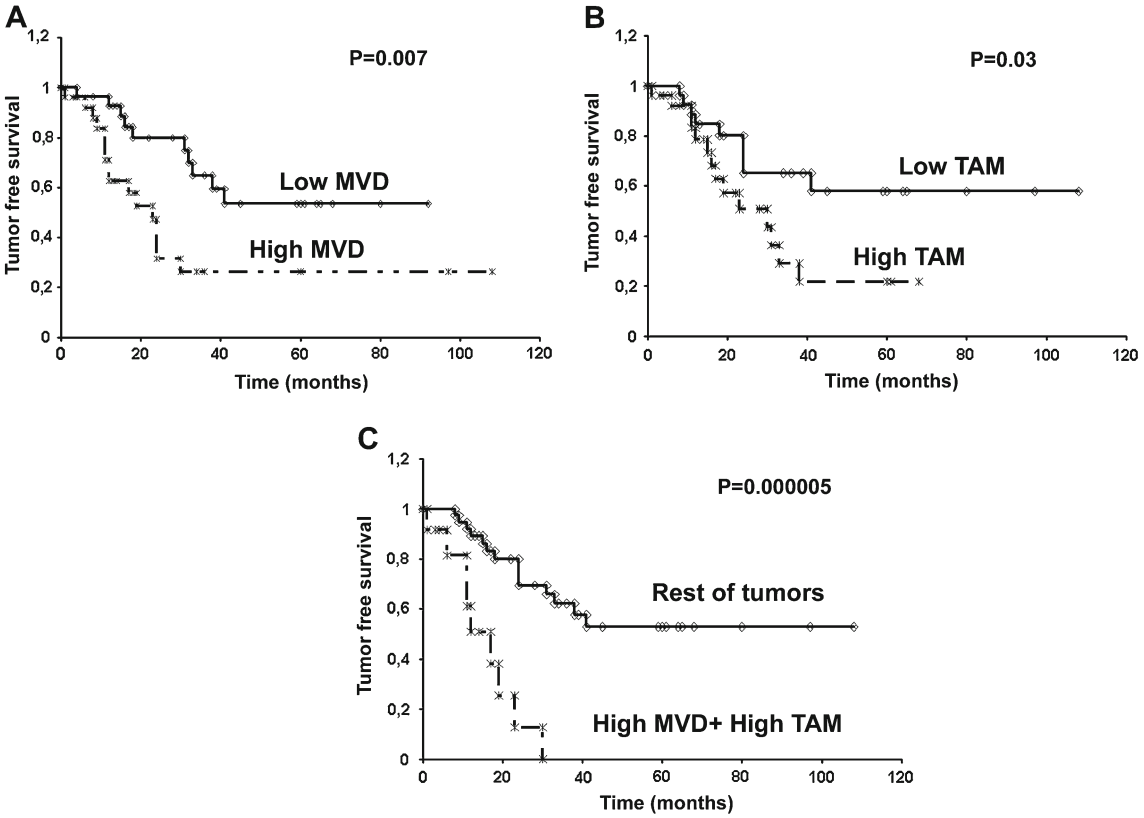

Fig. 2 **a** Kaplan–Meier plot showing that patients with a high MVD (>9/0.6 mm core) have a higher tendency to recur than patients with low MVD (≤9/0.6 mm core; $P=0.007$). **b** Kaplan–Meier plot showing that patients with high number of tumor-associated macrophages (TAM; >25/0.6 mm core) have a higher probability to recur than those with sparse infiltrate of macrophages (≤25/0.6 mm core; $P=0.030$). **c** Kaplan–Meier plot showing that patients with a high density of microvessels (>9/0.6 mm core) and a dense infiltrate of macrophages (>25/0.6 mm core) have a higher tendency to recur than the rest of the patients ($P=0.000005$)

39 cases (83 %). Four different point mutations in three different codons were found in all mutated cases: T41A ($n=30$, 77 %), S45F ($n=7$, 18 %), S45P ($n=1$, 2.5 %), and T40S ($n=1$, 2.5 %). There was no correlation between any specific mutation and prognosis (Table 3). Nuclear β-catenin expression was observed in 81 % of desmoid samples (56/69). Mutation of the *CTNNB1* gene was found in the majority of β-catenin negative cases (9/13; 70 %).

Discussion

TAMs can promote tumor development through activation of angiogenesis [2–4, 13]. In fact, TAMs and microvessel density are associated with adverse prognosis in several tumors [5–7, 10, 14, 15]. We have analyzed the role of tumor angiogenesis and tumor-associated macrophages in primary desmoid-type fibromatosis; a tumor with a high tendency to recur. Our results show that the density of microvessels and tumor-associated macrophages were predictive of recurrences. Of note, the combination of microvessel density and tumor-associated macrophages improved the prognostic significance. All together suggest that macrophages and microvessels may play an important role in the clinical behavior of desmoid-type fibromatosis.

Desmoid-type fibromatosis is a mesenchymal tumor that exhibits evidence of fibroblastic–myofibroblasltic differentiation. Local recurrence is frequent and histological examination alone does not permit accurate prediction of the clinical outcome. There are currently no well-established prognostic factors. Prognostic factors including age, tumor size, tumor location, and the extent and adequacy of initial excision remain controversial [1, 16–18]. In the 69 DTF cases studied in the current report, only tumor location and sex correlated with recurrence-free survival. Tumors located in extremities and male patients were associated with an increased propensity for local recurrence.

Thus, the identification of novel prognostic factors, particularly ones that are relevant to the oncobiology of desmoid-type fibromatosis, will therefore be of clinical value in the management of these patients. Recently, the presence of specific mutations in the β-catenin gene (*CTNNB1*) has been associated with local recurrence in sporadic desmoid-type fibromatosis. *CTNNB1* 45 F mutations significantly correlated with increased desmoids tumor recurrence [19]. In our cases, although tumors with *CTNNB1* 45 F

mutations showed poorer prognosis than tumors with *CTNNB1* 41A mutations, the difference was not significant.

Our findings suggest that CD163 macrophages and CD31 microvessels play an important role in the pathogenesis of DTF and suggest a relationship between macrophages and angiogenesis. A previous study suggested that microvessel density was not prognostic of clinical outcome in desmoid-type fibromatosis [20]. The small number of desmoid-type fibromatosis cases (33) or the variability of the morphology of the areas selected for each case may explain why the association between microvessel density and poor clinical prognosis in desmoid-type fibromatosis was not apparent in that study.

The relationship between TAMs and angiogenesis has been implicated in the tumorigenesis of several carcinomas and sarcomas [10, 11]. Espinosa et al., demonstrated that colony-stimulating factor 1 (CSF1)-associated macrophages highly correlated with microvessel density and poor prognosis in nongynecological leiomyosarcoma cases [10]. In addition, Kubota et al. showed that CSF1 depletion in a mouse model of osteosarcoma resulted in the suppression of tumor angiogenesis [21]. All together suggest that anti-angiogenic molecules or therapies that prevent the attraction of macrophages into the tumor stroma may help in the management of desmoid-type fibromatosis patients.

In summary, our results indicate that high microvessel density predicts poor outcome in desmoid-type fibromatosis. When combining high microvessel density with dense macrophage infiltrate, an even stronger prognostic correlation with patient outcome was obtained. Therapies that act on cancer cells but also targeting non-neoplastic cells may help in the management of these patients.

Abstract Oncogene amplification is a key step in cell transformation towards malignancy. Chromosomal aberrations involving the long arm of chromosome 11, including amplifications at 11q13 and 11q22, have been previously reported in cervical cancer. While the role of the *CCND1* gene as the driver gene for 11q13 amplification is well established in different tumor types, the significance of the 11q22 amplicon is less clear. The 11q22 amplicon corresponds to several putative target genes including the apoptose inhibitor *BIRC2*, recently detected as amplified in cervical cancer cell lines. To better understand the distribution and frequency of 11q amplification sites in uterine cervical carcinomas, we analyzed *BIRC2* and *CCND1* copy number changes using fluorescence in situ hybridization in a tissue microarray containing 238 cervical cancers. High-level amplification of *BIRC2* was found in 12.9 % of tumors. Amplification of *BIRC2* in cervical carcinomas was homogeneous as shown in corresponding whole tissue sections of amplified tumors at the tissue microarray. *BIRC2* amplification was significantly more frequent than *CCND1* amplification (2.1 %) in our cohort ($p<0.01$), and amplification of both genes were independent from each other. *BIRC2* amplification was associated with younger-patient age ($p<0.05$) and squamous cell differentiation ($p=0.025$) of cervix carcinomas. However, *BIRC2* copy number changes were not related to tumor stage, grading and nodal status of cervical cancers. In conclusion, *BIRC2* is amplified in a subset of squamous cell carcinoma of the uterine cervix. Further studies are necessary to evaluate possible prognostic effects of *BIRC2* copy number gains in cervical carcinomas.

Introduction

Human papillomavirus (HPV) infection plays a pivotal role in cervical cancer development as shown in numerous studies [1, 2]. Despite this, deregulation of additional cellular signaling pathways is necessary for transformation towards malignancy. Amplification of oncogenes might be a key step in this process. Commonly amplified chromosomal regions in cervical carcinomas are located at 1q, 3q, 5p, 8q, 11q, and 20q [3–7]. So far, little is known about possible candidate oncogenes at the long arm of chromosome 11. At 11q13, the regulator protein cyclin D1 (CCND1) is generally accepted as a biologically relevant amplification target. CCND1 promotes as cofactor of cyclin-dependent kinases progression through G1-S-phase of the cell cycle via phosphorylation and inactivation of the retinoblastoma protein [8]. Chromosomal *CCND1* aberrations can be observed in a variety of cancer types including carcinomas of the uterine cervix [9, 10]. Imoto et al. [11] first reported on an amplicon at 11q22 comprising the baculoviral IAP repeat-containing protein 2 (*BIRC2*) gene in cervical cancer cell lines as well as in primary carcinomas of the uterine cervix. Recently, high resolution array CGH revealed the same amplicon at 11q22 containing the *BIRC* gene cluster in the cervical cancer cell Ca Ski [12]. *BIRC2* encodes for the protein c-IAP1 which is a member of the inhibitor-of-apoptosis family [13]. The c-IAPs play a role as caspase inhibitors

and co-factors in the tumor necrosis factor (TNF) signaling pathway. Down-regulation of c-IAP1 through activation of the Akt pathway results in apoptosis of endometrium cancer cell lines [14]. Several studies have shown that the 11q22 amplicon is not restricted to cervical cancer but also occurred in carcinomas of the lung and esophagus [15, 16].

To explore the potential significance of *BIRC2* and *CCND1* amplification in cancer of the uterine cervix, we analyzed a tissue microarray containing 238 cervical carcinoma specimens by FISH and correlated the results with clinicopathological prognostic parameters. Our results indicate a possible important role of the *BIRC2* amplicon in the development of a subset of cervical carcinomas.

Materials and methods

Cervix cancer tissue microarray

A total of 238 formalin-fixed (buffered neutral aqueous 4 % solution), paraffin-embedded cervical carcinomas with a median patient age of 47.5 (range 23–85) years were assembled in a tissue microarray (TMA) format as previously described [17]. Briefly, we punched one tissue cylinder per case with a diameter of 0.6 mm from representative tumor areas of a "donor" tissue block using a home-made semiautomatic robotic precision instrument. Tumor specimens (217) were analyzable for *BIRC2* and 193 specimens for *CCND1* by fluorescence in situ hybridization (FISH). Homogeneity analysis of *BIRC2* was carried out by hybridization of corresponding whole tissue sections of amplified tumors at the TMA. The use of these human tissues for protein expression and FISH studies was approved by the local ethics committee of the University of Hamburg.

FISH analysis

A FISH probe was generated from genomic clone RP11-864 G5 (length 186 kB) containing the entire *BIRC2* gene. The probe was labeled with digoxigenin-dUTP by nick translation (Invitrogen). A commercially available pericentromeric probe for chromosome 11 was used as reference (CEP 11 D11Z1 SpectrumOrange, Abbott, Downers Grove, IL, USA). The probe combination for FISH of the *CCND1* gene was LSI Cyclin D1 (11q13) SpectrumOrange/CEP 11 SpectrumGreen (order # 05J41-001). For dual-color FISH analysis, 4-μm sections of the cervical cancer tissue microarray blocks were transferred to an adhesive-coated slide system (Instrumedics, Hackensack, NJ, USA). For proteolytic slide pretreatment, a commercial kit was used (Paraffin pretreatment reagent kit; Vysis). Before hybridization, tissue microarray sections were deparaffinized, air dried, and dehydrated in 70 %, 85 %, and 100 % ethanol followed by denaturation for 5 min at 74 °C in 70 % formamide-2× SSC solution. After overnight hybridization at 37 °C in a humidified chamber, slides were washed and counterstained with 0.2 mmol/l 40,6-diamidino-2-phenylindole in an antifade solution. Detection of the digoxigenin-labeled probe was conducted using fluorescent antibody enhancer set (Roche) containing an FITC-conjugated antibody. For each tissue spot, the predominant gene and centromere copy numbers in the tumor cell nuclei were estimated. Differences between arrayed and analyzed tumor spots were either due to missing tissue samples on the tumor tissue microarray or lack of interpretable FISH signals.

A tumor was considered amplified if the ratio of *BIRC2*/centromere 11 and *CCND1*/centromere 11, respectively, was ≥2.0. Ratios of >1.0 and <2.0 were considered as gains and a ratio of ≤1.0 as normal.

CCND1 immunohistochemistry

Standard indirect immunoperoxidase procedures were used for the detection of CCND1 according to the recommendations of the manufacturer (DAKO; clone SP4). The CCND1 staining intensity and the fraction of stained tumor cells were recorded for each tissue spot. The staining intensity was estimated in a 4-step scale (0, no staining; 1+, faint intensity; 2+, moderate intensity; and 3+, strongest intensity). The fraction of stained cells was scored according to the following criteria: score 0 (no stained cells), score 1 (≤25 % stained cells), score 2 (≤50 % stained cells), score 3 (≤75 % stained cells), and score 4 (>75 % stained cells). A final immunohistochemistry (IHC) result was calculated from these scores. Negative, no staining at all; weak, intensity 1+, or intensity 2+ in ≤50 % of cells, or intensity 3+ in <25 % of cells; moderate, intensity 2+ in 50 % to 75 % of cells, or intensity 3+ in 25 % to 50 % of cells; and strong, intensity 2+ in >75 % of cells, or intensity 3+ in >50 % of cells.

Statistics

The Pearson χ^2 test was used to determine the correlation between gene amplification status of carcinomas and clinicopathologic parameters as well as CCND1 IHC. The Student's *t* test was used for the analysis of metric parameters. Analysis was performed using R statistical software package for Windows (version 2.7.2; R Foundation for statistical computing).

Results

BIRC2 and *CCND1* amplification

Tables 1 and 2 summarize the results of *BIRC2* and *CCND1* FISH analysis of 238 cervical carcinomas. *BIRC2* FISH

analysis was successful in 217 arrayed tissue samples. Amplification of *BIRC2* was found in 28 of 217 (12.9 %) tumors. Amplification levels were usually high with an average of 18.1 FISH signals per nucleus and an average ratio of 6.9. Homogeneity analysis was performed on all *BIRC2* amplified cervical carcinomas at the TMA by using corresponding whole tissue sections for FISH analysis. *BIRC2* amplification was homogeneous in the 28 at the TMA detected tumors. Figure 1 illustrates a representative example.

Table 2 Gene copy number and copy number ratio of 28 *BIRC2*-amplified cervical carcinomas and 4 cervical carcinomas with *CCND1* amplification

	Amplified tumors	Copy number			Ratio			*p* value
		Median	Average	Range	Median	Average	Range

CCND1	4	6.5	6.5	4–9	3.25	3.25	2–4.5	

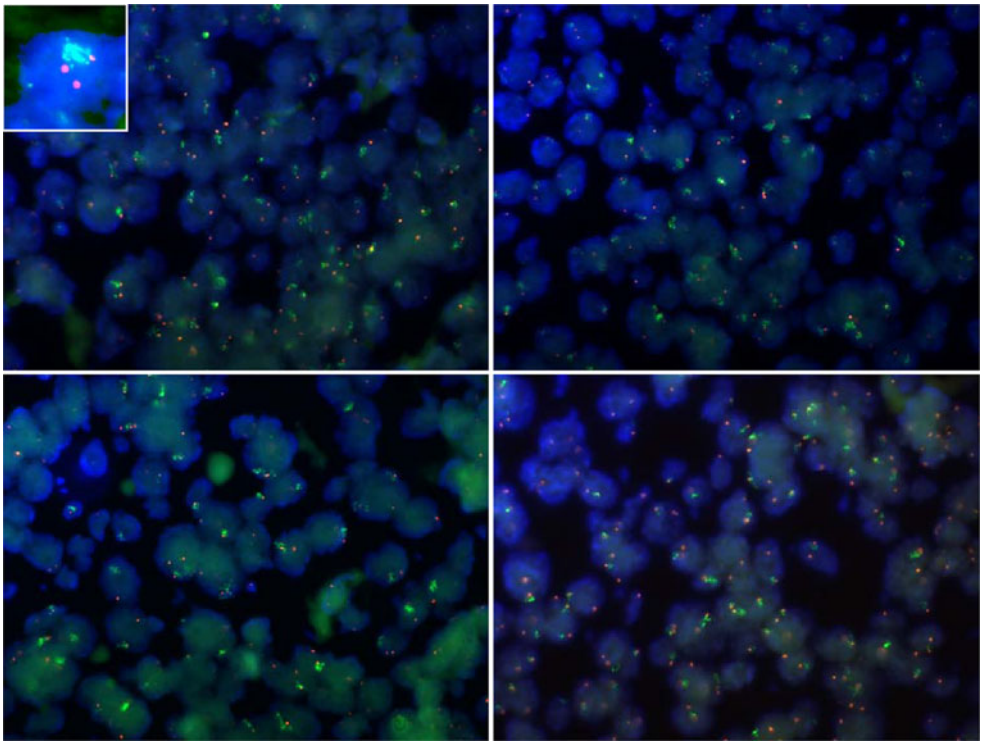

Fig. 1 Representative example of *BIRC2* FISH analysis in squamous cell carcinoma of the cervix: homogeneous BIRC2 amplification in four different tumor areas (*green signals* indicate BIRC2 copy number and *red signals* indicate copy number of chromosome 11)

Copy number alterations of *CCND1* occurred in 11 of 193 (5.7 %) interpretable cervical carcinoma samples including amplification in 4 (2.1 %) tumors and gains in 7 (3.6 %) tumors according to our predefined criteria. All *CCND1* amplified tumors only showed low-level copy number gains with <10 FISH signals per nucleus. *CCND1* amplification was statistically less frequent and the average ratio significantly lower than in tumors with amplifications of the *BIRC2* gene ($p<0.01$, each).

Furthermore, we studied the immunohistochemical expression of CCND1 in our data set (Table 3). In general, carcinomas of the uterine cervix with gains and/or CCND1 amplification showed significantly enhanced CCND1 staining intensity ($p=0.003$). Nevertheless, 3 of 4 *CCND1* amplified carcinomas exhibited no or only weak CCND1 expression.

Table 3 Analysis of immunohistochemical CCND1 expression compared to *CCND1* gene copy number in cervical carcinomas ($n=184$)

CCND1 IHC	***CCND1*** amplification status			
	Normal (%)	Gain (%)	Amplification (%)	*p* value
Negative	103 (59.5)	2 (28.6)	2 (50.0)	0.003
Weak	39 (22.5)	0	1 (25.0)	
Moderate	30 (17.3)	4 (57.1)	0	
Strong	1 (0.6)	1 (14.3)	1 (25.0)	
Total	173	7	4	184

We did not detect any tumors with co-amplification of *BIRC2* and *CCND1* in our examination of 181 tumor samples which were analyzable for both gene loci by FISH (Table 4). Only three tumors with *CCND1* copy number gains were simultaneously *BIRC2* amplified. There was no statistical difference between the observed (1.7 %) and the expected (0.8 %; based on the frequencies of individual amplifications) co-occurrence frequency of *BIRC2* amplification and *CCND1* copy number changes ($p=0.3$).

Clinicopathological associations

Clinicopathological features of cervical carcinomas with *BIRC2* and *CCND1* amplification/gains are given in Table 1. Patients with *BIRC2* amplified tumors were younger compared to patients with *BIRC2* disomy or *CCND1* amplification ($p<0.01$ and $p=0.046$, respectively). There was no association between *BIRC2* amplification status and tumor stage, tumor diameter, nodal status, or grading

Table 4 Occurence of co-amplifications of *BIRC2* and *CCND1* in 181 assessable cervical carcinomas

BIRC2	***CCND1***			*p* value
	Normal (%)	Gain (%)	Amplification (%)	
Normal (%)	149 (87.6)	4 (57.1)	4 (100)	0.3
Amplification (%)	21 (12.4)	3 (42.9)	0 (0)	
Total	170	7	4	181

of cervical carcinomas. *BIRC2* amplification was preferentially observed in squamous cell carcinomas of the cervix (p=0.025). Only one adenocarcinoma and one adenosquamous carcinoma showed amplification of *BIRC2*. The number of *CCND1* amplifications and *CCND1* gains was, in general, too low for further statistical analysis. *CCND1* amplified carcinomas were mostly observed in older patients with locally advanced tumors. The tumor diameter of *CCND1*-amplified carcinomas was higher than in *BIRC2*-amplified carcinomas. However, there were no obvious associations to pT category, nodal stage, grading, and histological subtype of cervical carcinomas.

Discussion

Gene amplification is an important mechanism for protein overexpression and oncogene activation in tumor cells [18]. Structural and numerical alterations of chromosome 11 have been reported in up to 48 % of cervical carcinomas [19]. In the majority of cases, these alterations occur as deletions of the region 11q23-qter. Nevertheless, copy number gains have also been found at 11q12-q23 [5].

The comparably high number of analyzed tumor samples at our TMA enabled a comprehensive survey of *BIRC2* and *CCND1* aberrations in cervical cancer and correlation with clinicopathological data. In the present study, 12.9 % of cervical cancers showed high level amplification of the *BIRC2* gene. This observation is in line with results recently achieved by Imoto et al. [11] describing *BIRC2* amplification in a small series of 5 of 27 (18.5 %) cervical cancer specimens. Taken together, the results of both studies suggest that *BIRC2* is amplified in a relevant proportion of cervical carcinomas. In contrast, *CCND1* aberrations were only detected in 11 of 184 (6 %) cervical carcinomas including four amplified tumors. Furthermore, amplification of the *BIRC2* locus occurred independently from *CCND1* amplifications in our study. Homogeneity of *BIRC2* amplification in cervical cancer as shown in this analysis also clearly indicates that our results are biologically significant. All these observations argue for an important and specific role of *BIRC2* in tumorigenesis of a subset of cervical carcinomas. *BIRC2* is located at 11q22 in the close proximity to *BIRC1*. The protein products of both genes (c-IAP1 and c-IAP2) play a role in the complex signal transduction system of the NF-κB pathway [20]. NF-κB proteins comprise a family of seven transcription factors which are responsible for regulation of different cellular functions including anti-apoptotic mechanisms [21]. TNFα receptor activation leads to unmasking cytosolic retained inactive NF-κB proteins which are translocated to the nucleus for binding at specific DNA target sites. The c-IAP proteins associate in this signaling cascade with TNF receptor-associated factors (TRAFs) and exert E3 ligase activities for ubiquinitation of downstream effectors and degradation of NF-κB inhibitory proteins [20]. The oncogenic capacities of the NF-κB pathway are rather complex, but the induction of caspase inhibitory proteins seems to be a key event [22, 23]. It may be hypothesized, that BIRC2 amplification and overexpression may constitutively activate the anti-apoptotic NF-κB signaling cascade and, therefore, promote tumor development. Further experimental data are required to pinpoint this assumption.

Remarkably, *BIRC2* amplification was strongly associated to squamous cell phenotype of cervical carcinomas and younger patient age. In contrast to adenocarcinomas which are more connected to HPV 18 infection, squamous cell carcinoma are mostly HPV 16 associated [24]. HPV integration into the host genome is associated with complex chromosomal rearrangements including DNA amplification inside and outside of the insertion locus [25–27]. Interestingly, Peter et al. detected 11q22 amplification in 2 out of 34 cervical carcinomas, both of which squamous cell carcinomas and associated to HPV 16. In the same study, eight cervical adenocarcinomas showed no 11q22 aberrations, while four of these tumors were associated with HPV 18. Thus, it may be speculated that specific types of HPV 16 perhaps in younger patients preferentially lead to amplification of 11q22 in a subgroup of cervical squamous cell carcinomas.

There are only few studies engaged in *CCND1* amplification frequency in carcinomas of the uterine cervix. In the present study, frequency of CCND1 alterations (5.7 %) was lower than in earlier publications (13.5 % and 24 %) [9, 28]. Methodological factors and differences in sample composition, as well as size of the examined data set, may be causative for the varying results. However, the rate of cervical carcinomas with positive CCND1 expression (40.4 %) in our examination was similar to previous analyses [29, 30]. Furthermore, we only found a loose correlation between immunohistochemically detectable expression and *CCND1* amplification status. This observation is in line with the results of Cheung et al. [28]. The exact role of CCND1 alterations in cervical cancer has not yet been determined. Our findings suggest that other mechanisms as amplification might be responsible for de-regulation of CCND1 expression in cervical carcinomas. The tendency to increased tumor diameters and older patient age in *CCND1* amplified tumors might be interpreted as late event in genetic instable tumors.

In summary, *BIRC2* is amplified in a subgroup of squamous-cell differentiated cervical carcinomas especially in younger women. *BIRC2* amplification is more frequent and independent from *CCND1* copy number changes in cervical cancer. Further studies will be necessary to confirm the clinicopathological relevance of *BIRC2* amplification in cervical cancer.

Conflict of interest statement We declare that we have no conflict of interest.

Abstract The purpose of this study is to evaluate whether activating mutations of the p110α catalytic subunit of class A phosphoinositide 3-kinases (*PI3KCA*) or complete loss of phosphatase and tensin homolog (PTEN) is associated with response to anti-human epidermal growth factor receptor 2 (Her2) treatment in breast cancer (BC). We analysed *PI3KCA* hot-spot mutations and PTEN immunohistochemical expression in 129 Her2-positive infiltrating BC treated with trastuzumab, including 26 cases treated with neoadjuvant therapy, 48 metastatic infiltrating breast cancer (IBC; MBC) and 55 early-stage IBC, with complete clinical information (mean follow-up 37, 66 and 32 months, respectively). *PI3KCA* hot-spot mutations were observed in 25 cases (19 %): 12 (9 %) in exon 9 and 13 (10 %) in exon 20. No correlations were observed between mutations and pathological and biological parameters. In patients treated with neoadjuvant therapy and in MBC, we did not observe any relationship with response to trastuzumab-based therapy. PTEN loss was observed in 24 out of 86 informative cases (28 %), 3 (13 %) of which were also mutated for *PI3KCA*. PI3K pathway activation, defined as *PI3KCA* mutation and/or PTEN loss, was not associated with response to treatment or clinical outcome in MBC. *PI3KCA* mutation and/or PTEN loss should not exclude patients from potentially beneficial anti-Her2 therapy.

Introduction

Human epidermal growth factor receptor 2 (Her2) is a tyrosine kinase receptor, which is overexpressed or amplified in 20 to 25 % of infiltrating breast carcinomas (IBC), which may behave more aggressively. Her2 overexpression may lead to increased receptor homo/heterodimerization, which induces phosphorylation of the intracellular domain, leading in turn to activation of many downstream signalling molecules, including class A phosphoinositide 3-kinases (PI3K)/AKT. Activated PI3K catalyzes the phosphorylation of inositol lipids to produce phosphatidylinositol-3,4,5-trisphosphate (PIP3), which in turn, as a negative feedback mechanism, is dephosphorylated to PIP2 by phosphatase and tensin homolog (PTEN). PIP3 activates the serine/threonine kinase AKT which in turn phosphorylates and regulates the mammalian target of rapamycin (mTOR).

Trastuzumab, a humanized monoclonal antibody targeting the extracellular domain of Her2, has good therapeutic efficacy in patients with Her2-positive IBC. Trastuzumab is effective in neoadjuvant therapy, in cases of metastatic breast cancer (MBC) and in the adjuvant setting in early-stage IBC.

However, not all patients benefit from trastuzumab-based therapy, and a relevant percentage shows an initial resistance to trastuzumab.

The underlying antitumoural mechanisms of trastuzumab are complex and not completely understood [1]. The hypothesized mechanisms include inhibition of Her2 homo/heterodimerization, Her2 endocytosis and degradation or reduced shedding of the extracelluar domain, leading to downregulation of downstream signalling through the PI3K–AKT pathway. An alternative mechanism of action could be related to the fact that trastuzumab, being an intact monoclonal antibody, may recruit Fc-competent immune effector cells and the other components of antibody-dependent cell-mediated cytotoxicity, leading to tumour cell death [2].

Several lines of evidence suggest that Her2-independent activation of the PI3K–AKT pathway may be related to resistance to trastuzumab [3–5]. Aberrations of the components of the PI3K–AKT pathway are frequent in IBC, including activating mutations of the p110α catalytic subunit of PI3K (*PI3KCA*) and PTEN loss, which have been described in 9 to 45 % of cases [6–17] and 4 to 28 % of cases [18–21], respectively. The vast majority of *PIK3CA* mutations, comprising approximately 90 % of cases, are clustered at two hot-spot regions in exon 9 (E542K and E545K) and exon 20 (H1047R and H1047L) encoding the helical and kinase domains, respectively [6–17]. *PI3KCA* mutations are among the most common genetic aberrations in human IBC and have generally been reported as more frequent in node-negative [8, 17], estrogen receptor (ER)-positive and Her2-negative IBC [8–10, 14, 22–24], but data are not consistent. Controversies exist also concerning the prognostic value of *PI3KCA* mutations: most authors report favourable relation with survival [9, 10, 25, 26] but again data are not consistent [14, 27, 28] probably due to the heterogeneity of the investigated series and to possible different pathogenetic significance of mutations occurring at different sites in the molecule [7]. *PI3KCA* mutations have also been indicated as possible markers for poor response to trastuzumab [21, 27–29], but data are still not conclusive [5, 27, 30, 31]. Preclinical studies also suggest that the *PI3KCA* gene could be a target for new drugs [32] suggesting the possibility to combine anti-Her2 therapy with different inhibitors targeting PI3K, TORC1, AKT or EGFR [33, 34].

In the present study, we analyse *PI3KCA* mutations at hot-spots in exon 9 and exon 20 and PTEN expression in a retrospective series of Her2-positive IBC treated with trastuzumab (26 cases treated with neoadjuvant therapy, 48 metastatic IBC and 55 early-stage IBC), investigating their frequency and their relationship with clinical and pathological parameters and response to trastuzumab treatment.

Material and methods

Patients and tumour samples

We retrospectively evaluated 129 Her2-positive IBC which had been treated with trastuzumab at the Santa Chiara Hospital of Trento Italy between 2000 and 2010. The study has been approved by the ethical committee of the Santa Chiara Hospital. The investigated cases include three groups of patients: 26 primary IBC treated with neoadjuvant trastuzumab therapy, 48 advanced MBC and 55 early-stage IBC treated with adjuvant therapy. Complete follow-up information was available for all cases; mean follow-up was 37, 66 and 32 months for the above three groups of patients. Neoadjuvant therapy consisted of doxorubicin and trastuzumab for three courses followed by paclitaxel and trastuzumab for 4 cycles followed by cyclophosphamide, methotrexate, fluorouracil associated with trastuzumab (according to NOAH trial regimen). In MBC patients, the first-line therapy consisted of trastuzumab associated with taxanes (weekly paclitaxel or docetaxel). All early-stage IBC patients received adjuvant trastuzumab for 1 year after surgery. All patients showing positive estrogen receptors also received hormonal therapy with tamoxifen±ovarian ablation if in premenopausal status and with aromatase inhibitors if in postmenopausal status. All cases were reviewed by a pathologist (MB). For each case, one representative tissue block was selected for further analyses. The percentage of tumour cells in each block was visually estimated, and only cases with more that 50 % of tumour cell content were included in the study.

For patients affected by primary IBC treated with neoadjuvant trastuzumab, pathological response at surgery was scored as: (a) *complete*, if no invasive residual disease in breast and axilla was found, (b) *partial*, if the residual tumour burden was inferior to the clinically estimated tumour diameter and (c) *absent*, if the residual tumour burden was identical or higher than the clinically estimated tumour diameter (stable or progressive disease). For MBC, response to therapy was evaluated clinically. The different pathological characteristics of the whole group of cases are shown in Table 1, and the characteristics of the three different series are illustrated in Tables 2, 3 and 4.

Her2 immunoreactivity was evaluated using the HercepTest kit (DakoCytomation, Glostrup, Denmark) according to the manufacturer's FDA-approved procedures, using manual or computer-assisted assessment [35]. All cases with Her2 score 2+ were further investigated with fluorescent in situ hybridization using the *HER2* FISH pharmDx™ kit (DakoCytomation). Tumours with a *HER2*/Cep17 ratio ≥2.2 were considered as amplified.

In all cases, ER, progesterone receptor (PgR) and Ki67 were evaluated using 6 F11 (Leica, Novocastra, Newcastle, UK), Pgr636 (DakoCytomation) and MIB1 (Leica, Novocastra) antibodies, respectively [36]. Ki67 labelling index was

[b]Proliferative activity was scored as high if Ki67-reactive cells were at least 25 %

evaluated manually in the peripheral areas of all tumours. In case of marked heterogeneity, Ki67 labelling was also evaluated using computer-assisted image analysis [37]. Cases with at least 1 % reactive cells were considered positive for ER and PgR. Ki67 labelling was scored as high if at least 25 % reactive cells were counted. A subset of 34 cases out of the series of advanced MBC and 52 out of 55 cases treated with adjuvant therapy were immunostained for PTEN, using the 138G6 antibody (Cell Signaling Technology, Celbio, Italy). PTEN immunohistochemistry was scored as absent (complete PTEN loss) when no immunostaining was observed in spite of positive internal controls, or positive, if any degree of cytoplasmic and nuclear staining was observed. In 14 cases, PTEN could not be evaluated because of lack of available histological samples or inadequate internal control immunostaining.

Mutational analysis

Sample DNA extraction

Five 10-μm sections were cut from each paraffin-embedded tumour block. Slides were deparaffinized twice with 1 mL of xylene, vortexed and centrifuged. The supernatant was removed and then washed with 1 mL absolute ethanol. The samples were resuspended in 180 μl lysis buffer containing 20 μl proteinase K. DNA was isolated with the Qiamp DNA mini-kit (Qiagen, Valencia, CA) and was incubated overnight at 56 °C at 300 rpm.

Real-time polymerase chain reaction amplification

Briefly, DNA fragments were amplified using RT-PCR with primers specific for exon 9 and exon 20 of the *PI3KCA* gene, designed to allow the identification of the following mutations: E542K, E545K and Q546K in exon 9 and M1043I, H1047R, H1047L, G1049S and G1049R in exon 20 (Diatech Pharmacogenetics, Jesi, Italy). Each mix contained 5× buffer Mg^{2+}-free, 50 mM Mg^{2+} solution, 10 mM of each dNTP, 1 μl of specific primers, EvaGreen dye (20× in water), 5 U/μl Hot Star Taq DNA Polymerase and 100 ng genomic DNA in a 50-μl final volume. The mixture was denatured for 3 min at 95 °C and underwent 40 cycles: at 95 °C for 20 s, at 57 °C for 30 s and at 72 °C for 30 s, followed by a final step for 6 min at 60 °C for the acquisition the green signal.

Pyrosequencing

Each sample submitted for pyrosequencing was prepared utilizing 3 μl streptavidin sepharose (GE Healthcare, Buckinghamshire, UK), 37 μl PyroMark binding buffer (Qiagen), 20 μl MB water (Qiagen) and 20 μl biotinylated PCR product. The plate was mixed and incubated for 15 min on a shaking table at 1,400 rpm. In the second step, the binding solutions were released into 40 μl of annealing buffer containing the respective sequencing primer. Primers were annealed to the target after incubation at 80 °C for 2 min and allowed to cool to room temperature prior to pyrosequencing. PyroGold reagents were used for the pyrosequencing reaction, and the signal was analysed using the PyroMark Q96 ID system (Qiagen). The software analyses the bioluminescence produced at the end of the enzymatic reactions, of which the intensity is proportional to the number of incorporated nucleotides. Positive controls were cases with known *PI3KCA* mutational status. The results of the experiments were interpreted according to the cut-offs provided by the manufacturer (Diatech Pharmacogenetics). For exon 9 mutations, the cutoff nucleotide substitution values to define a case as mutated were: E542K A>5 %, E545K A >10 %, Q546K G>10 % and Q546K A>5 %. For exon 20 mutations, the cut-off nucleotide substitution values to define a case as mutated were: M1043I T>10 %, M1043I A>10 %, H1047R C>12 %, H1047L A>10 %, G1049S G>6 % and G1049R T>5 %.

Statistical methods

Statistical analysis was performed using the SPSS 15.0 software for Windows (SPSS Inc., Chicago, IL). In the groups of primary IBC treated with neoadjuvant trastuzumab therapy and MBC groups, we evaluated the possible association of *PI3KCA* mutations/PTEN loss with response to therapy; in the series of MBC, we evaluated also their relation with overall and disease-free survival (DFS). No survival analysis was performed in early IBC because of the short follow-up (all patients are alive and disease free).

Contingency tables were used to analyse the relationships between the categorical variables: absence/presence of mutation/loss of PTEN vs. pathological and biological parameters. Fisher's exact test (2×2 tables) and chi-square test (general contingency tables) were used to test the significance of the association between two classifications. Kaplan–Meier survival analysis with log-rank test was used to determine the difference in DFS and overall survival between groups. All tests were two sided. The statistical significance level was chosen at 5 %. All analyses were performed blinded to the study endpoints.

Results

Clinical outcome of the patients

In the series of patients treated with neoadjuvant trastuzumab therapy, 11 (42 %) showed complete pathological response, 14 (54 %) partial pathological response and 1 (4 %) showed stable disease. At a mean follow-up of 37 months, 3 patients died of disease, 3 were alive with relapsing disease and 20 were alive without evidence of disease.

In the series of patients affected by MBC treated with trastuzumab therapy, 4 (8 %) showed complete clinical response, 18 (38 %) partial clinical response with more than 50 % reduction of the tumour, 14 (29 %) partial clinical response with less than 50 % reduction of the tumour, 8 (17 %) stable disease and 3 (6 %) showed progressive disease. In responsive cases (complete and partial responses), median response duration was 9.5 months with two patients having durable complete response over 3 years of trastuzumab treatment. At a mean follow-up of 66 months, 39 patients died of disease, 7 were alive with disease and 2 were alive without evidence of disease. In the series of 55 early-stage IBC treated with adjuvant therapy at a mean follow-up of 32 months, all patients were alive without evidence of relapse.

Frequency of *PI3KCA* mutations and relationships with pathological and biological characteristics

In the whole series of 129 IBC, *PI3KCA* mutations were observed in 25 cases (19 %): 12 (9 %) in exon 9 (2 Q546K and 10 E545K) and 13 (10 %) in exon 20 (1 H1047L and 12 H1047R; Fig. 1). *PI3KCA* mutations were observed in 15 % of locally advanced IBC treated with neoadjuvant therapy, in 10 % of MBC and in 29 % of early-stage IBC treated with adjuvant trastuzumab therapy. The relationships between *PI3KCA* mutation and pathological and biological characteristics are shown in Table 1 for the whole series and in Tables 2, 3 and 4 for the three different groups of patients. No statistically significant correlations were observed between mutations and pathological and biological parameters. In particular, we did not observe any relationship with histological type, nodal status and hormone receptor status.

Association of *PI3KCA* mutation with response to therapy and clinical outcome

In the series of patients treated with *neoadjuvant therapy*, *PI3KCA* mutations were observed in 3 out of the 11 cases with complete pathological response (three exon 20 H1047R mutations with 14.1, 33.9 and 71.2 % substitution frequency, respectively) and in 1 out of 14 cases with partial response (one exon 9 Q546K mutation with 19.5 % substitution frequency) (Table 5). These data suggest that *PI3KCA* mutations are not a major determinant of trastuzumab resistance because even cases with very high percentages of the mutated allele showed complete pathological response.

In the series of *metastatic breast carcinomas*, *PI3KCA* mutations were observed in 3 out of the 29 cases with partial clinical response (two exon 9 E545K mutations with substitution frequency of 11.6 and 38.4 % respectively, and one exon 20 H1047R mutation with 28.1 % substitution frequency) and in 1 out of 10 cases with stable/progressive disease (exon 20 H1047R mutation with 21.1 % substitution frequency; Table 6). No gene mutations were observed in the four patients showing complete clinical responses. These data suggest that *PI3KCA* mutations are not a major determinant of trastuzumab resistance in metastatic IBC treated with trastuzumab. Survival analysis in metastatic IBC showed that *PI3KCA* mutations are not related to adverse clinical outcome. However, the survival analysis has limited statistical power due to the limited number of investigated cases.

PTEN expression and PI3K mutation

PTEN immunohistochemical expression was evaluable in 86 cases and ranged from complete loss of reactivity in tumour cells, in spite of positive internal controls, to various degrees of immunoreactivity (Fig. 2). PTEN loss was observed in 24 (28 %) cases, 3 (13 %) of which were also mutated for *PI3KCA*. PTEN immunostaining was observed in 62 (72 %) cases, 17 (27 %) of which showed PI3K mutation. These data show that in the present series of IBC, PTEN loss, although less frequent in cases with concurrent *PI3KCA* mutation (13 versus 27 %), was not mutually exclusive with *PI3KCA* mutation.

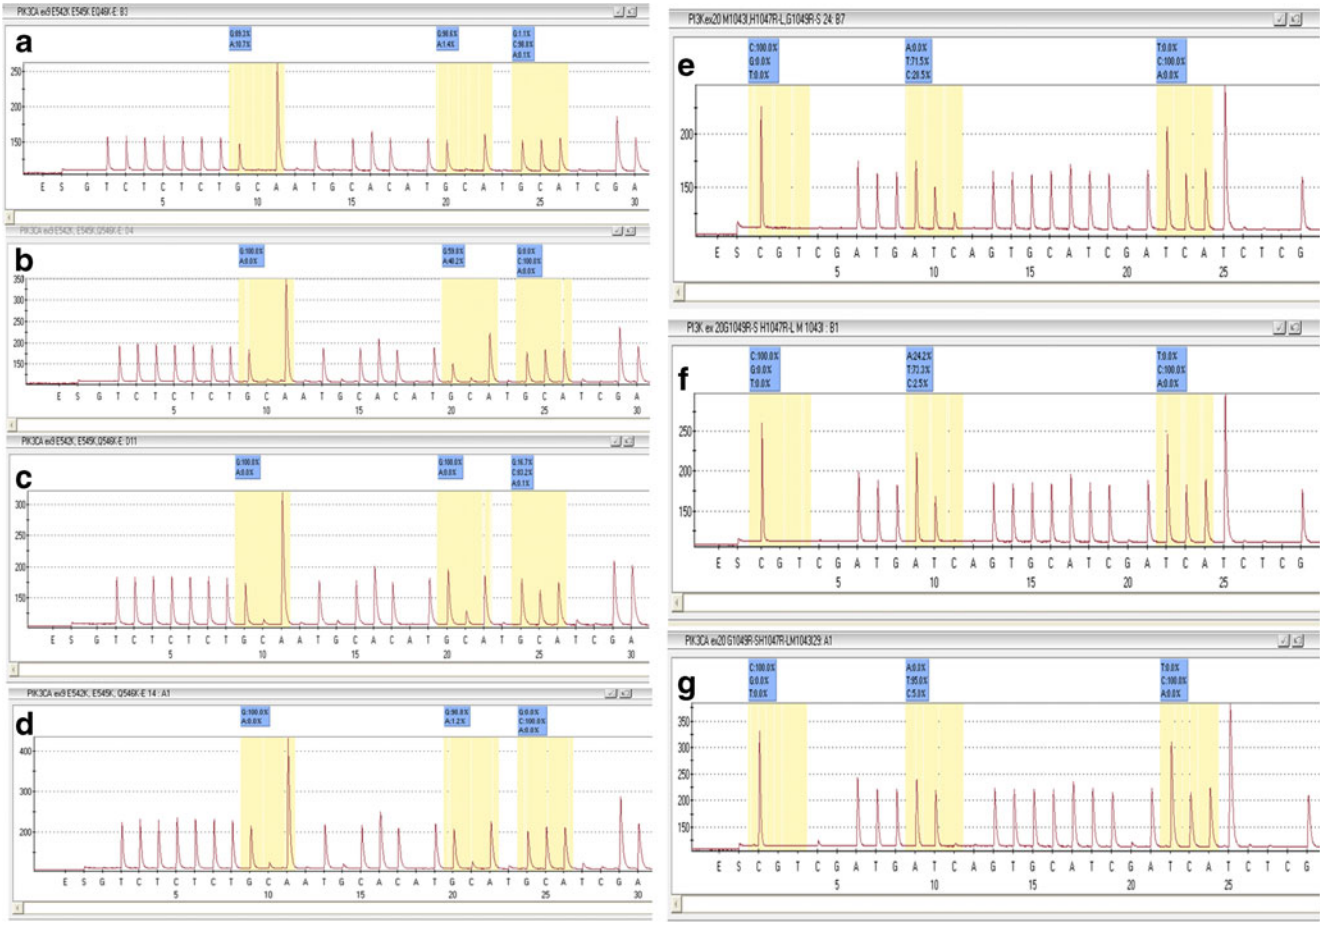

Fig. 1 Pyrosequencing reports of five different cases with **a** exon 9 E542K mutation, **b** exon 9 E545K mutation, **c** exon 9 Q546E mutation, **d** exon 9 wild-type genotype, **e** exon 20 H1047R mutation, **f** exon 20 H1047L mutation and **g** exon 20 wild-type genotype

Combined evaluation of *PI3KCA* mutation and PTEN loss in relation to clinical outcome in metastatic breast carcinomas

PTEN immunostaining could be evaluated in 34 of the 48 MBC, 10 of which showed complete PTEN loss. *PI3KCA* mutations were observed in 1 out of these 10 cases with complete PTEN loss and in 3 of the 24 cases with PTEN expression. PI3K pathway activation, defined as PTEN loss and/or *PI3KCA* mutation, was seen in 13 out of these 34 cases, including 1 case with complete clinical response, 5

mt Ex 9 PI3KCA mutation in exon 9 of the *PI3KCA* gene, *mt Ex 20 PI3KCA* mutation in exon 20 of the *PI3KCA* gene, *wtPI3KCA* wild-type *PI3KCA* gene

[a] Partial response with residual tumour burden inferior to 50 % of the clinically estimated initial tumour diameter

[b] Partial response with residual tumour burden greater than 50 % of the clinically estimated initial tumour diameter

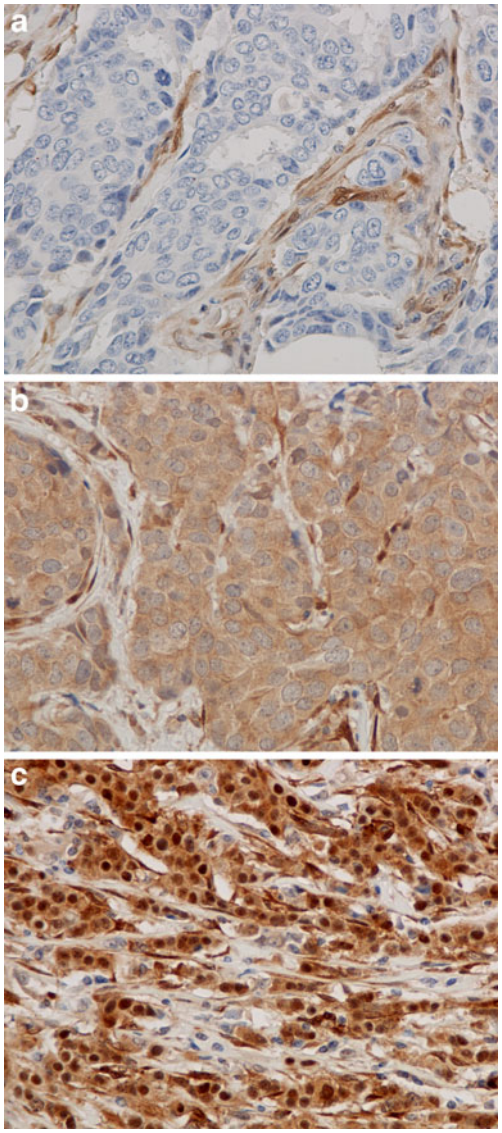

Fig. 2 Different levels of PTEN immunohistochemical expression in breast carcinomas, ranging from complete absence in tumour cells with concurrent positive internal controls (**a**) to mild cytoplasmic positivity (**b**), to strong cytoplasmic and nuclear reactivity (**c**)

cases with prominent clinical response (>50 % reduction in tumour burden) and 5 cases with partial clinical response (<50 % reduction in tumour burden), and in 2 cases with stable disease (Table 7). These data suggest that PI3K pathway activation is not a major determinant of trastuzumab resistance in MBC.

Discussion

Our present study on 129 Her2-positive IBC treated with trastuzumab, analysed with the highly specific and sensitive pyrosequencing technique, shows that *PI3KCA* mutations occur in 19 % of cases and are not related to pathological features of the tumours. In retrospective analyses of small groups of MBC and locally advanced IBC treated with neoadjuvant trastuzumab, we show that *PI3KCA* mutations are not related to response to treatment. In a subset of cases, we also show that *PI3KCA* mutations are not mutually exclusive with PTEN expression loss, and that, in MBC, PI3K pathway activation, defined as *PI3KCA* mutation and/or PTEN loss, is not associated with response to treatment. Survival analysis in the group of MBC shows that neither *PI3KCA* mutations nor PI3K/PTEN pathway activation is related to clinical outcome, but the limited number of investigated cases could have precluded the study to reach statistical significance.

Partial responder <50 %[b]	9	5
Complete responder	3	1

wtPI3KCA wild-type *PI3KCA* gene, *mtPI3KCA* mutated *PI3KCA* gene

[a] Partial response with residual tumour burden inferior to 50 % of the clinically estimated initial tumour diameter

[b] Partial response with residual tumour burden greater than 50 % of the clinically estimated initial tumour diameter

The reported frequency of *PI3KCA* mutation in literature is quite variable, ranging from 15 [30] to 29 % [38]. This wide range of frequencies in Her2-positive IBC could in part be related to the limited number of investigated cases in some studies, to the different analytical methods used, or could be related to differences between population groups. The latter is a well-known phenomenon, which has been observed not only between different ethnic groups, such as for example frequency of EGFR mutations lung carcinoma in Western and Japanese populations, but also within the same ethnic group, such as *B-raf* mutations and *PTC/Ret* translocations in thyroid carcinomas [38, 39]. In a previous study of a consecutively collected series of IBC from the same geographical area (Trentino, Northeast Italy), we observed a frequency of *PI3KCA* mutation (26 % mutated cases) which is slightly higher than the one observed in the present study [7]. This difference might be related to the different composition of the two series, as the previous series included mainly Her2-negative ER-positive IBC, while the present one includes only Her2-positive cases,

with a higher percentage of ER-negative cases. Several studies have indeed shown that *PI3KCA* mutation is more frequent in ER-positive and Her2-negative IBC [8–10, 14, 22–24] suggesting that in these cases PI3K/AKT pathway activation occurs through a Her2-independent mechanism. However, discordances exist, and other studies have either not found such associations or even provided opposite results, such as an association between *PI3KCA* mutations and Her2 overexpression [13]. Comparison between the different studies is extremely difficult as the inclusion criteria are different. Moreover, since the pathogenetic role of mutations in different regions of the *PI3KCA* gene could provide different activating effects, with potentially different pathogenetic and clinic relevance [7], further studies, and possibly a meta-analysis of currently available data, should further investigate these relationships.

The most intriguing aspect of the study of *PI3KCA* mutations is their possible role as predictive markers of resistance to anti-Her2 therapy, either using trastuzumab or the reversible dual kinase inhibitor lapatinib, which is active also against EGFR. Preclinical and preliminary data suggest that *PI3KCA* mutations might predict resistance to anti-Her2 therapy [5, 21, 27–29]. The study of Razis et al. [28] is of particular interest as it includes a series of partly Her2-positive and partly Her2-negative metastatic IBC treated with trastuzumab: in Her2-negative cases, *PI3KCA* mutations were not related to time to progression, while in the Her2-positive group, a strong and independent association between *PI3KCA* mutations and worse prognosis was found. However, data are still not conclusive, and some studies suggest that *PI3KCA* mutations are not associated with response or clinical outcome [31, 39] or are of limited predictive value [5, 30]. Our present study shows that *PI3KCA* mutations occur in patients responding to trastuzumab treatment (i.e. four neoadjuvant patients and five MBC patients), further supporting the hypothesis that *PI3KCA* mutations do not exclude the possibility of clinical benefit to trastuzumab therapy.

Previous reports suggested that *PI3KCA* mutation and PTEN loss are mutually exclusive [13]. However, in our study 3 (12.5 %) out of 24 PTEN-negative IBC showed also *PI3KCA* mutation, as also reported by Perez-Tenor et al. [10] and Wang et al. [31]. The reason for this redundancy in the activation of the PI3K pathway is not clear, but could be related to different yet unknown cross-talk mechanisms between different pathways, or to an additive effect of these two activating hits along the same metabolic pathway.

The lack of a clear-cut relationship between *PI3KCA* mutation and therapeutic response to anti-Her2 agents can be interpreted in the light of the complex and poorly understood mechanisms of action of trastuzumab. First, resistance could be related to the fact that the PI3K/AKT signalling pathway is very complex and may be improperly constitutionally activated at several levels with different mechanisms, which, beside *PI3KCA* mutation, potentially include loss of PTEN expression, *PI3KCA* gene amplification, mutations or amplification of *AKT*, deregulation of mTOR activity, altered expression of p70S6K, etc. In particular, PTEN loss has been associated with resistance to anti-Her2 therapy in cell lines and patients [21, 27, 28, 30, 38]. The combined evaluation of alterations of the PI3K/AKT pathway at several levels could provide a rationale for combining anti-Her2 therapy with PI3K/AKT inhibitors [29, 40]. Preliminary data indeed show that concurrent evaluation of *PI3KCA* mutations and PTEN and p70S6K expression may identify patients without PI3K/AKT pathway activation who could benefit more from trastuzumab-based therapy [27, 28, 30, 31]. However, in our small series of MBC, PI3K/PTEN pathway activation was not related to clinical response to trastuzumab, and further studies are needed to clarify this issue. Alternatively, the fact that *PI3KCA* mutated cases may respond to trastuzumab therapy could be interpreted in the light of the possible role of trastuzumab in determining antibody-dependent cell-mediated cytotoxicity. Trastuzumab is an intact monoclonal antibody which, binding to the Her2 molecule, could elicit antibody-dependent cellular cytotoxicity which could lead to tumour cell necrosis and hence clinical/pathological response [41–43].

In conclusion, our study shows that *PI3KCA* mutations are frequent in Her2-positive breast cancer and that there is no significant correlation with response to trastuzumab-based therapy. The study also shows that PI3K pathway activation, defined as PTEN loss and/or *PI3KCA* mutation, is not associated with response to treatment or with clinical outcome. Since most reported series of IBC treated with anti-Her2 treatment are small and the possible variables influencing the results are many, including the confounding effects of the patients' background treatments [5], an effort should be undertaken to pool all data together to perform a meta-analysis and possibly to study PI3K pathway activation mechanisms in a more comprehensive way, including also less frequently studied biomarkers such as *AKT* mutation and phosphorylation status, mTOR and p70S6K expression levels. More importantly, the value of the combined use of trastuzumab with different inhibitors targeting the PI3K pathway at different levels needs to be tested. Finally, our data show that *PI3KCA* mutation and/or PTEN loss are not criteria to exclude patients from potentially beneficial anti-Her2 therapy.

Abstract Endometrial polyps are very common benign endometrial lesions, but their pathogenesis is poorly understood, except for a few studies indicating the possibility of benign stromal neoplasm. Although the histopathological diagnosis of endometrial polyp on a surgical specimen is straightforward, it is often difficult to differentiate endometrial polyp from endometrial hyperplasia on a biopsy or curettage specimen. Presently, there is no immunohistochemical marker helpful in this differential diagnosis. In this study, we examined p16 expression in 35 endometrial polyps and 33 cases of endometrial hyperplasia that included 16 simple hyperplasias, 14 complex atypical hyperplasias, and 3 complex hyperplasias without atypia. Stromal p16 expression differed significantly between the two groups; it was seen in 31 (89 %) endometrial polyps, but in only 1 (3 %) endometrial hyperplasia. The percentage of p16-positive stromal cells ranged from 10 to 90 % (mean, 47 %) and the positive cells tended to be distributed around glands. Six cases of endometrial hyperplasia within an endometrial polyp were also examined and all cases showed stromal p16 expression. There was no difference in glandular p16 expression between endometrial polyps 33 (94 %) and hyperplasia 27 (82 %). The p16-immunoreactivity was mostly confined to metaplastic epithelial cells in both groups. Stromal p16 expression might be a peculiar characteristic of endometrial polyp and constitute a useful marker for the diagnosis, especially in fragmented specimens from biopsy or curettage. Stromal p16 expression might be a reflection of p16-induced cellular senescence, which has been documented in several benign mesenchymal neoplasms.

Introduction

The endometrial polyp is a relatively common gynecologic lesion that can cause abnormal genital bleeding. It can occur at any age, but many of the patients are perimenopausal [1]. Endometrial polyp is the most frequent endometrial lesion occurring in patients who are taking tamoxifen therapy for breast cancer [2].

The histological diagnosis of endometrial polyp in a hysterectomy specimen is usually not difficult due to its easily recognized characteristic polypoid configuration. The glands within the polyp vary in size and shape and frequently show cystic dilatation, and their distribution is rather random compared with normal endometrial glands. The stroma of the polyp is typically fibrotic and contains thick-walled blood vessels [3]. However, histological diagnosis of endometrial polyp on curettage or biopsy specimens is difficult. The polypoid configuration of the lesion is not always apparent because of the fragmented nature of the specimens. Indeed, according to a classical study by Winkler et al. [4], endometrial polyp is commonly overdiagnosed as endometrial hyperplasia. Interobserver agreement with respect to the diagnosis of endometrial hyperplasia has also been reported as very low, especially when the amount of tissue was not adequate and the lesion contained elements of an endometrial polyp [5]. The confusion between endometrial hyperplasia, especially simple hyperplasia, and endometrial polyp seems to result from the close resemblance in glandular morphology of these two lesions. The only hallmark for histological differentiation between the two lesions is the difference in stromal appearance. The thick-walled blood vessels in endometrial polyps are relatively easy to recognize and their vascular pattern is different from that of endometrial hyperplasia, which has small spiral artery-like blood vessels. The long axis of endometrial glands arranged parallel to the surface epithelium was recently reported to be a useful histological feature for diagnosing endometrial polyp [6]. However, there has been no useful immunohistochemical marker to differentiate endometrial polyp from endometrial hyperplasia.

Recently, during workup of endometrial serous adenocarcinomas associated with endometrial polyps, we noticed stromal p16 expression in endometrial polyps. Although the stromal component of endometrial polyp has been described as "neoplastic" in some textbooks [7, 8], the histopathological and immunohistochemical characteristics of the stromal cells in endometrial polyps are poorly understood. In this study, we examined and compared the stromal p16 expression in endometrial polyps and endometrial hyperplasia, and its significance for differential diagnosis between these lesions.

Materials and methods

Thirty-five cases of endometrial polyp and 33 cases of endometrial hyperplasia were retrieved from the surgical pathology file of Social Insurance Chukyo Hospital from August 2008 to April 2011 and the consultation files of SM. Patient ages ranged from 32 to 83 years (mean±SD, 54.63±14.10, median 54.6) for endometrial polyp and from 17 to 69 years (mean±SD, 49.20±10.18, median 49) for endometrial hyperplasia, respectively (p=0.0789). Of the 35 cases of endometrial polyp, 17, 10, 7, and 1 were diagnosed in a hysterectomy, curettage, hysteroscopic polypectomy, and autopsy specimen, respectively. Of the 33 cases of endometrial hyperplasia, 18 and 15 were in a hysterectomy or curettage specimen, respectively. In this study, we did not include any cases of which the histological differential diagnosis between endometrial polyp and endometrial hyperplasia was ambiguous. For the cases of endometrial polyp in a curettage specimen, we only selected those in which polypoid configuration, and fibrous stroma with thick-walled blood vessels were clearly identified. Polyp size was measured for all except for curettage specimens. The presence and type of epithelial metaplasia within a polyp and hyperplasia were described. For the cases that had metaplastic changes, the proportion of metaplastic epithelia was estimated. We also selected six cases of endometrial hyperplasia within a polyp. Patient age ranged from 29 to 62 years (mean±SD, 42.67±13.24, median, 41). A simple hyperplasia without atypia should not be diagnosed in a polyp [8], we only selected complex hyperplasia with or without atypia within a polyp. As controls, four cases of endometrial stromal sarcoma, four cases of adenosarcoma, and 23 cases of endometrioid adenocarcinoma were selected from the same files.

A representative slide from each case was selected and 4-μm-thick sections were cut for immunohistochemistry. After dewaxing and rehydrating, the sections were treated in citrate buffer (10 mM, pH 6.0) in an autoclave (121 °C). Immunohistochemical staining was performed using anti-Human p16INK4a antibody (clone E6H4, prediluted, mtm laboratories AG, Heidelberg, Germany) and the CINtec Histology kit, following the manufacturer's instructions. The percentage of positive cells and the location of positive signals (nuclear or cytoplasmic) visually estimated for both glandular and stromal components of all lesions. A cut-off index was arbitrarily defined as the presence of more than 10 % immunoreactive cells. The estimated percentages were categorized as 0 for <10 % positive cells, 1 for ≥10 % or more but <25 %, 2 for ≥25 % or more but <50 %, and 3 for ≥50 %.

Results

The clinicopathological features of the endometrial polyps and endometrial hyperplasias included in this study are summarized in Table 1. Endometrial polyps ranged in size from 3 to 45 mm (mean±SD 14.06±1.78 mm, median 10 mm). Polyps were classified according to Malpica et al. [9]. Eighteen (51 %) endometrial polyps had proliferative-type endometrial glands and relatively hypercellular stroma,

Table 1 Histological and immunohistochemical features of endometrial polyp and hyperplasia

	Endometrial polyp		Endometrial hyperplasia	
n	35		33	
Age* (years)	32–83 (54.63±2.45)		17–69 (49.2±10.18)	
Size (mm)	3–45 (14.06±1.78)		–	
Histologic type	Hyperplastic	18 (51 %)	Simple without atypia	16 (48 %)
	Atrophic	13 (37 %)	Complex atypical	14 (42 %)

corresponding to a hyperplastic polyp. Thirteen (37 %) endometrial polyps had glands with low proliferative activity and fibrotic hypocellular stroma, corresponding to atrophic polyp, and three (9 %) showed secretory changes, corresponding to functional polyp. The single remaining endometrial polyp had a mixed endometrial and endocervical-type epithelium, corresponding to mixed polyp. All ten curettage specimens of endometrial polyps showed thick-walled blood vessels in the stroma and/or three sides lined by endometrial surface epithelium. Various kinds of epithelial metaplasia were seen in various proportions in 32 (91 %) of the 35 endometrial polyps. The most frequent metaplasia was tubal metaplasia, seen in 32 cases (91 %), followed by eosinophilic cell change (two cases, 5 %) and mucinous change (one case, 3 %). Tubal metaplasia occupied less than 10 % of the glands within a polyp in five cases (16 %), 10 % or more and less than 25 % in 7 (22 %), 25 % or more and less than 50 % in 6 cases (19 %), and 50 % or more in 14 cases (43 %). Eosinophilic cell change occupied less than 20 % of the glands in two cases.

Sixteen (48 %) of the 33 endometrial hyperplasia cases were simple hyperplasia without atypia, 14 (42 %) were complex atypical hyperplasia, and 3 (10 %) were complex hyperplasia without atypia. Various types of epithelial metaplasia were seen in various proportions in 28 (85 %) cases of endometrial hyperplasia. The most frequent metaplasia was tubal metaplasia, seen in 25 cases (75 %), followed by eosinophilic cell change (nine cases, 27 %), morular metaplasia (three cases, 10 %), and surface papillary/syncytial change (one case, 3 %). Tubal metaplasia occupied less than 10 % of the glands within hyperplastic lesions in two cases (8 %), 10 % or more and less than 25 % in seven (28 %), 25 % or more and less than 50 % in nine cases (36 %), and 50 % or more in seven cases (28 %). Eosinophilic cell change occupied less than 20 % of the glands within hyperplastic lesion in seven cases (78 %).

Of six endometrial hyperplasia cases within a polyp, two were complex hyperplasias without atypia, and four complex hyperplasias with atypia. All but one case of complex hyperplasia without atypia showed tubal metaplasia ranging in proportion from less than 10 to 90 %. Morular metaplasia was seen in one complex hyperplasia with atypia.

Stromal p16 expression was found in 31(89 %) of 35 endometrial polyps. The immunoreactivity was located in the nucleus (Fig. 1). The percentage of positive stromal cells ranged from 10 to 90 % (mean, 47 %; median, 40 %). The stromal p16 immunoreactivity score was 1 in 3 cases, 2 in 15 cases, and 3 in 13 cases (Table 2). In cases with less than 50 % stromal cells positive, the p16-positive cells tended to be distributed around glands, but in some cases they clustered evenly within the stroma. The p16-positive stromal cells were distributed diffusely within the polyp from the surface onto the deeper portions. Even in the four negative cases, a small number of positive stromal cells were noted sporadically. Two of the four negative cases were atrophic polyps and the other two were hyperplastic polyps. Stromal p16 expression did not differ between the histological types of endometrial polyp or according to patient age. In hysterectomy and autopsy cases, there were no p16-positive stromal cells in the endometrium. In the curettage specimens, stromal p16 expression was seen exclusively in the fragments derived from endometrial polyp.

Stromal p16 expression was positive in only 1 (3 %) of 33 endometrial hyperplasia cases. Thus, there was a statistically significant difference in stromal p16 expression between endometrial polyp and endometrial hyperplasia (P< 0.01). In 28 (87.5 %) of 32 negative cases, there were absolutely no p16-positive cells in the stroma. A small number of positive cells were noted in the remaining four

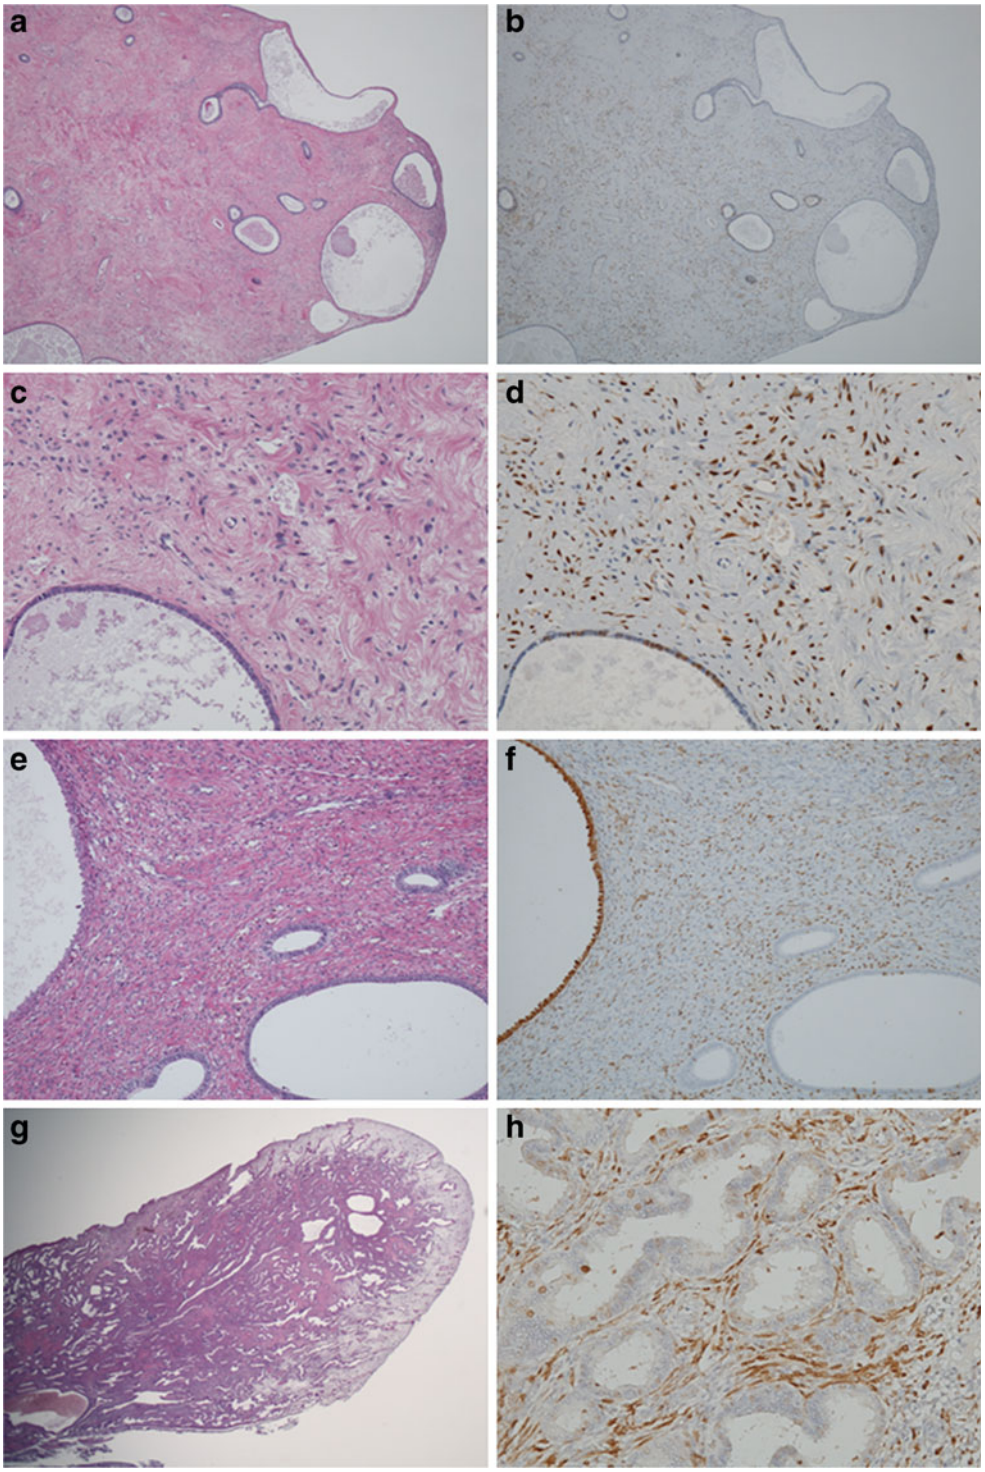

Fig. 1 Stromal p16 expression in endometrial polyps. **a**–**d** Atrophic polyp. The polyp has fibrotic hypocellular stroma and cystically dilated glands lined by inactive epithelial cells. More than 50 % of the stromal cells are positive for p16. **e**, **f** Hyperplastic polyp. The polyp has abundant stromal cells and proliferative-type endometrial glands. More than 50 % of the stromal cells are positive for p16. A cystically dilated gland with tubal metaplasia (left side) also showed p16. **g**, **h** Functional polyp. The polyp has tortuous secretory-type endometrial glands. Most of the stromal cells are positive for p16

negative cases, three of which were simple hyperplasia, and the other complex atypical hyperplasia. The only case with stromal p16 expression was a hysterectomy sample with simple hyperplasia without atypia. In this case, the hyperplastic endometrium showed multiple polypoid excrescences. The p16-positive stromal cells were located in the superficial part of the stroma, just beneath the surface epithelium covering the polypoid excrescences.

In all six cases of endometrial hyperplasia within polyps, the typical fibrous stroma characteristic to endometrial polyps was identified at least focally. Stromal p16 expression was positive in all six endometrial hyperplasias within polyps. Two cases were scored as 1, 3 as 2, and one case was scored as 3 (Table 2). In two cases, the p16-positive stromal cells tended to be distributed near the surface of the polypoid excrescences, where the stroma was somewhat fibrous,

*$P<0.01$; **$P=0.8009$

unlike cellular non-fibrous stroma of the typical endometrial hyperplasia (Fig. 2a, b). In the other four cases, p16-positive stromal cells were distributed randomly but tended to occur in areas where characteristic fibrous stroma was evident. There was no significant difference in the proportion of p16-positive stromal cells between complex hyperplasia with and without atypia. The existence of p16-positive stromal cells seemed to reflect the persistence of original stromal cells of an endometrial polyp. The proportion of p16-positive stromal cells decreased where non-fibrous cellular stroma predominated. There were no p16-positive stromal celsl in the non-polypoid areas of the same specimens in all the six cases.

There was no stromal p16 expression in any of the 23 cases of endometrioid adenocarcinoma. The neoplastic endometrial stromal cells in two of four endometrial stromal sarcomas and two of four adenosarcomas were positive for p16 (Table 2). One endometrial stromal sarcoma and one adenosarcoma showed focal p16 positivity in about 10 % of the tumor cells. The other adenosarcoma showed sarcomatous overgrowth and 90 % of the tumor cells were positive for p16. The other endometrial stromal sarcoma showed focal p16 positivity in about 50 % of the tumor cells.

Glandular p16 expression was noted in 33 cases (94 %) of endometrial polyp and 27 cases (82 %) of endometrial hyperplasia (Fig. 3a–d). The immunoreactivity was located both in nuclei and cytoplasm. Most of the positive epithelial cells showed tubal metaplasia in both endometrial polyp and hyperplastic areas, and all foci of eosinophilic cell change and surface papillary/syncytial change were p16 positive (Fig. 3e, f). We found p16 expression in morular metaplasia in one case of complex hyperplasia with atypia within a polyp. Atypical epithelial cells without metaplastic changes were negative in all 14 cases of complex atypical hyperplasia. Epithelial p16 expression seemed to be almost exclusively located in tubal metaplasia, eosinophilic cell change, and surface papillary/syncytial change, and the percentage of p16-positive epithelial cells closely reflected the degree of these metaplastic changes. There was no difference in epithelial p16 expression between endometrial polyp and hyperplasia ($P=0.1108$). Glandular p16 expression was seen in five of six cases of endometrial hyperplasia within polyps and the immunoreactivity was mostly confined to metaplastic epithelial cells.

Discussion

P16 is a very useful immunohistochemical marker in the area of gynecological pathology [10]. The strong nuclear and cytoplasmic immunoreactivity in high-risk HPV-associated cervicovaginal neoplasms greatly helps in differentiating these neoplasms from problematic benign mimics [11, 12]. Recently p16 expression was found to be positive in most endometrial serous adenocarcinomas and it is now widely used as a sensitive and discriminating marker of

All stromal cells are negative for p16. **e**, **f** Complex atypical hyperplasia with eosinophilic cell change. P16 is positive in the epithelial cells with eosinophilic metaplasia

endometrial serous adenocarcinoma and its precursor, endometrial intraepithelial carcinoma (EIC) [13, 14]. Compared with studies on p16 immunohistochemistry in epithelial lesions, there have been very few studies applying p16 immunohistochemistry to stromal gynecologic lesions except for leiomyosarcoma and undifferentiated endometrial sarcoma [15, 16]. More diffuse and stronger p16 staining was seen in leiomyosarcoma than in leiomyoma. In the present study, we found prominent p16 expression in the stromal cells of endometrial polyps, regardless of patient age, and the histological type of the polyp. There was a marked difference in stromal p16 expression between endometrial polyp and endometrial hyperplasia. We consider stromal p16 expression in endometrial polyps to be very characteristic and useful in differentiating endometrial polyp from endometrial hyperplasia.

In our study, nearly half of the cases consisted of non-surgical samples. Although the accuracy of diagnosis in these non-surgical cases, especially of polyp and simple hyperplasia without atypia, may be questioned, we selected these cases very carefully, paying attention to the histological features of polyp, and excluded any ambiguous cases. In both surgical and non-surgical samples, stromal p16 expression was seen almost exclusively in endometrial polyps. In addition, stromal p16 expression was seen only in fragments derived from an endometrial polyp in curettage specimens. We consider p16 immunohistochemistry especially useful in the pathological diagnosis of endometrial polyp on fragmented curettage specimens.

Recent studies using endometrial biopsy and curettage specimens showed relatively high interobserver agreement for a diagnosis of endometrial polyp [17, 18]. However, poorer agreement was seen in cases of endometrial intraepithelial neoplasia (EIN) arising in a polyp with or without extensive metaplastic changes [18]. To make a diagnosis of EIN or complex hyperplasia within a polyp, benign components of the polyp should be recognized and it should be regaded as the reference point. In our study, stromal p16

expression was also seen in all six cases of endometrial hyperplasia within a polyp. The p16-positive stromal cells tended to occur in the areas where characteristic fibrous stroma of the polyp persisted, which makes p16 immunohistochemistry useful in that it highlights the characteristic stroma. It is of interest that only one case of simple hyperplasia without atypia showed focal stromal p16 expression. This case showed multiple polypoid excrescences and p16-positive cells were seen in the surface of polypoid excrescences. Stromal p16 expression might be at least partly related to the polypoid growth of endometrium.

P16 is a cyclin-dependent kinase-4 inhibitor that is encoded by a gene localized on chromosome 9p21 within the INK4a/ARF locus. The role of p16 in tumorigenesis is variable and the significance of its overexpression differs from tumor to tumor [19]. P16 overexpression occurs in tumours along at least two different mechanisms. The first is an abnormality in the Rb pathway. Normally, p16 inactivates CDK4/6, blocking phosphorylation of Rb, and induces cell cycle arrest. Loss of this p16 function allows uncontrolled cellular proliferation [20]. Some malignant tumors, such as malignant peripheral nerve sheath tumor, have been reported not to express p16, in association with loss of the p16 gene [20]. Paradoxically, other malignant tumours show p16 overexpression, the well-known example being HPV-related neoplasms. The HPV oncoprotein E7 inactivates Rb, which results in the release of p16 from its negative feedback control and an increase in the level of p16 protein [21]. Some HPV-unrelated malignant tumors also overexpress p16, which has been explained by a positive feedback mechanism caused by deregulation of Rb [22]. The second situation of p16 overexpression is related to another important function of p16, oncogene-induced senescence (OIS). P16 induces cellular senescence in response to oncogene expression, and induces cell cycle arrest [23]. This mechanism is well exemplified in some benign tumors such as nevi, neurofibroma, and schwannoma. These tumors overexpress p16 and show senescence-associated acidic β-galactosidase activity, BRAF mutations, and growth arrest [23]. As the malignant counterparts of these tumors are negative for p16, overexpression of p16 in benign tumors seems to control proliferation and protect the tumor cells from malignant transformation [24]. As an endometrial polyp is a benign lesion, stromal p16 expression in an endometrial polyp is likely explained by this second mechanism of p16 overexpression. There is limited information on p16 expression in malignant endometrial stromal tumors, notably endometrial stromal sarcoma. However, a very limited study showed lower expression of p16 in endometrial stromal sarcoma than in leiomyosarcoma and undifferentiated endometrial sarcoma [16]. As it is of interest to explore whether or not the function of p16 as a tumor-suppressor gene is lost in malignant endometrial stromal tumors, we also examined p16 expression in four cases of endometrial stromal sarcoma and four cases of adenosarcoma and of both two cases were positive for p16. The staining pattern was focal in three cases and diffuse in one case, which was an adenosarcoma with stromal overgrowth. As the staining pattern of p16 in malignant endometrial stromal cells was quite variable, the significance of p16 immunorectivity in these cases remains to be clarified.

Although endometrial polyp is considered to be a benign stromal neoplasm, the data to support this hypothesis are limited. Fletcher et al. reported clonal 6p21 rearrangement restricted to the mesenchymal component of an endometrial polyp [25]. Cin et al. found amplification of the HMGIC gene in endometrial polyps and identified HMGIC expression in the nuclei of the stromal cells in endometrial polyps [26]. The HMGIC gene is known to be expressed in benign mesenchymal tumors, but has rarely been reported in malignant tumors [26].

There have been a few immunohistochemical studies focusing on endometrial stromal cells. Normally functioning endometrial stromal cells are positive for calretinin [27, 28]; its immunoreactivity has been reported to be negative or reduced in the stroma of dysfunctional bleeding, postmenopausal, ectopic, hyperplastic, and neoplastic endometrium including polyp [27]. CD34 is positive in the stromal cells of the basalis of normal endometrium, and increased in dysfunctional uterine bleeding and endometrial polyp [28]. These studies imply stromal cell alteration in various endometrial abnormalities whether or not they are neoplastic. As our study here focused only on endometrial polyp and endometrial hyperplasia, it is unclear whether p16 expression in endometrial polyps indicates neoplastic stromal proliferation or non-neoplastic stromal abnormalities. To clarify this issue, whether or not the stromal proliferation is clonal must be elucidated.

The mechanism and significance of p16 overexpression in non-neoplastic gynecological lesions are poorly understood. Horree et al. found that p16 was consistently expressed in endometrial tubal metaplasia [29]. In their study, p16 expression was paralleled by aberrant expression of cell cycle proteins and resembled the pattern of p16 expression frequently seen in endometrial carcinomas. They proposed endometrial tubal metaplasia to be a potential premalignant endometrial lesion [29]. P16 has also been reported to be expressed in endocervical tubal metaplasia [30], but as this is a very common epithelial change, it is not clear from the very small numbers of cases reported whether or not all tubal metaplasia are premalignant lesions. In our study, in addition to p16 expression in almost all foci of tubal metaplasia, eosinophilic cell change and surface syncytial change were also p16-positive. Although the mechanism of endometrial metaplasia is still unknown, it seems likely that p16 plays some role in the altered endometrial glandular differentiation.

Abstract Urothelial cell carcinoma (UCC) with musculus detrusor (MD) invasion is treated by cystectomy. Subsequent pathologic evaluation of cystectomies does not reveal MD invasion (<pT2) in a subgroup of patients. Our objective was to identify features at diagnostic transurethral resection (TUR) predicting down-staging (<pT2) at cystectomy. Patients with pathologically confirmed MD invasion at TUR followed by cystectomy for UCC without (neo-) adjuvant therapy were included (N=106). Slides of both TUR and cystectomy specimens were reviewed, and survival analyses were performed. In total, 27/106 (26 %) tumors were down-staged at cystectomy, of which 13 (12 %) had no residual tumor (pT0). There was no significant difference in age, gender, time interval between TUR and operation, number of slides sampled, and presence of TUR scar between down-staged (<pT2) and pT2 UCC. At review of TUR specimens (N=52) with UCC initially diagnosed as pT2, MD invasion was not confirmed in eight cases (15 %). One case showed extensive histiocytic reaction misinterpreted as UCC; in four cases, muscularis mucosae had been considered MD, and in three cases, desmoplastic reaction mimicked MD. No histologic parameter at TUR was significantly associated with down-staging at cystectomy. Overall and disease-specific survival was not statistically different in down-staged and pT2 UCC. In conclusion, down-staging of UCC (<pT2) at cystectomy occurred in 26 %. At review of diagnostic TURs, MD invasion was not confirmed in 15 %. No clinical or pathologic parameter was predictive for down-staging at cystectomy. There was no difference in survival between down-staged and pT2-staged UCC.

Introduction

Bladder cancer is the fourth most common cancer in males and ninth most common cancer in females [1]. The majority of bladder tumors primarily appear as non-muscle invasive disease (<pT2), whereas 20 % of urothelial carcinomas (UCCs) are infiltrating the musculus detrusor (MD) at presentation. Up to 25 % of initially non-muscle invasive tumors will eventually progress to MD invasive disease. Tumors limited to the mucosa (pTa/pT1) are conservatively treated, while bladder cancer infiltrating within or beyond the MD (≥pT2) requires aggressive treatment [2, 3]. After radical surgery, the 5-year recurrence free-survival of ≥pT2 UCC is only 56–58 % [4, 5]. Accurate pathologic staging of UCC at diagnostic transurethral resection (TUR) specimens is, therefore, an important parameter to determine the optimal therapy for individual patients.

Although accurate pathological staging at diagnostic TUR is pivotal for therapeutic decision-making, definite tumor stage can only be perceived after pathologic evaluation of cystectomy specimens. In a substantial number of patients, no invasion in the MD is identified at cystectomy, prompted by MD invasion at diagnostic TUR. These patients either show residual UCC without stromal invasion

(pTa), UCC with invasion of the lamina propria (pT1), carcinoma in situ (CIS) (pTis), or no residual tumor at all (pT0). Down-staging of UCC to pT0 in cystectomy specimens is reported in 5 to 20 % [6–10]. Although down-staging is a well-known feature, it can be confronting for patient, urologist, and pathologist, raising the question whether the initial diagnosis prompting radical surgery was adequate.

Several pathologic features might mimic MD invasion of UCC. Infiltration of the muscularis mucosae (MM) and extensive desmoplastic stromal reaction can both be misinterpreted as MD invasion. Furthermore, it is not well-established whether UCC located directly adjacent to but not within the MD should be staged as pT2 disease. The objective of the present study was (a) to identify clinical and pathological features of UCC at diagnostic TUR, which correspond with down-staging at cystectomy and (b) to investigate the clinical outcome of patients with down-staged UCC after cystectomy.

Material and methods

Study population

In this study, we included patients with pathologically confirmed MD invasion at diagnostic TUR, followed by cystectomy for UCC without neo-adjuvant chemotherapy or radiotherapy. All patients were treated for UCC of the urinary bladder at Erasmus MC, location Dijkzigt, between June 1989 and May 2010. Patients were routinely followed up every 3 months on the first 2 years after cystectomy, semiannually on the third to fifth year, and subsequently at 12-month intervals. In case of progression, patients were followed up every 3 months. Loco-regional recurrent disease or distant metastases were assessed by CT of the abdomen and pelvis, chest X-rays, and bone scans (if indicated). Death was reported by treating physicians or general practitioner. Follow-up was defined as time from operation to event or last patient contact. Patients that deceased from other causes than bladder cancer, or that were lost to follow-up, were censored at the date of last contact. All clinical data were collected retrospectively from the electronic patient database.

Pathologic review

Slides of cystectomies and diagnostic TUR specimens were retrieved from the archives and reviewed by a urogenital pathologist (GvL). Initial diagnoses had been made by a group of general clinical pathologists. At review, stage and grade were reassigned according the UICC 2002 TNM staging system and the WHO grading system 1973 and 2004, respectively. The following additional pathological parameters were recorded at review of the cystectomy specimens: number of slides of the urinary bladder sampled, presence of a TUR scar, and presence of CIS. At review of the diagnostic TUR specimens, the depth of invasion was established paying special attention to potential pitfalls such as MM invasion, extensive desmoplastic stromal reaction, invasion adjacent to but not within the MD, and invasion in between MD bundles. If classification was uncertain based on routine haematoxylin and eosin staining (HE), immunohistochemistry was performed. In case MD invasion was not obvious despite histology and additional immunohistochemistry, the tumor was classified as pT1 (N=1), which is similar to our approach in daily practice, in which these tumors are reported as “pT1 at least.” The use of the samples for research purposes was approved by the Erasmus MC Medical Ethics Committee according to the Medical Research Involving Human Subjects Act (MEC-2004-261).

Immunohistochemistry

Formalin-fixed, paraffin-embedded tissue sections (5 μm) from TUR specimens were cut and mounted on aminoacetylsilane-coated slides (Starfrost, Berlin, Germany). Sections were deparaffinised in EZprep (Roche Diagnostics, Indianapolis, IN, USA). For all antibodies, heat-induced epitope retrieval was performed in CC1 buffer (high pH) (Roche Diagnostics) for 64 min. The slides were incubated with monoclonal Desmin antibody (clone DE-R-11; 1:50; Novocastra, Newcastle, UK) or monoclonal keratin 7 antibody (clone OV-TL 12/30; 1:1,000; Biogenex, San Ramon, CA, USA) at 36 °C for 32 min, followed by amplification using UltraView Universal DAB detection kit (Roche Diagnostics). All reactions were performed in an automatic BenchMark Ultra device (Roche Diagnostics). Finally, the slides were counterstained, dehydrated, cleared in xylene, and mounted in Pertex (Histolab Products, Gothenburg, Sweden).

Statistical analysis

For comparison of continuous and categorical parameters of the pT2 and the down-staged group at cystectomy, Mann–Whitney and Fisher's exact test were performed, respectively. Kaplan–Meier curves with log-rank analysis were used for comparison of survival. A p value <0.05 was considered statistically significant. All analyses were performed using the Predictive Analytics Software 17 (SPSS Inc., Chicago, IL, USA).

Results

Patient characteristics

Between May 1989 and June 2010, a total of 160 patients had undergone cystectomy for a urothelial malignancy at Erasmus MC, comprising of 135 (84.4 %) males and 25 (15.6 %) females (Table 1). The mean age of the patients at operation was 62.4 years (range 33.2–82.5 years). The majority of male patients had undergone a radical cystoprostatectomy (N=128; 94.8 %), which was combined by a left (N=4), right (N=4), or bilateral (N=1) nephro-ureterectomy. Four (3.0 %) male patients had been treated by simple cystectomy, of whom three had undergone a previous radical prostatectomy for prostate adenocarcinoma. Three men (2.2 %) had been treated by partial cystectomy. A total of 17 (68 %) female patients had undergone a cysto-hysterectomy with adnexa extirpation, combined with a left (N=1) or right (N=1) nephro-ureterectomy. Eight (32 %) females had been treated with simple cystectomy (Table 1).

The clinical indication for cystectomy was UCC with MD invasion (≥cT2) in 137 patients (85.7 %), therapy-resistant recurrence of superficial high grade pTa/pT1 UCC and/or CIS (N=17; 10.6 %), involvement of the prostatic urethra by superficial high grade UCC/CIS (N=4; 2.5 %), a very large superficial UCC (pTa; N=1; 0.6 %), and urothelial CIS combined with sigmoid adenocarcinoma with potential involvement of the urinary bladder (N=1; 0.6 %). Of the 137 patients who had been operated for MD invasion, 23 (16.8 %) patients had undergone neo-adjuvant therapy and 8 (5.8 %) had clinical MD invasion without pathological confirmation. For further analysis, we included the remaining 106 (77.4 %) patients who had pathologically confirmed MD invasion (≥pT2) at diagnostic TUR, followed by cystectomy without neo-adjuvant therapy.

Characterization of down-staged UCC

Of the 106 patients with ≥pT2 UCC at TUR, histologic evaluation of the cystectomy specimen revealed 13 cases (12.3 %) without residual tumor (pT0), 5 (4.7 %) with CIS only, 3 (2.8 %) with pTa, 6 (5.7 %) with pT1, 33 (31.1 %) with pT2, 37 (34.9 %) with pT3, and 9 (8.5 %) with pT4 disease. Therefore, 27 (25.5 %) cases had lower stage UCC at cystectomy, then at initial diagnostic TUR, which showed ≥pT2 disease (Table 2). No statistically significant difference in age (p=0.64), gender (p=1.00), or number of days between diagnostic TUR and operation (p=0.96) existed

Review of pathologic cystectomy characteristics was performed only on the down-staged (<pT2) and pT2 urothelial cancers

TUR transurethral resection

between down-staged (<pT2) and concordantly staged (≥pT2) cystectomies (Table 3).

To investigate whether down-staging was due to difference in sampling, we histologically reviewed all cystectomy slides of ≤pT2 UCC. Stages pT3 and pT4 were not evaluated (N=46). In two cases, slides were not available for review, leaving a total of 58 cases for analysis. The mean number of slides sampled from the urinary bladder was ten in both the down-staged and the concordantly staged pT2 group (p=0.62). Histological reaction to previous TUR was found in 20/27 (74 %) cases of the down-staged group as compared to 17/31 (55 %) cases in the pT2 group (p=0.13), indicating that under-sampling of the cystectomy specimen was not the cause of tumor down-staging after operation (Table 3).

In order to find histological features at diagnostic TUR that corresponded with down-staging at cystectomy, we reviewed all diagnostic TUR slides of the 58 patients with ≤pT2 UCC. Six cases were not available for review, leaving 52 cases for further analysis. At review, one case showed extensive histiocytic infiltration while no UCC was found in the diagnostic TUR specimen, which was verified with

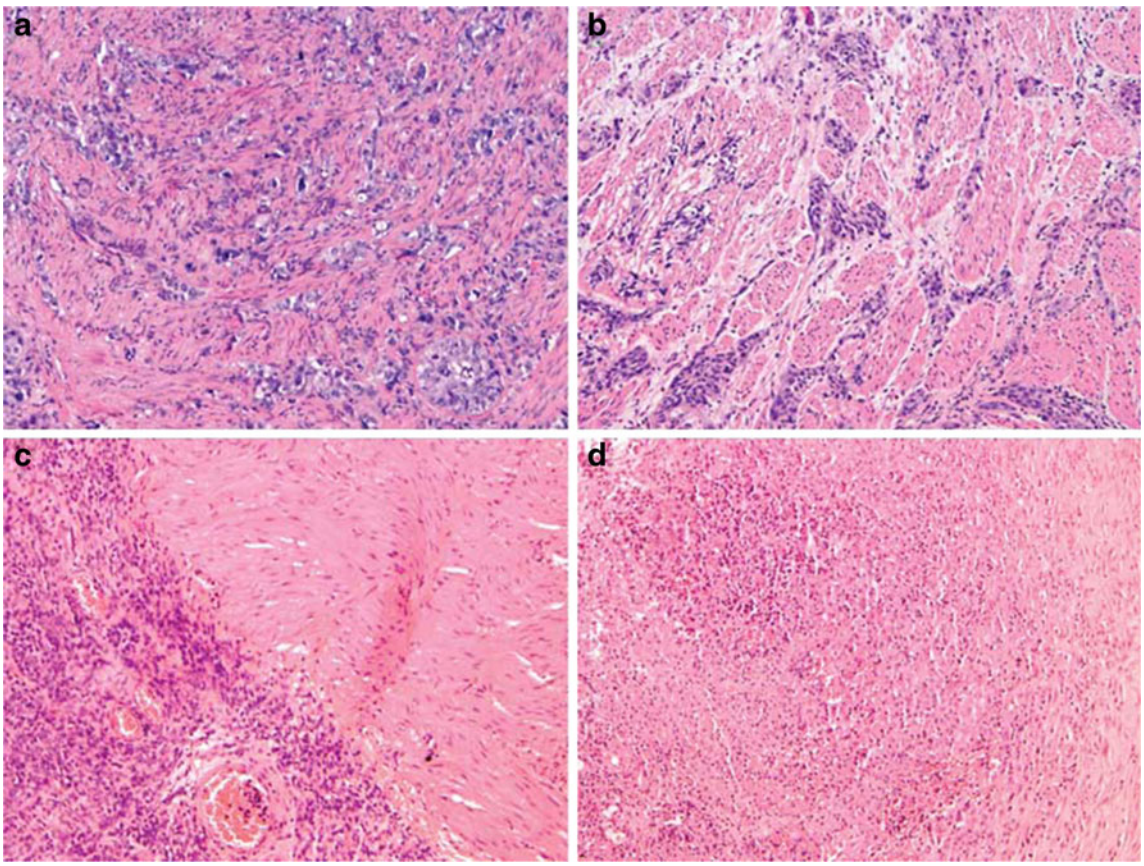

Fig. 1 Assessment of urothelial cell carcinoma invasion in relation to the musculus detrusor. **a**, **b** Urothelial carcinoma invading in between musculus detrusor fascicles. **c** Urothelial cancer located adjacent to but no in between musculus detrusor fascicles. **d** Histiocytic reaction after previous diagnostic transurethral resection, misinterpreted as urothelial cancer invading the musculus detrusor. Fig. 3 Survival analysis of down-staged and pT2-staged urothelial cell carcinoma after cystectomy. There was no difference in overall **a** (p=0.53) or disease-specific **b** (p=0.76) survival of patients with <pT2 versus pT2 urothelial cancer at cystectomy

negative immunohistochemical Ker7 staining (Fig. 1). This case was incorrectly diagnosed as UCC at the time of diagnosis; subsequent cystoprostatectomy indeed did not reveal UCC (pT0). In the remaining 51 cases, grade according to WHO 1973 (p=0.28) or 2004 (p=0.26), and concomitant CIS (p=0.55) were not associated with down-staging at cystectomy. Of the tumors, 40/51 (78.4 %) demonstrated invasion into the MD, 4 (7.8 %) showed tumor adjacent to the MD but not in between the muscle fascicles, and 7 (13.5 %) did not reveal invasion up to MD bundles convincingly (Fig. 2). Of these seven cases, four (7.7 %) showed invasion in between small smooth muscle fascicles, which were not characteristic for MD, but could represent MM and three (5.8 %) demonstrated extensive desmoplastic stromal reaction without tumor infiltration into the MD. The desmoplastic stromal reaction was probably interpreted as MD invasion at initial diagnosis (Fig. 3). In four cases, Desmin immunohistochemistry expression was used to facilitate identification of smooth muscle fascicles at review, in case of cauterization or differentiation with desmoplastic stromal reaction. There was no significant relation of the type of tumor invasion in the TUR specimen and the subsequent findings at cystectomy (Table 4).

Survival analysis

The mean follow-up of the pT2 group and the down-staged group was 61.6 and 70.9 months, respectively. To investigate whether patients who were down-staged at cystectomy had a favorable outcome versus those with stage pT2 at cystectomy, survival analysis was performed. We excluded 9/60 (15 %) patients with positive regional lymph nodes from the analysis, i.e., 4/27 (14.8 %) in the down-staged group and 5/33 (15.2 %) in the pT2 group. There was no significant difference in overall (p=0.53) and disease-specific (p=0.76) survival between the adequately staged and down-staged group (Fig. 3).

Discussion

In a significant number of cases, urologists and pathologists are confronted with UCC down-staged (<pT2) at cystectomy, although operation was prompted by an MD invasive tumor at diagnostic TUR. Down-staging at cystectomy might have several causes, such as successful neo-adjuvant therapy, complete UCC resection at TUR, or false-positive diagnosis at TUR. In the present study, we investigated the incidence and the possible origin of down-staging in a well-defined cohort of 106 cystectomy patients, of whom operation was prompted by pathologic MD invasion at diagnostic TUR and who had not undergone neo-adjuvant therapy.

We found down-staging at cystectomy in 26 % of the study population. In 12 %, no residual UCC (pT0) was identified, which is in line with numbers (6–20 %) reported by others [6–9]. Age, gender, and interval between TUR and operation were not statistically different between concordantly staged pT2 and the down-staged group. Since the number of slides sampled at grossing and frequency of identifying a TUR scar at microscopic evaluation of cystectomy specimens was similar in both groups, down-staging was not due to sampling error.

At review of the diagnostic TUR specimens, in 12 out of 52 (23.1 %) cases, UCC infiltration into the MD could not be confirmed. Discrepancy with the original TUR staging was caused by false interpretation of (a) histiocytic reaction as invasive UCC (1.9 %), (b) invasion of the MM as MD invasion (7.7 %), (c) extensive desmoplastic stromal reaction as MD (5.8 %), and (d) UCC impinging upon the MD as invasion into the MD (7.7 %). As far as we know, the latter subtle distinction has not been subject of study yet. If UCC adjacent to MD would be classified as pT2 disease, as is often done in pathologic practice, the prevalence of down-staging UCC at review of TUR specimens was 15.4 % (8/52). Interestingly, this percentage of staging discordance is in line with the percentage of original pT1 UCC up-staged to pT2 disease at review, indicating that inter-observer variability is also existing in assessing MD invasion [11]. Distinguishing between MM and MD invasion at diagnostic TUR is a well-known challenge in surgical pathology, which is hampered

Table 4 Pathologic characteristics of urothelial cell carcinoma at diagnostic transurethral resections (TUR) in the down-staged (N=21) and adequately pT2-staged group (N=30)

N=51	Down-staged N (%)	Adequate pT2 N (%)	p value
G2/G3	2/19 (10/90)	7/23 (23/77)	0.28
LG/HG	0/21 (0/100)	3/27 (10/90)	0.26
Concomitant CIS	8 (38)	9 (30)	0.55
Desmoplastic stromal reaction	0 (0)	3 (100)	N/A
MM invasion	2 (50)	2 (50)	1.00
Adjacent to MD	2 (50)	2 (50)	1.00
In between MD fascicles	17 (43)	23 (57)	1.00

LG low grade, *HG* high grade, *CIS* carcinoma in situ, *MM* muscularis mucosae, *MD* musculus detrusor

by problems in tissue orientation and potential MM hyperplasia. In addition, MD-infiltrating tumors may partially destruct muscle fibers, leaving thin residual MD bundles resembling MM [12]. Despite these difficulties, accurate recognition of MD invasion is crucial for patient treatment according to the current guidelines. Immunohistochemical expression of the cytoskeletal protein Smoothelin is reported to be stronger in MD than in MM [13–15]. Therefore, additional immunohistochemistry using Smoothelin can be useful in differentiating both muscle layers. While variable Smoothelin expression patterns can be appreciated when both layers are present in the same specimen, its value in classifying a limited amount of smooth muscle fibers in small specimens remains to be established. Therefore, we decided not to include this marker in the current study. Finally, extensive desmoplastic myofibroblastic reaction evoked by UCC invasion might histologically mimic MD [16]. In this case, immunohistochemical detection of Desmin is helpful to distinguish myofibroblasts from MD smooth muscle cells [17].

No statistically significant difference in overall and disease-specific survival was found between the down-staged and concordantly staged pT2 group. Interestingly, the percentage of patients with positive lymph nodes was similar between the two groups as well. Regarding the patients with pT0 disease, survival after cystectomy was not different from the patients with higher tumor stages. This is in accordance with the findings of Thrasher et al. [18]. This implicates that MD invasive UCC at diagnostic TUR with down-staging at cystectomy should still be regarded as pT2 disease. The clinical significance of pT0 disease at cystectomy is, however, still under debate. Volkmer et al. excluded patients with neo-adjuvant therapy and found a significantly better disease-specific survival in patients with pT0 disease at cystectomy versus patients with maximal pT2a disease at cystectomy [19]. Likewise, Tilki et al. investigated a group of 4,430 patients treated with radical cystectomy and found significantly better clinical outcomes in patients with pT0 disease than those with clinical and pathological stage T2 [20]. These results are conflicting with the findings in our study, which could be explained by the fact that in our study a relatively small number of patients were included.

This relatively low number of patients is a limitation of this study and was due to our strict selection criteria, i.e., exclusion of non-urothelial cancer such as squamous carcinoma and adenocarcinoma, presence of neo-adjuvant therapy, availability of slides for review, and omitting high-stage disease (pT3/4) from analysis. Nevertheless, to the best of our knowledge, this is the first study specifically investigating the nature of down-staging in UCC, in which we retrospectively demonstrate 15 % inter-observer variability in the diagnosis of clinically decisive MD invasion. For practical purposes, important lessons can be drawn from this study. First, UCC invasion directly adjacent to MD bundles can be classified as pT2 disease at TUR since down-staging in this group did not occur more frequently than in UCC with invasion into the MD fascicles. Secondly, the presence of pT2 disease at cystectomy in patients with MM invasion or extensive desmoplastic stromal reaction yet no MD invasion at TUR as well as the significant inter-observer variability of T1-2 staging raises the question whether the current clinicopathologic guidelines for treatment of invasive UCC can be optimized. Herr performed a re-staging TUR in patients with histologically proven pT2 disease [21]. If re-staging revealed pT0 or pT1 disease, patients were offered immediate cystectomy or careful follow-up. Interestingly, the 10-year disease-specific survival was similar in both groups with significantly better survival in patients with pT0 as compared to pT1 tumor at re-staging. Since cystectomy is a surgical procedure with 90-day complication rates as high as 46 % and peri-operative mortality ranging from 1 to 4 % [3, 22], further studies on the use of re-TUR and imaging modalities for the treatment and follow-up as alternative for radical operation in a subgroup of UCC patients are mandatory.

In conclusion, we have shown that 26 % of patients with initial pT2 stage at diagnostic TUR were down-staged at subsequent cystectomy. No clinical or pathologic parameters could be identified that were associated with down-staging (<pT2) of UCC at cystectomy. Review of diagnostic TUR specimens revealed inter-observer variability, with pT2 to <pT2 in 15 % of the cases. No difference in survival was found in patients with down-staged versus pT2 UCC at cystectomy.

Abstract Castration-resistant prostate cancer is the second most common cause of cancer death and results in a median survival of less than 2 years. In prostate cancer, fusions between *TMPRSS2* and *ERG* are common. The *ERG* rearrangement prevalence in local recurrent castration-resistant prostate cancer compared to distant metastatic prostate cancer is unknown. We investigated the frequency of *ERG* rearrangement in local recurrent castration-resistant prostate cancer compared to distant metastatic prostate cancer, and assessed for associations between androgen receptor (*AR*) amplification and *ERG* rearrangement status. Samples from 134 patients diagnosed with prostate cancer (84 local recurrent castration resistant prostate cancer, 55 distant metastatic prostate cancer) were assessed for their *ERG* rearrangement and *AR* amplification status by fluorescence in situ hybridization. Statistical analysis was performed using the χ^2 test. We found that the *ERG* rearrangement occurs at a significantly lower frequency in distant metastatic prostate cancer (25 %) than in local recurrent castration-resistant prostate cancer (45 %). The *AR* amplification frequencies were 45 and 35 % in local recurrent castration-resistant prostate cancer and distant metastatic prostate cancer, respectively. The *ERG* rearrangement occurred at a lower frequency in distant metastatic prostate cancer compared to local recurrent castration-resistant prostate cancer.

Veit J. Scheble and Gregor Scharf equally contributed to this study.

Introduction

Castration-resistant prostate cancer (CRPC) is the second most common cause of male cancer-related death [1], and is known to be associated with a median survival of less than 2 years [2]. Recurrent gene fusions, occurring between the androgen-regulated gene *TMPRSS2* and the ETS transcription factor *ERG*, are one of the most common genomic alterations in locally defined prostate cancer (PCa) [3, 4]. Since their discovery, the potential clinical utilization of the *ERG* rearrangements in PCa has been studied extensively [5–7]. The *ERG* rearrangements have been reported to be specific to PCa [8], and are reported to occur in about 15–80 % of PCa [3, 9, 10] depending on the cohort design and the histological subtypes of PCa [11, 12]. While the *ERG* rearrangements are believed to be an early and clonal event in PCa progression [13, 14], other molecular events such as androgen receptor (*AR*) or *PTEN* copy number status vary during disease progression [15]. Moreover, *AR* amplifications have been reported to occur almost exclusively in CRPC [16, 17].

As only few studies have addressed the *ERG* rearrangement in CRPC (Table 1) [18–23], we aimed in this study to investigate the frequency of *ERG* rearrangement in CRPC in the view of comparing the frequency of the rearrangement in local recurrent CRPC (recurrent CRPC) to distant metastatic PCa (metastatic CRPC). Furthermore, we aimed at assessing the potential associations between the *AR* amplification and the *ERG* rearrangement status.

Materials and methods

This study has been approved by the institutional ethical review board of the University Hospital Tuebingen, Germany.

Cohorts

We assessed tissue samples from a cohort of 134 patients diagnosed with PCa (84 samples recurrent CRPC, 55 samples metastatic CRPC). Thirty-nine patients were treated surgically at the University Hospital of Tuebingen in Germany, and 95 patients were treated surgically at the University Hospital of Basel in Switzerland. The samples were then separated into two subcohorts, one consisting of 84 samples from recurrent CRPC and the other consisting of 55 samples from metastatic CRPC. The metastatic CRPC subcohort consisted of 42 samples from bone metastases, 9 samples from CNS metastases and 4 samples from other metastatic sites. For 5 cases both primary tumour and metastatic tissue were available. Due to the small number of cases, these were not evaluated separately. Before the appearance of the local recurrence, all patients had received hormone ablation either surgically (orchiectomy) or chemically (steroid treatment) or combined.

Tissue microarrays

Tuebingen cohort

Tissue microarrays (TMAs) were constructed as described earlier [8]. Formalin-fixated, paraffin-embedded cancer specimen were cut in 3-μm-thick sections, mounted on slides and stained with hematoxylin and eosin (H&E). Subsequently, the PCa and normal prostatic tissues were differently marked on the H&E slide (GS and VJS). We then designed TMAs using the software TMADesigner (Alphelys, Plaisir, France). TMA

Table 1 ERG rearrangement in recurrent and metastatic CRPC in literature

recurrent CRPC local recurrent castration resistant prostate cancer, *metastatic CRPC* distant metastatic prostate cancer, *ERG+* number of cases revealing an *ERG* rearrangement, *rtPCR* real-time polymerase chain reaction, *FISH* fluorescence in situ hybridization

recipient blocks were constructed using a semiautomatic tissue array instrument (Beecher Instruments, Sun Prairie, WI, USA). Three cores per case with a diameter of 0.6 mm from representative tumour regions were included. Recipient blocks were cut into 3-μm-thick sections and placed onto superfrost slides.

Basel cohort

The Basel TMA was constructed as described previously [24]. Briefly, cancer regions were marked on an H&E slide, and two to three cores per tumour with a diameter of 0.6 mm were taken. Castration resistance was defined as palliative transurethral resection due to local recurrence despite ongoing androgen withdrawal.

For both cohorts we used three cores per surgical specimen, cases were excluded if there was too little tumour tissue available. Cases that were not assessable due to technical issues have been excluded before we performed statistical analysis. Whenever possible, we randomly selected for three different TUR-P pieces, avoiding TUR material with heat-related or mechanical artifacts. Due to the TUR technique, multifocality was no longer detectable. We avoided sampling errors as far as possible by punching three cores per patient.

FISH Probes

The *ERG* rearrangement status was evaluated by fluorescence in situ hybridization (FISH), applying a break apart assay as described previously [12]. For the androgen receptor amplification status, we performed an amplification FISH assay with one red target probe (RP11-479J1, Invitrogen, Paisley, UK) and a green reference probe covering a stable region on chromosome X (RP11-308F2, Invitrogen). We assessed for amplifications semi-quantitatively by comparing the number of red signals (*AR* target region) to the number of corresponding green signals (reference region). A red/green ratio greater than 2:1 up to 5:1 was defined as low level amplification. Red/green ratios greater than 5:1 were defined as high-level amplifications. All TMA slides were analyzed under a ×63 oil immersion objective using a fluorescence microscope (Zeiss, Jena, Germany) equipped with appropriate filters, a charge-coupled device camera and the FISH imaging and capturing software Metafer 4 (Metasystems, Altlussheim, Germany). FISH evaluation was independently performed by two experienced observers (VJS and GS). At least 100 nuclei per case were assessed.

Statistical analysis

In order to test the significance of the differences in the *ERG* rearrangement frequencies and the *AR* amplification status between recurrent CRPC and metastatic CRPC, we performed the χ^2 test. We then determined Cramèrs V to measure the effect size of our findings.

Results

Out of 84 recurrent CRPC specimens, we found *ERG* rearranged cases at a frequency of 45 % (38 out of 84; 95 % CI, 34–56 %; Figs. 1a and 2b). More specifically, 13 cases (34 %) showed an *ERG* rearrangement through insertion and 25 cases (66 %) via deletion (Fig. 1a). In the recurrent CRPC samples, *AR* amplification was found in 38 out of 84 (45 %; 95 % CI, 34–56 %) cases (Figs. 1c and 2a).

Within 55 metastatic CRPC specimens, we found a frequency of 14 out of 55 (25 %; 95 % CI, 14–39 %) *ERG* rearranged cases (Figs. 1b and 2b). More specifically, six cases (43 %) showed an *ERG* rearrangement through insertion and eight cases (57 %) revealed rearrangement via deletion (Fig. 1b). Furthermore, we assessed the cases for the *AR* amplification and found an amplified *AR* status in 19 out of 55 (35 %; 95 % CI, 22–48 %) assessable cases (Figs. 1d and 2a).

Within the five cases with both primary tumour and metastatic sites available, we found intrafocal homogeneity regarding the *ERG* rearrangement status—all cases showed a normal status without *ERG* rearrangement both in primary tumour and metastatic site. For *AR* one case showed heterogeneity with a normal status in the primary tumour and amplification in the metastasis, three cases were normal both in primary and metastatic focus and one showed an amplification of *AR* both in the prostate and the metastatic site.

Statistical analysis using the χ^2 test revealed that the *ERG* rearrangement occurs at a significantly lower frequency in metastatic CRPC than recurrent CRPC ($p=0.018$). In *AR* amplification status, χ^2 analysis revealed no significant difference between metastatic CRPC and recurrent CRPC ($p=0.21$). We then determined the effect size by calculating Cramèrs V, which equals 0.2.

Discussion

The *ERG* rearrangement frequency in PCa is reported in several studies, and it varies widely (15–80 %), depending on cohort design [3, 9, 10]. A few studies investigated the *ERG* rearrangement prevalence in CRPC, but each of the studies mentioned in Table 1 has its inconsistencies [18–23]. Thus, the *ERG* rearrangement frequency in CRPC remains vague, in particular the frequency of rearrangement in recurrent CRPC compared to metastatic CRPC. In this study, FISH assessment of two independent CRPC cohorts consisting of recurrent CRPC and metastatic CRPC revealed frequency of 45 and 25 % *ERG* rearranged cases,

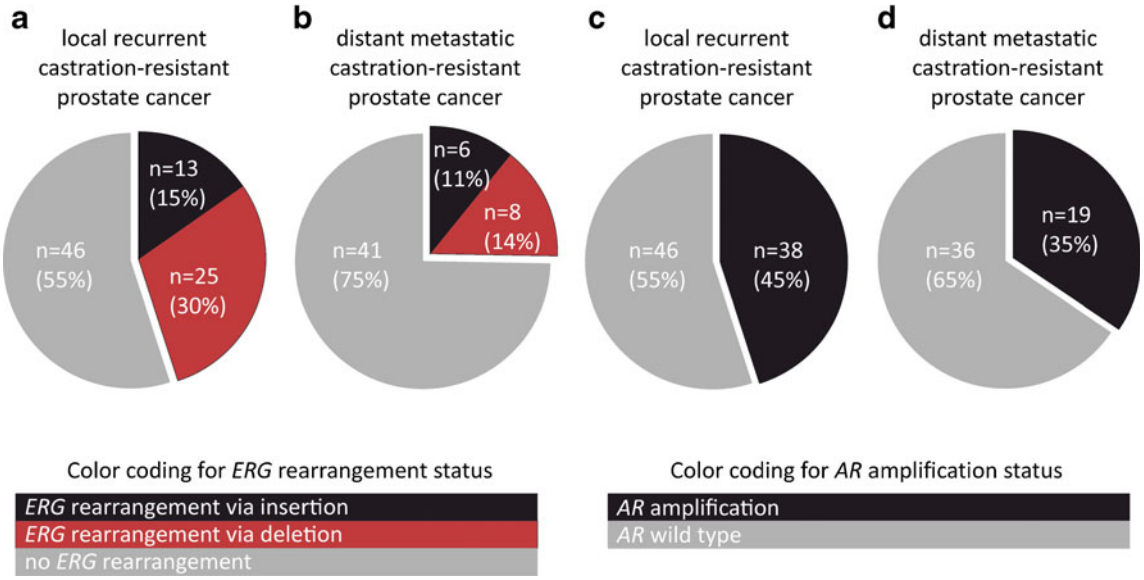

Fig. 1 **a**–**d** Pie chart displaying *ERG* rearrangement and *AR* amplification prevalences in local recurrent and distant metastatic prostate cancer

respectively. Previous studies reported *ERG* rearrangement frequencies between 34.6 and 37.9 % in recurrent CRPC, and 34.9 to 37.9 % in metastatic CRPC cohorts (Table 1). The differences in *ERG* rearrangement frequencies between our study and the previously reported studies (Table 1) are due to the fact that we have used the same experimental setting for the evaluation of both recurrent CRPC and metastatic CRPC simultaneously with a clear cohort definition. In all prior studies mentioned, the *ERG* rearrangement frequency in either recurrent CRPC or metastatic CRPC was assessed, but never compared directly. Furthermore, it partially remains unclear, whether local recurrences or distant metastases of CRPC were examined. We have to admit that our results might be influenced by various differences between the Basel and the Tuebingen subcohort, such as different medical treatments or differences in lifestyle. On the other hand, the *AR* amplification prevalence in our cohorts matches the range of amplification frequencies described in earlier studies, both in metastatic CRPC and recurrent CRPC [17, 25–27].

Earlier studies reported that the *ERG* rearrangement is an early and clonal event during tumour progression [13, 14]. However, our results show a lower frequency of *ERG* rearrangement in the most advanced stage of disease, metastatic CRPC, than in recurrent CRPC. Due to the design of our study, we currently can only speculate on the cause of the differences: A plausible explanation may be that the sensitivity to androgen might be higher in the prostatic region compared to other regions or the blood circulatory system. Thus, the androgen-dependent serine protease *TMPRSS2* might be more active in the prostate and in the prostatic lymphatic region compared to distant organs. As a result, a negative selection of androgen-dependent *ERG* rearranged PCa might occur in a subset of distant metastases. Another possible explanation is that *ERG* promotes the local invasiveness of PCa, but has no influence on metastatic spread.

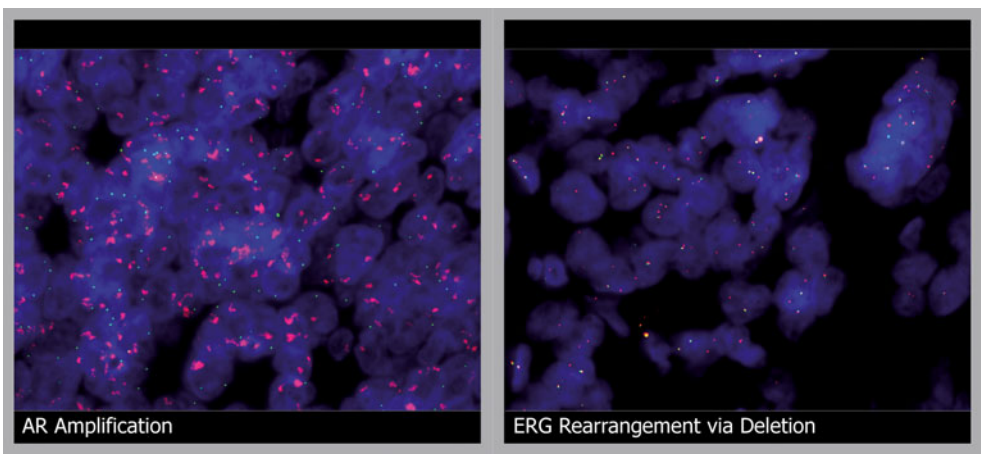

Fig. 2 **a** FISH images showing a high-level amplification of the androgen receptor (*red clusters*) compared to the centromere of chromosome X (*green signals*). **b** FISH image showing an *ERG* rearrangement via deletion represented by one overlapping red and green signal (wild-type allele) and one single red signal per nucleus with a loss of the second green signal, indicating a gene fusion

Several other factors might be causative for these findings as well: Clinical features such as different medicinal treatments, molecular factors such as interindividual molecular and genetic variations as well as environmental and lifestyle events diverging between different cohorts. Taken together, our findings that *ERG* rearrangement occurs at a lower frequency in metastatic CRPC compared to recurrent CRPC may have clinical implications that remain to be studied and may potentially be utilized in the future as a stratification tool for prediction or therapy.

In summary, we examined local recurrent and distant metastatic PCa for the *ERG* rearrangement status and found a lower frequency of *ERG* rearrangement in distant metastatic prostate cancer compared to local recurrent prostate cancer. In contrast, there is no significant difference for *AR* amplification status between these two groups. This is the first study to compare these two divisions of advanced prostate cancer. Our surprising results may potentially be used in clinical decision settings.

Acknowledgments We thank Christine Beschorner for the exceptional technical support and Veit Scharf for helpful contributions to statistical analyses. This work was supported by a grant of the German Research Foundation [Deutsche Forschungsgemeinschaft (DFG), Emmy-Noether-Program, PE1179/2-1], the Wilhelm-Sander-Stiftung (grant no. 2011.077.1) and the Rudolf-Becker-Foundation to SP, a junior grant of the University Hospital of Tuebingen (fortüne-Programme) to VJS and by a grant of the DFG (WE1104/11-1) and German Cancer Aid (Deutsche Krebshilfe, 107827) to NW.

Conflict of interest The Brigham and Women's Hospital and the University of Michigan have filed a patent on ETS gene rearrangements in prostate cancer, on which SP is co-inventor and the diagnostic field of use has been licensed to GenProbe Inc. GenProbe has neither played a role in the design and conduct of the study, nor in the collection, analysis or interpretation of the data and no involvement in the preparation, review or approval of the manuscript.

In oral squamous cell carcinoma, high FAK expression is correlated with low P53 expression

Abstract Focal adhesion kinase (FAK) and p53 have been associated with metastatic activity and a poor prognosis in oral squamous cell carcinoma (OSCC). Recently, a feedback mechanism in which FAK regulates p53 has been proposed. The present study aims to determine the role of p53 in FAK regulation in these tumors. FAK and p53 expression was examined by immunohistochemistry in normal oral mucosa and in 67 oral squamous cell carcinomas. $p16^{INK4a}$ was also studied in view of its association with human papillomavirus infection. The association between FAK and p53 was subsequently analyzed. FAK expression in OSCCs was heterogeneous: 22 (33 %) cases showed weak expression, 16 (24 %) showed moderate expression, and 22 (33 %) cases showed high expression. Regarding p53, 31 of 67 (46 %) available tumor specimens showed negative staining, and 36 of 67 (54 %) showed positive nuclear staining for p53. FAK expression was inversely correlated with p53 expression (Fisher's exact test, $p=0.005$). There was no association between $p16^{INK4a}$ and p53 or FAK expression. In conclusion, our results support the hypothesis that FAK activity might be involved in the down-regulation of p53 expression in OSCC.

Introduction

Focal adhesion kinase (FAK) is a protein tyrosine kinase located in the cytoplasm, which has been shown to play an important role in the onset, progression, and development of metastasis of cancer of the breast [1], colorectum [2], liver [3], endometrium [4], esophagus [5], stomach [6], larynx [7], lung [8], ovary [9], prostate [10], and thyroid [11]. These studies have correlated the increased expression of FAK with metastatic activity and poor prognosis. We have also recently studied FAK expression in oral squamous cell carcinoma (OSCC) by means of immunohistochemistry and have found a significant association with neck node metastasis and survival.

There is strong evidence that FAK signaling pathways can stimulate tumor progression and metastasis formation through the regulation of cell migration, apoptosis, invasion, and angiogenesis [4]. Its role in tumor development has been linked to different factors. On the one hand, the expression of FAK has been associated with cell proliferation through activation of cyclin D1 [12]. On the other, some studies have shown that FAK-dependent signaling can promote changes in cell shape and formation of invadopodia, leading to an invasive cell phenotype [13–15]. Recently, FAK has been involved in cell survival by interacting with p53 and inhibiting anoikis [16]. Golubovskaya et al. [17] were the first to find direct binding of FAK to p53 protein. Moreover, it has been proposed that a feedback regulation mechanism functions between these proteins [18].

Inactivation of the p53 gene by means of mutation, deletion, or binding to viral proteins has been demonstrated in oral cancers in up to 40–50 % of cases [19]. Mutated p53 can repress promoter activity of certain anti-apoptosis and cell cycle-associated genes. Several studies have suggested a possible role for this protein in patient prognosis in OSCC, although a recent meta-analysis revealed that these are inconclusive [20].

So far, no studies exploring a possible relationship between FAK and p53 in oral carcinomas have been performed. OSCC is the sixth most common human neoplasm accounting for 3 % of all newly diagnosed cancers [21]. The main accepted risk factors are tobacco and alcohol consumption, but recently high-risk subtypes of the human papillomaviruses (HPV) have also been postulated to play a role [22]. As a result, a distinction can be made between "traditional" and HPV-associated oral cancer patients. The former are typically older than 50 years, usually male, and their tumors are characterized by high levels of EGFR expression, mutant p53, and generally poor outcome. Conversely, patients with HPV-associated head and neck squamous cell carcinomas are typically younger, more likely to be never-smokers/never-drinkers, have tumors mainly located at the oropharynx and characterized by wild-type p53, $p16^{INK4a}$ overexpression, and have a more favorable outcome [23]. Persistent high-risk HPV infections may promote malignant transformation of stratified squamous epithelium, which is mediated by inactivation of p53 and pRb by the viral gene products E6 and E7 [24]. The inactivation of pRb results in overexpression of $p16^{INK4a}$ [25], a cyclin-dependent kinase inhibitor and G1/S cell cycle phase checkpoint regulator and a marker of HPV E7-mediated functional inactivation of pRb. The method of HPV detection in tumor tissue includes the polymerase chain reaction, in situ hybridization for HPV DNA and E6/E7 messenger RNA, and immunohistochemistry for $p16^{INK4a}$ [26]. Its expression is easily detectable by immunohistochemistry and it has been proposed as a biomarker that would allow unambiguous identification of tumors related to HPV infection [27].

This study aims to determine the role of p53 in FAK regulation in OSCC and the immunohistochemical expression of $p16^{INK4a}$.

Materials and methods

Tissue microarray

An OSCC tissue microarray (TMA) was constructed similar to the arrays previously described [28]. The TMA was built with institutional review board approval from archived formalin-fixed, paraffin-embedded tissue samples (Department of Pathology at the Hospital Universitario Central de Asturias) from 69 patients whose surgical procedures took place between 1990 and 1992. A pathologist reviewed the original archived hematoxylin–eosin-stained slides. At least three samples of each donor tissue block were taken to adequately represent each case. The TMA also contained morphologically normal oral mucosa samples, which were obtained from non-oncological patients undergoing oral surgery. In order to ascertain the histopathological diagnosis and the adequacy of tissue sampling, a section from each microarray was stained with hematoxylin and eosin and examined by light microscopy.

Fifty-four patients were male and 15 were female. The mean age was 61 years (range, 24–87 years). All patients underwent radical surgery and, in all cases, resection margins were free of tumor. Postoperative radiotherapy was administered to 31 (45 %) patients. The characteristics of the patients studied and the clinical and pathological features of their tumors are provided in Table 1. The stage of disease was determined after the surgical resection of the tumor according to the TNM system of the International Union Against Cancer (7th edition) [29].

Immunohistochemistry

The OSCC TMA was evaluated for FAK and p53 expression using immunohistochemical staining. Briefly, 4-μm-thick TMA sections were cut and dried on capillary-gap glass slides (Dako Cytomation). The sections were deparaffinised with standard xylene and hydrated through graded alcohols into water. Antigen retrieval was performed using Target Retrieval Solution pH 6.0 in PTLink (Dako). Staining was done at room temperature on an automatic staining workstation (Dako Autostainer Plus) with mouse IgG anti-FAK monoclonal antibody clone 4.47 (Upstate Biotechnology Inc, Lake Placid, NY, USA) at 1:250 dilution for 1 h and 30 min, anti-p53 IgG monoclonal antibody (clone DO-7, DakoCytomation, Carpinteria, CA, USA) at 1:50 dilution for 45 min, and prediluted mouse monoclonal anti-$p16^{INK4a}$ antibody clone E6H4 (MTM Laboratories, Westborough, MA, USA) at 50 mmol/L for 30 min. The Dako EnVision Flex+Visualization System (Dako Autostainer) was used. Counterstaining with hematoxylin for 1 min was the final step. Following staining, the slides were dehydrated through graded alcohols and mounted with a coverslip using a standard medium. Negative controls, consisting of slides stained with omission of the primary antibody, were also included. Colon adenocarcinoma, breast carcinoma, and endometrium samples were used as positive controls for FAK, p53, and $p16^{INK4a}$, respectively.

The slides were viewed randomly, without clinical data, by two of the authors. FAK staining was

cytoplasmic with equal intensity in all tumor cells within a tumor sample. FAK immunostaining was scored based on the percentage of stained cells into four categories: no expression (score 0; 0 % of stained cells), low expression (score 1; 1–33 % of stained cells), moderate expression (score 2; 34–66 %), and high expression (score 2; >67 % of stained cells). For the p53, according to literature [23, 24], we considered that it was overexpressed when more than 10 % of the tumor cells showed nuclear staining. Below this cutoff, the expression was considered negative. For $p16^{INK4a}$, staining of tumor cell nuclei and/or cytoplasm was interpreted as positive. Slides were scored for the percentage of $p16^{INK4a}$-stained cells from 0 to 4+.

Statistical analyses

All statistical analyses were performed using the PASW statistical software, version 18. Cross-tabulation analyses were performed using Pearson chi-square (χ^2) and Fisher exact (for tables with values <5) tests for comparison between categorical variables. All tests were two-sided. *P* values less than 0.05 were considered to be statistically significant.

Results

Expression of FAK in OSCC specimens

FAK expression in OSCCs was observed in 60 (90 %) out of 67 cases (Fig. 1). This expression was heterogeneous: 22 (33 %) cases showed weak expression, 16 (24 %) moderate expression, and 22 (33 %) cases showed high expression. FAK was strongly expressed in the cytoplasm and on the cell membrane. FAK staining was negligible in tumor stromal tissue.

Expression of p53 in OSCC samples

Thirty-one of 67 (46 %) available tumor specimens were negative for p53, and 36 of 67 (54 %) showed positive nuclear staining for p53 in more than 10 % of tumor cells (Fig. 2). The immunoreactivity was weaker in the center of infiltrating tumor nests or cords, whereas it was stronger and more diffuse in the peripherally located cells.

Expression of $p16^{INK4a}$ in OSCC samples

Immunohistochemical analysis showed that 21 % (14 of 67) of the cases were positive for $p16^{INK4a}$, while the remaining

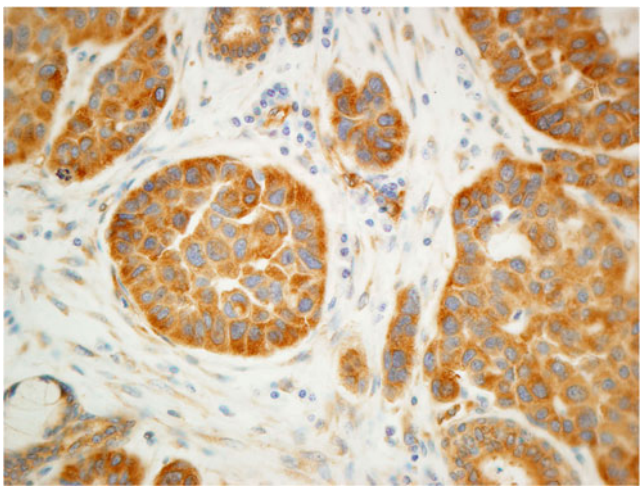

Fig. 1 Immunohistochemical study of FAK in oral squamous cell carcinoma. Intense cytoplasmic staining in tumor nests. Original magnifications, ×400

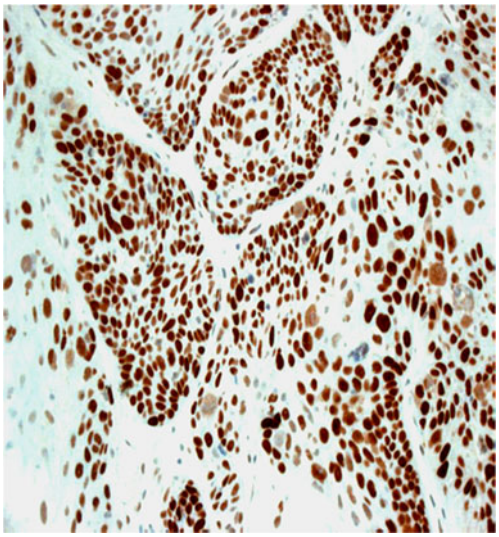

Fig. 2 Immunohistochemical study of p53 in oral squamous cell carcinoma. Original magnifications, ×200

53 tumor samples were negative (Fig. 3). In all positive cases, the immunoreactivity was focal, which we interpreted as negative because $p16^{INK4a}$-positive foci are found in many squamous cell carcinomas negative for high-risk HPV.

Relationship between p53, FAK, and $p16^{INK4a}$ staining

The relationship between p53 and FAK is summarized in Table 2. The immunoreactivity for FAK showed a negative correlation with nuclear expression of p53 (Fisher's exact test, $p=0.005$). Thus, p53-negative OSCC significantly more frequently showed overexpression of FAK than p53-positive OSCC. There was no statistically significant correlation between $p16^{INK4a}$ expression and p53 or FAK expression.

Discussion

FAK has different roles in cancer development with different mechanisms involved [30]. First, FAK is an important regulator of cell migration and angiogenesis which are both required for cancer cell invasion and metastasis as it controls the dynamic regulation of focal adhesions, cadherin dependent cell–cell adhesions, and actin structure in the cell periphery. Second, FAK is involved in remodeling of the actin cytoskeleton by modulating RHO-GTPase pathways [31]. Third, it has been implicated in matrix metalloproteinase expression which is involved in tumor cell invasion. Fourth, FAK mediates adhesion-dependent survival (known as anoikis), which is often lost in tumor cells. Finally, studies have indicated that FAK has a direct role in tumor growth through the ERK–MAPK pathway.

Although little is known about FAK regulation, some authors have shown that p53 can inhibit the transcriptional activity of FAK promoter both in vitro [32] and in vivo [33] and have suggested that p53 can suppress metastasis through down-regulation of FAK. Moreover, a feedback regulation mechanism has been proposed in which FAK regulates p53 via FERM-induced degradation: FERM binds to p53, and FERM-enhanced Mdm2-dependent p53 ubiquitination decreases p53 transcriptional functions [16].

P53 protein is normally present in cells at a very low level and has a very short half-life (around 20 min). Therefore, it is hard to detect in normal tissue by immunohistochemistry [30]. However, when mutated resulting in a defect in the degradation pathway or by binding to viral proteins, p53 protein remains more stable and can be detected by immnohistochemistry. p53 immunohistochemistry has been widely used as a surrogate marker for p53 mutation. However, the correlation is not perfect because immunohistochemistry results are strongly dependent on the selected antibodies and fixation procedures.

Only few studies have analyzed in vivo whether or not loss of p53 function contributes to abnormal FAK expression. In 2005, Rodrigo et al. [34] studied by immunohistochemistry how the loss of p53 function influences FAK

expression in squamous cell carcinomas of the larynx. Their results showed no relationship between the expressions of these molecules. More recently, Golubovskaya studied also by immunohistochemistry a population-based series of breast carcinomas. They found that FAK expression and p53 mutation are positively correlated and FAK-positive carcinomas are 2.5 times more likely to be p53-mutation-positive than FAK-negative tumors [35].

The present study reports on the possible role of FAK in p53 regulation in OSCC. Our results show a negative correlation between the expression of these two molecules, contrasting with studies performed in breast and endometrial cancer that have found a positive correlation between them [35, 36]. Lim et al. [37] proposed a model for FAK regulation of p53. Proline-rich kinase-2 (Pyk2) and FAK are protein-tyrosine kinases that contain an N-terminal 4.1, ezrin, radixin, moesin (FERM) domain. Lim et al. [37] showed that Pyk2 promotes cell proliferation and survival through FERM domain-mediated nuclear translocation, p53 binding, and enhanced Mdm2-dependent p53 ubiquitination leading to p53 inhibition. Thus, loss of FAK expression leads to elevated p53 levels. However, adaptative or compensatory elevation of Pyk2 levels may counteract p53 activation, leading to a reduction in p53 and p21 levels and allowing for cell cycle re-initiation. Interestingly, the cellular and environmental context may dictate whether FAK or Pyk2 FERM domains function as positive or negative regulators. This is due to the fact that FAK FERM overexpression can inhibit FAK tyrosine phosphorylation in trans [38] and block FAK signaling, promoting cytokine gene expression [39].

As the cases included in this study might have been infected by high-risk HPV, we determined the immunoexpression of $p16^{INK4a}$. Despite molecular evidence that $p16^{INK4a}$ overexpression is due to functional disruption of pRb by E7, a small subset of HPV-negative tumors overexpress p16, indicating alternative mechanisms of p16 overexpression. HPV-positive tumors are commonly associated with $p16^{INK4a}$ overexpression, whereas tumors not associated with HPV are rarely p16-positive [40]. In fact, p16 immunohistochemistry reportedly has 100 % sensitivity in screening for transcriptionally active HPV infection; however, with a specificity of 79 %, alternative HPV-independent mechanisms of $p16^{INK4a}$ overexpression have to be considered [26].

Kumar et al. [41] showed that the rate of p53 mutation is quite low in HPV-associated OSCC, and Karsai et al. found that loss of $p16^{INK4a}$ expression is associated with aberrant expression of p53, which is more prevalent in the hypopharynx and in the most advanced stage tumors [42]. In our study, 54 % of tumors showed overexpression of p53, but only 23 % of tumors were $p16^{INK4a}$-positive, and there was no correlation between their expressions. The negative correlation between p53 mutation and over-expression and HPV strengthens the etiologic role of HPV in OSCC [43].

In conclusion, we found a negative correlation between p53 and FAK expression. Further studies are needed to clarify the role of FAK, both in patient survival and in p53 regulation in OSCC.

Abstract The enzyme alpha-methylacyl-coenzyme A racemase plays an important role in the beta-oxidation of branched-chain fatty acid and its derivatives. It has been used to detect prostatic adenocarcinoma and high-grade intraepithelial neoplasia, and recently also as a marker for other neoplasms, including those of the genitourinary system, breast, upper and lower gastrointestinal tract and their precursor lesions. We assessed expression of alpha-methylacyl-coenzyme A racemase by immunohistochemistry in neuroendocrine tumours of the stomach to determine differences in the incidence and pattern of expression among different types of gastric neuroendocrine tumours. While none of the grade 1 neuroendocrine tumours were immunoreactive, 67 % of grade 2 neuroendocrine tumours and 90 % of neuroendocrine carcinomas were positive for alpha-methylacyl-coenzyme A racemase. Furthermore, an adenocarcinoma component was found in 72.5 % (37 of 51) of neuroendocrine carcinomas, whereas none of the grade 1 and 2 neuroendocrine tumours contained an adenocarcinoma component. In 83 % of neuroendocrine carcinomas, the adenocarcinoma component was positive for alpha-methylacyl-coenzyme A racemase, and both adenocarcinoma and neuroendocrine carcinoma components stained positively in 78 % of these cases. Our results indicate that alpha-methylacyl-coenzyme A racemase is a useful marker for distinguishing between grade 1 (negative) and grade 2 neuroendocrine tumours, and neuroendocrine carcinoma of the stomach (frequently positive). Different patterns of alpha-methylacyl-coenzyme A racemase expression between gastric neuroendocrine tumours and neuroendocrine carcinoma suggest that these might develop via different tumourigenic pathways.

Keywords Alpha-methylacyl-coenzyme A racemase · Stomach · Neuroendocrine tumour · Neuroendocrine carcinoma

Introduction

Neuroendocrine neoplasms generally show characteristic histological features, such as trabecular, sheet-like and solid alveolar architecture, and neuroendocrine granules in the cytoplasm of tumour cells, which sometimes contain hormonal products. According to the latest World Health Organization (WHO) classification of digestive system tumours (fourth edition, 2010), gastric neuroendocrine neoplasms are divided into neuroendocrine tumour (NET) and carcinoma (NEC), and the former is further divided into grade 1 NET (NET G1) and grade 2 NET (NET G2). This classification is based on the proliferative activity of tumour cells. NET G1, NET G2 and NEC of the stomach correspond to what was formerly called carcinoid tumour (synonymous with well-differentiated endocrine tumour), atypical carcinoid tumour and endocrine cell carcinoma (synonymous with small cell carcinoma), respectively. Gastric NET G1 is usually composed of uniform small cells with little atypia, limited growth within the submucosa and rare angioinvasion or distal metastasis, corresponding clinically with low-grade malignant potential and favourable

The first two authors (AA and KN) contributed equally to this work.

prognosis. NET G2 is also known as a malignant carcinoid and sometimes demonstrates aggressive biological behaviour [1]. NEC is predominantly composed of atypical cells, larger than those of NET with conspicuous mitotic figures, and demonstrates aggressive biological behaviour with frequent angioinvasion, distant metastasis and poor prognosis. Ki67 and p53 are reported to be helpful markers to distinguish between neuroendocrine cell neoplasms, but the histopathological distinction between NET G1 and NET G2, or between NET G2 and NEC [2], remains difficult.

Alpha-methylacyl-coenzyme A racemase (AMACR) is an enzyme that plays an important role in the beta-oxidation of branched-chain fatty acids and their derivatives [3–5]. AMACR was originally identified in mitochondria and peroxisomes of rat liver cells. Given the involvement of AMACR in the metabolism of lipids, it was speculated that overexpression of this protein might lead to alterations in the balance of cellular oxidants, which in turn might contribute to the pathogenesis of neoplasms. AMACR has been primarily used to detect prostatic adenocarcinoma and high-grade intraepithelial neoplasia [6, 7], and recently also as a differential and prognostic marker of several other neoplasms and their precursor lesions, including those from the prostate, genitourinary system, breast and upper and lower GI tract [7–21].

As yet, only two reports have considered AMACR expression in neuroendocrine neoplasms [17, 22], and only five reports mention AMACR expression in gastric neoplasms [18–21, 23]. These studies found that AMACR expression distinguishes between adenoma and/or ordinary adenocarcinoma and non-neoplastic conditions, and that AMACR expression may depend on tumour differentiation. However, none of these studies mention gastric NET or NEC. The aim of our study was to clarify the differences in the incidence and patterns of immunohistochemically determined expression of AMACR between NET G1, NET G2 and NEC of the stomach.

Materials and methods

Case selection

For the present study, 82 cases of gastric neuroendocrine neoplasms, registered between 1985 and 2011 at the Division of Molecular and Functional Pathology, Niigata University Graduate School of Medical and Dental Sciences, Niigata City, Japan, were selected. The tumours came from 1 Russian and 80 Japanese patients, who had undergone endoscopic resection or surgical resection without systemic adjuvant therapy. All samples had been fixed in 10 % formalin solution and embedded in paraffin. Clinical information was obtained from the medical records of each patient.

Endocrine differentiation of tumour cells was confirmed by diffuse and intense immunoreactivity of at least one of well-known endocrine markers, including chromogranin A, synaptophysin and neural cell adhesion molecule (NCAM, CD56).

The neuroendocrine cell neoplasms were divided into three groups according to the 2010 WHO classification [1]: (1) NET G1 (22 cases), with a mitotic count of less than two per ten high-power fields (HPF) and/or a Ki67 index ≤2 %; (2) NET G2 (9 cases), with a mitotic count of 2–20 per ten HPF and/or a Ki67 index of 3–20 %; and (3) NEC (51 cases), with a mitotic count >20 per ten HPF and/or a Ki67 index >20 %. The study was approved by the ethics committee of Niigata University Graduate School of Medical and Dental Sciences.

Histological diagnosis

The diagnosis of gastric neuroendocrine neoplasms was confirmed by two pathologists (AA and KN), who reviewed the clinical information and histological slides. The histological analysis recorded the following: depth of tumour invasion, lymphatic invasion, angioinvasion, mitotic frequency and lymph node metastasis. Lymphatic invasion and angioinvasion were confirmed via immunostaining for D2-40 and CD34.

Immunohistochemistry

The most invasive area of each tumour was selected, and the corresponding paraffin block was cut into consecutive 3-μm sections for immunostaining, after a representative haematoxylin and eosin (H&E) section was stained.

Immunohistochemical analysis was performed via the high polymer method, using the Histofine MAX-PO (MULTI) kit (Nichirei Biosciences Inc., Tokyo, Japan). Sections were deparaffinized and rehydrated, then microwaved at 98 °C for seven cycles of 3 min (i.e. for synaptophysin, CD34, D2-40, and AMACR) or autoclaved at 121 °C for 20 min (i.e. for Ki-67, chromogranin A, NCAM and p53) in 10 mmol/L of citrate buffer (pH 6.0, for all antibodies except AMACR) or 1 mmol/L Tris–EDTA buffer (pH 9.0, for AMACR) to retrieve antigenic activity. Endogenous peroxidase activity was blocked by 0.3 % hydrogen peroxide in methanol for 20 min. In all sections, except Ki-67, non-specific binding was blocked with 10 % normal serum. Sections were incubated overnight with the following primary antibodies: mouse monoclonal antibodies against chromogranin A (DAK-A3, dilution at 1:500, Dako, Glostrup, Denmark), NCAM (1B6, 1:100, Novocastra, Newcastle, UK), CD34 (QBEnd-10, 1:200, Dako), D2-40 (D2-40, 1:200, Signet Laboratories, Dedham, MA, USA), p53 (PAb1801, 1:40, Novocastra) and Ki67 (MIB-1, 1:200, Dako), as well as rabbit monoclonal antibodies against synaptophysin (1:100, Dako) and AMACR (p504s, clone 13H4, 1:100, Dako). Sections were then incubated with Histofine Simple Stain MAX-PO (MULTI) (Nichirei Biosciences Inc.) for 30 min at room temperature. Antibody–antigen reactivity was visualized with diaminobenzidine, and sections were lightly counterstained with haematoxylin. Finally, the sections were dehydrated with graded ethanol and xylene and mounted with coverslips.

Interpretation of AMACR immunohistochemical expression

Sections from ten cases of prostate cancer served as positive control for AMACR, whereas sections incubated with non-immune mouse IgG served as negative controls. AMACR expression was considered positive when the cytoplasm of >5 % of tumour cells was stained. Positive AMACR staining was divided into

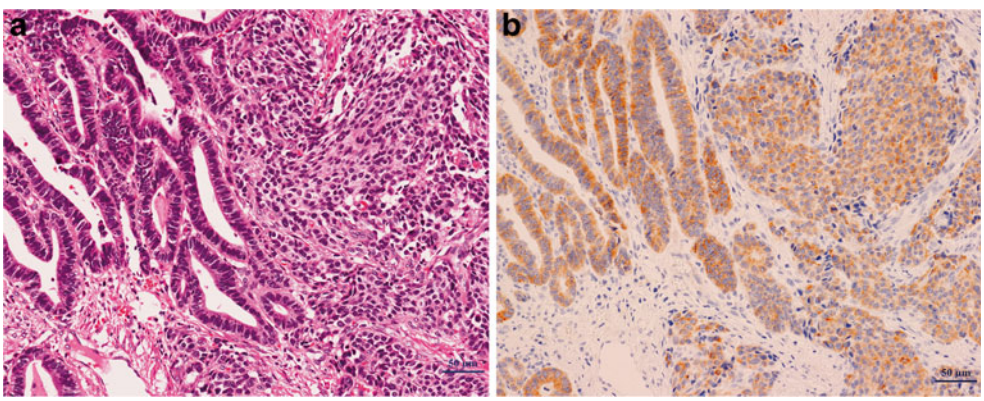

Fig. 2 Immunoexpression of AMACR in adenoNEC case. The adenocarcinoma part and NEC part showed histologic continuity (**a**) and similar strong immunoexpression pattern of AMACR (**b**)

Table 2 AMACR expression in neuroendocrine neoplasms of the stomach

Type of tumour	Number	AMACR expression				*p* value
		Weak	Intermediate	Strong	Total	
NET G1	22	0	0	0	0	<0.001
NET G2	9	3 (33.3 %)	1 (11.1 %)	2 (22.2 %)	6 (66.7 %)	
NEC	51	7 (13.7 %)	16 (31.4 %)	23 (45.1 %)	46 (90.2 %)	

NET neuroendocrine tumour, *NEC* neuroendocrine carcinoma

three patterns: strong (intense and granular cytoplasmic stain), weak (faint and diffuse cytoplasmic stain) and intermediate (mixture of strong and weak patterns) (Fig. 1).

Interpretation of Ki67 index and p53 immunohistochemical expression

The Ki67 index was determined via MIB-1 antibody staining and was expressed as a percentage of 1,000 tumour cells counted in areas with strongest nuclear labelling ("hot spots"). Expression of p53 protein was classified as follows: (−) negative, (+) scattered positive cells, (++) focal aggregates of positive cells and (+++) positive cells occurring in most tumour cells. The staining patterns (++) and (+++) were considered as overexpression of p53 protein, consistent with our previous report [2].

Statistical analysis

Differences between groups were determined via Fisher's exact and χ^2 tests. All statistical analyses were conducted with PASW statistics 17.0 (SPSS Japan Inc. Tokyo, Japan). A $p<0.05$ was considered statistically significant.

Results

Clinicopathological features

The clinicopathological features of the studied endocrine neoplasms of the stomach are summarized in Table 1. The three types of gastric neuroendocrine neoplasm demonstrated significant differences in tumour size, invasion into the muscular layer or deeper, mitosis, lymphatic invasion, angioinvasion and lymph node metastasis.

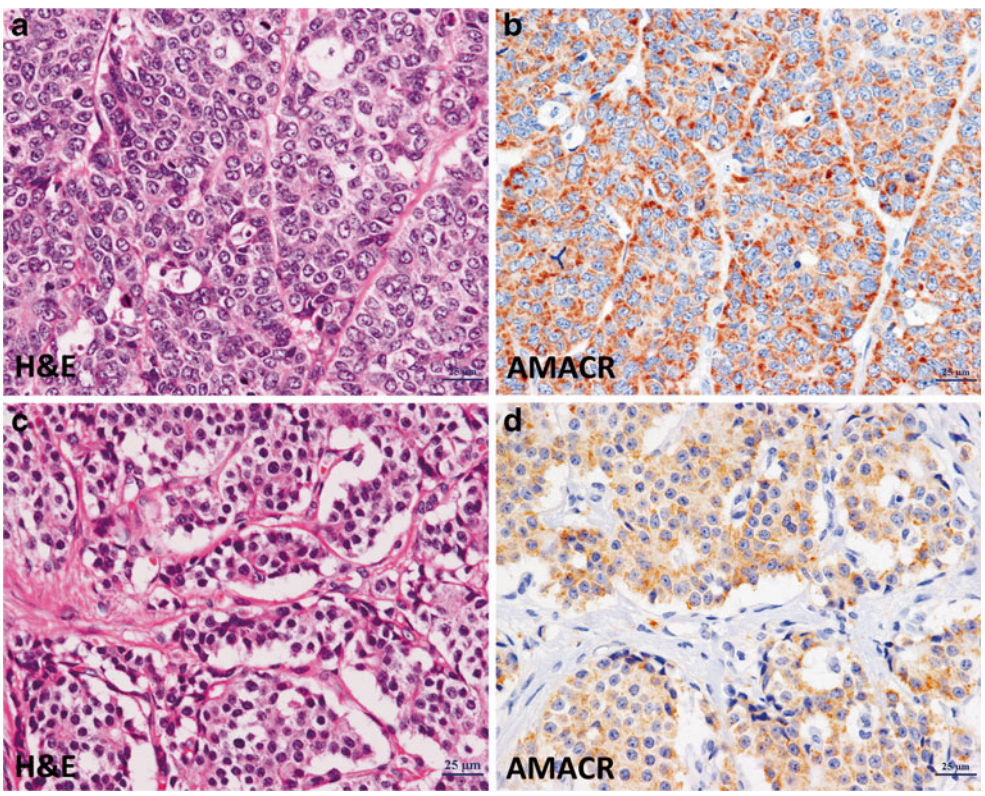

Fig. 3 Immunohistochemical staining of NEC and NET G2. NEC (**a**, H&E) demonstrates strong immunoexpression of AMACR (**b**), and NET G2 (**c**, H&E) shows intermediate intensity of AMACR expression (**d**)

Table 3 Relationship between the AMACR-positive and AMACR-negative cases of NEC and clinical features

	AMACR positive	AMACR negative
Tumour size (mm), median (quartile range)	49 (18–61)	57 (20–60)
mp invasion	35/46 (76 %)	4/5 (80 %)
Lymphatic invasion	43/46 (93 %)	4/5 (80 %)
Angioinvasion	35/46 (76 %)	4/5 (80 %)
LN metastasis	30/43 (70 %)	3/5 (60 %)

Histological features

An adenocarcinoma component was associated with 37 of 51 (73 %) NEC cases (adenoNEC), and 12 of 37 (32.4 %) cases were diagnosed as mixed adenoneuroendocrine carcinoma (MANEC), a special type of adenoNEC with either component of adenocarcinoma and NEC exceeding 30 % according to the current WHO classification [1]. The remaining 14 cases demonstrated NEC without any signs of adenocarcinoma. Specifically, the adenocarcinoma component that was associated with NEC was limited to the mucosa (68 %, 25 of 37) or submucosa (32 %, 12 of 37), and 34 of 37 cases (92 %) were of well to moderately differentiated adenocarcinoma. Furthermore, 89 % of the differentiated adenocarcinoma components were histologically continuous with NEC components in the submucosal layer (Fig. 2). Conversely, no NET G1 or G2 cases contained an adenocarcinoma component (0 of 22 and 0 of 9).

AMACR expression in the non-neoplastic epithelium

AMACR was not expressed in the non-neoplastic gastric mucosa surrounding each tumour. Intestinal metaplasia was weakly positive for AMACR staining in <5 % of cells of the 9 % of cases that were considered negative.

AMACR expression in NET G1, NET G2 and NEC

AMACR expression levels in gastric neuroendocrine tumours are summarized in Table 2. While none of the NET G1 cases expressed AMACR (0 of 22), 67 % (six of nine) of NET G2 cases expressed AMACR. Specifically, there was strong staining in 33 % (two of six), intermediate staining in 17 % (one of six) and weak staining in 50 % (three of six) of NET G2 (Fig. 3). Furthermore, AMACR was expressed in 90 % (46 of 51) of NEC cases, where 50 % (23 of 46) showed strong staining, 35 % (15 of 46) showed intermediate staining and 15 % (7 of 46) weak staining. Of the NEC cases associated with adenocarcinoma (adenoNEC), the adenocarcinoma component expressed AMACR in 84 % (31 of 37) and the NEC in 89 % (33 of 37). In adenoNEC cases, there was no significant difference in AMACR expression between MANEC and non-MANEC (91.6 vs 80.0 %). Interestingly, 93 % (13 of 14) of NEC without an adenocarcinoma component was positive for AMACR. The adenocarcinoma and NEC components were both positive in 78 % (29 of 37) of cases (Fig. 2). The AMACR expression status was concordant between the adenocarcinoma and NEC component in 83.8 % (31 of 37) of cases, both positive in 78 % (29 of 37) and both negative in 5.5 % (2 of 37) (Fig. 2). For adenoNEC cases, AMACR staining was concordant between the adenocarcinoma and NEC components in 52 % (15 of 29), and the staining patterns were similar (i.e. strong–intermediate, intermediate–weak) in 86 % (25 of 29) of cases. AMACR staining was strong for both adenocarcinoma (15 of 31, 48 %) and NEC (23 of 46, 50 %) (Fig. 2). There were no significant differences between the AMACR-positive and AMACR-negative NEC, and NET G2 cases with respect to clinical features, including tumour size, depth of invasion, lymphatic invasion, angioinvasion and lymph node metastasis (Table 3).

Correlations between Ki67-index, p53 expression and AMACR expression

Expression of p53 and Ki67 index are presented in Table 4. Overexpression of p53 and AMACR expression correlated in neuroendocrine tumours of the stomach. In NET G1 cases, both p53 and AMACR were negative. In NEC cases, p53 overexpression (67 %) and AMACR expression (90 %)

Table 4 Correlation between Ki67 index, p53 overexpression and AMACR positivity in neuroendocrine neoplasms of the stomach

Type of tumour	Ki67 index, mean (range)	p53 overexpression (*n*)	AMACR positivity (*n*)
NET G1	1.7 % (1.5–2)	0 (0/22)	0 (0/22)
NET G2	7.2 % (4.5–10)	0 (0/9)	66.7 % (6/9)
NEC	67.1 % (55.4–78.9)	66.7 % (34/51)	90.2 % (46/51)

NET neuroendocrine tumour, *NEC* neuroendocrine carcinoma

often concurred (67 %). However, in NET G2 cases without overexpression of p53, 67 % (six of nine) of cases expressed AMACR. The Ki67 showed a linear correlation with AMACR expression in NET G1, NET G2 and NEC.

Discussion

Although AMACR is expressed in numerous tumour types, its expression has never been studied in neuroendocrine neoplasms of the digestive system. There are only two papers showing significant AMACR expression in neuroendocrine neoplasms of the lung. In the present study, the incidence and pattern of immunohistochemical expression of AMACR in NET G1, NET G2 and NEC of the stomach were investigated.

AMACR overexpression has been observed in prostate and colorectal carcinomas, and linked to a high-fat diet [13]. However, the exact mechanism by which a high-fat diet might contribute to tumourigenesis in these organs remains unclear. Furthermore, AMACR expression may not be limited to tumours linked to dietary factors and may be involved in carcinogenesis via a degradation pathway of branched-chain fatty acids, or an epiphenomenon. The pathologenetic link between dietary branched-chain fatty acids and cancer has not yet been determined, and it remains unclear why branched-chain fatty acids appear to be more carcinogenic than straight-chain fatty acids. Some investigators have speculated that the overexpression of AMACR may lead to alteration in the balance of cellular oxidants, resulting in the production of reactive oxygen species, which leads to oxidative stress, and then DNA damage [24].

In the present study, we found that AMACR expression was significantly higher in NEC (90 %) and NET G2 (67 %) than in NET G1 (0 %), and that AMACR expression correlated with the Ki67 index (Table 4). These findings suggest that AMACR might be a good marker for differentiating between these neoplasms. Overexpression of p53 has been considered to be the best marker to distinguish between NEC and NET. Indeed, 67 % of our NEC but no NET cases overexpressed p53. Furthermore, AMACR was more often positive than p53 (90 vs 67 %) in NEC, and furthermore, AMACR was expressed in 67 % of NET G2, suggesting that AMACR may better discriminate between grade 1 and 2 gastric neuroendocrine neoplasms (i.e. not only between NEC and NET, but also between NET G1 and NET G2). Only a few studies have been performed regarding the prognostic significance of AMACR expression in gastric tumours, and it is still controversial [18–20]. We did not find a correlation between aggressive features, such as lymphatic invasion or lymph node metastasis, and AMACR expression in NET G2 and NEC. This may be due to the small number of samples, and future study with a higher number of cases, especially of NET G2, might clarify this issue.

Many gastric NET cases are formed by aggregation of endocrine cell micronests, predominantly composed of enterochromaffin-like cells, and caused by the trophic effect of hypergastrinemia, which occurs upon extensive atrophy of the fundic gland mucosa [25]. Patterns of AMACR expression concurred between adenocarcinoma and NEC components of adenoNEC. The absence of an adenocarcinoma component in NET G1 and G2 cases might suggest not only the histological features, but also the tumourigenic pathway between NET and NEC are different. The possibility that NEC originates from a preceding adenocarcinoma component might be considered.

Shilo et al. reported overexpression of AMACR in pulmonary neuroendocrine tumours, with AMACR expression in 72 % (31 of 43) of typical carcinoids, 52 % (15 of 29) of atypical carcinoids, 70 % (16 of 23) of large cell neuroendocrine carcinomas and 51 % (32 of 63) of small cell carcinomas [22]. Jiang et al. reported that pulmonary small cell carcinomas (zero of five) and pulmonary carcinoid tumours (zero of ten) are negative for AMACR [17]. These data suggest that the malignant potential of pulmonary carcinoids is different from that of gastric carcinoids, as reflected in AMACR staining.

One important limitation of our study is that we used a small number of specimens, especially of NET G2, and therefore, additional studies are necessary to further clarify the overexpression of AMACR in the development of NEC and NET G2, as well as the use of AMACR in differentiating between various neuroendocrine neoplasms of the stomach.

Frozen section diagnosis in donor liver biopsies: observer variation of semiquantitative and quantitative steatosis assessment

Stefan Biesterfeld · Jasmin Knapp · Fernando Bittinger · Heiko Götte · Martin Schramm · Gerd Otto

Abstract Donor livers are not generally accepted for liver transplantation if intraoperative frozen section histology on wedge biopsies provides evidence for more severe steatosis. In this reliability study, assessment of steatosis in donor liver biopsies by different approaches (frozen sections vs. paraffin sections; macrovesicular steatosis vs. microvesicular steatosis), different observers, and different evaluation methods (conventional microscopy vs. point grid analysis on digital microphotographs) was compared. One hundred twenty consecutive donor liver biopsies were investigated. Intraoperative diagnosis was made on hematoxylin and eosin (H&E)-stained frozen sections. The residual portion of each biopsy was analyzed later on H&E-, diastase-resistant PAS-, and Elastica van Gieson-stained paraffin sections. Microvesicular steatosis and macrovesicular steatosis were classified semiquantitatively into 5 % steps. Additionally, point grid counting was applied on ten digital microphotographs per slide. The values for steatosis revealed a wide range of data between 0 and 70 or 85 % (mean values, 12.0–18.3 %), considering all types of specimens. The results of the two observers were highly correlated for macrovesicular steatosis ($r \geq 0.925$) and for microvesicular steatosis ($r \geq 0.880$). The values for macrovesicular and microvesicular steatosis, however, showed poor correlation ($r \leq 0.581$). The rate of agreement between the two observers ranged between 84.2 and 95.8 % (κ, 0.763–0.937), depending on the threshold setting. For point grid analysis, significantly lower mean values and ranges for both types of steatosis compared to conventional histopathology were found ($p < 0.001$). Comparing the results of point grid analysis with those of conventional histopathology, a relatively loose correlation was found (r, 0.581–0.779). Intraoperative histology remains a reliable and highly relevant method for the assessment of steatosis in liver donor grafts. It represents one important component in the decision-finding whether or not a donor liver should be accepted and should possibly be combined with results of preoperative computed tomography imaging. Considering our data, macrovesicular and microvesicular steatosis should be analyzed separately due to the limited correlation between them.

Introduction

Significant liver steatosis means a risk factor for severe complications after major hepatic surgery. Cases with hepatic steatosis showed an up to twofold increased risk for postoperative complications and those with at least 30 % steatosis also had an almost threefold increased risk of postoperative death [1–3]. Similar results have also been reported for liver transplantation. While mild steatosis did not affect the clinical result [4–7], more severe steatosis

influenced the graft function and the short-term and long-term outcome of the patients [8–26]. As a consequence, donor livers with more severe steatosis are not generally accepted. However, there is no consensus about a suitable threshold of steatosis: whereas in some institutions donor livers with a degree of steatosis of 25–30 % [8, 22] are declined, those with steatosis up to 50–60 % have been accepted by others [23, 27]. The prognosis of the allograft function also depends on additional factors, such as cold and warm ischemia time, type and duration of intensive care treatment and medication of the donor, and finally numerous recipient factors. Therefore, it has been stated that donor livers should not be declined depending on the degree of steatosis alone [2, 14, 28].

Due to the limited period of time between explantation and transplantation, the analysis of frozen section histology on wedge biopsies has been widely accepted as standard procedure for the assessment of steatosis. However, the interpretation mode has not yet been standardized. Mostly, quite rough cutoff points for grouping (0–30, 30–60, >60 %) have been applied. Further, there is no consensus if the degree of steatosis in general or the degree of macrovesicular or microvesicular steatosis in particular is to be used as a variable. Additionally, aspects of interobserver reliability must also be taken into account. Furthermore, it has to be considered that a biopsy may not always reflect the degree of steatosis in the whole organ [29], for example, due to the phenomenon of focal steatosis [30]. Finally, the effects of tissue fixatives [31] or the use of different staining methods [27, 32, 33] might further influence the results.

In this study, the assessment of steatosis of donor liver biopsies using different approaches (frozen sections vs. paraffin sections; macrovesicular steatosis vs. microvesicular steatosis), different observers, and different evaluation methods were compared. From our data, we conclude that both types of steatosis can be interpreted with substantial reliability in frozen sections and in paraffin sections. However, macrovesicular and microvesicular steatosis revealed an only limited correlation and thus represent independent phenomena with probably independent clinical meaning.

Patients and methods

Patients

One hundred twenty consecutive intraoperative donor liver biopsies, provided by the German Organ Transplantation Foundation (DSO), were investigated. Histopathological analysis was performed at the Institute of Pathology of the Johannes Gutenberg University of Mainz where 24-h pathology on-call service is available. We received the specimens as unfixed ice-cooled subcapsular wedge biopsies measuring 0.7–2 cm in longest diameter.

Methods

After macroscopic description of size, color, and consistency, biopsies were snap-frozen in liquid nitrogen. The intraoperative diagnosis was made on representative hematoxylin and eosin (H&E)-stained, 4-μm-thick frozen sections. Without impact on the transplantation process, the residual portion of each biopsy was formalin-fixed and later analyzed using H&E-, diastase-resistant PAS-, and Elastica van Gieson-stained paraffin sections. Evaluation of the slides was performed by two independent observers. The original diagnoses had been made by observer 1, one of the chief consultants of the institution. Observer 2 who has a position as resident was introduced into the principles of steatosis assessment by observer 1 and by a second independent chief consultant and performed the evaluation of the slides retrospectively. For standardized interpretation, we investigated the slides in a conventional light microscope as follows. Ten consecutive viewing fields in the length axis of the biopsy were interpreted using the ×20 and the ×40 objective magnification. Per viewing field, the rates of liver cells with macrovesicular and microvesicular steatosis [34] were estimated separately in 5 % steps (0, 1, 5, 10, 15 %, etc.), and the mean values of the ten fields were taken as final scaling values for the respective type of steatosis.

For point grid counting [35], ten digital microphotographs of each H&E-stained slide were stored at 40-fold objective magnification using the software package Adobe Photoshop CS2 9.0. The first field of view was chosen in the longest diameter of the biopsy close to the end. In order to prevent overlapping images, steps along the longitudinal axis of the biopsy measuring 1.5 viewing fields were chosen for each new image. This procedure was continued until all images had been grabbed. A grid with 24 crosspoints (6×4) was superimposed on each image (Fig. 1). Considering only cells being in touch with a crosspoint, the number of hepatocytes with macrovesicular or microvesicular fat vacuoles and the total number of hepatocytes were counted manually, resulting in up to 240 counts per slide. Hits on connective tissue or bile duct epithelium were not considered.

Statistical analysis

To analyze the relationship between the different assessments of steatosis, the following statistical variables were calculated:

- The coefficient of correlation (r) was used to analyze interrelationships in uncategorized data.
- Cohen's kappa value (κ) [36] that enables the comparison of categorized data was used for better comparability with previous studies. The κ values were interpreted according to Landis and Koch [37] as slight (0–0.2), fair (0.21–0.4), moderate (0.41–0.6), substantial (0.61–0.8), or almost perfect (>0.8).

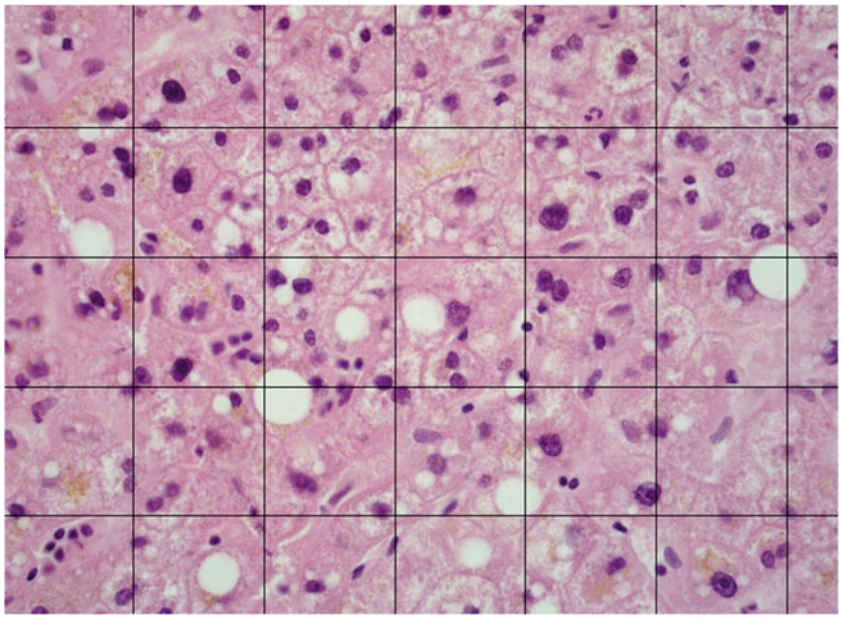

Fig. 1 Principle of point grid analysis. A grid of six horizontal and four vertical lines is superimposed to an H&E-stained slide of a liver biopsy. Only those hepatocytes found on the 24 crosspoints of the lines are considered for evaluation

- For compact data illustration, a factor analysis was performed (for details, see [38]). In brief, the original data are rearranged to a smaller two-dimensional set of factors on a scale between −1 and +1 as source variables for the observed interrelations in the data. The nearer the relative positions of the factors are, the closer the respective variables are correlated. Thus, a two-dimensional (*x*/*y*) diagram of a factor analysis sums up the results of many correlations and of various multifield tables in a visual way.
- In Bland–Altman plots [39], the mean values of two assessments (*x*-axis) and the differences between them (*y*-axis) were presented. Considering a respective threshold, usually the ±2 SD level around the mean value, outliers and trends in the data distribution may be detected more easily.

Results

Conventional histopathology

Macrovesicular steatosis and microvesicular steatosis revealed a wide range of data (Table 1). The mean values ranged between 12.0 and 14.2 % for macrovesicular steatosis and between 15.8 and 18.3 % for microvesicular steatosis; the standard deviations were well comparable. A high correlation between the results of the two observers could be confirmed by correlation analysis (Table 2) for macrovesicular steatosis (*r*, 0.925–0.984) and for microvesicular steatosis (*r*, 0.880–0.953). The degrees of macrovesicular and microvesicular steatosis were quite independent from each other (Table 3): the coefficients of correlation between the two types of steatosis were significantly lower than those found for interobserver analysis (*r*, 0.490–0.581). The close correlation of the assessments of the two observers and the only loose interrelationship between the degree of macrovesicular and microvesicular steatosis are further illustrated in Fig. 2.

In a few cases, outlying values occurred. Focusing on the clinically more important macrovesicular steatosis, in six cases of frozen section analysis (=5.0 %) and in three cases of paraffin section analysis (=2.5 %), the two observers came to differences exceeding the respective ±2 SD interval (Figs. 3 and 4). Comparing the results on frozen sections

Table 1 Mean values, standard deviations, and ranges of steatosis assessment in 120 wedge biopsies of donor livers

Observer/method	Mean	SD	Min	Max
Macrovesicular steatosis				
Observer 1, frozen section	12.0	15.8	0	60
Observer 1, paraffin section	12.2	16.0	0	70
Observer 2, frozen section	14.2	15.4	0	50
Observer 2, paraffin section	13.8	16.4	0	60
Point grid analysis, frozen section	3.4	5.5	0	31.5
Point grid analysis, paraffin section	2.8	5.0	0	23.7
Microvesicular steatosis				
Observer 1, frozen section	15.8	16.4	0	80
Observer 1, paraffin section	15.8	16.8	0	85
Observer 2, frozen section	15.9	16.4	0	80
Observer 2, paraffin section	18.3	15.8	0	70
Point grid analysis, frozen section	5.4	4.9	0	29.0
Point grid analysis, paraffin section	3.3	3.9	0	21.6

All values are given in percent

Table 2 Coefficients of correlation (*r*) for the assessment of steatosis of 120 wedge biopsies of donor livers by two observers, comparing different types of specimens

	Observer 1, frozen section	Observer 1, paraffin section	Observer 2, frozen section	Observer 2 paraffin section	Point grid analysis, frozen section	Point grid analysis, paraffin section
Observer 1, frozen section	–	*0.953*	*0.942*	*0.880*	*0.665*	*0.618*
Observer 1, paraffin section	0.984	–	*0.931*	*0.919*	*0.651*	*0.691*
Observer 2, frozen section	0.947	0.939	–	*0.908*	*0.688*	*0.669*
Observer 2, paraffin section	0.925	0.932	0.946	–	*0.637*	*0.746*
Point grid analysis, frozen section	0.780	0.779	0.808	0.809	–	*0.581*
Point grid analysis, paraffin section	0.792	0.807	0.799	0.867	0.785	–

Values for macrovesicular steatosis are rendered in normal font, while values for microvesicular steatosis are rendered in italics

and on paraffin sections per observer, we found four more severe differences for observer 1 (=3.3 %) and two for observer 2 (=1.7 %). It has to be considered, however, that the ±2 SD interval was significantly lower for observer 1 (SD, 2.9 vs. 5.3 %).

Additionally, we calculated the agreement of the two observers after data categorization (Table 4). Thresholds were set after 10 and 30 %, resulting in the three groups of "<10," "10–30," and ">30 %," or after 30 and 60 %, resulting in the three groups of "<30," "30–60," and ">60 %." The rate of agreement ranged between 84.2 and 95.8 % (κ, 0.763–0.937, "substantial" or "almost perfect", respectively).

Point grid analysis

The data distribution of the point grid analysis (Table 1) revealed significantly lower mean values and ranges compared to conventional histopathology (*U* test: $p<0.001$). Additionally, lower values were found for the coefficients of correlation, comparing the results with those of conventional histopathology for macrovesicular steatosis (*r*, 0.779–0.867) and for microvesicular steatosis (*r*, 0.581–0.746) (Table 2; Fig. 2). The intraobserver reproducibility was tested on 20 randomly chosen cases. Evaluating frozen sections and paraffin sections separately, an almost linear relation was found for macrovesicular steatosis ($r=0.992$) and for microvesicular steatosis ($r=0.971$).

Discussion

Histological assessment on liver biopsies remains the principal approach to quantify hepatic steatosis in the donor liver, but bears controversial issues such as sampling error, different methods of tissue processing, intraobserver and interobserver variation, and finally discrepancies encountered when visual and morphometric results are compared. In addition to this, macrosteatotic and microsteatotic alterations

Table 3 Coefficients of correlation (*r*) for the assessment of steatosis of 120 wedge biopsies of donor livers by two observers, correlating the values for macrovesicular steatosis and for microvesicular steatosis

	Observer 1, frozen section	Observer 1, paraffin section	Observer 2, frozen section	Observer 2, paraffin section	Point grid analysis, frozen section	Point grid analysis, paraffin section

clearly need to be distinguished. With the exception of sampling error, this study focuses on these principal issues, especially on the reliability of steatosis assessment under intraoperative conditions.

Comparing frozen sections and paraffin sections, only slight differences were found: The results for evaluating macrovesicular and microvesicular steatosis were highly correlated (r>0.88, κ>0.76) and are well comparable to those of two previous studies [11, 40] which reported κ values >0.8 for the comparison of macrovesicular steatosis, microvesicular steatosis, or steatosis in general, respectively. Concerning intraobserver and interobserver variation of

steatosis assessment, comparably sparse data exist [35, 41–44]. Well comparable κ values for interobserver agreement between 0.51 and 0.71 or between 0.42 and 0.65 for intraobserver agreement, respectively, have been reported. In our study, the overwhelming majority of specimens in the evaluation of the slides by a second independent observer led to very similar results as compared to the original assessment on the date of liver explantation, resulting in κ values >0.76. Our comparably high κ values might be due to the fact that the degree of steatosis has not been roughly estimated but has been calculated as the mean value of steatosis in a defined number of viewing fields evaluated separately in 5 % steps. As a result of the separate assessment of macrovesicular and microvesicular steatosis, the weak correlation of both forms of steatosis deserves further consideration. However, that issue has not been systematically

Table 4 Agreement analysis and kappa statistics (κ) for the assessment of macrovesicular and microvesicular steatosis of 120 wedge biopsies of donor livers in three groups

Thresholds for grouping	Rate of agreement and κ value			
	Macrovesicular steatosis		Microvesicular steatosis	
Frozen sections				
10/30 %	88.3 %	0.825	84.2 %	0.763
30/60 %	95.0 %	0.925	95.8 %	0.937
Paraffin sections				
10/30 %	89.2 %	0.838	85.0 %	0.776
30/60 %	94.2 %	0.913	95.0 %	0.925

compared and described yet. The only weak correlation between both types of steatosis (r, 0.490–0.581) underlines the need for separate assessment of both types of steatosis. This is not only important regarding their different impacts on graft function but may also have different underlying pathophysiological mechanisms leading to consequences in the treatment of prospective organ donors. To overcome methodological limitations of conventional histology by computed image analysis or by point grid analysis will not clearly improve diagnostics. Up to now, there is no evidence that point grid analysis could be superior to conventional histopathology. Further, its use in routine pathology would require a modified scaling for "mild," "moderate," or "severe" steatosis: our finding that conventional histopathology resulted in almost 3.75-fold values for macrosteatosis and microsteatosis as compared to point grid analysis fits well with those of other groups who reported average values between 2.70-fold and 3.78-fold investigating biopsies from donor livers [45] or from cases with metabolic syndrome [46] or hepatitis C [47, 48]. From the point of view of transplantation pathology, it should be further noted that, for the moment, the application of an image analytical technique will be too time-consuming under the conditions of intraoperative diagnostics. Possibly, digitalization of microscopic slides will open a field of computer-assisted or even automated intraoperative microscopy in the nearer future.

In the context of clinical decision-making as to whether a donor liver should be accepted for transplantation or not, a comprehensive interpretation of intraoperative steatosis assessment could be supplemented by results from preoperative imaging. Unfortunately, results on hepatic sonography showed a limited sensitivity for the prediction of steatosis and contradictory results concerning specificity [24, 49]. Applying unenhanced computed tomography (CT), however, at least two studies gave evidence that the calculation of the ratio of attenuation values in the liver to those in the spleen could be clinically used as a valid noninvasive method to evaluate hepatic steatosis preoperatively for donor livers [50], also regarding the aspect of macrovesicular steatosis [51].

From our point of view, the use of intraoperative histology remains a reliable and most important method for the assessment of steatosis in liver donor grafts, if well-defined criteria are used and as far as methodological limitations are considered in data interpretation. Following our data, it can be reliably applied also on frozen sections and definitely implies a separate determination of macrovesicular or microvesicular steatosis. For clinical purposes, it remains the most important component for the acceptance of a donor liver, especially in cases with a limited macroscopic quality [52], and may be combined with results of preoperative CT imaging. Validation of steatosis assessment by analyzing the clinical course of the recipients after transplantation is highly recommended and should be performed on our patient group in the near future.

Conflict of interest We declare that we have no conflicts of interest.

Abstract The International Association for the Study of Lung Cancer (IASLC), the American Thoracic Society (ATS), and the European Respiratory Society (ERS) proposed a classification for lung adenocarcinomas (ADC) based on the predominant growth pattern. This classification has been shown to have prognostic and maybe even predictive impact. However, until now, the reproducibility of this classification has not been sufficiently demonstrated. Digital images of 40 selected ADC cases were shown twice to members of the Pulmonary Pathology Working Group of the German Society of Pathology. Each time a teledialogue-based survey on the classification was performed. Between the voting procedures, salient features of the novel classification were presented and discussed in detail by its

members. The mean percentages of consensual votes per pattern ranged between 59.6 and 75 %, with lepidic and solid being the pattern with the most discordant and concordant votes, respectively. The other patterns ranged in between (papillary 65.8 %; acinar 67.8 %; micropapillary 74.2 %). The extent of disagreement decreased after the educational session. This decrease, however, was heterogeneous for the different patterns with acinar being the pattern with the strongest improvement. The overall number of abstentions decreased significantly after the educational session ($p<0.001$) as well. The IASLC/ATS/ERS classification of lung ADC can be applied with reasonable consensus even for difficult cases in a nationwide context. The reproducibility evidently improves following educational sessions, even among experienced lung pathologists. Worldwide harmonization is clearly the next step on the way to a clinically meaningful, internationally accepted use of this novel prognostic and potentially predictive tool in lung pathology.

Introduction

Pulmonary carcinomas are very frequent neoplasms, heading cancer death statistics for both sexes in the western world [1]. Of these, the most prevalent tumor type is adenocarcinoma (ADC) accounting for approximately half of all lung cancers.

As well as in other neoplasms, a reliable estimation of patient survival probability is crucial in pulmonary tumors, since the selection of conventional therapy regimens, administered in the palliative or adjuvant setting, is largely based on the estimated risk of the patient to die of the disease in a given time frame. For lung cancer, the cornerstone of clinical survival estimation is stage categorization. Besides tumor staging, tumor grade as determined by the pathologist on the basis of conventional histomorphology is a reliable predictor of survival in a broad variety of solid human tumor entities and strongly influences clinical decision making, e.g., in breast cancer, prostate cancer, or sarcomas [2–4]. However, up to now, grading in lung cancer has largely been performed without internationally accepted criteria and without any clinical impact. Similarly, histological subtyping in some regard is not very well standardized in pulmonary ADC either. In response, several groups have tried to establish standardized subtyping and grading schemes for lung cancer [5, 6]. On the basis of these new data, an international multidisciplinary expert panel of the International Association for the Study of Lung Cancer (IASLC), the American Thoracic Society (ATS), and the European Respiratory Society (ERS) has proposed a novel classification system for ADC. This system is based on the evaluation of ADC architecture and is intended to facilitate standardized tumor grading [6]. ADC are now categorized according to their predominant growth pattern. The independent prognostic impact of this classification across all tumor stages has subsequently been confirmed by us and others in large ADC cohorts from Europe, Australia, and the USA [7–10]. Thus, grading of pulmonary ADC on the basis of the predominant pattern will very likely enter clinical decision making in the near future. However, prior to the application of this classification in routine diagnostics, it is mandatory to validate this classification in terms of reliability and reproducibility when used by different evaluators, outside a well-defined study setting. This implies that all pathologists involved in lung pathology need to share the same criteria regarding the evaluation of tumor architecture as outlined by the IASLC/ATS/ERS consensus. In order to provide a nationwide basis for this issue, the Pulmonary Pathology Working Group of the German Society of Pathology organized a meeting to introduce and discuss the novel classification, to test for reproducibility among pulmonary pathologist, and to identify potential problems and pitfalls which should be further clarified. Here, we present the results of this meeting, provide information on the level of agreement/disagreement in the evaluation of selected complex patterns among a large group of pulmonary pathologists, and assess the impact of expert discussions and training in this context.

Material and methods

Participants of the meeting and selection of cases

The annual autumn meeting of the Pulmonary Pathology Working Group of the German Society of Pathology took place from the 25th to 26th November 2011 at the Thoracic Hospital Heidelberg, Germany. The meeting was attended by a total of 77 pathologists and clinicians with a special interest in pulmonary pathology. Prior to the meeting, all participants were asked to provide digital images of difficult patterns of pulmonary ADC to the organizing committee (AW, PAS). A total of five institutions followed our call for photomicrographs of complicated patterns. The organizing committee in Heidelberg supplemented some additional cases to allow for a total of 40 images for the test sessions.

Test setting

The meeting started with a 1-h state of the art lecture by one of the authors of the IASCL/ATS/ERS classification (Prof. Keith Kerr, Royal Infirmary Hospital, Aberdeen, Scotland). Subsequently, all interested pathologists were asked to

participate in an anonymous teledialogue-based study (TED) to vote for the predominant pattern (lepidic, acinar, papillary, micropapillary, or solid) of 40 selected ADC images (30 s per image; only H&E stains). Images were presented as beamer projections to the audience and all participants agreed to the manner and quality of the presentation. On day 1, 27 pathologists took part in the evaluation round, while on day 2, 24 pathologists participated. To avoid any bias, votes were given anonymously. All images as well as the votes for the predominant pattern can be seen and evaluated again using the following link: http://www.klinikum.uni-heidelberg.de/Online-Tutorial-for-Pulmonary-Adenocarcinoma-Subtyping.125267.0.html.

All participants also had the chance to abstain if indecisive. The TED results were not reported to the participants. The first TED round was subsequently followed by specific lectures of expert pulmonary pathologists (AFE, KJ, IP, PAS, FL) concerning all five patterns (25 min each), which were intensively discussed with the audience. The following day, the same pictures of all 40 cases were presented again to the participating pathologists in a second TED round (same conditions) in order to test for resolved or still evident problems in pattern definition according to the IASLC/ATS/ERS consensus.

Statistics

Differences in pattern classification between both evaluation rounds as well as differences in the percentages of voters who did abstain to classify the respective patterns were compared with the non-parametric Wilcoxon test for paired sample analysis. p values<0.05 were considered significant. All statistics were done with SPSS Statistics 19 (IBM, Ehningen, Germany) and with GraphPad Prism 4.03 (GraphPad Software, La Jolla, CA, USA).

Results

Designation of the predominant patterns

The number of votes per case for predominantly lepidic, acinar, papillary, micropapillary, and solid growth patterns for both evaluation rounds was noted. The predominant pattern was designated by definition as the pattern which attained the highest number of votes in the second evaluation round after the discussions. Only if votes for two patterns were equal in the second evaluation, the first evaluation round was included for the calculation in order to designate the predominant pattern.

This resulted in 6 (15 %) cases with a predominantly lepidic, 15 (37.5 %) cases with a predominantly acinar, 10 cases (25 %) with a predominantly papillary, 6 (15 %) cases with a predominantly micropapillary, and 3 (7.5 %) cases with a predominantly solid pattern of ADC. The uneven distribution of cases in the respective pattern groups is explained by the fact that obviously some patterns were deemed more problematic than others by the contributors of cases; these patterns were therefore overrepresented in the test set. In order to allow for a direct comparison of the results with the standards defined, the following sections are headed by a short definition of each pattern according to the IASLC/ATS/ERS.

Problems and pitfalls in the definition of predominant lepidic growth

According to definition, lepidic growth consists of neoplastic cells growing along pre-existing alveolar structures. Papillary or micropapillary patterns and intraalveolar tumor cells are absent [6].

In the first round, 57.4 % of voters classified lepidic predominant cases as being lepidic, and this value increased insignificantly to 59.6 % of voters in the second round (Fig. 1, Table 1; p=1.0). This was the lowest number of consensual votes for all patterns. The most frequent problems occurred in the separation of lepidic from papillary (misclassified by 13.9 % of voters) and acinar (misclassified by 7.6 % of voters) differentiation. The former problem is depicted exemplarily in one of the cases, were the votes for lepidic and papillary were equal in the second evaluation round (Fig. 2a). The number of participants who abstained from voting in the lepidic group was 16.8 %, the highest of all patterns.

Problems and pitfalls in the definition of predominant acinar growth

According to the consensus definition, acinar growth consists of glands which are round to oval-shaped with a central luminal space surrounded by tumor cells. Acinar structures may also consist of aggregates of tumor cells with peripheral nuclear polarization and with central cytoplasm without a clear lumen. When the alveolar architecture is lost and/or myofibroblastic stroma is present, invasive acinar adenocarcinoma is considered present. Cribriform arrangements are also regarded as a pattern of acinar adenocarcinoma [6].

Acinar predominant cases were classified as being acinar by 51.4 % of voters in the first evaluation round (Fig. 1, Table 1). This value increased significantly (p=0.001) to 67.8 % of voters in the second evaluation round. The most problematic pattern to delineate was lepidic with 8.7 % of voters misclassifying, followed by solid (4.9 %) and papillary growth (4.5 %). The separation between acinar and lepidic can be quite challenging, most likely as a consequence of different appraisals concerning the maintenance or the loss of alveolar

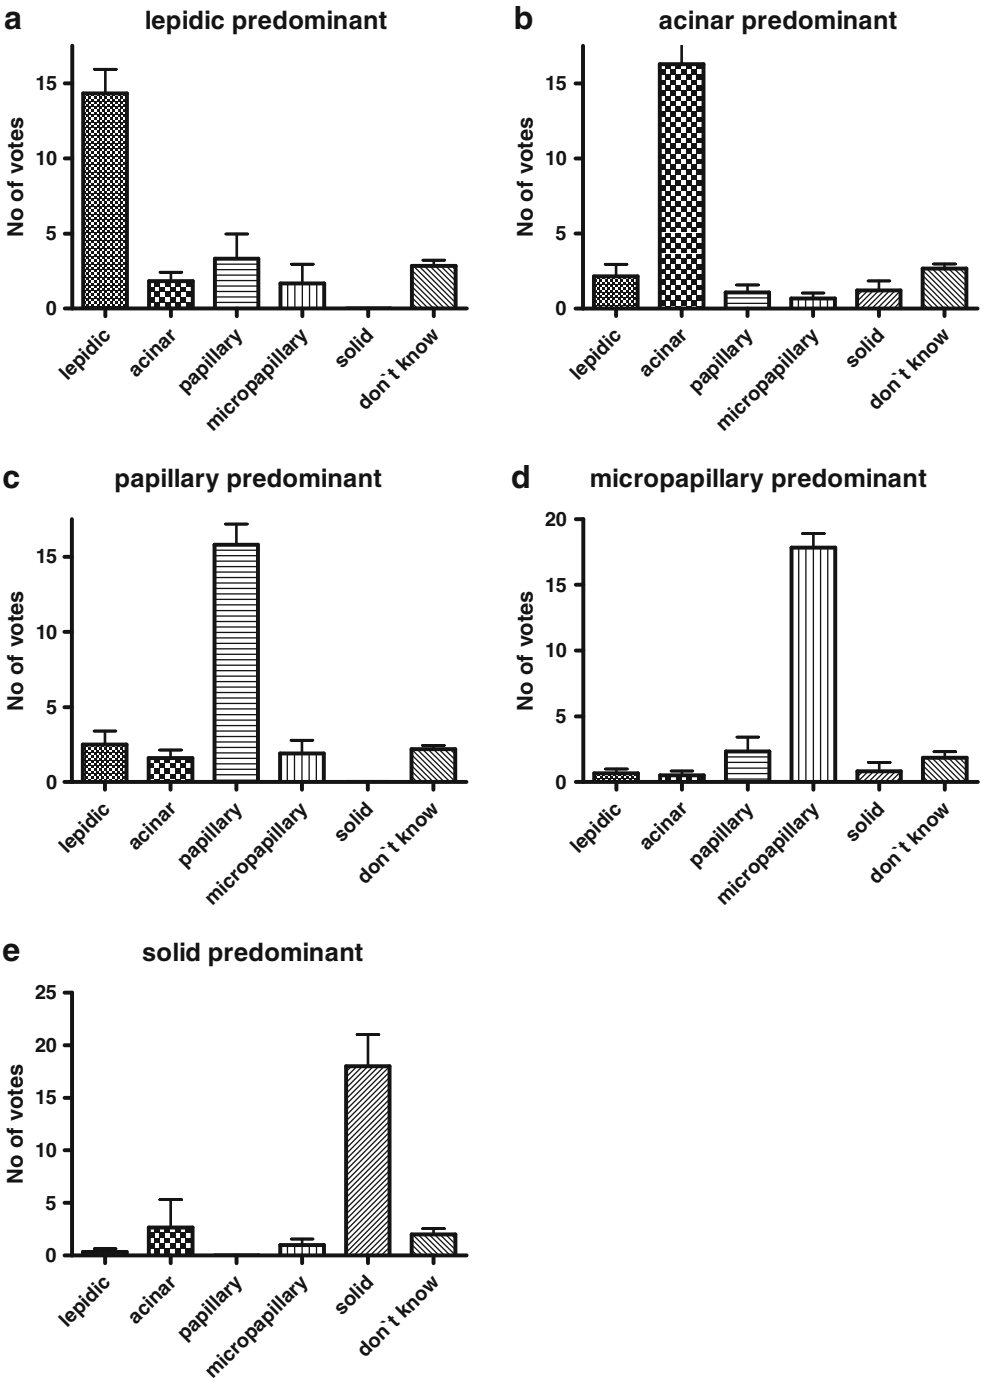

Fig. 1 Number of voters per pattern in the second evaluation round for lepidic predominant (**a**), acinar predominant (**b**), papillary predominant (**c**), micropapillary predominant (**d**), and solid predominant (**e**) cases

structures. Additional histochemical stains can be helpful in this regard. Two typical problematic cases from our set with initially almost equal number of votes for both patterns are shown in Fig. 2b, e.

Problems and pitfalls in the definition of predominant papillary growth

According to the consensus classification, papillary architecture is characterized by growth of columnar cells along central fibrovascular cores. If a tumor has lepidic growth but the alveolar spaces are filled with papillary structures, the tumor is classified as papillary ADC. Myofibroblastic stroma is not needed to diagnose this pattern [6].

Papillary predominant cases were classified as papillary by 63.2 % of pathologists participating in the first round (Fig. 1, Table 1). The proportion of voters who classified these cases as papillary increased insignificantly to 65.8 % in the second round (p=0.887). Following lepidic, this pattern was the second most complicated to classify. Specific

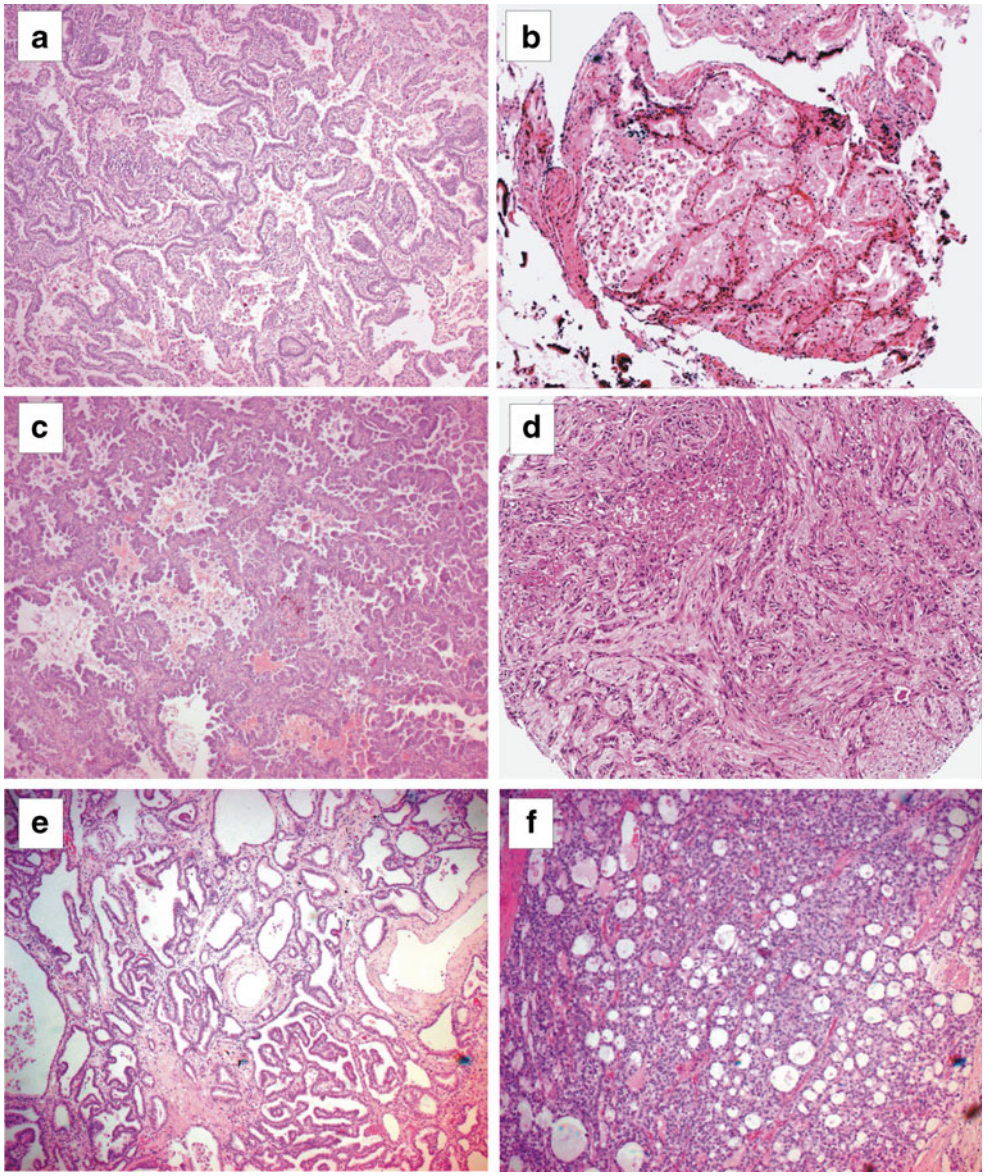

Fig. 2 Exemplary images of cases with difficulties in pattern classification. **a** The problem in the delineation of cross cut alveolar walls from true papillae in the separation of lepidic from papillary growth. We believe that this case is still lepidic. **b** A problematic case in the separation between lepidic and acinar differentiation. In such cases, the presence of desmoplastic stroma whose visualization can be enhanced by the use of elastic stains is helpful to decide whether the alveolar structure is still maintained or already lost. **c** An exemplary case to depict difficulties in the separation between papillary structures from micropapillary growth. Here some of the secondary structures still have fibrovascular cores while others had not. In this case, we would opt for micropapillary predominance. **d** Parts of a predominant "collapsed" acinar ADC with extensive desmoplastic stromal reaction. The aggregates of tumor cells tend to have peripheral nuclear polarization with central cytoplasm. However, clear lumina are hardly visible. This obviously is challenging with respect to the separation of acinar and solid growth. **e** A case with difficulties in the separation of acinar from lepidic structures. Since the overall architecture is largely maintained, one might rather classify this case as lepidic predominant. **f** A case where solid tumor cell nests contain a moderate amount of lumina. In such cases, problems in the differential between acinar and solid growth may occur. One might rather classify this case as acinar (cribriform) predominant. For further examples with comments for all cases of this study, please refer to the online tutorial mentioned in the text

problems arouse with lepidic (10.4 % of voters), micropapillary (7.9 %), and acinar (6.4 %) misclassifications. A problematic case depicting the difficult differential between papillary and micropapillary is shown in Fig. 2c (see below).

Problems and pitfalls in the definition of predominant micropapillary growth

According to the IASLC/ATS/ERS definition, micropapillary growth is characterized by tumor cells growing in micropapillary

tufts which lack fibrovascular cores. The tumor cells may appear detached and/or connected to alveolar walls. The tumor cells are usually small and cuboidal with minimal nuclear atypia. Ring-like glandular structures which "float" within alveolar spaces are regarded as micropapillary as well [6].

The predominantly micropapillary pattern was classified as micropapillary by 64.8 % of voters in the first round. This value increased insignificantly to 74.2 % of voters in the second evaluation round (Fig. 1, Table 1; $p=0.194$). This pattern thereby was the second most reliable to classify. Misclassifications usually occurred in the differential diagnosis from papillary growth, usually when both differentiation patterns were intermixed in one area (Fig. 2c).

Problems and pitfalls in the definition of predominant solid growth

According to the consensus criteria, solid growth is characterized by polygonal tumor cells forming sheets which lack other recognizable patterns of adenocarcinoma, i.e., acinar, papillary, micropapillary, or lepidic growth [6]. The solid pattern was the easiest to classify and the one with the highest percentages of consensual votes in both the first round (73 %) as well as the second round (75 %) (Fig. 1, Table 1; $p=0.564$). When problems occurred, they were usually with acinar growth (11.2 % of misclassifications) either when nests of cells without clearly discernable lumina were present or in cribriform tumor areas. The former issue is depicted in Fig. 2d, the latter in Fig. 2f. In addition, problems in the differential diagnosis of solid versus micropapillary pattern (4.2 %) occurred in cases where the alveolar spaces were filled with discohesive tumor cell aggregates. It must be mentioned that pure solid ADC diagnosis in the routine setting requires mucin stains, which were not used in this study for reasons of practicability (preselection of cases was done including mucin stains).

Accuracy of classification

As mentioned above, educational sessions improved identification of acinar as well as micropapillary patterns (Fig. 3). For lepidic, papillary, and solid growth, the single discussion session did not result in a statistically significant improvement of consensus. As a consequence, the overall number of misclassifications decreased only slightly but significantly ($p=0.001$, Fig. 3). As a second important consequence of the discussions, the number of participants who did initially abstain from voting for a specific pattern decreased in all pattern groups as well as overall (Fig. 3). These differences were statistically significant for acinar ($p=0.006$) and papillary ($p=0.010$) patterns and for the overall classification ($p<0.001$). The differences failed to reach statistical significance for lepidic ($p=0.104$), micropapillary ($p=0.056$), and solid growth ($p=0.109$).

Discussion

The novel IASLC/ATS/ERS classification of lung ADC has been shown to have impact on overall, disease-specific, and disease-free survival in several retrospectively analyzed patient cohorts from all over the world [7–10]. In addition, there are hints that this classification based on predominant patterns might have predictive value with respect to radio/chemotherapy response [9]. All this strongly points to the potential clinical usefulness of this simple, cheap, and effective way to classify these neoplasms.

However, prior to clinical use, harmonization of diagnostic standards and testing for reproducibility of such a novel classification is mandatory. Specifically, it is essential to show that intra- and interobserver reproducibility is adequate and that the classification can reliably be used in daily routine practice. To test for these factors and to improve the conformity of pattern interpretation, we held a nationwide meeting of pulmonary pathologists in Heidelberg, Germany, where we discussed difficult cases and probed for our respective standards. Our study aimed to measure agreement in the interpretation of complex patterns among a large group of pulmonary pathologists. To address this, the selection of specific tumor areas by photomicrographs was chosen as the most reliable approach. We did not aim for an emulation of the real world diagnostic setting. The latter has been done in a complementary study which we recently published on this topic [11], which comprised of a full slide evaluation of 100 unselected cases by a limited number of reviewers, while in the present study we focused on the presentation of a smaller number of selected problematic tumor areas with a higher number of voters (up to 27). It is evident that a selected photomicrograph shows only small parts of a tumor compared to full slide evaluation, which might influence the interobserver agreement reported.

The way the "reference" for the designation of the predominant pattern was set in our study merits discussion. We feel that the best way to define such a reference is to rely on the majority votes of a large number of pulmonary pathologists after they discussed the novel IASLC/ATS/ERS classification together. Alternative strategies to define the "correct" pattern classification, notably the use of an "expert opinion" as standard, have limitations given that for some of the cases a majority of trained pulmonary pathologists might have a different opinion than the "expert panel". In addition, the "expert" approach would not allow for the incorporation of a variety of different views.

In our present study, we demonstrate that the evaluation of histological patterns in pulmonary ADC leads to a quite

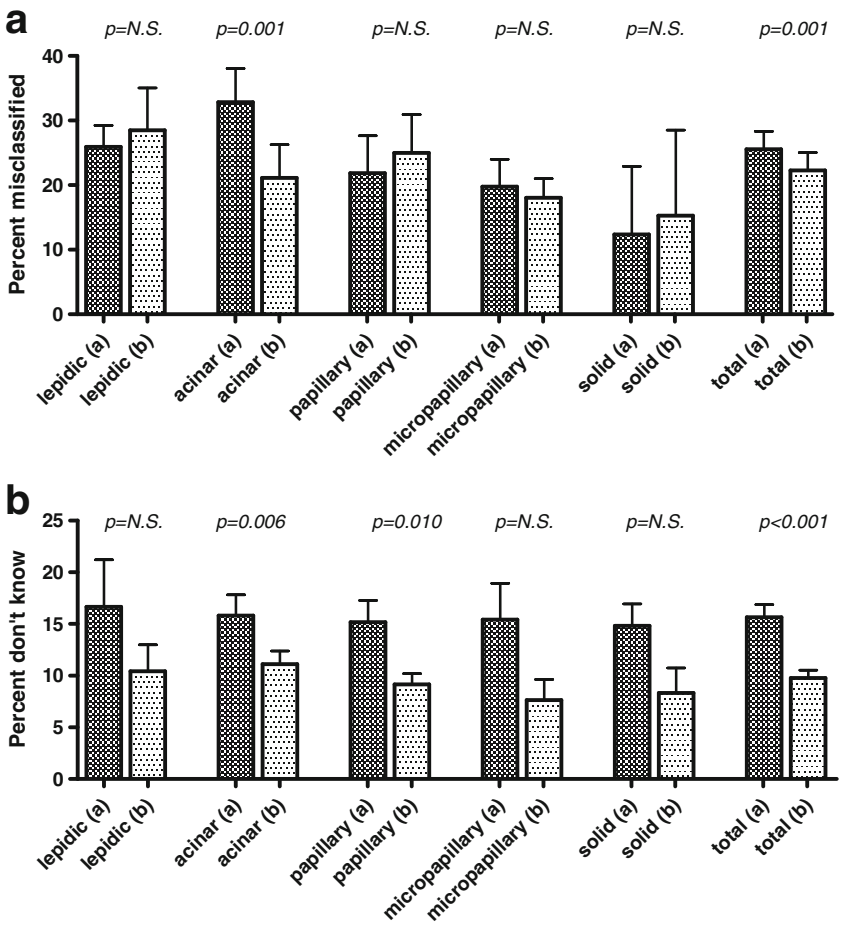

Fig. 3 Percentage of voters per pattern (**a**) as well as percentage of voters who abstained (**b**) overall and per pattern. N.S. = not significant

fair overall consensus. The notion that the consensus for the predominant pattern is indeed surprisingly high is in line with our data from the only other yet published study on this topic [11]. When focusing on difficult cases, we found that especially separation of lepidic and papillary patterns but also the clear-cut separation of both patterns from the acinar pattern is quite hard to achieve with a sufficiently high consensus level. The observation that papillary growth is difficult to determine and somewhat hard to delineate from lepidic growth (true papillae versus cross sections of branching alveolar walls) and micropapillary growth (often intermixed with papillary growth) is also supported from our previous work [11]. Solid growth did not pose any problems. In contrast, lepidic growth was problematic to evaluate when only difficult cases were considered, specifically the distinction from papillary growth (see above) and acinar growth (neoplastic acini with desmoplastic stroma versus pre-existing alveolar structures with thickened septa) was tricky. In the previous study on unselected cases, the consensus results for the lepidic pattern were fairly high [11]. This discrepancy might be explained by the fact that specifically in difficult tumor areas (as selected in this study) lepidic predominant pattern can be very challenging.

In our study, we demonstrated that training sessions for pattern classification are beneficial in two regards. First, they significantly decrease the number of evaluators who are unsure how to classify a given growth pattern and therefore providing support in the daily diagnostic challenge. Second, training sessions increase consensus [11]. Also for other tumor entities, including Gleason grade in prostate cancer [12], Elston–Ellis grade in breast cancer [13], and grading of sarcomas [14], training significantly increases the quality of the histopathological evaluation of grading schemes. Our data underline the value of expert discussions in order to ultimately improve the consensus of ADC pattern classification among pathologists. However, the modesty of improvement also indicates that for specific problems in pattern definition, we still have to do a more in-depth training effort either slide based or based on photomicrographs.

Our study shows that consensus approaches are possible on a nationwide level and provide a useful starting point for further discussions on this topic. However, what we clearly need is an international harmonization of pattern evaluation and a comparison with the results presented here. To support this, we set up a website in English dedicated to this topic:

(http://www.klinikum.uni-heidelberg.de/Online-Tutorial-for-Pulmonary-Adenocarcinoma-Subtyping.125267.0.html).

The website includes a database of ADC images (including the ones used in this study) and participants might give their own opinion on specific difficult cases. It can be easily reached through the homepage of the Institute of Pathology of the University Heidelberg. After the vote for the predominant pattern, one can see the consensus pattern according to all other participators Pathologists all over the world are very much invited to upload images of difficult ADC pattern to be included into the database. Thereby, we hope to contribute to the necessary discussions in this field of pathology. Such approaches have been shown to be successful in comparable fields of diagnostic surgical pathology such as Gleason grading in core needle biopsies [12].

In summary, we found that the novel IASLC/ATS/ERS classification of lung ADC can be applied with reasonable concordance even in difficult cases. In addition, we confirmed that discussions and training might overcome insecurities on how to classify and increase the congruence.

Conflicts of interest None.

Abstract Intraoperative consultation (IOC) with frozen section (FS) allows the surgeon to make therapy decisions during the operation. However, there is relatively little information on the use of IOC in skeletal lesions. We performed a retrospective study to examine the indications for IOC and compare the histological findings of FS and permanent paraffin section (PS) results to determine its clinical benefits. Ninety-seven consecutive cases evaluated between 2008 and 2011 were retrieved from IOC archives of our Pathology Department. In 79 % of the cases, there was no prior core needle biopsy (CNB), and IOC was performed to confirm the clinical or radiological diagnosis. In 5 (5 %) cases, no definitive result could be obtained with FS, and diagnosis was deferred. The reasons for a deferred diagnosis (DD) included poor section quality in two lipomatous lesions and the sample heterogeneity in the others. When adjusted for DD, FS and PS results showed 100 % concordance in terms of discriminating "benign vs. malignant" and defining diagnostic categories as "benign non-tumoral," "benign tumoral/tumor-like," "malignant primary tumor," "malignant metastatic tumor," or "hematopoietic malignancy." The presence of non-sclerotic osseous tissues does not have a significant adverse impact on the FS section quality and diagnosis made by FS. Thus, sections with diagnostic value can be obtained from bone lesions via FS. In this study, specific diagnoses were made in 88 % of the cases. We believe that IOC with FS can be safely performed in tertiary referral centers where there is a multidisciplinary team working in collaboration.

Introduction

The frozen section (FS) technique is utilized for intraoperative consultation (IOC) in many fields of surgical pathology. The major indication of FS is to obtain a diagnosis of an unknown pathological process to distinguish malignant from benign lesions intraoperatively [1]. It is also used to determine the adequacy of resection margins, tumor spreading, lymph node status [2], presence of residual tumor or recurrences, and to identify the content and/or adequacy of the specimen for definitive diagnosis. The reported concordance rate between FSs and permanent paraffin sections (PS) vary between 89 % and 98.3 % in many organ systems [3–10]. However, there is relatively little information regarding the use and efficacy of IOC in bone pathology [11–13].

Tumors or tumor-like lesions of bone and, in particular, primary malignant bone tumors are uncommon lesions that require a multidisciplinary approach for proper diagnosis and management. The diagnostic approach to a bone lesion requires a comprehensive clinical history, physical examination, and radiological evaluation. Moreover, it is essential that suspicious lesions undergo a histopathologic assessment and are treated accordingly [14]. Percutaneous core needle biopsy (CNB) has widely been accepted as the standard diagnostic

tool for such lesions due to its relative ease of application, safety, and cost-effectiveness [15]. In light of the CNB results, benign or metastatic lesions are managed with follow-up and/or treatment by lesional surgery, whereas certain primary sarcomas of the bone (e.g., osteosarcoma, Ewing sarcoma) are treated with neoadjuvant chemotherapy and/or radiotherapy followed by wide resection and limb-salvage surgery. In cases of inadequate material or a suspicious diagnosis in CNB, an open biopsy is recommended.

In the majority of the bone lesions, the histopathologic diagnosis and treatment decisions are generally made prior to curative surgery. IOC is primarily used in bone pathology to assess the efficacy of biopsy [16] by ascertaining whether the obtained diagnostic tissue is sufficient for the evaluation of the permanent section. Other indications include confirming an infection when septic loosening is suspected in joint prosthesis [17–19] and evaluating bone marrow margins to rule out intramedullary tumor extension [20,21].

We conducted a retrospective study at our regional tertiary referral centre to review our IOC experience, evaluate the clinical indications for IOC, compare the concordance rates of FS with PS results, determine the number of cases where it was possible to establish a specific diagnosis, and determine the effect of tissue content on section quality and its ability to yield a diagnosis.

Materials and methods

In this study, we reviewed 97 consecutive cases retrieved from IOC archives of our Pathology Department FS files between 2008 and 2011.

Intraoperative consultation

In our center, clinical and radiological findings of all the bone lesions are evaluated by a multidisciplinary council consisting of an orthopedic surgeon, a pathologist, a radiologist, medical and radiation oncologists, and nuclear medicine specialists. The primary objective of the IOC for the selected cases was also identified in this council.

All of the samples were performed, in accordance with open biopsy procedures for suspicious malignant bone lesions, by a surgical team experienced in orthopedic oncology. Pathological assessment was either performed by or in consultation with pathologists competent in osseous pathologies.

Preparation of FS

Tissue samples consisting of trabecular bone fragments with minimal thickness or soft tissue components representing the lesion were selected for freezing and subsequent cutting. Large cortical bone fragments were not sampled even if they were present in the material. In order to reduce the amount of tissue with in evitable freezing artifacts in permanent sections, the tissue was not completely frozen unless the first sample was inadequate for defining the lesion. Selected tissues were frozen at −35 °C with Thermo Scientific Cryotome FSH and fixed with 80 % alcohol for 1 min after 4–8 μm thick sections were obtained. Manual hematoxylin-eosin staining was performed as follows: 1 min of hematoxylin staining, rinsing with distilled water, 5 s of differentiation with acid alcohol, rinsing, 30 s of eosin staining, rinsing, alcohol dehydratation, and xylene treatment to increase transparency and mounting with Entellan.

Reporting of IOC findings

Cases were initially evaluated for the diagnostic adequacy of material and subsequently categorized as “benign non-tumoral,” “benign tumoral/tumor-like,” “malignant primary sarcoma,” “metastatic tumor,” or “hematopoietic malignancy” as previously discussed in the above mentioned multidisciplinary council to determine the type of therapeutic surgery. When frozen sections were equivocal in diagnosis, the case was assigned a “deferred diagnosis” (DD) status. Subsequent PS was performed for definitive diagnosis. In most of studied subjects, the IOC also provided a comment regarding the final diagnosis (e.g., benign, tumor/tumor-like lesion, consistent with fibrous dysplasia).

Evaluation of the technical quality of the FS

All FS samples were retrospectively evaluated and their tissue content (presence of bone and/or soft tissue) was recorded. The section quality was also semi-quantitatively classified as “good quality” if it was comparable with permanent sections, or “low quality” if the sections were too thick, fragmented, corrugated, or if the staining was suboptimal for evaluating nuclear and cytoplasmic details. The effect of tissue content on section quality and its ability to yield a diagnosis were also examined.

Comparison of FS and PS results and statistical analysis

Clinical and radiological data, the indication for IOC, as well as FS, PS, and CNB results were retrieved from the files of the departments of Orthopedics, Radiodiagnostics, and Pathology. The SPSS 13.0 software was used for descriptive analyses and kappa calculations.

Results

A total of 97 subjects (48 female, 49 male) with a mean age of 33.2 years (22.1 SD) were included in the study.

Table 1 IOC indications

	Frozen section results						
	Benign		Malignant			DD	Total n, (%)
	Non-tumoral	Tumoral/tumorlike lesion	Primary sarcoma	Metastatic	Hematopoietic Tm		
IOC performed for diagnosis and treatment							
To confirm the clinical/radiological diagnosis in cases without a prior CNB							77 (79 %)
Excluding primary malignancy in benign considered cases	7	29	2	1		1	40 (41.2 %)
Excluding primary malignancy in suspected cases of metastasis				7	1		8 (8.2 %)
Identify the cause of pathologic fracture	6	5	1	4	1		17 (17.5 %)
Determining the cause of prosthetic loosening (infection/tumor recurrence)	9	2				1	12 (12.4 %)
To confirm the clinical/radiological diagnosis and tumor spread in cases with a prior CNB							20 (20.6 %)
Cases with non-diagnostic CNB	3	1	1			2[a]	7 (7.2 %)
Cases with disconcordant clinical and radiological findings with CNB[a]		6					6 (6.2 %)
Cases in which the benign-malignant discrimination cannot be made with CNB						1	1 (1 %)
Lymph node evaluation (evaluation of primary bone tumor spread)	3		2				5 (5.1 %)
Surgical margin evaluation (evaluation of primary bone tumor spread)			1				1 (1 %)
Total	28	43	7	12	2	5	97 (100 %)

DD Deferred diagnose

[a] Two intraosseous lipoma cases

Diagnoses by FS were 71 benign (73 %), 21 malignant (22 %), and 5 DD (5 %).

IOC was performed for diagnosis and treatment in 91 cases and for the evaluation of tumoral spread in 6 previously diagnosed cases. The indications for IOC and FS results are shown in Table 1. Of the 91 cases undergoing IOC for diagnostic and therapeutic purposes, 14 had CNB prior to IOC. Of these, seven had inadequate non-diagnostic biopsies, and six underwent open biopsy/IOC due to discordance between the CNB diagnosis with clinical and radiological findings; in one case, the reason was the failure to discriminate between malignant and benign histology. For the six cases, the results of FS were consistent with CNB and the lesions were excised/or curetted in the same session as the diagnosis of "benign tumor/tumor-like lesion category". The diagnosis remained unchanged after subsequent excision/curettage specimens. In two cases with non-diagnostic CNB, and one additional case in which the benign-malign discrimination could not be made by CNB, the FS also failed to yield a diagnosis and these cases were referred to as a "DD." Subsequent PS of the former two cases provided diagnoses of intraosseous lipomas.

In the 77 patients who did not have a CNB, indications for IOC included: (1) to exclude primary malignancy in a case of "benign" diagnosis on clinical and radiological grounds (n=40, 52 %); (2) to identify the cause of pathological fracture (n=17, 22 %); (3) to exclude primary bone malignancy in cases with clinically suspected carcinoma metastasis (n=8, 10 %); and (4) to determine the cause of prosthetic loosening (infection/tumor recurrence) (n=12, 16 %) (Table 1). Among the "pre-IOC benign considered" cases, 16 involved patients under 10 years of age who required general anesthesia for CNB, and in five cases, the lesion was located in the acetabulum, where it was technically difficult to reach with CNB. In this group, one case was diagnosed as pleomorphic sarcoma, whereas another was diagnosed as squamous cell carcinoma metastasis, although both were initially diagnosed as osteomyelitis on a clinical and/or radiological basis. An additional case suspicious for "osteoblastoma" was radiologically diagnosed as pleomorphic sarcoma by FS. Among the 17 cases sent for IOC to identify the cause of pathological fracture, six cases were determined to be malignant, whereas one was revealed as a primary sarcoma.

Of the 97 total samples, 28 were classified as benign/non-tumoral (29 %), 43 as benign tumor/tumor-like lesion (44 %), 2 as malignant tumor of hematopoietic origin (2 %), and 12 as metastatic carcinoma (12.4 %). Seven cases were diagnosed as malignant primary sarcoma, of which four were primary diagnoses and three were metastases and/or surgical margin invasion by a primary bone sarcoma (Table 2). A diagnosis of prosthetic infection was made in six cases with prosthetic loosening (infection/tumor recurrence group) in the benign non-tumoral group. However, in one case, in tissues selected for FS, the appearance was suggestive of reactive-reparative changes related with prosthetic wear and tear but failed to prove infection, whereas the remaining tissue subsequently submitted for PS showed prosthetic infection.

In five cases (5 %), no definitive result could be obtained with FS (DD) (proportion=0, 0515 with exact confidence interval=0.017–0.12). DD cases were diagnosed as chondroblastoma, giant cell tumor, chondrosarcoma, and intraossous lipoma in two cases according to their PS results. A comparison between FS and PS showed a 100 % concordance (kappa=1) following adjustment for DD, both with regard to the technique's ability to discriminate between benign and malignant lesions and in terms of diagnostic category. A comparison between the techniques for

DD Deferred diagnose

definitive diagnosis obtained from the FS and PS records showed that a final diagnosis could be achieved in 85 of the 97 cases (88 %) (Table 3). Five of these 12 low concordance cases were DD cases. Among the other seven cases, one case was diagnosed as pleomorphic cell sarcoma through FS, PS showing a dedifferentiated chondrosarcoma. Other diagnostic entities with low concordance were fibrous lesions, giant cell lesions, and reparative tissues with a heterogeneous character. In two cases classified as having reparative changes with FS, on PS osteomyelitis or prosthesis infection were diagnosed. When the effects of section quality on FS results were examined, "good quality" was obtained in 79 cases (81 %) and "low quality" in 18 (19 %) (Table 4). Of these low quality cases, 11 samples (21 %) contained bone tissue and 7 (16 %) consisted of soft tissue alone. The presence of bone tissue in the sample did not have a significant effect on the section quality (p=0.541). Of the soft tissue samples with low section quality, two had non-evaluable tissue content with a diagnosis of intraosseous lipoma in paraffin sections.

Discussion

As suggested by Rosai [22], FS is a crucial but difficult procedure requiring experience, a good knowledge of clinical medicine and pathology, an ability to make quick decisions under time constraints, good judgment skills, an attitude that is conservative but not excessively so, and an awareness of methodological limitations.

In the present study, 92 of 97 cases exhibited full-concordance between FS and PS in terms of discriminating benign versus malignant. Similar results were also achieved in categorizing the lesions as "benign non-tumoral," "benign tumoral/tumor-like," "malignant primary tumor," "malignant metastatic tumor," or "hematopoietic malignancy". The concordance rate was 100 % following adjustment for five cases with DD (deferral rate, 5 %). Regarding the final diagnosis, a specific diagnosis could be made in 88 % of the cases. Overall, our results were comparable with the published approximate concordance, discordance, and deferral rates of 98 %, 2 %, and 4 %, respectively, for many organ systems [5]. Although there is relatively little information on the concordance rates in bone pathology, previous studies report a diagnostic accuracy varying between 90 % and 96.5 %, and a specific diagnosis between 85.9 % and 86.3 % [2,13,23], which is very similar to our findings.

Despite the reassuring results, the role of IOC in bone pathology is limited in clinical practice, largely due to histopathological evaluation with CNB and the therapeutic decision made prior to curative surgery. Furthermore, primary bone sarcomas, such as osteosarcoma and Ewing sarcoma, are treated with neoadjuvant chemoradiotherapy prior to surgical resection. During the study period of 3 years, 611 CNB evaluations were conducted in our center. However, review of the IOC cases over the same period showed that in 65 of 97 cases, FS was preferred for diagnostic purposes (i.e., benign considered cases, suspected metastasis cases, pathological fractures). Most centers can assess clinically and radiologically unsuspected cases where the multidisciplinary team opts for curettage or total excision without a CNB. This approach may also apply to some of our cases. This is also one of the reasons for the relatively high number of IOC cases without a core needle biopsy in our series, many of which were referred to our center for surgery without performing a CNB beforehand. For those clinically and radiologically unsuspicious cases, if the decision is in favor of curettage or total excision without a CNB, IOC is used as a "histological check" before final surgery. In benign assessed deep-seated tumoral/tumor-like lesions or very young patients who require general anesthesia for CNB, this approach is also preferred. Twenty-one of the 40 cases which were considered benign exhibited these features. As a result of this approach, two cases, which were initially evaluated as "osteomyelitis," were finally diagnosed as osteosarcoma and squamous cell carcinoma. One case involved tissue that was located within the acetabulum and was previously considered to be an "aggressive osteoblastoma"; this case was also initially diagnosed as osteosarcoma by FS. An additional primary sarcoma was found

Table 4 FS section quality/FS tissue content and diagnostic ability of FS

Frozen section quality

DD Deferred diagnose, *FS* Frozen section

[a]Two intraosseous lipoma cases

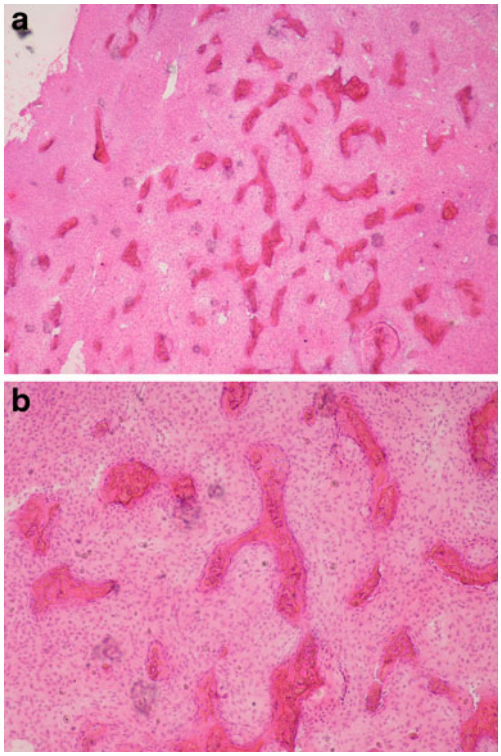

Fig. 1 **a**–**b** Osteofibrous dysplasia: preserved architecture of properly cut metaplastic bone. Note the few hematoxylin remains (**a** HE. ×40, **b** HE. ×200)

among the pathological fracture group. Thus, the diagnosis of primary sarcoma with FS provided the surgical team with the opportunity to design a detailed treatment plan consisting of neoadjuvant therapy following resection to be undertaken under elective conditions. When prior CNBs were discordant with clinical and radiological findings, IOC confirmed the prior CNB diagnosis. In the "benign tumor/tumor-like lesion category," FS was used as an alternative to open biopsy and enabled the surgeon to complete the therapeutic surgery (excision or curettage) during the same session. However, in 2 of 7 cases with non-diagnostic CNB, FS did not provide a diagnosis. Due to the lipomatous

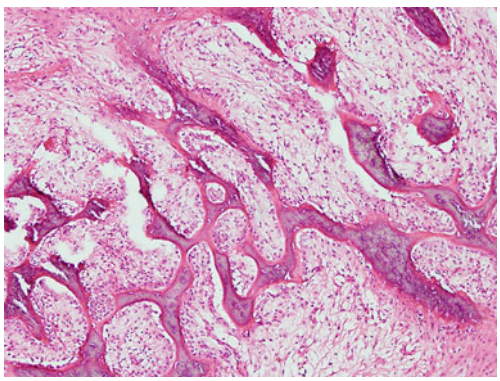

Fig. 2 Fracture healing: cellular details of osteoblasts. The osteoclasts are easily observed (HE. ×200)

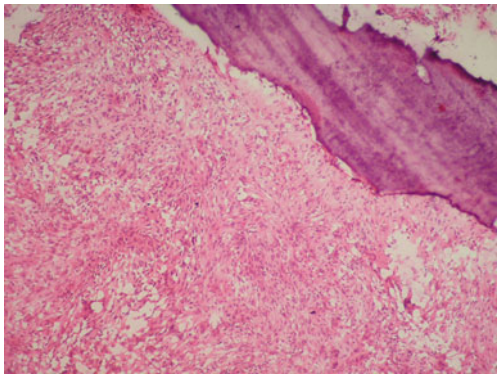

Fig. 3 Fibrous cortical defect: Note the thick cortical bone and preserved cortico-medullary junction (HE. ×200)

nature of the lesions, both cases were classified as "DD" due to technical limitations. The other three samples in the DD category were chondroblastoma, giant cell tumor, and low grade chondrosarcoma according to their subsequent PS results. The failure to make a diagnosis with FS in these samples was due to the tissue characteristics, which required multiple samples, rather than poor section quality. However, in one prosthetic infection case, which was "missed" by FS, the tissues selected for freezing were not representative; however, the FS diagnosis could have been resolved by submitting additional tissue or the specimen entirely, although the pathological foci in subsequent PS were small and could just as easily have been overlooked.

The common belief shared by many surgical pathologists is that frozen section examination is not feasible on osseous lesions due to difficulties associated with histological assessment and tissue consistency, i.e., hardness. However, many bone lesions and tumors are associated with bone lysis and bone-forming tumors usually do not cause formation of sclerotic bone. Samples may contain cortical bone and/or hard tissue fragments. Sampling from soft and tiny trabecular regions rather than peripheral sclerotic zones, which are likely reactive or cortical bone in nature and therefore unsuitable for the preparation of thin sections,

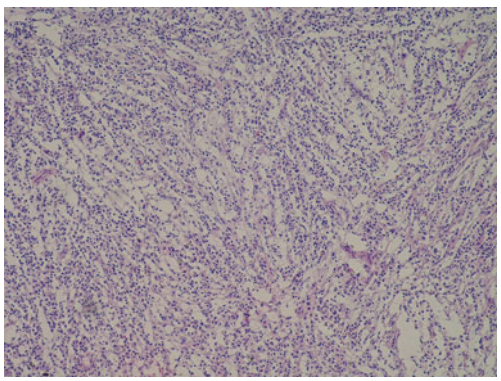

Fig. 4 Reparative tissue: poor quality section. Note the artifactual bubbles and lines due to freezing artifacts (HE. ×200)

may help to overcome this problem. In our study, FS sampling was performed accordingly, and in 95 samples (98 %), diagnostic findings were evident.

It should be noted that undecalcified trabeculae provide smoother FS sections compared to PS (Figs. 1a, b, 2, 3, 4). Technically, paraffin and undecalcified bone present significant differences in hardness. The main objective of tissue follow-up is to achieve similar tissue consistency (similar to the hardness of paraffin) throughout the sample, which is a prerequisite for smooth sectioning. In this regard, the similar consistency of frozen embedding medium, frozen tissue, and bone allows for smoother sectioning with FS for tissues containing tiny bone trabeculae in comparison with (undecalcified trabeculae) PS. In our series, among 11 low-quality samples that contained bone trabeculae, only one was not properly prepared due to thick bone tissue, and intense freezing artifacts resulting from significant stromal bleeding and edema affected the remaining samples (Fig. 4). Increased water content within the tissue, such as bleeding and edema, is associated with poorer section quality. Nevertheless, apart from those two "intraosseous lipoma" cases in which the diagnosis was deferred for technical reasons, it was still possible to obtain a diagnosis with FS in all osseous tissue bearing "low quality" sections. However, although the presence of osseous tissues does not have a significant adverse impact on the diagnosis made by FS, it may be impossible to harvest good quality sections from adipose tissue during frozen examination since adipose tissue does not freeze. Bui et al. [12] observed a similar limitation for adipocytic lesions as well as myxoid lesions and recommend pursuing cytology in conjunction with histopathology for these cases.

Technological advances in the last three decades have resulted in the advancement and development of novel pathological examination methods and auxiliary techniques. However, with the exception of a few tumor types, the use of these techniques in bone lesion and tumors is less common, rendering the traditional hematoxylin-eosin staining the predominant method of histological diagnosis. Therefore, good quality tissue samples from bone tissue obtained at FS may still provide significant diagnostic information similar to PS.

IOC would certainly be useful in the assessment of suspicious areas of invasion or metastasis after neoadjuvant treatment followed by wide resection, as well as for determining the etiology of a pathologic fracture, the cause of prosthetic loosening [16–18], and the adequacy of CNB and open biopsies [19–21]. It may also be suitable for cases that are not easily accessible—such as those involving the acetabulum—which carry increased risk of fracture with CNB, those located under thick sclerotic/cortical bone, or those that may not yield adequate tissue for sampling with CNB, such as cystic lesions. If a primary malignancy of the bone is excluded, a definitive treatment can be administered during the same session. The importance of a multidisciplinary approach and provision of adequate clinical and radiological data to the pathologist should be underscored to avoid from erroneous diagnostic conclusions at IOC because of the well-known heterogeneous characteristics of bone lesions.

Conclusion

In addition to the indications reported in the literature, FS can be used in lesions thought to be metastatic and in cases of pathological fractures. The FS technique can also be used to obtain histopathological data in cases with inadequate biopsy results. In cases where radiological findings are discordant with CNB results, in cases where open biopsy is indicated and in "clinically and radiologically" unsuspected cases where the multidisciplinary team opts for curettage or total excision without a CNB. In cases where primary bone sarcoma is excluded, final surgical treatment can be performed during the same session. When FS examination reveals primary bone sarcoma or defers diagnosis, it can be considered as an open biopsy and treatment is planned after PS results are obtained. It must be kept in mind that patients with suspected primary bone sarcoma are not good candidates for IOC and should always be evaluated with prior CNB instead.

The final diagnosis was obtained in 87.6 % of all the cases via FS, and we believe it is possible to obtain sections with diagnostic value from bone lesions via FS. We suggest that IOC with FS can be safely performed in tertiary referral centers or in sites with a comprehensive multidisciplinary team—including an orthopedic surgeon experienced in orthopedic oncology, pathology specialists competent in skeletal pathologies, a radiologist, medical and radiation oncologists, and nuclear medicine specialists—working in collaboration.

Conflict of interest We declare that we have no conflict of interest.

Abstract Multinucleated cells termed chondroclasts have been observed on the deep surface of resorbed hyaline cartilage but the relationship of these cells to macrophages and osteoclasts and their role in rheumatoid arthritis (RA) and other arthritic conditions is uncertain. Multinucleated cells in RA and other arthritic conditions showing evidence of cartilage resorption were characterised immunohistochemically for expression of macrophage/osteoclast markers. Mature human osteoclasts formed from circulating monocytes and tissue macrophages were cultured for up to 4 days on slices of human cartilage and glycosaminoglycan (GAG) release was measured. Multinucleated cells resorbing unmineralised cartilage were seen in osteoarthritis, RA, septic arthritis, avascular necrosis and in four cases of giant cell tumour of bone that had extended through the subchondral bone plate. Chondroclasts expressed an osteoclast-like phenotype (TRAP+, cathepsin K+, MMP9+, CD14−, HLA-DR−, CD45+, CD51+ and CD68+). Both macrophages and osteoclasts cultured on cartilage released GAG. These findings indicate that chondroclasts have an osteoclast-like phenotype and that mature human osteoclasts are capable of cartilage matrix resorption. Resorption of unmineralised subchondral cartilage by chondroclasts and macrophages can be a feature of joint destruction in inflammatory and non-inflammatory arthropathies as well as inflammatory and neoplastic subchondral bone lesions.

RANKL	Receptor activator of nuclear factor kappa B ligand
M-CSF	Macrophage-colony stimulating factor
MMP	Matrix metalloproteinase
TRAP	Tartrate-resistant acid phosphatase
OA	Osteoarthritis
GAG	Glycosaminoglycan

Introduction

Resorption or degradation of the deep surface of joint cartilage is seen in a number of pathological conditions, including inflammatory and non-inflammatory arthropathies as well as primary and secondary epiphyseal tumours and infections involving overlying cartilage. Multinucleated cells termed chondroclasts have been identified at sites of mineralised and non-mineralised articular hyaline cartilage erosion in the rheumatoid joint [1–3]. These cells have not been characterised in other arthritic conditions and remain poorly defined in terms of their relationship to other matrix-resorbing cells, particularly osteoclasts.

Osteoclasts are multinucleated cells which form part of the mononuclear phagocyte system [4]. These cells are specialised to carry out mineralised matrix resorption and are formed, in the presence of receptor activator of nuclear factor kappa B ligand (RANKL) and macrophage-colony stimulating factor (M-CSF), by fusion of CD14+ cells found

in monocyte and macrophage populations [5, 6]. Osteoclasts exhibit a number of specific ultrastructural, immunophenotypic and functional features [4]. Isolated mature osteoclasts have not been shown to be capable of cartilage matrix resorption and these cells are unable to carry out lacunar resorption of a demineralised bone matrix [7]. Osteoclasts are thought to resorb the organic matrix of bone principally through the production of acid proteases, such as cathepsin K, rather than neutral matrix collagenases [4, 8]; however, osteoclasts are known to produce some types of matrix metalloproteinases (MMPs), some of which, like cathepsin K, have been shown to play a role in cartilage matrix resorption [9–11].

In this study, our aim has been to characterise the nature of multinucleated cartilage-resorbing cells which have been termed chondroclasts. We have analysed a number of subchondral lesions showing evidence of cartilage resorption from cases of inflammatory and non-inflammatory arthritis, as well as other lesions, including infections and epiphyseal primary and metastatic bone tumour, in order to determine phenotypic characteristics of chondroclasts. To investigate the precise relationships between chondroclasts, osteoclasts and macrophages, we have also sought by cell culture to determine whether osteoclasts and macrophages are capable of cartilage matrix resorption.

Materials and methods

Phenotypic analysis of chondroclasts

Pathological bone and joints specimens showing evidence of cartilage resorption by multinucleated cells were obtained from files of the Nuffield Orthopaedic Centre, Oxford. These specimens were processed routinely for histology and included 15 cases of rheumatoid arthritis of the knee, 15 cases of osteoarthritis (OA) of the knee, 5 cases of septic arthritis (hip and knee joint), 5 cases of avascular necrosis of the hip, 4 cases of giant cell tumour of bone, 2 cases of osteosarcoma and 3 cases of metastatic carcinoma. The tissues were fixed in formalin and 5-μm sections of paraffin-embedded tissue were stained with haematoxylin–eosin. This study was approved by the Oxford Clinical Research Ethics Committee (C01.071).

Immunohistochemistry, using an indirect immunoperoxidase technique, was carried out with the monoclonal antibodies PD7/26, CR3/43, KP1 (all from Dako UK), NCL-CD14, NCL-CD51, (both from Leica Microsystems UK), 24-9C5 (Invitrogen), 182-12GJ and 56-2A4 (both from Daiichi Fine Chemical, Toyama, Japan) to determine expression of the macrophage/osteoclast markers CD45, HLA-DR, CD68, CD14, CD51, tartrate-resistant acid phosphatase (TRAP), cathepsin K and matrix metalloproteinase 9 (MMP-9), respectively. Immunohistochemistry for CD14, CD68 and CD51 was also carried out on macrophage and osteoclast cultures on cartilage (see below) to confirm the identity of cultured cells.

Cell cultures of macrophages and osteoclasts on cartilage

Morphologically intact normal human knee articular cartilage (derived from above knee amputation specimens carried out for primary bone tumour in young patients) provided the substrate for cell culture of macrophages and osteoclasts. Slices of cartilage were stored at −80 °C and then cut to approximately 3×3-mm squares before being placed in the wells of a 96-well tissue culture plate containing alpha MEM culture medium (Lonza, Wokingham, UK) supplemented with 10 % heat-inactivated FBS, 50 IU/ml Penicillin, 50 μg/ml streptomycin sulphate (Invitrogen, Paisley, UK) and 2 mM L-Glutamine (Lonza).

Peripheral blood mononuclear cells were isolated from buffy coat blood using Histopaque. CD14+ monocytes were selected using an AutoMACS cell separator (Miltenyi Biotech, Surrey, UK) as previously described [12]. CD14+ cells were seeded onto cartilage slices at 0.25×10^6 cells/well. Non-adherent cells were removed after 2 h. CD14+ monocyte-derived macrophages were incubated with 25 ng/ml M-CSF (R&D, Abingdon, UK) for 4 days. To generate osteoclasts, CD14+ cells were incubated with 25 ng/ml M-CSF and 50 ng/ml RANKL (Pepro-tech, UK), with medium and cytokines replaced every 3–4 days, for 14–16 days. Osteoclasts were also cultured on dentine slices to confirm active lacunar resorption.

Human osteoclasts were obtained directly by curettage from two cases of GCTB, a tumour known to contain large numbers of mature human osteoclasts [13, 14], and cultured for 48 h on the cartilage slices. Giant cells were also isolated from a case of pigmented villonodular synovitis, as previously described [15].

Glycosaminoglycan release from cartilage

Glycosaminoglycan (GAG) release from cartilage was measured using the dimethylmethylene blue (DMB) assay [16]. Four-day conditioned media from monocytes or mature osteoclasts on cartilage was spun down to remove cell debris. Ten microlitres media was mixed with 250 μl DMB reagent and the absorbance measured at 525 nm. The GAG concentration was read from a chondroitin sulphate standard curve and normalised to cartilage weight.

Results

Chondroclast resorption of cartilage

Multinucleated cells actively resorbing the subchondral bone plate and the deep surface of articular cartilage (chondroclasts)

were seen in all the lesions examined (Fig. 1a, b). These multinucleated cells were found on the surface of mineralised articular hyaline cartilage and on the deep surface of unmineralised articular cartilage where the subchondral bone plate had been completely resorbed. In some areas, multinucleated cells were found in contiguous areas of resorption of unmineralised cartilage and mineralised subchondral cartilage and bone. Numerous multinucleated cells resorbing cartilage were seen in GCTBs that had extended through the subchondral bone plate (Fig. 1c, d). Scattered macrophage-like mononuclear cells were also present at sites of cartilage and bone resorption in all the above lesions.

Antigenic phenotype of chondroclasts

Immunohistochemical analysis showed that the multinucleated cells resorbing cartilage expressed an osteoclast phenotype [17], being CD14−, HLA-DR−, CD45+, CD68+ CD51+, TRAP+, cathepsin K+ and MMP9+ (Table 1, Fig. 1b). Some, but not all, of the mononuclear macrophage-like cells at sites of cartilage resorption also expressed an osteoclast phenotype, with others expressing a macrophage phenotype (i.e. CD14+, HLA-DR+ and CD51−).

Cartilage matrix resorption by osteoclasts and macrophages

CD14+ macrophages and osteoclasts formed in vitro from CD14+ monocyte precursors stimulated GAG release when cultured on cartilage (Fig. 2). These cultures also exhibited MMP13 activity (data not shown). When osteoclast and macrophage cell cultures on cartilage slices were fixed in formalin and processed for histology, it was found that these cells expressed the immunophenotypic markers characteristic of macrophages (CD68+, CD14+ and CD51−) and osteoclasts (CD68+, CD14− and CD51+) respectively. Confirmation that mature human osteoclasts are capable of releasing GAG from cartilage in vitro is shown in cultures of GCTB-derived osteoclasts which showed increased GAG release relative to controls (Fig. 3). It was also noted that osteoclast-like giant cells isolated from a case of PVNS were capable of releasing GAG from cartilage (Fig. 3).

Discussion

Bromley and Woolley were the first to characterise multinucleated cells resorbing mineralised and unmineralised articular cartilage at sites of subchondral erosion in rheumatoid knee joints [1–3]. They noted that these multinucleated cells (chondroclasts) contained intracellular vacuoles, phagocytosed collagen fibres and lysosomal bodies in which there was histochemically demonstrable acid phosphatase, an enzyme marker of cells of the mononuclear phagocyte system. Ultrastructural studies showed that cytoplasmic extensions into cartilage of these chondroclasts were noted, but structures similar to the specialised ruffled border and sealing zone elaborated by a resorbing osteoclast were not identified.

[a] Some mononuclear macrophage-like cells at sites of cartilage resorption expressed an osteoclast phenotype (see text)

In this study, multinucleated cells which resorb unmineralised articular hyaline cartilage were found in both inflammatory and non-inflammatory arthritic conditions; these cells were also noted in epiphyseal tumours and inflammatory lesions that had extended through the subchondral bone plate into overlying cartilage. These multinucleated cells expressed the specific phenotypic features of osteoclasts, being CD51+, CD14−, HLA-DR−, TRAP+, cathepsin K+ and MMP9+ [4, 17]. Multinucleated cells expressing some of the histochemical and ultrastructural characteristics of osteoclasts have been noted in cartilage at sites of endochondral bone formation in the growth plate and maturing skeleton of experimental animals and in deer antlers and other tissues [18–22]. These cells have been designated chondroclasts, although this term has been used rather loosely in these studies to include multinucleated cells that resorb the mineralised cartilage found at sites of new bone formation; as contact with bone mineral is thought to be the stimulus for osteoclast resorption, it is expected that osteoclasts would be able to resorb calcified cartilage. Ruffled border formation is observed in osteoclasts on calcified bone

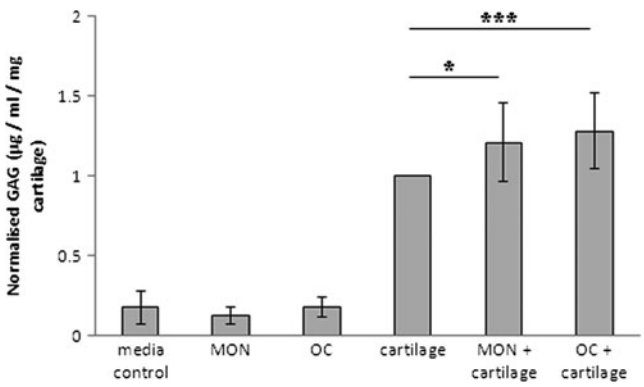

Fig. 2 CD14+ monocyte-derived macrophages (*MON*) and in vitro-differentiated human osteoclasts (*OC*) stimulate GAG release from cartilage $p<0.05$, $p<0.005$ versus cartilage control

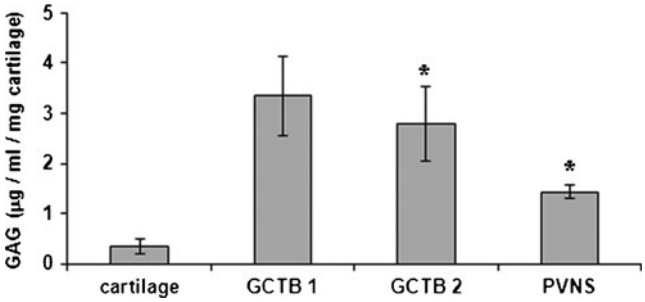

Fig. 3 Osteoclast-like giant cells from GCTB and PVNS stimulate GAG release from cartilage in vitro. *$p<0.05$ versus cartilage control

and decalcified bone slices in cultures of bone marrow macrophages, cultures of osteoclast-like cells on cartilage slices do not show a true ruffled border. These cells have irregular cell projections and a clear zone-like structure but do not have a true ruffled border. These results suggest that the mineral component of bone may determine terminal osteoclast differentiation [23].

Several studies have shown that substrate composition has a major effect on bone resorption by osteoclasts. Osteoclasts do not resorb bone covered by an unmineralised layer of osteoid but are able to resorb bone that is rendered anorganic [7, 24, 25]. Osteoclasts do not form a ruffled border or clear zone on a poorly calcified or cartilage substrate [1, 2, 23] and it has been suggested that bone cells, such as osteoblasts initiate the process of bone resorption by releasing collagenase that degrades the organic matrix leading to exposure of mineral to osteoclast contact [7, 26–28]. The mRNA for MMP-1 has been localised in osteoblasts, osteocytes and chondrocytic cells but not osteoclasts [8]. Osteoclasts, however, are capable of resorbing both the organic and inorganic components of bone [29]; these cells release cysteine proteinases such as cathepsin K which break down collagen in the acid microenvironment of the resorption lacuna; various neutral MMPs, including MMP13, are also thought to play a role in osteoclast lacunar resorption in specific pathological conditions [9].

We noted that chondroclasts shared many of the specific phenotypic features of osteoclasts. These cells elaborated the tartrate-resistant isoform of acid phosphatase, as well as cathepsin K and MMP-9, osteoclast-associated enzymes which break down the organic matrix of bone and cartilage [10, 11, 30]. Supportive evidence for chondroclasts and osteoclasts being closely related is also provided by our finding that mature human osteoclasts are capable of releasing GAG from hyaline cartilage. Numerous osteoclastic giant cells are found in GCTB, an osteolytic epiphyseal bone tumour that can involve overlying articular cartilage. GCTB contains mononuclear stromal cells that are known to have collagenase activity [31]. Evidence that chondroclasts, like osteoclasts, may play a role in joint pathology comes from our observation that PVNS-derived giant cells also released GAG from cartilage. PVNS is a lesion which

contains numerous macrophages and giant cells which have an osteoclast phenotype [15]; in addition, as inflammatory macrophages and tumour-associated macrophages are known to differentiate into osteoclast [32, 33], it is possible that these mononuclear cells in subchondral pathological lesions may have differentiated into chondroclasts as well as regarding cartilage directly. Mononuclear cells expressing an osteoclast-like (CD14− and CD51+) and a macrophage-like (CD14+ and CD51−) antigenic phenotype were also noted at sites of cartilage resorption. Cell culture results showed that CD14+ monocyte-derived macrophages are capable of releasing GAG from cartilage. Osteoclasts form from CD14+ macrophage precursors in the presence of RANKL and M-CSF [4, 6], and it is possible that these subchondral CD14+ cells represent the mononuclear precursor cell population that differentiates into the osteoclasts and chondroclasts that resorb bone/mineralised cartilage and unmineralised cartilage, respectively.

RANKL is required for osteoclast formation and it has been shown that both RANKL and osteoprotegerin (OPG), the decoy receptor for RANKL, are found in areas of cartilage resorption [34]. Bone resorption is markedly reduced by inhibitors of osteoclast formation and activity. Accelerated cartilage resorption by chondroclasts has been noted in mice lacking OPG [35]. Bisphosphonates and inhibitors of cathepsin K prevent cartilage loss in animal models of inflammatory and degenerative joint disease [36, 37]. Our findings indicate that chondroclasts are closely related to osteoclasts and that these cells may play a role in joint destruction in inflammatory and non-inflammatory arthritis, suggesting that there may be a role for anti-osteoclast therapies in controlling cartilage destruction.

Acknowledgments We wish to thank Mrs C Lowe for typing the manuscript and R. Taylor for providing the PVNS cells. This study was supported by the Rosetrees Charitable Trust and EuroBoNet a Network of Excellence, funded by the European Union.

Conflict of interest We declare that we have no conflict of interest.

Virtual CT autopsy in clinical pathology: feasibility in clinical autopsies

Abstract For the past century, autopsy techniques in clinical pathology have not changed significantly, while autopsy rates are declining. Modern imaging techniques offer interesting prospects of supportive post-mortem diagnostic investigation. In a prospective study of 29 autopsy cases, complimentary virtual autopsy using unenhanced post-mortem computed tomography (pmCT) was performed. We analysed in a prospective cohort study 29 unenhanced pmCT scans, generated prior to autopsy. Clinical information regarding clinical history and circumstances of death were provided. The objective of the study was to find consistency and/or discrepancy between virtual autopsy and conventional autopsy findings regarding cause of death and death-related diagnoses, reconstruction of the pathogenetic mechanisms involved, side diagnoses and CPR (cardiopulmonary resuscitation)- or death-related post-mortem changes. Accuracy of pmCT for cause of death was 68 % and the positive predictive value (PPV) was 75 %. Regarding the pathogenetic mechanisms, accuracy of pmCT was 21 % and PPV was 29 %. The combined diagnostic yield of autopsy and pmCT was 133 % compared to autopsy only. Modern imaging techniques give an opportunity for post-mortem diagnostics to complete but not yet replace traditional autopsy. We could show that in two out of three cases, the cause of death found by pmCT matched the diagnosis from classical autopsy. While both disciplines, pathology and radiology, will profit from the mutual exchange of data, it seems a realistic aim to strive for virtual autopsy possibly further supported by biopsies and contrast-enhanced pmCT as an alternative to the classical clinical autopsy. A combination of both methods enhances diagnostic quality and completeness of the autopsy report.

Introduction

Autopsy is an essential tool for student and pathology resident teaching. At the same time, it is a valuable performance measure for any hospital [1]. Autopsy can be of great importance regarding economic and legal consequences for hospitals and clinicians [2]. In the long term, decline in autopsy rates must lead to a lack of accuracy of mortality statistics, on which the financial support of specific research areas are based. In Europe, autopsy rates have been declining [3–6]. In the USA, Australia and Asia, trends are the same [7–9]. Influential factors include request rates by

clinicians, laws determining legal autopsy consent, and consent rates [10].

Autopsy methods used by departments of pathology all over the world have not changed much during the past century. Basically, pathologists rely on macroscopic organ morphology and microscopic examination. As diagnostic methods have changed and improved significantly in the field of radiologic imaging, our aim was to find out whether medical autopsy pathology benefits from modern diagnostic imaging.

In forensic medicine, post-mortem imaging has a long tradition. New imaging techniques, such as spiral multislice computed tomography (CT) and magnetic resonance imaging (MRI), offer excellent utilities for post-mortem examination. Forensic research groups in Europe, the UK, USA, Australia and Asia attend to the concept of post-mortem imaging [11–15].

In medical autopsy pathology, post-mortem imaging has not yet been used to an extent comparable to forensic pathology. Our goal was to investigate the potential of unenhanced post-mortem CT (pmCT) imaging for virtual autopsy. Native CT autopsy imaging in comparison to full autopsy, to our knowledge, has only rarely been used in non-forensic settings [16]. Often, MRI is used in combination with pmCT [17–19]. MRI is more time consuming and more expensive than CT, and the availability of MRI scanners is limited. Therefore, a systematic evaluation of the feasibility and accuracy of finding the cause of death with native pmCT in comparison to the results of conventional autopsy was conducted.

The objectives for virtual autopsy were to provide the examiner with sufficient material to report on the following topics:

1. Cause of death
2. Death-related diagnoses
3. Reconstruction of pathogenetic mechanisms involved
4. Unspecific findings (post-mortem changes, changes related to CPR)
5. Side diagnoses

Materials and methods

This study was conducted at a German university hospital. The study was approved by the local ethics committee.

We included in this prospective study 29 randomly selected cases of deceased persons delivered to the Department of Pathology for conventional autopsy. Sex ratio was *f*/*m*=10:19. Mean age at death was 59 years, ranging from 0 months to 91 years. The cases comprised 17 deaths on a standard hospital ward, eight deaths in an intensive care unit, two deaths in the emergency room, one intrauterine death and one death at home. The manner of death was due to natural cause in all cases.

We used the combination of imaging and classical autopsy prospectively whenever feasible, i.e. availability of CT for consented classical autopsies.

Virtual autopsy

Before conventional autopsy, at a mean time of 50 h (±40 h) after death, the body was wrapped (arms attached laterally) in an artefact-free body bag in the supine position, placed in the CT gantry, and scanned from head to toe with a 64 dual-source CT scanner (SOMATOM Definition, Siemens, Forchheim, Germany) with 64×0.6 mm collimation, a tube voltage of 120 kV and an effective tube current-time product of 160 mAs_{eff}. From raw data, axial images with 5- and 1-mm slice thickness and a recon increment of 4 or 0.7 mm were reconstructed using medium smooth (B30f) and sharp (B60f) convolution kernels. Including positioning of the body on the scanner, the duration of the average pmCT scan was 10 min. After reconstruction of the raw data, the reconstructed images were transferred to a Picture Archiving and Communication System (iSite Radiology, Philips Medical Systems, the Netherlands). The CT scanner was used out of working hours (before 0730 or after 1800 hours).

Afterwards, the pictures were evaluated by two experienced general radiologists with no previous experience of post-mortem imaging. The clinical information given by the autopsy request form was provided to radiologists before image interpretation. The radiologists reported their findings in a standard form, including the neurocranium, thorax, abdomen and extremities.

Conventional autopsy

The autopsy was performed in a standardized form (accredited Department of Pathology, IS0/IEC 17020) by experienced pathologists at a mean time of 62 h (±45 h) after death. All three body cavities (neurocranium, thorax and abdomen) were opened except in two cases. In one case, only cardiac autopsy was consented. In one case of systemic echinococcosis, classical clinical autopsy was omitted due to infection hazard. Following complete autopsy, the autopsy findings were demonstrated to the clinicians requesting the autopsy. The clinical picture was correlated with findings at autopsy.

Statistical analysis

Statistical analysis was conducted using Microsoft® Office Excel 2003 (Microsoft Corporation, Redmond, WA, USA). All cases in which pmCT and autopsy were performed were included in the statistical analysis (n=28).

Results

The results are structured according to the report about the Swiss Virtopsy® project published in 2003 [20]. The results of pmCT and conventional autopsy were compared with regard to the detection of

1. Cause of death
2. Death-related diagnoses
3. Reconstruction of pathogenetic mechanisms involved
4. Unspecific findings (post-mortem changes, changes related to CPR)
5. Side diagnoses

The cause of death was distributed as shown in Table 1, with predominance of diseases of the circulatory system, infectious diseases and diseases of the respiratory system. Summing up the total number of diagnoses found at autopsy in combination with pmCT, 33 % additional diagnoses were found using pmCT (190 at autopsy, 124 with both methods and 103 with pmCT only). Including CPR-related and post-mortem changes, the combined diagnostic yield was 48 % higher than without pmCT (190 at autopsy only, 128 at both autopsy and pmCT, 154 additional diagnoses with pmCT). The distribution in the diagnostic groups is shown in Table 2 and visualized in Fig. 1.

Table 1 Autopsy and radiology cause of death

	Autopsy		pmCT	
	n	%	*n*	%
Reported cause of death				
Cardiac failure	12	43	8	42
Haemorrhage	7	25	6	32
Cardiorespiratory failure	2	7	1	5
Multi-organ failure	2	7	1	5
Acute respiratory failure	2	7	1	5
Lung emboli	1	4	1	5
Meningoencephalitis	1	4	0	0
None proven (intrauterine death)	1	4	1	5
Total[a]	28		19	
Diagnostic group				
Diseases of the circulatory system	22	54	18	69
Infectious and parasitic diseases	6	15	0	0
Diseases of the respiratory system	4	10	4	15
Diseases of the digestive system	2	5	1	4
Neoplasms	2	5	2	8
Diseases of the nervous system	2	5	1	4
Congenital malformations, deformations and chromosomal abnormalities	1	2	0	0
Injury, poisoning and certain other consequences of external causes	1	2	0	0
None proven (intrauterine death)	1	2	1	4
Total[b]	41		26	

[a] One case excluded (no autopsy due to infection risk)

[b] Sum exceeds number of patients because in some cases, several systems/pathologies were involved equally

1. Cause of death

   The cause of death was assigned to a specific site or pathology, e.g. cardiac failure, cardiorespiratory failure, acute respiratory failure, multi-organ failure or haemorrhage, whenever possible. In one case of intrauterine death, no cause of death could be proved by either method.

   In 19 of 28 cases, the cause of death diagnosis after pmCT matched the diagnosis after conventional autopsy (Table 3).

2. Death-related diagnoses

   Five-percent more death-relevant diagnoses were found in the combination of classical autopsy and pmCT (122 at autopsy, plus six with pmCT). In a case of multiple myeloma with multiple osteoblastic and osteolytic lesions, the lesions were found with pmCT as well as after macroscopic examination in classical autopsy (Fig. 2).

   With pmCT, atherosclerosis of cerebral arteries was found in one of five cases with cerebral atherosclerosis in classical autopsy. In one case of fatal subarachnoidal haemorrhage, the haemorrhage was visible with pmCT (Fig. 2). In one case of meningoencephalitis and circumscript subarachnoidal haemorrhage, the haemorrhage was not visible with pmCT. Brain lesions, such as Alzheimer's disease, in two cases and a small haemorrhage were missed with pmCT.

   Generalised atherosclerosis with calcification was found in 13 cases with equal results of pmCT and classical autopsy. Coronary sclerosis was identified with pmCT in 16 of 19 cases at classical autopsy. In six cases, in which coronary sclerosis was associated with myocardial infarction and cardiac failure, the cardiac cause of death was diagnosed correctly with regard to characteristic changes of the organs on a balance of probabilities. There were no false-positive findings of coronary sclerosis with pmCT. One basilary artery aneurysm was missed with pmCT, as well as one out of three other aneurysms.

   In our patient cohort, thromboses were missed with unenhanced pmCT images in one case of an in-stent thrombosis and two cases of bypass thrombosis.

   In our study, out of 12 cases of cardiac failure in clinical autopsy, ten cases were diagnosed correctly by use of pmCT. There were no false-positive findings for cardiac failure. Although myocardial lesions (infarction, myocarditis) were not visible with pmCT, cardiac failure was diagnosed correctly from death-associated diagnoses, such as coronary atherosclerosis, organ congestion and pleural effusions. Myocardial hypertrophy was reported at

Table 2 Distribution of diagnoses

	Number	Percent	Autopsy	Autopsy+pmCT	pmCT
Circulatory system	162	34	66	76	20

Unspecific/post-mortem changes	55	12	0	4	51
Total	472		190	128	154

autopsy in 19 cases, but only in ten cases with pmCT. One left ventricular aneurysm was missed with pmCT.

Ground glass attenuation was diagnosed with pmCT in 12 cases. The pathomorphologic findings in those cases in classical autopsy were acute pulmonary congestion in nine cases, pulmonary oedema in three cases, hyaline membranes and pneumonia in one case, severe bacteremia in one case and bone marrow embolisation in one case. Seven out of nine cases of pulmonary emphysema were missed with pmCT. Mixed dust pneumoconiosis was found with pmCT due to calcified lesions in two cases (100 %).

There were one false-positive, one true-positive and two false-negative diagnoses of pneumonia in pmCT. Pleural effusions were found with pmCT in 19 cases, compared to 18 cases at autopsy. A small pneumothorax was found with pmCT in three cases, which had been missed at autopsy.

Fluid with a density of more than 50 HU in one of the body cavities or preformed spaces (ventricles, pericardium) was found in eight cases with pmCT. The finding correlated with the autopsy finding of haemorrhage in all cases (intraabdominal haemorrhage in five cases, pericardial tamponade in two cases, intraventricular haemorrhage in one case) (Fig. 2). Diffuse haemorrhage, as present in one case, was not visible with pmCT.

3. Reconstruction of the pathogenetic mechanism

The reconstruction of the pathogenetic mechanism using pmCT was correct in 5 of 28 cases, i.e. three cases of intraabdominal haemorrhage, one case of intracranial haemorrhage and one case of pulmonary embolism (Table 4). In one case (intrauterine death), the cause of death and the pathogenetic mechanism remained unclear after both pmCT and classical autopsy. In most cases, the site of death could be assigned to the lung or the heart correctly with pmCT, but the exact cause of organ failure remained unclear. At traditional autopsy, the cause of organ failure could be defined precisely by means of histologic examination and assessment of characteristic macroscopic tissue changes, such as yellow necrosis of myocardial tissue with hemorrhagic margin in case of myocardial infarction. Differing results in the reconstruction of the pathogenetic mechanism were found in a case of severe bacterial infection of the lungs and in cases of cardiac failure due to myocarditis or myocardial infarction with or without pericardial tamponade, as well as chronic ischaemic cardiomyopathy or chronic heart transplant vasculopathy. One case of dilated cardiomyopathy was missed with pmCT, and death

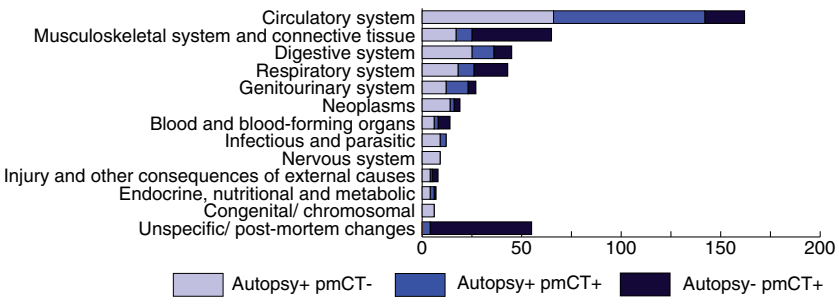

Fig. 1 Distribution of diagnoses (*light blue*, diagnoses found at autopsy/missed with pmCT; *ink blue*, diagnoses found with both methods; *dark blue*, diagnoses found with pmCT/missed at autopsy)

Table 3 Cross-tabulation cause of death in pmCT vs. classical autopsy

Cause of death (CoD)			Classical autopsy				
			CoD found			CoD not found	
			(A+C)	22		(B+D)	6
pmCT	CoD found A+B=	23	A (true pos)=	18		B (false pos)=	5
	CoD not found C+D=	5	C (false neg)=	4		D (true neg)=	1
			Total A+B+C+D				28
Sensitivity=			85.71 %				
Specificity=			14.29 %				
Positive predictive value=			75 %		95 % CI=	55.100 to 88.000%	
Negative predictive value=			25 %		95 % CI =	4.5587 to 69.935%	
Accuracy=			67.86 %				

was assigned to myocardial hypertrophy. In one case of respiratory distress, the pulmonary oedema was found, but atelectasis had been missed with pmCT, and therefore, the pathogenetic mechanism remained unclear. In one case of COPD, heart failure was correctly found as the cause of death, but the pathogenetic mechanism with right heart failure due to COPD was not reconstructed correctly. In three cases of haemorrhage, haematoperitoneum was found with pmCT, but the exact localisation of the bleeding site was missed. In one case of diffuse bleeding, the haemorrhage was missed with pmCT. Two cases of bronchopneumonia and one case of meningoencephalitis were missed with pmCT. In one case of sepsis after chemotherapy, death was attributed to cardiopulmonary insufficiency, while at autopsy, multi-organ failure was believed to be the cause of death. In one case of respiratory failure, the radiologists suspected air embolism to be the cause of death; therefore, the reconstruction of the pathogenetic mechanism differed from the autopsy result as well.

4. Unspecific findings

After the combination of pmCT with classical autopsy, more than ten times more unspecific death-related and CPR-related diagnoses were documented (4 at classical autopsy, 51 additional with pmCT). Cardiopulmonary resuscitation and putrefaction may cause artefacts on pmCT images. Rib fractures are usually examined during classical autopsy but were missed on macroscopic examination in two cases. One case of multiple rib fractures was missed with pmCT. One sternum fracture was found with both methods; one was missed at autopsy.

Gas in the cardiovascular system was found in ten cases with pmCT, associated with CPR before death in seven cases. Aerobilia was described in eight cases with pmCT, as well as six cases of subcutaneous emphysema. None of these findings were documented at clinical autopsy.

5. Side diagnoses

After a combination of side diagnoses found at classical autopsy and additional diagnoses found with pmCT, 35 % additional diagnoses were found (202 at classical autopsy, 70 additional diagnoses with pmCT). With pmCT, hernias were seen in five cases. Traditional autopsy revealed no hernia. Muscle atrophy was found in three cases with pmCT, compared to five cases at autopsy.

Neoplastic lesions were reported by the radiologists; missed at autopsy were one lipoma and two cartilaginous exostoses. On the other hand, at autopsy, one rectum carcinoma, one colon carcinoma, one renal cell carcinoma, one prostate carcinoma, one transitional cell carcinoma and ten cases of low-grade intraepithelial neoplasia of the colon, as well as one pulmonary metastasis of a squamous cell carcinoma, were reported, which were missed with pmCT. Radiologists reported one false-positive "tumour" in the pleural cavity, which at autopsy proved to be coagulated blood.

Calcified lesions, such as cholecystolithiasis, were visible with pmCT in three of five cases at autopsy. Prostate enlargement was diagnosed in two cases with pmCT, compared to three cases at autopsy. Two cases of mixed dust pneumoconiosis were diagnosed with pmCT, in agreement with autopsy findings.

Organ size and configuration as well as hypodense lesions, such as cysts, could be assessed with pmCT. Myocardial hypertrophy was diagnosed with pmCT in 10 of 18 cases at autopsy. Goitre was found with pmCT in one of four cases in conformity with autopsy. Hepatosplenomegaly was found with pmCT in three of four cases at autopsy. Fatty liver was found in one case in agreement with autopsy, as well as liver or kidney cysts in five cases.

Fluid accumulations (anasarca, ascites) were diagnosed in seven cases with pmCT, compared to six cases at autopsy. One small pneumothorax was found with pmCT, which was not visible at autopsy. Thirteen

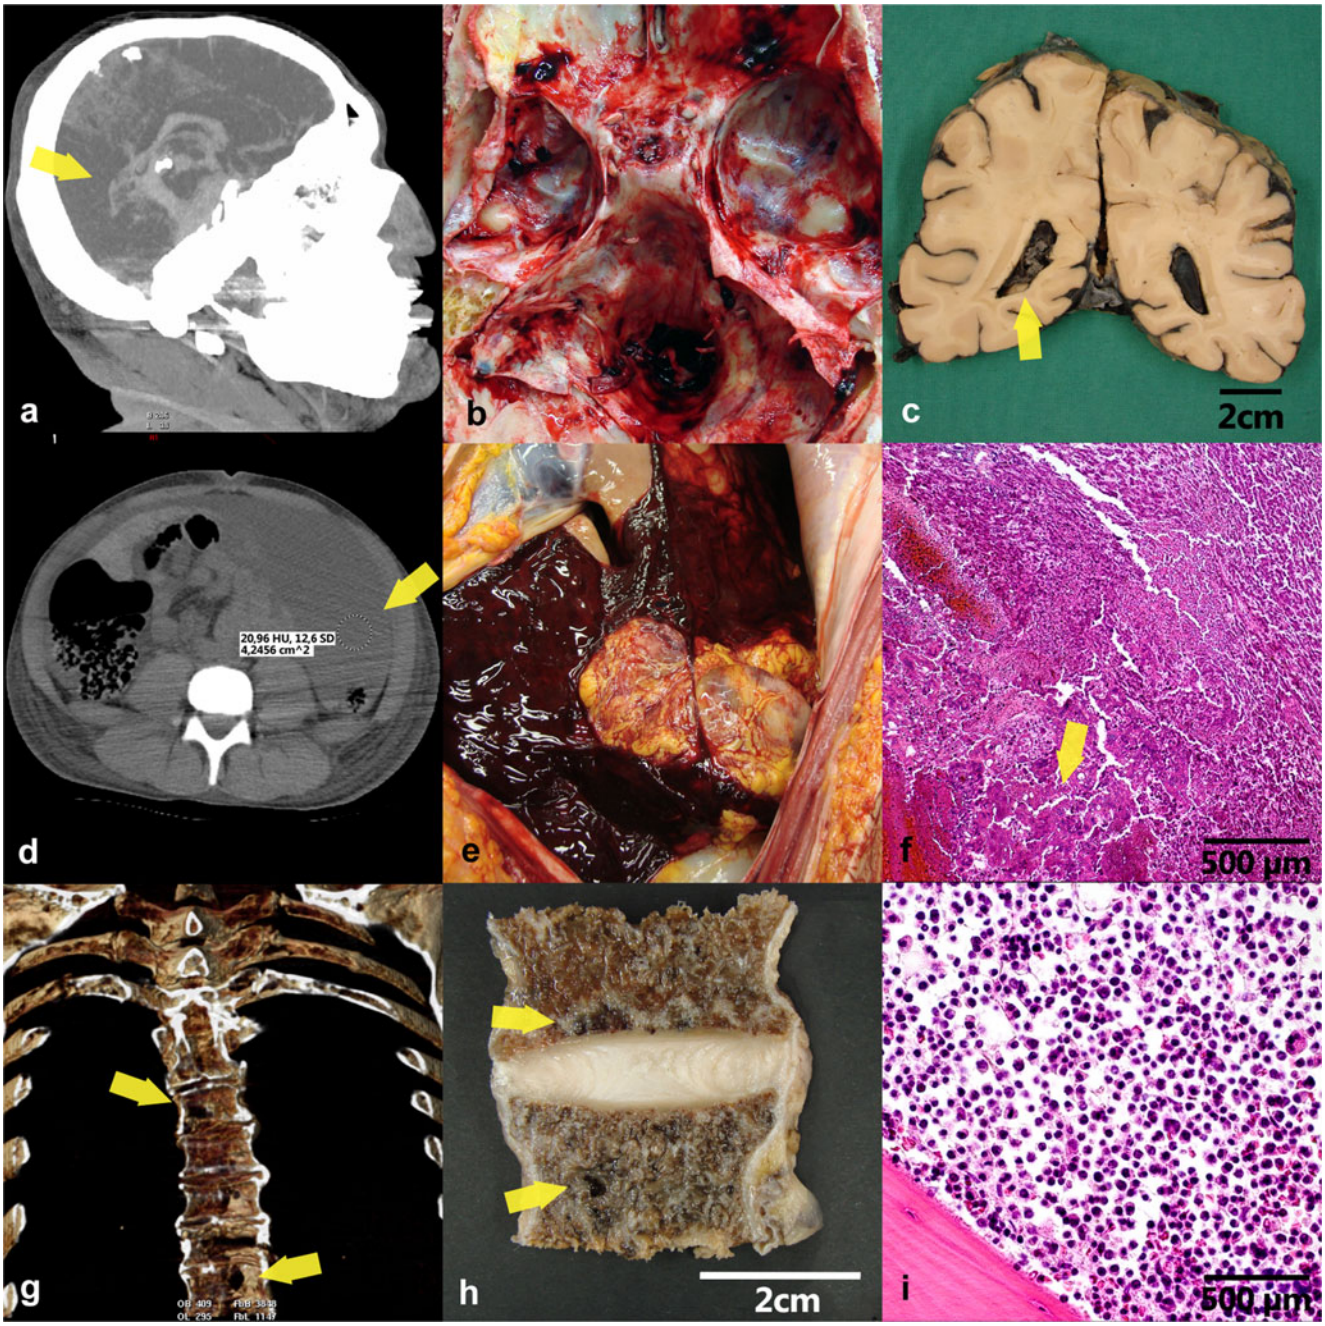

Fig. 2 **a** Subarachnoid and intraventricular haemorrhage, visible as hyperdense fluid with pmCT (*arrow*); **b** macroscopic view of skull base with haemorrhage; **c** macroscopic view of brain slice with subarachnoid and intraventricular haemorrhage (*arrow*, ventricle); **d** abdominal pmCT with intraabdominal haemorrhage, visible as hyperdense fluid with pmCT (*arrow*); **e** Macroscopic view of haematoperitoneum (*top*, liver; *middle right*, transverse colon and omentum; *down*, colon descendens); **f** hemorrhagic metastasis of chorion carcinoma in liver (*arrow*, chorion carcinoma cells); **g** three-dimensional reconstruction of spine and ribs with multiple osteolyses (*arrows*); **h** macroscopic view of vertebral bodies with osteolyses (*arrows*); **i** microscopic view of plasmocytoma cells in bone marrow

skeletal degenerations and four cases of arthroses, one of herniated vertebral disc, one of a bone cyst and one cartilaginous exostosis, were missed at autopsy.

Discussion

The basic methods of clinical autopsy technique including macroscopic and microscopic examination have not changed much since Virchow's time. We discuss whether radiologic imaging is capable of providing valid information

Table 4 Cross-tabulation Pathogenetic mechanism in pmCT vs. classical autopsy

Pathogenetic Mechanism (PM)			Classical autopsy			
			PM found		PM not found	
			(A+C)	15	(B+D)	13
pmCT	PM found A+B=	17	A (true pos)=	5	B (false pos)=	12
	PM not found C+D=	11	C (false neg)=	10	D (true neg)=	1
			Total A+B+C+D			28
Sensitivity=			33.33 %

Accuracy=			21.43 %			

for diagnosing the cause of death with certainty and reliability and if pmCT adds value to the classical autopsy. Finally, a short outlook on future perspectives is given.

The diagnosis of the cause of death after pmCT matched the diagnosis after autopsy in two out of three of our cases (Table 3). The discrepancy rate of 1/3 is similar to the discrepancy rate of 30 % reported by Roberts et al. [21] and the major discrepancy rate of 12.5–40 % (depending on type of pathology) by Wichmann et al. [16]. Weustink et al. [17] report a discrepancy rate of 23 % with minimal invasive autopsy, consisting of pmCT, MRI and biopsy. The positive predictive value (PPV) of 75 % (Table 3) is obviously not representative for the wide range of diagnoses found. The PPV would ideally be calculated per diagnosis, which would require a much larger sample size.

Other publications on post-mortem imaging report difficulties in finding artery occlusions, myocardial infarctions and pulmonary lesions [22, 23].

The results show that coronary thromboses and in-stent thromboses and myocardial infarction were not found with pmCT in any case. Nevertheless, in all cases of coronary or in-stent thrombosis with myocardial infarction, a cardiac cause of death was diagnosed correctly with pmCT by deduction from associated diagnoses (congestion, coronary atherosclerosis, pleural effusion). Therefore, although the pathogenetic mechanism could not be reconstructed in full detail by the radiologist, the cause of death was diagnosed correctly. The lung is subject to post-mortem sedimentation of blood, which causes density shifts (internal livores) and makes the differentiation between pneumonia and pulmonary oedema difficult. In our study, there was only one false-positive finding of pneumonia. Still, it is difficult to correlate pathologic findings of the lung and the radiologic finding of ground glass attenuation, which not only may partly correlate with pulmonary pathologies but may partly also be caused by internal livores of the lung [24].

In contrast to artery occlusions, myocardial infarctions and pulmonary lesions, haemorrhage and haematoma can be differentiated from other liquids due to their high attenuation in pmCT (unclotted blood, 30–45 HU; clotted blood, .45–70 HU [25]). In our study, in cases of fatal haemorrhage, the intracavital bleeding was recognized equally well with pmCT and macroscopic examination. Organ sizes and configurations as well as cysts could be assessed with pmCT (myocardial hypertrophy, goitre, hepatosplenomegaly, fatty liver, liver and kidney cysts). There was a discrepancy in diagnosis of myocardial hypertrophy between radiologists and pathologists (19 at classical autopsy, 10 with pmCT). This discrepancy might be due to the poor contrast between myocardium and left ventricular lumen in unenhanced pmCT, which makes the differentiation between myocardial hypertrophy and left ventricular dilation difficult for the radiologist. Moreover, post-mortal contraction of the ventricles limits the appraisal of the imaging findings. These shortcomings caused the misinterpretation in the cause of death due to dilated cardiomyopathy, in which the myocardial hypertrophy was reported from pmCT, but dilation of the left ventricle was missed.

While dilation of heart cavities can be easily detected in vivo using contrast-enhanced CT in pmCT, the assessment of cardiac myopathy can be hindered by collapse of the heart cavities and lack of clear delineation of the myocardium due to the missing contrast agent. This is a possible explanation for the discrepancy between autopsy and pmCT findings.

A complete autopsy includes external examination for the documentation of sure signs of death (rigour mortis, livores, putrefaction, injuries not compatible with life) and other external findings. Livores and putrefaction are visible with pmCT as internal livores and intravascular gas [24]. Nevertheless, rigour mortis or punction marks cannot be assessed with pmCT. Therefore, the external examination cannot be completely replaced by imaging methods.

Information on organ colour, not only characteristic for myocardial infarction, but also other characteristic colour changes such as icterus, antracosis or colour of ascites, pleural or pericardial effusion, bile, stomach and intestinal content and “nutmeg liver” (sign of chronic passive congestion of the liver) are not visible.

The results show that the reconstruction of the pathogenetic mechanism is still challenging (Table 4). In the study, the attempt of the radiologists to reconstruct the pathogenetic mechanism was dismissed when it was not identical with the pathogenetic mechanism reconstructed by the pathologists. Probably, in some constellations, there is more than one valid interpretation of findings. Therefore, the discrepancies may be due to different focuses on the pathologies found. The presentation of the autopsy findings to the clinical colleagues requesting autopsy and the interdisciplinary discussion of case progression and autopsy findings imply an important, possibly decisive, advantage to the pathologists. Thus, an interdisciplinary discussion of pmCT findings with autopsy findings and clinical progression of every case would be desirable for the most valid diagnosis of cause of death.

There are special areas in which pmCT may even prove superior to classical autopsy: The results show that pmCT is an excellent tool for assessment and documentation of calcified and bone lesions. Histological assessment of calcified tissue is extremely time consuming, as it is necessary to decalcify tissues prior to sectioning. Furthermore, the comparison of imaging autopsy findings with findings of intravital clinical examinations, such as coronary angiography, is very simple and readily accessible for clinicians. The extremities and the joints are examined only on very rare occasions, in order not to mutilate the body. Pathologies of the musculoskeletal system, especially of the viscerocranium and the extremities, are therefore easily missed by conventional autopsy. Fractures can be missed with both methods when there is no dislocation or haemorrhage [16, 25]; therefore, a combination of both methods gives most valid results. In cases of metallic implants, beam hardening artefacts occur on pmCT images, impairing assessment of underlying structures.

Vessels and organs are opened for macroscopic examination at autopsy. Therefore, air accumulations, such as subcutaneous emphysema, intravascular or intrapericardiac air and aerobilia, are more efficiently visualized and documented with pmCT than at macroscopic examination.

The same applies to small pleural effusions and small pneumothoraces, which were seen on radiological images, but not found at clinical autopsy. With the opening of the body cavities, pressure is released; thus, lesions depending on intracavital pressure such as hiatal or inguinal hernia become invisible at macroscopic examination but are easily recognized with pmCT. The presence of catheters and tracheal tubes can be documented three-dimensionally with pmCT, as well as the site of catheter tip or tracheal tube.

Unlike at conventional autopsy, the data generated with pmCT stay stored and are readily accessible afterwards for repeated examination. Compared to CT images from living patients, with pmCT, we do not have to deal with motion artefacts or limitation of dose of radiation. In contrast to notes or pictures taken at autopsy, the images acquired with pmCT are a three-dimensional snapshot not limited by the point of view or knowledge of the individual generating them.

In the future, a method to overcome diagnostic difficulties resulting from lack of inspiration and dependent density may be post-mortem ventilation [26]. With the use of contrast enhancement, post-mortem imaging of the cardiovascular system might become equal, if not superior, to macroscopic examination, as a bleeding site might be found by extravasation of the contrast agent. In cases of haemorrhage from an unknown site, pmCT angiography could help to find an extravasation site at macroscopic examination and support macroscopic findings. The diagnostic problems concerning myocardial hypertrophy with pmCT could be overcome with contrast filling of the heart cavities. Also, the above-mentioned assessment of in-stent stenosis, in-stent thrombosis, coronary artery occlusion and aneurysms might become possible. Still, signs of intravitality of the lesions would yet need confirmation by macroscopic and histologic analysis, in order to exclude artificial extravasation or post-mortem blood clots.

Conclusion

It is amazing how much we already see on unenhanced post-mortem CT images. Concluding from our observations, unenhanced virtual autopsy represents a valuable tool for documentation of pathologic findings such as calcified lesions of the cardiovascular system, bone fractures, lesions of the musculoskeletal system, air accumulations and herniations. Therefore, pmCT complements traditional autopsy techniques. The combination of both methods enhances the diagnostic quality and completeness of the autopsy report. Furthermore, imaging data can be acquired and stored in a less observer-dependent manner to be re-evaluated ad libitum. In addition to traditional autopsy findings, visualization of pathomorphologic findings by post-mortem imaging is likely to be appreciated by clinicians and students. The acceptance of virtual autopsy as a complementary method to traditional autopsy by clinicians needs to be further evaluated.

We believe that many limitations of pmCT will be overcome in the future with the help of post-mortem angiography and CT-guided biopsy from areas of special interest. Furthermore, by interdisciplinary discussion of the results, pathologists and radiologists will get an opportunity to correlate their diagnoses with clinical findings and experience a learning curve interpreting post-mortem imaging and reconstructing the underlying pathogenetic mechanism. In order to avoid systematic errors and to define the limitations

of pmCT accurately, traditional autopsy should always be performed as a gold standard. As an instrument of clinical quality control, resident training in pathology and student teaching, traditional autopsy is still unsurpassed.

CASE REPORT

Transdifferentiation of pituitary thyrotrophs to lactothyrotrophs in primary hypothyroidism: case report

Abstract Primary hypothyroidism causes adenohypophysial hyperplasia via stimulation by hypothalamic thyrotropin-releasing hormone (TRH). The effect was long thought to simply result in thyroid-stimulating hormone (TSH) and prolactin (PRL) cell hyperplasia, an increase in TSH and PRL blood levels with resultant pituitary enlargement, often mimicking adenoma. Recently, it was shown that transformation of growth hormone (GH) cells into TSH cells takes place in both clinical and experimental primary hypothyroidism. Such shifts from one cell to another with a concomitant change in hormone production are termed "transdifferentiation" and involve the gradual acquisition of morphologic features of thyrotrophs ("somatothyrotrophs"). We recently encountered a unique case of pituitary hyperplasia in a 40-year-old female with primary hypothyroidism wherein increased TSH production was by way of PRL cell recruitment. The resultant "lactothyrotrophs" maintained TSH cell morphology (cellular elongation and prominence of PAS-positive lysosomes) but expressed immunoreactivity for both hormones. No co-expression of GH was noted nor was thyroidectomy cells seen. This form of transdifferentiation has not previously been described.

Introduction

Primary hypothyroidism has been shown to be associated with increased blood TSH and PRL levels, which often normalize after treatment with thyroid hormones [1, 2]. Hypothyroidism-induced pituitary hyperplasia is a well-documented phenomenon known to result from lack of feedback-inhibition by thyroid hormones. Decreased circulating levels of T3 (triiodothyronine) and T4 (thyroxine) lead to the hypersecretion of both TSH and PRL, the stimulatory result of hypothalamic TRH [3]. PRL is known to be secreted in response to TRH and is the basis for hyperprolactinemia in the setting of primary hypothyroidism [4, 5]. Originally, "one cell–one hormone" was the paradigm of adenohypophysial pathophysiology. With the recognition of plurihormonal pituitary adenomas [6], the concept was abandoned, a pattern also justified upon the demonstration of transdifferentiation, the conversion of one cell type to another with simultaneous secreting of two different hormones, in both the clinical and experimental

setting. A classic example is primary hypothyroidism wherein one sees somatotrophs transform to so-called "somatothyrotrophs," GH cells co-secreting GH and TSH [7]. Such transdifferentiation also occurs in experimentally induced primary hypothyroidism in dogs and rats [8, 9]. Herein, we describe a form of transdifferentiation not reported to date.

Clinical history

The patient is a 40-year-old female with longstanding primary hypothyroidism and poor medication compliance. She presented with a 4-month history of constant, gradually worsening headaches and occasional double and/or blurred vision. On computer tomographic (CT) and magnetic resonance imaging (MRI) scans (Fig. 1), a 1-cm sellar mass thought to represent a pituitary adenoma was seen to cause superior displacement of the optic chiasm. Within a month of surgery, the blood PRL level was 54 ng/mL (normal 3–30 ng/mL); the mild elevation was thought to be due to pituitary stalk compression. Serum TSH levels had been markedly elevated at over 800 μIU/mL (normal 0.4-4.5 μIU/mL) but were presently normal due to recent, short-term compliance in taking Synthroid. Blood cortisol, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels were normal.

Materials and methods

A transsphenoidal resection was undertaken in hopes of relieving headaches and avoiding chiasmal damage. Upon incising the dura, soft, somewhat lobulated yellow tissue was seen. The lesion was debulked until more normal-appearing pituitary tissue remained. Initial assessment of the specimen revealed abnormal pituitary tissue but not an adenoma as had been clinically suspected. The possibility of thyrotroph hyperplasia was entertained since acinar architecture, despite expansion, was relatively preserved.

Results

On consultative review of the specimen, the pituitary tissue revealed the usual morphologic heterogeneity of adenohypophysial cell types (Fig. 2) but was associated with conspicuous acinar expansion. Affected acini featured cytologically monomorphous, chromophobic cells, often elongate and extending across the variably expanded acini. Periodic acid-Schiff staining demonstrated cytoplasmic lysosomes of varying size within their cytoplasm (Fig. 3). Also of note were small numbers of psammomatous calcifications. Immunohistochemistry (avidin–biotin–peroxidase complex method) revealed the full spectrum of pituitary hormones. Antibody sources and dilutions of the pituitary battery consisting of TSH, PRL, GH, adrenocorticotropin (ACTH), LH, and FSH as well as control methods are described elsewhere [10]. The monotonous cells, both within expanded acini as well as in the surrounding pituitary, were immunopositive for TSH and to a lesser extent PRL. Cells staining for GH, ACTH, LH and FSH were normal in distribution.

Immunohistochemistry for transcription factors and techniques are as follows; Pit-1 (polyclonal antibody; dilution, 1:100; sc-442; Santa Cruz) and GATA-2 (polyclonal antibody; dilution, 1:100; sc-1235; Santa Cruz). The sections were deparaffinized in xylene, dehydrated in graded ethanol, and endogenous peroxidase activity was blocked with 0.3 % hydrogen peroxide in methanol. They were then soaked and autoclaved for 5 min in the antigen retrieval solution, Citra-Plus Reagent (pH 6.0, BioGenex) at 121 °C, allowed to cool to room temperature and washed with 0.01 M phosphate-buffered saline (PBS). The sections were treated with primary antibodies overnight at 4 °C. After washing in 0.01 M PBS, sections were incubated with biotinylated anti-rabbit, anti-

mouse or anti-goat secondary antibody (1:50 dilution; Jackson Immuno-Research, Laboratories, West Grove, PA) for 1 h at room temperature. The immunohistochemical reaction was developed using a Vectastain ABC kit (Vector Laboratories, Inc., Burlingame, CA), and antigens were visualized by treatment of the slide with 50 mM Tris–HCl buffer (pH 7.6) containing 0.3 % 3,3-diaminobenzidine (DAB) and 0.03 % H_2O_2 for 3–5 min at room temperature.

Dual immunohistochemical staining was performed to determine colocalization for TSH and PRL; the methods for dual immunohistochemical staining are described elsewhere [11]. Dual staining for TSH and PRL was noted within some cells in the hyperplastic acini (Fig. 4).

Discussion

Our case is an example of adenohypophysial hyperplasia occurring in the setting of primary hypothyroidism. It has its basis not only in TSH cell (thyrotroph) and PRL cell (lactotroph) hyperplasia but is known to involve transdifferentiation of GH cells (somatotrophs) to ones secreting both GH and TSH [7]. Such cells are termed "thyrosomatotrophs." While these biphenotypic cells stain for both hormones, they ultrastructurally have come to resemble thyrotrophs. The present case differs from this response. The hyperplastic cells in our case morphologically resembled thyrotrophs in being elongate in configuration and containing abundant, sizable lysosomes. Furthermore, the second hormone expressed was not GH but PRL. As expected in hypothyroidism, preoperative serum elevations of both TSH and PRL were noted. The presence of rare psammoma bodies in normal adenohypophysis, a feature in our case, is a reflection of hyperprolactinemia. They are seen in 10 % of prolactinomas [12] and have previously been documented in combined lactotroph and thyrotroph hyperplasia in the setting of primary hypothyroidism [5]. Psammoma bodies are also a feature of the pituitary in the neonatal period, which is characterized by PRL elevations [13, 14].

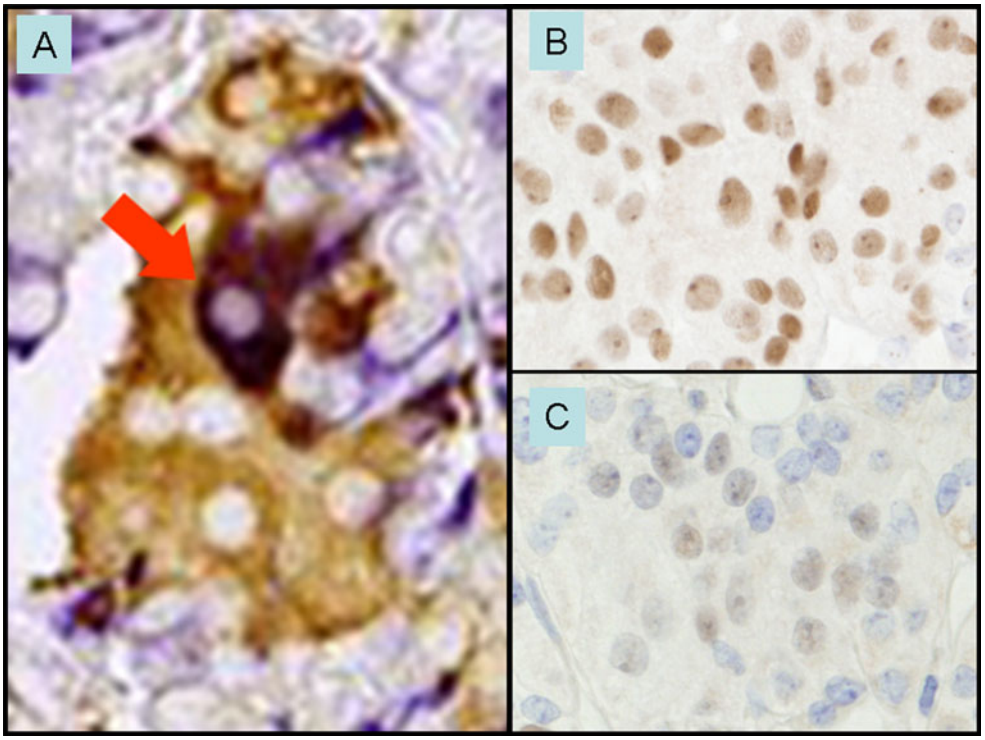

Fig. 4 Dual immunohistochemical staining (**a**) performed for TSH (*brown*) and PRL (*blue*); dual positive cell present within hyperplastic lobules as represented by the *arrow*; immunohistochemical staining for transcription factors in the areas of hyperplasia; nuclei strongly positive for Pit-1 (**b**) weakly positive for GATA-2 (**c**)

The literature clearly indicates that combined thyrotroph and lactotroph cell hyperplasia occurs in the setting of primary hypothyroidism. It has been well documented histologically, immunohistochemically and at the biochemical level [3, 5, 15]. This results in pituitary enlargement as well as increases in blood TSH and PRL levels which often resolves after replacement therapy [3, 15]. On occasion, however, mass effect and hormone elevations persist and necessitate surgical intervention [5].

Two main mechanisms appear to contribute to increased blood PRL levels and lactotroph hyperplasia in primary hypothyroidism. Both involve stimulatory effects upon lactotrophs, one being the hypothalamic-releasing hormone TRH and the other effect of interruption of down flow of hypothalamic dopamine ("stalk section effect"). Inhibition of PRL secretion, the physiologic effect of dopamine, results in mild to moderately elevated PRL levels [4]. In addition, TRH is known to stimulate lactotrophs. As a result, blood PRL levels are elevated in up to 20 % of patients with primary hypothyroidism [4]. Both of these mechanisms likely contributed to hyperprolactinemia in our case. It is of note that TRH-R1 receptor-deficient mice have decreases in both blood PRL levels and pituitary PRL mRNA when compared to control mice [16]. In comparison, suckling produces less of an increase in both [16]. In yet another study, TRH-deficient mice demonstrated significantly decreased pituitary PRL mRNA levels in response to primary hypothyroidism [17]. The levels normalized with thyroid hormone replacement, leading to the conclusion that the reduction in PRL mRNA level seen in TRH-deficient mice was also the result of primary hypothyroidism. Interestingly, such TRH-deficient mice had normal blood and pituitary concentrations of PRL [17]. A TRH receptor-inactivating mutation causing lack of TRH binding was recently reported in a child and resulted in lack of an increase in TSH and PRL following intravenous TRH administration. As in the TRH-deficient mice, this patient's blood PRL levels were also within normal limits [18]. Reports, such as these, show that TRH is indeed involved in the regulation of PRL, although the extent to which it does remains unclear.

The mechanism by which TRH induces TSH and PRL gene expression is unclear, but there is evidence that TRH activates calcium–calmodulin-dependent protein kinase cascade in pituitary cells [19]. Thyrotroph hyperplasia in our case is undoubtedly the result of TRH elevation, itself the result of primary hypothyroidism. Although TRH likely played a role in increasing serum PRL levels, pituitary enlargement with resultant stalk section effect may have further promoted PRL secretion.

Transdifferentiation in pathologic states is an uncommon event. In normal physiology, it is well-known to occur in pregnancy wherein GH cells transform to PRL cells, an event reversed postpartum or upon cessation of breastfeeding [20, 21]. Although primary hypothyroidism is the only documented pathophysiologic example [5], it may be that GH-to-PRL cell transformation occurs in estrogen-mediated prolactin cell hyperplasia. Interestingly, LH/FSH cell transition to ACTH cells in gonadotropic adenomas has also been documented, although this phenomenon is rare [22, 23]. TSH, GH, and PRL cells are particularly prone to undergo transdifferentiation, which may be a reflection of their

cytogenesis. All three share the common transcription factor Pit1 [5]. This explains the multi-hormonal immunophenotype pattern (GH, PRL, and TSH) of pituitary in acromegaly-associated pituitary adenomas [24]. Recent studies have also shown that TTF-1 regulates PRL and GH transcription in the GH3 tumor cell line, suggesting that it may also be involved in transdifferentiation of cells expressing PRL, GH, and possibly TSH [25]. The hyperplastic cells in our case were strongly positive for Pit-1 and less intensely for GATA-1 (Fig.4). It has been reported that Pit-1 promotes the differentiation of the pituitary cells to GH, PRL, and TSH [26].

In any event, regardless of the mechanisms underlying TSH and PRL cell hyperplasia, our case provides an example of adenohypophysial transdifferentiation in primary hypothyroidism. The hybrid cells (lactothyrotrophs) have not previously been described.

LETTER TO THE EDITOR

Intestinal metaplasia and colonization of endometriosis in a case of an appendiceal mucinous neoplasm

Louis Libbrecht · Christophe Snauwaert · Martine De Vos · Karel Geboes · Claude Cuvelier · Liesbeth Ferdinande

Received: 1 June 2012 / Accepted: 13 June 2012 / Published online: 27 June 2012
© Springer-Verlag 2012

Intestinal endometriosis is reported in 15–37 % of patients with pelvic endometriosis [1]. Making a correct diagnosis can be challenging for clinicians as well as for pathologists as this disease is able to mimic other pathologies such as inflammatory bowel disease, infectious etiologies, or neoplasms. The appendix is less commonly involved than the small or large intestine. Endometriosis of the appendix is often asymptomatic and discovered as an incidental finding, but it may also present as an acute or chronic appendicitis, occasionally with the formation of an inflammatory mass, mimicking a neoplasm [1]. A few case reports describe the development of obstructive mucocoeles secondary to endometriosis of the appendix. These mucin-filled cystic dilatations of the appendix were lined by normal epithelium without hyperplastic or neoplastic changes [2]. We report the case of an appendiceal mucinous neoplasm in association with endometriosis in a 48-year-old woman. The appendiceal lesion was an incidental finding in this patient who underwent imaging for an episode of pancreatitis. Surgery was performed. Microscopic examination demonstrated that the cystic lesion was covered by a mucosa with serrated and dilated crypts that assumed L- and inverted T-shapes (Fig. 1). The crypts were lined by columnar epithelial cells with low-grade atypia. With the presence of extra-appendiceal acellular mucin, this lead to the diagnosis of a low-grade mucinous neoplasm with low risk of recurrence [3]. In addition, the wall of the appendix showed numerous foci of endometriosis consisting of endometrial glands embedded in variable amounts of endometrial stroma, confirmed with ER and CD10 immunohistochemistry (not shown). Interestingly, some of the glandular structures that were embedded in the endometrial stroma were lined by mucinous epithelium, very similar to the epithelium observed in the appendiceal mucinous neoplasm. Immunohistochemistry demonstrated CK7 expression in the normal endometrial epithelium and CK20 expression in the mucinous epithelium. Two theories could explain this finding.

Firstly, the epithelium of the appendiceal mucinous neoplasm colonizes the endometrial glands of the appendiceal endometriosis. In intestinal endometriosis, endometrial glands can merge with the surface epithelium and be continuous with it [1, 4]. Secondly, the endometrial glands undergo metaplastic mucinous changes. Mucinous metaplasia in endometriosis is a well-known phenomenon, although it more often mimics endocervical epithelium. Intestinal-type mucinous metaplasia with goblet cells and Paneth cells has been described, but is rare [5]. In our opinion, both explanations can account for the observations in this case. In a few glands, both types of epithelium were continuous. The transition between the normal endometrial epithelium and the mucinous epithelium was very abrupt. Focally, some Paneth cells were present. The glands were dilated and showed serrated growth pattern. Similar cytological and architectural characteristics as recognized in the neoplasm and the sharp demarcation between both types of epithelium suggest that the mucinous changes of the epithelium are due to colonization of the endometrial glands (Figs. 2, 3, 4, and 5). In other areas, the

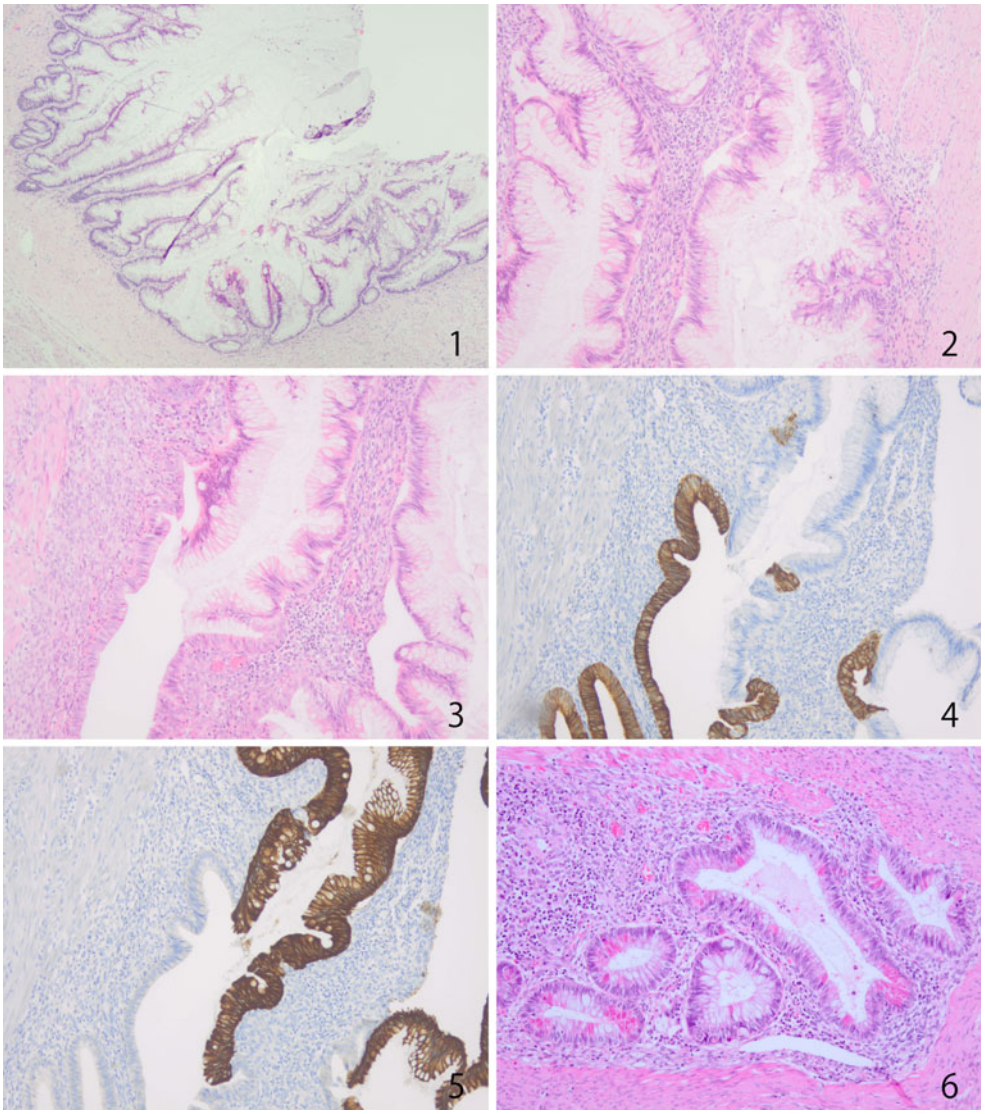

Figs. 1–6 *1* Low-grade mucinous neoplasm with low risk of recurrence (haematoxylin-eosin). *2–5* The appendiceal mucinous neoplasm colonizes the glands of the appendiceal endometriosis. In these areas, an abrupt transition between both types of epithelium is observed with different immunohistochemical profiles (*2–3* haematoxylin-eosin, *4* CK7 immunohistochemistry, *5* CK20 immunohistochemistry). *6* Intestinal-type mucinous metaplasia of the appendiceal endometriosis with mucinous cells and Paneth cells (haematoxylin-eosin)

glands did not display complex serrated architecture and the epithelium consisted of an equal mixture of mucinous cells and Paneth cells. Probably, these areas represent metaplastic changes, featuring intestinal-type mucinous metaplasia (Fig. 6).

In the context of mucinous appendiceal neoplasms, it is important not to consider the glands lined by mucinous epithelium as invasive neoplastic glands, but as metaplastic or colonized endometrial glands. The lack of nuclear atypia and desmoplastic reaction and the presence of endometrial stroma surrounding the glands are in favor of the latter.

In contrast to the previously described mucocoeles, the development of the appendiceal mucinous neoplasm was probably not a consequence of the endometriosis as it concerns a true neoplasm with more complex pathogenesis than merely an obstructive problem. Whether there is an association between the endometrial metaplasia and the mucinous neoplasm, however, remains unclear. Endometrial metaplasia may arise as a response to hormonal or other stimuli and it cannot be excluded that in this case the mucinous metaplasia in the endometrial glands was induced by the vicinity of a mucinous neoplasm and its growth factors.

Abstract When colorectal cancer (CRC) metastasizes, this is mostly to the liver via the portal circulation. In addition, 10–25 % of CRC patients eventually show metastases in the peritoneum. A selection of these patients is treated with cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC). However, several clinical needs still exist in which biomarkers could play an important role. Relatively little is known about the biology of peritoneal spread of CRC. The development of peritoneal metastases (PM) involves several steps, including: detachment of malignant cells; anoikis evasion; attachment to and invasion of the peritoneal surface ultimately ending in a colonization phase in which the malignant cells thrive in the newly formed niche. In this paper, we provide an overview of molecules associated with peritoneal dissemination and explore the clinical possibilities of these candidate biomarkers. A literature search was conducted using the PubMed database of the U.S. National Library of Medicine and Medline to identify studies on the biological behaviour of PM of CRC. In a series of over 100 studies on PM published between 1990 and 2010, IGF-1, HIF1α, VEGF, EGFR and ITGB1 emerge as the most interesting candidates for possible clinical application. Even though these promising candidate biomarkers have been identified, all of these require extensive further validation prior to clinical application. Yet, the pace of the omics revolution makes that the question is not if, but when biomarkers will be introduced to improve diagnosis and ultimately outcome of patients with PM due to CRC.

Introduction

Colorectal carcinoma (CRC) is a major health problem, being the third most common cancer worldwide. Each year, more than 1 million people develop CRC, and over 600,000 patients die of this cancer, despite improvements in diagnostic and treatment modalities [1]. Approximately half of CRC patients develop metastases, mainly to the liver via the portal vein system [2, 3]. Another category of distant metastases from CRC are those to the peritoneum, i.e., peritoneal metastases (PM). In up to 25 % of patients with metastatic CRC, the peritoneum is the sole site of metastasis [3, 4]. Untreated PM is associated with poor survival of about 6–12 months, while systemic chemotherapy alone does not appear to yield any clinically significant survival benefit [5, 6].

In the early 1990s, a treatment with a curative intent for patients with PM of CRC, without evidence of distant metastasis to other sites, was introduced. This consists of debulking surgery (cytoreductive surgery [CRS]) combined with heated intra-peritoneal chemotherapy (HIPEC) [7, 8]. This approach is based on the hypothesis that peritoneal

dissemination is a form of local rather than systemic spread, which in theory makes PM amenable to a form of local disease control, i.e., surgery [9]. This theory is further supported by the observation that a subgroup of patients, in whom no residual macroscopic tumour is left after resection, shows a 5-year survival of 35–45 % [10]. This is equal to the survival of patients undergoing resection for liver metastasis, which to date is part of the standard of care for liver metastases of colorectal origin (CRLM) [3, 10, 11].

Thus, patients with resectable metastatic colorectal cancer, either to the liver or the peritoneum, have benefitted from the aggressive surgical management. However, because treatment with CRS and HIPEC has a morbidity and mortality rate of 15–18 % and 5 %, respectively, it is of utmost importance to be able to carefully select those patients who will benefit most from this treatment [4, 5, 10, 12]. In addition, major challenges in diagnosing and treating PM remain. For example, most early peritoneal lesions are smaller than 1 cm, and as such not visible on pre-operative computed tomography (CT) or positron emission tomography (PET) scans, which hampers both timely diagnosis and adequate monitoring of patients with PM [12]. Furthermore, the chemotherapy that is used in HIPEC is still based on the "one size fits all" principle, without any biological stratification.

At present, the selection of patients is made roughly on clinical parameters and intra-operative findings. Based on the hypothesis that the phenotype, and thus clinical behaviour, of PM in CRC is driven by underlying biological mechanisms, readouts of disease biology (i.e., biomarkers) will be of help for more refined identification of suitable patients. Additionally, adequate targets may be of great value in prognosis assessment, imaging and guidance of therapy.

The aim of the present paper is therefore to provide an overview of promising molecular changes reported to be involved in peritoneal dissemination of CRC and to evaluate the potential for clinical application of these biomarkers.

Materials and methods

A literature search was conducted using the PubMed database of the U.S. National Library of Medicine and Medline using the following keywords: peritoneal metastasis, CRC, biological behaviour, detachment, motility, anoikis, attachment, invasion, angiogenesis, proliferation, epithelial to mesenchymal transition (EMT), immunohistochemistry (IHC), proteins, HIPEC and combinations of these keywords. These search terms were used in order to include as many articles as possible on the subject. Additional papers were included by cross-referencing from papers retrieved in the first search.

Articles from 1990 up to 2010 on biomarkers in PM of CRC were included for individual review, and only so when fitting the scope of this paper. A second reader conducted additional review when necessary. Studies on ovarian, gastric, and carcinoma of the pancreas spread to the peritoneum were included for review as well. Reports on in vivo, in vitro as well as ex vivo experiments were included.

Results

The process of metastasis in general comprises different phases: First, tumour cells detach from the primary tumour, second, they migrate to the distant site, and third they adapt to the new microenvironment, i.e., niche, and grow out [13, 14].

The niche in question, the peritoneum, is the surface of the abdominal wall. It is made up of a single layer of mesothelial cells on a basement membrane supported by a connective tissue or stroma compartment, also referred to as the submesothelium, which forms the niche for PM. This submesothelium consists of stromal cells and extracellular matrix (ECM), which is composed of laminin, collagen, fibronectin, proteoglycan and elastin [15].

Cellular mechanisms involved in peritoneal spread

Below, candidate biomarkers are discussed in the order of the sequential steps of the metastatic process. However, as considerable interactions exist between these processes, this classification is by no means absolute.

Detachment and increased motility

Upon detachment from the primary CRC, in addition to anoikis evasion, tumour cells have to enable motility in order to reach the target organ [16]. This is acquired by downregulation of cell–cell adhesion molecules (CAMs) and changes in the cytoskeleton, such as the extension of lammellipodia and filopodia [17].

Cell–cell adhesion molecules include the integrin family of proteins, cadherins, selectins and members of the immunoglobulin superfamily (e.g., ICAM and VCAM), which are discussed in Section 3. Also, other adhesion molecules, like CDH2, and cell surface molecules with signal transduction function, like epidermal growth factor receptor (EGFR) and c-MET play a role here [18]. These phenotypic alterations that take place during invasion, with tumour cells exhibiting reduced adhesion and increased motility, are also referred to as EMT [17, 19]. In the context of PM, the molecule TWIST is reported to be involved in this process.

Twist homolog 1 (TWIST)

TWIST is a transcription factor that is most abundantly expressed in tissues of mesodermal origin. TWIST is known as an EMT trigger [13, 14]. Studies aiming to block the function of TWIST by siRNA in ovarian adenocarcinoma cells have shown suppression of adhesion molecules and matrix metalloproteinases (MMPs). Levels of migration, invasion and adhesion to peritoneal mesothelium were significantly lower in siTWIST cells, supporting that downregulation of TWIST could, in theory, ultimately inhibit peritoneal dissemination [20].

Met proto-oncogene (c-MET)

c-MET is a proto-oncogene that encodes for the hepatocyte growth factor receptor (HGFR). It has tyrosine kinase activity and is essential in embryonic development and wound healing [21]. Activation of MET by hepatocyte growth factor (HGF) initiates an invasive growth program [22], which physiologically occurs during embryonic development and organ regeneration, but that is hijacked by cancer cells to promote invasion [23]. Abnormal MET expression in cancer has been linked to poor survival in several malignancies, including CRC [24]. c-MET was found to play an important role in peritoneal dissemination of ovarian carcinoma (OvCa) cells in culture, most probably through an $\alpha5\beta1$ integrin-dependent mechanism [25]. Using tissue microarrays (TMAs), cell lines and animal models, the role of c-MET in PM of OvCa was investigated. The disease specific survival of patients with high c-MET protein expression was significantly lower than those with low expression (N=138). In experiments using ECM components, primary mesothelial cells, full-thickness human peritoneum and in vivo mouse peritoneum, marked inhibition of dissemination was noted by siRNA targeting c-MET [25, 26]. Furthermore, a reduction in $\alpha5\beta1$ protein and mRNA, accompanied by a reduction in MMP2 and MMP9 activity, was noted [25]. As such, theoretically c-MET represents a very attractive candidate biomarker of PM formation risk as well as a possible therapeutic target in prevention of peritoneal dissemination.

Epidermal growth factor receptor

EGFR is a cell surface protein and when its ligand binds, a signalling cascade starts that leads to cell proliferation [3, 10, 11, 26]. Activation of EGFR is thought to promote the downregulation of E-cadherin, causing disruption of adherens junctions, through induction of MMP9. This interaction has been investigated in OvCa by blocking with an siRNA directed against MMP9 [27]. This study involved two cell lines and tissue samples from 146 primary OvCas, including 17 paired samples of primary tumour and PM. Treatment with recombinant MMP9 or transient expression of MMP9 was sufficient to regain function and reduce E-cadherin levels in the cell lines, which subsequently caused a migratory and invasive response. These findings were validated by IHC on TMAs containing patient material, which exhibited co-localization of activated EGFR and MMP9 accompanied by E-cadherin loss [27]. Clinically elevated levels of both EGFR and MMP9 have been associated with worse survival [28–30].

Other markers associated with detachment and increased motility in in vitro and in vivo studies in the context of PM are HGF, RHOA and CDH2 [24, 27, 31–34]. However, the clinical significance of up- or downregulation of these specific genes in PM of CRC remains to be verified.

Anoikis evasion

Anoikis is a form of programmed cell death that takes place when cells detach from the surrounding ECM, thereby loosing integrin–ligand interactions, as occurs during tumour cell invasion [13, 35]. In normal tissue anoikis is critical in maintaining tissue homeostasis by preventing tissue proliferation in unwanted sites. Evading anoikis is a condition for cancer cells to survive and is believed to be an essential step in metastasis [36, 37]. This also is the case during the process of PM formation where detached cells exhibit anchorage independent growth, meaning that they are able to survive without intact cell–cell signalling, a requisite for cell survival in normal cells [38]. In PM, this is most likely achieved by forming tumour cell clusters and retaining the ability to proliferate in cell clusters, as opposed to the adherence to platelets as described in haematogenous spread [35, 39].

In peritoneal spread, two molecules are reported to play a role in anoikis evasion.

Kallikrein-related peptidases

The process of evading anoikis in PM involves the activation of the kallikrein-related peptidases (KLKs), a group of serine proteases. There are 15 proteins belonging to the kallikrein family [40]. Known functions of the KLKs include degradation of ECM molecules, contributing to activation of growth factors and proteases. One of the most well-known KLKs, utilized in diagnosis and follow-up of prostate cancer, is KLK3 or prostate-specific antigen (PSA) [41]. Interestingly, there is a link between cell clustering and KLK expression. Cell clustering is a frequent event in OvCa ascites, which may contribute to anoikis evasion [40]. The aggregation of these malignant cells was associated with a higher protein expression of KLK7 [40]. Hence, it is assumed that treatment response is, at least partly, governed by anoikis resistance under the influence of KLK7. Further investigation revealed that $\alpha5\beta1$ integrins and KLK7

co-express in OvCa. Based on these findings, an association between KLK7 levels and PM via cell aggregates and α5β1 integrin-mediated cell adhesion was assumed. Several integrin inhibitors, such as Volociximab [42, 43] are currently under development and are of interest as targeted therapy in PM, based not only on the abovementioned results but also on a proof of principle study with blocking of β1 integrin (ITGB1) in a murine and ex vivo peritoneal model, described under "Adhesion to peritoneal surface" [44].

KLKs have also been investigated as prognostic markers in CRC in primary tumours. A higher KLK 7 protein expression was found to be associated with a shorter overall and disease free survival in a study containing 105 patients [45, 46]. In addition, analysis of a panel of KLKs shows overexpression of KLK5, KLK7 and KLK 14 to be prognostically relevant in patients with primary CRC in a multivariate analysis [46].

V-Src sarcoma viral oncogene homolog (Src)

Src is a tyrosine kinase that is described as a key player in cell-matrix contact-mediating focal adhesions, in cell–cell contact-mediating adherens junctions and in cell-anchorage dependent signalling [39, 47]. A Src-dependent mechanism has been reported that provides transient protection of colonic epithelial cells from anoikis [48]. Using a Src-specific inhibitor, loss of protection from anoikis was shown in various experiments [48, 49]. CRC cell line experiments have shown that enforced Src expression increases resistance to anoikis [50]. As well as having a role in anoikis evasion, upregulation of c-SRC causes adherent cells to scatter and to extend their lamellipodia, thus making tumour cells highly motile [50]. In a murine model, blocking of Src showed reduced peritoneal dissemination compared to control transfectants. These results support the hypothesis that c-SRC may play a role in detachment and motility of CRC cells.

Adherence to peritoneal surface

After evasion of anoikis, detached malignant cells will have to adhere to the peritoneal surface to be able to ultimately invade and colonize the peritoneum. Adherence to the peritoneal surface depends largely on the interaction between malignant cells and ECM components through integrins, cadherins, and cell-adhesion molecules.

Integrins

Integrins are a family of receptors that play a major role in cell-ECM attachment and signalling. Integrins may also play a role in attachment of malignant cells to the peritoneum. The integrin family consists of 24 members, and function in different combinations of α and β subunits [2, 18]. Integrins are expressed on epithelial as well as endothelial cells, leukocytes and platelets. Altered expression patterns of integrins are frequently associated with a malignant phenotype, supporting invasive and metastatic behaviour [51, 52].

One of the integrins involved is the ITGB1. In a surgical trauma animal model, blocking ITGB1 caused less tumour cells to adhere to the peritoneum, followed by impaired outgrowth of tumours. These results were confirmed in an ex vivo peritoneal and in vivo mesothelial model. This suggests a role for integrins in the adherence and growth of tumour cells on (surgically traumatized) peritoneum [44]. Another integrin, α5β3, has been identified in PM of pancreatic cancer. It is the primary receptor for Cyr61, one of the molecules described under "Inducing Angiogenesis". The experiments involving this receptor–ligand couple were carried out on a murine pancreatic cancer model, using microarray analysis, reverse transcription-polymerase chain reaction (RT-PCR) and IHC to confirm the results [33]. With IHC, co-localization of Cyr61 and α5 was observed, suggesting that the interaction between Cyr61 and α5β3 promotes the formation of PM [33].

Cadherin 1 (CDH1 or E-cadherin)

This protein is part of the cadherin family of cell adhesion molecules, consisting of glycoproteins that mediate cell–cell adhesion in epithelial cells. Reduced cell surface expression of this protein has been observed in many cancers, including oesophageal, colon, breast and OvCa [53]. As a consequence these cells show easy disaggregation, facilitating invasion and metastasis [39, 54].

In PM of CRC one in vivo study has been described with a LoVo clone showing E-cadherin downregulation to be associated with metastasis [55]. These cells formed a primary colon carcinoma in the host model, which was then resected. Seven out of ten mice showed isolated mesenteric lymph node metastases, not peritoneal carcinomatosis, after resection, compared to ten disease-free mice in the control group.

In an OvCa model, however, downregulation of E-cadherin by siRNA was followed by upregulation of α5β1integrin [34]. In this study, intra-peritoneal administration of an α5β1integrin antibody significantly reduced ascites and the number of metastases compared to the control group [34]. In a cohort of 107 OvCa patients, the overexpression of α5-integrin correlated with worse survival [34]. Altogether, these findings imply an effect of downregulation of E-cadherin through an integrin-mediated pathway.

Intercellular adhesion molecule 1 (ICAM-1)

The ICAMs are a subfamily of the immunoglobulin superfamily of cell adhesion molecules. ICAM 1 is one of five ICAMs [18]. The role of ICAM 1 has been investigated in a

pneumoperitoneum-simulated environment using a CRC cell line and a mesothelial cell monolayer [56]. In this study, increased adhesion of CRC cells to the stimulated mesothelium was observed [56]. In an attachment assay to detect MMP's activity in naive (unstimulated) mesothelium, it was confirmed that increased expression of ICAM-1 led to increased adhesion of malignant cells [57]. Moreover, the link between ICAM1-CD43 interaction and MMP production was analysed on invasion of attached cells. An increase in adhesion and invasion was noted, which was manifested by an increase in MMP expression [57].

Epithelial cell adhesion molecule (Ep-CAM)

Ep-CAM is a type 1 transmembrane glycoprotein and not structurally related to the four major families of cell adhesion molecules [58]. Ep-CAM is frequently highly expressed in malignancies of epithelial origin, including CRC [58, 59].

In peritoneal dissemination of OvCa the expression of Ep-CAM in primary, metastatic and recurrent epithelial OvCa was studied [60]. Using real-time PCR (qRT-PCR) and IHC in patient material and cell lines, high expression of Ep-CAM was detected in all three disease stages, with a significant difference in Ep-CAM expression levels between metastatic, recurrent and chemotherapy-resistant OvCa compared to normal ovarian epithelium [60].

CD 44 molecule (CD44)

The protein encoded by the CD44 gene is a cell surface glycoprotein that plays a role in cell-adhesion, cell–cell interaction and migration. It is a receptor for hyaluronic acid and can interact with MMPs and collagens as well. It participates in several cellular functions, one of which is metastasis [61].

Alternative splicing of CD44 pre-mRNA results in different isoforms of the protein. In CRC, CD44 exon v6 splice variants are present in advanced stages of disease [62, 63].

In PM, in vitro adhesion assays have been performed with the use of mesothelial cell cultures and OvCa cells. A CD44 monoclonal antibody partially inhibited adhesion of tumour cells to the mesothelium. In nude mice, treatment with CD44 monoclonal antibody led to significantly less tumour implants on the peritoneal surface [61]. Although some adhesion of OvCa cells to the mesothelial layer still occurred, albeit to a lesser extent, it ultimately lead to less PM [61, 64].

Interactions have also been reported between chemokine receptors present on malignant cells and targets in the mesothelium in OvCa. Examples of this mechanism are the binding of CXCR4 to CXCL12 and the binding of MUC16 to Mesothelin [65, 66].

Altogether, these data suggest that the blocking of these attachment-mediating molecules could be of clinical importance. For example, in the peri-operative window, blocking of these candidates could lead to less implantation and subsequently less tumour outgrowth [44, 56, 57, 61].

Invasion of the peritoneum

Proteolytic enzymes to degradate the ECM are necessary for tumour cells to be able to invade beyond the basement membrane. These enzymes are secreted by tumour cells themselves or by the stromal cells surrounding them [67]. ECM degrading metallopeptidases (MMPs) have been extensively linked to this step in peritoneal dissemination [13].

Matrix metallopeptidases (MMPs)

Proteins of the MMP family break down the ECM in normal physiological processes as well as in disease, including cancer [68]. MMPs facilitate invasion of the tumour cells into the nearby stroma by degrading multiple types of ECM proteins. They play a role in metastasis of CRC, including in liver- and lung metastases [68, 69].

In gastric carcinoma, overexpression of MMP7 in primary tumours, as seen by IHC and RT-PCR, was an independent risk factor for formation of PM [16]. In OvCa, overexpression of MMP9 was reported to promote a migratory and invasive phenotype in functional experiments performed in two OvCa cell lines [27]. Altogether, the invasion of the peritoneal surface by cancer cells has been linked to altered MMP2, MMP7 and MMP9 expression in several gastrointestinal tract malignancies [16, 27, 69–71]. For this reason, attempts have been made to treat PM with MMP inhibitors. Indeed, inhibition of MMPs with the drug Batimastat in rats inhibited development of CRC metastasis [72]. However, intra-peritoneal administration of this drug resulted in marked peritoneal inflammation and ascites, reason why no clinical studies with Batimastat in humans have been initiated to date.

In addition, the Wilms' tumour gene protein 1 (WT1) and TIMP2 are also reported to promote invasion. Contact between malignant cells and the submesothelial collagen results in WT1 overexpression and subsequent invasion in OvCa [73]. Furthermore, decreased invasive capacity is observed after blocking WT1 by siRNA [73]. TIMP-2 is a tissue inhibitor of metalloproteinases, for which a twofold upregulation of TIMP-2 mRNA was observed in the PM of CRC patients, next to upregulation of HIF-1α and IGF-1 that are described below [74]. TIMP-2 is part of the TIMP gene family and proteins encoded by this gene are inhibitors of the MMPs [75]. In contrast to other TIMP family members, TIMP-2 also has the ability to directly suppress the proliferation of endothelial cells [76].

Several other genes have also been implicated in invasion of the peritoneum. These include c-MET[23, 32], ITGB1 [38, 44, 77, 78] and CDH1 [61], which have been discussed previously under "Adhesion to the peritoneal surface".

The colonization phase — survival in the new niche

Sustaining proliferative signalling, enabling replicative immortality and evading growth suppressors

One of the most fundamental characteristics of malignant cells is their ability to sustain proliferation. Cancer cells can achieve this by various methods, such as producing growth factors and receptors for autocrine stimulation and by stimulating the tumour-associated stroma to deliver various growth factors [79]. Additionally, changing receptor and downstream signalling facilitates ligand-independent signalling, also leading to proliferation induction [13]. In this category, IGF-1, VEGF and HIF1α have been reported in PM.

Insulin like growth factor 1 (IGF-1)

IGF-1 is part of a family of peptides that play important roles in growth and development in mammals [80]. In a microarray study on PM and liver metastasis from CRC patients, IGF-1 mRNA was exclusively and fairly consistently overexpressed in PM when compared to liver metastasis [74]. Conversely, circulating levels of insulin-like growth factor binding protein 3 (IGFBP3), an endogenous antagonist of IGF-1, correlates with slower progression in patients with metastatic CRC [81, 82]. Both of these findings imply a role for IGF-1 in the formation of PM and underline that gene expression profiles differ per site of metastasis [74, 81].

Inducing angiogenesis

As with all cells, cancer cells are in need of nutrients for survival and 150–180 μm is the maximum distance at which these nutrients can diffuse from blood vessels. Beyond this distance the tumour cannot proliferate without active angiogenesis, since the resulting hypoxia induces apoptosis [13, 83, 84]. One of the mechanisms used by cancer cells to overcome this limitation is the induction of angiogenesis, a process in which genes like hypoxia inducible factor 1 (HIF1) and vascular endothelial growth factor (VEGF) play a role [13, 83, 85].

Hypoxia inducible factor (HIF) 1

Hypoxia within the tumour microenvironment can induce angiogenesis by release of HIF1, which regulates production of VEGF [83, 85].

In the same study discussed above, 20 colorectal adenocarcinomas and eight high-grade appendiceal adenocarcinomas were analysed for genome wide mRNA expression using oligonucleotide microarrays. Site-specific gene expression profiles were observed. A twofold upregulation of HIF1α specific for PM was noted in this cohort, next to TIMP-2 and IGF1, which were discussed above [74]. HIF1α has also been described as being upregulated in primary CRC when compared to normal mucosa [83].

Vascular endothelial growth factor and VEGF receptor (VEGFR)

VEGF has been extensively described as one of the most important angiogenic factors in solid tumours [13]. An IHC study of PM tissue samples from patients with adenocarcinoma of the appendix or colon demonstrated that higher VEGF expression was associated with a worse clinical prognosis. However, no significant correlation was noted between micro-vessel density and survival [86]. Mutations in VEGF, as well as the tumour suppressor gene p53 have been shown to play a role in metastasis of CRC [2]. About 50 % of patients with metastatic disease are known to be positive for both mutations in p53 and VEGF [2, 87]. VEGF targeted therapies are clinically widely used in combination with chemotherapeutic agents in patients with histologically confirmed CRC metastasis and measurable disease in the absence of absolute contraindications [87]. In a PM of CRC murine model, blocking of VEGFR with DC101, a VEGFR-2 specific antibody, has been shown to have a negative effect not only on angiogenesis but also on the proliferation of both tumour cells and endothelial cells, effectively showing significantly reduced intra-abdominal tumour burden and ascites formation [88–90].

Immune aggregates and VEGF

As an alternative mechanism for the pathogenesis of PM, one paper described the preferential attachment of malignant cells to immune aggregates in the omentum. In a murine model using several cell lines, including one OvCa cell line, these immune aggregates in the omentum were noted to have a complex network of capillaries with a high vascular density [91]. The mesothelial cells overlying these immune aggregates were observed to be hypoxic and VEGF-A production co-localized with these hypoxic regions. This mechanism was hypothesised to contribute to the survival of these tumour cells on the peritoneum, due to apparent constitutive readiness of the vasculature in the immune aggregates to expand [91, 92]. Interestingly, these immune

aggregates have also been observed in humans [93–97]. Theoretically, their presence and reported make-up could form a plausible explanation for the attachment of free cancer cells to these sites in the peritoneal surface.

Cysteine-rich protein 61 (Cyr61)

Cyr61, already referred to above, is a secreted matricellular protein that binds to integrins [98]. The connective tissue growth factor, cysteine-rich protein, and nephroblastoma overexpressed gene (CCN) family consists of six members that play a role in processes such as fibrosis, angiogenesis and wound healing [98]. Overexpression of Cyr61 in tumour cells has been linked to PM in pancreatic cancer [33]. Cyr61 is the ligand for the α5β3 integrin, described under "Attachment to peritoneum". Therefore, Cyr61 is known to activate both angiogenesis and cell–cell attachment related signalling pathways in PM [33].

Molecules such as CD44 and α5β3 have also been linked to angiogenesis in disseminated disease in several experiments [33, 61, 64]. These results are mostly based on comparative genomic hybridization and IHC (validation) studies in pancreatic, colorectal and OvCa.

Taken together, these findings support an important role of angiogenesis in the process of peritoneal dissemination. For this reason, interfering with angiogenesis has been investigated as a method for treating PM. In nude mice, inhibition of growth of PM of CRC was demonstrated when intra-peritoneally injected tumour cells were treated with the angiogenesis inhibitor TNP-470 [99]. TNP-470 inhibits methionine aminopeptidase type II, which causes proliferation of endothelial cells [99–101]. The TNP-470 treated mice in this study had significantly less tumour foci intraperitoneally, smaller tumours and a longer survival compared to the control group [99]. These effects are similar to those that have been reported in the aforementioned VEGFR-blocking experiments, suggesting that anti-angiogenic therapy holds promise in the treatment of PM.

A summary of the process of peritoneal dissemination and the proposed effects of the identified molecules in PM of CRC is depicted in Fig. 1. Of all the described molecules, albeit highly experimental, several show not

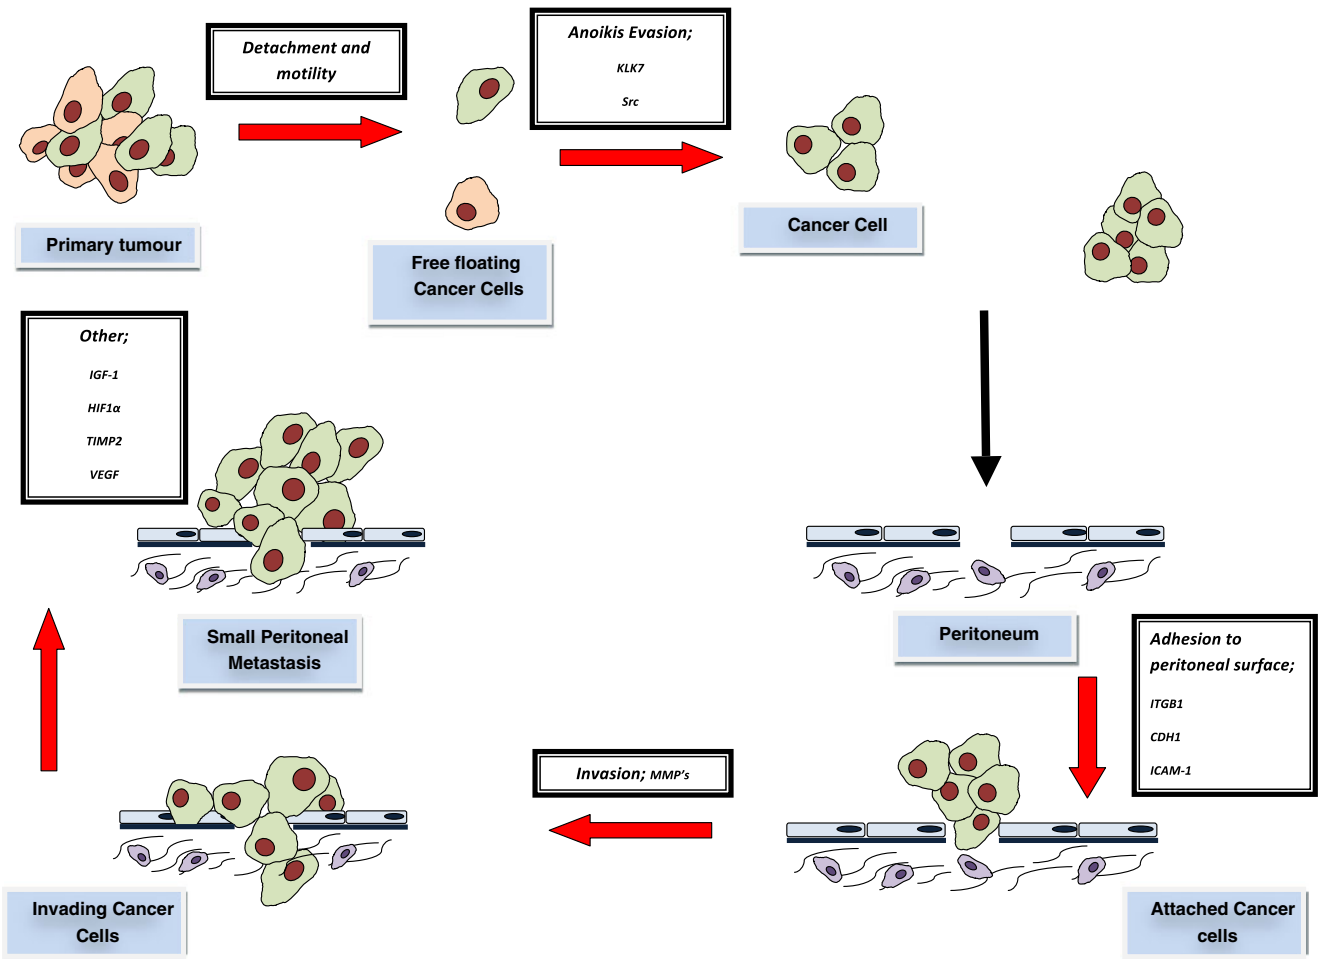

Fig. 1 Roles of the identified molecules in PM of CRC per dissemination step

only biological relevance, but have been shown to have either a prognostic effect in PM or hold promise as a therapeutic target in the future (Table 1).

Discussion

PM of CRC, but also other malignancies, form a serious threat for the patient's survival. While systemic drug therapy has only limited effect on the patient's outcome, the best option for changing the clinical course is aggressive surgery in combination with HIPEC. At least a subset of patients has been demonstrated to benefit from this approach. Yet despite the reported survival benefit reported after CRS and HIPEC in patients with PM of CRC, several unmet clinical needs still exist, mainly in the field of diagnostics. Basically, they fall apart into three topics. A first major issue is the challenge to be able to diagnose the presence of PM earlier, at a stage when the disease is less widespread. Secondly, there is a need for diagnostic tools to discriminate between patients who are likely to benefit from this intensive treatment, and those that will not, and thus would be exposed to the risk of

Table 1 Summary of targets with possibility for clinical implementation in PM in the future

Promising target in PM	Biological relevance in PM	Difference with CRLM	Prognostic relevance	Possible therapeutic implications
IGF-1	Growth factor	Yes, >2-fold change in mRNA [74]	Not clear	Monoclonal antibody Figitumumab [107, 108]
KLK7	Anoikis Evasion	Not clear	Yes, worse overall survival in CRC [45, 46]	Inhibition of KLK7 would lead to less evasion of anoikis [40]. However, interaction with α5β1 integrin, thus integrin inhibitors such as Volociximab may also be of interest [42, 43].
HIF1	Angiogenesis	Yes, >2-fold change in mRNA [74]	Not clear, trend was observed	HIF1 inhibitors could potentially be of interest in PM. HIF1 upregulation seems also to be specific for PM [74, 109]
VEGF	Angiogenesis	No	Yes, high VEGF expression correlated to worse survival [86]	Currently anti-VEGF antibody therapies already in use in clinical setting, very promising for clinical application [87].
Cyr61	Angiogenesis	No	Not clear	Is the ligand for α5β3. If possibility for blocking this interaction blocking of attachment to peritoneal surface ensues and subsequent angiogenesis is inhibited [33].
TWIST	Detachment and motility	No	Not clear	In experimental model blocking of TWIST showed less migration, invasion and adhesion to peritoneal surface. In theory powerful inhibition of PM formation [20].
c-MET	Detachment and motility	No	Yes, higher expression of c-MET correlated to worse survival [24]	In multiple experimental models blocking of c-MET showed marked inhibition of dissemination. Theoretically attractive therapeutic target [25].
EGFR	Detachment and motility	No	Not clear	Cetuximab is a clinical grade antibody already widely in use for metastasized CRC. No clinical data on specific EGFR inhibition in PM is available.
Integrins	Adhesion molecule	Not clear	Not clear	In multiple experimental models blocking of integrins showed marked inhibition of dissemination. Theoretically attractive therapeutic target [44, 77, 78]. Several integrin inhibitors currently under development [42, 43].
ICAM-1	Adhesion molecule	Not clear	Not clear	Highly experimental, dubious if therapeutically significant. Theoretically blocking of ICAM-1 leads to less PM due to less attachment to peritoneum [56].
Ep-CAM	Adhesion molecule	Not clear	Yes, higher expression of Ep-CAM correlated to worse survival [60]	Dubious if therapeutically significant. Theoretically blocking of Ep-CAM leads to less PM due to less attachment to peritoneum.
CD44	Adhesion molecule	Not clear	Yes, exon v6 variant in advanced disease [62, 63]	Highly experimental, dubious if therapeutically significant. Blocking of CD44 does not completely block attachment to peritoneum in experimental model [61].
MMPs	Proteolytic enzyme	No	Yes, higher expression of MMP7 in primary tumour independent risk factor for PM [16].	In experimental model, treatment with Batimastat showed inhibition of PM. However serious adverse events reported, thus no clinical studies to date [72].

morbidity and mortality of this treatment in vain. A third, but perhaps more remote goal, is to arrive, even in this disease state, to a more personalised approach. In an ideal situation the cytoreductive drugs used during HIPEC would be more in tune with the biological characteristics of the individual tumour, rather than the current "one size fits all" approach.

A common denominator in trying to achieve these goals is making use of relevant information on the biology of the disease process, because these biological mechanisms ultimately dictate the clinical phenotype. This biological information can be read out from patient samples at the DNA, RNA or protein level, but in principle also by molecular imaging modalities. These reporter molecules are then referred to as biomarkers. As the present review shows, the field of biomarkers for these three indications is still rather in its infancy. Most observations concern initial proof of concept studies, there is hardly any validation in independent series, and no prospective stratification studies yet. Most work has been done on retrospectively collected tissue samples, and limited efforts have been conducted to develop assays that would work in clinical diagnostic settings. Moreover, the field of molecular imaging of PM is still in its early days.

More specifically, with respect to biomarkers for early detection of PMs, several clinical studies have shown that a lower peritoneal cancer index (PCI) — i.e., the amount of PM present at the start of treatment — as well as the extent to which the surgeon has succeeded in removing all PM, are both strongly associated with disease outcome after CRS and HIPEC for PM of CRC [4, 10, 102]. Yet, detection of small lesions remains a challenge, making pre- and intra-operative assessment of the extent of PM difficult [12]. Recently, targeted imaging strategies have been applied in PM of OvCa by means of intra-operative tumour specific fluorescent imaging using a Folate Receptor-α-targeted fluorescent agent [103]. This allows for a more precise resection of small lesions that are otherwise overlooked [103]. Theoretically, similar approaches could work in PM of CRC, e.g., targeting molecules like EGFR and VEGFR. As for pre-operative imaging, alternative PET-tracers to 18-FDG could provide the additional accuracy needed for timely diagnosis of PM. However, challenges here also exist in the fact that the currently available pre-operative imaging modalities such as CT, PET and MRI come with technical limitations, such as a maximum resolution of the obtained image.

After meticulous analysis of the available literature we have to conclude that currently the only targets that have the potential to be assessed in a clinical setting in the near future are IGF1, TIMP2, HIF1 and VEGF. These are the only known targets to have been solely extracted by analysis of PM of CRC in two separate studies [74, 86]. It is also known that HIF1 regulates production of VEGF [83, 85], making VEGF, an even more interesting target. As to biomarkers for the prediction of response to CRS and HIPEC for PM of CRC — i.e., discriminating between patients that may and patients that probably will not benefit from the treatment — only VEGF has been reported to be associated with outcome after CRS and HIPEC [86]. Yet, all four markers currently lack enough promise for translation on short notice into a diagnostic test of use in a clinico-pathological setting in the assessment of material acquired from PM of CRC (Table 2).

With respect to personalised therapy approaches, currently little data exist on candidate biomarkers for prediction of response to mitomycin C (MMC), despite the fact that this drug has been around for quite some time. Interestingly, MMC based functional assays are used for the diagnosis of Fanconi anaemia, a rare hereditary disorder in which the function of one of several genes in the Fanconi pathway is disrupted. So far, however, no clear role for the Fanconi pathway has been established in CRC. Also, other biomarkers that may be associated with response to cross-linking agents have not yet been evaluated in CRC PM [104]. To date, established targeted therapies in CRC include drugs against EGFR, like Cetuximab, or anti-angiogenic drugs like Bevacuzimab. For the former drug, a number of biomarkers exist, of which KRAS mutation status is most established, while for the latter so far no good biomarkers have been established [105, 106]. Remarkably, most of the molecules involved have not yet been reported as having an effect on survival in PM of CRC, except for VEGF.

Table 2 Targets extracted from PM of CRC studies and possible clinical implications

Target expressed in HIPEC patient material from PM of CRC	Possible clinical implementation	Correlation with outcome of HIPEC patients after treatment with CRS and HIPEC
IGF-1 [74, 107, 108]	Therapeutic	Unknown
TIMP2 [16, 74]	Possible stratification tool	Unknown
HIF1 [74, 84]	Possible stratification tool Therapeutic	Unknown
VEGF [86, 87]	Possible stratification tool Therapeutic	Yes [86]

Areas for further investigation

The present review of literature suggests that there is opportunity for both discovery studies and further validation of the identified candidates for implementation in treatment stratification in patients with PM of CRC. Mainly the lack of genome-wide studies on well-defined patient cohorts poses an interesting avenue of research to identify other molecules possibly omitted by the thus far implemented candidate based approach.

Several other aspects of metastasis also require further elucidation. One of which is acquiring insight into the differences or similarities between the biology of primary colorectal tumours versus their corresponding metastases. Secondly, a better understanding of metastasis promoting features of the peritoneal environment itself, including tumour–stroma interaction.

Conclusions

Currently, several promising candidates have been identified that may have potential for use as a biomarker in PM of CRC, but all of these require extensive further validation. Therefore, rapid changes in clinical decision-making and therapy design based on current data would be premature. Yet, the pace of the omics revolution makes that the question is not *if* — but *when* — biomarkers will be introduced to improve diagnosis and ultimately outcome of patients with PM due to CRC. This will certainly have the potential for a significant reduction in treatment related morbidity and mortality in this population by bringing the right treatment to the right patient.

Conflict of interest The authors declare that they have no conflict of interest.

REVIEW AND PERSPECTIVES

EML4-ALK testing in non-small cell carcinomas of the lung: a review with recommendations

Abstract In non-small cell lung cancer, epidermal growth factor receptor gene mutations and anaplastic lymphoma kinase (ALK) gene rearrangements have a major impact upon the level of response to treatment with specific tyrosine kinase inhibitors. This review describes the molecular basis of ALK inhibition, summarizes current data on the effectiveness and safety of ALK inhibition therapy, describes the different testing methodologies with their advantages and disadvantages, provides a suggested testing algorithm and puts forward a proposal for an external quality assessment program in ALK testing.

Introduction

In 2008, lung cancer was the most commonly diagnosed cancer and caused the highest number of cancer-related deaths [1]. Currently, only 10–15 % of lung cancer patients will be cured [2]. Strategies to maximize treatment benefit have centred on individualizing treatment according to the molecular profile of the disease [3, 4]. Mutations of the epidermal growth factor receptor (EGFR) gene have a major impact upon the level of response to treatment with tyrosine kinase inhibitors [5]. In addition to mutations in the EGFR gene, alterations in hepatocyte growth factor receptor (MET), vascular endothelial growth factor (VEGF), VEGF receptor, GTPase KRAS (KRAS), receptor tyrosine protein kinase erbB-2 (HER2), echinoderm microtubule-associated protein-like 4-anaplastic lymphoma kinase (EML4-ALK), phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha isoform, serine/threonine protein kinase B-raf, insulin-like growth factor 1 receptor [6], ROS1 [7], and the KIF5B and RET fusion gene [8, 9] have also been implicated as oncogenic drivers in the pathogenesis of non-small cell lung cancer (NSCLC), especially adenocarcinoma.

In 2007, Soda et al. [10] reported that a small inversion within chromosome 2p results in the formation of a fusion gene comprising portions of the EML4 gene and ALK in NSCLC cells. A recently developed MET inhibitor (PF-02341066, crizotinib; Pfizer) was shown to also inhibit ALK [11, 12]. Phase I [13, 14] and II [15, 16] studies have revealed encouraging data [14], leading to an accelerated approval of crizotinib by the FDA in August 2011 [16]. Pathologists will play a key role in the identification of aberrations of ALK in NSCLC. The aim of this article is to provide information on how ALK alterations in NSCLC can be detected, with an emphasis on the uncertainties regarding methodology.

Molecular basis of ALK inhibition therapy

Transforming rearrangements of the ALK gene were first identified in anaplastic large cell lymphomas [17, 18], and subsequently in inflammatory myofibroblastic tumours [19] and a subset of NSCLC [10]. An inversion event on the short arm of chromosome 2, resulting in the fusion of ALK gene with the EML4 gene locus, is the most common aberration of the ALK gene in lung cancer (Fig. 1) [10]. This rearrangement leads to the production of a chimeric protein, which has constitutive ALK kinase activity [14]. Over ten EML4-ALK variants have been identified in lung cancer so far, as well as other fusion partners TFG and KIF5B [20]. In addition, as single fluorescence in situ hybridization (FISH) signals (3′) are also associated with a positive response to crizotinib treatment, it seems that small deletions of 5′ end of the ALK gene may also occur [14, 21].

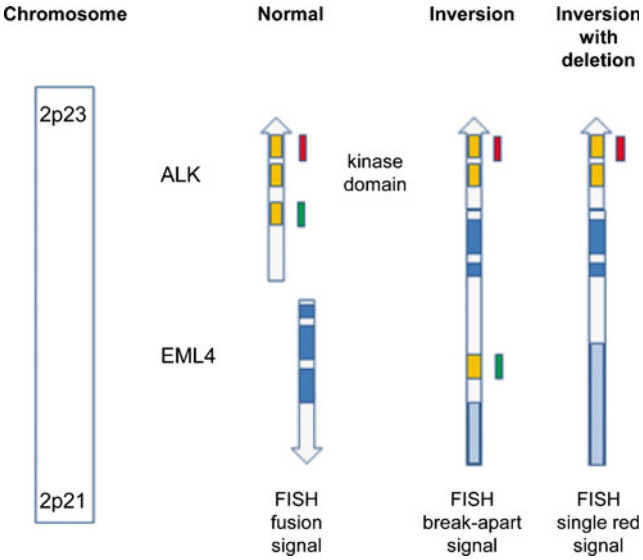

Fig. 1 Signal pattern of Vysis ALK Break Apart FISH Kit. ALK and EML4 are located on chromosome 2p21–2p23. Note that EML4 is normally on the opposite strand to ALK, and that both probes on the ALK gene (*red orange* and *green*) are close together, explaining the FISH fusion signal. The EML4-ALK fusion gene is the result of an inversion of the N-terminal portion of EML4 with the kinase domain of ALK [10]. This inversion leads to an increased distance between the red orange and green probes. A deletion of the proximal part combined with the inversion explains the single red orange signal. The EML4-ALK fusion protein has a fully functional ALK kinase domain and has gain-of-function properties [5, 10]. Cells are considered ALK FISH positive when there is: (1) ≥1 set of red and green signals that are ≥2 signal diameters apart, or (2) a single red signal without a corresponding green signal in addition to fused (normal) signals. A sample is considered negative if <5 cells (<10 %) are positive and positive if >25 cells (>50 %) are positive. A sample is considered equivocal if 5–25 cells (10–50 %) are positive

Current estimates suggest that the EML4-ALK fusion is present in approximately 3–6 % of adenocarcinomas, depending upon on the population studied and the ALK detection methods used [22, 23].

Clinical characteristics associated with the EML4-ALK gene fusion are adenocarcinoma histology, never/light smoking history and younger age [24–26]. However, these characteristics are not shared by all carriers. The ALK fusion has also been detected in older patients (aged 76 years) with a smoking history [24]. Therefore, clinical characteristics are insufficient and molecular testing is necessary to determine ALK status [27].

ALK-positive tumours have been detected in all histological subtypes of adenocarcinoma, but especially in solid signet-ring cell and mucinous cribriform patterns [24, 28–31].

Effectiveness and safety of ALK inhibition therapy

Crizotinib is the most advanced ALK inhibitor in clinical development [3]. In ALK-positive patients (n=119), an

overall response rate (complete responses + partial responses) of 61 % (95 % CI, 52–70 %), a clinical benefit rate (complete responses + partial responses + stable disease) of 88 % and a preliminary median progression-free survival of 10 months (95 % CI, 8–15 months) have been shown [13]. The median overall survival has not been reached. In a retrospective case-match analysis, Shaw et al. [32] found that ALK-positive NSCLC patients had a longer overall survival rate after crizotinib as second- or third-line therapy. Crizotinib seems to show poor penetration of the blood–brain barrier [33].

Crizotinib is well tolerated, with reported treatment-related adverse events of nausea (46 %), vision disorder (45 %), vomiting (39 %) and diarrhoea (29 %), mostly of grade 1/2. Grade 3/4 adverse events were reported in 15 % of patients (mostly increased alanine aminotransferase, dyspnoea and neutropenia) [13].

A proportion of ALK-positive patients with NSCLC (in most studies <10 %) continue to show progressive disease in spite of crizotinib treatment [15, 34]. Several mechanisms of resistance have been suggested to explain this lack of efficacy: (1) ALK kinase domain mutations (found in 4/11 samples); (2) copy number gain of the ALK gene rearrangement (found in 2/11 samples); (3) EGFR/KRAS mutations (found in 3/11 samples) [35]. Some patients never showed (intrinsic resistance) and some initially showed (acquired resistance) a response to treatment [35].

Neither percentage of positive cells nor signal copy number appears to be predictive of benefit from ALK inhibition treatment [21]. In other words, using ALK FISH, there is no greater likelihood of a treatment response to crizotinib in a patient with a sample showing nearly 100 % positivity than for a patient with a sample showing just above the positivity threshold. However, it is still important to know the percentage of positive cells to determine whether the threshold has been reached.

Detection of ALK gene rearrangements

Increasing availability of targeted agents with selective biomarkers has introduced new challenges in NSCLC diagnosis [36]. Issues related to small sample diagnostics, the interaction between pulmonologists and pathologists, tissue management and required clinical information have recently been described [37]. Current diagnostic approaches to detect ALK rearrangements include immunohistochemistry (IHC), FISH and reverse transcriptase polymerase chain reaction (RT-PCR). Unpublished information from pilot studies suggests that ALK fusions may be demonstrated with massive parallel sequencing. However, sufficient details for an adequate comparison with FISH are currently lacking.

Tissue management

With personalized tumour medicine in mind, tissue sample size should be maximized whenever feasible. In addition, tissue handling, processing and sectioning should be standardized to minimize wastage and optimize use of tissue for staining procedures and PCR-based molecular tests. Histological and cytological specimens are both potentially suitable for ALK testing. Currently, the only clinically validated test to determine ALK status is the Vysis/Abbott ALK FISH break apart test. However, this test and the interpretation algorithm are only designed and validated for histopathological use on intact formalin-fixed paraffin-embedded (FFPE) tissue biopsies or resection specimens. If cytological material is to be used, laboratories must take steps to validate their testing methodology.

Tumour tissue should preferentially be taken from metastases if access is less dangerous. Sampling of these sites ensures that the more important fraction of total tumour cell burden is collected. Furthermore, potential heterogeneity problems within the primary tumour are avoided when sampling metastases.

Standardized tissue and cell processing

Tissue handling steps have recently been described [37]. While so-called ‘reflex’ IHC and molecular testing provides a rapid diagnosis, it should be avoided if tissue resources are marginal. In anticipation of obligatory biomarker testing, an algorithm for reflex block cutting could be employed.

If the initial tissue sample is small, some (three to four) additional sections (extra spare cut sections) may be taken to avoid tissue loss by recutting. The quality of some epitopes and DNA/RNA may be lost (within hours/days) when sections are not immediately used [38–40]. Various treatments for the cut sections may prevent oxidation [37].

An algorithm that laboratory staff may find useful when handling lung biopsies is presented in Electronic supplementary material (ESM 1).

Clinical diagnostic tests

IHC

Immunohistochemical detection of the ALK protein has considerable potential as a screening tool to test NSCLC samples for ALK rearrangements. The biological premise is that the translocation or inversion of part of the ALK gene with its numerous possible partners leads to over-expression of the ALK protein, and therefore overactivity of the ALK tyrosine kinase. This protein ALK tyrosine kinase is the target of crizotinib. It therefore makes sense to assess the drug target directly.

IHC has several advantages over either an ISH method (especially when based on fluorescent probes) or an approach based upon mRNA (RT-PCR) to detect the actual rearrangement. These advantages are that it is cheap, rapid and easily integrated into a diagnostic protocol and familiar to all pathologists. Although IHC is only minimally quantitative, in practice it is used as a semiquantitative test [41]. However, challenges with IHC are: (1) the tissue preparation; (2) the choice of antibody; (3) the signal enhancement system; (4) the scoring system.

Pre-analytical phase Currently, the role that pre-analytical issues, like fixative and duration of fixation, may have on ALK epitope preservation has not been evaluated. However, compared to what has been observed for other antibodies [39], here the pre-analytical steps appear to be particularly critical and mistakes are irremediable. False-negative cases may be due to poor fixation. Such issues may be of particular concern in surgically resected tumours, where a gradient in positivity can be observed due to the gradient in fixative penetration in the sample [42]. Ultimately, any test for abnormal ALK genes in NSCLC is likely to be most important in small biopsy or cytology samples, where intra-sample heterogeneity is less likely to be appreciated because fewer cells are present, but where the possibility of heterogeneity of expression may lead to a false-negative test.

Analytical phase One of the particular challenges in IHC detection is that the protein concentrations in ALK-rearranged NSCLC are relatively low. Standard detection methodology, as used in the identification of ALK-rearranged anaplastic lymphomas, is inadequate for the detection of all cases of ALK-rearranged NSCLC. Currently, there are three primary antibodies commonly referred to in the published literature; clone 5A4 (Novocastra, Leica, but also available pre-diluted from Abcam), ALK1 (Dako) and D5F3 (Cell Signalling Technology). Experience with the first two antibodies is widest, and more success (and excellent comparison with the outcome of FISH testing for the rearrangement) has resulted from their use with detection systems with a substantial degree of signal amplification (Leica/Novocastra Novolink, Dako Advance, Tyramide, Envision+, Ventana i-view). For more details, see Tables 1 and 2. If using FISH as the gold standard, use of these antibodies in this way has resulted in both a very high negative predictive value (all IHC-negative cases are also FISH-negative) and high positive predictive values (90–100 % probability of being FISH positive when IHC is strongly positive) [23, 24, 43–51]. For more details, see "Concordance between IHC and FISH" section. Good concordance has also been shown between RT-PCR and the antibodies ALK1 [22, 44] and 5A4 [45]. With current knowledge, all IHC positive (+/++/+++) cases would be best screened with FISH to confirm probable rearrangement.

In the literature (Table 1) and in the experience of the authors, there is some variation in the best concentrations of various primary antibodies and the antigen retrieval methodology. Personal experience with the 5A4 clone has found better results with pH6- when compared to pH9-buffered solution.

Comparing primary antibodies is very difficult since there are few published studies with comparative data. One study did compare the D5F3 clone with the ALK1 clone and found the former far superior [49], but the latter was not used with any special detection amplification. At this moment, it is very difficult to reach a conclusion from the literature; there may be a marginally better performance from the 5A4 clone when compared to the ALK1 clone, borne out by anecdotal experience, but it must be emphasized that other variations in study methodology make comparison problematic.

Post-analytical phase In NSCLC, ALK-rearranged staining is cytoplasmic. It may have a granular character, and in some cases there may be membrane accentuation. Opinions differ as to the degree of staining heterogeneity that may be encountered. Whilst some assert that it is generally homogeneous in tumours, others, including the authors, have certainly seen variation in staining intensity in sections of surgically resected tumours (see comment above regarding fixation).

One of the most neglected issues in the literature is the question of definitions of degree of staining. Many studies do not even indicate how different grades of staining were defined. There is no clear consensus on this matter. Prospectively, it may be of value to determine a so-called histoscore (H-score) utilizing the proportion of tumour cells showing each different intensity (+, ++ and +++) of staining. Assessment of staining intensity is very subjective. The use of successive microscope objectives with related spatial resolutions as a physical aid in establishing intensity (as first applied on HER2 by Ruschoff et al. [50]) may lead to more uniformity in intensity scoring. Strong staining (+++) is clearly visible using a ×2 or ×4 objective, moderate staining (++) requires a ×10 or ×20 objective to be clearly seen, whilst weak staining (+) cannot be seen until a ×40 objective is used. This approach is called the modified H-score. Frequently used scoring systems are presented in Table 2.

For the time being, the modified H-score is recommended because it will allow sufficient detail for comparison with other studies. It may turn out that a more simplified scoring system is suitable as well. Ultimately, studies are required where prospectively determined IHC scores can be directly related to clinical outcomes in patients treated with crizotinib.

Table 1 IHC protocols described in the literature

	Antibody	Source	HIER	Dilution	Incubation	Detection system
Yi et al. [46]	ALK1	Dako	EDTA, pH 8, 30 min	1/100	30 min at RT	Advance (Dako)

[a] For anaplastic large cell lymphomas

[b] For lung adenocarcinomas and inflammatory myofibroblastic tumours

Pathologists should be aware of various artefacts that may lead to false-positive staining; these are generic issues, not necessarily specific to ALK IHC. The possibility of false-negative tests can be guarded against, at least to some extent, by the use of positive control material with every test staining run. Such material may not be readily available, and it is important that the control material is from ALK-rearranged NSCLC or similar and has the same levels of ALK protein epitopes. ALK-rearranged lymphomas are not suitable as a control because he protein epitope level is much higher than in NSCLC, thus giving false confidence of sufficient staining.

Table 2 IHC scoring systems

	Score			
	0	1+	2	3
Yi et al. [46]	No staining	Faint cytoplasmic staining	Moderate smooth cytoplasmic staining	Intense granular cytoplasmic staining in ≥10 % of tumour cells
Kim et al. [27]	No staining	Faint or weak staining intensity with >5 % tumour cells or any staining intensity with ≤5 % tumour cells [a]	Moderate staining >intensity with >5 % tumour cells [b]	Strong and granular staining intensity with >5 % tumour cells [c]

[a] Average of 14.7 % positively stained cells

[b] Average of 58.2 % positively stained cells

[c] Average of 97.3 % positively stained cells

FISH

The majority of clinical studies examining ALK mutations have used FISH. In the USA, prescription of crizotinib is dependent upon the use of the Vysis ALK Break Apart FISH Probe Kit (Abbott Molecular, Inc.) [16]. Although FISH can be performed on FFPE tumour specimens and detect multiple ALK fusion variants [28], there are various challenges related to the FISH technique, e.g. the break apart red and green signals indicating ALK rearrangements (Fig. 2) can be subtle and occasionally difficult to recognize.

Pre-analytical phase A protocol for cytology is provided in ESM 2.

Processing and sectioning—For an effective procedure for surgical specimens, it is recommended that embedded tissues do not exceed 2 cm in length and 3 mm in thickness. Samples should be processed according to a standard protocol.

In practice, ALK testing works well on 3- to 5-μm sections. A minor preference exists for a thickness of 5 μm. Sections should be mounted on coated slides to prevent cleavage artefacts and washing off during the procedure. Sections should be dried at 60 °C for 1 h or at 45 °C overnight.

The maximum storage time for tissue or cell block sections should be 1–6 months (based on the authors' experience) and 6–12 months for conventional cytological specimens [52] to avoid hybridization failure and either false-negative or false-positive results. A protective coating

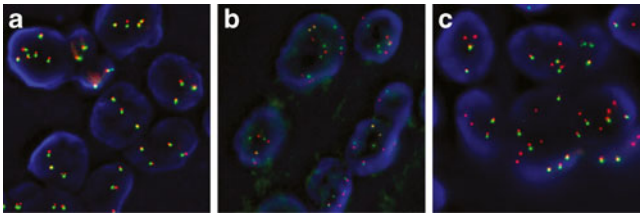

Fig. 2 Representative examples of ALK FISH findings in three pulmonary adenocarcinomas (Vysis ALK Break Apart FISH probe). All three carcinomas show increased ALK copy number. **a** Normal signals, no rearrangement. Note that some of the signals are fused and produce a yellow signal, while others have *green* and *red* signals in close proximity. **b** One or two break apart signals per nucleus, indicative of inversion. **c** Single red signals, indicative of inversion and deletion. Note that the cancer cells in **b** and **c** contain both rearranged and normal ALK signals. Cells are considered ALK FISH positive when there is: (1) ≥1 set of red and green signals that are ≥2 signal diameters apart, or (2) a single red signal without a corresponding green signal in addition to fused (normal) signals. A sample is considered negative if <5 cells (<10 %) are positive and positive if >25 cells (>50 %) are positive. A sample is considered equivocal if 5–25 cells (10–50 %) are positive

of paraffin to histological sections prevents loss of antigenicity caused by photo-oxidation and drying of the tissues [37]. In order to avoid problems of irregular or background staining of histological specimens, it is essential to deparaffinize the samples properly [37].

Relocation of tumour cells by a software-driven automated stage is highly desirable for 'restrained' cytological specimens with a tumour cell proportion of <50 %. This allows precise distinction of the tumour cells from admixed benign cells and facilitates review of the results at the microscope.

Analytical phase

Method—Use of diagnostic kits certified by the FDA (Abbott Vysis ALK Break Apart FISH Probe Kit, Abbott Molecular, Inc.) is recommended. The package insert contains a detailed protocol of the technical procedures and interpretation. In practice, the Vysis kit has some limitations: (1) appropriate optical filters are required for the probes used; (2) the green signal may fade earlier than the red signal, increasing the likelihood of false-positive single-red signals. Other, not yet FDA-approved, FISH assays are commercially available (e.g. ZytoLight® SPEC ALK/EML4 TriCheck™ Probe, ZytoVision). Every assay should undergo validation in the laboratory before clinical implementation. This validation can be conducted with five to ten positive and five to ten negative cases. The results are compared with a reference centre, and concordance of at least 95 % should be obtained. In addition, laboratories should participate in external quality assessment schemes as soon as they become available. When a laboratory authorized to conduct FISH adopts another bright-field ISH for diagnostic purposes, an internal validation can be conducted in the laboratory comparing the new technique with FISH. Again, a concordance of 95 % must be obtained. This 95 % threshold may change in time, after more experience is gained with the external quality assessment. The use of standardized kits requires strict adherence to the manufacturers' instructions, i.e. without any deviation.

A minimum norm for ALK experience is not known yet, but for Her2 it was suggested that at least 150 ISH cases per annum (minimum of 100 breast and 50 gastric cases by ISH per annum) would be the optimal volume to ensure quality and cost effectiveness [53] (see "Proposal for an external quality assessment program" section).

The number of annual tests considered optimal for guaranteeing the technical sufficiency of a laboratory is 150 ISH tests on any type of tumour [51]. Analysis of complete histological sections is recommended in order to minimize signal loss on the Z-axis. In FISH procedures, it is essential to use fluorescence filters with excitation and emission wavelengths appropriate to the fluorochromes of the probes contained in the kit.

Controls—With ISH techniques, the case for study serves as a control when consistently presenting signals, both in tumour cells and in the accompanying normal cells. Nevertheless, the use of separate controls is strongly advised. A pre-hybridization assessment of digestion is useful in difficult samples (e.g. very small biopsies with low tumour content).

Post-analytical phase

Assessment of the results—A pathologist should interpret the results. When other persons score the specimens, they should be well trained and experienced in histo- and cytomorphology. In such a case, a pathologist should coordinate, validate, review and sign off the interpretation. A total of 50 nuclei should be scored using an epifluorescence microscope equipped with a DAPI, a Spectrum Orange, Spectrum Green and double-filter set, using a ×60–100 oil immersion objective lens. The spectral orange probe is mostly called the 'red probe/signal' in the literature, and this terminology has been used throughout the manuscript.

Assessment must be conducted exclusively on nuclei with sufficient hybridization quality, in a consecutive

manner, and with the microscope focus adjusted to each nucleus in order to correctly identify all the signals present in the nucleus of the cells.

When conducting FISH as an ISH technique, given the difficulty of dark-field assessment, the following are recommended:

a. Cells are considered ALK FISH positive when: (1) at least one set of red and green signals have a distance between the signal borders of ≥2 diameters of the largest of the two signals (break apart of the two differently coloured probes indicates gene fusion by inversion), or (2) when there is a single red signal without a corresponding green signal in addition to fused (normal) signals (indicating gene fusion by inversion and deletion) (Figs. 1 and 2). Note that a single green signal without a corresponding red signal is considered negative. Similarly, an increased copy number of non-rearranged ALK genes with fused signals corresponds to polysomy of chromosome 2 or ALK amplification, but is negative for rearrangement.
b. A sample is considered negative if <5 cells (<10 %) are positive and positive if >25 cells (>50 %) are positive.
c. A sample is considered equivocal if 5–25 cells (10–50 %) are positive. In this case, a second reader should evaluate the slide. If the average of the two readings contains at least 15 % positive cells, the sample is considered ALK FISH positive. It should be kept in mind that the digestion time needs to be adjusted for some samples. Examples of typical FISH findings are shown in Fig. 2.

During interpretation, the spatial distribution of the distance between the two signals in the *Z*-direction also needs to be taken into account. In cases of only one signal, adjusting the plane of focus (by turning the microscrew) is frequently necessary when using the conventional FISH microscope. An advantage of a digitized automatic FISH analysis system is that fluorescent images may be compressed in the *Z*-direction (*Z*-stacks), often making this automated stage more convenient than live microscopy. The presence of all signals in one horizontal plane facilitates scoring and review, and allows permanent documentation. In our experience, a positive scoring result that cannot convincingly be illustrated by fluorescence photography is of questionable value.

Cytological specimens offer the advantage of analysing entire cells/nuclei containing all chromosomal signals. Instead, a part of the nuclei in histological tissue sections are truncated, leading to a lower number of fluorescence signals, and this effect depends on the section thickness.

Note that in most ALK-positive samples, not all alleles are abnormal (e.g. only one in a disomic cell or one or two in tetrasomic cells). Typically, there is one predominant type of rearrangement in one sample (either break apart or deletion). Great variability in signal patterns within one sample might suggest technical artefacts.

There is evidence that ALK rearrangements are truly diffuse rather than heterogeneous within ALK-positive tumours [21, 54]. First, IHC typically shows diffuse ALK expression in ALK-positive tumours [47, 55]. Second, the distribution of cell positivity by FISH is diffuse; there are no discrete foci of ALK rearrangements within a tumour [21, 54]. This suggests that any observed variability is not biological, but rather caused by technical factors.

Given the presumed homogeneous distribution of ALK rearrangements, the percentage of FISH-positive cells in an ALK-positive tumour lying between 20 and 80 %, and not reaching 100 % may appear contrary. The ‘single red’ signal is found in a higher fraction of tumour cells than the ‘break apart’ signal [21]. This discrepancy can readily be explained by the distribution of signals in three-dimensional space and their projection by the assessing pathologist to the horizontal plane. A separated signal can be located anywhere on a virtual sphere around the other signal. In a disomic tumour cell with one rearranged ALK gene copy, the probability of detecting break apart signals in the two-dimensional projection may therefore not exceed 25–30 %.

In the authors' experience, the minimum number of tumor cells required in histological specimens is at least 100, as approximately half will not be stained with the fluorescence probes for reasons related to the stereological analysis. Less than 40 tumor cells/neoplastic nuclei with FISH signals are unreliable for determining positivity.

Increased ALK gene copy number (3 to >6 gene copies), which is mostly due to polysomy of chromosome 2, has been reported in 80 % of NSCLC [56]. In cases of polysomy, one rearranged signal per nucleus is sufficient for a ‘positive’. High gene copy number of non-rearranged ALK does not appear to influence response to crizotinib. A possible predictive value of the copy number of the rearranged ALK gene in tumour cells and its influence on the

level of ALK protein expression remains to be investigated.

Overall, interpretation of the ALK FISH analysis is more complex than for other FISH assays, e.g. with amplifications or interchromosomal translocation. This is due to the fact that: (1) fusion inversion occurs on the same chromosome arm—in contrast to fusion processes in SYT-SSX and BCR-ABL FISH tests, for example, where genes from different chromosomes are involved; (2) in some ALK wild-type cells (especially with larger nuclei or after prolonged digestion) the red and green signals may be slightly separated and the fusion to yellow fluorescence is not apparent; (3) the process of cutting and subsequent signal separation may lead to a low number of false-positive break apart signals in cells without the ALK fusion. These characteristics mean that a low threshold of positive cells can still select patients who will react to ALK inhibitor treatment. However, this complexity highlights the need for specific training and experience with ALK FISH.

Personnel—The number of laboratory technicians who conduct tests and the number of pathologists who interpret them must be as low as possible in order to guarantee the effectiveness of the undertaking. Both the technicians and the pathologists must have undergone training. For assessing the post-analytical (interpretation) phase, correlation with the reference result of at least 95 % in 10–20 cases is recommended. Periodically, the aforesaid training should be refreshed in dedicated working sessions.

Report—While the report should be adapted to the different information systems used in different hospitals, it must include, at minimum, the data presented in Table 3. The recommended turnaround time is <7 working days.

FISH is not feasible in all laboratories and the results are not always clear. McLeer-Florin et al. [48] reported that 19 % of cases analyzed by FISH were not interpretable.

Concordance between IHC and FISH

The results from the three larger FISH/IHC concordance studies have shown that in FISH-negative cases, IHC is always negative (i.e. 100 % concordance) [46, 47, 57]. This complete concordance is also seen between a positive FISH result and an IHC 3+ score [46, 47, 57]. Very good concordance levels between FISH and IHC have also been demonstrated by Jokoji et al. [58]. McLeer-Florin et al. [48] also found good concordance between FISH and IHC. In their research, the Novocastra 5A4 antibody was used. The authors suggested using IHC to evaluate the cases that were not interpretable by FISH.

Some of the panel have had different experiences: namely that it is possible to have a sample that is IHC 3+ and FISH negative. In one such patient, a response to Crizotinib was seen (E.T.). Also a sample may be FISH positive and IHC negative. Some discordant results have been observed in tumours expressing ALK with a weak (1+) to moderate (2+) signal. Table 4 provides a summary of published articles comparing ALK analysis by FISH and IHC.

PCR-based molecular assays

RT-PCR provides a highly sensitive technique in which a very low copy number of RNA molecules can be detected. As for EML4/ALK the forward and backward primers are

Table 4 Summary of published articles comparing ALK analysis by FISH and IHC

Reference	Antibody	Source	Detection method	Samples, *n*	ALK+		ALK−		Comments
					FISH	IHC	FISH	IHC	
Shaw et al. [25]	ALK1	Dako	n.a.	NSCLC, 141	19 (13 %)	19 (13 %)	n.a.	n.a.	Only FISH+ cases were confirmed with IHC
Boland et al. [44]	ALK1	Dako	n.a.	NSCLC, 335	6 (1.8 %)	6 (1.8 %)	n.a.	n.a.	The 6 cases testing positive using IHC were positive with FISH. 8 of the IHC ALK− cases were also tested using FISH. All were negative
Rodig et al. [24]	ALK1	Dako	EnVision +	Adeno, 358	20 (5.6 %)	n.a.	n.a.	n.a.	8 of the 10 FISH ALK+ cases with sufficient tissue were also IHC ALK+ (sensitivity=80 %); 1 case ALK– by FISH was ALK+ by IHC
Mino-Kenudson et al. [49]	ALK1	Dako	EnVision +	Adeno, 153	22 (14.3 %)	n.a.	n.a.	n.a.	Sensitivity and specificity of IHC were 67 and 97 %, respectively
	D5F3	Cell ST	EnVision +	Adeno, 153	22 (14.3 %)	n.a.	n.a.	n.a.	Sensitivity and specificity of IHC were 100 and 99 %, respectively
Yi et al. [46]	ALK1	Dako	Advance	Adeno, 101	10 (9.9 %)	11[a] (10.9 %)	91 (90.1 %)	90[a] (89.1 %)	Of the 10 FISH+ cases, 8 were IHC 3+, 1 was IHC 2+ and 1 was IHC +; of the 91 FISH– cases, 2 were IHC 2+, 20 were IHC 1+, 69 were IHC 0; sensitivity and specificity[a] of IHC were 90 and 97.8 %, respectively
Paik et al. [47]	5A4	Novocastra	i-view	NSCLC, 453	19 (4.2 %)[a]	26 (5.7 %)	434 (95.8 %)	427[a] (94.3 %)	Of the 19 FISH+ cases, 16 were IHC 3 +, 3 were IHC 2+; of the 434 FISH− cases, 7 were IHC 2+, 14 were IHC 1 +, 413 were IHC 0; sensitivity and specificity[a] of IHC were 100 and 92.5 %, respectively
Mitsudomi et al. [64]	5A4	Santa Cruz	EnVision +	NSCLC, 345	n.a.	12 (3.5 %)	n.a.	n.a.	All these 12 IHC ALK+ cases were also FISH ALK+; all IHC ALK– cases were also FISH ALK–
Martinez et al. [65]	D5F3	Cell ST	n.a.	NSCLC, 71	6 (8.5 %)	n.a.	n.a.	n.a.	All FISH ALK– negative cases were also IHC ALK–. 4/6 FISH ALK+ cases were also ALK IHC+; 1 case was IHC ALK–; 1 sample could not be analysed.
Paik et al. [66]	5A4	Novocastra	n.a.	NSCLC, 735	28 (3.8 %)	35 (4.8 %)	707 (96.2 %)	700 (95.2 %)	Of all cases, 15 were IHC 3+, 20 were IHC 2+, 20 IHC 1+, 700 were IHC0; all IHC0/1+ were ALK FISH–, all IHC 3+ cases were ALK FISH+, and 13 of the 20 IHC 2+ were FISH+; sensitivity and specificity[a] of IHC were 100 and 96.2 %, respectively
				Adeno, 395	27 (6.8 %)	n.a.	368 (93.2 %)	n.a.	
McLeer-Florin et al. [48]	5A4	Abcam	i-view	Adeno, 441	n.a.	29 (6.5 %)	n.a.	n.a.	Of 81 cases with interpretable IHC and FISH results, 21 were FISH ALK+; of these 21 cases, 19 were IHC ALK+ and 2 were IHC doubtfully positive; of the 60 FISH ALK– cases, 1 was IHC ALK+ and 59 were IHC ALK–
Yang et al. [43]	ALK1	Dako	Advance	Adeno, 300	22/216 (10.2 %)	32 (10.7 %)[a]	194/216 (89.8 %)	268 (89.3 %)	All IHC 0 cases were FISH ALK– and all IHC 3+ were FISH ALK+; 96.9 % of IHC 1+ cases were FISH ALK− and 85.7 % of IHC 2+ cases were FISH ALK+

IHC scores of 0 and 1+ are regarded as negative; scores of 2+ or 3+ as positive

[a] Using FISH as the gold standard

complementary to gene fragments, which are normally on opposite strands, the specificity is high. RT-PCR can be used on mRNA/cDNA to directly detect EML4-ALK; hence, it does not suffer from the problems inherent in interpreting FISH or IHC. Therefore, it has been used as a gold standard to assess the sensitivity and specificity of IHC [55], FISH [55, 59] and CISH [27, 59]. It has also been used as a stand-alone test instead of FISH or IHC [60].

However, RT-PCR has several disadvantages that make it unlikely to become the standard test for this mutation. Firstly, good quality RNA is required [59]: some of the amplicons are more than 1,000 bp in size and require proper cryopreservation of tumour samples that may be lacking in routine practice [55]. In FFPE sections, RT-PCR above 300 bp is not reliable. Secondly, multiplex systems are required because of the wide variations in fusion types [59]. Thirdly, only known alterations can be tested (at least 10 are currently known for ALK) [20]. Furthermore, the clinical relevance of multiplex RT-PCR is unclear because so far in all clinical trials FISH has been used to identity ALK-positive patients. RT-PCR is included in the diagnostic algorithm proposed by Just et al. [55], but only after IHC and FISH have been performed, and only as a source of further information on the ALK fusion variant and expression level, rather than for diagnosis.

RT-PCR for ALK mutation testing is being offered by some commercial vendors (e.g. Response Genetics, Inc., in the USA); however, it is not clear how reliable these tests are. The panel strongly suggested that any such tests should involve pathologists early in the development and should be diagnostically orientated.

Testing algorithm

In the National Consensus from Spain [61], ALK rearrangement testing is recommended in patients with advanced NSCLC who are negative for the EGFR mutation (all histological subtypes in non-smokers; non-squamous-cell carcinoma subtype in current or ex-smokers). In contrast, the most recent NCCN guidelines (version 1.2012) [62] recommend ALK rearrangement testing concurrent with EGFR mutation testing for adenocarcinomas, large cell carcinomas and NSCLC NOS. This differs from recent guidelines in Switzerland [63] and France (French National Cancer Institute; INCa) [48] proposing ALK testing only by FISH and only in EGFR-negative KRAS-negative adenocarcinoma patients.

Since phase II and III clinical trials with crizotinib in ALK-positive patients have used FISH, this technique should be considered the ‘gold standard’ for determining ALK positivity. However, following successful validation with large series and different antibodies, IHC could also become a good screening method.

The authors agree that more data for an evidence-based algorithm are needed. It is possible that the algorithm presented in Fig. 3 may in the future be the algorithm of choice.

Proposal for an external quality assessment program

For optimal ALK mutation testing in NSCLC, the quality of the sample, the analytical procedure and the reporting of the test result are crucial (Table 3). European quality assessment projects will examine different steps of ALK mutation testing.

One important ongoing quality assurance project in Europe is the FALKE (Fusion of EML4-ALK epidemiology Evaluation) project. This initiative was set up by the German Society of Pathology for German-speaking countries. The basis of this ring trial is to test 1,000 samples from NSCLC patients. For the FALKE project, it was decided to test all NSCLC and not to focus on adenocarcinoma. For all samples, ALK IHC and ALK FISH will be performed.

In 2012, the European Society of Pathology (ESP) will run two external quality assessment programs for lung cancer. Registration will take place through the ESP website (QA activities: http://esp-pathology.org/).

In the first round, starting March 2012, ALK FISH and optional ALK IHC will be offered. The pre-validated tissue microarray slides will have both positive and negative controls (n ≥10). The second round, in September 2012, will offer assessment of ALK1, EGFR and KRAS on tissue microarray samples. Participation is voluntary. Laboratories meeting the predefined performance threshold will be listed on the ESP website.

Conclusions

For the personalized treatment of patients with NSCLC, it is necessary to sample as much tumour tissue as possible.

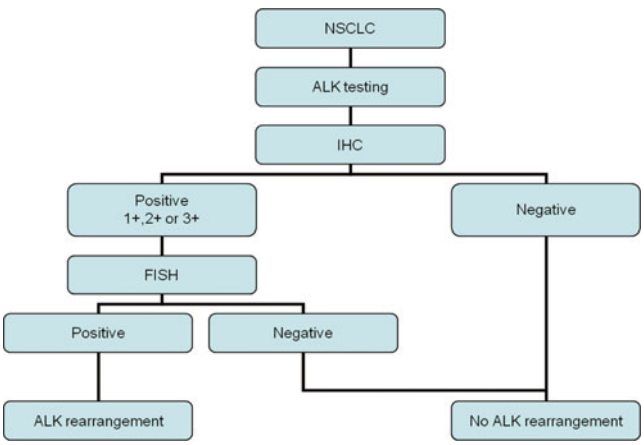

Fig. 3 Possible ALK testing algorithm in NSCLC if IHC becomes fully validated

Adequate clinical information is essential for the optimal tissue management.

Patients with ALK fusion adenocarcinomas confirmed by FISH have been shown to respond favourably to crizotinib treatment, and a phase III trial is currently ongoing. However, the question of how best to select patients that may benefit from crizotinib treatment remains to be answered.

There is evidence that IHC could be useful and less expensive than FISH. Some of the difficulties in interpreting FISH results may be alleviated by automated procedures.

Whether FISH or IHC becomes the primary method of ALK mutation testing in Europe, it is clear that rigorous quality assessment is of the utmost importance to ensure reliable results and appropriate patient selection.

Acknowledgments We would like to extend our thanks to Pfizer for sponsoring the consensus meeting. Also, we would like to gratefully acknowledge the help of Monika Leonhardt and Paul Lavender, archimed medical communication AG, Zofingen, Switzerland, for writing support sponsored by Pfizer.

Conflict of interest This paper was produced following a consensus meeting on 22 November 2011, Zurich, organized and sponsored by Pfizer. L.B., G.R., K.K. and F.P.-L. have worked as consultants/advisers to Pfizer. K.K. has worked in the speaker's bureau, and L.B. and F.P.-L. have received research funding.

Abstract In our study we systematically compared the alternative fixatives acidified formal alcohol (AFA), PAXgene®, HOPE®, and combinations of AFA or formalin with ultrasound treatment to standard (buffered) formalin fixation. We examined general morphology and detectability of protein structures by immunohistochemistry of the membrane receptors epidermal growth factor receptor (EGFR), insulin-like growth factor 1 receptor (IGF-1R), and phosphorylated human epidermal growth factor receptor 2 (phospho-HER2). In order to allow for stringent comparability of different fixation techniques, we used matched mouse xenograft tumor samples from three different human cancer cell lines (colon, ovarian, and non-small cell lung cancer), either fixed conventionally with formalin or an alternative fixative. Tissue morphology after fixation with AFA and PAXgene® was comparable to formalin-fixed paraffin-embedded tissue (FFPET) morphology. Ultrasound fixations resulted in slightly inferior morphology and HOPE® fixation preserved morphology only poorly compared to FFPET in this system. None of the tested alternative fixatives enabled immunohistochemical detectability of all three targets in the same manner as FFPET. Pronounced staining was possible for EGFR and IGF-1R with all alternative fixatives but HOPE®, and phospho-HER2 staining was only noteworthy with formalin-ultrasound-fixed tissue. Therefore, the use of alternative fixatives comes with the need for careful validation of obtained IHC results individually for each target.

Keywords Formalin fixation · Immunohistochemistry · AFA · HOPE® · PAXgene® · Ultrasound

Introduction

Antibody-based therapeutics and targeted therapies in oncology have achieved great importance in recent years. With the ongoing development of personalized healthcare, pathologists are in need of specific diagnostics, often based on protein detection in patients' tissue. Tissue diagnostics in biomedical research and routine practice are either performed with fresh frozen tissue or with formalin-fixed tissue, which has been used in histopathology for decades, firstly mentioned by Blum in 1893 [1, 2]. The advantages of formalin are firstly the antibacterial and antiviral effect, which protects laboratory personnel from infections and secondly the complete fixation of the tissue due to the chemical properties of formaldehyde [3]. However, formalin is toxic and its cross-linking effect on tissue structures often makes specific bioanalysis of proteins and nucleic acids difficult [4–9]. Therefore, powerful fixation techniques are

needed which can produce highly conserved tissues from which an analysis for every target is possible.

In the past years, many alternative fixation studies have been carried out, most of them dealing with one novel or optimized fixative in comparison to standard formalin, but only a few studies on many different fixatives were conducted. Comparative studies between formalin and an alternative fixative for example, were about Streck's tissue fixative [9], Bouin's fixative [10], methacarn [11], ethanol [5], HOPE® [12–18], and UMFIX [8, 19, 20]. Broad-ranging studies on various fixatives for example have been from Prento and Lyon [21] in 1997 (Histochoice, Kryofix, Mirsky's fixative, NoTox, Omnifix II, Streck's Tissue Fixative/Tissue-Tek, Clarke's ethanol-acetic acid, and ethanol) and from Atkins et al. [7] in 2004 (Bouin's fixative, AFA, PreFer, and Pen-fix).

The aim of this study was to compare standard buffered formalin fixation (3.9 % formaldehyde, *w/v*) to fixation with acidified formal alcohol (AFA), which is widely used in France, with HOPE® fixation [12–18], with the recently introduced non-cross-linking fixative PAXgene® [22, 23] and with combinations of AFA and formalin with ultrasound treatment, since ultrasound-accelerated tissue fixation has been reported for formalin fixation previously [24–28]. In order to allow for stringent comparability of the different fixation techniques matched mouse xenograft tumor samples were used. The samples were removed in the exact same manner with minimized ischemia ranging at most to 60 s and standardized fixation parameters such as duration or temperature were applied.

On the other hand, the study was aligned to routine histopathology and downstream workflows in pathological laboratories

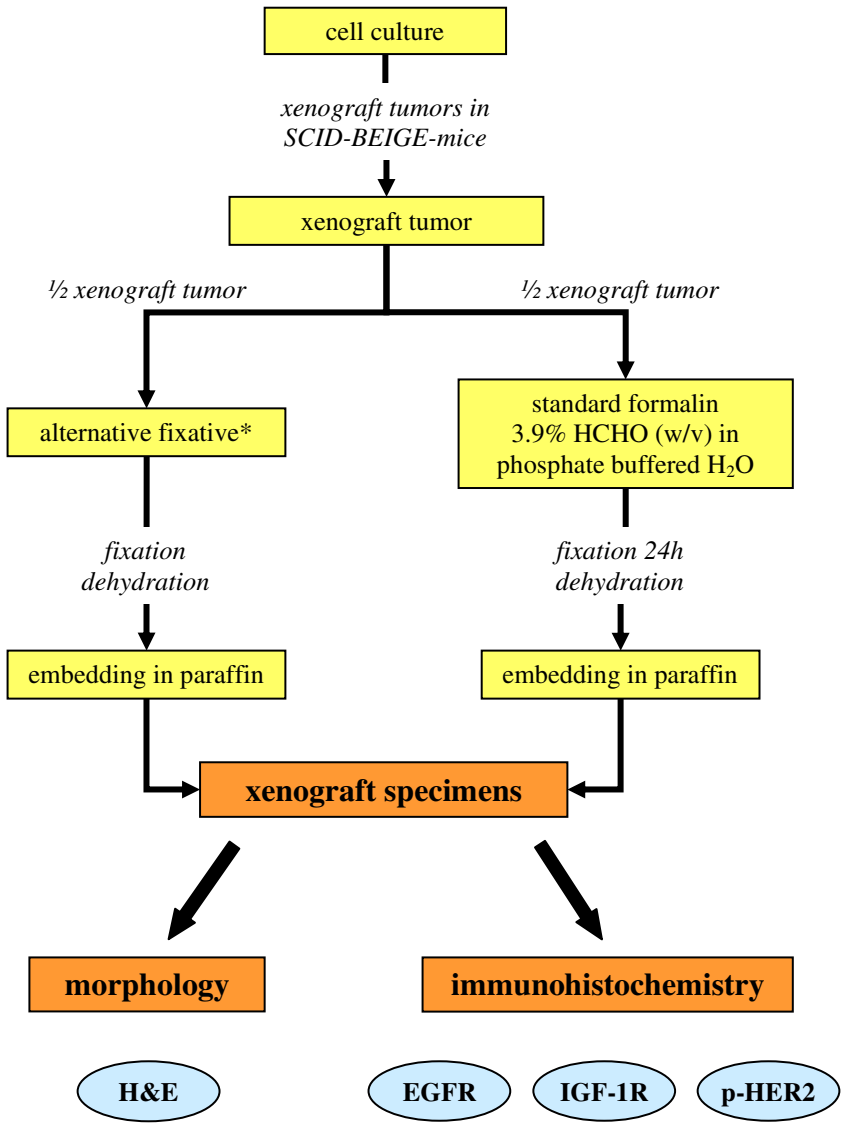

Fig. 1 Experimental setup

as much as possible. Therefore, alternative fixations were coupled to the usual dehydration process, subsequent paraffin embedding and fully automated immunohistochemistry on the BenchMark XT instrument (Ventana Medical Systems; Tucson, USA), which at the same time enabled maximized standardization. Comparison of alternative fixatives was also oriented to immunohistochemical targets which have significant impact on patient care as well as to exploratory tissue biomarkers. Immunohistochemistry was applied for epidermal growth factor receptor (EGFR) as an established target in cancer diagnostics, insulin-like growth factor 1 receptor (IGF-1R) as an exploratory marker and phosphorylated human epidermal growth factor receptor 2 (phospho-HER2) as a signal transduction marker in order to test detectability of phosphorylated antigens.

Material and methods

In the study, the alternative fixatives AFA, PAXgene®, HOPE®, and combinations of AFA or formalin with ultrasound treatment were compared to standard (buffered) formalin fixation. For this comparison tumor samples obtained from mouse xenograft tissue models of the human cancer cell lines COLO-205, OVCAR-5, and NCI-H322M were used. For every alternative fixative at least five xenografts of every cell line from five different mice were generated. In order to systematically compare all fixatives with formalin, one half of every tumor underwent fixation in standard formalin and the other half of this tumor was fixed in one of the alternative fixatives (Fig. 1). For comparison of alternative fixation with formalin fixation both H&E staining and IHC staining of the membrane receptors EGFR, IGF-1R, and phospho-HER2 were performed (Fig. 1).

For detailed methodology of the study and fixation protocols please refer to Supplementary file 1. Staining protocols of IHC targets on the BenchMark XT instrument (Ventana Medical Systems; Tucson, USA) are included in Supplementary file 2.

Results

In an initial screen, we selected the best fixation conditions for fixation of xenografts with AFA, AFA-ultrasound, formalin-ultrasound, PAXgene®, and HOPE® by evaluation of tissue preservation/tissue morphology. It was assumed that a fixation which allows good preservation of morphological details would be beneficial for IHC analyses.

Morphology

H&E-stained sections of NCI-H322M xenograft tissue of all tested fixatives are shown in Fig. 2. Preservation of xenograft tissue structures was comparable to standard formalin fixation after fixation with AFA for 24 h, PAXgene®, and ultrasound fixation with AFA and formalin (both for 7 h). Tissue structures were well preserved for the abovementioned fixatives and, in the cases of AFA 24 h, PAXgene®, and AFA-ultrasound fixation, more nuclear details like nucleoli and mitoses were detectable (Fig. 2a–c). HOPE® fixation however, led to decreased morphological detail compared to standard formalin fixation, in which many nuclei developed a characteristic condensed and polygonal shape. Furthermore, the cytoplasm of some cells was shrunken to a considerably larger extent than with the standard FFPET method and typical tissue architecture was partially destroyed after fixation with HOPE®, visible in artificial fissures (Fig. 2e).

Immunohistochemistry

Optimization of immunohistochemical staining methods

Immunohistochemical assay parameters like deparaffinization and antigen retrieval times were optimized individually for each fixative other than standard formalin for maximal IHC signal over background when analyzing xenografts from COLO-205 cells. The resulting modified protocols were then applied accordingly to the other xenograft models. In summary, for fixation with AFA, PAXgene®, and AFA-ultrasound, manual deparaffinization led to better staining results (intensity and quantity) than the automatic deparaffinization using the BenchMark XT for all tested IHC targets. In most of the cases, antigen retrieval times were shorter or of the same duration as for the use of standard formalin-fixed tissue. For the detailed methodology and results refer to Supplementary file 3.

Immunohistochemical staining of EGFR, IGF-1R, and phospho-HER2

EGFR Staining of EGFR obtained from fixation with AFA, AFA-ultrasound, and PAXgene® resulted in very intense staining with more cells stained than in standard formalin-fixed tissue. For AFA and AFA-ultrasound the EGFR staining was comparable for all three xenograft models (COLO-205, OVCAR-5, and NCI-H322M) and, in comparison to standard formalin, more intensive in all cases with a good counterstaining and detailed nuclear morphology (Fig. 3d–i). PAXgene® fixation led to better staining results of EGFR for all xenograft models (Fig. 3a–c); whereas the difference to standard formalin was smallest for COLO-205 xenografts. Fixation with formalin-ultrasound led to slightly stronger EGFR staining intensity with a few more cells stained in OVCAR-5 and NCI-H322M xenografts and to the same EGFR staining intensity with more cells stained (~5–10 %) for COLO-205 xenografts compared to standard formalin fixation (Fig. 3j–o). The detection of EGFR was not

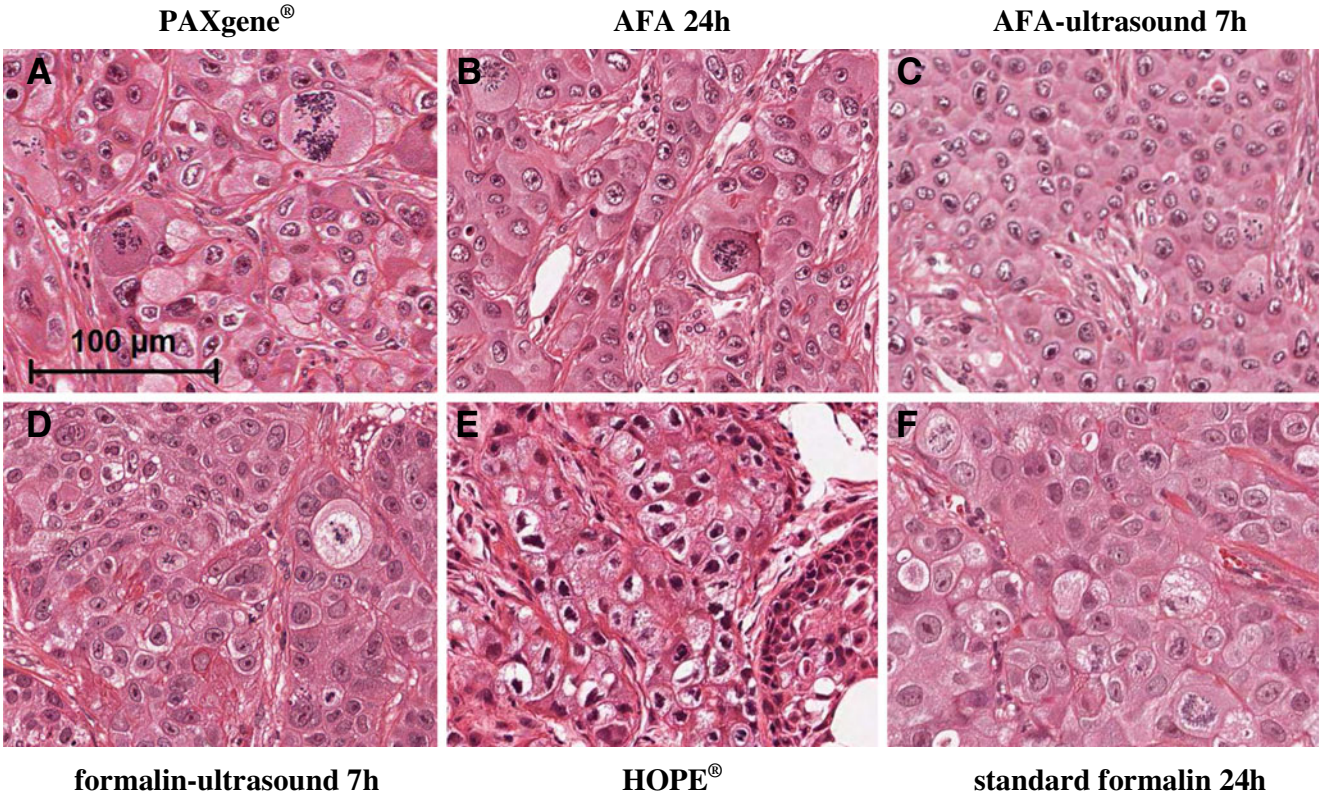

Fig. 2 H&E staining of NCI-H322M xenografts **a** PAXgene®, **b** AFA 24 h, **c** AFA-ultrasound 7 h, **d** formalin-ultrasound 7 h, **e** HOPE®, **f** standard formalin 24 h

possible for tissue that was fixed with HOPE® due to unspecific staining, which also occurred when performing a negative control with an IgG control antibody.

IGF-1R Detection of IGF-1R was possible with all alternatively fixed tissues. The best results, which were nearly comparable to the IGF-1R staining of standard formalin-fixed tissue, were achieved with COLO-205 xenografts fixed with AFA, AFA-ultrasound, and PAXgene®. However, for NCI-H322M and OVCAR-5 xenografts, quantity of IGF-1R staining was less for tissue fixed with AFA, AFA-ultrasound, and PAXgene® than for standard formalin-fixed tissue (Fig. 4a–i and p–r). Formalin-ultrasound-fixed tissue showed an IGF-1R staining which was comparable to staining results of standard formalin-fixed tissue (Fig. 4j–l and p–r). HOPE®-fixed tissue showed a more intense IGF-1R staining (Fig. 4m) with fewer cells stained than the standard formalin-fixed tissue for all three xenograft models. Nevertheless, HOPE®-fixed OVCAR-5 and NCI-H322M xenografts (Fig. 4, N+O) showed cells with condensed shape and shrunken cytoplasm, which made histopathological evaluation difficult.

Phospho-HER2 The immunohistochemistry of p-HER2 only led to noteworthy staining with formalin-ultrasound-fixed tissue. p-HER2 staining intensity in formalin-ultrasound-fixed tissue (Fig. 5j–l) was comparable to staining intensity of standard formalin-fixed tissue (Fig. 5p–r), whereas the staining quantity in all three xenograft models over all the tumors was less for formalin-ultrasound-fixed tissue. HOPE® fixation led to a weak membrane staining of p-HER2 and to an unspecific cytoplasmic staining for all three xenograft models (Fig. 5m–o). HOPE®-fixed OVCAR-5 xenografts (Fig. 5n) had a decreased morphology which did not allow a histopathological evaluation for p-HER2 staining. No significant staining of p-HER2 could be observed after fixation with AFA, AFA-ultrasound, and PAXgene® (Fig. 5a–i).

All results of the study are summarized in Table 1, showing the results for morphology and the different immunohistochemical targets. Evaluation of IHC experiments with complete scoring is included in Supplementary file 4.

Discussion

In the present study we demonstrate that careful validation of the usage of alternative fixatives has to be done as the impact on the biomarker results obtained by IHC in relation to standard formalin fixation is significant. A comparison of fixation with formalin, AFA, PAXgene®, HOPE®, and ultrasound accelerated fixation with formalin and AFA was

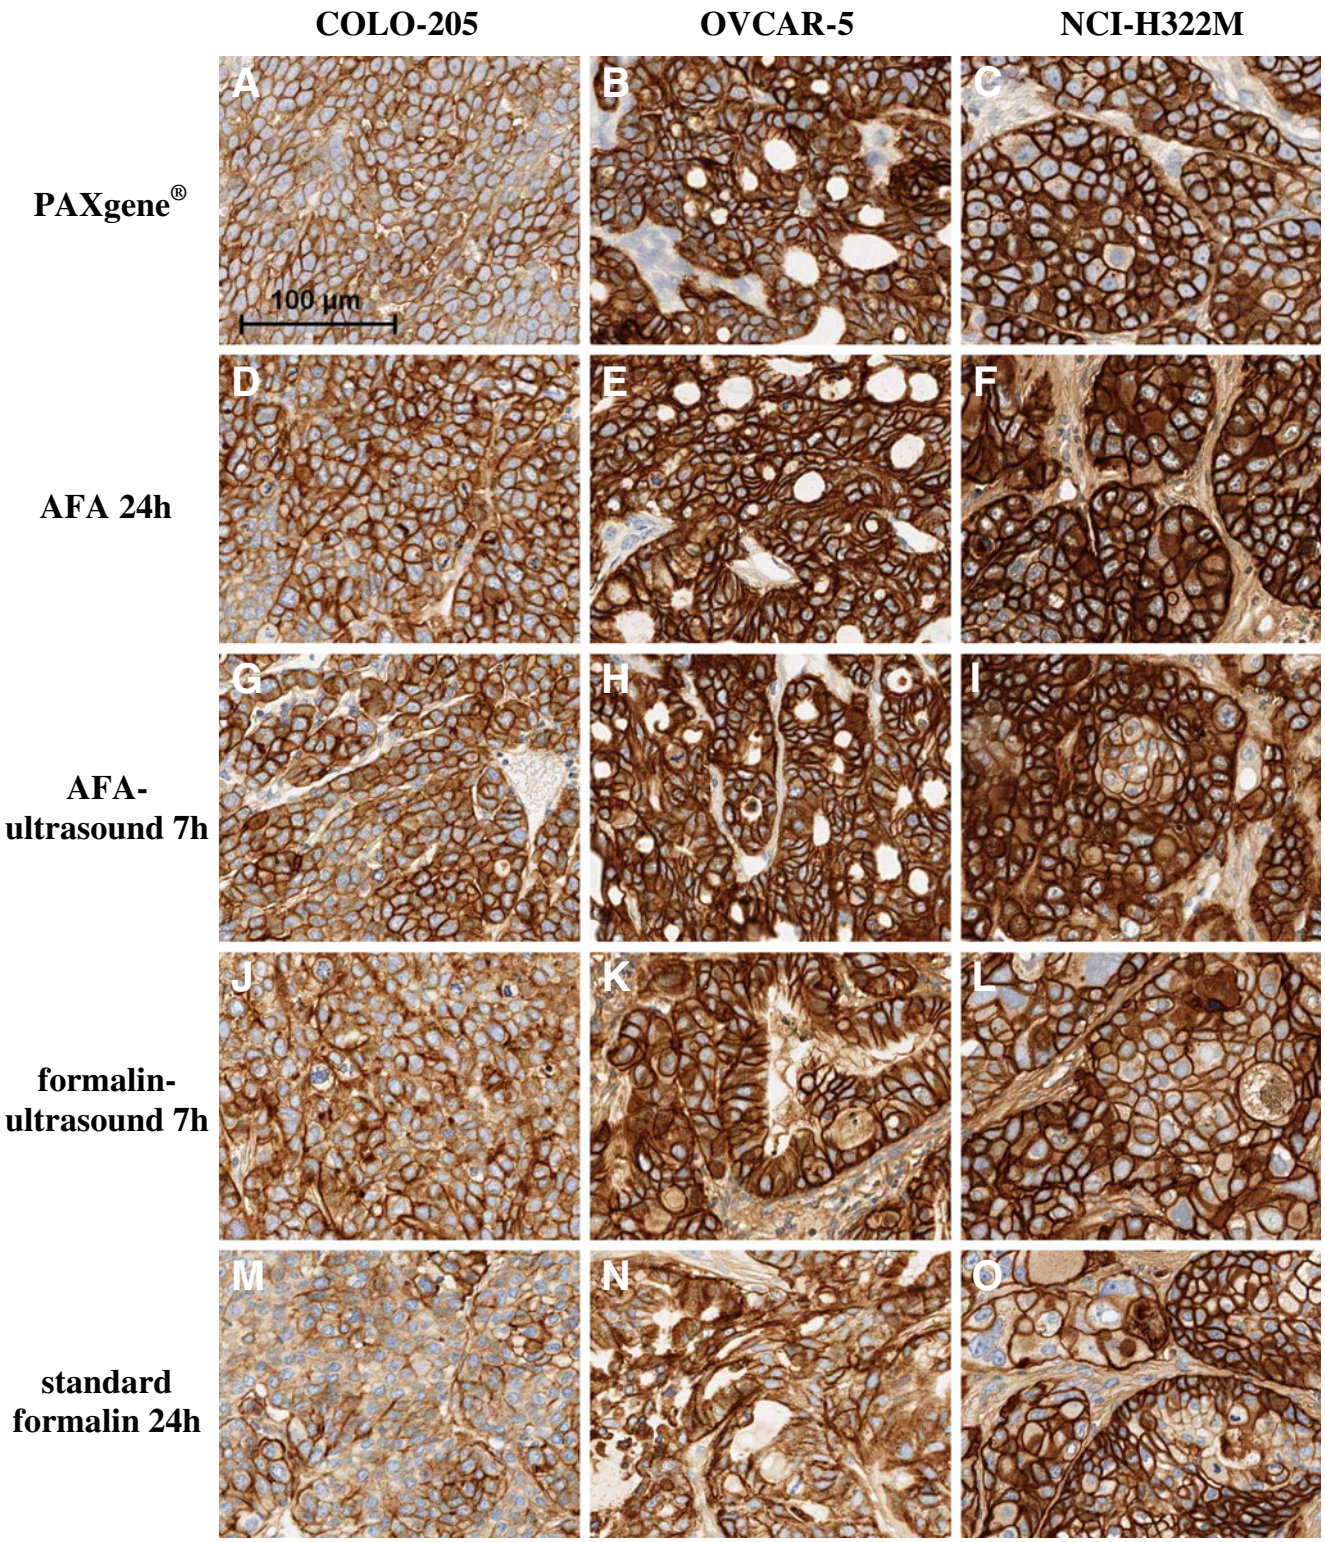

Fig. 3 IHC staining with anti-EGFR of different xenograft tissues fixed with alternative fixation methods and standard formalin. All pictures are shown in the same scale (*100-µm scale bar picture top left*)

performed on the basis of tissue morphology and immunohistochemical detection of three membrane receptors (EGFR, IGF-1R, and p-HER2). For each fixative five mouse xenograft tumors of three different human cancer cell line models from five different mice have been analyzed. The use of xenograft tissue enabled a direct comparison with human cellular background in a consistency (controlled ischemia, controlled cut halves and infiltration of the

fixative to small sample sizes) which would not be achievable with diagnostic human tissue (as biopsies would be too valuable). To our knowledge, this is the first study on alternative fixation with AFA-ultrasound compared to fixation with buffered formalin in a systematic model system.

Morphology of alternatively fixed tissue

This study clearly showed that the morphology of xenograft tissue was well preserved after fixation with AFA for 24 h, AFA-ultrasound for 7 h, PAXgene® (complete fixation duration 5 h), and formalin-ultrasound for 7 h. The detailed nuclear morphology after fixation with AFA is consistent to the results of Foster et al. [3] who describe that nuclear chromatin structure is better preserved after ethanol fixation than after formalin fixation, since AFA consists of 75 % ethanol (plus 18 % water, 5 % acetic acid, and 2 % formaldehyde solution, meaning 8 g formaldehyde/L). With regard to PAXgene®, our results are concordant to the results from Kap et al. [22], who reported on well-preserved human tissue morphology after PAXgene® fixation in most of the cases.

However, in our study, tissue morphology of xenografts after fixation with HOPE® was not preserved as well as after standard formalin fixation, in contrast to recently published results of fixation of human tissue with HOPE® [17, 18], despite extensive testing of different parameters following manufacturer's recommendations. The artificial fissures of HOPE®-fixed tissue, like in our study, have also been mentioned from Olert et al. [12].

Immunohistochemical detectability in alternatively fixed tissue

Immunohistochemical detectability of EGFR, IGF-1R, and phospho-HER2 in our study was the best for tissue fixed with standard formalin throughout all xenograft tumor models. We observed that fixation with AFA (with or without ultrasound sonication) and PAXgene® led to a more intense and quantitative staining of EGFR than formalin fixation, were nearly comparable to formalin fixation for IGF-1R analyses, but surprisingly gave no significant signal in immunohistochemical detection of p-HER2. Our results are consistent to the results of the study on EGFR detectability in alternatively fixed tumor tissue from Atkins et al. [7]. They describe that staining of EGFR in tissue fixed with AFA for 24 h and buffered formalin for 24 h had a comparable performance up to 9 months storage after fixation and that EGFR staining in AFA 24 h-fixed tissue was slightly better compared to buffered formalin-fixed tissue after 12 months storage. However, our additionally performed immunohistochemistry of IGF-1R and p-HER2 in AFA- and formalin-fixed tissue emphasize that not in all cases is AFA as powerful as formalin as a fixative in histopathology.

Especially the unavailable signal for detection of the phospho-site of HER-2 in AFA-fixed tissue does not concur in the experience that total HER2 IHC shows a higher signal in alcohol-fixed specimens. This has to be seen critical in the background of the comparison of results obtained with the non-formalin fixatives to formalin, because there are indications that probing phosphorylated states of therapeutical targets might be more precise in predicting therapeutic response, as presence of phosphorylation surrogates an actively signaling pathway. Therefore, one should carefully validate the performance of alcohol-based fixatives when using it as an alternative to formalin in immunohistochemistry in each case.

For HOPE® fixation we could not achieve IHC results comparable to formalin fixation concerning the three selected receptors. The reasons might lie in the HOPE® fixation procedure for some reason not being amenable to the xenograft model system. Furthermore, we cannot concur with the statement from Olert et al. [12] and Goldman et al. [30] that HOPE®-fixed tissues do not require any pretreatment for immunohistochemistry since we only detected IGF-1R and p-HER2 with IHC in HOPE®-fixed tissue after antigen retrieval with CC1 buffer and CC2 buffer, respectively.

The best results in comparison to standard formalin fixation were achieved with formalin-ultrasound fixation in our study, whereupon staining of p-HER2 in formalin-ultrasound-fixed tissue was not as quantitative as in standard formalin-fixed tissue. However, we do not see underfixation of tissue with formalin-ultrasound as an issue here because detectability of EGFR and IGF-1R was consistently comparable to formalin fixation without ultrasound (standard formalin), but we assume that ultrasound itself could be a reason for the difference. Besides the enhanced reactivity and diffusion of formaldehyde in the tissue [25–27], ultrasound treatment may also trigger chemical reactions or may influence chemical reactions in certain directions [31–34]. One hypothesis could be that phosphorylated proteins are more sensitive to ultrasound treatment than other proteins.

IHC methodology and alternative fixatives

On the one hand, the often-stated better protein quality and antigenicity of alternatively fixed tissue [4, 5, 9, 11, 35, 36] in our opinion, has to be limited. Our results (improved detection of EGFR with protease treatment in AFA/PAXgene®-fixed tissue, improved detection of IGF-1R with CC1 buffer incubation in AFA/PAXgene®/HOPE®-fixed tissue) imply that also for alternatively fixed tissue, an epitope unmasking pretreatment—the so-called antigen retrieval—can improve immunohistochemical detectability. Similar results have been

reported from Nassiri et al. [20] in a study on the alternative fixative UMFIX and from Prento and Lyon [21] in a study on several alternative fixatives. Besides the need for optimized antigen retrieval for alternatively fixed tissue, we observed that one-step on-instrument deparaffinization from alternatively fixed tissue on the BenchMark XT platform led to worse results in immunohistochemistry.

On the other hand, we applied IHC assays, which had been optimized for standard formalin-fixed tissue and thus probably probe denatured epitopes, to alternatively fixed tissue, as we wanted to test alternative fixation methods with regard to performance in routine histopathology. A potential superiority of the alternative fixatives in preserving immuno-detectability of native or conformational epitopes, that might be lost during standard formalin fixation, remains to be elucidated in further studies.

In addition to continuative IHC analyses of more proteins, also comprehensive techniques focusing on detection

of various proteins present in fixed tissue, like proteomics-based approaches, could be beneficial [37, 38]. Such approaches have already been applied for the fixative PAXgene® [23] and are showing great potential. Nevertheless, the differing results of alternative fixatives to buffered formalin in IHC could be an indicator, that also with other protein/immuno-based methods (proteomics like MALDI mass spectrometry and protein microarrays or also Western Blot and ELISA) a careful validation and interpretation of the collected data has to be carried out.

Conclusions

In summary, fixation of xenograft tissue with standard formalin resulted in the best immunohistochemical detectability of the chosen membrane receptors when deparaffinization is performed with the BenchMark XT autostainer. When manual deparaffinization is applied, alternatively fixed tissues show both more intense staining (EGFR) and decreased staining (IGF-1R, p-HER2). While most of the alternative fixatives preserved histomorphology, HOPE®-fixed tissue showed decreased morphology. With regard to clinical routine, it is important to know that IHC staining in alternatively fixed tissue may be dependent on the deparaffinization technique (manual vs. automatic) used. Therefore, the use of alternative fixation methods comes with the need to verify the performance of IHC assays individually for each target.

Acknowledgments We are grateful to Prof. Dr. Ralf Huss and Prof. Dr. Wolfgang Schwack for helpful advices and collaborative support. We thank Adriana Zabarella for support in IHC techniques and Christa Bielmeier and Gunther Muth for support in preparing xenograft tumor samples. The authors also thank Dr. Alexandra Farfsing and Dr. Corinna Wolf for useful discussion and valuable comments on the manuscript.

Abstract Salivary gland carcinomas encompass a wide spectrum of histological entities. To identify candidate therapeutic targets and innovative treatment options for these carcinomas, we examined epidermal growth factor receptor (EGFR), phosphorylated EGFR (p-EGFR), HER2, and phosphorylated forms of Akt (p-Akt) and mammalian target of rapamycin (p-mTOR) in 47 salivary gland tumors using immunohistochemistry. EGFR overexpression was found in 51 % of the tumors (24/47); in particular, EGFR overexpression occurred in mucoepidermoid (seven out of seven) and salivary duct carcinomas (9/12). Although *EGFR* amplification was not detected by fluorescence in situ hybridization analysis, increased copy number due to polysomy of chromosome 7, which houses *EGFR*, was observed in 4 of the 24 tumors with EGFR overexpression; this polysomy occurred most frequently in salivary duct carcinomas (three out of nine). HER2 overexpression was observed in 21 % (10/47) of all tumors; in these 10 tumors, *HER2* gene amplification was found in seven cases. p-Akt was found in 51 % (24/47) of all tumors, most frequently in mucoepidermoid carcinomas (six out of seven). p-mTOR was found in 57 % of the latter (four out of seven). Consequently, different signaling cascades were found activated: (1) an EGFR/HER2(–Akt)–mTOR-dependent axis, with gene gains of *HER2* and/or *EGFR*, activated in salivary duct carcinoma and carcinoma ex pleomorphic adenoma; (2) an EGFR(–Akt)–mTOR-dependent pathway activated in mucoepidermoid carcinoma or acinic cell carcinoma, without HER2 or EGFR gene alterations; and (3) an Akt-dependent pathway without EGFR/HER2 activation in other types. These findings indicate that phosphoprotein mapping of components in the EGFR/HER2–Akt–mTOR pathways may be a useful guide to select appropriate targeting regimens.

Introduction

Salivary gland carcinomas are rare malignant tumors for which it is difficult to assess prognostic factors (0.4–2.6 cases per 100,000) [1]. Moreover, the histopathology of these tumors is diverse; the World Health Organization (WHO) classification describes at least 24 different types of salivary gland carcinoma [1]. The different types of salivary gland carcinoma can be assigned to distinct prognostic groups; for example, acinic cell carcinomas are usually low-grade tumors and salivary duct carcinomas are usually high-grade tumors. In addition, 33 % of salivary duct carcinomas will recur locally, and 46 % will give rise

to distant metastases [1]. Moreover, other types of salivary gland carcinoma tend to have an unpredictable clinical course, despite recent progress in diagnostic strategies and surgical and chemotherapeutic interventions [1]. These facts highlight the need for optimized treatment of those carcinomas with aggressive behavior, through tailored therapeutic approaches.

A potentially effective approach to tailored treatment of aggressive tumors is to inhibit the function of growth factor receptors, because aberrant expression of growth factors is often associated with metastasis, advanced disease, and poor prognosis in a variety of human tumors [2, 3]. Among the myriad of growth factor receptors, two—epidermal growth factor receptor (EGFR; erbB1) and HER2 (erbB2)—have been extensively studied in salivary gland carcinomas [4–11].

EGFR is a 170-kDa membrane glycoprotein that is encoded by the *EGFR* gene, which is located on chromosome 7p12. Many strategies for inhibiting EGFR have been and are being developed, and several such strategies are in clinical use [12–16]. A regimen involving a monoclonal anti-EGFR antibody (cetuximab, panitumumab) has been established for the treatment of colorectal and head and neck cancers that overexpress EGFR [12, 16]. Additionally, several activating mutations within the tyrosine kinase domain of EGFR have been discovered, and these mutations can be used to identify non-small cell lung carcinomas (NSCLC) that respond to tyrosine kinase inhibitors (TKIs), including gefitinib and erlotinib [13]. Other molecular alterations, including gene amplification or chromosomal polysomy, also promote tumorigenesis [14], and some of these alterations have been associated with a higher response rate to TKIs in NSCLC [15]. Although one third of salivary gland carcinomas overexpress EGFR, little is known about the status of the *EGFR* gene and EGFR protein activation in these carcinomas [4–9].

HER2 is a 185-kDa membrane glycoprotein that is encoded by the *HER2* gene, which is located on chromosome 17q12. Accumulated evidence from studies on breast carcinoma has led to the consensus that *HER2* gene amplification and HER2 overexpression are biomarkers for assessing responsiveness to targeted therapy with a humanized monoclonal anti-HER2 antibody, trastuzumab [2, 17]. However, in the clinic, a substantial population of cases shows equivocal expression of HER2 upon immunohistochemical analysis (IHC); in these cases, initial IHC followed by gene amplification analysis by fluorescence in situ hybridization (FISH) has become standard [17]. Although it has been suggested that HER2 overexpression is an indicator of poor prognosis of salivary duct carcinomas [5] and mucoepidermoid carcinomas [10], this claim is controversial [4]. Furthermore, only a few studies have focused on genetic alterations of *EGFR* and *HER2* [7, 18], and therefore, the significance of such alterations in salivary gland carcinomas remains unclear.

Akt and mammalian target of rapamycin (mTOR) function downstream of EGFR and HER2, and both Akt and mTOR seem to be critical transmitters of the oncogenic signal in tumors (Fig. 1) [19–21]. We found that the EGFR–Akt–mTOR pathway is constitutively active in defined subsets of NSCLC [19, 20] and mTOR to be a possible determinant of nodal metastasis [19]. In this sense, Akt and mTOR, like EGFR and HER2, may be suitable therapeutic targets. However, to our knowledge, only one study on salivary carcinoma, specifically on adenoid cystic carcinoma, has focused on p-Akt [22], and no such studies have focused on mTOR.

Accordingly, detailed information with respect to the participation of EGFR and HER2 signaling through Akt and mTOR will help further the development of rational clinical strategies. With this goal in mind, we analyzed (1) activation of the EGFR and HER2 proteins, (2) *EGFR* and *HER-2* copy number, and (3) activation of the Akt–mTOR pathway. The functional involvement of EGFR and HER2 signaling in salivary gland carcinomas was evaluated with particular focus on the aggressive subtypes, i.e., salivary duct carcinoma, mucoepidermoid carcinoma, and carcinoma ex pleomorphic adenoma.

Materials and methods

Tissue samples

We examined samples from 47 salivary gland carcinomas; these tumor samples were obtained from 47 consecutive

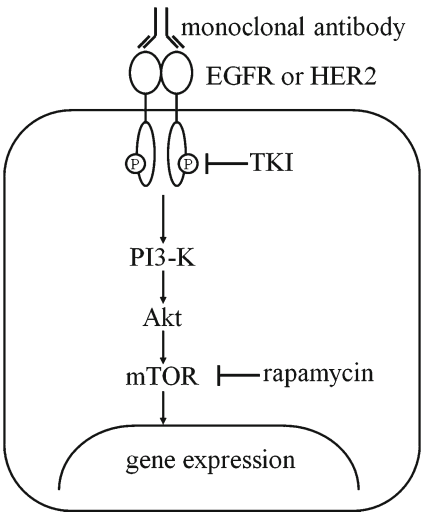

Fig. 1 Schematic presentation of the signaling pathway from the growth factor receptor through the Akt/mTOR effectors. *EGFR* epidermal growth factor receptor, *mTOR* mammalian target of rapamycin, *PI3K* phosphatidylinositol 3-kinase, *TKI* tyrosine kinase inhibitor

surgeries performed between 1995 and 2010 at the Department of Otolaryngology—Head and Neck Surgery, Kanazawa University. The subjects included 24 male and 23 female patients with a mean age of 59.2 years (median, 63 years; range, 28–83 years). For each tumor, the stage of extension was assessed according to the system for staging primary tumor/regional lymph nodes/distant metastasis described in the AJCC Cancer Staging Manual [23]. The 47 tumors were classified as follows: 11 were pT1, 24 were pT2, and 12 were pT3; 12 cases were classified as lymph node-negative (pN0), 11 were lymph node-positive (pN1/2), and the pN status was unknown in the other 24 cases because lymph node dissection was not performed at surgery.

According to the WHO classification [1], the specimens were classified as salivary duct carcinoma (n=12), mucoepidermoid carcinoma (n=7), carcinomas ex pleomorphic adenoma (n=7), acinic cell carcinoma (n=6), adenoid cystic carcinoma (n=5), myoepithelial carcinoma (n=3), basal cell adenocarcinoma (n=2), epithelial–myoepithelial carcinoma (n=2), lymphoepithelial carcinoma (n=2), or adenocarcinoma, NOS (n=1). All seven cases of mucoepidermoid carcinoma were classified as low grade [1]. The seven cases of carcinoma ex pleomorphic adenoma comprised of four salivary duct carcinomas, two adenocarcinomas, NOS, and one mucoepidermoid carcinoma. This laboratory study was approved by the Institutional Review Board at Kanazawa University, and written informed consent was obtained from all patients.

Immunohistochemical analysis

All tissue samples were processed using standard methods, and serial sections were used for IHC. Sections were autoclaved for epitope retrieval and stained with primary antibodies. Antibodies against the following antigens were used: the cytoplasmic domain of EGFR (clone EGFR.25, Novocastra, Newcastle upon Tyne, UK) 1:100 dilution, HER2 (polyclonal, Nichirei, Tokyo, Japan) 1:400, phosphorylated form of EGFR (p-EGFR^{Tyr1068}, polyclonal; Invitrogen, Carlsbad, CA, USA) 1:50, p-Akt^{Ser473} (clone 193 H12, Cell Signaling Technology, Beverly, MA, USA) 1:300, and p-mTOR^{Ser2448} (clone 49 F9, Cell Signaling Technology) at 1:100 dilution. The sensitivity and the specificity of these antibodies for use in IHC analysis of cancerous tissue specimens have been validated by us and others in previous studies [8, 19, 24]. All primary antibodies were visualized using a CSAII kit (Catalyzed Signal Amplification System 2; Dako, Glostrup, Denmark) according to the manufacturer's instructions.

Immunohistochemical staining was evaluated by the three authors (SS, YD, AO). As in previous studies by us and others, in tumor sections immunohistochemically stained for anti-EGFR or anti-HER2, membranous expression was scored as follows: score 0, no staining or staining in <10 % of tumor cells; score 1, faint and partial staining in ≥10 % of tumor cells; score 2, weak to moderate complete membrane staining in ≥10 % of tumor cells; and score 3, strong complete membrane staining in ≥10 % of tumor cells [7, 11, 18, 19, 24]. Scores of 2 or 3 were classified as overexpression because it is widely recognized that only the samples with scores of 2 or 3 in IHC analyses are frequently associated with amplification of the *EGFR* or *HER2* gene [11, 17, 19, 20]. For the other primary antibodies, results were evaluated as significant, when clear staining with higher intensity than in non-neoplastic cells was observed, or not significant. The IHC result for each antibody was considered positive when more than 10 % of the neoplastic cells had significant staining [8, 19].

Fluorescence in situ hybridization

Of the 47 tumors examined, 27 tumors overexpressed EGFR and/or HER2; each of these 27 tumors was subjected to FISH analysis to assess *EGFR* and/or *HER2* copy number. FISH probes for the *EGFR* (7p12) and *HER2* (17q12) loci were generated using two bacterial artificial chromosomes, RP11-339F13 and RP11-62 N23, respectively [24]. These probes were labeled with SpectrumOrange using a nick translation reagent kit (Abbott, Abbott Park, IL, USA). In order to standardize chromosome number in each sample, a SpectrumGreen-labeled pericentromeric probe (Abbott) was also used on each FISH preparation; two such probes, one specific for chromosome 7 and the other for chromosome 17, were used. FISH was performed using standard methods as previously described [24]. The tissue sections were counterstained with 4′,6-diamidine-2′-phenylindole dihydrochloride and *p*-phenylenediamine in phosphate-buffered saline and glycerol (DAPI II) (Abbott) and examined under a fluorescence microscope (Olympus, Tokyo, Japan) equipped with a Triple Bandpass Filter set (Abbott) to discriminate DAPI II, SpectrumOrange, and SpectrumGreen. The number of *EGFR, HER2*, and centromeric signals were counted in each cancer cell nucleus, and the signals were evaluated using the following definitions: definite gene clusters were regarded as high-level amplification for both *EGFR* and *HER2*. In addition, an *EGFR*/centromere ratio greater >2.0 or an average *EGFR* gene copy number >4.0 was interpreted as positive, i.e., an amplification event [25]. In contrast, a *HER2*/centromere ratio >2.2 or an average *HER2* gene copy >6.0 was interpreted as positive, i.e., an amplification event [26]. Increased gene copy number due to polysomy was defined as the presence in more than 50 % of the tumor cells of more than two gene signals accompanied by an identical number of centromeric signals on which the target gene is located [19]. FISH images were

taken using a charged coupled device camera and stored on a personal computer.

Statistical analysis

StatView software (version 5.0; Abacus Concepts, Berkeley, CA, USA) was used for the data analysis. The correlations between immunohistochemical scores were assessed with the χ^2 and Fisher's exact tests. For all tests, statistical significance was defined as a probability value less than 0.05.

Agreement among observers for the interpretation of IHC specimens was assessed by kappa (κ) statistics [27]. In accordance with the criteria of Landis and Koch [28], the κ-values were divided into several classes to evaluate the degree of agreement: $\kappa<0.00$, poor; $0.00<\kappa\leq0.20$, slight; $0.20<\kappa\leq0.40$, fair; $0.40<\kappa\leq0.60$, moderate; $0.60<\kappa\leq0.80$, substantial; and $0.80<\kappa\leq1.00$, nearly perfect.

Results

IHC

We examined the expression and phosphorylation status of EGFR, HER2, and two downstream effector molecules, Akt and mTOR, using IHC. The results of the IHC analysis are summarized in Table 1; the tumors were grouped according to histological type. Overall inter-observer agreement was nearly perfect (the lowest $\kappa=0.84$: 95 % confidence interval, 0.76–0.92 for EGFR).

In tumor cells, positive EGFR staining was confined mainly to the plasma membrane, occasionally with associated cytoplasmic staining. Weak staining was occasionally observed in non-neoplastic ductal, acinar, and stromal cells; however, the intensity of this staining was much weaker than that in tumor cells (Fig. 2). Expression of EGFR was found in 79 % (37/47) of all cases. Of the EGFR-positive cases, 14 showed strong staining (score 3), 10 had intermediate staining (score 2), and 13 had weak staining (score 1). EGFR overexpression (defined as scores of 2 or 3) occurred more frequently in mucoepidermoid carcinoma (seven out of seven) and salivary duct carcinoma (9/12) than in all other types of salivary gland carcinoma (8/28); this difference was statistically significant (the mucoepidermoid and salivary duct carcinomas vs all others, $p=0.0002$).

Positive p-EGFR immunohistochemical staining was found at the plasma membrane and in the cytoplasm of tumor cells. p-EGFR staining was observed in 25 cases (53 %) including large proportion of mucoepidermoid carcinomas (six out of seven) and adenoid cystic carcinomas (three out of five).

Since it has been described that overexpressed HER2 is generally accompanied by HER2 activation [29], we evaluated its expression. HER2 staining was observed in tumor cells mainly at the plasma membrane, with occasional cytoplasmic staining (Fig. 2). Overexpression of HER2 was found in 21 % (10/47) of all cases. With respect to histological types, overexpression of HER2 was found in some salivary duct carcinomas (6/12), some carcinomas ex pleomorphic adenoma (three out of seven), and one myoepithelial carcinoma (one out of three), but not in the other types (0/25).

Positive p-Akt staining was found predominantly in the cytoplasm and, occasionally, in the nucleus of tumor cells

Table 1 Immunohistochemical analysis of 47 tumors

Histological subtypes	EGFR score			p-EGFR		HER2 score			p-Akt		p-mTOR		Total

(+) positive for expression of p-Akt or p-mTOR, *p-EGFR* phosphorylated epidermal growth factor receptor, *mTOR* mammalian target of rapamycin

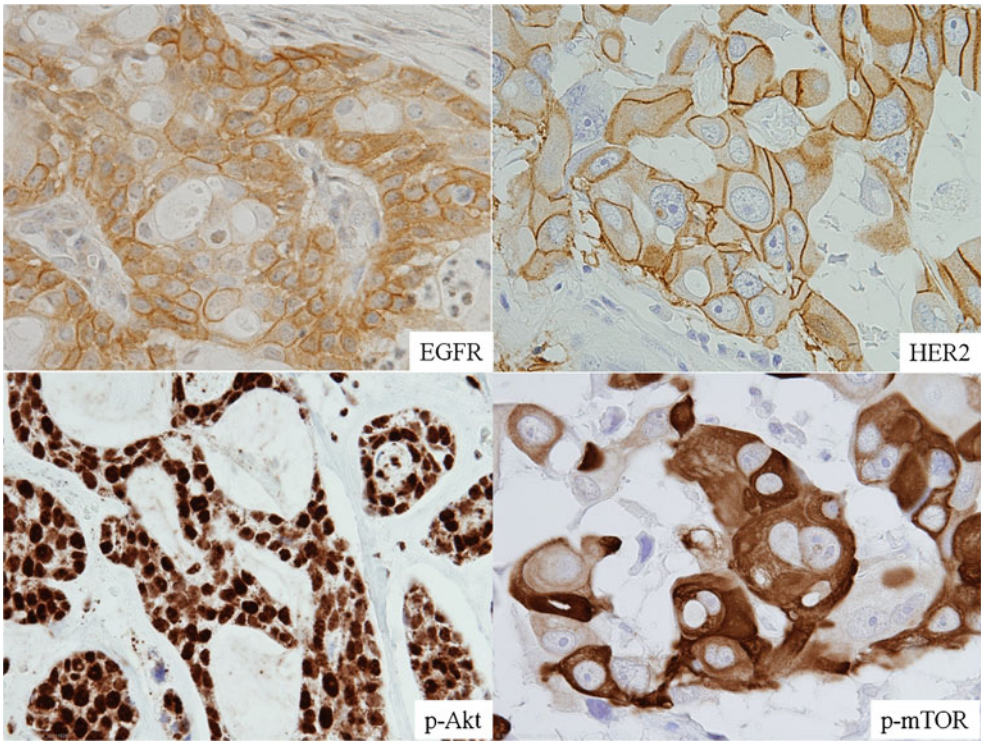

Fig. 2 Immunohistochemical staining of the EGFR and HER2 proteins, as well as downstream signaling intermediates, in representative cases. Positive staining for EGFR or HER2 was confined almost exclusively to the plasma membrane of tumor cells, but occasionally there was associated cytoplasmic staining. Staining for p-Akt and p-mTOR was mainly observed respectively in the nuclei and the cytoplasm of tumor cells. *EGFR* epidermal growth factor receptor, *p-mTOR* phosphorylated mammalian target of rapamycin

(Fig. 2). p-Akt staining was found in 51 % (24/47) of all tumors and was present in most mucoepidermoid carcinomas (six out of seven) and adenoid cystic carcinomas (three out of five).

Positive p-mTOR staining was observed in the cytoplasm and also in the nuclei of tumor cells (Fig. 2). Expression of p-mTOR was found in 57 % (27/47) of all tumors, and it was present in almost every salivary duct carcinoma (10/12) and most carcinomas ex pleomorphic adenoma (five out of seven) and mucoepidermoid carcinomas (four out of seven); p-mTOR staining was found in less than half of the tumors in all other classes (8/21), but these differences were not statistically significant (the former three types vs all other types, p=0.0206).

Correlations between staining patterns

EGFR and HER2 In consecutively stained serial sections (Fig. 3), the areas of EGFR and HER2 staining partially overlapped within a single tumor nodule in seven cases (five cases of salivary duct carcinomas and two cases of carcinoma ex pleomorphic adenoma). In addition, co-expression of these proteins in one cell was occasionally observed.

EGFR and p-EGFR p-EGFR-positive cell groups were generally found in areas of extensive EGFR expression (Fig. 3). Furthermore, 68 % of EGFR-positive cases (EGFR score 1–3, 25/37) showed p-EGFR expression, and conversely, p-EGFR expression was not observed in any EGFR-negative cases (EGFR score 0, 0/10). These results indicate that EGFR expression is a prerequisite for EGFR activation. Accordingly, p-EGFR staining was seen more frequently in mucoepidermoid and salivary duct carcinomas, which frequently exhibited EGFR overexpression; specifically six of seven mucoepidermoid carcinomas were p-EGFR-positive, and 5 of 12 salivary duct carcinomas were p-EGFR-positive. Tumors that overexpressed EGFR (EGFR score 2 or 3, 18/24) were significantly more likely (p= 0.0034, Table 2) to have p-EGFR-positive cells than tumors that did not overexpress EGFR (EGFR score 0 and 1, 7/23). Therefore, EGFR overexpression most often but not always accompanied p-EGFR expression.

p-EGFR and p-Akt Nineteen tumors were p-EGFR-positive but HER2-negative. p-Akt was positive in 11 of these 19 cases. Hence, EGFR staining, regardless of HER2 staining, was associated with p-Akt staining in up to 58 % of the cases. Consistently, the p-EGFR-positive areas in those 11 tumors overlapped with the p-Akt-positive areas (Fig. 3).

HER2 and p-Akt There were four tumors that were HER2-positive but p-EGFR-negative. p-Akt staining was positive in two of these, suggesting that, in the absence of the EGFR signaling, HER2 might activate p-Akt. However, HER2 and p-Akt staining in these two cases only partially overlapped.

p-EGFR/HER2 and p-Akt Six tumors were p-EGFR-positive and HER2-positive. Of these six tumors, three showed p-Akt staining, and in two of these, the areas of p-Akt staining almost completely overlapped with p-EGFR

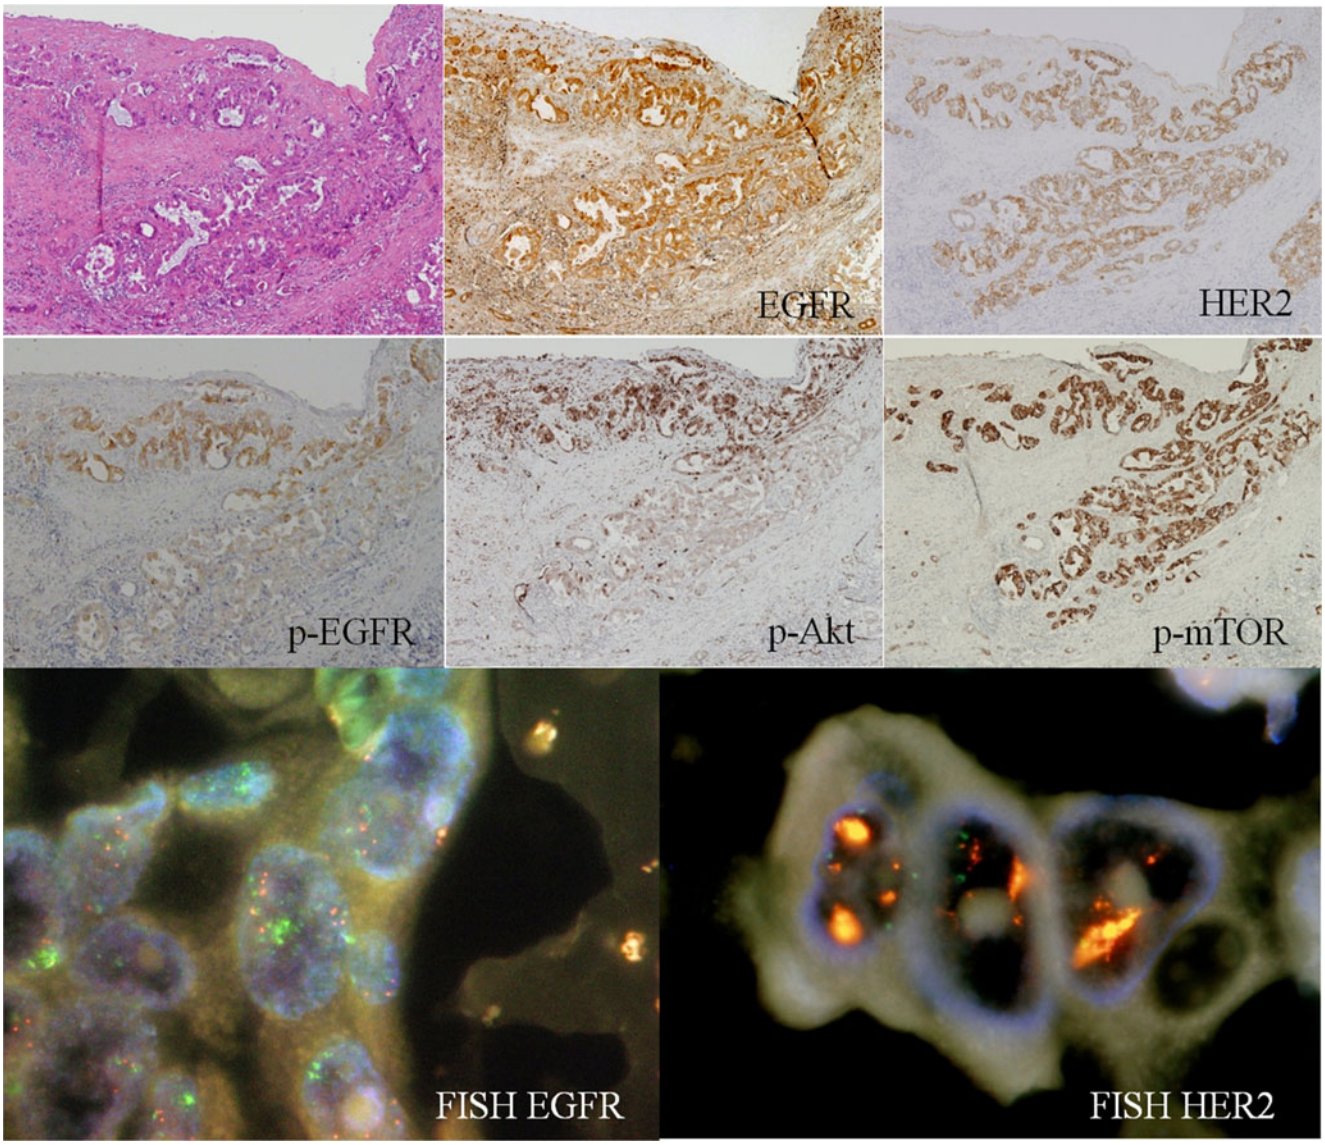

Fig. 3 Hematoxylin and eosin staining (HE), immunohistochemical staining for proteins of the EGFR/HER2 and their downstream signaling intermediates, and *EGFR/HER2* gene alterations. A case of salivary duct carcinoma showed co-overexpression of EGFR (score 2) and HER2 (score 3), and the areas of EGFR overexpression partially overlapped those of HER2 overexpression. The p-EGFR-positive areas were restricted to areas within broader EGFR overexpressing areas. The areas with p-EGFR or HER2 staining tended to overlap with areas of p-Akt and p-mTOR staining, respectively. FISH revealed *EGFR* gene copy gain due to chromosome 7 polysomy and high-level *HER2* gene amplification. *EGFR* epidermal growth factor receptor, *FISH* fluorescence in situ hybridization, *mTOR* mammalian target of rapamycin, *p-EGFR* phosphorylated EGFR

Table 2 Relationship between overexpression of EGFR or HER2 and expression of p-Akt or p-mTOR

	p-EGFR			p-Akt			p-mTOR		
	(+)	(−)		(+)	(−)		(+)	(−)	
EGFR									
(+)	18	6		14	10		14	10	
(−)	7	16	$p=0.0034$	10	13	$p=0.3868$	13	10	$p>0.9999$
HER2									
(+)	6	4		5	5		9	1	
(−)	19	18	$p=0.7298$	19	18	$p>0.9999$	18	19	$p=0.0292$

staining, whereas HER2 and p-Akt staining only partially overlapped.

p-Akt and p-mTOR Of 24 p-Akt-positive cases, 12 were p-mTOR-positive. However, 15 of 23 p-Akt-negative cases were also p-mTOR-positive. This suggests that mTOR signaling was induced by both Akt-dependent and Akt-independent mechanisms.

Gene alteration and protein expression of EGFR and HER2 and phosphorylation of downstream molecules

FISH was performed in 27 cases in which overexpression of EGFR, HER2, or both was observed. The results are summarized in Table 3.

EGFR Among 24 cases exhibiting EGFR overexpression, no *EGFR* amplification was detected. However, *EGFR* gene copy gain due to chromosome 7 polysomy was present in four of these cases (three salivary duct carcinomas and one lymphoepithelial carcinoma), and all showed p-EGFR staining consistent with EGFR activation.

HER2 Among the 10 cases exhibiting HER2 overexpression, *HER2* amplification was observed in seven cases, including five salivary duct carcinomas (five out of six) and two cases of carcinoma ex pleomorphic adenoma (two out of three).

EGFR and HER2 Nine cases (six salivary duct carcinomas, two carcinomas ex pleomorphic adenomas, and one lymphoepithelial carcinoma) showed *HER2* amplification, chromosome 7 polysomy, or both. Among these cases, two salivary duct carcinomas had both chromosome 7 polysomy and *HER2* amplification (Fig. 3). In these two cases, expression of both proteins overlapped. Furthermore, focal co-expression of EGFR and HER2 was observed in single cells in one of these. Of the other seven cases, two (one salivary duct carcinoma and one lymphoepithelial carcinoma) showed chromosome 7 polysomy only, and five cases (three salivary duct carcinomas and two carcinomas ex pleomorphic adenoma) showed *HER2* gene amplification only.

Correlation between status of EGFR/HER2 and their downstream signaling intermediates in each histological type

The activation of EGFR and HER2 was evaluated by assessing p-EGFR signal and HER2 overexpression, respectively, using IHC [29]. Cases were stratified into four categories: p-EGFR(+) and HER2(+), p-EGFR(+) and HER2(−), p-EGFR(−) and HER2(+), and p-EGFR(−) and HER2(−). Results were evaluated for each histological type of tumor with five or more cases (Fig. 4).

In the 12 cases of salivary duct carcinoma, p-EGFR was expressed in five cases, three of which harbored chromosome 7 polysomy, and HER2 was overexpressed in six cases, five of which harbored *HER2* amplification. All but one of the cases showing p-EGFR expression, HER2 overexpression, or both (eight cases in total) were p-mTOR positive. In contrast, p-Akt staining was observed in only four of these. Among the seven cases of mucoepidermoid carcinoma, six showed p-EGFR staining, but not HER2 overexpression, and p-Akt or p-mTOR staining in five and four cases, respectively.

In carcinoma ex pleomorphic adenoma (seven cases), p-EGFR staining was found in four cases, and three of these were accompanied by HER2 overexpression. All four cases were positive for p-mTOR, but p-Akt was positive in only two cases. None of the cases showed evidence of *EGFR* copy

Table 3 Immunohistochemical phenotypes of and genetic alterations in tumors showing evidence of *EGFR* or *HER2* gene alteration

EGFR epidermal growth factor receptor, *IHC* immunohistochemistry, *FISH* fluorescence *in situ* hybridization, *pEGFR* phosphorylation of EGFR, *amp* gene amplification

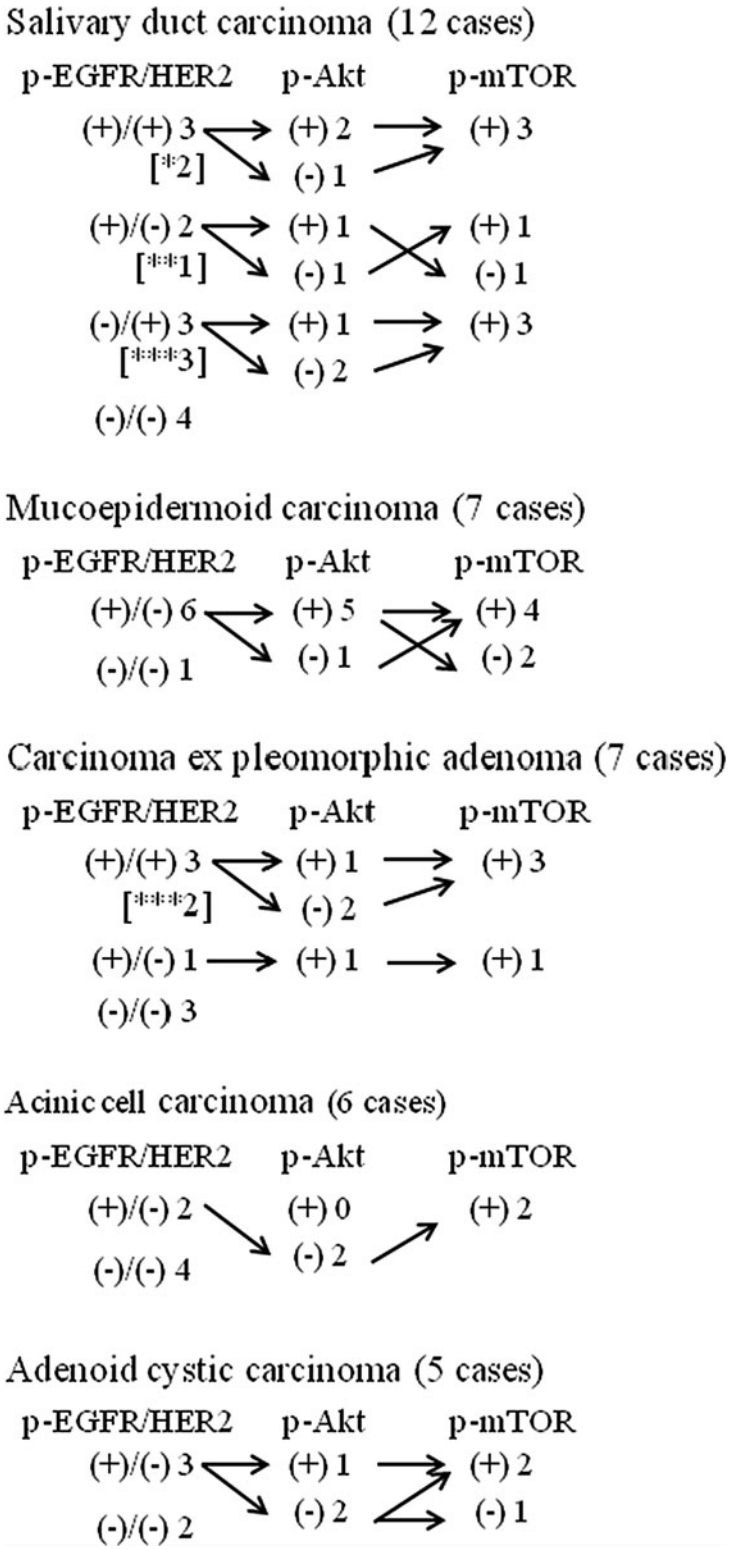

Fig. 4 Results of immunohistochemical analysis in representative histological subtypes. One asterisk: Cases showing both EGFR gene gain and HER2 gene amplification; two asterisks: cases showing EGFR gene gain; three asterisks: cases showing HER2 gene amplification

number gain; instead, two cases showed evidence of *HER2* amplification. In acinic cell carcinomas (six cases), p-EGFR was positive in two cases, and both showed p-mTOR staining; however, p-Akt was negative in both cases. Moreover, HER2 overexpression was not observed in any of these cases.

In adenoid cystic carcinomas (five cases), p-EGFR was positive in three cases; p-Akt was positive in one of these three cases, and p-mTOR in two. HER2 overexpression was not observed in any of the adenoid cystic carcinomas.

In carcinomas of all histological types listed above, p-EGFR(−) and HER2(−) cases accounted for 38 % (14/37, ranging from 14 % [one out of seven] in mucoepidermoid carcinoma to 67 % [four out of six] in acinic cell carcinoma). Among these 14 cases, p-Akt staining was positive in seven cases (two adenoid cystic carcinomas, two salivary duct carcinomas, one acinic cell carcinoma, one carcinoma ex pleomorphic adenoma, and one mucoepidermoid carcinoma), and p-mTOR staining was found in two (salivary duct carcinoma and acinic cell carcinoma) of these.

Altogether, three signal transduction pathways were identified (Fig. 5). The first is the EGFR/HER2–(Akt)–mTOR pathway: 7 of 12 salivary duct carcinomas and four of seven carcinomas ex pleomorphic adenoma exhibited signs of activation of this pathway associated with gene gains of *EGFR* and/or *HER2*. The second is an EGFR(–Akt)–mTOR-dependent pathway: five of seven mucoepidermoid carcinomas, two of six acinic cell carcinomas, and two of five adenoid cystic carcinomas exhibited signs of activation of this pathway without increased gene copy number of *EGFR* or *HER2*. The last pathway is p-Akt-dependent but unrelated to EGFR or HER2 and mostly p-mTOR negative.

Discussion

A large body of evidence links overexpression of EGFR, HER2, or both to malignancy in a wide array of human tumors [2, 3]; therefore, EGFR and HER2 and downstream effector molecules are promising candidates as targets for effective therapies. Drugs targeting EGFR [12–16], HER2 [2], and mTOR [30] are available, and Akt inhibitors have also been assessed in clinical trials as treatments for solid tumors [31]. Although salivary gland carcinomas are in general not highly aggressive, they constitute a biologically heterogeneous group, and depending on the histological types, they are occasionally life-threatening [1]. Therefore, patients should be treated based on their unique phenotype. However, there are very few studies that provide a comprehensive picture of the expression or activation status, or gene alteration status of components in the EGFR/HER2–Akt–mTOR pathways in human salivary gland carcinomas. The present study was intended to provide phosphoprotein mapping of this pathway as a potentially promising guide for the selection of appropriate targeting regimens.

Our results offer insight into the role of EGFR- and HER2-mediated signaling. Past studies have described the frequency of EGFR expression in salivary gland carcinomas, ranging from 36 to 85 %, depending on the selection of histological types and the diversity in the scoring criteria used in IHC analyses [4–9]. Here, we observed EGFR expression in 79 % (37/47) of all cases and found overexpression in specific histological types, e.g., mucoepidermoid carcinoma (seven out of seven) and salivary duct carcinoma (9/12). p-EGFR staining was consistently observed in these two histological types. Therefore, the monoclonal antibody against EGFR, cetuximab, might be a candidate for targeted treatment of patients with either mucoepidermoid or salivary duct carcinoma.

Although the mutations in the TK domain of *EGFR* that are frequently found in lung cancer were rare in salivary gland carcinomas [13, 32], recent studies of lung and colonic carcinomas indicate that a high level of chromosome 7 polysomy, which goes along with increased *EGFR* copy number, may also function as a biomarker for responsiveness to TKIs [15, 33]. If this is the case, salivary gland carcinoma might also be successfully treated with TKIs. Regarding numerical aberrations of the *EGFR* gene, there has been only one report describing polysomy of chromosome 7 in salivary duct carcinomas [7]. In the current study, chromosome 7 polysomy was present in four cases (three salivary duct carcinomas and one lymphoepithelial carcinoma), corresponding to 9 % of all cases. Hence, more

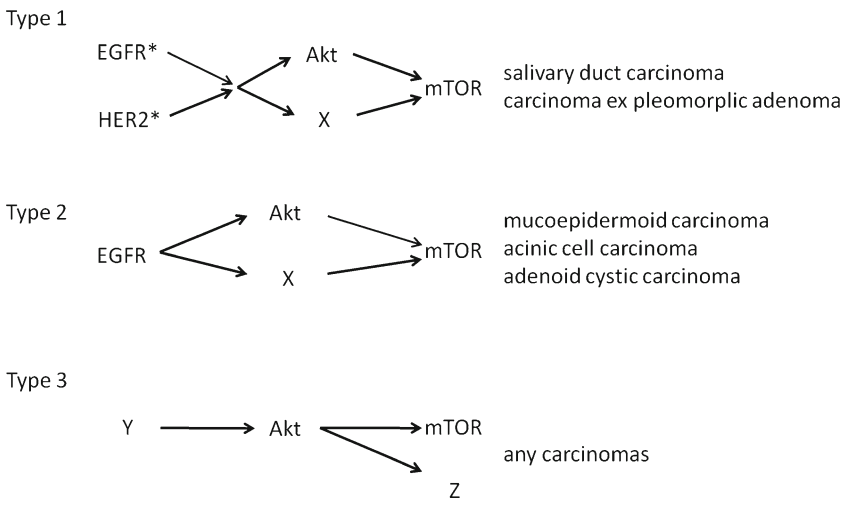

Fig. 5 Putative signaling pathways active in salivary gland carcinomas. *EGFR* epidermal growth factor receptor, *mTOR* mammalian target of rapamycin, *X* responsible kinase(s) for mTOR other than Akt, *Y* growth factor receptor(s) other than EGFR or HER2, *Z* substrate(s) of Akt other than mTOR. *Asterisk* indicates increase of gene copy by amplification or polysomy

extensive exploration of *EGFR* aberrations may contribute to effective and optimal EGFR-targeted therapy with TKIs.

Past studies revealed HER2 overexpression in 10–38 % of salivary gland carcinomas [4–7, 10, 11]. We found this in 21 % of all 47 cases, restricted to salivary duct carcinomas (50 %), carcinomas ex pleomorphic adenoma (43 %), and myoepithelial carcinomas (33.3 %). Unlike EGFR, antibodies against the phosphorylated form of HER2 have not been widely used on paraffin-embedded sections. A previous study of human mammary epithelial cells showed that the basal phosphorylation level of HER2 increased due to enhanced HER2 autophosphorylation, cross-phosphorylation by EGFR, or even through increased autocrine stimulation of HER2 heterodimers [29]. Thus, we interpreted the HER2 overexpression observed in the current study as being equivalent to HER2 activation.

Unlike *EGFR* gene amplification, *HER2* gene amplification was often (70 % of HER2-overexpressing tumors) responsible for HER2 overexpression; *HER2* amplification occurred most frequently in salivary duct carcinomas (42 %, 5/12 cases), and the frequency was higher than that (12 %) in the previous study [7]. In addition, we observed *HER2* gene amplification in 29 % (two out of seven) of carcinomas ex pleomorphic adenoma; interestingly, *HER2* gene amplification in carcinomas ex pleomorphic adenoma has not been reported previously. Although it was not clear whether gene gains of *EGFR* or *HER2* influence the pattern of activation of downstream molecules, tumors harboring *EGFR* or *HER2* gene gains generally showed activation of EGFR or HER2, as well as the Akt/mTOR axis.

Only two studies [7, 18] on the relationship between *EGFR* and *HER2* gene alterations in salivary gland carcinomas have been published. One study showed that three out of eight *HER2*-amplified tumors harbored chromosome 7 polysomy (*EGFR* gene copy gain) [7]. Two of seven *HER2*-amplified tumors harbored chromosome 7 polysomy in our study, and co-expression of EGFR and HER2 proteins within a tumor nodule was confirmed by immunohistochemical analysis; focal co-expression on a cell-by-cell basis was observed in one case. These cases showed mTOR activation.

From a therapeutic point of view, inhibiting EGFR or HER2 alone is not optimal for effective inhibition of tumor cells, highlighting the need for multipoint intervention. For this purpose, general assessment of effector protein activation through phosphoprotein study needs to be performed. The status of p-Akt in salivary gland carcinomas has not been evaluated extensively. One study revealed a high frequency (86 %) of p-Akt expression in adenoid cystic carcinomas based on IHC [22]. However, that study did not focus on other histological types nor on the expression or the activation status of EGFR or HER2 [22]. In the current study, p-Akt staining was found in 51 % of all 47 cases, in 58 % of the cases showing EGFR activation, and in 50 % of the cases showing HER2 activation. Moreover, p-Akt was frequently seen in mucoepidermoid carcinomas (six out of seven), and five of these six p-Akt-positive mucoepidermoid carcinomas showed evidence of EGFR phosphorylation. Indeed, in these cases, the area showing positive p-EGFR staining tended to overlap with the areas of p-Akt staining.

The mTOR protein is a critical downstream modulator of Akt and is an appealing therapeutic target because it has an established inhibitor, rapamycin [30, 34]. However, no previously published pathological study focused on mTOR in salivary gland carcinomas. We found that mTOR is activated in 57 % of all 47 tumors, notably in a high percentage of salivary duct carcinomas (83 %). These findings indicate that, in a significant percentage of this subset, mTOR is activated, and therefore, tailored treatment with rapamycin may be considered.

The correlation between the activation patterns of EGFR/HER2 and Akt, or between the activation patterns of Akt and mTOR, was not entirely consistent in the current study, possibly due to complex cross-talk between pathways. For example, although Akt is a major positive regulator of mTOR, ras-extracellular signal-regulated kinase 1/2 also converges to mTOR [34]. Another possibility is that activation of Akt by p-EGFR or activation of mTOR by p-Akt may be executed in a transient manner, and thus, histopathological evidence of simultaneous activation of these kinases may be difficult to detect in fixed tissue specimens.

Overall, dysregulation of the kinase-driven EGFR/HER2(–Akt)–mTOR pathway might constitute a critical mechanism underlying the pathology of a substantial fraction of salivary gland carcinomas, although other signaling pathways including c-kit and Wnt/β-catenin signaling pathways might be involved in p-EGFR-negative and HER2-negative cases [1]. Moreover, we teased out specific categories that could be defined by the activation profiles of this axis and, therefore, found three types of signal transduction cascades (Fig. 5).

The first category of tumors involve a EGFR/HER2(–Akt)–mTOR-dependent pathway that is frequently associated with *EGFR* and/or *HER2* gene gains. Theoretically, cocktails of monoclonal antibodies against EGFR, cetuximab, or anti-HER2, trastuzumab, or possibly, a dual inhibitor of both EGFR and HER2, e.g., lapatinib [35], combined with rapamycin, could be candidate treatments for the tumors in this group. Moreover, EGFR-TKIs and/or an Akt inhibitor could be useful depending on the presence of *EGFR* gene gains or Akt activation, respectively.

The second category of tumors involved a EGFR(–Akt)–mTOR-dependent pathway, but no gene gains. This category of tumors may be sensitive to combination regimens involving anti-EGFR agents and rapamycin directed against mTOR.

The last category comprises Akt-dependent carcinomas that do not depend on signals from EGFR or HER2. This

particular subset of tumors could be candidates for treatment with Akt inhibitors, e.g., perifosin [31].

The present study on archival tissues of salivary gland carcinomas provides a detailed description of EGFR and/or HER2 activation via the mTOR pathway, and overall these findings provide insight into possibilities for treatment regimens for salivary gland carcinomas that involve tailored combination therapies.

ORIGINAL ARTICLE

Cancer of unknown primary originating from oropharyngeal carcinomas are strongly correlated to HPV positivity

Abstract Human papillomavirus (HPV)-associated oropharyngeal squamous cell carcinoma (OSCC) has been identified as a distinct entity within squamous cell carcinoma of the head and neck. It is associated with special characteristics and is preponderantly restricted to palatial tonsils and base of tongue. These primary locations have for long been associated with the clinical situation of cancer of unknown primary (CUP). In order to investigate the putative relationship between CUP and HPV, we investigated 26 patients who initially presented as CUP and were finally diagnosed with carcinomas of these two locations. Twenty-one cases proved to be positive for high-risk HPV. Primary carcinomas were small and frequently presented in a submucosal location. HPV-positive carcinomas, presented more often in women, showed atypical basaloid differentiation and correlated to cystic lymph node metastases. This study demonstrates an over-representation of HPV-associated OSCC in patients who were initially diagnosed with CUP. This finding indicates a strong relationship between HPV-association and CUP in OSCC. The frequent manifestation as CUP is presumably caused by the unusual predisposition for small size and submucosal location combined with early lymphatic metastization. In order not to miss clinically occult carcinomas, consequent interdisciplinary cooperation in combination with meticulous histological workup is mandatory.

Keywords HPV · CUP · Oropharyngeal carcinoma · Lymphoepithelial carcinoma · p16

Introduction

The majority of squamous cell carcinomas of the head and neck (HNSCC) are attributable to chronic alcohol and/or tobacco abuse [1, 2]. In the last 10 years, an enormous amount of knowledge has been accumulated regarding the significance of high-risk human papillomavirus (HPV) in oropharyngeal carcinoma [3, 4]. In contrast to HNSCC associated with alcohol and/or tobacco, high-risk HPV-associated oropharyngeal squamous cell carcinoma (OSCC) are characterised by the following typical clinical, histological and molecular aspects: occurrence at younger age on average, frequent absence of classical risk factors, correlation with oral sexual habits, strong predilection for the palatial tonsils and the base of tongue, unusual basaloid or lymphoepithelial histological differentiation instead of squamous differentiation, higher degree of radiosensitivity and overall better survival [5–10].

The multi-step process of infection of squamous epithelial by high-risk HPV involves obligatory contact to the basal membrane, which might be enabled by the reticulated nature

The results were presented at the meeting of the German Society of Pathology in Leipzig 2011.

of the cryptal epithelium [11]. High-risk HPV subtype 16, which affects crucial molecular pathways in squamous cells through its viral oncoproteins E6 and E7 [12], has been identified in about 90 % of these carcinomas [13]. E7 binds to the retinoblastoma protein, leading to a release of the transcription factor E2F which causes an upregulation of p16 in the infected epithelial cells [14, 15]. The resulting immunohistological overexpression of p16 has been suggested as a diagnostically valuable surrogate biomarker of oncogenic HPV infection [16, 17]. A recent Swedish study documents a seven-fold increase of HPV-associated tonsillar carcinoma during the years 1970–2006 [18]. This increased incidence has been primarily attributed to a change in sexual habits [6].

Due to these major differences, in particular in clinical presentation, molecular carcinogenesis and better prognosis, HPV-associated oropharyngeal carcinoma is now regarded as a new entity, distinct from classic alcohol- and tobacco-associated HNSCC [19–21].

In approximately 3–9 % of all metastasized HNSCC, the primary carcinoma cannot be detected despite thorough clinical and radiological examinations that resulted in the clinical situation of cervical cancer of unknown primary (CUP) [22–25]. In many cases following the initial presentation as cervical CUP, the clinically occult primary tumour can finally be detected in the palatinal tonsils, the base of tongue, the nasopharynx or rarely in other locations. Therefore, bilateral tonsillectomy and biopsies in the base of tongue and in the nasopharynx have long been recommended in cases of cervical CUP [23, 26].

The two anatomical regions of palatinal tonsils and of base of tongue, therefore, play a paramount role both in the new entity of HPV-associated OSCC and in the clinical setting of cervical CUP. Regarding the extensive literature accumulated on HPV-associated OSCC, it is remarkable that only few data statistically support association with cervical CUP. In order to investigate this relationship, we decided to study clinical, histological and molecular aspects of 26 consecutive patients who initially presented as cervical CUP and were finally diagnosed with primary carcinomas of the palatinal tonsils and the base of tongue.

Materials and methods

Materials

The retrospective analysis involved 26 patients of the Department of Otorhinolaryngology, Head and Neck Surgery at the Ludwig Maximilian University in Munich, Germany between the years 1994 and 2009 who initially presented with cervical lymph node metastases and occult primary tumours. All patients underwent clinical investigation, computer tomography of the head and neck, thorax and abdomen, and endoscopy of the pharynx, larynx, trachea, bronchi and oesophagus without detection of a primary tumour (cervical CUP). Diagnostic lymph node dissection was performed to confirm the malignancy of the disease. Then, diagnostic tonsillectomy and multifocal biopsies in the base of the tongue and the nasopharynx were performed. Lastly, patients underwent selective or modified radical neck dissection. All cases were included in which a primary carcinoma was finally detected in the palatinal tonsils (n=12) or in the base of tongue (n=14). The tumour specimens were independently reviewed by two expert oral pathologists (GA and SI).

Clinical data from patient files were used to ascertain age, sex, and risk factors associated with tobacco and alcohol. Patient age ranged from 45 to 86 years, with a median of 62, and the gender breakdown consisted of 18 males and eight females. Clinical follow-up was not part of the study objectives.

Methods

Surgical specimens from the tonsils and the base of tongue were completely embedded and processed in serial sections in order to enhance detection of small tumours. The pathological workup consisted of: dominant tumour differentiation as either lymphoepithelial (with abundant intraepithelial lymphocytes), basaloid syn: transitional or squamous; maximum size of the primary tumour and of the largest lymph node metastasis; presence of microscopic involvement of the superficial mucosa and of macroscopic cysts in nodal metastases.

Immunohistological and molecular studies were performed on the primary tumour (in four small tumours, molecular studies had to be performed on the nodal metastases). Tissue sections were immunostained with antibodies against p16, p53, pan-keratin and Ki67 using a Ventana Bench Mark XT and Ventana reagents according to slightly modified standard protocols of the manufacturer [27].

A positive result of p16 immunostaining was defined as strong nuclear and cytoplasmic reaction in the majority of tumour cells and a negative result as none or minor reaction in some scattered tumour cells. HPV was detected and subtyped by E6 nested multiplex polymerase chain reaction, as described elsewhere [28]. Briefly, a nested-PCR assay with degenerate E6/E7 consensus primers and with type-specific primers for the detection and typing of HPV genotypes 6/11, 16, 18, 31, 33, 35, 39, 42, 43, 44, 45, 51, 52, 56, 58, 59, 66 and 68 was performed. Furthermore, all cases were tested for the presence of Ebstein-Barr virus (EBV)-encoded RNA antigen to detect an infection with EBV by in situ hybridization on a Ventana BenchMark XT with Ventana reagents applying Ventana protocols. The significance of experimental data was quantified using the Excel software (Microsoft Corp., Redmond, WA) to calculate Student's t test, Fischer's exact test and odds ratio. For comparative groups in which the unadjusted value of the directly calculated odds ratio was 0 due to a zero size sample; all group values were adjusted by 0.5 to provide a

more meaningful result. In particular, the groups involving no HPV-negative women and no HPV-negative non-smokers were adjusted.

Results

Clinical, (immuno)-histological and molecular data are summarised in Table 1.

Primary tumour

The average size of the primary tumour was 1.1 cm in the tonsils (0.3–2.4 cm) and 0.8 cm in the base of the tongue (0.2–2.2 cm). In 17 of the 26 cases (65 %), the size of the primary tumour was 1.0 cm or less (Figs. 1c and 2a, b). In many cases, serial sectioning and additional immunohistological staining with pan-keratin, p16 and/or Ki67 proved to be helpful or necessary for the detection, especially of small carcinomas

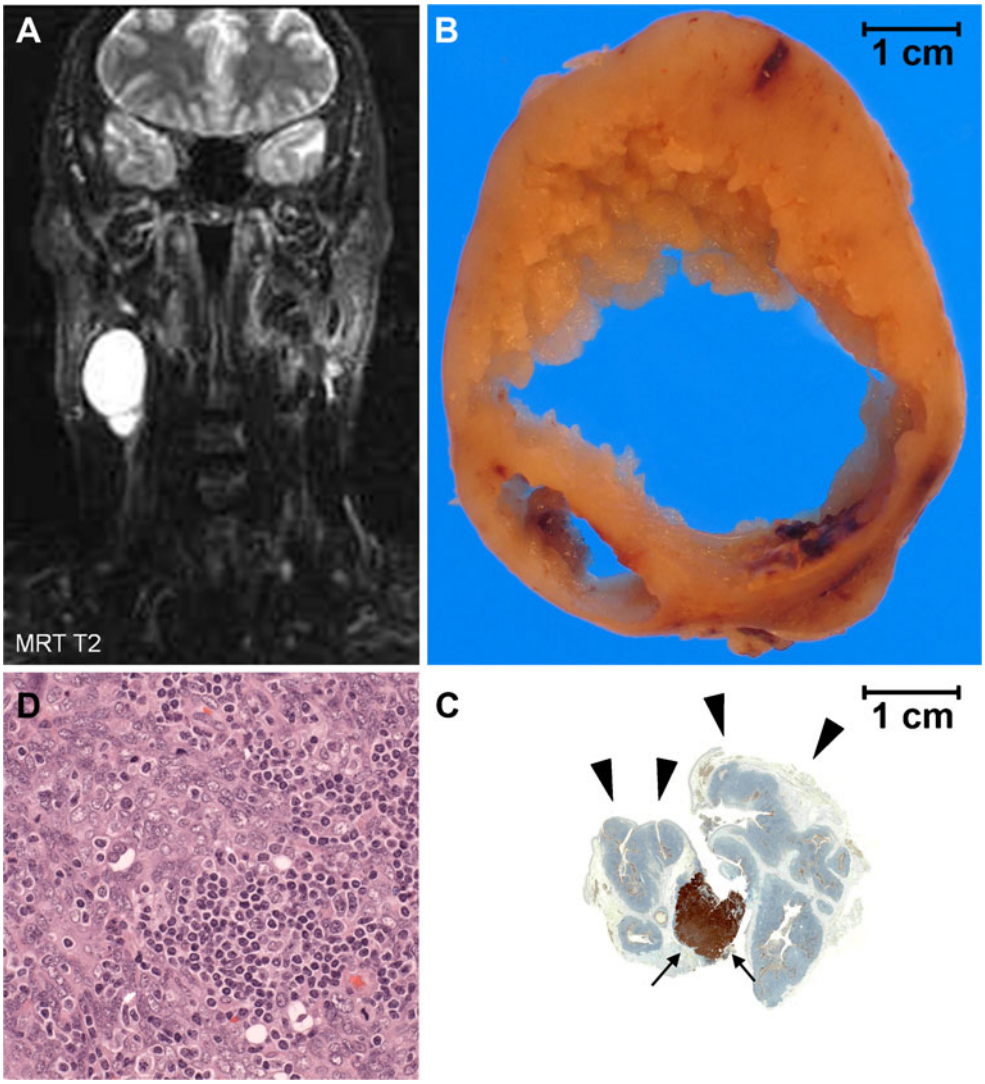

Fig. 1 **a** a 54 year old male patient (case no. 6) with a large cystic cervical lesion in magnetic resonance tomography, T2-weighted image; **b** Macroscopic image of a cystic lymph node metastasis (6.3 cm); **c** Ipsilateral palatial tonsil (*arrowheads*: surface epithelium) with a small, deep and submucosal located HPV-associated carcinoma (p16-positive: *brown*; *arrows*; 0.8 cm; identical magnification to **b**); **d**: Lymphoepithelial histological differentiation of the tonsillar carcinoma

and/or of carcinomas with lymphoepithelial differentiation resembling reticulated cryptal epithelium (Figs. 1c, d and 2b). Eight of the 12 tumours of the tonsils (67 %) and nine of the 14 tumours of the base of tongue (64 %) were completely devoid of infiltration of the superficial mucosa (Figs. 1c and 2a, b).

Histological differentiation revealed a continuum from lymphoepithelial to basaloid and conventional squamous type (usually non-keratinizing), often with a mixture of different patterns (Fig. 3). The quantitatively dominant pattern was lymphoepithelial in 19 %, basaloid in 74 % and squamous in 7 % of the cases.

Lymph node metastases

The average size of the largest lymph node metastasis (2.9 cm; 3.1 cm in tonsillar and 2.7 cm in base of the tongue carcinoma) was significantly larger than the average size of the primary tumours (0.9 cm, $p \leq 0.001$ (tonsils) $p \leq 0.0001$ (base of tongue)). With the exception of only two cases (nos. 9 and 10, Table 1), all lymph node metastases were generally larger than the respective primary tumours (Table 1; Fig. 1). Macroscopic cysts in lymph node metastases were present in 12 of the 26 cases (46 %; 50 % in tonsillar and 43 % in base of the tongue carcinoma; Fig. 1a, b). The spectrum of histological differentiation in the lymph node metastases was equivalent to the spectrum in the primary tumours (Fig. 3). In all cases in which the primary tumour was located in the tonsils, the lymph node metastasis was ipsilateral. In the cases in which the primary tumour was located in the base of tongue, lymph node metastasis was ipsilateral in nine cases and ipsilateral and contralateral in four cases. We performed modified radical neck dissection in seven cases and selective neck dissection in 19 cases.

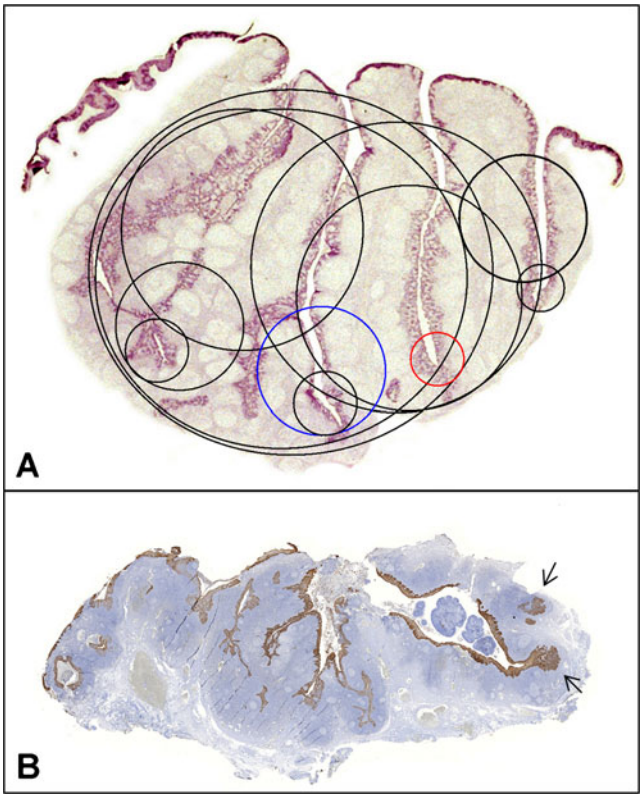

Fig. 2 **a** All ten HPV-positive tonsillar carcinomas are projected onto a regular palatial tonsil (pan-Keratin), corresponding to relative size and topographical location. *Red circle*: case no. 11 (Fig. 2b); *blue circle*: case no. 6 (Fig. 1c). **b** Small HPV-associated carcinoma (case no. 11; 0.4 cm), developing from the base of a tonsillar crypt (*arrows*; pan-Keratin)

Status of HPV and EBV

Twenty-one of the 26 cases (81 %) showed both immunohistological overexpression of p16 and molecular proof of high-risk HPV (83 % in tonsillar and 79 % in base of the tongue carcinoma), whereas 19 % showed negative results for both techniques. Molecular subtyping showed high-risk HPV type 16 in 18 cases, type 33 in two and type 58 in one case. Analysis for EBV (based on in situ hybridization) was negative in all cases (Table 1).

Comparison of tonsillar and base of the tongue carcinomas

Comparing carcinomas from the tonsils and the base of the tongue, no relevant differences were found concerning the average size of the primary tumour or the lymph nodes, the spectrum of histological differentiation or the presence of risk factors or cystic metastases. Whereas base of the tongue carcinomas mostly involved the full thickness of the lymphoepithelial tissue, in seven of the 12 tonsillar carcinomas (58 %), tumours were restricted to the bottom half of the tonsils adjacent to or in direct contact to the crypts (Figs. 1c and 2a, b).

Comparison of HPV status

Both general comparison as well as statistical analysis of HPV status was hampered by the fact that only five of the 26 cases proved to be HPV-negative (two in the tonsils and three in the base of the tongue; Table 1). For this reason, tonsillar and base of the tongue carcinomas were combined for this analysis.

HPV-positive and HPV-negative carcinomas showed a minor difference concerning the average size of the primary tumour (1.1 cm in HPV-positive versus 0.4 cm in HPV-negative carcinomas) but no difference in the average size of the largest lymph node metastasis (2.9 cm in HPV-positive versus 3.1 cm in HPV-negative carcinomas). Both groups showed a comparable spectrum of the histomorphological differentiation.

Relevant differences between HPV-positive and HPV-negative carcinomas were present for the following aspects:

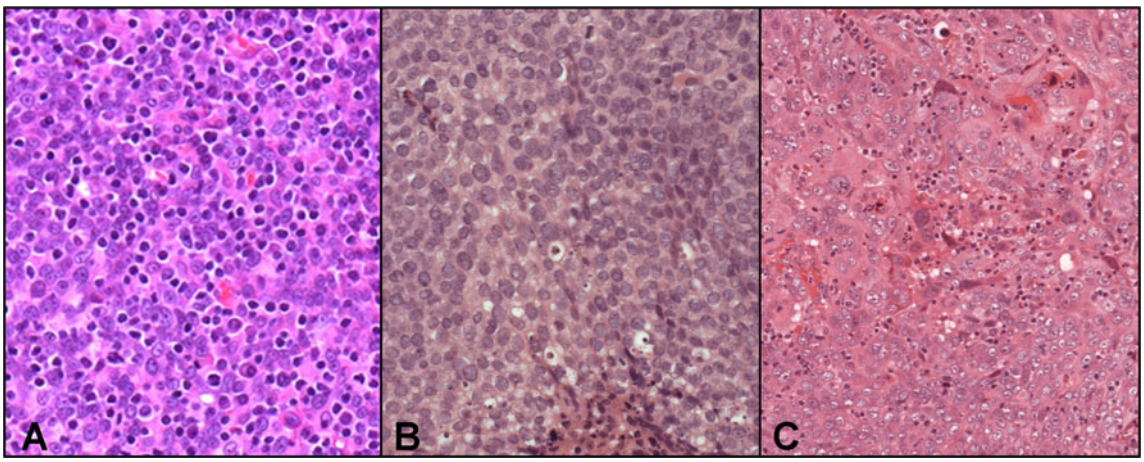

Fig. 3 Atypical, continuous histological spectrum of HPV-associated oropharyngeal carcinoma: Dominance of lymphoepithelial (**a**) and basaloid (**b**) differentiation. Rarely squamous (usually non-keratinizing) differentiation (**c**)

All eight female patients had HPV-positive carcinomas (100 %), whereas thirteen of the 18 male patients had HPV-positive carcinomas (72 %), resulting in an odds ratio of 7.08 (95 %CI) and Fisher's exact test of $p=0.13$. The risk factors tobacco and/or alcohol were present in all five HPV-negative cases (100 %) but only in 32 % of HPV-positive cases, providing an odds ratio of 15 (95 %CI) and p value of 0.03. Cystic nodal metastases were present in 20 % of HPV-negative carcinomas but in 52 % of HPV-positive carcinomas (corresponding to 92 % HPV-positivity in those cases with cystic lymph node metastasis), corresponding to an odds ratio of 3.0 and $p=0.29$.

Discussion

HPV-associated OSCC has been identified as a distinct entity with clinical, histological, molecular, prognostic and therapeutic characteristics that are distinct from classical HNSCC associated with tobacco and/or alcohol [19, 20, 29]. One of these characteristics is the preponderant topographical restriction to the palatinal tonsils and the base of tongue [10, 30]. These two special locations, on the other hand, have for long been known to be the predominant sites of occult primary carcinomas in cases of cervical CUP [24–26]. This parallelism leads to the consideration of whether a causal relationship exists between HPV positivity and cervical CUP. This clinically important question has not been sufficiently investigated in the existing literature.

Correlation between HPV-association and CUP

To the best of our knowledge, this is the first study demonstrating an over-representation of HPV-associated carcinoma in a large cohort of OSCC that presented as cervical CUP. Eighty percent of our 26 CUP cases with subsequent histological detection of occult tonsillar and base of the tongue carcinomas proved to be positive for high-risk HPV in the majority for type 16. This ratio surpasses by far the average rate of HPV-positivity of 51 % (from 39 to 84 %) of HNSCC in these two special sites, independent of CUP [20, 31, 32].

So far, a relationship between HPV-positivity and CUP had only been addressed in the inverse direction by Weiss et al. [33]. Their study demonstrated that 33 % of HPV-associated tonsillar and base of tongue carcinoma clinically presented as cervical CUP, surpassing the reported figures of 3–9 % CUP in HNSCC in general, independent of HPV status [23]. In summary, the data of our study and of the study by Weiss et al. [33] together strongly support a positive relationship between HPV-association and CUP in OSCC. The following aspects contribute to this relationship.

It has been shown that HPV-associated OSCC generally tend to be small, as indicated by a dominance of low pT-stages (pT1/pT2) [18, 31]. However, detailed data on the exact tumour size are lacking. Our investigation demonstrates for the first time that the majority of occult HPV-associated carcinoma in CUP is small or very small in size between 0.3 and 1.0 cm, rendering preoperative clinical or radiological detection of these carcinomas difficult or impossible (Table 1; Figs. 1 and 2).

In parallel, it has been postulated that HPV-associated OSCC develop from basal cells of the reticulated cryptal epithelium as a result of their susceptibility for productive infection with high-risk HPV, analogous to the well-understood situation in the transitional epithelium of the cervix uteri and anorectal zone [32]. Our demonstration of a deep, submucous location of small carcinomas for the most part in contact to basal parts of crypts (Fig. 2) strongly supports this postulated development both in the tonsils and the base of tongue. This pathogenetic development from lymphoepithelial cryptal epithelium correlates to the high rate of basaloid and lymphoepithelial histologic differentiation of these tumours (Figs. 1d and 3).

Unexpectedly for their small size, HPV-associated OSCC are characterised by a high rate of lymph node metastases at the time of clinical diagnosis (65–93 %). In particular, large and cystically transformed lymph node metastases are a strong indicator for HPV-association (92 % in our study) [18, 31]. This strong tendency for early lymphatic metastization, in combination with frequent small size and deep, submucosal location, combines to contribute to the frequent clinical presentation of those carcinomas as cervical CUP, both in the tonsils and the base of tongue. The reasons for the frequent, early and rapid lymphatic metastization remain unclear and necessitate further investigation.

HPV-negative OSCC can, in a minority of cases, also present clinically as cervical CUP with or without cystic lymph node metastases, manifest as small and submucosal tumours and show atypical histological differentiation, all features which appear to be typical for HPV-associated

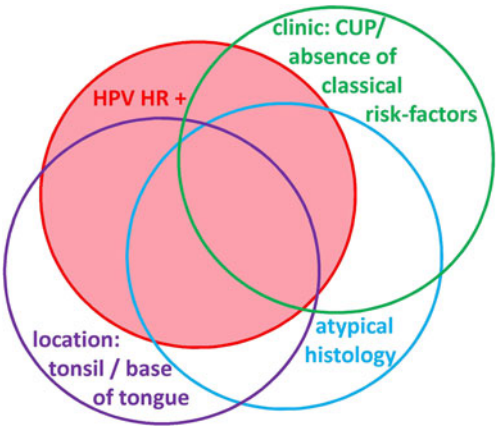

Fig. 4 The entity of HPV-associated oropharyngeal carcinoma is characterised by a variable overlap of typical, however not specific or obligate clinical and histomorphological criteria

HNSCC. As illustrated in Fig. 4, all these criteria are typical and diagnostically important; however, they are neither obligatory nor sufficient for the determination of HPV-association. In this complex clinicopathological constellation, further immunohistological and/or molecular studies are therefore often necessary.

Clinical-pathological algorithm for detection of occult carcinomas

Regarding the special prognostic and therapeutic implications of HPV-associated oropharyngeal carcinoma, their frequent clinical presentation as cervical CUP necessitates a consequent search for any occult primary tumour. In cases of cervical CUP with one or more of these clinical (absence of classical risk factors) and/or histological characteristics (cystic transformation of nodal metastases; atypical histological differentiation), additional immunohistological (p16) and/or molecular studies should be performed in the lymph node metastasis to prove or exclude HPV association. In case of HPV-positivity, a recommendation should be given in the pathology report for diagnostic tonsillectomy and meticulous biopsies in the base of the tongue, as there is a high likelihood that occult primary carcinoma may be situated in one of these two locations. In contrast, HPV-associated carcinoma only rarely develops in the nasopharynx [34].

Regarding the small size and deep location of the majority of these carcinomas, a meticulous histological workup of the surgical specimens is necessary in order not to miss these carcinomas. The palatinal tonsils must be completely embedded, often combined with serial sections. Additional immunohistological staining (keratin, p16, Ki67) can assist in the detection, especially of small carcinomas with lymphoepithelial differentiation, which resemble physiological cryptal epithelium (Figs. 1, 2, and 3a).

This algorithm for a consequent search for occult primary carcinomas demands intense communication between clinicians and pathologists. Deficits in this communication may lead to a failure in detecting occult carcinomas, resulting in a prolonged or life-long situation of cervical CUP, which harbours the risk of insufficient or improper treatment such as overly aggressive adjuvant radiotherapy or ultimately resulting in severe adverse psychological effects.

Summary

This study strongly supports a causal relationship between HPV-associated oropharyngeal carcinoma and the clinical situation of cervical CUP. This relationship is due to the unusually small size of many of these carcinomas in a deep, submucous location, combined with frequent and early lymphatic metastization. Due to the unique prognostic and therapeutic specialities of HPV-associated OSCC and the severe negative psychological consequences resulting from a life-long CUP condition, early and consequent interdisciplinary cooperation is mandatory to effectively detect occult primary tumours.

Abstract In patients with serous adenocarcinoma (SAC) of the endometrium, we evaluated the prognostic importance of clinicopathological parameters, DNA ploidy, and immunoexpression of p53, estrogen receptor (ER), progesterone receptor (PR), and Ki-67. In a series of 73 stage I and II SAC, DNA ploidy analysis was performed on hysterectomy specimens using DNA image cytometry. Immunohistochemical analysis of p53, ER, PR, and Ki-67 expression was additionally performed. In the review of the histological slides by three gynecologic pathologists, the presence of a serous component was not agreed upon in 17 (23 %) cases. The remaining 56 cases, consisting of pure SAC or SAC mixed with endometrioid adenocarcinoma, were further analyzed. Tumor recurrence was observed in 14 patients, and 28 patients died during the follow-up period. Patients with diploid (n=19), aneuploid (n=29), and tetraploid (n=8) tumor had 5-year recurrence rates of 10, 38, and 53 %, respectively (p=0.09). A DNA ploidy parameter, 5c exceeding rate, was found to be a prognostic marker for recurrence (p=0.03), progression-free survival (p<0.01), and overall survival (p=0.02). Immunoexpression of p53, ER, PR, and Ki-67 did not have prognostic value, and the same was true for FIGO stage, lymphovascular invasion, the extent of myometrial invasion, and lymphadenectomy. The histological diagnosis of SAC may be difficult in some cases. Established clinicopathological parameters do not seem to be strong prognosticators in stage I and II disease. A DNA ploidy parameter, 5c exceeding rate, may be a prognostic marker in this patient group and should be further validated in larger series.

Introduction

Endometrial carcinoma (EC), the most common gynecological malignancy in the Western world, is considered to be a relatively less aggressive tumor with a good prognosis. Nearly 30 years ago, Lauchlan and Hendrickson et al. recognized a distinct histological type, serous adenocarcinoma (SAC), which has a more aggressive behavior [1, 2]. SAC is a rare tumor accounting for 4–10 % of all EC [3, 4]. SAC usually arises from atrophic endometrium and therefore

occurs in relatively older women [3, 5]. SAC differs from endometrioid adenocarcinoma (EAC) in a number of respects; estrogen receptor (ER) and progesterone receptor (PR), usually present in normal endometrium and EAC, are less frequently expressed in SAC [6]. The mutation of *TP53*, coding for the tumor suppressor p53, is considered to be an early event in SAC as the mutation has been demonstrated in intraepithelial carcinoma [7]. Ki-67, a nuclear protein associated with cell proliferation, is more extensively expressed in SAC compared to EAC [8]. In contrast to EAC, SAC has not been found to be associated with *PTEN* and *KRAS* mutation or microsatellite instability [9]. Recent gene expression studies have demonstrated different profiles in SAC compared to EAC grade 1 and 2 [10]. SAC is associated with DNA aneuploidy, and most of the tumors show a DNA index >1.60 and a higher 5c exceeding rate (5c ExR) than EAC [11].

The incidence of recurrence after primary therapy is higher in SAC than EAC [12, 13]. Furthermore, SAC is more often diagnosed at advanced stage compared to EAC [3]. In spite of its rarity, SAC has been shown to be responsible for 39 % of all EC-related deaths [4]. However, in an accumulated multinational series of 8,033 EC patients, SAC was found in 323 cases (4 %) with 80 % overall 5-year survival in stage I patients [3]. This indicates that a substantial number of SAC patients have a good prognosis, but reliable prognostic indicators are lacking. In the present study, we evaluated the prognostic role of clinicopathological parameters, DNA ploidy, and immunohistochemical markers in stage I and II SAC.

Materials and methods

This is a study of consecutive patients with SAC of the endometrium referred to the Norwegian Radium Hospital from October 1998 to December 2007. Altogether, 215 patients were diagnosed with SAC in the period, out of which 73 stage I and II cases were available for DNA ploidy and histological review in hysterectomy specimen. The specimens were retrieved from the archives of the Department of Pathology. Data regarding FIGO stage (2009), the extent of myometrial invasion, and lymphovascular invasion (LVI) were retrieved from pathological reports. Clinical data were provided by the Department of Gynecologic Oncology. Data on patient death were acquired from the death register of the Central Bureau of Statistics, which is based on the transmitted death certificates by the patient's physician. Simple and radical hysterectomies were performed in 60 and 13 cases, respectively. In 29 patients, infracolic omentectomy was performed. Both pelvic and paraaortic lymphadenectomy were done in 16 cases and only pelvic lymphadenectomy in 26 cases. Twenty-three patients received adjuvant chemotherapy, ten patients received radiotherapy, and five patients received both. Patients with recurrence were treated with chemotherapy (six cases), radiotherapy (five cases), hormonal therapy (one case), both chemotherapy and radiotherapy (two cases), chemotherapy and antihormonal treatment (one case), and all three therapeutic modalities (two cases). Ethical approval for the study was obtained from the Regional Committee for Medical and Health Research Ethics, Southeastern Norway.

Histologic review

All H&E slides from the area from which DNA ploidy and immunohistochemical analysis were performed were independently reviewed by three experienced gynecological pathologists (BD, BR, and VA). The World Health Organization recommendation [14] was used to classify the tumors. Pure SAC and SAC mixed with EAC were entered in the study. Discrepant cases were discussed at a consensus session.

DNA image cytometry

Using thick 50-μm sections from paraffin-embedded blocks from hysterectomy specimens, a monolayer of cells was prepared on a slide. After staining with the Feulgen method, nuclear DNA content was measured indirectly using Ploidy Work Station (Room4, Crowborough, UK). DNA ploidy histograms were created using PWS classifier (Room4, Crowborough, UK). The histograms were classified as diploid, aneuploid (DNA index, DI, 1.06–1.89 and >2.10), tetraploid (DI 1.90–2.10), and polyploid. DNA ploidy-related parameters such as DI, 5c ExR, and 9c exceeding rate (9c ExR) of the tumors were also noted. A detailed description of the procedure, DNA content measurement, and histogram classification criteria are given elsewhere [11].

Immunohistochemistry

From the formalin-fixed, paraffin-embedded tissue blocks of the hysterectomy specimen, 4–5-μm thick sections were cut and stained using a Dako Autostainer. Sections were deparaffinized, and epitopes were unmasked using Dako PT link with high pH buffer for 20 min. Endogenous peroxidase was blocked using EnVision FLEX Peroxidase-Blocking Reagent. The sections were incubated with primary mouse monoclonal antibodies against p53 (1:5,000, Santa Cruz Biotechnology, Inc., Santa Cruz, CA), ER (1:200, Novocastra Laboratories Ltd, Newcastle-upon-Tyne, UK), PR (1:300, Novocastra Laboratories Ltd.), and Ki-67 (1:200, DakoCytomation, Glostrup, Denmark) for

30 min. EnVision FLEX+ Mouse (LINKER) was applied for 15 min for signal amplification. After applying Dako EnVision FLEX+HRP for 30 min, diluted DAB chromogen was applied for 10 min. The slides were counterstained with hematoxylin and mounted. Relevant positive and negative controls were used with each antibody, with satisfactory results. In mixed tumors, expression was scored only in the serous component. Based on percentage of cells showing immunoexpression, slides were scored as negative (0–10 %), weakly positive (11–50 %), and strongly positive (51–100 %).

Statistical analysis

Predictive Analytics SoftWare statistics 18 (SPSS Inc., Chicago, IL) was used for statistical analysis. All statistical tests were two-sided, and p value <0.05 was considered as statistically significant. Progression-free survival (PFS) was calculated from the hysterectomy date to recurrence or 31 March 2009. Both recurrence and death due to any cause were considered as an event for PFS. Overall survival (OS) was calculated from the date of surgery to death or 31 March 2011 using death due to any cause as an event. For survival analysis, median value was used as cutoff for age, 5c ExR, and 9c ExR. The Kaplan–Meier method was used to calculate the 5-year recurrence rate, PFS, and OS. Log-rank test was used for univariate survival analysis.

Results

Histological review

After review and consensus discussion, all three or two of the three pathologists agreed on the SAC diagnosis in 56 cases, which were included in further analyses. We used the reviewed diagnosis as the basis for the present study as it was found to be better in predicting prognosis in EC [15].

Patient characteristics

The median age of patients with SAC was 73 years (mean, 72; range, 56–89 years). There were 43 patients diagnosed at stage IA, 8 at stage IB, and 5 at stage II (Table 1). There was no myometrial invasion in 10 cases, invasion of less than half the myometrial thickness in 34 cases, and more than half in 12 cases. LVI was present in 17 cases. Recurrence was detected in 14 patients, of whom 2 had recurrence in the vagina, 5 in the pelvis, and 7 outside the pelvis. The majority of recurrences occurred in the first year after operation (eight cases); the earliest detected was after 3 months.

[a] Overall *p* value by log-rank test

[b] Median cutoff was used to group the cases

[c] No statistics were computed because all cases were censored

DNA ploidy

The mean and median CVs of the diploid peaks were 3.02 and 2.80, respectively. The mean number of nuclei analyzed was 1,005 (median, 1,192; range, 280–2,546). The majority of tumors (n=29, 52 %) were aneuploid, of which 2 cases had DI≤1.20 and 27 cases had DI> 1.20. Tetraploidy and diploidy were detected in 8 (14 %) and 19 (34 %) tumors, respectively (Table 2). Median 5c ExR was 2.28 (mean, 6.08 %; range, 0–72.82 %). Median 9c ExR was 0.07 (mean, 0.42 %; range, 0–13.76 %).

Immunohistochemistry

Immunohistochemistry was performed in 53 cases for p53, 52 cases for ER and PR, and 46 cases for Ki-67. The majority of tumors (n=34, 64 %) had strong nuclear expression of

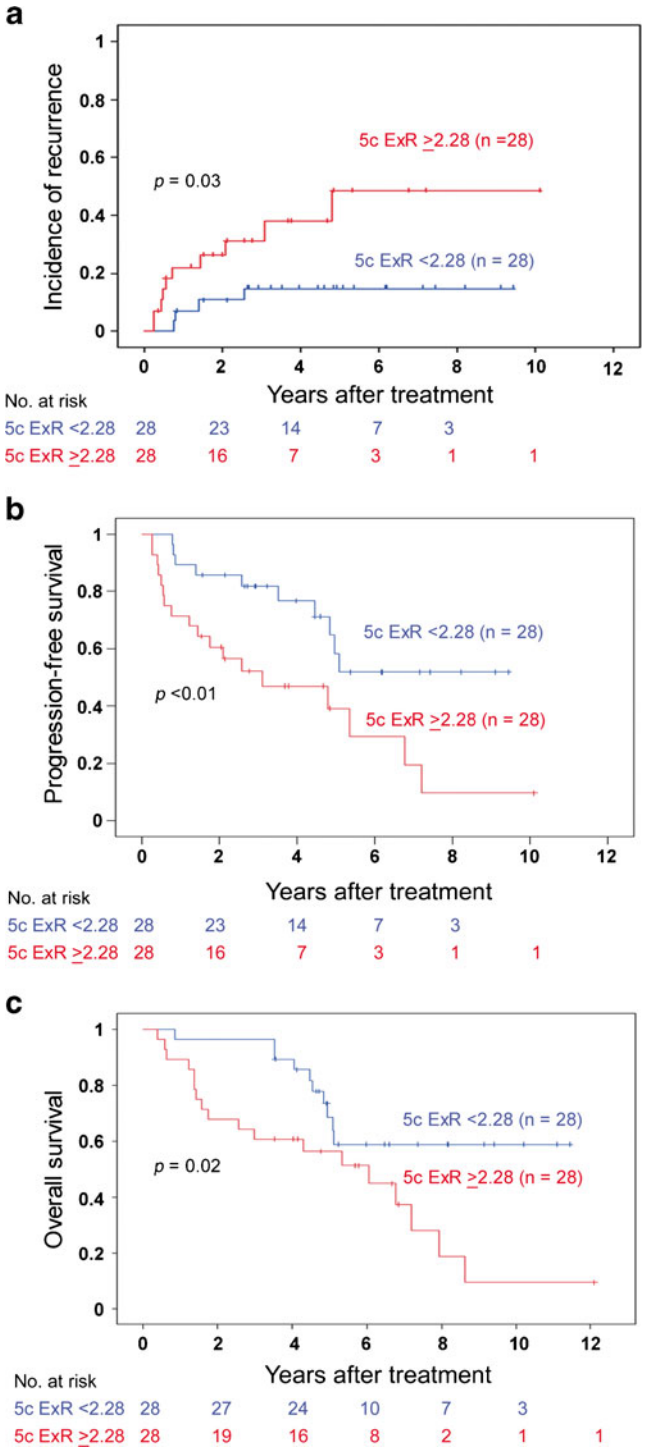

Fig. 1 Recurrence rate, progression-free survival, and overall survival based on 5c exceeding rate in patients with serous adenocarcinoma stage I and II

p53 in >50 % of cells. ER and PR expression in >50 % of cells was found in six (12 %) and two (4 %) tumors, respectively. Ki-67 score >50 % was seen in 24 (52 %) cases (Table 2).

Survival analysis

Altogether, 14 patients had recurrent disease, and 28 patients died during the follow-up period. The 5-year PFS and OS for all cases were 48±9 and 62±7 %, respectively. Patients with aneuploid and tetraploid tumors had a higher recurrence rate and lower 5-year PFS and OS compared to patients with diploid tumors (Table 2). DNA ploidy approached, but did not reach statistical significance for recurrence (p=0.09). A DNA ploidy parameter, 5c ExR, was found to be prognostic for 5-year recurrence rate (p=0.03), PFS (p<0.01), and OS (p=0.02; Table 2, Fig. 1). p53, ER, PR, and Ki-67 expression was unrelated to prognosis. Stage, the extent of myometrial invasion, LVI, lymphadenectomy, and the extent of hysterectomy failed to show prognostic significance (Table 1). Shorter 5-year PFS (22 %) and OS (42 %) were observed for patients who did not receive any form of adjuvant therapy. Notably, patients who received radiotherapy as adjuvant treatment had no recurrences.

Discussion

In this study, we evaluated the prognostic importance of various clinical, pathological, DNA ploidy, and immunohistochemical markers in early-stage SAC. The only significant prognostic marker we found was the 5c ExR, a parameter that can simply be extracted from a DNA ploidy analysis. The explanation is that 5c ExR is high in proliferating tetraploid tumors and aneuploid tumors with high DI. Non-diploid tumors with low S-phase fraction and diploid tumors show low 5c ExR. Therefore, less aggressive non-diploid tumors are separated from highly aggressive tumors. Earlier, Strang et al. reported that 5c ExR is a prognostic parameter in patients with EC [16]. In our previous study, in which exclusively endometrioid carcinoma was analyzed, 5c ExR (1 % as a cutoff) failed to show prognostic importance [13]; however, when the cutoff was changed to 2.28, same as in this series, 5c ExR was a prognostic indicator (unpublished data). Therefore, 5c ExR can be an objective DNA ploidy parameter for patients with endometrial carcinoma. Additionally, 5c ExR has also been found to be a prognostic parameter in other cancers, e.g., non-small cell lung carcinoma, uterine cervical carcinoma, neuroendocrine tumors, and ependymoma [17–20]. There was also a tendency, though not statistically significant, for patients with diploid tumors to have lower recurrence rate and increased overall survival. Kato et al. investigated 30 patients with SAC in all stages and found no association between aneuploidy and survival [21].

SAC is usually diagnosed based on morphology alone. However, some tumors are difficult to classify due to overlapping features between SAC and EAC [22–24]. We

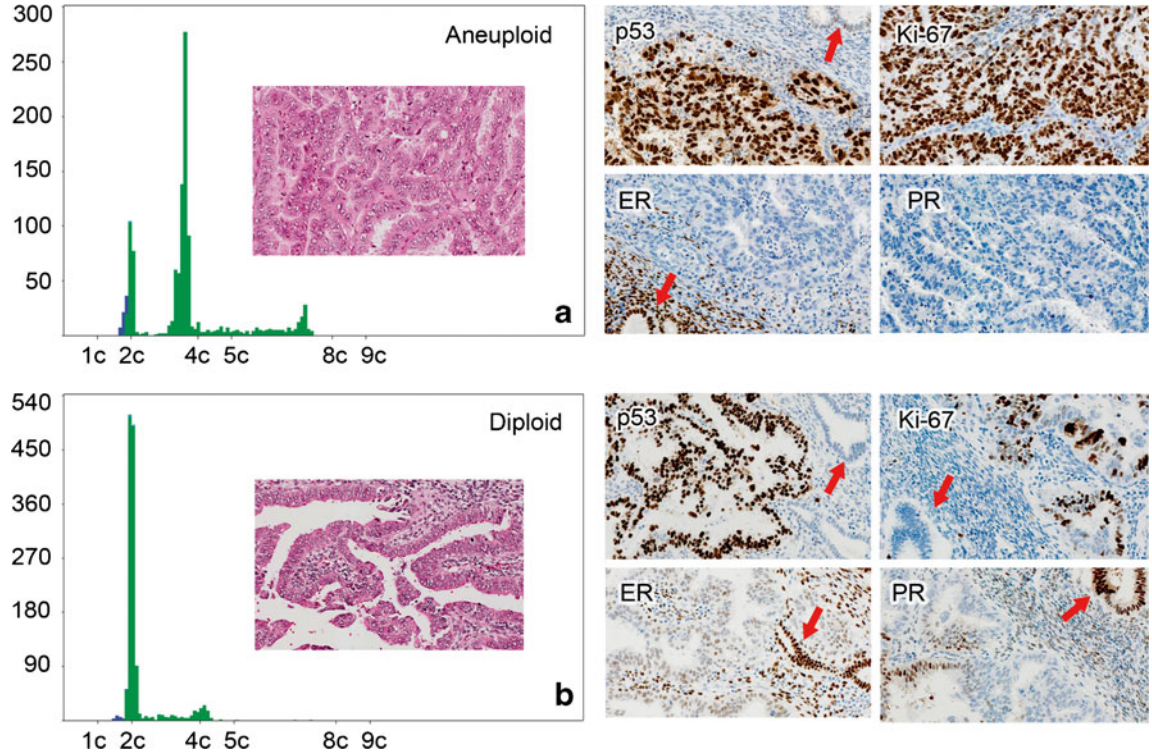

Fig. 2 **a** DNA ploidy histogram of an aneuploid serous adenocarcinoma showing high 5c ExR, strongly positive p53, and Ki-67 expression and negative staining for estrogen and progesterone receptors. **b** A diploid serous adenocarcinoma with low 5c ExR showing strong expression of p53 and Ki-67 and weak expression of estrogen and progesterone receptors. Benign glands are marked with *red arrows*

observed lack of agreement in a substantial number of cases at consensus session. This indicates that SAC, even after being a distinct entity for more than 30 years, is not so easy to diagnose morphologically in a certain number of cases. Nordström et al. reported that 12 % of EC were reclassified as SAC following histological review of 266 cases [25]. The differential diagnosis of SAC included both benign and malignant lesions, including EAC with small non-villous papillae, papillary CAC, and malignant mullerian mixed tumors [26]. Therefore, there is a need for ancillary techniques for SAC diagnosis. Many pathologists use overexpression of p53 and Ki-67 together with underexpression of ER and PR as additional diagnostic aids (Fig. 2). Since SAC is associated with aneuploidy with DI >1.60, DNA ploidy might also be a potential parameter supporting the diagnosis [11]. There are reports on markers such as insulin-like growth factor II mRNA-binding protein 3 which may be useful in this differential diagnosis [27].

In EC, stage, myometrial invasion, and LVI are established prognostic parameters [28]. However, these parameters had no prognostic role in our series. Grade and depth of myometrial invasion did not predict prognosis in SAC in an earlier study, and these tumors are currently not graded [21]. Goff et al. analyzed 50 cases of SAC and similarly found no prognostic importance for the depth of myometrial invasion [29].

p53 mutation is considered to be an early event in SAC since it is found in serous intraepithelial carcinoma [7]. Usually, mutation leads to overexpression of mutant p53 protein which can be detected using immunohistochemistry. However, nonsense mutation leads to total absence of protein expression [30]. Although overexpression of p53 has been reported to be a prognostic factor in EC [31], p53 immunostaining was not informative of disease outcome in the present series of SAC. This finding is similar to the observation by Alkushi et al. where p53 overexpression was not a prognostic indicator in patients with SAC but was of prognostic importance in the analysis of patients with low-grade EAC [32]. p53 expression may be helpful in morphologically ambiguous cases due to the higher rate of overexpression in SAC [22]. ER and PR are expressed in normal endometrial tissue, as well as in the majority of EAC, mainly of low grade. In SAC, ER and PR expression was found to be lower than in EAC [33]. ER and PR expression was unrelated to prognosis in our series. High expression of Ki-67, a proliferation marker, was shown to be associated with poor prognosis in patients with EC [31]. However, Ki-67 had no prognostic value in our series of SAC.

In conclusion, established clinicopathological parameters and immunohistochemical markers do not provide prognostic information for patients in SAC stage I and II with high risk of

recurrence and death of disease. A DNA ploidy parameter, 5c exceeding rate, may be a prognostic marker in this patient group and should be further validated in larger series.

Abstract Gliomatosis peritonei (GP) is commonly associated with ovarian teratoma and is not thought to have an adverse prognostic effect. However, the prognostic impact and characteristics of GP remain to be clarified. In this study, we investigated the clinicopathologic features of ovarian teratoma associated with GP, and we further compared ovarian immature teratoma (IT) with GP to ovarian IT without GP. During the study period, there were a total of 16 ovarian teratomas associated with GP. Among them, 15 cases were ovarian ITs of various grades. When ovarian IT with GP (n=15) was compared to ovarian IT without GP (n=27), it was found that ovarian IT patients with GP had larger tumor size (median, 19 vs. 13 cm; P<0.001), more frequent recurrence (40 %, 6/15 vs. 3.7 %, 1/27; P=0.005), and frequently elevated preoperative CA-125 level (100 %, 12/12 vs. 50 %, 10/20; P=0.004). All recurrences occurred within 2 years of the initial surgery. Survival curves indicated that ovarian IT patients with GP had significantly shorter recurrence-free survival compared to those without GP (P= 0.002). The 2-year recurrence-free survival rates were 59.3 and 96.3 % in IT with GP and IT without GP, respectively. However, all but one case of IT with GP are currently alive. In conclusion, GP is an adverse prognostic factor characterized by frequent recurrence in patients with ovarian IT.

GP	Gliomatosis peritonei
IT	Immature teratoma
BEP	Bleomycin, etoposide, and cisplatin
GFAP	Glial fibrillary acidic protein

Introduction

Gliomatosis peritonei (GP) is a very rare entity characterized by disseminated implants composed of mature glial tissue in the peritoneal cavity. GP is almost exclusively associated with ovarian teratoma, usually immature teratoma [1–4]. Ovarian teratoma with GP is usually regarded as advanced disease (stage III) [5]. However, GP has long been thought not to have an adverse prognostic effect, and the prognosis of an immature teratoma (IT) with GP is better than would be expected based on grading of the primary tumor [6, 7]. However, the prognostic significance of GP and characteristics of patients with GP have still not been clarified because studies reported in the literature were performed in a small sample or are isolated case reports over a short-term

follow-up period. In addition, few studies have made a direct comparison of clinicopathologic features between IT with GP and IT without GP. It was recently demonstrated that GP is genetically unrelated to the associated teratoma, but is probably derived from nonteratomatous cells via metaplasia of submesothelial cells [8], and multiple tumors arising in the patients with immature teratomas and GP are independent rather than the result of tumor spread [9]. A few instances of GP have also been associated with growing teratoma syndrome after chemotherapy [4, 10, 11]. These findings suggest a difference in clinicopathologic features between IT with GP and IT without GP.

ITs with GP predominantly affect young women and adolescents. Therefore special consideration for limited surgery is needed. However, there is no standard treatment for GP because of its rarity, and there is debate with regard to whether or not omentectomy should be mandatory. Patients with high-grade (grade 2 or 3 in a three-tiered grading system) IT are most often treated with cisplatin-based chemotherapy after the initial operation. Cisplatin-based chemotherapy regimens have dramatically improved the prognosis of IT [12, 13]. The most common combination chemotherapy regimen is BEP (bleomycin, etoposide, and cisplatin). However, most cases of GP were reported before the BEP protocol was widely used. In addition, the prognostic role of omentectomy has rarely been studied. In this study, we investigated the clinicopathologic features of patients with ovarian teratomas associated with GP and compared the characteristics of ITs with GP to those of ITs without GP in patients who all were uniformly treated at single institution between 1995 and 2010.

Materials and methods

Patients

This study included 16 patients with ovarian teratomas with GP and 27 patients with ovarian ITs without GP who were diagnosed at Samsung Medical Center (Seoul, Korea) between January 1995 and August 2010. No cases were excluded, and all patients were treated uniformly according to the institutional treatment protocol. All high-grade ITs and a few low grade (grade 1) ITs with capsular rupture were treated with chemotherapy (BEP regimen) after initial surgery. ITs were graded according to published guidelines [14]. All cases were staged surgically with or without omentectomy. In patients who did not undergo omentectomy, the diagnosis of GP was made based on multiple omental/peritoneal biopsies that were performed for any suspicious lesions during the operation. Clinicopathologic features were reviewed retrospectively from medical or pathological records. Tumor size was measured in two dimensions using the gross specimen and the largest dimension was used for analysis. The median follow-up period was 2,547 (range, 428 to 6,362) days for ITs with GP, and 2,085 (range, 250 to 4,919) days for ITs without GP.

Recurrence evaluation

During the course of regular follow-up after the initial surgery, newly growing masses detected on radiographs including CT and/or MRI were considered recurrences, but the development of another teratoma in the contralateral ovary was not.

Immunohistochemistry

Surgical specimens were fixed in 10 % buffered formalin and embedded in paraffin. Sections were cut to a thickness of 4 μm, and immunohistochemistry was performed by standard methods using an avidin–biotin complex. Deparaffinized sections were treated with 3 % hydrogen peroxide in order to block endogenous peroxidase activity. Primary antibody against glial fibrillary acidic protein (GFAP; dilution 1:3,000; Biogenex, CA, USA) was used.

Statistical analysis

Various clinicopathologic parameters including age, tumor size, grade, initial surgery (omentectomy), chemotherapy, recurrence, and preoperative CA-125 level were included for analysis. Correlations were examined using either Pearson's χ^2 or Fisher's exact test, as appropriate. Continuous values such as patient age and tumor size were analyzed using the Mann–Whitney U test. Recurrence-free survival and overall survival were measured from the date of initial surgery to the date of first recurrence or death until January 2012. Survival curves were generated using the Kaplan–Meier method, and survival curves were compared using the log-rank test. All tests were two-sided and P values less than 0.05 were considered statistically significant. Statistical analysis was performed using Stata/IC statistical software (version 12, StataCorp Ltd., TX, USA).

Results

Characteristics of ovarian teratoma with GP

During the study period, there were a total of 16 ovarian teratomas associated with GP. The median patient age was 15 years (range, 4 to 38), and the mean tumor size was 19.8 cm (median, 18 cm; range, 15 to 36). Among the 16 ovarian teratomas associated with GP, all but one case were associated with immature teratomas of various grades (grade 1, four cases; grade 2, two cases; grade 3, nine cases). GP was

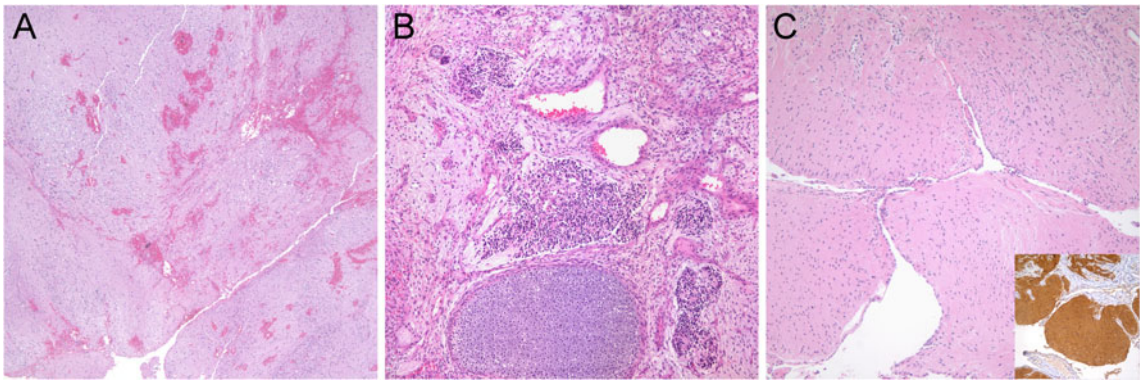

Fig. 1 A recurrent mass composed of mature glial tissue (**a**). Immature teratoma of ovary (**b**) with gliomatosis peritonei (**c**). Strong immunoreactivity for glial fibrillary acidic protein in gliomatosis peritonei (**c**, *inset*)

identified during the initial surgery in 15 of the 16 total patients. In the remaining case, GP was identified during the second operation performed due to a recurrent mass in the abdomen after chemotherapy for grade 3 IT.

During the follow-up period, six patients (37.5 % of 16 patients) experienced a recurrence (diaphragm and/or liver surface in five patients; omentum in one patient). Among them, five patients underwent a second operation, and all recurrent masses were composed of mature glial tissues (Fig. 1a). The remaining patient refused further treatment and died 536 days after the initial diagnosis. Representative figures for ovarian IT with GP are given in (Fig. 1b). GFAP immunostaining highlighted mature glial tissue in the GPs (Fig. 1c).

Clinicopathologic features of IT with GP compared to those of IT without GP

Because almost all cases of GP were associated with IT, we selected ITs without GP diagnosed in the same time period and treated with the same treatment modality for comparative analysis. During the study period, 27 patients were diagnosed with ovarian IT without GP. When the two groups were compared with various clinicopathologic factors, tumor size ($P<0.001$), recurrence rate ($P=0.005$), and preoperative CA-125 elevation ($P=0.004$) were found to differ significantly (Table 1). IT patients with GP had larger tumors (median of 19 cm vs. median of 13 cm), more frequent recurrence (40 %, 6/15 vs. 3.7 %, 1/27), and an elevated preoperative CA-125 level (100 %, 12/12 vs. 50 %, 10/20) compared to IT patients without GP.

We also compared the tumor size in our patients with those in 18 published reports of ovarian ITs with GP (33 cases total) [2–4, 6, 10, 11, 15–24]. The mean tumor size of the 33 previously reported cases was 20.9 cm (median, 21 cm; range, 11.5 to 32). The tumor size of previously reported cases of ovarian IT with GP did not differ from the tumor size in our patients ($P=0.360$), and was significantly larger than the tumor size of ITs without GP that included in this study ($P<0.001$; Fig. 2).

Table 1 Clinicopathologic features of ovarian immature teratomas (ITs) with gliomatosis peritonei (GP) compared to ovarian ITs without GP

	Total no.	IT with GP	IT without GP	*P* value
Age, median	42	13 years (from 4 to 29)	18 years (from 2 to 38)	0.237
Tumor size, median	42	19 cm (from 15 to 36)	13 cm (from 4 to 23)	<0.001
Grade				
Low (grade 1)	14	4 (26.7 %)	10 (37.0 %)	0.495
High (grade 2 or 3)	28	11 (73.3 %)	17 (63.0 %)	
Initial surgery

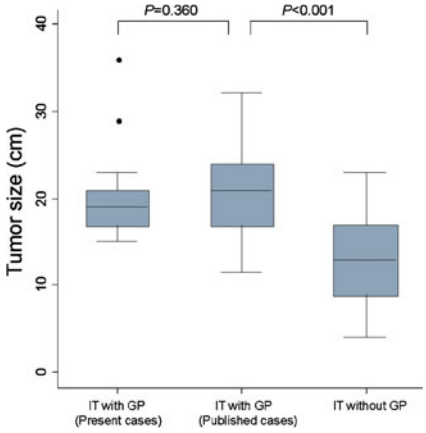

Fig. 2 Tumor sizes of ovarian immature teratoma with gliomatosis peritonei (n=15) and ovarian immature teratoma without gliomatosis peritonei (n=27) in this study were compared with published cases of ovarian immature teratoma with gliomatosis peritonei (n=33). (*IT*, immature teratoma; *GP*, gliomatosis peritonei)

Impact of GP on the survival of patients with ovarian IT

Survival curves for each group (IT with GP vs. IT without GP) differed significantly in terms of recurrence-free survival (P=0.002, Fig. 3a). All recurrences occurred within 2 years of the initial surgery. The 2-year recurrence-free survival rates were 59.3 and 96.3 % in the IT with GP and IT without GP groups, respectively. When the cases were restricted to high-grade IT, there was also a significant difference in recurrence-free survival (P=0.011, Fig. 3b). However, overall survival did not differ between the two groups. All patients with IT without GP survived, and only one IT patient with GP died due to the tumor 536 days after the initial surgery.

Comparison of characteristics between recurring and non-recurring ITs with GP

Various clinicopathologic factors including age, tumor size, grade, initial surgery (omentectomy or not), and chemotherapy after surgery (received or not) were analyzed in order to identify characteristics that differed between patients who experienced recurrence of their IT with GP and those who did not. None of the tested factors differed significantly between the two groups, and omentectomy was not associated with tumor recurrence (P=1.000). Of six patients who experienced a recurrence, half underwent omentectomy, as did 55.5 % of nine patients who did not experience recurrence. Patients with ITs with GP that recurred tended to have larger tumors than patients who did not experience a recurrence; however, this tendency was not statistically significant (P=0.083).

Discussion

In this study, we investigated the clinicopathologic features of ovarian teratoma with GP, and we demonstrated the prognostic impact of GP in patients with IT. GP has long been known for its association with a good outcome [6, 7]. However, in this study, we found that GP was associated with frequent recurrence and shorter recurrence-free survival in patients with IT, although it did not affect overall patient survival.

A recent large study of mature and immature extracranial teratomas in children conducted by the UK Children's Cancer Study Group included 54 ovarian ITs, and reported that 3 of 10 (30 %) patients with ovarian IT with GP experienced a recurrence compared with 2 of 44 (4.5 %) ovarian ITs

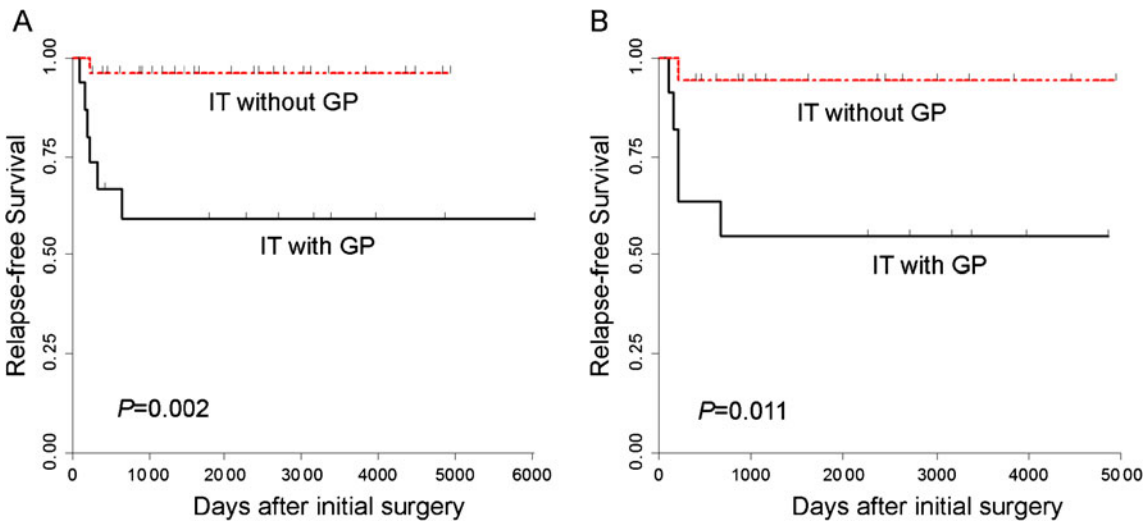

Fig. 3 Recurrence-free survival curves showing the impact of gliomatosis peritonei in all patients with ovarian immature teratomas (**a**) and in patients of ovarian immature teratoma with high-grade (grade≥2) (**b**). (*IT*, immature teratoma; *GP*, gliomatosis peritonei)

without GP (P=0.0389) [5]. They also indicated that there were no deaths among the ovarian teratoma patients. A recent study of 34 immature ovarian teratomas diagnosed at a single institution found that 4 of 34 (12 %) ITs recurred and the 2-year progression-free survival rate was 87.1 % [25], although there was no mention of whether or not GP was included. In the present study, the 2-year recurrence-free survival rate was 59.3 %. Overall, the previous findings strongly suggest that GP is associated with frequent recurrence, and this is confirmed by our series of IT with GP patients, which is the largest study reported to date.

Although GP did not affect overall survival in our series, it was important clinically because frequent recurrence in patients with GP led to a second operation in most cases. In this study, all tumors recurred during chemotherapy or within a short time after chemotherapy. This finding may suggest that at least some of the recurrent GPs were associated with the conversion of a metastatic immature teratoma into a mature tumor as a result of chemotherapy. Therefore, complete removal of the tumor during the initial surgery may be important for preventing recurrence after chemotherapy. However, in this study, most recurrences were found in the liver and/or the diaphragmatic surface. This finding may explain why radical surgery including omentectomy did not prevent recurrence in our study. However, elimination of as many lesions as possible during surgery may be important because a few cases of GP showed adverse outcomes, which were commonly associated with recurrence and malignant transformation, such as glioblastoma [15, 23], and a few recurrences were a form of growing teratoma syndrome [4].

In this study, we compared the IT patients with GP to those without GP in order to identify characteristics unique to IT patients with GP. We found that IT with GP was characterized by larger tumor size as well as frequent recurrence compared to IT without GP. Smaller (<15 cm) ovarian teratomas are usually associated with benign status [26], and tumor size correlates with survival and stage [27]. These findings seem to be consistent with our findings showing that ITs with GP tended to be larger than ITs without GP because IT with GP was usually considered advanced disease. In addition, the elevated CA-125 levels observed in all IT patients with GP may also be related to the presence of a large, widespread tumor.

In conclusion, GP was associated with frequent recurrence and shorter recurrence-free survival in patients with ovarian IT, and ovarian IT with GP was characterized by larger tumor size and frequent elevation of the preoperative CA-125 level. Therefore, identification of GP in ovarian ITs is important and it should be classified as a distinctive entity.

Conflict of interest statement We declare that we have no conflict of interest.

Abstract *BRCA1* mutations have been associated with hereditary breast cancer only. Recent studies indicate that a subgroup of sporadic breast cancer might also be associated with reduction in BRCA1 mRNA levels and protein expression. However, the mechanism of reduced mRNA and protein expression is yet not fully elucidated. This study aims to assess BRCA1 protein expression and the role of *BRCA1* promoter methylation in sporadic breast cancer in North Indian population and to correlate these with known prognostic factors and molecular profiles of breast cancer. BRCA1 protein expression was normal (>50 % tumour cells) in 41 (43 %) cases, reduced (20–50 % tumour cells) in 33 (35 %) cases and absent/markedly reduced (<20 % tumour cells) in 21 (22.1 %) cases. Cases which were negative for BRCA1 protein were more frequently positive for basal markers (29 versus 5 %) and were more often ER-negative (62 versus 39 %) than BRCA1-positive tumours. Methylation of *BRCA1* promoter region was seen in 11/45 cases (24 %). All 11 cases showing *BRCA1* methylation had absent (eight cases) or reduced (three cases) BRCA1 protein expression. BRCA1 protein-negative tumours were more frequently basal marker-positive and ER-negative, highlighting the 'BRCAness' of sporadic breast cancer with loss of BRCA1 protein expression through promoter hypermethylation similar to hereditary breast cancer with BRCA1 mutations. Loss of BRCA1 in sporadic breast cancer suggests that therapeutics targeting BRCA1 pathway in hereditary breast cancer like PARP inhibitors might be used as therapeutic targets for sporadic breast tumours.

Introduction

The *BRCA1* gene located on the long (q) arm of chromosome 17 at position 21 belongs to a class of tumour suppressor genes. BRCA1 protein expression controls and regulates cell growth and division. Mutations in BRCA1 gene have been associated with breast and ovarian cancer. The most coherent data on *BRCA1* are available from hereditary breast cancers only. Mutations of *BRCA1* are thought to account for approximately 45 % of families with a significantly high breast cancer incidence and at least 80 % of families with an increased incidence of both early-onset breast and ovarian cancers [1].

Majority of breast cancers are 'sporadic' (non-hereditary). No evidence of *BRCA1* mutations have been found in sporadic breast cancers. However, the demonstration of a

reduction in BRCA1 mRNA levels and methylation of the *BRCA1* promoter region in breast cancer cells compared with normal breast epithelium suggests a potential role of *BRCA1* in sporadic tumours. Decreased BRCA1 mRNA expression is also significantly associated with acquisition of metastatic capacity in sporadic breast cancer [2]. These results indicate that a certain level of normally functioning *BRCA1* is required for the maintenance of negative growth regulatory mechanisms in breast epithelial cells.

In the absence of germline mutations, it has been anticipated that somatic *BRCA1* mutations and allelic imbalance (AI) would be found to contribute to sporadic breast carcinogenesis. Surprisingly, somatic *BRCA1* gene mutations and AI have not been found in sporadic breast tumours [3–5]. For these reasons, the involvement of the *BRCA1* genes in sporadic breast tumours has been questioned. An alternative mechanism for BRCA1 inactivation has been suggested to be gene silencing by epigenetic mechanisms. Hypermethylation of CpG island promoters is known to be strongly associated with gene silencing. Once established, methylation is passed on to daughter cells during DNA replication by the activity of DNA methyltransferases, thereby conserving the overall pattern of methylated CpG islands [6].

A considerable amount of research is going on to elucidate the role of BRCA1 protein expression in sporadic breast tumours; however, there are conflicting results in various studies. In this study, we studied the association of BRCA1 protein expression with known prognostic parameters and the molecular profile of human breast cancer. We also addressed the role of *BRCA1* promoter methylation in decreased protein expression.

Materials and methods

A total of 95 cases of lumpectomies or mastectomies for invasive breast cancer received over a period of 2 years were included in the study. Cases with adequate material (in the form of adequate representative viable tumour in the sections or the specimen) were studied. Cases with family history of breast cancer, those which had been treated by chemotherapy prior to the surgery and those with previous history of lumpectomy followed by mastectomy for residual disease, were excluded.

Morphological examination

All cases were processed for paraffin sections for routine haematoxylin and eosin staining and immunohistochemistry. The histological type, tumour size, nuclear grade, mitoses, in situ component, necrosis, lymphovascular emboli (LVE) and nodal status was noted. A section showing tumour as well as normal mammary gland was selected for immunohistochemical studies.

Immunohistochemistry

The selected sections were cut and mounted on poly-*l*-lysine-coated glass slides. Immunohistochemistry was performed using CK8/18(Novacastra, Clone NCL-5D3, 1:100), CK14 (Novacastra, Clone NCL-LL002, 1:100), CK 5/6 (Dako, Clone D5/16B4, 1:50), ER (Dako, Clone 1D5, 1:20), PR (Dako, Clone PgR636 1:50), Her2/neu (Dako, Polyclonal, 1:250) and BRCA1 (Biocare Medical, Clone MS110, 1:25).

Molecular classification

The cases of invasive breast carcinoma were classified into molecular subtypes using the following immunohistochemical markers: oestrogen receptor (ER), progesterone receptor (PR), Her-2/neu and cytokeratins (CK), CK8/18 for luminal phenotype and CK5/6 and CK4/14 for basal phenotype [7]. For CK 8/18, 5/6 and 4/14, cytoplasmic and membranous immunoreactivity even in 1 % of tumour cells was taken as positive. For oestrogen and progesterone receptors, the intensity of nuclear staining was graded as weak, moderate or strong. Moderate or strong nuclear staining in >10 % tumour cells was taken as positive. Her2/neu immunostaining was considered positive when strong (3+) complete membranous staining was observed in at least 30 % of tumour cells, whereas cases with 0 to 2+ staining were regarded as negative.

BRCA 1 immunostaining

The sections were deparaffinized in xylene and rehydrated in a series of graded alcohol. Blocking of endogenous peroxidase was done for 5 min with Biocare's Peroxidazed 1, and antigen retrieval was performed by heating in a pressure cooker. To block non-specific staining, sections were incubated for 10-15 min at room temperature with background Sniper (Biocare). Incubation with primary antibody was done for 60 min at room temperature followed by incubation with polymer for 30 min and by incubation with biotinylated secondary antibody for 40 min. Di-amino benzidene was used as a chromogen.

BRCA1 methylation

BRCA1 methylation status was assessed in 45 cases. The tumour samples of primary breast cancer patients, who underwent surgery, were collected and stored at −80 °C for further use. DNA was extracted from the frozen

tumour tissues by Qiagen DNeasy Blood & Tissue Kit (Catalog No. 69504) according to the manufacturer's instructions. Final elution was done in 50 μl of elution buffer. The quality and integrity of DNA from tissues was checked by electrophoresis on 0.8 % agarose gel, quantitated spectrophotometrically and stored at −20 °C until further use.

Methylation-specific PCR

As per the protocol provided by the manufacturer, DNA samples (500 ng) were modified with sodium bisulfite that converts the unmethylated cytosine but not the methylated ones to uracil (EZ DNA Methylation-Gold™ Kit, Zymo Research Catalog No. D5005)**.** The bisulfite-treated DNA was amplified using specific primers for methylated and unmethylated alleles. The sequence of the primers was as follows:

Methylated: F: 5′-CCGTGGCAACGGAAAAGCGC -3′, R: 5′-AGCGAGCTCACGCCGCGCAG-3′

Unmethylated: F: 5′-CCGTGGCAACGGAAAAGCGC -3′, R: 5′-AGCGAGCTCACGCCGCGCAG-3′

PCR was carried out in a total volume of 20 μL containing 20 pM of each primer pair, 0.4 μl of 10 mM dNTPs, 0.8 μl of 25 mM $MgCl_2$, 2 μl of 10× Taq buffer and 1.5 U of Taq DNA polymerase (Fermentas). Each PCR reaction underwent initial denaturation at 95 °C for 5 min and 35 cycles of the following profile: 30 s at 95 °C, 30 s at optimal temperature and 1 min at 72 °C followed by a final 10-min extension at 72 °C. Fully methylated DNA (provided with the kit) and DNA from lymphocytes from healthy individuals were used as positive controls for methylated and unmethylated DNA, respectively. A template control without DNA was included in each PCR assay. After amplification, products were electrophoresed using 2.5 % agarose gels, stained with ethidium bromide and visualized under UV illumination.

Statistical analysis

Correlation among variables in the univariate analysis was determined by Pearson chi-square test and Fisher's exact test. Significance was assumed at p value <0.05.

Results

Clinicopathological parameters

The age of the patients (n=95) ranged from 29 to 81 years with a mean of 53.3 years. The majority of cases (55 %) were>50 years and 45 % were below 50 years of age. The largest dimension of the tumour ranged from 1 to 8 cm. Twenty-four percent of tumours were<2 cm (pT1), 73 % of tumours were in the range of 2–5 cm (pT2) and 3 % tumours were greater than 5 cm (pT3) in largest dimensions.

The most frequent histological subtype was infiltrating ductal carcinoma, not otherwise specified (IDC-NOS, 89 cases). There were two cases of invasive lobular carcinoma (ILC), three cases of invasive papillary carcinoma and one case each of mucinous carcinoma and metaplastic carcinoma. The majority of tumours (56 %) were classified as infiltrating ductal carcinoma, NOS grade II, followed by grade III (19 %), and the remaining 14 % of cases were grade I tumours. Both cases of ILC were grade I tumours. One case of invasive papillary carcinoma was classified as grade I and the remaining two cases as grade II. The mucinous carcinoma was a grade I tumour and the metaplastic carcinoma was a grade III tumour. Fifty-two percent of cases did not have axillary lymph node metastasis. In 28 % of cases, there were less than four lymph nodes involved, and in the remaining 20 % cases, more than four lymph nodes were involved. Lymphovascular emboli were seen in five of 17 grade I tumours, 27 of 58 grade II tumours and eight of 20 grade III tumours.

Molecular phenotyping

Based on ER/PR/Her-2 neu expression, 95 cases were categorized into four subgroups [7] (Fig. 1): ER + and/or PR + and HER2− (44 cases), ER + and/or PR + and HER2+ (14 cases), ER − and/or PR − and HER2+ (20 cases) and ER−, PR − and HER2− (triple negative, 17 cases). All cases demonstrated immunoreactivity for the luminal CK8/18. Additionally, 10 % of these tumours showed expression of the basal markers: six cases (6 %) were positive for both CK14 and CK5/6 and four (4 %) were positive for only CK5/6. Out of the 17 triple negative cases, eight were positive for one of the basal markers. The remaining two cases with basal marker expression were Her2 +.

BRCA 1 protein expression

Interpretation of BRCA 1 immunostaining

Staining of normal breast epithelial cells on the tumour sections and/or normal breast tissue sections from the same breast was used as control. BRCA1 expression in the benign epithelial cells in the samples was detected as a strong, dark brown, dotted nuclear stain. No cytoplasmic expression was observed in these cells. BRCA1 expression was also observed in tumour-infiltrating lymphocytes present in the sections. Staining in breast cancer cells was predominantly localized to the nucleus, but the intensity of staining varied from strong to absent.

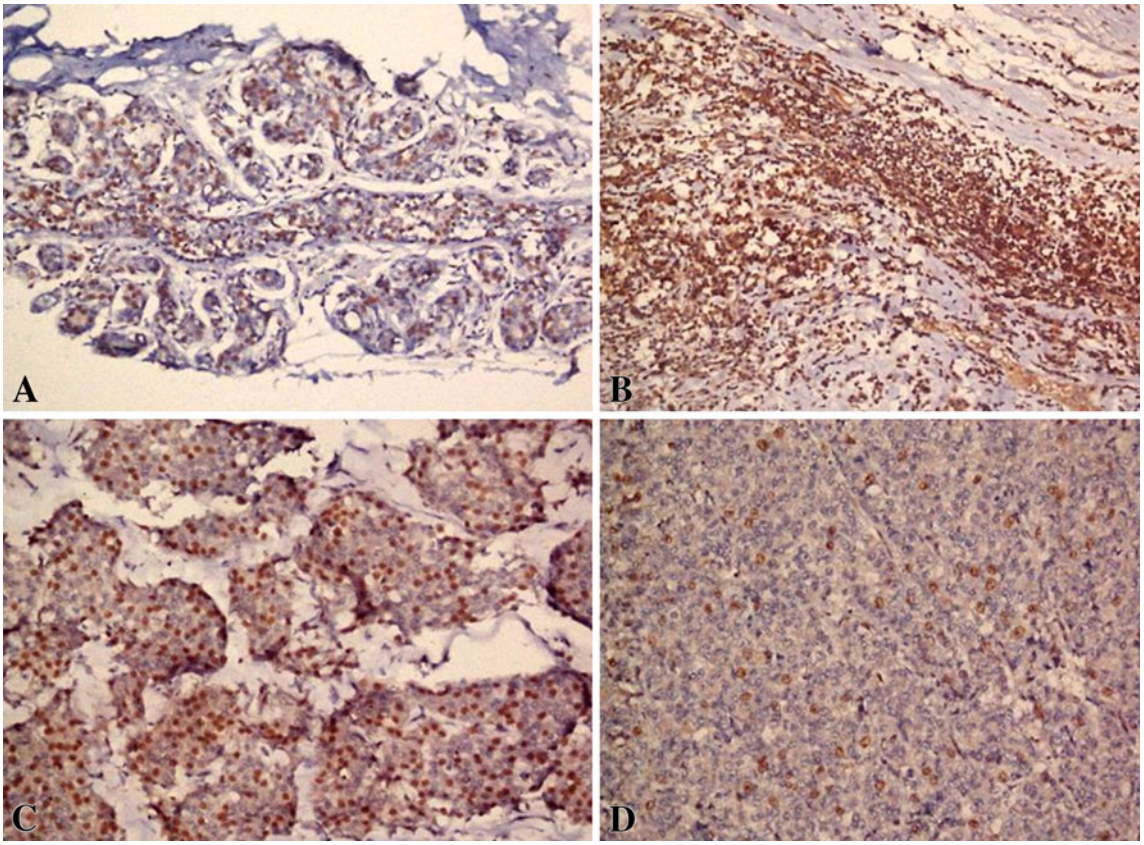

Fig. 1 Photomicrographs showing **a** BRCA1 positivity in normal breast lobule, **b** BRCA1 positivity in lymphocytes, **c** level 3 BRCA1 positivity and **d** level 1 BRCA1 positivity (BRCA1 immunostain)

The protein expression levels in tumour sections were assessed as follows:

Level 3 (normal expression): when the immunoreactivity was comparable to that of the normal breast epithelium or moderate to strong nuclear staining in >50 % of tumour cells

Level 2 (reduced expression): when the staining was clearly weaker than normal surrounding cells or moderate to strong nuclear staining in 20 to 50 % of tumour cells

Level 1 (absent/markedly reduced expression): when there was no staining or weak nuclear staining in <20 % of tumour cells

BRCA1 protein expression was assessed in all 95 cases. BRCA1 protein expression was normal (level 3, >50 % tumour cells) in 41 (43 %) cases; it was reduced (level 2, 20–50 % tumour cells) in 33 (35 %) cases and absent/markedly reduced (level 1, <20 % tumour cells) in 21 (22 %) cases (Fig. 1).

Comparison of BRCA1 protein expression with existing prognostic factors

The level of expression of BRCA1 protein in the tumour samples was compared with existing prognostic factors as depicted in Table 1. BRCA1 staining was not statistically significantly correlated with various histological and clinical prognostic factors. BRCA1 expression was compared in different subtypes of breast cancer; out of 21 cases showing loss of BRCA1 expression, 19 cases were IDC-NOS and one case each of metaplastic carcinoma and invasive papillary carcinoma. Among the BRCA1-negative tumours, 26 % cases were grade III, which is higher than the percentage of BRCA1-positive grade III tumours (19 %). The BRCA1-negative tumours had a higher percentage of basal marker positivity (29 versus 5 %), and this association was statistically significant (p=0.007). BRCA1 nuclear staining correlated with basal marker expression in each grade of tumours; grade III tumours significantly more often showed basal marker expression (p=0.007) as shown in Table 2. None of the grade I tumours expressed basal markers and the association among grade II tumours was not statistically significant (p=0.51 and p=0.49, respectively).

ER-negative status seemed to be more frequent in the BRCA1-negative group as compared to BRCA1-positive group (62 versus 39 %), though this association was not found to be statistically significant (p=0.83).

Table 1 Comparison of BRCA1 protein expression with existing prognostic factors

		BRCA (95 cases)				
		Negative (21)		Positive (74)		*p* value
Size	<2 cm	4	19.0 %	18	24.3 %	0.77
	>2 cm	17	81.0 %	56	75.7 %	
Grade	I	3	14.3 %	14	18.9 %	0.76
	II	12	57.1 %	46	62.2 %	
	III	6	28.6 %	14	18.9 %	
DCIS	Absent	9	42.9 %	35	47.3 %	0.80
	Present	12	57.1 %	39	52.7 %	
LN	No	11	52.4 %	39	52.7 %	0.85
	Yes	10	47.6 %	35	47.3 %

	Positive	6	28.6 %	27	36.5 %	
Basal markers	Negative	15	71.4 %	70	94.6 %	0.007
	Positive	6	28.6 %	4	5.4 %	

Methylation of BRCA1 gene and protein expression

Hypermethylation of the *BRCA1* was assayed in 45 primary sporadic breast tumours. Cases were selected with respect to BRCA1 protein expression profile (15 cases with absent BRCA1 protein expression, 15 cases with reduced BRCA1 protein expression and 15 cases with normal BRCA1 protein expression) on immunohistochemistry. Methylation was detected in 11/45 (24 %) tumours. Figure 2 shows methylation-specific PCR (MSP) analysis of breast tumours. Lane 1 shows a 50-bp ladder as molecular weight marker; lanes 2, 3, 5, 9 and 11 show the presence of methylated DNA in tumour. Lane 13 shows a positive methylated DNA control and lane 12 shows a negative control.

Out of these 11 cases showing methylation, eight cases were those without BRCA1 expression (level 1) and three were cases with reduced BRCA1 expression (level 2) (Fig. 3). If level 2 and level 1 BRCA1 expressions are taken together, all cases (100 %) of reduced BRCA1 expression showed BRCA1 promoter methylation. None of the tumours with normal BRCA1 expression on immunohistochemistry was methylated. The association between BRCA1 protein expression and *BRCA1* methylation was found to be statistically significant ($p=0.003$).

Table 2 Comparison between BRCA1 nuclear staining and basal marker expression in each grade of tumours

			CK classification		*p* value
			Luminal	Basal	
BRCA-positive	Grade	I	16/20	0	0.51
		II	42/52	2/3	0.49
		III	12/13	2/7	0.007

Association of *BRCA1* promoter methylation with clinicopathological and immunohistochemical prognostic parameters

A statistically significant correlation was found between *BRCA1* methylation and ER status ($p=0.002$) and with basal marker expression ($p=0.02$) as shown in Table 3. Ninety percent of tumours with *BRCA1* methylation were ER-negative as compared to 35.3 % unmethylated tumours, and this difference was statistically significant. A significant difference was also found in terms of basal marker expression; 36 % of tumours with *BRCA1* methylation expressed one of the basal markers, whereas only 6 % of unmethylated tumours were positive for basal markers. The rest of the parameters did not show any significant association. Patients with *BRCA1* promoter methylated tumours were younger than those with unmethylated tumours (54.5 vs 35.3 %, $p=0.21$) and the majority (81.8 %) of the methylated tumours were of >2 cm in size ($p=0.45$). Another difference between the two groups was a higher frequency of high-grade tumours showing methylation (45.5 vs 17.6 %), though this association was not statistically significant ($p=0.06$).

Triple negative and BRCA1 expression (17 cases)

All the triple negative cases were distributed according to their grade, BRCA1 protein expression and basal marker expression. Among nine cases of grade III, five cases (29.4 %) revealed basal marker positivity, and these cases were also found to be negative for BRCA1 protein expression. One case expressed basal markers as well as BRCA1 protein. Among eight grade II cases, two expressed basal markers, out of which one revealed absent BRCA1 expression. None of the triple negative cases were grade I. Eight TN cases were analysed for BRCA1 methylation, six of which showed methylation.

Discussion

BRCA1 gene is a tumour suppressor gene and is linked with key metabolic processes such as DNA damage repair, regulation of gene expression and cell cycle control. A major function of *BRCA1* is in double-strand break repair by homologous recombination (HR), a DNA repair mechanism that uses the sister chromatid as a template and repairs double-strand breaks in an error-free manner. Deficiencies

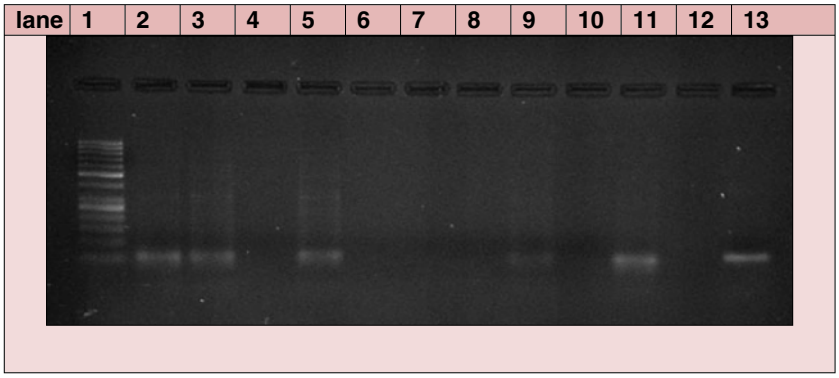

Fig. 2 MSP analysis of BRCA1 promoter region in breast tumours. *Lane 1* shows a 50-bp ladder as molecular weight marker; *lanes 2*, *3*, *5*, *9* and *11* show the presence of methylated DNA in the tumour. *Lane 13* shows positive methylated DNA control and *lane 12* shows the negative control

in homology-directed DNA repair cause high levels of genomic instability that increases the risk of tumorigenesis. Furthermore, *BRCA1* interacts with p53, OCT-/POU2F1 or ZBRK1 and participates in controlling the genes involved in the cell cycle: CDNK1A and GADD45. Alterations of *BRCA1* that impair such functions lead to increased proliferation and chromosomal instability [8].

It has been shown that germline mutations are associated with inherited forms of breast cancer, but somatic mutations are very rare in the sporadic forms of breast cancer. However, several studies demonstrated loss of heterozygosity and a reduced level or absence of *BRCA1* mRNA and protein in a subset of sporadic breast cancer, suggesting that transcriptional and/or posttranscriptional repression of BRCA1 may be involved in the development of sporadic breast cancer [9–11]. One of the common mechanisms of functional inactivation of tumour suppressor genes in cancer cells is aberrant DNA hypermethylation of CpG islands in the promoter region of the gene that is associated with loss of gene expression. Similarities between the morphology and molecular biology of sporadic breast cancers with hypermethylation of *BRCA1* and inherited *BRCA1* breast cancer have led to the concept of 'BRCAness' [12, 13].

Cells with BRCA1 dysfunction are extremely sensitized to the inhibition of poly (ADPribose) polymerase (PARP) enzymatic activity, either alone or when combined with DNA-damaging agents relative to isogenic cells with an intact BRCA pathway. The impairment of base excision repair by PARP inhibitors is highly effective in cells deficient in HR, such as in tumours with loss of BRCA1 function, however, it is not lethal in cells with alternative mechanisms of DNA repair, thus providing a therapeutic opportunity [14, 15]. The model for sensitivity to PARP inhibition is dependent upon HR deficiency rather than inherited BRCA mutation. Therefore, PARP inhibitors might be applicable to sporadic tumours with loss of function of BRCA1 due to hypermethylation or other impairments of the HR pathway.

A few studies have assessed BRCA1 protein expression in sporadic breast cancer using immunohistochemistry [16, 17] In our study, BRCA1 expression was assessed in 95 cases and was found to be normal in 41 (43.1 %) cases, reduced in 33 (38 %) cases and absent/markedly reduced in 21 (22 %) cases. The BRCA1-negative breast cancer had a higher percentage of basal marker positivity (29 versus 5 %). ER-negative status was found to be more frequent in the BRCA1-negative group as compared to the BRCA1-positive

group (62 versus 39 %). Lambie et al. [18] demonstrated a statistically significant inverse correlation between nuclear expression of BRCA1 and histological grade; higher-grade carcinomas were associated with a progressive loss of expression of BRCA1 (p=0.002). In contrast, our study did not demonstrate such inverse relationship with the tumour grade. BRCA1 expression was also compared in different histological subtypes of breast cancer. Lambie et al. [18] also reported a significant association between BRCA1 nuclear expression and the proportion of medullary, atypical medullary and high-grade carcinomas IDC-NOS. However, in our study, cases showing loss of BRCA1 expression were predominantly high-grade IDC-NOS and one case each of metaplastic and invasive papillary carcinoma. There was no case of medullary carcinoma.

Unlike sporadic cancers, where basal-like cancer represents around 15 % of invasive cancers [19, 20], 80–90 % of cancers arising in *BRCA1* germline mutation carriers are of the basal-like subtype [19]. Expression microarray analyses have also indicated strong similarities in gene expression between *BRCA1* familial cancers and sporadic basal-like cancers [21, 22]. This phenotypic overlap has raised the possibility that inactivation of *BRCA1* gene function may also underlie sporadic basal-like cancers and that loss of *BRCA1* gene function may have an etiological role in the development of the basal-like phenotype. Some studies have examined *BRCA1* in unselected sporadic breast cancer, identifying both methylation of the *BRCA1* promoter in 10–15 % of cancers and loss of BRCA1 expression in a number of breast cancers [23, 24]. The incidence of *BRCA1* methylation has appeared to be more common in cancers with a high histological grade and with a triple negative phenotype, suggesting that BRCA1 methylation could underlie basal-like cancers [25]. However, recent studies examining the basal-like subtype specifically have generated conflicting results, and it is presently unclear whether *BRCA1* gene is dysfunctional in these cancers [26]. Data from this study reveal that loss of BRCA1 expression correlates with the expression of basal cytokeratins and thus may play a significant role in the pathogenesis of sporadic basal-like breast tumours.

In breast cancer, more than 40 genes have been shown to be inactivated by methylation, including those involved in DNA repair, cell cycle regulation, tumour suppression, cell adhesion and cell signalling [27–29]. The identification of these methylated genes has significantly contributed to elucidate the molecular pathways which are altered in breast carcinoma and provided potential targets for molecular detection. In this study, *BRCA1* methylation was detected in 24 % of the cases which had absent to reduced BRCA1 protein expression. None of the tumours with normal BRCA1 expression on IHC had methylation of the *BRCA1* promoter. The association between BRCA1 protein expression and *BRCA1* promoter methylation was statistically significant (p=0.003) as was the correlation between *BRCA1* promoter methylation and ER status (p=0.002) and the basal marker expression (p=0.02). In the literature, hypermethylation of the *BRCA1* promoter has been observed in 11–32 % of sporadic breast cancers [30]. It has previously been suggested that *BRCA1*-methylated tumours might phenocopy familial BRCA1 tumours [31]. In support of this notion, we observed the absence of ER expression to be significantly associated with *BRCA1* methylation (p= 0.004), a well-established characteristic of familial BRCA1 tumours. In Indian literature, Mirza et al. [32] reported *BRCA1* to be methylated in 13 of 50 (26 %) tumours. Of these, ten cases were analysed for BRCA1 protein expression and eight showed loss or reduced expression of BRCA1 protein. They also observed the absence of ER expression to be significantly associated with *BRCA1* methylation (p=0.024). From the same centre in India, Raju Bagadi et al. [33] reported *BRCA1* methylation in 15/54 (28 %) cases, which was also associated with lack of ERα expression and nodal metastasis.

Conclusions

This study highlights the role of *BRCA1* gene in sporadic breast cancer. BRCA1 protein-negative tumours showed a

statistically significant association with basal marker expression and ER-negative status, thereby highlighting the 'BRCAness' of sporadic breast cancer with loss of BRCA1 protein expression and promoter hypermethylation similar to hereditary breast cancer with BRCA1 mutations. Loss of BRCA1 in sporadic breast cancer implies that therapeutics targeting the BRCA1 pathway in hereditary breast cancer like PARP inhibitors might also be applicable to sporadic breast tumours.

Conflict of interest The authors declare that they have no financial or non-financial conflict of interests.

Abstract Cytokeratin (CK) immunohistochemistry can play an important role in breast carcinoma evaluation. We evaluated the expression of a panel of commonly used CKs in a large cohort of breast cancers and assessed its correlation with other biomarkers and breast cancer subtypes. Expression of CK7, CK8, CK18 and CK19 was observed in more than 90 % of all breast carcinomas in this study, confirming their efficacy in immunohistochemical identification of breast cancer. A combination of CK8 and CK7 gave the highest sensitivity for detection of a minute number of breast cancer cells. Expression of other CKs, including CK5/6, CK14 and CK20, correlated positively with high tumour grade. The expression of CK5/6 and CK14 in a significant number of high-grade tumours raised concern regarding the use of absence of their expression to identify breast carcinoma. For identification of the basal subtype, CK5/6 gave a higher detection rate than CK14. CK20 expression was found more frequently than reported in previous studies, might constitute an indicator of poor prognosis and may be associated with the molecular apocrine subtype. This study highlights the diagnostic and prognostic relevance of the unique CK expression patterns in breast cancer.

Introduction

Immunohistochemical assessment of members of the cytokeratin (CK) family has been used in the histopathological evaluation of breast carcinoma. CKs constitute two of the six types of intermediate filaments in mammalian cells (the other four are desmin, vimentin, glial fibrillary acidic protein (GFAP) and neurofilament). Twenty different types have been identified: CK 1 to 20 [1, 2]. They can be subgrouped into a high molecular weight and a low molecular weight subgroup, or into acidic or basic types based on their isoelectric points. In general, CK9 to CK20 are called type I CKs, whereas CK1 to CK8 are called type II CKs. Type I CKs are encoded on chromosome 17q whereas type II CKs are encoded on chromosome 12q [3–6].

In normal breast tissue, CK5 and CK14 are expressed in myoepithelial cells. CK7, CK8, CK18 and CK19 are expressed in the ductal epithelium. CK20 is not detectable

in breast epithelium [7]. During the development of malignancy, the original CK profile of the cell is frequently retained. As a result, different types of breast cancers are sometimes characterized according to a purported cell of origin within the breast, based on differential CK expression patterns.

In current practice, evaluation of CK profiles is used for the detection of small tumour foci in sentinel lymph nodes or other metastatic sites [8, 9]. Cytokeratin expression is also helpful in differentiating between specific breast cancer subtypes [10–16], and as prognostic indicator [17–20]. Despite extensive analysis of expression of individual CK's in breast cancer, only a few large studies have been published on the use of CK panels. Immunohistochemical studies on large case series have shown the added value of assessing the expression of combinations of biomarkers rather than individual markers [21]. As CK expression is important in the differential diagnostic workup of breast cancer and given its heterogeneity, a thorough evaluation of CK expression in different breast cancer subtypes is essential. This should be based on a large cohort, allowing accurate analysis of even less common subtypes and cancers showing low CK expression. In the present study, the correlation between the expression of various CKs, other important biomarkers and histological and molecular subtypes, was analysed.

Materials and methods

Patient data

The histological files of two of the involved institutions were searched for breast carcinomas over periods of 3 and 7 years, respectively. All cases for which excision specimens were available were included. Haematoxylin and eosin (H&E)-stained 4-μm slides of the corresponding tumour blocks were reviewed by two of the authors. The diagnosis and histotypes were confirmed using the WHO criteria [22], and the tumours were graded according to Bloom and Richardson [22]. Patient details and clinical information including patient age and lymph node involvement were retrieved from medical records.

Tissue microarray construction

Cellular areas of the tumours were selected and marked on the H&E slides, and sampled for tissue microarray (TMA) construction. Two to three 1.5-mm-tissue cores were obtained from paraffin blocks of each case, depending on tumour cellularity. The TMAs were assembled with a tissue arrayer (Beecher Instruments, Silver Springs, MD). Forty-one composite TMA blocks, each containing up to 54 tissues cores, were constructed. Serial 4-μm sections were cut onto Superfrost Plus glass slides (Menzel-Glaser, Germany). One section from each tissue array block was stained with H&E and reviewed to confirm that representative tumour samples were included in the TMA blocks.

Immunohistochemistry and scoring

TMA slides were subjected to immunohistochemical staining for CKs and other biomarkers. The biomarker panel included antibodies against ER, PR, HER2, Ki-67, p63, c-Kit, chromogranin (CG), synaptophysin (Syn) and EGFR. The CK panel included CK5/6, CK7, CK8, CK14, CK18, CK19 and CK20. Slides were deparaffinized, rehydrated and subjected to antigen retrieval. Immunohistochemical staining of all markers was performed using a BenchMark XT-automated slide-staining instrument (Ventana, Arizona, USA) with Ultraview Universal DAB dectection kit (Ventana, Arizona, USA). The slides were then counterstained with haematoxylin. Details of the antibodies and staining conditions used are listed in Table 1.

The TMA slides were scored for staining intensity and area stained by two of the authors blinded to the clinical information and staining results for other markers. For ER, PR, Ki-67 and p63, staining was nuclear; for Syn and CG, staining was cytoplasmic; for CK5/6, CK7, CK8, CK14, CK18, CK19, CK20 and C-Kit, staining was both cytoplasmic and membranous; for EGFR and HER2, staining was membranous. The staining was considered positive when there was moderate to strong nuclear immunoreactivity in≥ 1 % of tumour cells for ER and PR. HER2 immunostaining was evaluated as 0, 1+, 2+ and 3+ according to the ASCO guidelines [23]. Tumours with 3+ staining were considered positive for HER2. For Ki-67, high expression was defined arbitrarily as 15 % or more of tumour cells showing moderate to strong immunoreactivity. For all other markers, a positive reaction was scored when 5 % or more cells showed strong/moderate staining.

The tumours were also classified into the five different molecular subtypes using immunohistochemical results as surrogate criteria as follows:

Luminal A: ER+and/or PR+, HER2−;
Luminal B: ER+and/or PR+, HER2+;
HER2: ER−, PR−, HER2+, CK5/6±;
Basal: ER−, PR−, HER2−, (triple negative), CK5/6 and/or EGFR+;
Unclassified: ER−, PR−, HER2−, (triple negative), CK5/6− and EGFR−.

Statistical analysis

The findings were analyzed using the statistical software SPSS for Windows, Version 16. Spearman correlation was

used to test for association of CK expression with tumour grade and lymph node status. Pearson's correlation was used to test for the association of all the markers and the histotypes and molecular subtypes. A p value of <0.05 was taken to reflect statistical significance.

Results

A total of 575 cases of breast cancer were included in this study. The age range of patients was 22 to 102 years (mean 55 years). Overall 167 cases (29.0 %) were grade I, 244 cases (42.5 %) were grade II and 164 cases (28.5 %) were grade III. Lymph node metastases were found in 190 cases (33.0 %). As to the histotypes, 435 cases (75.7 %) were infiltrating duct carcinoma not otherwise specified (IDC NOS). Eight cases (1.4 %) showed apocrine features, 87 (15.1 %) were mucinous carcinoma, 11 (2.0 %) were infiltrating lobular carcinoma, 9 (1.5 %) were medullary-like carcinoma, 5 (0.9 %) were metaplastic carcinoma and 28 (4.8 %) were other minor subtypes. Using the immunohistochemical marker expression as surrogate for molecular classification, 446 cases (77.5 %) were luminal A, 50 (8.7 %) were luminal B, 35 (6.1 %) were HER2 and 44 (7.7 %) were triple negative, including 19 (3.3 %) basal like and 25 (4.4 %) unclassified cancers.

Expression of biomarkers

The overall expression rate of each of the biomarkers was: ER: 471 cases (81.9 %), PR: 445 cases (77.4 %), HER2: 85 cases (14.7 %), high Ki-67: 236 cases (41 %), p63: 29 cases (5 %), EGFR: 53 cases (9.2 %), c-Kit: 120 cases (20.8 %), CG: 32 cases (5.6 %) and Syn: 59 cases (10.3 %). The expression rate of each biomarker stratified by grade is shown in Table 2. ER and PR were significantly and more frequently expressed in low-grade tumours (96.4 % in grade I, 86.9 % in grade II and 59.8 % in grade III tumours for ER; 89.8 % in grade I, 78.3 % in grade II and 63.4 % in grade III tumours for PR; $p<0.001$ for both). In contrast, the expression of HER2, EGFR, Ki-67, c-Kit and p63 was significantly associated with higher tumour grade ($p<0.001$ for all markers except p63 with $p=0.001$).

Expression of CKs and correlation analysis

The number of cases expressing the different CKs was for CK5/6 39 (6.8 %), CK7 532 (92.5 %), CK8 566 (98.4 %), CK14 26 (4.5 %), CK18 566 (98.4 %), CK19 539 (93.7 %) and CK20 10 (1.7 %). Figure 1 shows representative staining patterns of CKs. The expression rate of each CK stratified by grade is shown in Table 2. CKs could be grouped into two groups according to the frequency of expression. A

'high expression' group (>90 % of all cancers positive irrespective of tumour grade) comprised of CK7, CK8, CK18 and CK19. The expression of CK7, but not of CK8, CK18 and CK19, showed a weak positive correlation with tumour grade (r=0.083, p=0.049) and a weak negative correlation with patient age (r=−0.084, p=0.044). In contrast, CK5/6, CK14 and CK20 composed the 'low expression' group (<15 % of all cancers positive). They showed a

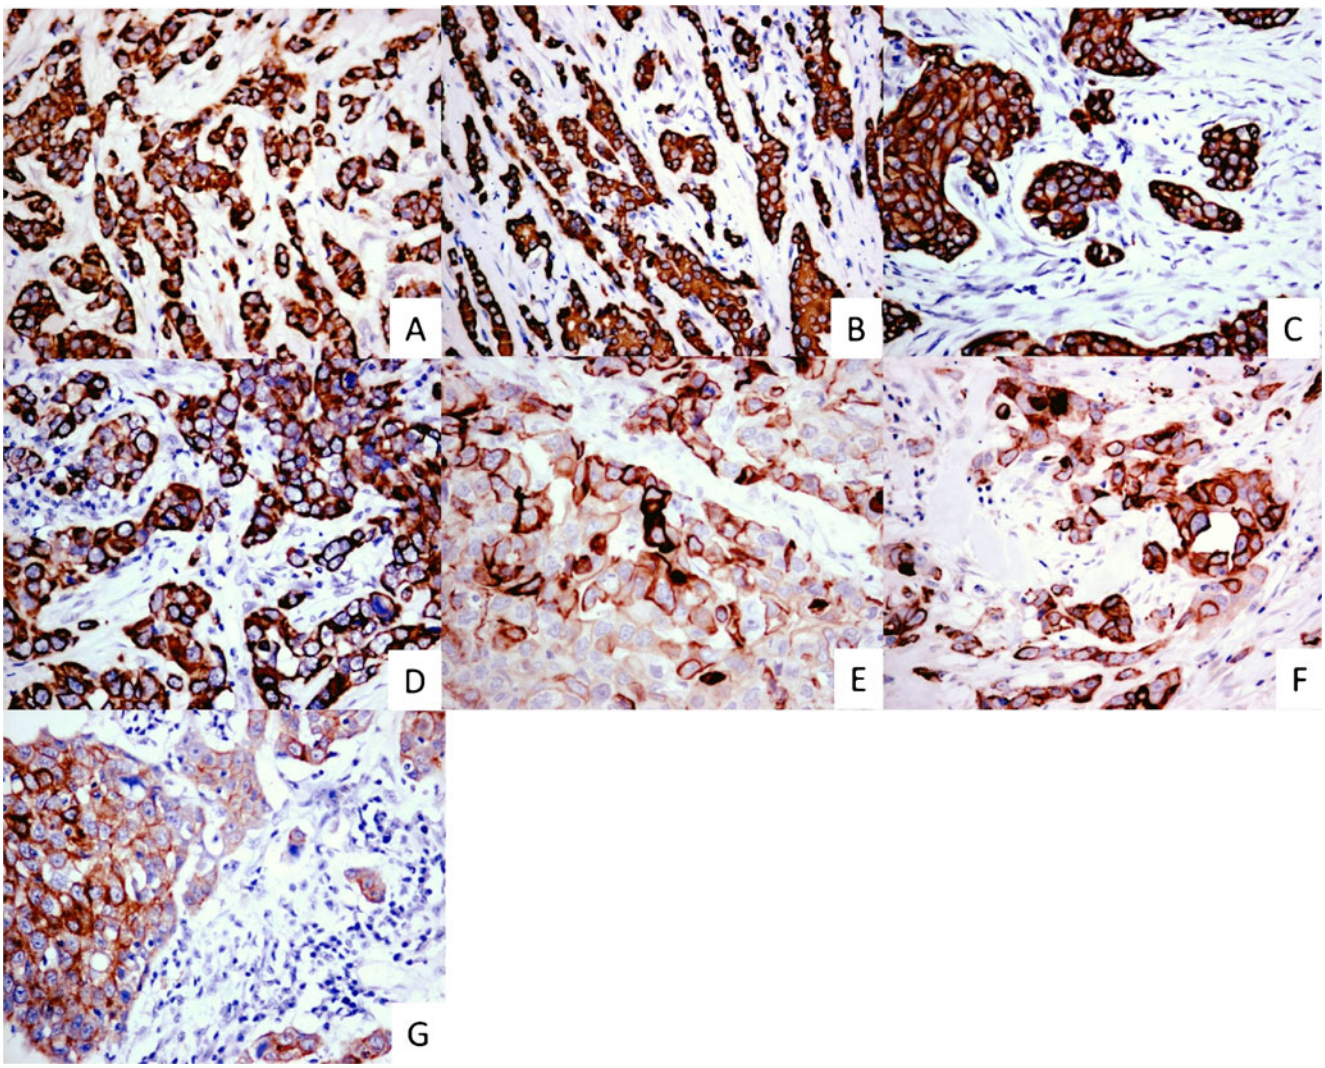

Fig. 1 Representative staining of CK7 (**a**), CK8 (**b**), CK18 (**c**), CK19 (**d**), CK5/6 (**e**), CK14 (**f**) and CK20 (**g**)

much lower overall expression rate (<7 %) but higher with high grade (<14 %). CK5/6 and CK20 expression also showed a stronger positive correlation with tumour grade than CK7 (r=0.144, p=0.001 for CK5/6 and r=0.110, p=0.009 for CK20). CK14 expression showed a negative correlation with lymph node status (r=−0.107, p=0.011).

Comparing CKs with other biomarkers (Table 3), CK5/6 expression correlated with negative ER, PR and high/positive Ki-67, EGFR, p63 and c-Kit expression (r=−0.186, -0.166, 0.281, 0.375, 0.454 and 0.371, respectively, all with p<0.001). Similarly, CK14 expression correlated weakly with negative ER (r=−0.11, p=0.008), HER2 (r=−0.082, p=0.05) and high/positive Ki-67, EGFR, p63 and c-Kit expression (r=0.146, 0.273, 0.396 and 0.272, respectively, all with p<0.001). CK20 expression correlated with negative ER (r=−0.104, p=0.013), PR (r=−0.116, p=0.005) but positive HER2 (r=0.162, p<0.001) expression.

In the 'high expression' CK group, expression of CK8, CK18 and CK19 showed similar correlation patterns with the biomarker panel: correlation with positive ER, PR and HER2 and low/negative Ki-67, EGFR, p63 and c-Kit expression (Table 3). CK18 expression correlated weakly with negative CG expression (r=−0.096, p=0.022). CK19 expression also correlated weakly with negative CG and Syn expression (r=−0.087, p=0.037 and r=−0.108, p=0.009, respectively). In addition, CK7 expression correlated with positive HER2 (r=0.139, p=0.001), but negative CG (r=−0.118, p=0.005) and Syn (r=−0.202, p=<0.001) expression.

The correlation between expressions of different CKs is listed in Table 3. Expression of CK5/6 and CK14 was strongly correlated (r=0.659, p<0.001). This was found also for CK8, CK18 and CK19 (r=0.694 between CK8 and CK18; r=0.507 between CK8 and CK19 and r=0.591 between CK18 and CK19, all with p<0.001). Furthermore, a significant negative correlation was found between expression of CK5/6 and CK14 as a group and of CK8, CK18 and CK19 as a group, in agreement with the obligatory heteropolymer patterns (CK14 partnering with CK5/6; CK18 or CK19 partnering with CK8). In line with previous reports showing more variable expression of CK7 in breast carcinoma as compared to that of CK8,18 and 19 [24], we found a weaker correlation of CK7 expression with that of CK8, CK18 and CK19 (r=0.365, 0.368 and 0.370, respectively, all with p<0.001). In addition, CK7 expression was not correlated with that of CK5/6 and of CK14. Interestingly, expression of CK20 did not show any correlation with that of any other CKs.

The use of combinations of 'high expression' CKs for immunohistochemical identification of breast carcinoma

In breast cancer, CKs have been used as markers to detect circulating tumour cells and micrometastases. We analysed the expression rate of the frequently used 'high expression' CKs and investigated whether their combination might improve immunohistochemical detection of breast cancer. The combination of CK8 and CK18 was expressed in 98.4 % of cases and the expression rate in breast cancer stratified by grade was at least 97 %. For CK7 and CK19, overall expression rates of 92.5 and 93.7 %, respectively, were

found. Combining two CKs, CK8+CK18, CK8+CK19 or CK18+CK19 did not showed any increase in expression rate (data not shown) while CK7 combined with CK8 or CK18 demonstrated an increased overall expression rate to 99 % (Table 4). If the threshold for calling a tumour positive for any CK would be increased from 5 to 60 %, the overall expression rates of CK7, CK8, CK18 and CK19 in breast cancer would be 83.8, 96.5, 90.8 and 82.1 %, respectively (Table 4). Combining CK7+CK8 would increase the expression rate to 98.1 % while a combined CK7+CK18 gave an expression rate of only 95.1 %. Of note, when the expression of CKs in the metastatic lymph nodes was analysed, combined CK7+CK8 continued to show the highest expression rate (96.1 % using a 60 % cutoff; Table 4).Interestingly, when the tumours were stratified by grade, combined CK7+CK8 did not show increased expression rate in grade I tumours but the expression rate was increased in grade III tumours (CK8 alone=96.3 % and CK7+CK8=100 %). The expression rate using CK7+CK18 was only 93.9 % in grade III tumours. Similar results were also observed in metastatic lymph nodes (data not shown).

CKs expression in histological subtypes of breast carcinoma

The expression rate of CKs was analysed in different histological subtypes (Table 5). Again, CK8 showed the highest expression rate (> 98 %) in all different histological subtypes. The expression rates of CK7, CK18 and CK19 were slightly lower than that of CK8. Except in metaplastic carcinoma (80 % positive for CK7 and 60 % positive for CK18/CK19), the expression rates for these CKs ranged from 88–100 % in all other histological subtypes. Notably, CK18 and CK19 expression showed a significant negative correlation with metaplastic carcinoma ($r=-0.189$, $p<0.001$ and $r=-0.130$, $p=0.002$, respectively). While the group of 'high expression' CKs were positive in most histological subtypes, the group of 'low expression' CKs showed a restricted pattern of expression. Expression of CK5/6 was mainly found in medullary-like and metaplastic carcinomas (66.7 %, $r=0.095$, $p=0.023$ and 40 %, $r=0.126$, $p=0.003$, respectively). For all other subtypes, the expression rate of CK5/6 was <10 %. The expression pattern of CK14 was similar to CK5/6 but with a lower expression rate, and CK14 expression occurred only in metaplastic carcinoma (40 %, $r=0.16$, $p<0.001$) but not in medullary-like carcinoma. CK20 expression was rare in most histological subtypes with only 1.4 % cases expressing CK20 in IDC NOS and none in most others. However, it was the only CK that was strongly expressed in 50 % of carcinomas with apocrine features ($r=0.428$, $p<0.001$.

CK expression in molecular subtypes of breast carcinomas

Further analysis of CK expression in different molecular subtypes revealed an over 90 % expression rate of CK7 and CK8 in all molecular subtypes (Table 5). A significant negative correlation of CK8 expression was found with triple negative breast cancer (TNBC) ($r=-0.122$, $p=0.003$). CK18 and CK19 also showed a >90 % expression rate in luminal A, luminal B and HER2 subtypes but only ≤80 % in triple negative subtypes. They were found to be associated positively with luminal A subtype but negatively with TNBC (CK18: luminal A subtype, $r=0.148$, $p<0.001$; triple negative subtype, $r=-0.302$, $p<0.001$ and CK19: luminal A subtype, $r=0.085$, $p=0.042$; triple negative subtype, $r=-0.169$, $p<0.001$). On the contrary, CK5/6 and CK14 showed high expression rates in TNBC (25 and 11 %, respectively) with significant associations (CK5/6: $r=0.209$, $p<0.001$ and CK14: $r=0.095$, $p=0.023$). Furthermore, CK5/6 expression was also negatively correlated with luminal A subtype ($r=-0.104$, $p=0.013$). CK20 expression was found in <10 % of all molecular subtypes. Despite its low frequency compared with other 'low expression' CKs, CK20 showed

Table 4 Expression rate of high expression CKs with different cutoff

Cut-off	Grade	CK7, %	CK8, %	CK18, %	CK19, %	CK7+CK8, %	CK7+CK18, %

ns not significant

the highest expression rate in HER2 subtype (9 % for CK20 vs 6 % for CK5/6 and 0 % for CK14). Importantly, a positive correlation with HER2 subtype was demonstrated only for CK20 expression but not for the others (r=0.136, p=0.001).

Molecular classification of breast carcinomas using basal CKs

Within the group of TNBC, the expression rate of basal CKs, namely CK5/6 and CK14 was 25 and 11 %, respectively. Furthermore, most of the breast cancers that expressed CK14 in the triple negative group also expressed CK5/6 (four of five cases, 80 %). In this group, the expression rate of EGFR was 75 %. Using a combination of EGFR or CK5/6 expression as immunohistochemical definition of basal-like subtype classified 43.2 % of triple negative breast cancers as basal subtype (11.4 % expressed only CK5/6, 18.2 % expressed only EGFR and 13.6 % co-expressed both markers), whereas if CK14 or EGFR are used, this would be 36.4 % (4.5 % expressed only CK14, 25 % expressed only EGFR and 6.9 % co-expressed both markers). In fact, only 2.2 % of TNBC expressed CK14 without CK5/6 or EGFR expression. Hence, CK5/6 was more sensitive than CK14 in the identification of basal like breast cancer in the current cohort.

Discussion

CK expression in breast cancer can be divided into three groups according to the expression rates and correlation patterns. One group includes CK7, CK8, CK18 and CK19 showing high expression rates (>90 %). The other group comprises CK5/6 and CK14 with low expression rates (<15 %). CK20, which appears to be distinct from CK5/6 and CK14, but also showing a low expression rate, composes the third group. Within these respective groups, there was significant correlation among members of the same group and similar correlation patterns with other biomarkers.

A clinically important role for the 'high expression' group of CKs is the detection of small amounts of breast cancer tissue. The overall expression rate of CK19 reported in breast cancer was high, ranging from 89 to 92 % [7, 25]. The presence of CK19 mRNA has been considered a reliable and sensitive marker for the detection of metastasis in sentinel lymph nodes [8, 26, 27]. In the current series, its overall expression rate was 93.7 %, and there was no difference according to grade of the tumours. However, CK19 was expressed in only 60 % of metaplastic carcinomas. This same observation was also made by others [8, 25, 28]. Using CK19 as the sole marker to detect minute foci of breast cancer may result in missing some of them. In our case series, CK8 was found to have the highest expression rate of >98 % irrespective of grade and tumour subtypes and might be a better marker for breast cancer detection. In most diagnostic scenarios, the quantity of malignant cells is limited. If the threshold for calling a case positive for the expression of a CK is increased from 5 to 60 %, the overall expression rate of CK8 and CK19 decreases to 96.5 and 82.1 %, respectively. Only 75 % of grade three tumours would then be CK19 positive. To improve the likelihood of detecting minute amounts of cancer tissue, CK8 might be complemented by CK7 (Table 4). Combined CK7+CK8 would achieve a 98.1 and 100 % expression rate in all cases and grade III tumours, respectively. Hence in samples with

little cancer tissue, CK7+CK8 might have a better sensitivity in detecting breast cancer than CK19 or CK8 alone, particularly for high-grade breast cancers.

In the course of diagnostic histopathology, the need frequently arises to differentiate between florid epithelial hyperplasia and low-grade atypical epithelial proliferation (atypical epithelial hyperplasia or low-grade carcinoma in situ), particularly in architecturally complex lesions like papillary lesions or complex sclerosing lesions. CKs have long been thought to be useful in this differentiation. While benign hyperplasia is usually positive for CK5/6 and CK14, the atypical to low-grade malignant epithelium tends to be negative [15, 29]. In the current series, the expression rate of CK5/6 and CK14 in grade 1/2 breast cancers was 4.1 and 3.1 %, respectively, but considerably higher (13.4 and 7.9 %, respectively) in grade 3 cancer. Thus the absence of expression of both CK5/6 and CK14 identifies low-grade breast cancer relative to florid epithelial hyperplasia. In high-grade cancer, assessment of CK5/6 and CK14 expression would have a lower specificity.

The initial description of molecular subtypes of breast cancer was based on microarray profiling [30, 31]. The basal subtype has been the focus of intense investigations, and many different profiles have been proposed for the immunohistochemical classification of this group. Apart from being triple negative, additional immunohistochemical criteria include expression of CK5/6 [16], CK14 [11] or both CK5/6 and CK14 [32]. Other definitions involve other markers, including expression of CK5/6 and/or EGFR [12, 33] as in this study, or combinations of CK5, p63 and p-cadherin [34], or basal CK, EGFR and osteonectin [35]. We show that the expression of most of these markers is correlated (Tables 4 and 5). Irrespective of the combinations, basal CK5/6 and CK14 remain key markers with the majority of CK14-positive cases and also in CK5/6 positive cases. Using EGFR with CK5/6 yielded a total of 43.2 % as of basal subtype. If CK14 is added, the basal subtype increases by 2.2 %. The expression rates of CK5/6 and CK14 were similar in metaplastic carcinoma but the CK14 expression rate was lower in medullary-like carcinoma. These findings point to CK14 as a marker for only a subset of the basal subtype. Overall, CK5/6 showed a higher sensitivity for the basal subtype than CK14 (58 vs 21 %), similar to the reported range of 58–62 % [12, 35, 36].

Besides serving as a diagnostic marker, basal CKs has also been reported to be related to TNBC prognosis with TNBC expressing either or both CK5/6 and EGFR having adverse outcome [17]. Others reported CK cocktail 34βE12 but not CK5/6 to be associated with improved overall survival [19]. These apparently conflicting results require further investigation. We found expression of CK5/6 and CK14 to be negatively correlated with ER and PR expression and positively correlated with high Ki-67, indicative of poor prognosis.

In the current cohort, 1.7 % of tumours expressed CK20. There was no association of CK20 with any other CK. Lack of CK20 expression is usually taken as characteristic for breast cancer and together with CK7 expression is commonly used for the diagnosis of metastatic breast carcinoma [7]. The small but probably not entirely negligible number of CK20-positive cases should be borne in mind. Of note, all CK20-positive cases were of intermediate to high grade, were negative for ER and PR but positive for HER2. It would thus appear that CK20 carries prognostic significance. In fact, CK20 gene expression had been reported to be associated with increased stage, metastases and lower overall survival in breast cancer [18, 20]. The CK20-positive group was also strongly associated with apocrine features and HER2 subtype. Interestingly, these features of CK20-positive tumours were also shared by a recently identified molecular subtype with poor prognosis, which has been called the molecular apocrine group [37]. It is tempting to speculate that the application of CK20 can help to identify this special subtype immunohistochemically. More investigation is required to clarify the significance of CK20 in breast cancer.

In summary, we show that CK expression is useful as an adjunct in the diagnosis, classification and prognostication of breast cancer. CK7 and CK8 in combination allow better detection of minute quantities of breast cancer than CK19, in particular for high-grade tumours. Caution is needed in the use of CK5/6 and CK14 to differentiate low-grade breast cancer from usual epithelial hyperplasia, as CK5/6 and CK14 are expressed in a significanct number of high-grade breast cancers. In the immunohistochemical classification of molecular groups, CK5/6 appeared more sensitive than CK14 for the basal subtype. Finally, despite the low expression rate, CK20 expression could be an indicator of poor prognosis in breast cancer and implicated in the molecular apocrine subytpe.

Conflict of interest The authors declare that they have no conflict of interest.

Abstract Angioimmunoblastic T cell lymphoma (AITL) is a relatively rare peripheral T cell lymphoma derived from follicular T helper cells. AITL has a varied presentation, both clinically and morphologically. AITL can pose a diagnostic challenge as it may be difficult to identify and characterize the neoplastic cells among the polymorphous infiltrates composed of polyclonal B immunoblasts and plasma cells. In AITL, the reactive B cell and plasma cell proliferation is secondary to dysregulated secretion of cytokines such as interleukin-6 by the neoplastic follicular T helper cells. SPBIP is a condition of unknown etiopathogenesis characterized by systemic involvement by polyclonal B immunoblasts and plasma cells. We report two cases of AITL, which are presented with atypical findings making it difficult to diagnose. The cases had features similar to SPBIP. Our cases highlight the importance of screening cases of polyclonal plasmacytosis and SPBIP like cases for underlying AITL.

Keywords Angioimmunoblastic T cell lymphoma · Polyclonal B immunoblastic proliferation

Introduction

Angioimmunoblastic T cell lymphoma (AITL) is a peripheral T cell lymphoma (PTCL) arising from follicular T helper cells [1]. It is a disease of middle-aged and elderly individuals [2] and characterized by very high incidence of Epstein–Barr virus (EBV) infection [3]; constitutional symptoms such as fever, night sweats, weight loss, and other symptoms depending upon the organ system involved [4]; and generalized lymphadenopathy with frequent involvement of spleen, liver, skin, and bone marrow [2]. Morphologically, lymph nodes show partial to complete effacement of lymph node architecture. The lymph node infiltrate ranges from polymorphic cells composed of immunoblasts, plasma cells, eosinophils, small lymphocytes, and follicular dendritic cells (FDC) to a monotonous infiltrate of atypical lymphoma cells, often with clear cytoplasm. Numerous arborizing blood vessels are usually seen [5, 6].

The diagnosis of AITL can be very challenging, especially at an early stage in the disease evolution, when the lymph node architecture is relatively preserved with many hyperplastic lymphoid follicles and the lymphoma cells are not readily identifiable. This is complicated by the fact that AITL retains some functional characteristics of non-neoplastic follicular T helper cells, such as the capacity to secrete cytokines like interleukin (IL)-6 and to stimulate immune cell growth and thus, AITL is associated with obscuring non-neoplastic immune cells [7]. As a result, identifying AITL presents two sets of challenges. The first is identifying AITL cases that present with partial effacement of architecture, hyperplastic germinal centers, and minimal expansion of FDC and separating them from reactive conditions. The second challenge is identifying AITL cases without readily identifiable CD10-positve lymphoma cells or FDC expansion and separating them from PTCL, unspecified. Once lymphoma is suspected, the most useful histological features to distinguish AITL from PTCL, unspecified are prominent vascularity, proliferation of follicular T helper cells, CD10-positive cells, EBV infection, and florid FDC proliferation [8]. Follicular T helper cells have emerged as a distinct helper T cell subset residing in reactive

germinal centers of lymph node and providing help to B cells. Consequently, several markers characteristically expressed by these follicular T helper cells can be used in the diagnostic practice. The markers include cell surface molecules CXCR5, CD154, PD-1 (CD279), ICOS, CD200, as well as cytoplasmic SAP, chemokine CXCL13, and transcription factors Bcl-6 and MAF [9]. While molecular studies can generally detect clonal T cell receptor (TCR) rearrangement, about 10–20 % of cases do not show any clonal TCR gene rearrangements [10, 11]. Also, clonal immunoglobulin heavy chain (IgH) gene rearrangements can be seen in addition to clonal TCR gene rearrangements in some cases of AITL [12].

AITL may be categorized into three overlapping architectural patterns, as described by Attygalle et al. [8]. In pattern I, there is partial preservation of lymph nodal architecture with hyperplastic follicles and a polymorphous paracortical infiltrate. Pattern II presents with depleted follicles and may have Castleman disease-like features. Pattern III presents with complete effacement of architecture, accompanied by perivascular proliferation of FDC. Cases intermediate between AITL and PTC, unspecified have been also described [8].

Systemic polyclonal B Immunoblastic proliferation (SPBIP) is a very rare atypical lymphoproliferative disorder with only a handful cases of SPBIP published in the literature [13–16]. SPBIP can present with a subacute onset of symptoms such as fever, dyspnea, malaise, weakness, and other symptoms depending on the organ systems involved. The process can involve lymph nodes, bone marrow, spleen, thymus, liver, kidneys, thyroid, adrenal glands, lungs, and skin. There may be evidence of infection reflecting either an initiating event or immunodeficiency secondary to the atypical proliferation process. The disease process is characterized by a systemic involvement by proliferating polyclonal B immunoblasts and plasma cells. There may be lymphocytosis with the presence of immunoblasts and plasma cells in the peripheral blood. The uncontrolled production of immunoglobulins may result in polyclonal gammaglobulinemia. The etiopathogenesis of SPBIP is unknown. While the cells appear polyclonal by immunoglobulin expression or gene rearrangement studies, clonality was demonstrated by cytogenetic studies in some cases [13, 16]. It is not entirely clear whether these proliferations are neoplastic or reactive in nature. It is also not clear if SPBIP is related to so-called polyclonal lymphomas [17]. Although SPBIP responds to corticosteroid therapy or chemotherapy, untreated or even treated cases can be fatal. Treatment with corticosteroids alone or in combination with cytotoxic agents can quickly induce complete remission with resolution of lymphadenopathy and normalization of peripheral blood picture [14, 15].

AITL and SPBIP share many clinical and morphologic features and especially an exuberant polyclonal B immunoblast and plasma cell proliferation. Extensive immunophenotypic, cytogenetic, and molecular testing is sometimes necessary to distinguish between AITL and SPBIP. We report our experience with two cases of AITL that initially presented with unexplained, massive, and systemic B immunoblastic and plasmacytic proliferation mimicking SPBIP.

Clinical history

Case 1

A 55-year-old African-American female with a past medical history of diabetes mellitus and hypertension first presented to her primary care physician with lymphadenopathy. A cervical lymph node biopsy was performed at an outside institution and showed atypical lymphoid hyperplasia. Approximately 5 days later, she was admitted to a hospital with weakness, dizziness, dyspnea, diffuse lymphadenopathy (inguinal, cervical, axillary, and retroperitoneal lymph nodes), hemoptysis, and bleeding gums. A complete blood count showed a leukocyte count of 29.1×10^9/L, hemoglobin 94 g/L, hematocrit 28 %, and platelet count of 10×10^9/L. Blood serology was negative for antinuclear antibodies, human immunodeficiency virus, acute cytomegalovirus infection, and acute EBV infection. Platelet-associated antibodies were detected. The patient was found to have polyclonal gammaglobulinemia with elevated serum IgG, IgA, IgM, and IgE. A repeat cervical lymph node biopsy and a bone marrow aspirate and biopsy were performed. The lymph node, peripheral blood, and bone marrow aspirate samples were studied by flow cytometric analysis. Gene rearrangement studies were performed on the peripheral blood and lymph node specimens. A diagnosis of SPBIP was suspected at this time. The patient was treated with methylprednisolone, dexamethasone, vincristine, and cyclophosphamide. The treatment resulted in complete clinical response with nonpalpable lymph nodes and normal peripheral blood findings.

About 2 months after her initial presentation, the patient was readmitted with a white blood cell count of 27.9×10^9/L and 38 % atypical lymphocytes. Peripheral blood flow cytometry demonstrated the presence of abnormal B immunoblasts. She was again treated with the same regimen of intravenous corticosteroids and chemotherapy and subsequently responded clinically.

A year later, she was admitted again with generalized lymphadenopathy. An axillary lymph node biopsy was performed. This time, the findings were more consistent with AITL. The patient received therapy with cyclophosphamide, adriamycin, vincristine, and prednisolone (CHOP) and remained in remission for 12 months. At the time of

evaluation for bone marrow transplantation, a positron emission tomography scan revealed uptake in the colon and colonoscopy revealed adenocarcinoma of the colon. A colectomy was performed and the patient received adjuvant chemotherapy with fluoruracil, oxaliplatin, and has remained disease free of her colon carcinoma. Fourteen months after receiving CHOP, she has again relapsed with adenopathy in the supraclavicular area and biopsy affirmed recurrence of AITL.

Case 2

A 70-year-old Caucasian female presented to her primary physician with a 2-week history of weakness, drenching sweats, early satiety, postprandial nausea, and vomiting, and 15 % weight loss. A complete blood count showed a leukocyte count of 24.7×10^9/L, hemoglobin 123 g/L, hematocrit 37 %, and a platelet count of 238×10^9/L. She had elevated serum IgG of 45.5 g/L. Serum and urine protein electrophoresis did not reveal evidence of monoclonal gammopathy. A computer tomography scan of chest and abdomen revealed enlargement of mediastinal, periaortic, and pericaval lymph nodes and mild splenomegaly. Review of peripheral smear was significant for plasmacytosis. Bone marrow aspirate and biopsy procedure, as well as right inguinal lymph node excision biopsy, were performed. Flow cytometry and gene rearrangement studies were performed on specimens of peripheral blood, bone marrow, and lymph node. The diagnosis of AITL was made, and the patient was treated with frontline chemotherapy with CHOP regimen. Interval evaluation showed persistent low level of disease in the bone marrow and low level of hypermetabolic uptake in the spleen. She received more chemotherapy with continued response on re-evaluation and proceeded to autologous stem cell transplantation. The patient remains free of disease 15 months from initial presentation.

Materials and methods

Histologic and immunohistochemical studies

Fresh biopsy tissue was fixed in 10 % neutral-buffered formalin, embedded in paraffin and sectioned at 3 μm. Sections were stained with hematoxylin and eosin for morphological evaluation. Immunohistochemical analysis was performed on the paraffin sections with the following antibodies: CD2, CD3, CD4, CD5, CD7, CD8, CD10, CD19, CD20, CD21, CD23, CD45, CD79a, PAX5, CXCL13, and PD-1/CD279. The immunohistochemical analysis was performed on an automated immunostainer with a streptoviridin–biotin peroxidase detection system, preceded by microwave antigen retrieval in citrate buffer.

Flow cytometric immunophenotyping

Four- or eight-color flow cytometry was performed on Canto II flow cytometer (BD Bioscience, San Jose, CA, USA). The data was analyzed by FACSDiva software (BD Bioscience). The following monoclonal antibodies were utilized: CD2, CD3, CD4, CD5, CD7, CD8, CD10, CD11c, CD13, CD14, CD15, CD16, CD19, CD20, CD22, CD23, CD25, CD33, CD34, CD36, CD38, CD45, CD56, CD57, CD61, CD71, CD103, CD117, CD138, Kappa, Lambda, FMC-7, and human leukocyte antigen (HLA)-DR (BD Bioscience).

Epstein–Barr virus in situ hybridization

A test utilizing alkaline phosphatase-conjugated detection chemistry to localize fluorescein-labeled oligonucleotide probes against EBER1 RNA was performed on paraffin-embedded tissue at Mayo Medical Laboratories (Rochester, MN, USA) as previously described [18].

Molecular analysis

A polymerase chain reaction based analysis was done on peripheral blood, bone marrow aspirate, and paraffin-embedded tissue at Mayo Medical Laboratories for clonal IgH and TCR gene rearrangements as previously described [19].

Results

Case 1

The initial cervical lymph node biopsy showed a partial effacement of the nodal architecture by interfollicular proliferation of B immunoblasts and plasma cells with a number of residual follicles with hyperplastic germinal centers (Fig. 1a and b). No increase in vascularity was appreciated. Cervical lymph node flow cytometry revealed 30 % B immunoblasts/plasma cells with expression of CD45 (moderate), CD19 (moderate), CD38 (bright), CD56 (dim), CD71 (dim), HLA-DR, and polytypic cytoplasmic light chains without surface light chain expression (Fig. 1c and d). No aberrant T cell phenotypes were detected by flow cytometry. The T cells were CD10 negative (Fig. 1e and f). Gene rearrangement studies performed on the lymph node were negative for clonal IgH gene rearrangement. However, clonal TCR gene rearrangement was detected in the lymph node.

Peripheral blood revealed numerous immunoblasts of intermediate to large size, round to oval nucleus with prominent nucleoli. Bone marrow aspirate and biopsy were hypercellular with a diffuse infiltration by immunoblasts and plasma cells. The peripheral blood flow cytometry

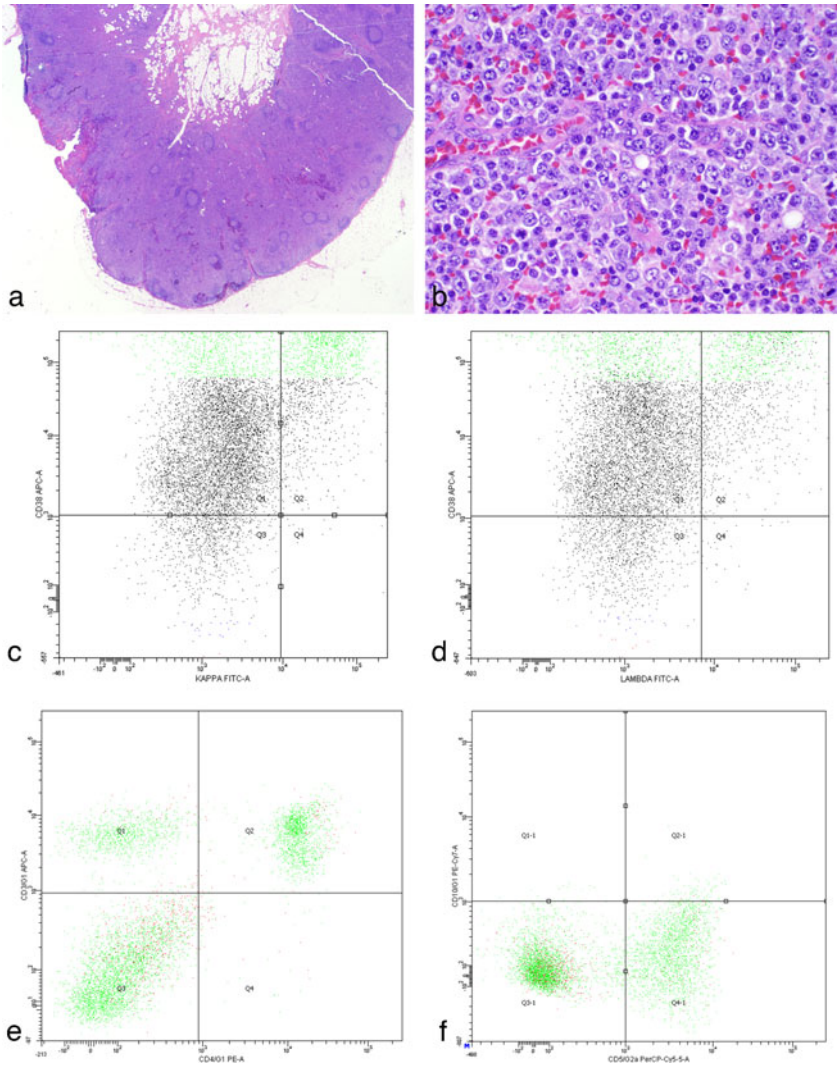

Fig. 1 Case 1: cervical lymph node with interfollicular atypical proliferation and preservation of hyperplastic follicles; hematoxylin and eosin (H&E) stain, magnification ×10 (**a**). High-power view of cervical lymph node showing immunoblasts and plasma cells; H&E stain, magnification ×400 (**b**). Flow cytometry reveals B immunoblasts/plasma cells strongly positive for CD38 with polytypic cytoplasmic light chains (**c** and **d**). Flow cytometry reveals T cells with no abnormal expression of CD3 or CD4 (**e**). Flow cytometry reveals T cells with no abnormal expression of CD10 (**f**)

revealed 27 % B immunoblasts/plasma cells with expression of CD45 (moderate), CD19 (moderate), CD38 (bright), CD56 (dim), CD71 (dim), HLA-DR, and polytypic cytoplasmic light chains without surface light chain expression. Bone marrow aspirate flow cytometry showed 34 % cells with the same phenotype. A cytogenetic study of peripheral blood was unsuccessful with the failure of cells to grow.

The axillary lymph node biopsy showed a diffuse and polymorphic infiltrate comprising small- and intermediate-sized atypical lymphoid cells, immunoblasts, and numerous plasma cells. Only rare, atrophic follicles with inconspicuous FDC were seen (Fig. 2a). There were occasional arborizing blood vessels with plump endothelial cells (Fig. 2b). Rare atypical cells had clear cytoplasm (Fig. 2c). The atypical T-cells expressed CD2, CD3, CD4, CD5, CD7, PD-1/CD279, TCR beta F1, and partial CXCL13, but not CD10 (Fig. 2d and e). Epstein–Barr virus in situ hybridization (EBV-ISH) revealed rare scattered cells containing EBV (Fig. 2f). Rare small follicles and numerous interfolicular immunoblasts were demonstrated by the CD20 stain (Fig. 2g). CD21 staining revealed irregular and mildly expanded FDC mesh works with some encircling of vessels (Fig. 2h). Flow cytometric analysis showed small polyclonal B cells (22 %), large polyclonal B cells (16 %), and T cells with apparently normal phenotype. The large B cells represented polyclonal activated B cells with immunoblastic or plasmacytic differentiation and expressed CD45, CD19, CD22, CD38, CD71, CD138, HLA-DR, FMC-7, and polytypic cytoplasmic kappa and lambda light chains. This immunophenotype was similar to that previously described for immunoblasts/plasma cells in the peripheral blood, bone marrow, and cervical lymph node. Molecular studies revealed no clonal IgH gene rearrangements, but clonal TCR gene rearrangement was detected. Cytogenetic studies done on the lymph node tissue revealed no abnormalities.

Case 2

Peripheral blood smear showed increased numbers of plasma cells (Fig. 3a). Bone marrow was hypercellular for age

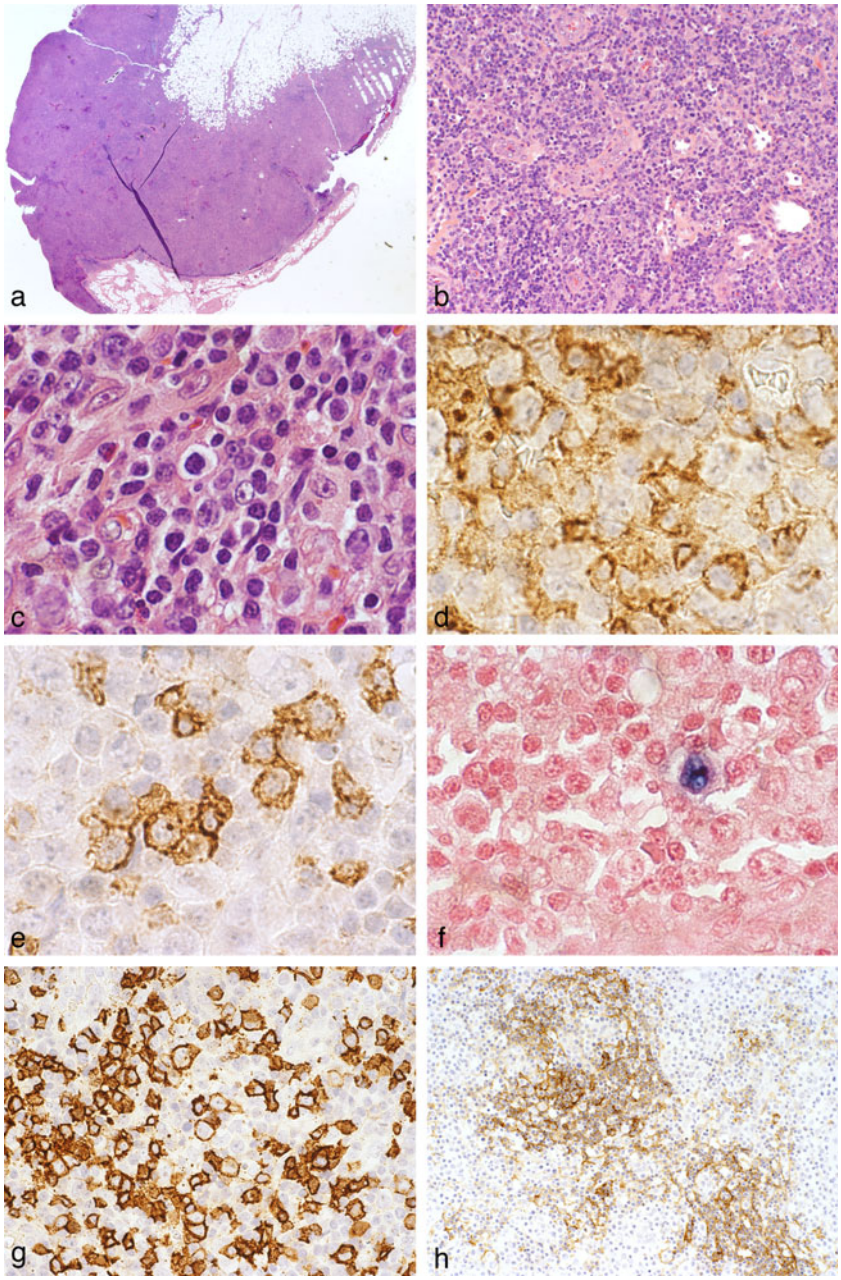

Fig. 2 Case 1: axillary lymph node with diffuse atypical proliferation and rare, indistinct follicles, H&E stain, magnification ×10 (**a**). Higher-power view of axillary lymph node showing vascular proliferation and polymorphous infiltrate, H&E stain, magnification ×200 (**b**). Atypical lymphoid cells with clear cytoplasm, H&E stain, magnification ×1000 (**c**). Atypical lymphoid cells positive for CD4, magnification ×1,000 (**d**). Atypical lymphoid cells positive for PD-1/CD279, magnification ×1,000 (**e**). Rare lymphoid cells positive for EBER, magnification ×1,000 (**f**). Immunoblasts positive for CD20, magnification ×400 (**g**). Mild expansion of follicular dendritic cells positive for CD21, magnification ×200 (**h**)

with marked plasma cell infiltration (Fig. 3b). The peripheral blood flow cytometry revealed 27 % plasma cells. The plasma cells were characterized by the expression of CD45 (bright), CD19, CD23 (dim), CD38, CD71, CD138, HLA-DR, and cytoplasmic polytypic light chains (Fig. 3c and d). There was no surface light chain expression. The bone marrow flow cytometry revealed 21 % plasma cells. The phenotype of bone marrow plasma cells was similar to that described above except for additional weak expression of CD56.

The inguinal lymph node biopsy showed architectural effacement with multiple vague but complex lymphoid nodules composed of variably sized lymphoid cells, immunoblasts, and plasma cells (Fig. 4a). There was mildly increased vascularity with rare arborizing vessels (Fig. 4b). Rare abnormal follicles were present with irregular germinal centers and absent mantle zones. Rare atypical cells had clear cytoplasm (Fig. 4c). A number of small or large lymphoid cells were positive for CD2, CD3, CD4, CD5, CD7, TCR beta F1, and PD-1/CD279, although no significant staining was noted for CD10 or CXCL13 (Fig. 4d and e). EBV-ISH revealed numerous cells containing EBV (Fig. 4f). There were numerous CD20-positive immunoblasts and markedly expanded CD21-positive FDC mesh works (Fig. 4g and h).

The inguinal lymph node flow cytometry revealed a predominance of T cells. A few polyclonal B cells and plasma cells were also detected. The B cells had a normal

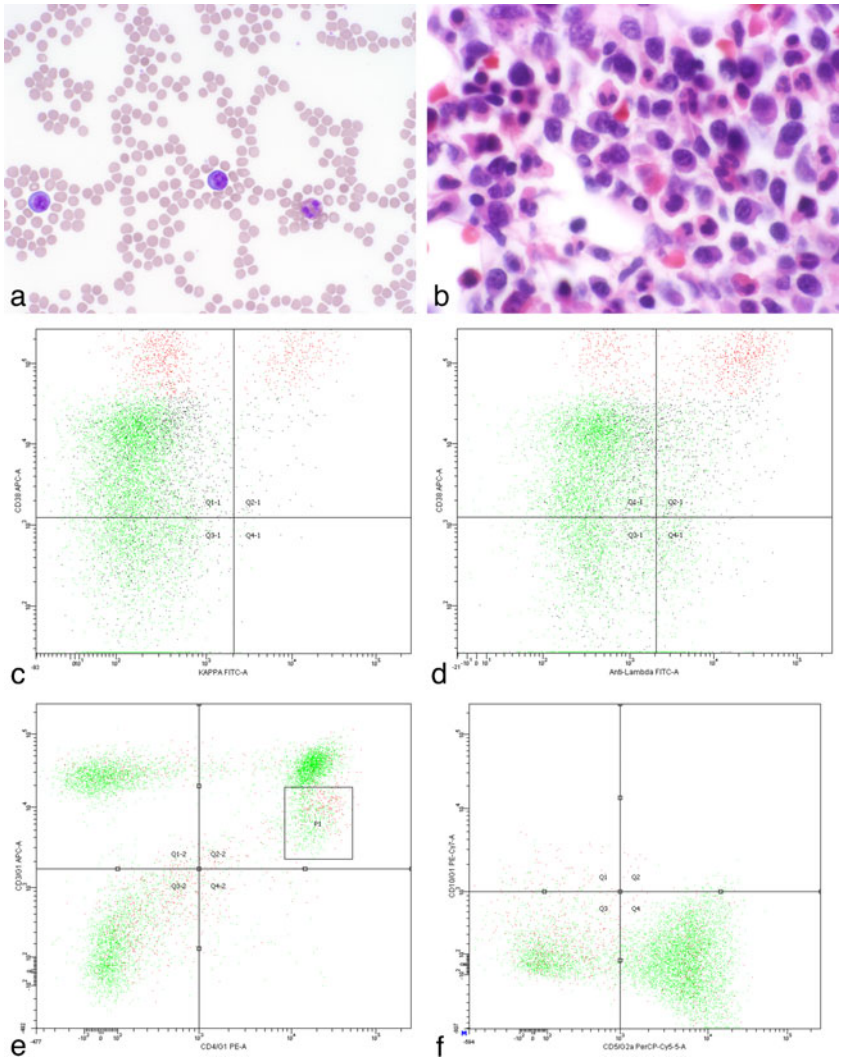

Fig. 3 Case 2: peripheral blood smear with circulating plasma cells, Wright stain, magnification ×400 (**a**). Bone marrow with increase in plasma cells, H&E stain, magnification ×1,000 (**b**). Flow cytometry reveals immunoblasts/plasma cells strongly positive for CD38 with polytypic cytoplasmic light chains (**c** and **d**). Flow cytometry performed on the inguinal lymph node reveals a subset of CD4 positive T cells with slightly weak expression of CD3 (**e**). The T cells have no abnormal expression of CD10 (**f**)

phenotype. A small population of CD4-positive T cells had slightly weaker expression of CD3 (Fig. 3e). No other T cell abnormalities were detected. The T cells were CD10 negative (Fig. 3f). While peripheral blood and bone marrow did not reveal any T cell clonality, inguinal lymph node had clonal TCR gene rearrangement. Cytogenetic studies performed on bone marrow aspirate were negative.

A follow-up bone marrow aspirate and biopsy, done 5 months after initial presentation, showed low level involvement of the bone marrow aspirate by lymphoma and the lymphoma cells had weak expression of CD3 by flow cytometry, similar to that previously detected in the inguinal lymph node.

Discussion

The diagnosis of AITL in the above cases was difficult due to a predominance of numerous polyclonal B immunoblasts or plasma cells in all the specimens examined, including blood and bone marrow, paucity of atypical cells, and lack of significant immunophenotypic T cell abnormalities. Case 1 was especially difficult as the flow cytometric studies failed to detect abnormal T cell immunophenotype and there was no expression of CD10 in T-cells typically seen in AITL [20]. Unfortunately, CD10 expression is neither sensitive nor specific for detection of AITL [20, 21]. Due to those factors, the initial presentation in case 1 was initially considered to be SPBIP. Later, clonal TCR gene rearrangement studies suggested a possibility of PTCL. In retrospect, it was pattern I of AITL. The relapse in case 1 had morphologhic findings more typical for AITL, and specifically pattern II. Case 2 was somewhat easier to diagnose as flow cytometry revealed a subset of CD4-positive T-cells with slightly weaker expression of CD3. That was the sole immunophenotypic abnormality and no CD10 expression was seen in this case. The immunoperoxidase studies were helpful and demonstrated increased staining for PD-1/CD279 in the atypical infiltrate in both cases. Weak CXCL13 staining was present in case 1, but absent in case 2. It is well

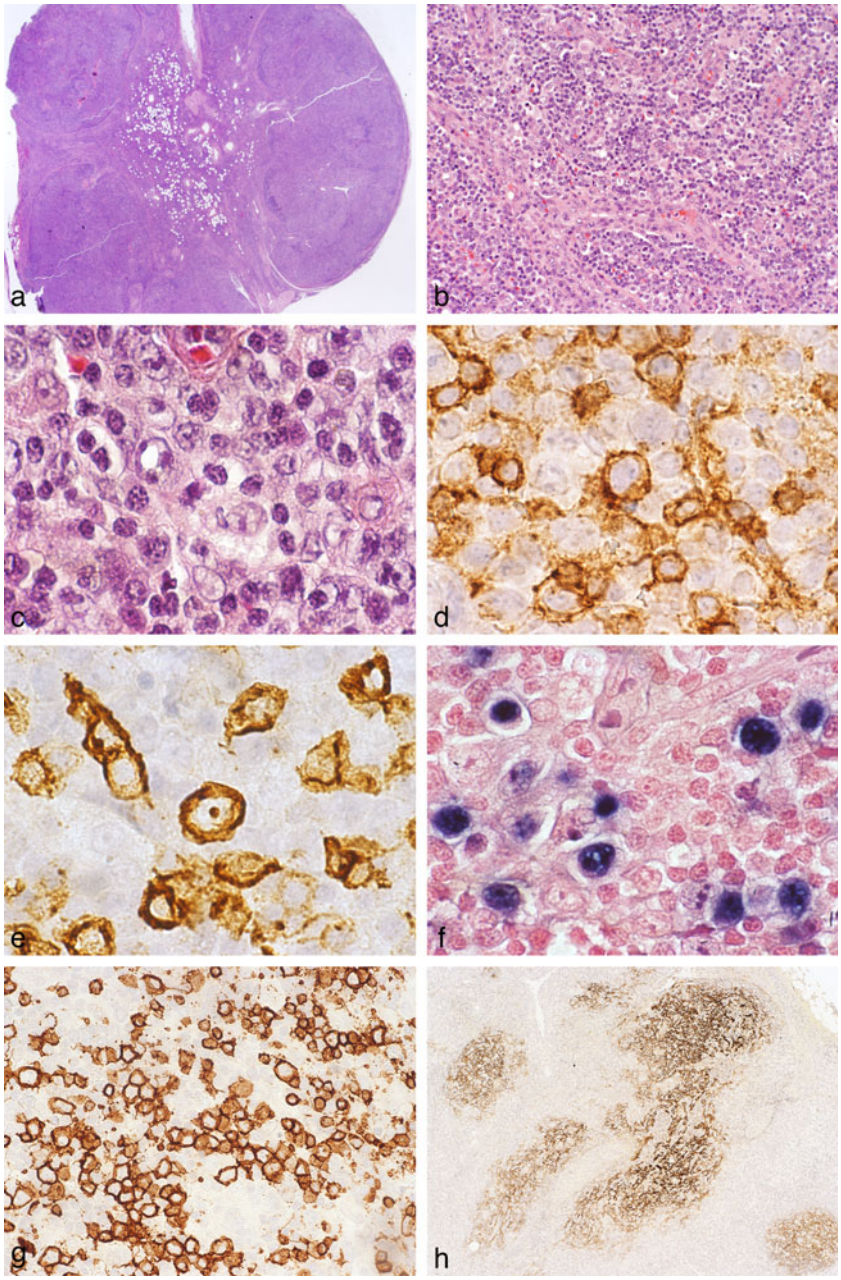

Fig. 4 Case 2: inguinal lymph node with a vaguely nodular atypical proliferation, H&E stain, magnification ×10 (**a**). Higher power view of inguinal lymph node showing vascular proliferation and polymorphous infiltrate, H&E stain, magnification ×200 (**b**). Rare atypical lymphoid cells, some with clear cytoplasm, H&E stain, magnification ×1,000 (**c**). Atypical lymphoid cells positive for CD4, magnification ×1,000 (**d**). Atypical lymphoid cells positive for PD-1/CD279, magnification ×1,000 (**e**). Lymphoid cells positive for EBER, magnification ×1,000 (**f**). Immunoblasts positive for CD20, magnification ×400 (**g**). Marked expansion of follicular dendritic cells positive for CD21, magnification ×40 (**h**)

established that markers of follicular helper T-cells, PD-1/CD279, and CXCL13, are helpful in the diagnosis of AITL [9, 22, 23]. The morphologic findings in case 2 were intermediate between pattern I (hyperplastic follicles) and pattern II (involuted follicles).

The molecular studies were contributory in both cases and revealed clonal TCR gene rearrangements and positivity for EBER in lymph node specimens from both cases. Of interest, while initial bone marrow in case 2 was very abnormal with marked plasmacytosis and similar to that reported in some bone marrows in patients with AITL [24], no involvement by lymphoma was found by flow cytometry or molecular studies at that time. This suggests that plasmacytosis is a secondary and systemic change rather than a local response to AITL.

The above cases highlight the importance of a high degree of suspicion for underlying AITL in lymph nodes with interfollicular or diffuse polyclonal plasma cell and/or immunoblastic proliferations, especially when a clonal T cell population is detected. Since neoplastic cells may be scattered and in extremely small numbers, when the suspicion is high, subtle abnormalities on the flow cytometry should be thoroughly investigated. Immunoperoxidase stains for CD10 and follicular T cell markers such as PD-1/CD279 and CXCL13 can be helpful, but may not be always conclusive as in the above cases.

Sometimes, a pathologist will be faced with peripheral blood or bone marrow specimens from patients with AITL before evaluating lymph nodes diagnostic for AITL. The extent of secondary plasmacytosis in those specimens can be very striking and potentially misleading as previously documented [24]. One should consider AITL in the long list of differential diagnosis of polyclonal plasmacytosis. Among other conditions, systemic polyclonal plasmacytosis can be seen in infections, drug reactions, hyperimmunization, toxins, serum sickness, Hodgkin lymphoma, autoimmune diseases, idiopathic conditions, and the previously mentioned SPBIP [25–36]. However, SPBIP is a diagnosis of exclusion and one needs to investigate alternative causes for polyclonal plasmacytosis or B immunoblastic proliferation before making a diagnosis of SPBIP.

In summary, ALTL should be considered a type of IL-6 syndrome as it has many clinical and pathologic features shared with other conditions associated with increased secretion of IL-6 [37].

Conflict of interest The authors declare that they have no conflict of interest.

Abstract Epithelial marker and adhesion molecule expression has been reported in Ewing's sarcoma family of tumors (ESFTs), although the prognostic significance has not been assessed systematically. We performed immunohistochemical analysis of epithelial cell adhesion molecule and epithelial mesenchymal transition markers on 415 genetically confirmed ESFTs. Survival analyses were performed in 217 patients. The atypical histological subtype expressed a high proportion of the epithelial markers compared with conventional and PNET variants. We observed that expression of desmoplakin ($p<0.001$) and PI3K ($p=0.003$) was higher in disseminated than in localized disease. Multivariate analysis showed that desmoplakin and pGSK3β constitute independent good prognostic factors for progression free survival (PFS), while ZO-1 and Snail represent independent good prognostic factors for overall survival (OS). In contrast, CK8/18 represents an independent poor prognostic factor for OS and the radiotherapy treatment group demonstrated an independent poor prognostic factor for PFS and OS. Although the expression of pan-cytokeratin has been previously highlighted in a significant proportion of ESFT, its expression did not reveal prognostic significance in the present series. Considering the results of prognostic analysis herein reported, we strongly recommend a prospective validation of at least the immunomarkers with prognostic significance (desmoplakin, ZO-1, CK8/18, pGSK3β, and Snail) in prospective series that include localized and disseminated tumors.

Introduction

Epithelial marker and adhesion molecule expression has been reported in Ewing's sarcoma family of tumors (ESFTs) [1–6], although the prognostic significance has not been assessed systematically in a large series of genetically confirmed tumors. The aim of the present study is to determine if epithelial cell adhesion molecules and epithelial mesenchymal transition (EMT) expression offer any prognostic significance in a large series of ESFT.

Table 1 Immunohistochemical study: antibodies, source, and dilution

Antibodies	Source	Dilution
CK (AE1/AE3)	Dako	1/50

Material and methods

In the present study, we performed immunohistochemical (IHC) analysis of epithelial cell adhesion molecule and EMT markers (Table 1) on 415 genetically confirmed ESFT retrieved from the prognostic and therapeutic targets in the Ewing's family of tumors (PROTHETS) and EuroBoNet European projects. The immunostaining score was classified as non-informative, negative (mild in <5 %), or positive: 1+ (mild in 5–10 %), 2+ (moderate in 10–50 %), and 3+ (intense in >50 %); mainly cytoplasmic, paranuclear, or membranous staining. All sections were independently evaluated by three pathologists (IM, SN, and ALLB). Any differences were resolved by agreement.

Survival analyses were performed in 217 patients with localized disease and available follow-up using Kaplan–Meier method with log-rank tests and Cox proportional hazards models [7]. Detailed clinical and follow-up data

Table 2 Immunoexpression of epithelial cell adhesion molecules and EMT markers n=415

Immunohistochemical markers	Negative (%)	Positive (%)
Claudin	91 (24)	285 (76)

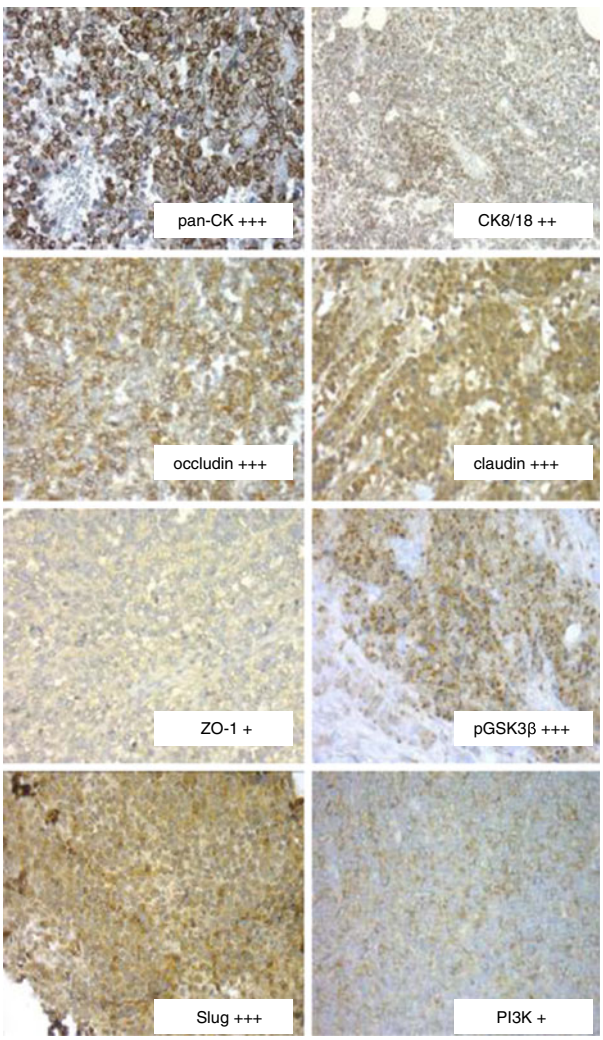
PI3K	192 (52.5)	174 (47.5)



are described in studies by López-Guerrero et al. [7] and Llombart-Bosch et al. [8].

Results

IHC expression results are summarized in Table 2. Although the statistical analysis did not reveal significant results, the atypical histological subtype expressed a high proportion of the epithelial markers compared with conventional and PNET variants. We observed that expression of desmoplakin ($p<0.001$) and PI3K ($p=0.003$) was higher in disseminated (disseminated primary tumors, recurrences, and metastasis) than in localized disease. However, in the univariate analysis, the association of the expression of epithelial and adhesion molecules with progression free survival (PFS) and overall survival (OS) in localized tumors revealed that desmoplakin represents an independent good prognostic factor for both PFS and OS (Fig. 1). Multivariate analysis (Table 3) showed that desmoplakin and pGSK3β constitute independent good prognostic factors for PFS, while ZO-1 and Snail represent independent good prognostic factors for OS. CK8/18 represents an independent poor prognostic factor for OS and the radiotherapy treatment group demonstrated an independent poor prognostic factor for PFS and OS.

Discussion

Comparative expression of epithelial markers and adhesion molecules with other ESFT series has been previously described, indicating heterogenous expression of epithelial markers across the diverse series [1–6]. In particular, Srivastava et al. [5] described follow-up information in 12 well-documented ESFT that stained strongly for pan-keratin with ultrastructural confirmation. This study showed that keratin-positive ESFT may represent a more aggressive subset of the ESFT group of tumors [5]. However, in additional series, Kavalar et al. [9] demonstrated that pan-CK immunoexpression ($p=0.934$) had no statistically significant impact on survival [9]. In fact, although pan-cytokeratin expression has been highlighted in a significant proportion of ESFT in several studies [1–6], in the present series, similar to Kavalar et al. [9], its expression did not reveal prognostic significance. Nevertheless, CK8/18 immunoexpression represents, at least in the present series, an independent poor prognostic factor for OS in localized ESFT, similar to that described by Makino T et al. [10] in squamous cell carcinoma of the esophagus, where CK8/18 immunoexpression represents a poor prognostic factor for OS [10]. As far as we know, prognostic significance of low molecular weight CK (CK8/18) in other series of sarcomas or mesenchymal tumors has not been described.

Although Schuetz et al. [4] described a very detailed study of adhesion molecules (desmoplakin, claudin, occludin, ZO-1, E-cadherin, and desmoglein) in ESFT, to our knowledge, this is the first study to report the prognostic involvement of these markers as well as EMT markers in ESFT. In the present series, desmoplakin and ZO-1 immunoexpression represent an independent good prognostic factor in localized ESFT. Our data are analogous with previous studies in other human tumors suggesting that reduced desmoplakin immunoreactivity is associated with an unfavorable prognosis as reported by Papagerakis et al. [11] proposing that downregulation of desmoplakin expression may represent a useful marker for evaluating the risk of metastasis in human carcinomas. Indeed, additional studies in sarcomas need to be performed in order to confirm the prognostic significance of this marker as well as other adhesion molecules (ZO-1) in mesenchymal neoplasms.

EMT markers have been implicated in sarcomagenesis, and particularly, the Snail family of transcription factors has been implicated in neural crest development, apoptosis, and neoplastic EMT [12]. Snail is a marker of malignancy in epithelial tumors and a prognostic study in gastric cancer demonstrated that overall survival rate of gastric cancer patients with high Snail expression was significantly lower than those patients with low Snail expression [13]. However, in sarcomas, this protein expression has been not systematically studied. Sharili et al. [14] have suggested a link between Snail2 expression and metastasis in osteosarcomas—this being the first study where Snail2 has been associated with sarcoma progression. This study shows that Snail2 may be a useful prognostic marker for osteosarcoma [14]. In the present series, in contrast with carcinomas [13] and sarcomas series [14], Snail expression represents an independent good prognostic factor for OS. The present study confirms the results of Lopez-Guerrero et al. [7] where radiotherapy groups (with surgery and/or chemotherapy) represent an adverse prognostic factor for OS and PFS, probably due to the presence of inoperable cases with advanced disease.

Considering the results for prognostic analysis herein reported, we strongly recommend a prospective validation of at least the immunomarkers having prognostic significance (desmoplakin, ZO-1, CK8/18, pGSK3β, and Snail) in independent series including localized and disseminated tumors of ESFT and other sarcoma series.

Acknowledgments This study was supported by prognostic and therapeutic targets in the Ewing's family of tumors, contract 503036, and EuroBoNet, European network to promote research into uncommon cancers in adults and children, contract 018814.

Conflict of interest None.

CASE REPORT

Clear cell sarcoma expressing a novel chimerical transcript *EWSR1 exon 7/ATF1 exon 6*

Abstract Clear cell sarcoma harbours recurrent translocation, resulting in *EWSR1*/*ATF1* or less commonly *EWSR1*/*CREB1* fusion. To date, six types of *EWSR1*/*ATF1* fusion have been reported, of which three are in-frame and encode functional proteins. We present a reverse transcription - polymerase chain reaction analysis of a tumour near the hallux of the right foot. The sequencing of obtained fragments revealed the presence of a novel chimerical transcript—the in-frame fusion between *EWSR1* exon 7 and *ATF1* exon 6 that represents the fourth in-frame type of *EWSR1*/*ATF1* fusion identified in clear cell sarcomas.

Keywords Clear cell sarcoma · Chimerical transcript · *EWSR1*/*ATF1* · qPCR

Introduction

Clear cell sarcoma (CCS), first described in 1965 [1], is perhaps the rarest clinicopathologic entity among mesenchymal tumours. Clear cell sarcoma mainly affects adolescents and young adults with female sex predominance. The most common locations of CCS are the foot and ankle. Other sites of involvement include the knee, thigh, hand, neck, trunk and, rarely, retroperitoneum and bone. So-called clear cell sarcoma of the kidney is a different entity [2] and should not be confused with CCS.

CCS displays morphologic or immunohistochemical features very similar to malignant melanoma, which is the most important differential diagnostic consideration. These two malignancies have overlapping immunohistochemical characteristics: expression of S-100 protein and melanocytic markers as HMB-45, Melan A and microphthalmia transcription factor. The tumour usually does not express cytokeratin, epithelial membrane antigen, desmin or smooth muscle actin [3]. However, CCS has been shown to be characterised by two recurrent chromosomal translocations *t* (*12*;*22*) (*q13*;*q12*) and *t* (*2*;*22*) (*q34*;*q12*), which do not occur in melanoma [4]. The most common chromosomal translocation *t* (*12*;*22*) (*q13*;*q12*) results in fusion of the *EWSR1* gene on 22q12 and the *ATF1* gene on 12q13. Less frequently, a chromosomal translocation *t* (*2*;*22*) (*q34*;*q12*) has been found which results in the *EWSR1*/*CREB1* fusion gene. These characteristic cytogenetic changes are considered to play a pivotal role in the development of CCS.

To date, six types of *EWSR1*/*ATF1* fusion and a single type of *EWSR1*/*CREB1* fusion have been described [4, 5]. Type 1 (*EWSR1 exon 8*/*ATF1 exon 4*; GenBank/EMBL/DDBJ accession no. JF290487), type 2 (*EWSR1 exon7*/*ATF1 exon 5*; GenBank/EMBL/DDBJ accession no. JF290488) and type 3 (*EWSR1 exon10*/*ATF1 exon 5*) are in-frame fusions and encode functional proteins. The other types of *EWSR1*/*ATF1* fusion—type 4 (*EWSR1 exon 7*/

ATF1 exon 7), type 5 (*EWSR1 exon 7*/*ATF1 exon 4*; GenBank/EMBL/DDBJ accession no. JN202448) and type 6 (*EWSR1 exon 9*/*ATF1 exon 4*; GenBank/EMBL/DDBJ accession no. JN202449)—are out-of-frame fusions and were identified only once, together with type 1 and type 2 transcripts (Fig. 1) [5, 6].

Clinical history

A 42-year-old male patient with no familial history of cancer presented with a 1-year history of painful lump near the hallux of the right foot. The lump was resected, and the patient was referred to our hospital for detailed examination and further treatment. The diagnosis of CCS was confirmed by biopsy, using the criteria from the WHO classification of tumours of soft tissues and bone [7]. Nuclear magnetic resonance imaging revealed a subcutaneous tumour mass 13×11 mm in size, accumulating contrast, near the first interphalangeal joint and flexor hallucis brevis muscle (Fig. 2a). Bone destruction was not observed. Computed tomography (CT) indicated mediastinal lymphadenophathy and metastases to the lungs (Fig. 2b) and omentum. The patient received three cycles of doxorubicin-based chemotherapy. Six months later, CT showed new metastases in inguinal lymph nodes and bones. High-dose ifosfamide monotherapy was started with palliative intent. The patient died 2 months later.

Materials and methods

Tumour samples and immunohistochemistry

Formalin-fixed and paraffin-embedded (FFPE) samples of tumour were presented for morphological and immunohistochemical analysis. FFPE sections were stained with haematoxylin and eosin and antibodies to S-100, HMB-45, Melan A, smooth muscle cell actin (SMA), CD34 and Pancytokeratin (Clones AE1/AE3) (Dako, Glostrup, Denmark).

RT-PCR analysis and sequencing

Total RNA was extracted from FFPE sections containing 90 % tumour cells. The extraction was performed using PureLink FFPE Total RNA Isolation Kit as described (Invitrogen, Carlsbad, CA, USA). RNA (1 μg) was reverse-transcribed in a 20-μl reaction volume using random hexamers and First Strand cDNA Synthesis Kit (Fermentas, Vilnius, Lithuania) according

the vendor's recommendations, and after reaction, it was diluted up to 100 μl with deionised water.

The integrity of extracted mRNA was evaluated by running a polymerase chain reaction (PCR) for a 150-bp fragment of the ubiquitously expressed ubiquitin C gene with primers UBC-F and UBC-R [5]. Five different specific PCRs (four reactions for each type of *EWSR1*/*ATF1* chimerical transcript and one reaction for *EWSR1*/*CREB1* [4]) were performed using the earlier reported forward and reverse primers and reaction conditions [5]. RT-PCR products were visualised on a 2 % agarose gel electrophoresis using SYBR Green I (Fig. 3a).

The resultant RT-PCR fragment was purified by incubation with Exonuclease I and FastAP™ Thermosensitive Alkaline Phosphatase (Fermentas) as recommended by the vendor. Nucleotide sequences were generated using BigDye Terminator v1.1 Chemistry (Applied Biosystems, Foster City, CA, USA), and data were collected on Genetic Analyzer 3500(Applied Biosystems). The public interface of BLAST software at the National Center for Biotechnology Information (Bethesda, MD, USA) was used for analysis of sequence data [8].

Results

Histologically, the tumour was composed of nests of spindle-shaped and polygonal neoplastic cells with eosinophilic or clear cytoplasm. Nests of tumour cells were surrounded by fibrous septa. The neoplastic cell nuclei were vesicular with prominent nucleoli (Fig. 2c). The degree of nuclear polymorphism was low. The mitotic rate was three to

The reference bands (indicated by *asterisk*) represent 1,000 bp (*top*), 500 bp (*middle*) and 200 bp (*bottom*) mass standards. **b** Partial sequencing chromatogram of chimerical transcript. Junction point of *EWSR1* and *ATF1* coding sequences indicated by *arrow*

five mitoses/ten high-power fields. The immunohistochemical examination showed tumour cells expressing protein S-100 (90 % of tumour cells) (Fig. 2d) and antigens associated with melanin synthesis: cytoplasmic immunoreactivity for HMB-45 (100 % of tumour cells) (Fig. 2e) and Melan A (100 % of tumour cells) (Fig. 2f). Tumour cells were negative for SMA, CD34 and Pancytokeratin (data not shown).

To determine the presence of either *EWSR1*/*ATF1* or *EWSR1*/*CREB1* fusion transcripts, RT-PCR analysis of total RNA isolated from tumour sample was performed. Agarose gel electrophoresis indicated that primers EWS-7F and ATF-7R amplified ≥300-bp-long fragment (Fig. 3a). Other primer combinations were negative. The calculated size of expected amplicon of out-of-frame fusion *EWSR1 exon 7*/*ATF1 exon 7* was 122 bp. Therefore, we considered alternative exon junctions: in the case of *EWSR1 exon 7*/*ATF1 exon 6* fusion, the resultant PCR fragment would have been 282-bp long and, in the case of *EWSR1 exon 8*/*ATF1 exon 7* fusion, the resultant PCR fragment would have been 303-bp long. To clarify this position, we purified and sequenced the resultant PCR fragment using the same primers, which showed the presence of a chimerical transcript of an in-frame fusion *EWSR1 exon 7*/*ATF1 exon 6* (Fig. 3b). The fusion sequence was deposited in the GenBank/EMBL/DDJB databases under accession no. JN624779.

Discussion

Approximately 15–20 % of sarcomas carry chromosomal translocations resulting in fusion genes. The fusion proteins frequently act as transcription factors, upregulating the expression of genes responsible for tumour growth [9]. Sarcomas with fusion genes have been classified in different ways, e.g. according to the genes participating in chromosomal translocation, the structural and functional features of each fusion gene or the variability of chimerical transcripts produced by the same fusion partners. Sarcomas with fusion genes usually harbour a single chimerical transcript, with the exception of synovial sarcoma and CCS. One report described the presence of two variant fusion genes, *SS18*/*SSX1* and *SS18*/*SSX2*, in tumour samples of 10 % of synovial sarcomas [10]. The translocation *t* (*X*;*18*) (*p11*;*q11*) resulted in the fusion of the *SS18* gene on chromosome 18 with either the *SSX1* or *SSX2* gene on the same chromosome X but with different breakpoint localizations. Each translocation resulted in a single chimerical transcript but in separate cell subpopulations of the tumour. This finding indicates that genetically variant subclones exist in synovial sarcoma.

The chromosomal translocation *t* (*12*;*22*) (*q13*;*q12*) resulting in a fusion of the *EWSR1* gene on chromosome 22q12 and the *ATF1* gene on chromosome 12q13, differentiates CCS from malignant melanoma or other tumours of a neuroectodermal or mesenchymal origin. CCS has been reported to harbour multiple types of the *EWSR1*/*ATF1* chimerical transcripts resulting from a single chromosomal rearrangement in one tumour [6]. Two different chimerical transcripts resulting from the same *EWSR1*/*ATF1* fusion are frequently observed in CCS. To date, two chimerical types have been found in more than one third of CCS [4], and two reports described the presence of three [6] and even four chimerical types [5]. This phenomenon suggests that post-transcriptional alternative splicing is taking place [4–6]. We have reported unequal quantitative distribution of different chimerical transcripts in a tumour [5]. Apparently, the *EWSR1* gene is very adaptable regarding the final structure of chimerical transcripts. Exons 7, 8, 9, 10 and 12 may serve as the fusion sites for tumours with different frequencies in different sarcomas. In the case of CCS, the exon 8 followed by the exon 7 have been identified as the most frequent fusion sites [6].

RT-PCR analysis of the present case of CCS revealed the presence of a novel *EWSR1 exon 7*/*ATF1 exon 6* fusion, which we propose to be designated as type 7. This concerns an in-frame fusion which most likely encodes a functional chimerical transcription factor since the conserved bZIP transcription factor domain [11] of cyclic AMP-dependent transcription factor ATF1 is encoded by exon 6 and exon 7 of the *ATF1* gene. This case expands the variability of the *EWSR1*/*ATF1* chimerical transcripts that result from chromosomal translocation *t* (*12*;*22*) (*q13*;*q12*) in CCS.

Conflict of interest We declare that we do not have conflict of interest.

CASE REPORT

Thyroid-like follicular carcinoma of the kidney: report of two cases with detailed immunohistochemical profile and literature review

Abstract Thyroid-like follicular carcinoma of the kidney (TLFC) is an unusual histological variant of renal cell carcinoma not included in the current WHO classification of renal tumors. Its morphological features resemble a large spectrum of benign and malignant renal and extra-renal conditions which should be ruled out in the diagnostic process. Because TLFC outcome is different from the other variants of renal cell carcinoma, the exploration for disease-specific markers is mandatory. The aim of the present paper is to illustrate the histological characteristics and immunohistochemical profile of two new cases along with a brief review of the literature.

Keywords Renal cell carcinoma · Oncology · Thyroid-like follicular carcinoma · Immunohistochemistry

Introduction

Thyroid-like follicular carcinoma of the kidney (TLFC) is an unusual histologic type of renal cell carcinoma, which morphologically closely mimics follicular carcinoma of the thyroid. First described in 1996 [1], only further 10 cases have been described so far [2–6]. The relevance of this peculiar histologic variant relies on its morphological resemblance to a large spectrum of benign and malignant renal and extra-renal conditions. As a consequence, an erroneous diagnosis could result in inadequate therapeutic solutions.

Given the relevance for the introduction of disease-specific markers, we report two cases of TLFC focusing on their immunohistochemical profile. A brief review of the previous published cases is also discussed.

Clinical history

Case 1

A 76-year-old white man with a past medical history significant for hypertension, atrial fibrillation, and prostate cancer underwent radical prostatectomy and adjuvant radiotherapy in 2007. The patient was admitted at the Urology Department of Padua University Hospital for hematuria in May 2011. An abdominal ultrasound showed the presence of a left kidney mass. The CT scan revealed a round moderately hyperdense and well-vascularized solid mass of about 5 cm with a necrotic central area at the upper pole of the left kidney and the presence of some enlarged lymph nodes (the largest of 17 mm) below the diaphragm pillars and in the para-aortic and interaortocaval area. The patient was submitted to an open radical left nephrectomy and he was discharged after 7 days. The gross specimen (measures of the kidney: 10×5.5×5 cm) showed a well-circumscribed round mass measuring 4.5 cm in its largest diameter. On cut surface, the lesion was pale yellow to whitish, with focal hemorrhagic zones. Focal extension into perinephric adipose tissue was grossly evident and subsequently confirmed

by microscopic examination. Neither invasion of renal pelvis nor macroscopic invasion of the renal vein was found. A single (non-metastatic) para-aortic lymph node was histologically confirmed. The patient is alive without signs of tumor relapse at an 11-month follow-up.

Case 2

A renal mass was incidentally discovered during an ultrasound exam (that showed normal internal genitalia) in a 41-year-old white woman with a past medical history significant of: (a) Hodgkin's lymphoma (treated with splenectomy, chemotherapy, and radiotherapy); (b) right video-assisted laparoscopic ovariectomy (benign serous cyst); (c) post-RT hypothyroidism; and (d) sinus tachycardia (treated with beta blockers). She subsequently performed a CT scan that highlighted the presence at the inferior pole of the right kidney of a 5-cm fluid-filled round mass. The lack of enhancement after contrast and the presence of septa were confident with a final radiological diagnosis of a hemorrhagic cyst or complex cysts. A subsequent MRI confirmed the presence of a round right kidney mass of about 5 cm with solid septa. On December 2011, the patient underwent to a robotic-assisted partial nephrectomy. The postoperative course was uneventful and the patient was discharged after 9 days. The gross specimen exhibited a well-circumscribed yellow-tan lesion (4.3 cm in its largest diameter) with cystic–hemorrhagic areas. The patient is alive without signs of tumor relapse at a 4-month follow-up.

Materials and methods

Surgical specimens were sampled according to the current protocols [7]. Formalin-fixed, paraffin-embedded tissue samples were obtained, and 4-μm sections were stained with hematoxylin and eosin.

Immunohistochemical analysis was performed using the Bond ™ Polymer Refine Detection System (Leica Microsystems, Newcastle upon Tyne, UK). A large panel of primary antibodies was used (source and solutions): cytokeratin 7 (Dakocytomation, Glostrup, Denmark; 1:800); cytokeratin 19 (Dakocytomation;1:100); cytokeratin 20 (Dakocytomation; 1:50); 34βE12 (Novocastra labs ltd, Newcastle upon Tyne, UK; 1:100); thyroid transcription factor 1 (TTF-1; Dakocytomation; 1:200); Thyroglobulin (TG; Dakocytomation; 1:50); galectin-3 (Cell Marque Corporation, Rocklin, CA; 1:50); Hector Battifora Mesothelial cell 1 (HBME-1; Cell Marque Corporation; 1:50); epithelial membrane antigen (EMA; Dakocytomation; 1:500); Vimentin (Novocastra labs ltd; 1:200); chromogranin (Dakocytomation; 1:100); synaptophysin (Dakocytomation; 1:400); CD56 (Novocastra labs ltd; 1:100); CD10 (Diagnostic Biosystems, Pleasanton, CA; 1:50); E-cadherin (Dakocytomation;1:200); renal cell carcinoma (RCC; Novocastra labs ltd; 1:100); neuron specific enolase (NSE; Dakocytomation; 1:200); carcino embryonic antigen (CEA; Biogenex, Fremont CA; 1:200); *Ulex europaeus* lectin (Ulex; Vector laboratories, Burlingame, CA; 1:50); and Wilm's tumor 1 (WT-1; Dakocytomation, 1:200).

Sections were lightly counterstained with hematoxylin. Appropriate positive and negative controls were run concurrently for all the applied antisera.

Results

Both tumors were histologically characterized by a striking follicular architecture composed of macro- and microfollicles filled with eosinophilic amorphous colloid-like material that mirrored follicular carcinoma of the thyroid (Fig. 1a, b, c). Follicles were lined by cuboidal cells with scant eosinophilic cytoplasm and round to oval nuclei with evenly distributed chromatin (Fig. 1d). Occasional nucleoli were also detected at high magnification. Mitotic activity was absent. Patchy lymphoid aggregates, focal areas of papillary differentiation (Fig. 1a), hemorrhagic zones, and cholesterol crystals were present. In case 1, the predominant follicular pattern was focally interrupted by solid areas of pseudosarcomatoid appearance, without well-formed follicles. The cells showed elongated cytoplasm with round–oval nuclei and mild atypia (Fig. 1d). Histologic examination of the single para-aortic lymph node revealed no metastasis. Surgical excision margins of case 2 were not involved by neoplasia.

In both lesions, immunohistochemical analysis showed identical results (Fig. 2). The tumor exhibited strong and diffuse cytoplasmic/membranous reactivity for cytokeratins (CKs) 7 (Fig. 2d) and 19, vimentin, and EMA (Fig. 2a), whereas CK 20 was not expressed. Focal staining for 34βE12 (Fig. 2b) and E-cadherin was detected. Histogenetic markers for follicular cell origin (TG and TTF-1) and markers usually overexpressed in thyroid malignancies (HBME-1 and galectin-3) were negative, as were markers of neuroendocrine differentiation (CD56, synaptophysin, chromogranin, and NSE). Tumor cells did not show any immunostaining for WT-1, CD10 (Fig. 2c), RCC, CEA, and Ulex.

Clinicopathologic characteristics and immunohistochemical profile of the present cases and the previously reported ones are listed in Table 1.

Discussion

TLFC is an unusual histological variant of renal cell carcinoma not included in the current WHO classification of renal

tumors and is a matter of debate within the pathologists' community [8, 9]. Its morphological features resemble a large spectrum of benign and malignant renal and extra-renal conditions which should be ruled out in the diagnostic process.

The striking follicular architecture featured by the presented cases and by those previously reported prompts differential diagnosis with a metastasis from a well-differentiated primary tumor of the thyroid. Renal metastasis of thyroid follicular carcinoma is a rare event, with only few cases described (usually associated to widespread neoplastic diffusion) [10–16]. Moreover, metastatic thyroid tumors usually preserve a thyroid-specific immunoprofile [17]. A

	41/F	Incidental	4.3	Right kidney/ inferior pole	pT1bNX	4		

thorough clinical and histopathological workup is therefore mandatory to definitely exclude a thyroid metastasis, especially in cases with clinical and/or immunophenotypic unexpected findings [4, 8, 9].

In patient #1, an endocrinological screening was performed after the pathological report, and any thyroid disease was excluded. Patient #2 was clinically followed for hypothyroidism, and all her subsequent diagnostic workup was negative for a primitive thyroid neoplasm.

In both cases, the negative immunostaining for thyroglobulin, TTF-1, HBME-1, and galectin-3 helped exclude a thyroid primary neoplasm.

In fact, nuclear reactivity for TTF-1 is constantly present in follicular cell-derived benign and malignant thyroid lesions. When used in combination with TG, TTF-1 is an effective marker for thyroid origin [17]. Overall in the thyroid, HBME-1 stains mostly follicular-derived malignant tumors, including well-differentiated and poorly differentiated carcinomas, with a variable sensitivity and specificity in different series [17]. Galectin-3 is one of the members of a family of non-integrin galactoside-binding lectins that may be a helpful tool to distinguish preoperatively benign from malignant follicular thyroid nodules [18].

Thyroidization of the kidney should also be considered in the differential diagnosis: this is a benign process that extensively involves the kidney, most frequently as a consequence of end-stage renal diseases or pyelonephritis. It is characterized by atrophic distal tubules and collecting ducts with colloid-like material in the lumen. Thyroidization can be easily distinguished from TLFC since the former is diffuse and bilateral, with clinical evidence of an underlying end-stage disease, whereas the latter is a well-circumscribed, unilateral, incidentally discovered mass [19].

In our female patient, a hypothetical metastasis from a malignant ovarian lesion has been ruled out. The gynecological evaluation she had before the operation was negative for ovarian masses. Struma ovarii is a germ cell tumor of the ovary mainly composed of thyroid tissue: malignant transformation is rare and localized to the liver, peritoneum, and omentum [20]. Commonly mentioned diagnostic features (optical clearing, grooves, pseudoinclusions, and mitoses) were absent in our lesion, along with TTF-1 staining, which is always present in metastatic struma [20]. WT-1 negative immunostaining was helpful to exclude serous and small cell carcinoma of the ovary [21, 22]: areas with papillary structures detected in our case could remind of papillary serous carcinoma, whereas small cell carcinoma form follicle-like spaces that almost always contain eosinophilic fluid.

Among the others, unusual renal tumors and also carcinoid tumors of the kidney should be excluded. These tumors are also very infrequent and are histologically similar to their counterparts in other organ sites. The tumor cells have abundant amphophilic cytoplasm, salt and pepper chromatin, and are arranged in an insular, nested, acinar, trabecular, or pseudoglandular pattern. Focal areas of tubular differentiation with dense eosinophilic secretions, similar to follicular architecture of our cases, could be found, but complete negative staining for neuroendocrine markers (CD56, NSE, chromogranin, and synaptophysin) allowed us to exclude this diagnostic hypothesis.

Primary epithelial tumors of the kidney could have focal zones of tubular architecture and/or contain dense eosinophilic material, but it is usually a limited finding in clear cell or papillary carcinoma [23, 24], oncocytoma, and metanephric adenoma. In TLFC, the neoplasia is entirely composed of variably sized tubules, many of which are filled with colloid-like material.

In cases when the differential diagnosis is not straightforward, an appropriate panel of immunohistochemical markers is available, including CD10, vimentin, high molecular weight keratins, CKs 7, 19, and 20, E-cadherin, and *U. europaeus* lectin [25]. The presented immunophenotypic profile is similar to the other cases reported in literature (Table 1; CK7+, CK 19+, CK20−, 34BE12+, E-cadherin+, vimentin+, CD10 −), except for the case by Jung et al. which showed positivity for CD10 [3] and the first case reported which was unexpectedly TG-positive despite the negative clinical and serum tests [1]. The distribution pattern of the above-mentioned markers, together with *U. europaeus* lectin, was investigated by Kim and colleagues to prove its usefulness in the discrimination among common epithelial kidney tumors [25]. The immunohistochemical profile characteristic of each histologic variant of renal cell neoplasm was different from the one of TLFC [25].

Of interest, also in an intrahepatic cholangiocarcinoma [26] and in five breast tumors [27], a remarkable follicular architecture resembling thyroid neoplasms has been reported. In all these cases, there was no clinical evidence of a previous and/or concomitant thyroid disease, and immunohistochemical markers for follicular cell origin (TG and TTF-1) were negative [26, 27].

In conclusion, the peculiar immunophenotype of this newly defined entity, along with the absence of a specific genetic alteration [2–4], underlines the importance of a wide-spectrum panel of markers to discriminate from metastases from thyroid or ovary tumors and to differentiate these neoplasms from other primary kidney tumors. A correct histolopathologic definition of these tumors may avoid unnecessary ancillary treatments and has important prognostic and clinical implications [28, 29].

DOI 10.1007/s00428-012-1250-y

There was an error in the original version of Fig. 7 representing the DNA imbalances of the 4 lung cancer subtypes as detected by conventional CGH. For large cell lung cancer (LCLC), the ideogram of chromosome 9 together with the histograms of DNA gains and losses was shown and not chromosome 8 harbouring the FGFR1 locus.

The corrected version with the chromosome 8 histogram (see new figure), however, indicates an identical finding, i.e. that chromosome 8p is more often affected by deletions than DNA gains.

The online version of the original article can be found at http://dx.doi.org/10.1007/s00428-012-1250-y.

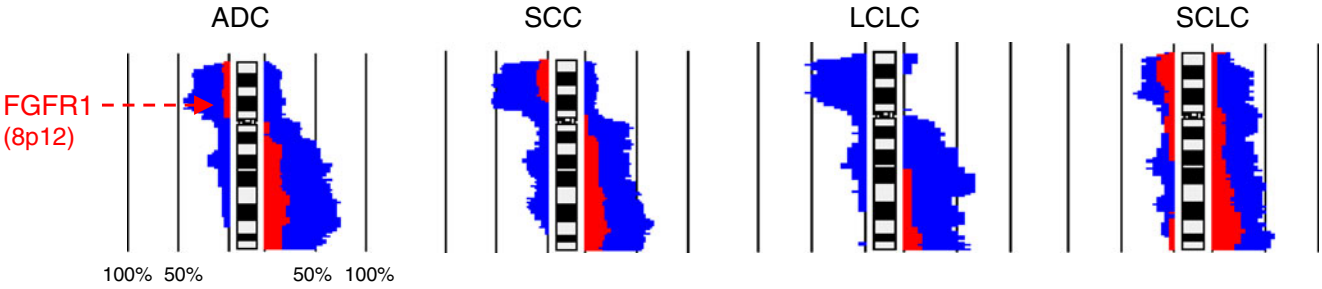

Fig. 7 DNA imbalances of lung cancer subtypes according to conventional comparative genomic hybridization/CGH (compiled from data of Petersen I in Travis et al. 2004, [30]). Cases with DNA gains were represented by the histogram on the *right side* of the chromosome ideogram, cases with DNA loss on the *left side*. The data indicated that 8p deletions are at least as frequent as DNA gains with pronounced gains (indicated by the *red colour*) as putative correlates of an amplification being undetectable in the NSCLC subtypes

Abstract Gastric cancer (GC) is one of the most common causes of cancer-related deaths worldwide. We investigated the differential expression and putative tumor biological significance of five G-protein-coupled receptors (GPCRs) in GC, i.e., LGR4, LGR6, GPR34, GPR160, and GPR171. Based on our previous microarray analyses, we identified five candidate genes in human GC samples. Real-time RT-PCR was carried out to validate their expression in malignant and non-malignant tissues on an independent collective comprising 32 GC patients with and without lymph node metastases. Selected protein targets LGR4 and LGR6 were further validated on paraffin-embedded sections of ten intestinal and ten poorly cohesive (diffuse)-type GCs and their corresponding non-malignant tissue using immunohistochemistry. Additionally, the putative tumor biological significance of LGR4 and LGR6 was studied using tissue microarrays obtained from a cohort of 481 GC patients. On transcriptional level, GPR34, GPR160, and GPR171 were not differentially expressed in GC compared with non-neoplastic mucosa. LGR4 and LGR6 were up-regulated on transcriptional (real-time RT-PCR) and translational (immunohistochemistry) levels in GC. Furthermore, in tissue microarray analysis, LGR6 expression was significantly associated with local tumor growth (T-category; $p=0.04$) and correlated with patient survival. LGR4 expression was significantly correlated with nodal spread (N-category; $p=0.025$). Our systematic analysis indicates that LGR4 and LGR6 may play a role in GC biology. Future studies will have to demonstrate whether these are also putative diagnostic, prognostic, and/or therapeutic targets for GC.

Keywords LGR4 · LGR6 · GPCR · Gastric cancer

Introduction

Despite a declining incidence in many Western countries, gastric cancer (GC) remains the fourth most common cancer worldwide with about one million new cases per year. It is also one of the most common causes for cancer-related deaths, ranking second behind lung cancer [1, 2]. The prognosis of GC is determined by the tumor stage at the time of the diagnosis [3]. As long as the tumor is restricted to the mucosa, surgery promises excellent outcome. However, in many Western countries, the majority of GCs are diagnosed at an advanced stage, when tumor cells have already reached the muscularis propria, limiting treatment options [4]. Following diagnosis, perioperative chemotherapy has become standard of care in Germany [5]. In the palliative setting, trastuzumab can be applied in GC overexpressing Her2/neu [6]. Despite these advancements, not all patients are eligible for currently available targeted therapies or perioperative chemotherapy, and novel treatment targets and predictive biomarkers are still urgently needed. For this purpose, G-protein-coupled receptors (GPCRs) are promising candidates. They represent the largest group of cell surface

receptors and about 40 % of all drugs currently used in medicine, target GPCRs [7]. GPCRs consist of a single polypeptide chain with seven transmembrane domains [8]. They are involved in a broad range of physiological processes and signal transduction systems, including immune response, hormone and enzyme release, or blood pressure regulation [9]. Furthermore, there is ample evidence now that GPCRs are involved in tumor cell biology and few are even expressed in stem cells [10]: LGR5 was recently identified as a putative cancer stem cell marker of gastric and colon cancer [11, 12].

In previous studies, we systematically searched for GPCRs differentially expressed in GC using gene array technology [9]. Fifty-two GPCRs and GPCR-related genes were up- or down-regulated in node-positive GC, including LGR5, GPR34, GPR160, and GPR171. Follow-up studies demonstrated that the expression of LGR5 in the tumor center and invasion front of GC correlated significantly with the local tumor growth (T-category) and the nodal spread (N-category). Furthermore, patients with $LGR5^{+}$ GCs had a shorter median survival (28.0±8.6 months) than patients with $LGR5^{-}$ GCs (54.5±6.3 months) [13]. LGR5 is a Wnt-signaling molecule and has two homologues, LGR4 and LGR6, which share approximately 50 % sequence homology with LGR5 [14]. LGR4 and LGR5 bind R-spondins and associate with the Frizzled/LrpWnt receptor complex. Conditional deletion of LGR4 and LGR5 in the mouse gut impairs Wnt target gene expression and results in the rapid demise of intestinal crypts, thus phenocopying Wnt pathway inhibition [15]. While the expression pattern of LGR5 in GC was investigated recently, little is known about the differential expression of its two homologues. In this study, we aimed to fill this gap of information by further exploring the putative biological significance of *LGR4*, *LGR6*, *GPR34*, *GPR160*, and *GPR171* in GC.

Material and methods

Subjects

Unfixed, fresh frozen tissue was available from an independent series of 32 intestinal-type GCs and corresponding non-malignant tissue. Patients were selected considering age, gender, tumor type, and nodal status. A total of 16 cases were node-positive (N1), and 16 cases were node-negative (N0). Poorly cohesive (diffuse)-type carcinomas were not included in the validation cohort since our initial gene array analyses were done only on intestinal-type GCs [9].

Formalin-fixed and paraffin-embedded malignant and corresponding non-malignant tissues of 20 GC cases were retrieved from the archives of the Institute of Pathology of the Christian-Albrechts-University Kiel. The cases were selected according to age, gender, and tumor type. All patients were operated at the University Hospital Schleswig-Holstein (1997–2009). The patient characteristics are summarized in Table 1.

For TMA construction, an independent cohort of 481 GC patients was retrieved from the archive of the Institute of Pathology of the Christian-Albrechts-University. These patients had undergone either total or partial gastrectomy for adenocarcinomas of the stomach or esophago-gastric junction. Each resection specimen had undergone histological examination by trained surgical pathologists. The time

of patient death was obtained from the *Epidemiological Cancer Registry* of the state Schleswig-Holstein, Germany. Follow-up data of patients still alive were retrieved from hospital records and by contacting the general practitioners.

Ethics statement

All tissue samples were obtained as part of a diagnostic or therapeutic surgery carried out after the patient gave written informed consent. Patients offering samples for the study were pseudonymized and analyzed anonymously, so no individual-related data are contained in the data base. The study was approved by the local ethics committee of the University Hospital in Kiel, Germany (ref. number D 453/10).

Real-time reverse transcriptase polymerase chain reaction (RT-PCR)

Total RNA was isolated from cryoconserved tissues using Ambion's mirVana miRNA Isolation Kit (Applied Biosystems, Darmstadt, Germany), followed by a DNase treatment with Turbo DNA-free kit (Ambion). cDNA synthesis was performed using the Transcriptor First Strand cDNA Synthesis Kit (Roche Diagnostics GmbH, Mannheim, Germany). Primers were obtained by BioTeZ Berlin-Buch GmbH, Berlin, Germany (LGR6, GPR160, GPR34) and biomers.net, Ulm, Germany (LGR4, GPR171). The following primer sequences were chosen: *LGR4* 5′GGC TGA GTG CTT TGC AGT CT, 5′CCT CCG TCA AGC TGT TGT C; *LGR6* 5′CCA AGG ACA GTT TCC CAA AA, 5′ GAC TCC TCA TCATCA AGG TGA A; *GPR34* 5′CGG TGA AAG GTT GCG ACT AT, 5′GGT TGG TCG CTA TGA TTG GT; *GPR160* 5′CGA CAG CCA TCG ATC CTC, 5′AGC GAG AGC GGT TCC TTC, *GPR171* 5′ATT CCG CTC AAA GGT CAC TG, 5′TCC AGT AAG GCC AGA ATT GG. Real-time RT-PCR was carried out using the Maxima™ SYBR Green qPCR Master Mix (Fermentas GmbH, St. Leon-Rot, Germany) and the LightCycler 480 system by Roche Diagnostics (Mannheim, Germany). Three housekeeping genes were selected as reference genes, which have especially been established for the used GC collective: *Homo sapiens succinate dehydrogenase complex*, *subunit A*, *flavoprotein* (*Fp*) (*SDHA*), *Homo sapiens calpain 2* (*CAPN2*), and *Cyclophilin C* (*CYCC*). The appropriateness of these genes has been proven by geNorm in advance. Each setting included two none template controls (no cDNA in PCR) in order to detect unspecific products or primer dimerization. All experiments were performed in duplicates.

Histology

For histological analyses, tissue samples were fixed in 10 % neutralized formalin and embedded in paraffin. Deparaffinized sections were stained using hematoxylin and eosin (H&E). Gastric carcinoma was classified according to the WHO classification [16]. The pTNM stage was determined according to the seventh edition of the international union against cancer [17].

Tissue microarray construction

Formalin-fixed and paraffin-embedded tissue samples were used to generate tissue microarrays as described previously [9]. Three representative tumor-bearing core cylinders were obtained from each paraffin donor block and transferred into the recipient paraffin block. Successful transfer of tumor tissue was confirmed microscopically using H&E-stained sections. Four-micrometer sections of the resulting tumor tissue microarray block were cut for further analysis.

Immunohistochemistry

For immunohistochemistry, formalin-fixed and paraffin-embedded sections were used. Prior to immunostaining, sections were deparaffinized in xylol for 20 min and rehydrated in a descending alcohol series. Antigen retrieval was carried out with ethylenediaminetetraacetic acid (95 °C) and washed in Tris-buffered saline. Subsequently, slides were incubated with the primary antibody (LGR4: polyclonal rabbit, 1:100, Atlas Antibodies, Stockholm, Sweden; LGR6: polyclonal rabbit, 1:800, antibodies-online GmbH, Aachen, Germany) in a moist chamber at room temperature for 30 min and afterwards at 4 °C overnight. The N-Histofine Simple Stain MAX PO system (Nichirei Biosciences Inc., Tokyo, Japan) served as the secondary antibody and was additionally used as carrier for the polymerase. Staining was carried out by utilizing a diaminobenzidine (DAB) substrate (Vector Laboratories Inc. Burlingame, USA). Counterstaining was performed with hemalaun. Sections were coverslipped with EZ-Mount™ (Thermo Scientific Anatomical Pathology, Runcorn, UK) after counterstaining. Omission of primary antibodies served as a negative control.

Statistical analysis

Statistical analysis was carried out with Microsoft Excel 2010 (Microsoft Deutschland GmbH, Unterschleißheim) and PASW Statistics 18 (IBM Deutschland GmbH, Ehningen). An immunoreactivity scoring system (IRS) consisting of two categories was established for interpretation of immunohistochemical data. Briefly, category A documented the intensity of immunostaining as 0 (no immunostaining), 1 (weak), 2 (moderate), and 3 (strong). Category B documented the percentage of immunoreactive cells as 0 (negative), 1 (scattered positive cells; ≤ 1 %), 2 (2–10 % positive cells), 3 (11–50 %), 4 (51–80 %) and 5 (>80 %). The addition of categories A and B resulted in a score ranging from 0 to 8. Cases with an IRS≥2

were considered as positive, and those with an IRS<2 as negative. Correlation of immunohistochemical staining with patient characteristics was performed with Fisher's exact test. Differences in terms of patient survival were assessed by the log-rank test. Results are presented as Kaplan–Meier curves. Statistical comparison of paired groups (e.g., the IRS of malignant and non-malignant tissues of the same patient) was evaluated with a paired two-sided *t*-test. Independent groups (e.g. node-positive vs. node-negative carcinomas) were analyzed using an unpaired two-sided *t*-test. Real-time RT-PCR data were logarithmized to obtain approximately normally distributed data. *P*-values<0.05 were considered as statistically significant, and *p*-values<0.001 as highly significant.

Results

Differential expression of GPCRs in malignant and non-malignant gastric tissues

In the first experiment, we aimed to validate the differential expression of our six prime candidates (*LGR4*, *LGR6*, *GPR34*, *GPR160*, and *GPR171*) in GC. mRNA was extracted from corresponding unfixed neoplastic and non-neoplastic gastric mucosae of 32 intestinal-type GCs. Real-time RT-PCR demonstrated that *LGR4* mRNA was significantly up-regulated in GC compared with corresponding non-neoplastic mucosa (p=0.0271). Interestingly, *LGR6* mRNA was markedly up-regulated. However, this did not reach statistical significance (p=0.0567). The mRNA expression of *GPR34*, *GPR160*, and *GPR171* showed no difference between GC and corresponding non-neoplastic mucosa of the same patients (Fig. 1).

Differential expression of GPCRs in node-positive and node-negative gastric cancer tissues

Next, we analyzed the mRNA expression in the primary tumor tissue of 16 node-positive and 16 node-negative intestinal-type GCs. None of our five target genes showed significant differences between metastatic and non-metastatic primary tumors (data not shown).

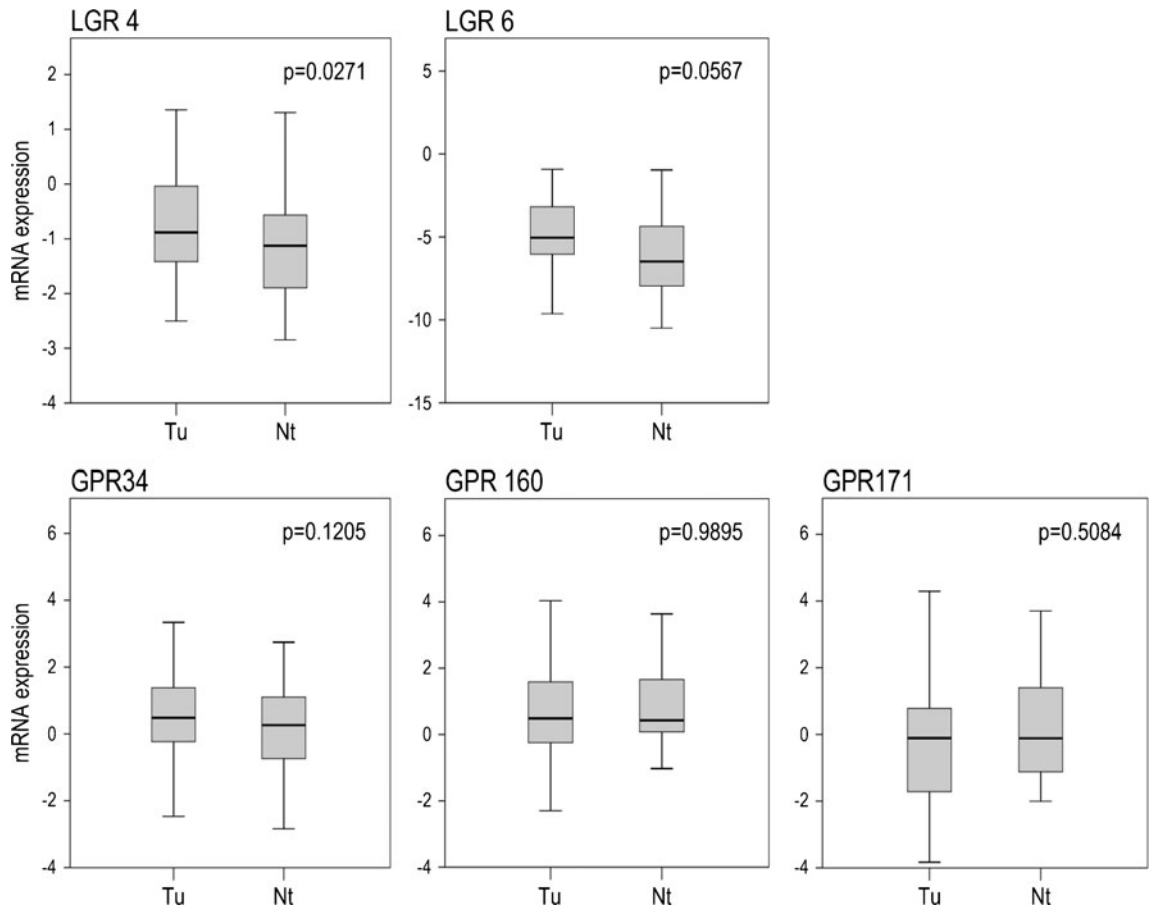

Fig. 1 mRNA expression levels of five target genes in malignant (*Tu*) and non-malignant (*Nt*) tissues. *P*-values were calculated with a paired two-sided *t*-test

Expression pattern of LGR4 and LGR6 in non-neoplastic and neoplastic gastric tissues

The differential expression of LGR4 and LGR6 was then explored on the translational level in GC by immunohistochemistry, now also including poorly cohesive-type GCs. Twenty GCs (ten poorly cohesive and ten intestinal types) were retrieved from the archive and forwarded to immunostaining. Immunostaining was carried out on large tissue sections enclosing neoplastic and non-neoplastic gastric mucosae. Comparing the IRS of neoplastic and non-malignant tissues by applying a paired *t*-test, LGR4 was significantly overexpressed in intestinal-type malignant tissue compared to non-neoplastic foveolar epithelium ($p=0.027$). Thirteen (65 %) cases showed cytoplasmatic immunostaining for LGR4 (Fig. 2a) including eight intestinal- and five poorly cohesive-type carcinomas. Additionally, nuclear positivity was observed in three samples (one intestinal and two diffuse GCs). LGR4 immunoreactive epithelial cells in non-malignant tissue were only found in six cases (30 %). However, positive staining was frequently observed in glandular cells of the non-neoplastic mucosa. Anti-LGR6 staining delivered eight (40 %) positive GCs (Fig. 2d), allocated into six intestinal-type and two poorly cohesive-type GCs. The LGR6 expression (IRS value) in intestinal-type tumor tissue significantly exceeded expression in non-neoplastic foveolar epithelium ($p=0.017$). The non-malignant foveolar epithelium was LGR6-positive in six (30 %) cases. Similar to LGR4, LGR6 was partially expressed by non-neoplastic gastric gland epithelia. In most GCs as well as in all sections of non-neoplastic gastric mucosa, detached LGR4- and LGR6-positive stromal cells were found (Fig. 2b, e). Additionally, in six cases, LGR6-positive vessels were observed in neoplastic as well as in non-neoplastic tissue.

Putative tumor biological significance of LGR4 and LGR6 in gastric cancer

Next, we explored the putative tumor biological significance of LGR4 and LGR6 by immunostaining of tissue microarrays obtained from formalin-fixed and paraffin-embedded tumor samples of 481 GC patients.

$LGR4^+$ tumor cells were found in 206 of 481 (43 %) patients. A strong cytoplasmic immunoreaction was observed in 12 (2.5 %) cases and a weak to moderate staining in 159 (33.1 %) cases. In addition, 17 % of the positive cases exhibited a nuclear immunostaining. Two hundred seventy five tumors (57 %) lacked LGR4 immunoreactivity. Next, we studied the correlation between the expression of LGR4 and various clinico-pathological patient characteristics (Table 2). The expression of LGR4 by tumor cells correlated with nodal spread ($p=0.025$). Subgroup analysis demonstrated this effect being restricted to poorly cohesive-type carcinomas (Table 4).

$LGR6^+$ tumor cells were found in 153 of 481 (32 %) patients. A strong cytoplasmic immunoreaction was observed in 7 (1.5 %) cases and a weak to moderate staining in 146 (30 %) cases. Three hundred twenty eight tumors (68 %) lacked LGR6 immunoreactivity. Next, we studied the correlation between the expression of LGR6 and various clinico-pathological patient characteristics (Table 2). The expression

of LGR6 by tumor cells correlated with local tumor growth (p=0.040) and was more frequently observed in early stage carcinomas (p=0.006). Interestingly, LGR4 and LGR6 were both more commonly expressed by intestinal-type GCs. However, this did not reach statistical significance.

The subgroup analyses (Tables 3 and 4) demonstrated that the expression of LGR4 in poorly cohesive-type GC correlated significantly with the N-category. Among intestinal cases, $LGR6^+$ tumor cells were more prevalent in male patients. However, this difference did not reach statistical significance (p=0.092).

Co-expression of LGR4 and LGR6 was observed in 98 cases allocated to 49 intestinal-type, 37 poorly cohesive-type, and 12 mixed-type carcinomas. Co-expression of LGR4 and LGR6 did not correlate with local tumor growth or nodal spread (Online Resource 1).

Survival analysis

Next, we explored the influence of LGR4 and LGR6 expression on patient survival (Fig. 3). GC patients with LGR6-positive tumors lived longer than patients with

LGR6-negative tumors (mean survival: LGR6-positive 28± 32 months, LGR6-negative 19±23 months; $p=0.052$). The subgroup analyses showed that the difference in patient survival was mainly restricted to poorly cohesive-type GCs (Fig. 3). No difference was found between patients with LGR4-positive and LGR4-negative tumors.

$LGR4^+/LGR6^+$ carcinomas had a better survival rate than $LGR4^-/LGR6^-$ carcinomas (Online Resource 2). However, in log-rank (Mantel–Cox) test, this effect did not reach statistical significance ($p=0.321$).

Finally, patient survival correlated significantly with tumor type ($p=0.007$), T-category ($p<0.001$), the presence of lymph node metastases ($p<0.001$), N-category ($p<0.001$), and tumor grade ($p<0.001$; data not shown). On multivariate analysis, LGR6 was not an independent prognosticator of patient survival.

LGR4, LGR5, and LGR6 expression in non-neoplastic gastric mucosa

Finally, we tested the hypothesis whether LGR4 and LGR6 are expressed in gastric stem cells. Serial sections of non-neoplastic gastric mucosa were stained with antibodies directed against LGR4, LGR5, and LGR6. LGR4 and LGR6 immunostaining was not found in LGR5 immunoreactive cells, and they are thus unlikely to stain gastric stem cells (Fig 4).

Discussion

The poor prognosis of GC is a major issue in gastrointestinal oncology. Most GCs are diagnosed at an advanced stage when local resection is no longer a therapeutic option [2, 18, 19], with nodal spread being the most important prognostic factor [19]. Inevitably, the search for new factors contributing to the pathogenesis of lymph node metastases and the detection of new therapeutic targets is of outstanding importance. GPCRs are prime candidates for novel cancer prevention and treatment strategies since they play an important role in regulating physiological and pathophysiological processes. These receptors form the largest family of human membrane-bound proteins and represent a target for more than 40 % of all drugs used in medicine [7].

In our present study, we explored and aimed to validate the differential expression and putative tumor biological significance of five GPCRs. Four GPCRs, i.e., LGR6, GPR34, GPR160, and GPR171, were depicted from a list of differentially expressed genes detected by gene array analysis of three node-positive vs. three node-negative intestinal-type gastric carcinomas published previously by our group [9]. We added LGR4 to this list, as LGR4 shares homology with LGR5 and LGR6, which both were found by gene array analysis. Interestingly, while we were unable to validate the differential expression of GPR34, GPR160, and GPR171, both LGR4 and LGR6 were found to be up-regulated in GC tissue compared with corresponding non-neoplastic tissue. Furthermore, using immunohistochemistry, we provide evidence that the expression of LGR4 correlates with nodal spread and of LGR6 inversely with local tumor growth. Interestingly, in TMA analysis, we found a positive impact of LGR6 expression on patient survival in poorly cohesive-type carcinomas. Thus, both LGR4 and LGR6 are probably involved in gastric cancer biology.

The leucine-rich repeat-containing G-protein-coupled receptors (LGR4, LGR5, and LGR6) are interesting GPCRs. Their functions as well as their ligands are still widely unknown [12, 20], even though it was recently shown that

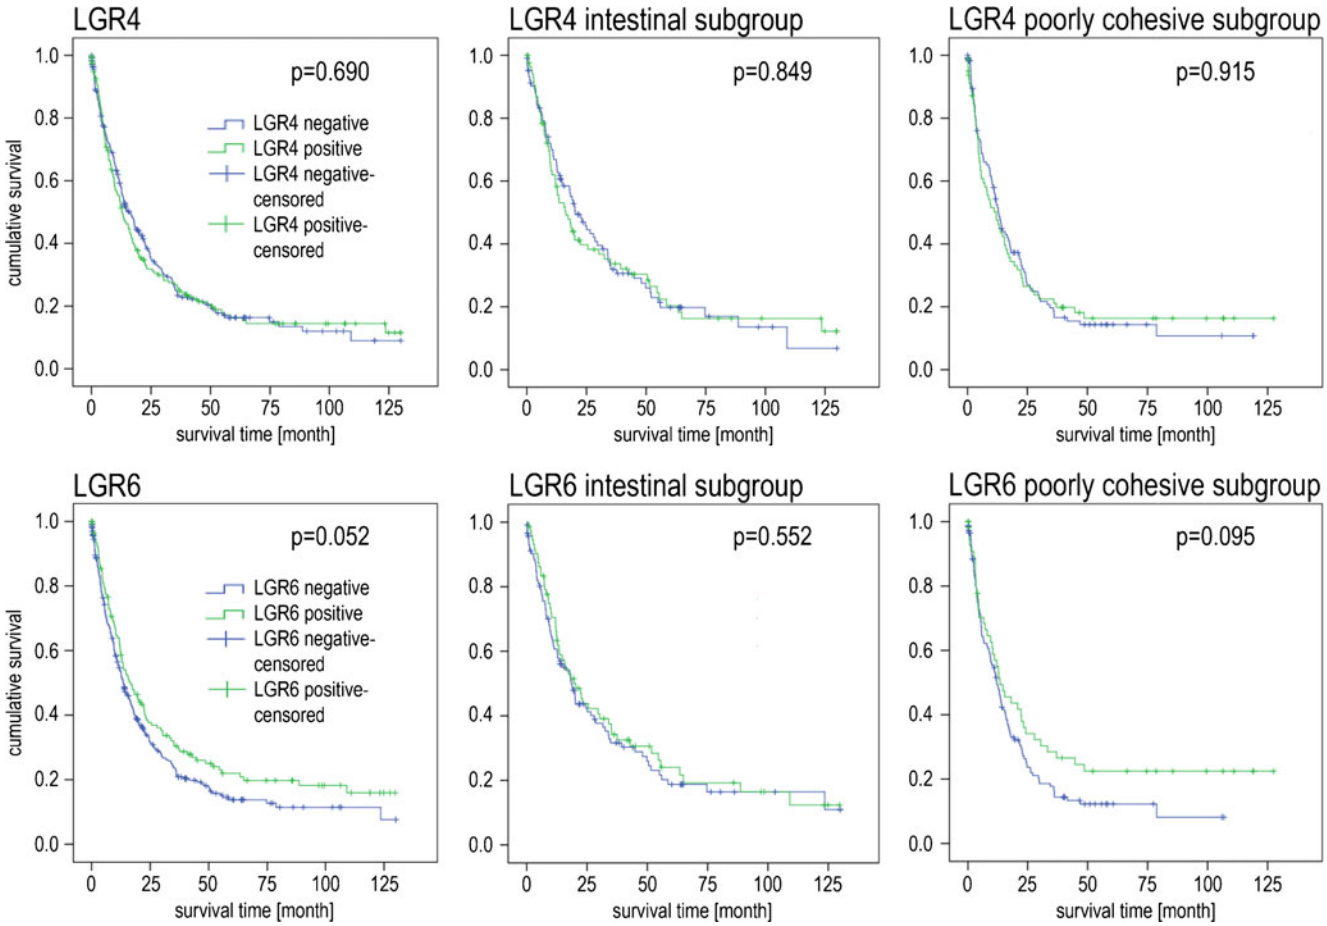

Fig. 3 Patient survival depending on LGR4 and LGR6 expression depicted by Kaplan–Meier curves. *P*-values were calculated using the log-rank (Mantel–Cox) test

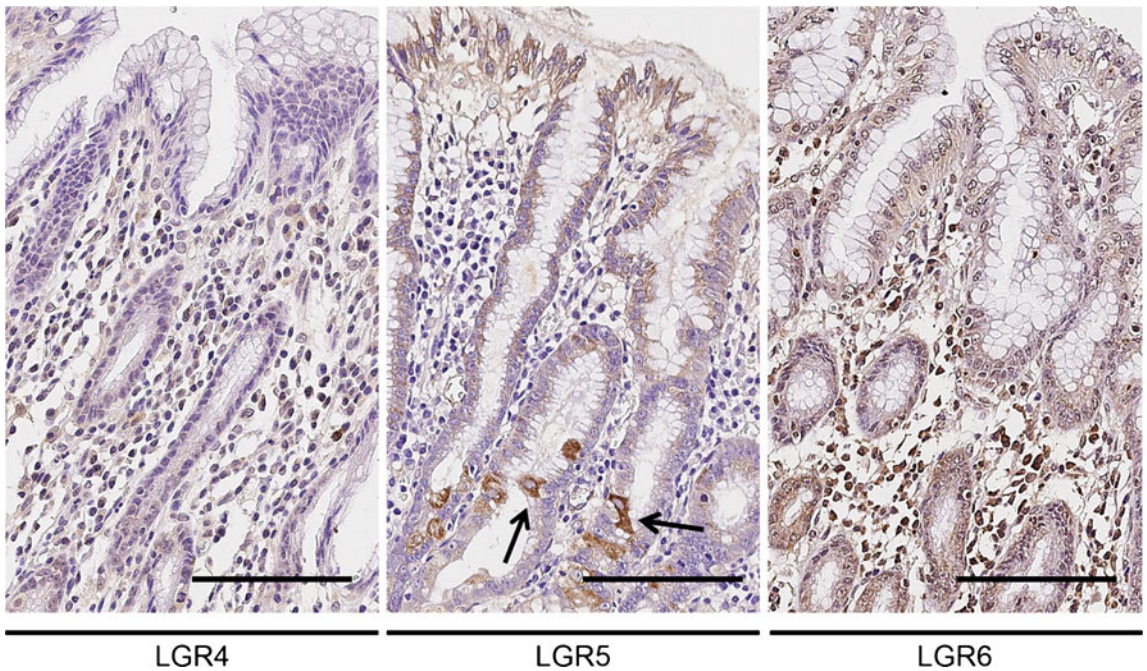

Fig. 4 Immunostaining of LGR4, LGR5, and LGR6 in non-neoplastic mucosa. Serial sections were obtained from a sample of non-neoplastic gastric mucosa. LGR5-positive staining was observed in putative gastric stem cells (*arrows*). In contrast to that, putative mucosal stem cells did not immunoreact with antibodies directed against LGR4 or LGR6. *Scale bar*: 100 μm. Original magnifications: ×200

R-spondin growth factors are able to bind LGR4 and LGR5 and, in this manner, interact with the Wnt pathway [21, 22]. LGRs have been previously reported to be of biological relevance in different physiological and pathophysiological processes. The importance of LGR5 as a marker of putative gastrointestinal stem cells and cancer stem cells in hepatogastrointestinal carcinomas was reported recently by our group [13]. LGR5 is expressed at the tumor center and the invasion front of GCs and correlates with local tumor growth and nodal spread. *LGR4* appears to be involved in fundamental embryonic development processes of all germinal sheets as was shown by Mazerbourg et al. [20]. LGR4 is broadly expressed in various highly proliferative tissues without being restricted to stem cell populations [12]. This is notable having in mind that its relative LGR5 was proven recently to be a stem cell marker in gastric and intestinal mucosae [11, 23] (Fig. 4). Gao et al. observed LGR4 overexpression promoting invasiveness and metastasis of colorectal carcinoma and postulated this gene being a potential marker for metastases and poor prognosis [24, 25]. Nevertheless, in log-rank (Mantel–Cox) test, we did not find an impact of LGR4 expression on survival of GC patients. As recently reported, LGR4 seems to be part of the Wnt pathway in the intestine [22, 26]. Due to this function, the receptor is hypothesized to be a potential new therapeutic target for intestinal cancers [26]. Our systematic analysis indicates that *LGR4* also plays a role in GC biology. Future studies will have to demonstrate whether it is also a putative diagnostic, prognostic, and/or therapeutic target for GC. Interestingly, in some GCs, we found a nuclear immunoreaction for LGR4. This observation is worth being subject of further research as nuclear immunostaining has already been published in connection with other GPCRs and their signaling pathways [27].

LGR6 is expressed in multiple tissues, e.g. brain, thymus, kidney, spleen, heart, and intestine [14]. This receptor was shown to mark a population of Wnt-independent stem cells in the skin, which is located in a certain domain of the hair follicle, just below the sebaceous gland [11, 28]. These stem cells seem to be involved in wound repair and hair follicle development [11, 12, 28]. Leushacke and Barker described the perspective to utilize isolated LGR6-positive stem cells for epithelial culture. These cells may have potential for new clinical treatment strategies of skin disorders [11]. However, in our patient cohort, LGR6 was not found in the stem cell niche of non-neoplastic gastric mucosa and did not colocalize with LGR5 immunoreactive cells. Thus, at present, we have no evidence of LGR6 being a stem cell marker in the stomach (Fig. 4).

Collectively, our current and previous findings lend support to the hypothesis that members of the LGR family of GPCRs, notably LGR4, LGR5, and LGR6, are differentially expressed in GCs and are tumor biologically relevant. While LGR5 might be a stem cell marker, the functions of LGR4 and LGR6 are unknown. Both LGR4 and LGR6 have potential in terms of diagnostics and therapy of GC, but they will need to be subject to future research. Further studies into this topic are urgently warranted.

Acknowledgments We would like to thank Sandra Krüger for her excellent technical support. This study was supported by grants from Deutsche Forschungsgemeinschaft (Ro 1173/12).

Abstract The AT-rich interactive domain 1A gene (ARID1A), which encodes one of the subunits in the Switch/Sucrose Nonfermentable chromatin remodeling complex, carries mutations and is responsible for loss of protein expression in gastric carcinoma, particularly with Epstein–Barr virus (EBV) infection and a microsatellite instability-high phenotype. We used immunohistochemistry to investigate the significance of ARID1A loss in 857 gastric carcinoma cases, including 67 EBV(+) and 136 MLH1-lost gastric carcinomas (corresponding to a microsatellite instability-high phenotype). Loss of ARID1A expression was significantly more frequent in EBV(+) (23/67; 34 %) and MLH1-lost (40/136; 29 %) gastric carcinomas than in EBV(−)MLH1-preserved (32/657; 5 %) gastric carcinomas ($P<0.01$). Loss of ARID1A correlated with larger tumor size, advanced invasion depth, lymph node metastasis, and poor prognosis in EBV(−)MLH1-preserved gastric carcinoma. A correlation was found only with tumor size and diffuse-type histology in MLH1-lost gastric carcinoma, but no correlation was observed in EBV(+) gastric carcinoma. Loss of ARID1A expression in EBV(+) gastric carcinoma was highly frequent in the early stage of gastric carcinoma, although EBV infection did not cause downregulation of ARID1A: EBV-positive nasopharyngeal carcinomas ($n=8$) and lymphomas ($n=15$) failed to show loss of ARID1A, and EBV infection did not cause loss of ARID1A in gastric carcinoma cell lines. Taken together, loss of ARID1A may be an early change in carcinogenesis and may precede EBV infection in gastric epithelial cells, while loss of ARID1A promotes cancer progression in gastric cancer cells without EBV infection or loss of MLH1 expression. Loss of ARID1A has different and pathway-dependent roles in gastric carcinoma.

Introduction

Gastric cancer (GC) is one of the most common malignancies in the world, particularly in East Asia [1]. The prognosis of advanced-stage GC is still poor, and investigation of pathological features and molecular mechanisms according to its specific subtypes is mandatory to develop more effective therapies for individuals with GC. Epstein–Barr virus (EBV)-associated

GC (EBV(+) GC) shows monoclonal growth of EBV-infected stomach epithelial cells, accounting for nearly 10 % of GCs. Its typical morphology is a poorly differentiated carcinoma with massive infiltration of lymphocytes, generally referred to as lymphoepithelioma-like carcinoma. The molecular mechanism is also distinctive [2–4], i.e., EBV(+) GC is a representative of GCs showing a CpG island methylator phenotype [5, 6], as well as GCs with high microsatellite instability (MSI). The latter GC subtype (MSI-high GC) is mostly caused by loss of MLH1 expression due to promoter methylation of the *MLH1* gene [7, 8].

Recent genome-wide sequencing studies have demonstrated that the *AT-rich interactive domain 1A gene* (*ARID1A*) is frequently mutated in EBV(+) GC and MSI-high GC [9, 10]. ARID1A is one of the subunits of the Switch/Sucrose Nonfermentable (SWI/SNF) chromatin remodeling complex and is currently thought to behave like a tumor suppressor gene [11–15]. Previous studies have identified an *ARID1A* rearrangement in primary breast cancer and an *ARID1A* deletion in a lung cancer cell line [12]. Mutation of *ARID1A* has been demonstrated in carcinomas of the ovary, for example, in approximately half of the clear-cell subtype and in 30 % of the endometrioid subtype, but in none of the serous or mucinous subtypes [13, 14]. Most *ARID1A* mutations are insertion/deletion mutations. This leads to truncation of ARID1A protein, and such a type of protein is assumed to be prone to degradation. *ARID1A* gene mutation correlated closely with loss of ARID1A expression (ARID1A loss) as assessed by immunohistochemistry even in the absence of mutation in other alleles [9, 14, 16], and ARID1A loss can be used as a surrogate marker for the gene mutations. One-third of endometrioid carcinomas of the uterine corpus and adenocarcinomas/adenosquamous carcinomas of the uterine cervix also showed ARID1A loss [17–19], but *ARID1A* mutation and ARID1A loss were not frequent in carcinomas of other organs [20].

To clarify the significance of ARID1A in GC, we performed immunohistochemistry of ARID1A using high-throughput tissue microarray (TMA) of GC, with special attention to two subtypes, EBV(+) GC and MSI-high GC. In addition, we also evaluated ARID1A expression in other types of EBV-associated malignancies, such as nasopharyngeal carcinomas and lymphomas. Furthermore, an experimental approach using genetically engineered EBV was applied to investigate the relationship between EBV infection and ARID1A expression in GC.

Materials and methods

Tissue samples

Formalin-fixed and paraffin-embedded GC tissues were obtained from the Department of Pathology, Tokyo University Hospital, and the Department of Pathology, Tokyo Metropolitan Cancer and Infectious Diseases Center, Komagome Hospital (893 cases). Biopsy samples of nasopharyngeal carcinomas (eight cases) and lymphomas (15 cases) were also obtained from the Tokyo University Hospital. Lymphoma samples included six diffuse large B cell lymphomas, four EBV-associated lymphoproliferative disorders, three Hodgkin lymphomas, one extranodal NK/T cell lymphoma, nasal-type, and one peripheral T cell lymphoma, unspecified. All tumors were retrieved from the archives of each institution.

For immunohistochemistry, TMAs were designed from paraffin tissue blocks of GCs, each made by punching out 2-mm-diameter cores of tumors from the block. At least two cores were obtained from each case. For clinicopathological analyses, all of the cases, including both early (T1 or Tis) and advanced (T2 or more) carcinomas, were used. For prognostic analyses, we used a subset of advanced carcinoma cases (n=254) with information about prognosis. Correlations of ARID1A expression status with the following clinical and pathological variables were evaluated: gender, age, size and location of the tumor, histological type (Lauren classification [21]), histological invasion depth, lymphatic and venous invasion, lymph node metastasis, EBV-encoded small RNA in situ hybridization (EBER-ISH) status, and MLH1 expression status. Negative immunostaining of MLH1 (MLH1-loss) was used as a marker of MSI-high GC [7, 8].

Some uterine endometrioid carcinomas have ARID1A-negative areas adjacent to positive areas, and the mutation is thought to arise in clones within the tumors [17]. To assess the distribution of positive and negative tumor cells in EBV(+) GC, whole sections of EBV(+) GC (45 cases) were stained for ARID1A. This study was approved by the ethics committee of each institution (Tokyo University Hospital and Komagome Hospital).

GC cell lines and EBV infection

GC cell lines MKN1, MKN74, TMK1, and SNU719 were used in the present study. MKN1 and MKN74 were obtained from Riken Bioresource Center Cell Bank (Tsukuba, Japan). TMK1 was a gift from Prof. W. Yasui (Hiroshima University). SNU719 cells were derived from EBV(+) GC and obtained from the Korean Cell Line Bank (Seoul, Korea). The cell lines were cultured in RPMI-1640 (Nacalai Tesque, Kyoto, Japan) supplemented with 10 % fetal bovine serum, penicillin (40 units/mL), and streptomycin (50 μg/mL) at 37 °C in a 5 % CO_2 incubator.

EBV-negative GC cell lines MKN1, MKN74, and TMK1 were infected with recombinant EBV using the cell-to-cell contact method as previously described [22]. Briefly, a Burkitt's lymphoma cell line, Akata, was modified to produce recombinant EBV, in which the

neomycin-resistant gene was inserted and was used as a source of the virus. Recombinant EBV was a gift from Prof. K. Takada (Hokkaido University). After removal of Akata cells, GC cells were subjected to bulk selection with G418 (Sigma Aldrich, St. Louis, MO, USA), yielding EBV-infected GC cell lines. To confirm EBV infection, noncoding small RNA of the EBV latent gene *EBER1* was evaluated using reverse transcription–polymerase chain reaction as previously described [23]. Cell blocks were then made from the cultured cells with and without EBV infection; cells were fixed with 4 % paraformaldehyde, collected, and embedded in paraffin using agarose as an embedding medium [24].

Western blotting

Whole cell extracts were prepared from GC cell lines, and Western blotting was performed as previously described [25]. The primary antibodies used were rabbit polyclonal anti-ARID1A (HPA005456, dilution 1:1,000; Sigma-Aldrich) and goat polyclonal anti-actin (sc-1616, dilution 1:1,000; Santa Cruz Biotechnology, Santa Cruz, CA, USA).

Immunohistochemistry and EBER-ISH

Immunohistochemistry was applied to tissue microarrays, cell blocks, and whole sections using the VECSTATIN ABC kit (Vector Laboratories, Burlingame, CA, USA) and DAB+Chromogen (Dako, Glostrup, Denmark) using the peroxidase method. The primary antibodies used were rabbit polyclonal anti-ARID1A (HPA005456, dilution 1:200; Sigma-Aldrich) and mouse monoclonal anti-MLH1 (550838, clone G168-15, dilution 1:50; BD Pharmingen, Franklin Lakes, NJ, USA). For ARID1A, the sections were autoclaved for 10 min in citrate buffer (pH 6) for antigen retrieval. For MLH1, the sections were microwaved for 15 min in citrate buffer (pH 6). Tumors were regarded as positive for ARID1A and MLH1 if tumor cells showed nuclear immunoreactivity. Non-neoplastic cells, such as fibroblasts, endothelial cells, and lymphocytes, served as internal positive controls for ARID1A. Lymphocytes in a germinal center and normal epithelium in the proliferative zone served as internal positive controls for MLH1.

EBER-ISH was performed on paraffin sections using a fluorescein isothiocyanate (FITC)-labeled peptide nucleic acid probe (Y5200; Dako) and anti-FITC (V0403, dilution 1:200; Dako).

Immunohistochemistry and EBER-ISH results were evaluated independently by two pathologists (H.A. and D.M.). Cores devoid of tumor tissues or inappropriate immunostaining results for evaluation (e.g., no staining of internal control cells) were excluded from analyses.

Statistical analysis

The chi-square test was used to examine the distribution of two variables—i.e., two or oligo-valued data. The unpaired *t* test was used to test for differences in tumor size and patient age. Overall survival and disease-free survival data were plotted by Kaplan–Meier methods, and *P* values were determined by the log-rank test. Prognostic factors were also analyzed by multivariate analyses (Cox proportional hazards model). *P* values less than 0.05 were considered statistically significant.

Results

Correlation of ARID1A loss with EBV infection and MLH1 loss

The results of the immunohistochemical investigations are presented in Table 1. In total, 857 of 893 cases in the TMAs were appropriate for immunohistochemical evaluation. Of these 857 GC cases, EBER-ISH revealed positive signals in 67 (8 %), and immunohistochemistry showed MLH1-loss in 136 (16 %). Only three cases of EBV(+) GC were negative for MLH1 expression.

ARID1A expression was determined by nuclear staining. Stromal cells, such as lymphocytes, fibroblasts, and endothelial cells, showed positive nuclear staining and served as a positive internal control (Fig. 1). Loss of ARID1A expression was observed in 23 of 67 cases of EBV(+) GC (34 %) and in 40 of 136 cases of MLH1-lost GC (29 %), whereas loss of ARID1A expression was observed in 32 of 657 cases of EBV(−)MLH1-preserved GC (5 %). Thus, ARID1A loss was significantly frequent in EBV(+) GC and MLH1-lost GC ($P<0.01$, $P<0.01$, respectively).

Clinicopathological characteristics of ARID1A loss in EBV (+) GC, MLH1-lost GC, and EBV(−)MLH1-preserved GC

The relationships between loss of ARID1A expression and other clinicopathological factors were analyzed (Table 1). ARID1A loss correlated with tumor location, larger tumor size, advanced invasion depth, as well as with frequent lymphatic and venous invasion. Gastric carcinoma cases were then classified into three subgroups: EBV(+) GC ($n=67$), MLH1-lost GC ($n=136$), and EBV(−)MLH1-preserved GC ($n=657$), followed by clinicopathological analysis in each group (Table 2). Of 67 cases of EBV (+) GC, three showed MLH1-loss, and these exceptional

cases were included in both EBV(+) GC and MLH1-lost GC for this analysis. No clinicopathological factor was associated with ARID1A loss in EBV(+) GC. ARID1A loss correlated only with larger tumor size and diffuse-type histology in MLH1-lost GC. However, ARID1A loss correlated with larger tumor size, advanced invasion depth, frequent lymphatic invasion, venous invasion, and lymph node metastasis in EBV(−)MLH1-preserved GC.

When the frequencies of ARID1A loss were compared between early and advanced carcinoma, ARID1A loss was also observed in EBV(+) GC (10/28 vs 13/39, P=0.84). However, ARID1A loss was more common in advanced carcinomas (31/481) than in early carcinomas in EBV (−)MLH1-preserved GC (1/176) (P=0.002).

Relationship between ARID1A expression loss and prognosis

The effect of ARID1A loss on survival was analyzed in 254 cases of advanced carcinomas (T2 or more). Immunohistochemistry was appropriate for evaluation in 250 cases, including eight EBV(+) GC and 36 MLH1-lost GC. In this series, only one case of EBV(+) GC was found to show MLH1 loss, and this case was included in both EBV(+) GC and MLH1-lost GC for the analysis. ARID1A loss was observed in 3 of 8 cases of EBV (+) GC (38 %), in 10 of 36 cases of MLH1-lost GC (28 %), and in 13 of 207 cases of EBV(−)MLH1-preserved GC (6 %). In each subtype, the frequencies of ARID1A loss were comparable with those in the whole cases.

Patients with ARID1A loss tended to show poorer prognosis, although this was not statistically significant

◀ **Fig. 2** Survival curves of ARID1A-positive and -negative gastric carcinoma. Disease-free survival and overall survival curves in all of the gastric carcinoma (**a** and **b**, respectively), EBV(+) gastric carcinoma (**c** and **d**, respectively), MLH1-lost gastric carcinoma (**e** and **f**, respectively), and EBV(−)MLH1-preserved gastric carcinoma cases (**g** and **h**, respectively). Loss of ARID1A expression significantly correlates with worse disease-free survival and overall survival in EBV(−)MLH1-preserved gastric carcinoma

(Fig. 2a, b). The prognostic analyses of each subtype failed to demonstrate a correlation between ARID1A loss and disease-free survival or overall survival in both EBV (+) GC and MLH1-lost GC, although the number of the cases was relatively small (Fig. 2c–f). Conversely, in EBV(−)MLH1-preserved GC, patients with ARID1A loss had a significantly shorter disease-free survival (P=0.016) and overall survival (P=0.027) (Fig. 2g, h). Multivariate analysis showed that ARID1A loss was an independent prognostic factor in both disease-free survival and overall survival in EBV(−)MLH1-preserved GC (Table 3).

ARID1A loss and EBV infection

Since ARID1A-loss was found to be highly frequent in the early stage of EBV(+) gastric carcinoma, the significance of ARID1A-loss was further evaluated in the whole section of EBV(+) GC and other types of EBV-associated malignancies.

To assess the distribution of ARID1A expression within an individual cancer tissue, whole sections of EBV(+) GC in the first series of TMA were evaluated in parallel by immunohistochemistry. All 45 cases of EBV(+) GC were either diffusely positive or totally negative for ARID1A in the entire lesion, except for one case which consisted of two discrete components of ARID1A-positive and -negative cells side by side (Fig. 3).

To evaluate whether ARID1A loss was specific to EBV (+) GC among EBV-associated malignancies, ARID1A expression was evaluated in EBV-positive nasopharyngeal carcinomas (n=8) and lymphomas (n=15). There was no case showing loss of ARID1A expression (Fig. 4).

In the following experimental approach, we tried to determine whether EBV infection induces ARID1A loss in GC cells. Three EBV(−) cell lines and one EBV(+) GC cell line showed positive expression of ARID1A. Using the Akata system of EBV infection, three EBV(−) GC cell lines were infected with EBV, in which the neomycin-resistant gene was integrated, and EBV-infected GC cell lines were successfully established. Western blot analysis showed that ARID1A expression was preserved after EBV infection (Fig. 5a). Investigating cell blocks immunohistochemically, we noted ARID1A expression in GC cell lines irrespective of EBV infection (Fig. 5b, c).

Discussion

ARID1A is one of the accessory subunits of the SWI/SNF chromatin remodeling complex, and is believed to provide specificity to this complex in the regulation of gene expression by binding to AT-rich DNA sequences [11]. *ARID1A* mutation and loss of ARID1A protein expression have been found to be highly frequent in carcinomas of the ovary and uterus, and with considerable frequency in subtypes of GCs. The presence of mutations is strongly correlated with the loss of ARID1A expression, even if the mutation is accompanied by a wild-type allele. Previous studies have reported loss of ARID1A expression in 100 % (9/9) [16] and 73 % (27/37) [14] of clear cell carcinomas of the ovary with *ARID1A* gene mutation. Wang et al. recently demonstrated *ARID1A* mutation and ARID1A loss in specific subtypes of GC, EBV(+) GC and MSI-high GC [9]. Performing immunohistochemistry for ARID1A and high-throughput TMA of 857 cases of GC, we found that in a Japanese population, ARID1A loss occurs in GC (11 %), with preference for EBV(+) GC and MLH1-lost GC (corresponding to MSI-high GC), the percentage amounting to 34 and 29 %, respectively. There were two new findings: First, the frequencies of ARID1A loss in the early and advanced stages were different when comparing the three groups. This suggests that the timing of ARID1A loss may be different in each subgroup. Second, ARID1A loss was correlated with multiple parameters of tumor aggressiveness in EBV(−)MLH1-preserved GC, such as larger tumor size, advanced invasion depth, frequent vessel invasion, and lymph node metastasis. ARID1A loss was confirmed to be a negative indicator of disease-free survival and overall survival for the patients with advanced GC. These facts clearly demonstrate that ARID1A loss is responsible for cancer progression in EBV(−)MLH1-preserved GC.

The significance of ARID1A loss or mutation in cancer is now subject to intensive investigation. Induction of ARID1A expression suppressed cellular proliferation of the cell lines of gastric, ovarian clear cell, and uterine endometrioid carcinoma harboring *ARID1A* mutation. Knockdown of ARID1A in gastric and ovarian cell lines with wild-type *ARID1A* increased cellular proliferation [10, 15]. These facts are compatible with our studies, in which we found that ARID1A-loss was prognostically unfavorable for patients with EBV(−)MLH1-preserved GC. On the other hand, Wang et al. reported that ARID1A expression loss was associated with better prognosis in gastric carcinoma [9]. In that study, the discrepancy might be explained by the possibility that the cases with loss of ARID1A included more EBV(+) GC and MSI-high GC. EBV(+) and MSI-high GC show a better prognosis than other types of gastric carcinomas [2, 26]. The significance of ARID1A-loss might be different in the three subgroups, as demonstrated in the present study.

In our recent study on the DNA methylation epigenotype with Illumina's Infinium BeadArray [27], two high methylation groups were found to exist: EBV-negative and EBV-positive. In that study, *MLH1* methylation and EBV infection were mutually exclusive, and GC cases with *MLH1* methylation belonged to the EBV-negative/high methylation group. In the present study, immunohistochemistry of MLH1 also revealed a relationship between MLH1 loss and EBV infection, which has also been reported by others [28]. In the MLH1-lost subgroup, the effect of ARID1A loss was limited as compared with that in the EBV(−)MLH1-preserved subgroup as described above. Because loss of MLH1 expression results in a MSI-high phenotype, *ARID1A* mutations in this subgroup are mostly considered to be caused by a slippage error on the short repeats of four to seven mononucleotides in the coding region [9]. A

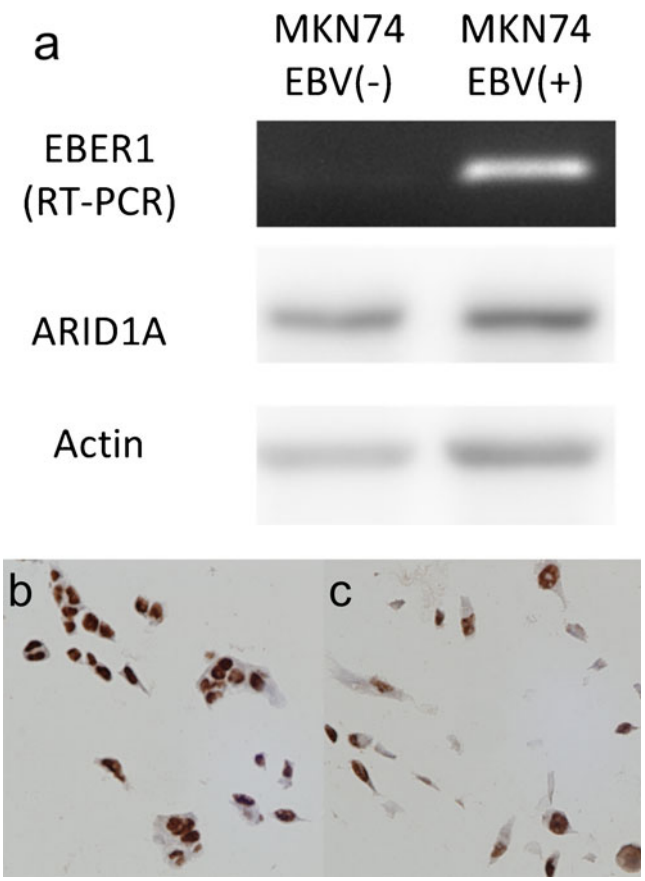

Fig. 5 Effect of EBV infection on ARID1A expression in gastric carcinoma cell lines. **a** ARID1A expression in MKN74 with and without EBV infection. *Upper column*: reverse transcription–polymerase chain reaction of EBER1. *Middle column*: Western blot of ARID1A. *Lower column*: Western blot of Actin. **b**, **c** Immunohistochemistry for ARID1A expression in cell blocks of parental MKN74 cells (**b**) and MKN74 cells with EBV infection (**c**). No difference in ARID1A expression was observed, as demonstrated by Western blotting (**a**) and by immunohistochemistry of cell blocks (**b**, **c**)

previous study revealed that loss of BRG1 or BRM, which are subunits of the SWI/SNF complex, cause DNA methylation in the promoter region of CD44 and E-cadherin [29]. Thus, ARID1A loss in this subset might also play a role in promoting epigenetic abnormalities through dysfunction of the SWI/SNF complex.

The clinicopathological characteristics associated with ARID1A loss were totally different in EBV(+) GC. The frequency rate of ARID1A loss in early carcinomas was nearly as high as that in advanced carcinomas, and no factor was correlated with loss of expression. In addition, the clonal nature of ARID1A loss was confirmed by immunohistochemistry of the whole section. One case had ARID1A-positive and -negative components within tumor, but the components appeared to be colliding. Furthermore, ARID1A loss was not observed in EBV-associated malignant neoplasms other than stomach neoplasms, and using the Akata infection system, we confirmed that EBV infection did not cause loss of expression in GC cell lines. These findings suggest that epithelial cells with ARID1A loss constitute one precursor lesion of the stomach for EBV infection and subsequent cancer development. Epithelial cells with ARID1A loss might be more susceptible to EBV infection. Alternatively, ARID1A loss, cooperating with EBV infection, may accelerate CpG-island methylation on the promoter region of DNA, which then forms the EBV-positive/high epigenotype in the infected stomach cells [27].

In the present study, ARID1A loss was frequent in EBV (+) GC or MLH1-lost (MSI-high) GC; both of which are known to show the CpG island methylator phenotype. The significance of ARID1A loss is different and may be pathway-dependent in EBV(+) GC, MLH1-lost GC, and EBV(−)MLH1-preserved GC. ARID1A loss is a negative predictor for the prognosis of patients with EBV(−)MLH1-preserved GC. Further studies are necessary to clarify the role of ARID1A loss, in association with the function of SWI/SNF complex, in the formation of EBV-negative and EBV-positive high epigenotypes.

Abstract Epitheliomesenchymal biphasic neoplasms are extremely rare in the duodenum, and most of these are carcinosarcomas. Miettinen et al. (Am J Surg Pathol 33:1370–7, 2009) recently reported three cases of a novel distinctive epitheliomesenchymal biphasic tumor of the stomach in young adults. In view of the resemblance to other childhood blastomas, they proposed to refer to this entity as a gastroblastoma. Since none of the components were sufficiently atypical, the gastroblastoma seemed more comparable to this kind of tumor than carcinosarcomas or other aggressive and malignant biphasic tumors. This report describes a duodenal location of a similar epitheliomesenchymal biphasic tumor in a 22-year-old woman. To our knowledge, this is the first reported case occurring primarily in the duodenum and might be the first case of "duodenoblastoma."

Introduction

In 2009, after a review of several gastrointestinal sarcomas, Miettinen et al. [1] identified a novel distinctive epitheliomesenchymal biphasic tumor of the stomach. They described three cases, arising in the stomachs of young adults. Following this publication, another case has been reported [8].

Our report describes a similar tumor in a young woman. However, it was located in the duodenum. Although the morphology was close to what Miettinen described for gastroblastoma, we noticed some differences in the expression profile of immunohistochemical markers. To our knowledge, this tumor is not a carcinosarcoma or other biphasic malignant or locally aggressive tumor. Therefore, we propose to classify this novel distinctive epitheliomesenchymal biphasic tumor as described by Miettinen and to report it as duodenoblastoma.

Clinical history

In June 2010, a 22-year-old woman checked in with a severe case of melena. She had no particular medical history but had recently delivered a baby. Gastroduodenoscopy followed by endoultrasonography revealed an ulcerated and hemorrhagic tumor located in the muscular layer of the proximal duodenum (Fig. 1). This 37-mm mass protruded into the duodenal lumen and was superficially ulcerated (Fig. 2). No locoregional lymphadenopathy was found. The patient underwent partial resection of the distal duodenum. Preoperative observations confirmed that the tumor was located at the free border of the descending duodenum and did not show any adhesion to nearby organs. The tumor was completely resected. The patient is still in full remission 16 months after surgery.

Fig. 1 Abdominal computed tomography scan showing a 37-mm mass protruded into the duodenum lumen

Materials and methods

The tumor was histologically examined, and patient follow-up was obtained from the electronic medical records. After surgical removal, the tumor was sampled and fixed in a 30 % ethanol-formaldehyde solution. It was then entirely embedded in paraffin. Paraffin sections (5 μm) were cut and processed for hematoxylin–eosin–safranin or immunohistochemical staining.

Primary sources of antibodies and dilutions used in the immunohistochemical studies are shown in Table 1. Immunohistochemical staining was performed using a Dako Autostainer (DakoCytomation, Trappes, France) and horseradish peroxidase-labeled secondary antibodies, with diaminobenzinidine or 3-amino-9-ethyl-carbazole as chromogens. Staining controls were either external or internal, depending on the antibody used.

Pathological findings

The tumor was an intramural 37-mm-diameter lesion within the wall of the duodenum. It was nodular, and the overlaying duodenal mucosa was ulcerated (Fig. 2). The cut surface was white and flaky without any hemorrhagic areas.

Histological examination showed a multinodular biphasic and grossly well-circumscribed tumor, infiltrating the muscularis propria, extending to the duodenal serosa, and pushing up the duodenal mucosa (Fig. 3). At low magnification, the main

Fig. 2 Resected specimen showing a 37-mm-diameter ulcerated, polypoid tumor located in the duodenum

component consisted of small spindle and round cells, with a high nucleocytoplasmic ratio, without any particular differentiation. A second component was epithelioid, consisting of cohesive lobulated cells, without glandular or squamous differentiation. Nuclear atypia or necrosis was not found. Mitotic activity varied up to a maximum of nine mitoses per 50 HPF. There was a very discrete collagenous stroma creating a fascicular architecture (Fig. 4).

The result of the immunohistochemical study is listed in Table 1. The spindle cell component was positive for vimentin and desmin. In some areas, it was positive for smooth muscle actin, but negative for PS100, KIT, DOG1, CD34, and neuroendocrine markers (synaptophysin, chromogranin A, and CD56). The epithelial component was positive for pan-keratin AE1/AE3 and keratin 7 (Fig. 5). The maximum proliferation index (Mib1-Ki67) was estimated at 20 % in some areas. Staining for progesterone receptor was positive, but negative for estrogen receptor. The molecular analysis provided no evidence for a SYT/SSX translocation.

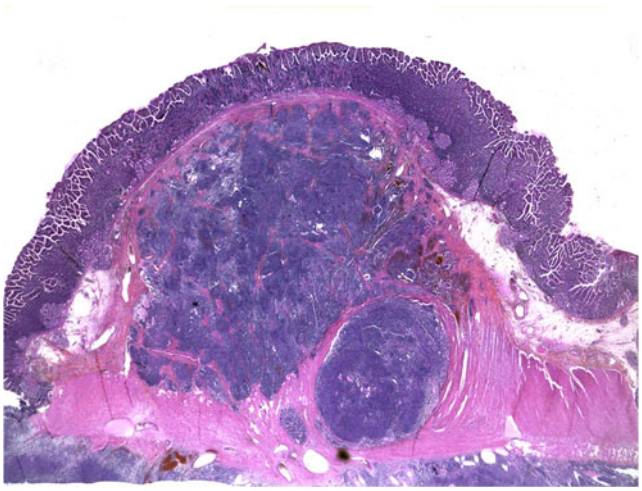

Fig. 3 Multinodular and roughly limited tumor, infiltrating the muscularis propria, extending to the duodenal serosa, and pushing out the duodenal mucosa

Discussion

Spindle cell tumors of the intestine are rare and represent 10 % of malignant tumors of the small intestine and 0.1 % of the large intestine [2]. Most of these tumors are gastrointestinal stromal tumor (GIST), metastases from melanoma or sarcoma. Moreover, epitheliomesenchymal biphasic neoplasms are extremely rare in the duodenum, and most of these are high-grade carcinosarcomas [5, 6, 9]. Duodenal synoviosarcomas with confirmatory molecular analysis of the SYT/SSX translocation have also been reported [3, 4].

We report a duodenal epitheliomesenchymal biphasic neoplasm without the cellular differentiation or nuclear atypia, justifying a diagnosis of carcinosarcoma or other malignancy. Our case presents clinical and morphological features similar to those of the "novel distinctive epitheliomesenchymal tumor of the stomach of young adults," recently described by Miettinen et al. [1]. They described three cases which occurred in the stomach of young adults and proposed to call these tumors gastroblastomas, in analogy to other childhood biphasic neoplasms for which the term blastoma is used. These three cases were grossly multinodular or lobulated. One tumor formed an exophytic polyp, and the two others were ulcerated and transmural.

These tumors had two components: uniform oval and spindled cells in diffuse sheets and clusters or cords of epithelial cells, occasionally forming glandular structures. The epithelial component was positive for keratin, partly for keratin 7 and negative for keratins 5/6 and 20 and epithelial membrane antigen. The mesenchymal component was positive for vimentin and CD10. Both of the two components were negative for smooth muscle actin, desmin, CD34, CD 99, estrogen receptor, KIT, PS100, p63, calretinin, chromogranin, synaptophysin, CDX2, and thyroid transcription factor. None of the three cases demonstrated SS18 gene rearrangement by FISH.

The tumors described by Miettinen [1] and our case share the similar clinicopathological features: occurrence in young adults, relatively large tumor size, multinodular shape, two components with low-grade features and relatively low-mitotic activity, low overall atypia, and absence of conspicuous nuclear pleomorphism.

However, we found some immunohistochemical differences with the gastroblastoma; the mesenchymal component of our case was positive for desmin, CD99, and smooth muscle actin and negative for CD10. Moreover, the tumor expressed progesterone receptor, but this might have been related to the fact that the patient was postpartum. The expression of desmin

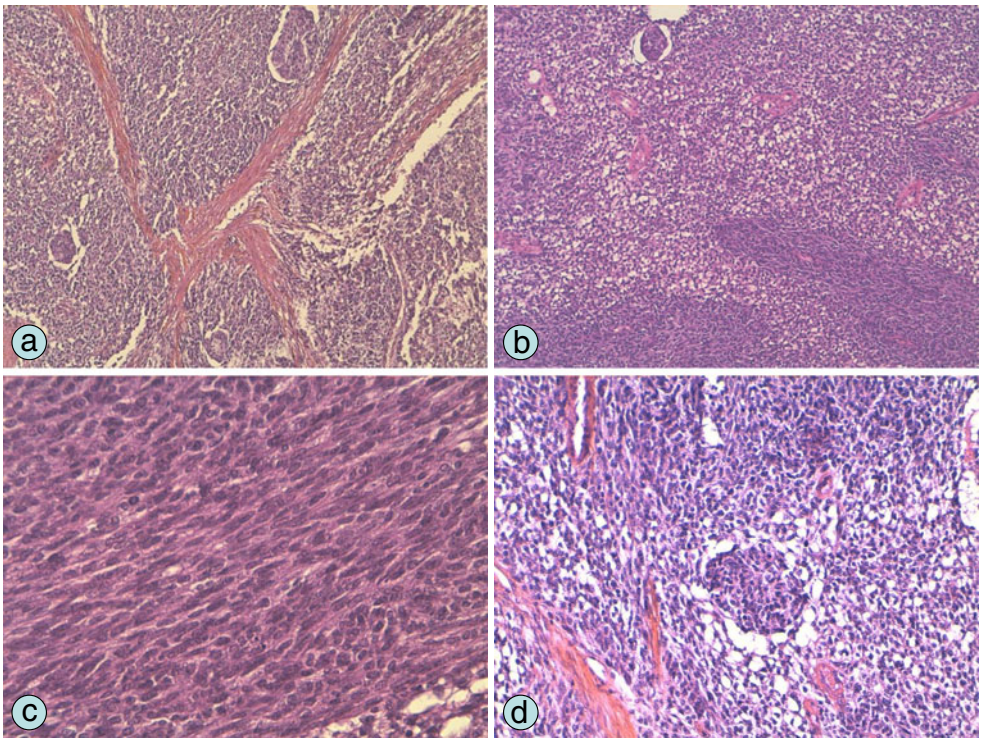

Fig. 4 Most of the tumor is composed of spindle cells, with some clusters of epithelioid cells (**a**, **b**). The two components show no nuclear atypia, uniform cytology with little mitotic activity (**c**, **d**)

and smooth muscle actin might suggest a diagnosis of a leiomyosarcoma, which was not compatible with the presence of epithelial cell nests. However, despite these immunochemical differences, the clinicopathological features so closely resemble those of gastroblastoma that we consider our case to be similar to those described by Miettinen.

The differential diagnosis of a low-grade malignant biphasic tumor of the duodenum comprises teratoma, mixed tumor (myoepithelioma) [1], GIST, pancreatoblastoma [7] in an ectopic pancreas, and gangliocytic paraganglioma. Teratoma would display more specific differentiation and would occur in younger patients. Mixed tumors (myoepitheliomas) of

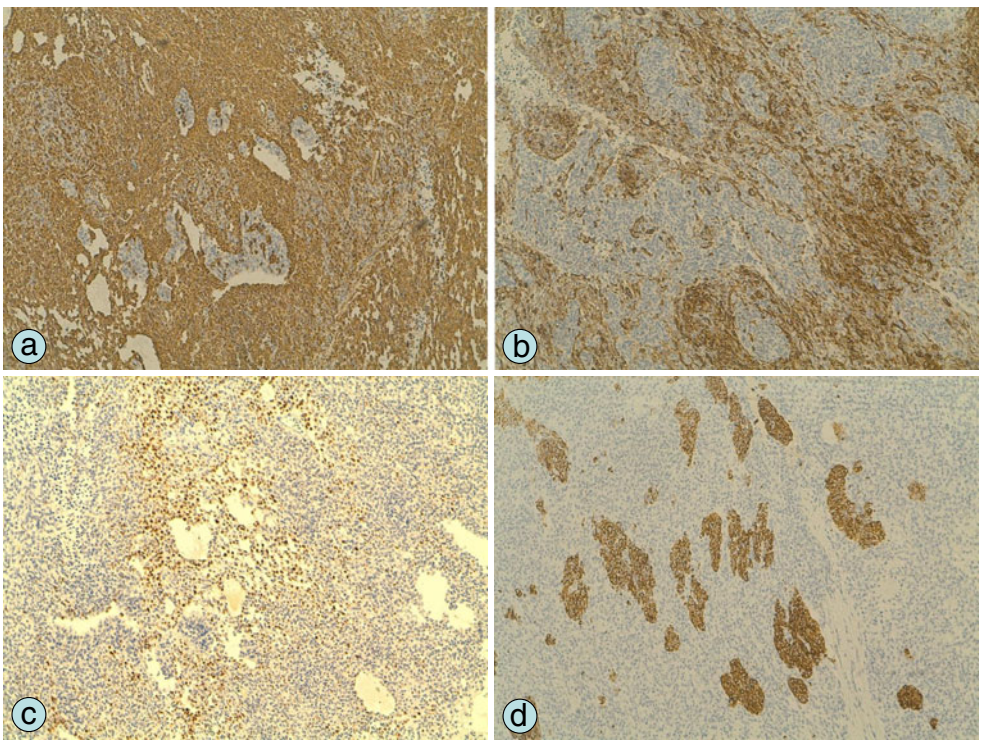

Fig. 5 Immunohistochemical features. The spindle cell component was positive for vimentin (**a**), smooth muscle actin (**b**), and progesterone receptor (**c**). The epithelial elements were positive for keratin 7 (**d**)

salivary gland or skin adnexal are not likely to occur in the gastrointestinal tract. A GIST is excluded because the tumor lacked immunoreactivity for KIT and DOG1. The morphology lacked distinct squamoid nests or acinar differentiation, excluding a diagnosis of pancreatoblastoma. Lack of expression of neuroendocrine markers excluded gangliocytic paraganglioma.

Our patient is still in full remission 16 months after surgery, with no evidence of tumor recurrence on surveillance CT scans. Of Miettinen's cases, the three patients were reported as alive, including one without any recurrence for 14 years. This suggests that these tumors should be considered as of low-grade malignancy.

Conclusion

We report an epitheliomesenchymal biphasic tumor in the duodenum that differs from other digestive biphasic tumors such as carcinosarcoma, synoviosarcoma, or teratoma. Four cases of gastric location have been recently described in the literature, and our case is both clinically and morphologically very similar to these. Although the immunohistochemical profile is slightly different, we believe this tumor to be similar to the gastroblastoma described by Miettinen.

Conflict of interest None.

ORIGINAL ARTICLE

The significantly reduced number of interstitial cells of Cajal in chagasic megacolon (CM) patients might contribute to the pathophysiology of CM

Abstract In addition to neurons, interstitial cells of Cajal (ICC) play an important role in coordinating intestinal motility with a pacemaker function. This study aimed to quantitatively analyze ICC, neurons, and muscular area, the latter to correct for quantitation errors resulting from dilation in case of a megacolon and from the dispersion of ICC that can be attributed to muscular hypertrophy. We analyzed 30 colon samples: ten chagasic megacolon (CM), ten chagasic colons without megacolon (CXM), and ten nonchagasic control patients (NC). We measured the area of muscularis propria and counted the number of neurons of the myenteric plexus in a histological section of an intestinal ring and the number of ICC at the level of the myenteric plexus and circular muscle layer, the latter in a section immunohistochemically stained for CD117. Muscular hypertrophy occurred only in the CM group. Compared to the NC group, we found in the CM group a statistically significant reduction of 80 % in the number of neurons, 60 % in the number of ICC in the myenteric plexus, and 38 % in the area of circular muscle. In the CXM group, these numbers were highly variable, and their reduction, less pronounced. We conclude that the number of ICC is significantly reduced in CM patients, and that this might contribute to the pathophysiology of CM. However, the development of CM requires severe denervation, whereas CXM generally exhibits less than 50 % denervation, favoring the hypothesis that the reduction in ICC number is, in part, a consequence of denervation.

Introduction

The World Health Organization estimates that there are 15 million people afflicted by Chagas disease in Latin America, with an annual incidence of 41,200 new cases and 12,500 annual deaths due to heart disease and digestive complications. With increasing population movement, Chagas disease has become a global challenge; nonendemic areas, including Europe and Japan, have reported cases of this disease, and it is estimated that there are currently more than 300,000 individuals infected with *Trypanosoma cruzi* in the USA [1]. Megacolon is the second most common manifestation of the digestive form of Chagas disease, which is found in 5–10 % of chronic Chagas patients in central Brazil. The digestive form of Chagas disease represents a model of intestinal denervation that affects digestive tract motility [2], and its study may help to further our understanding of other diseases that result in dysmotility.

The pathogenesis of chagasic megacolon has been linked to intramural denervation, particularly of the myenteric plexus [3–5], which impairs organ motility and dilation over time and is occasionally associated with organ elongation [3]. Köberle [3, 6] devised a way to correct neuronal counts for dispersion caused by dilation of the megacolon, which

often expands to three to four times its normal perimeter. According to Köberle [3], colon denervation in excess of 55 % could induce the development of megacolon, and denervation exceeding 90–95 % could result in megaesophagus, which was confirmed by Adad et al. [4, 5]. Notably, occasionally, a correction of neuronal counts was required to account for neuronal hypertrophy [5].

Recently, in addition to neurons, the interstitial cells of Cajal (ICC) have been demonstrated to play an important role in coordinating intestinal motility, functioning as pacemakers [7–9] that generate slow-wave activity [9, 10] and act as intermediaries in the spatial coordination of the neural activity of smooth muscle [11, 12]. Abnormalities in the ICC population have been reported in several intestinal motility disorders such as Hirschsprung's disease [13], congenital hypertrophic pyloric stenosis [14, 15], chronic idiopathic intestinal pseudo-obstruction [16], and slow-transit constipation [10]. Wedel et al. [10] evaluated patients with slow-transit constipation and megacolon (Hirschsprung's disease and congenital hypoganglionosis) and found a reduction of ICC with concomitant loss of neurons, suggesting a mutual influence between ICC and the enteric nervous system. According those results, ICC might "play a crucial role in the pathophysiology of colorectal motility disorders." However, the authors note that "there is no clear cutoff between controls and patients" with slow-transit constipation, as both groups have overlapping ICC values, "suggesting that a decreased number of ICC per se do not necessarily lead to symptoms of chronic constipation" [10].

Regarding the assessment of ICC in chagasic megacolon, we found only three studies [17–19]. However, none of these studies corrected for the dispersion of ICC and neurons induced by the dilation of the megacolon. Hagger et al. [17] and Geraldino et al. [18] noted that decreased ICC can promote the development of megacolon. However, a reduction of ICC in the colon does not necessarily induce megacolon development. Also, it is important to analyze ICC and neuron counts using a systematic and quantitative approach. The ICC in normal human tissues, which have an apoptotic rate of 1–2 %, are completely renewed every 6 months [20] and thus can easily regenerate. In contrast, neurons are postmitotic cells that do not regenerate in mature tissues after injury and elimination, despite functional compensation by noninjured neurons. Intense denervation can occur during the acute phase of Chagas disease, but megacolon generally develops several decades later, with slow and age-related loss of neurons, accompanied by the functional overloading and exhaustion of the residual neurons [3]. The slow, chronic, inflammation-induced destruction of neurons, which persists during the chronic phase, also contributes to denervation [4, 21].

This study aimed to quantitatively analyze ICC, neurons, and muscular area to correct for quantitation errors resulting from dilation in the megacolon and from the dispersion of ICC attributed to muscular hypertrophy. We, furthermore, investigated the possible correlation of these variables between the chagasic megacolon (CM) and chagasic colons without megacolon (CXM) groups, with the CXM group representing a transitional stage between normal and CM states.

Materials and methods

Colon tissue samples from 30 adults obtained from surgery (CM) or necropsy [CM, CXM, and nonchagasic control patients (NC)] were obtained for analysis and grouped as follows: ten from CM patients, ten CXM patients, and ten from NC; all patient ages were statistically similar (CM=54±13, CXM=52±16, and NC=57±21 years of age). The diagnosis of Chagas disease was based on a positive result in at least two of the following three blood and/or pericardial fluid reactions: ELISA, passive hemagglutination, and indirect immunofluorescence for *T. cruzi*. The diagnosis of megacolon was established from clinical (intestinal constipation frequently accompanied by complications, such as fecaloma and volvulus) and radiological data (opaque enema showing dilation and loss of haustration, possibly accompanied by lengthening of the colon, and/or single X-ray of the abdomen showing fecaloma and intestinal dilation).

A ring from the rectosigmoid transition was extracted, no more than 6 h after death or surgery, and the external perimeter and thickness of the muscularis propria were measured. The samples were then fixed in 4 % formaldehyde and processed for paraffin embedding.

Serial histological sections (7 μm) were cut; one was hematoxylin–eosin stained for overall evaluation; one was Masson's trichrome stained to measure the area of muscularis propria; one was Giemsa stained for neuronal counting, and one was immunohistochemically CD117 (c-kit) stained for ICC counts (DakoCytomation Code A4502 1:400 dilution; polymer technique). Chronic myositis was diagnosed when a mononuclear infiltrate associated with degeneration and/or necrosis of myocytes were found. Chronic ganglionitis was diagnosed when a mononuclear infiltrate was found within the ganglia of the myenteric plexus.

As the intestinal perimeter is much larger in the CM group compared to the NC group (Fig. 1) which causes dispersion of neurons, using a standard area for neuronal count in different groups would induce errors in these cell numbers. To correct for this potential error, we counted all of the neurons within the myenteric plexus in the Giemsa-stained section of a complete intestinal ring. For the CM group, in which neuronal hypertrophy (enlargement of the perikaryon of neurons) is detected, a correction factor was

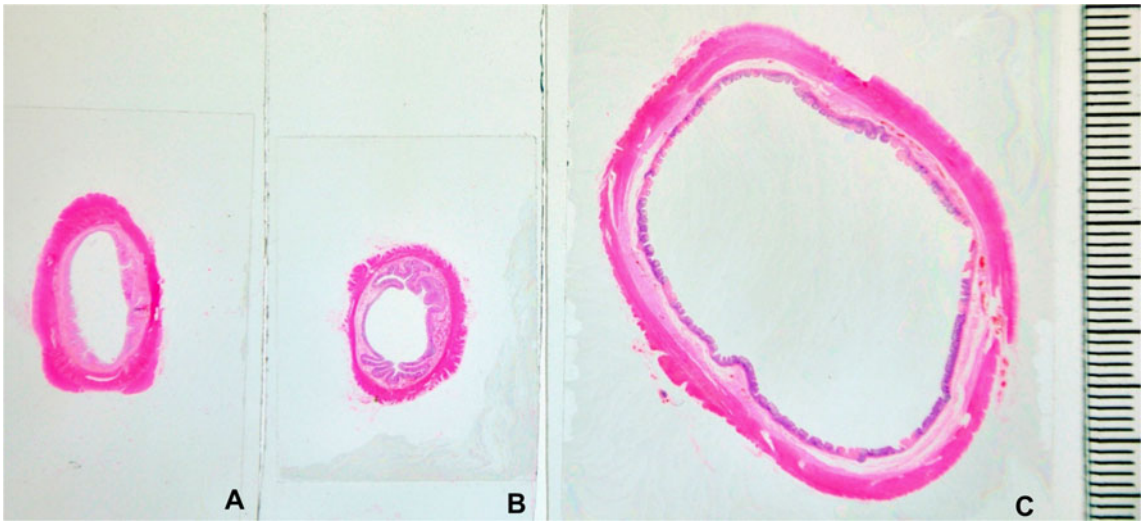

Fig. 1 Histological sections of intestinal rings, showing similar perimeters in a nonchagasic control intestine (**a**) and a chagasic intestine without megacolon (**b**), which have significantly smaller perimeters than that of chagasic patients with megacolon (**c**), highlighting the need for counting neurons throughout the ring in order to correct for the dispersion of these cells resulting from intestinal dilation

applied as described previously [5]. This correction factor was calculated by dividing the average ganglion cell diameter in the NC group (15.53 μm) by the average in the CM group (28.42 μm). This factor (0.62) was then multiplied by the number of neurons for each case in the CM group. ICC were counted at the level of the myenteric plexus and the circular muscle layer in half of a section ring due to technical immunohistochemical difficulties that limited the preservation of the entire ring within a single histological section. After counting, the resulting cell number was doubled to account for the uncounted half of section ring and for comparison to the number of neurons. The percentage neuron and ICC loss in each case was calculated, e.g., for neurons by subtracting from the average number of neurons in the NC group the number of neurons found in each case, divided by the average number of neurons of the NC group×100.

Immunohistochemistry

The sections were deparaffinized and rehydrated though a graded alcohol series ending in distilled water. The sections were then subjected to heat-induced antigen retrieval by immersion in a heat-resistant container filled with Tris-buffered solution containing EDTA and treatment in a pressure cooker for 30 min. Endogenous peroxidase activity was blocked by incubation with 3 % solution of H_2O_2 for 15 min. Immunostaining was performed using the polymer technique (Novolink, Novocastra), according to the manufacturer's protocols. ICC and mast cells were c-kit positive. Mast cells were round with a round central nucleus and served as an internal control. ICC exhibited a fusiform cell body with two or more processes; both nucleated cells and c-kit-positive elongated structures were considered ICC.

The measure of muscular areas was made directly on Masson's trichrome-stained histological sections with the aid of a graphic-measuring table coupled with a semiautomatic image analyzing system (MOP-Videoplan, Eletronik Kontron, Germany). First, the inner contour of the circular muscle layer and then the outer contour of the longitudinal muscle layer were outlined to measure the area (in square millimeters) of the muscularis propria. This measurement accounts for acute bowel distension due to excessive gas and fecal accumulation, which could alter the perimeter of the intestine and the thickness of muscular layer without changing its area.

For statistical analysis, the variables were evaluated using GraphPad Instat version 3.0. For variables with normal distribution, an analysis of variance was performed using Bartlett's test to assess the homogeneity of variance and the Kolmogorov–Smirnov test to assess whether the distribution was normal. Variables that did not exhibit normal distribution and/or heteroscedastic distribution were compared using the Kruskal–Wallis test. For all of the tests, the statistical significance was defined as $p<0.05$. Ethical approval for the study protocols was obtained from the research ethics committee of the Universidade Federal do Triângulo Mineiro, Uberaba, MG, Brazil.

Results

The neuron and ICC counts and the area of muscularis propria of each case are shown in box 1. The comparison between the mean values of each group is shown in Table 1.

Box 1 The patients' age as well as the intestinal perimeter, muscular layer thickness, area of the muscularis propria, number of interstitial cells of Cajal in the circular muscle layer and myenteric plexus and number of neurons in the myenteric plexus in a histological section of a full intestinal ring of the rectum-sigmoid transition, according to the study groups

NC nonchagasic patients, *CXM* chagasic patients without megacolon, *CM* chagasic patients with megacolon

[a] The number of neurons obtained in each case of the CM group was multiplied by a correction factor (0.62) to account for the enlargement of the perikaryon of neurons found in the CM group

We found that the intestinal perimeter, the muscularis propria thickness, and the muscularis propria area of the CM samples significantly increased compared to the NC and CXM samples ($p<0.05$), between which there were no significant differences. These data indicate that, in CM, the development of permanent dilation is accompanied by muscular hypertrophy.

In the CM samples, the number of neurons in the myenteric plexus was significantly reduced in comparison with both NC and CXM samples ($p<0.05$). The average percentage of denervation in the CM samples was 80 %, and in only 1 case, the loss of neurons was less than 55 % (in this case, the patient had been constipated for a year only). Neuronal loss in the CXM group was highly variable (ranging from 0 to 47 %, with an average of 20 %), which might explain why the difference between the CXM and NC groups was not statistically different ($p=0.07$), indicating just a trend (Table 1). Chronic ganglionitis was observed in nine (90 %) cases of the CM group and in four (40 %) cases of the CXM group, but not in the NC group. Chronic myositis was observed in nine (90 %) cases of the CM group and in two (20 %) of the CXM group, but not in the NC group (Fig. 2a–c).

[a] ANOVA

[b] Kruskal–Wallis test

There was a significant reduction in the ICC counts at the level of the myenteric plexus in the CM group compared to both the NC and CXM groups (p<0.05). However, although the ICC count was slightly lower in the CXM group than in the NC group, the difference was not statistically significant (p>0.05). The reduction of ICC counts in the CM group was more significant at the level of the plexus (average reduction of 60 %) than in the circular muscle layer (average reduction of 38 %). In the circular muscle layer, we observed a significant decrease in the ICC count in the CM group only relative to the NC group (p<0.05), which did not differ statistically from the CXM group (p>0.05) (Table 1, Fig. 2d–f).

Figure 3 shows the reduction in the number of neurons and ICC in CM and CXM groups compared to the NC group, which was found more striking in regard of the number of neurons. The CXM group seems to be an intermediate group between CM and NC.

Discussion

To our knowledge, this is the first study of ICC in the colon of Chagas patients without overt megacolon. It is also the first study to morphometrically evaluate CM and to study simultaneously the muscular hypertrophy and the number of ICC and neurons in the myenteric plexus. Additionally, counting cells in a complete intestinal ring in each case, instead of counting them in an identical area sample for all cases, allowed us to correct the neuron and ICC dispersion due to intestinal dilation and muscular hypertrophy of the megacolon.

The CM and CXM groups demonstrated significantly different ICC counts at the level of the myenteric plexus, but not in the circular muscle layer. The significant difference in ICC counts observed predominantly in the level of the myenteric plexus, where there was concurrent reduction of neurons, might suggest that the loss of ICC occurs after denervation, as the enteric neurons and the ICC are interdependent [10]. Furthermore, during the development and progression of Chagas disease, a population of ICC might have been simultaneously destroyed with enteric neurons as a result of ganglionitis, either during the acute phase or slowly during the chronic phase. At this phase, although the parasite load is low, it is nonetheless persistent [4, 21–24], providing constant and chronic antigenic stimulus to the immune system, favoring ganglial inflammation by cross reaction between antigens of *T. cruzi* and neuronal antigens [25–27].

Previous studies have only quantitated ICC in chagasic individuals with megacolon [17–19]. Our data, demonstrating a reduction of ICC in the level of the myenteric plexus in the CM group compared to the NC group, are consistent with previous findings by Hagger et al. [17], Geraldino et al. [18], and Iantorno et al. [19]. However, we detected a reduction—albeit less significant—in the number of ICC in the muscular layer, consistent with previous findings by Hagger et al. [17] and Geraldino et al. [18], but in contrast to those by Iantorno et al. [19]. Surprisingly, Iantorno et al. [19] found an increase in ICC in the muscular layer of the CM group compared to the NC group. These authors suggested that this finding could represent a compensatory mechanism and further commented that the ICC in the muscular layer are more

distal from the main inflammatory site in Chagas disease—the myenteric plexus. However, such results could at most account for a minor reduction in ICC, not an increase in ICC counts. Despite the regenerative capacity of ICC, myositis exists during the chronic phase of Chagas disease [4, 21], which contributes to the reduction of the ICC population.

Although muscle hypertrophy has been previously described and demonstrated in chagasic megaesophagus, there has been no morphometric characterization of the colon. In previous morphometric studies, we assessed cases from the current study, and an increase in the fibrous tissue in muscular layer of CM was observed [28, 29]. The connective tissue,

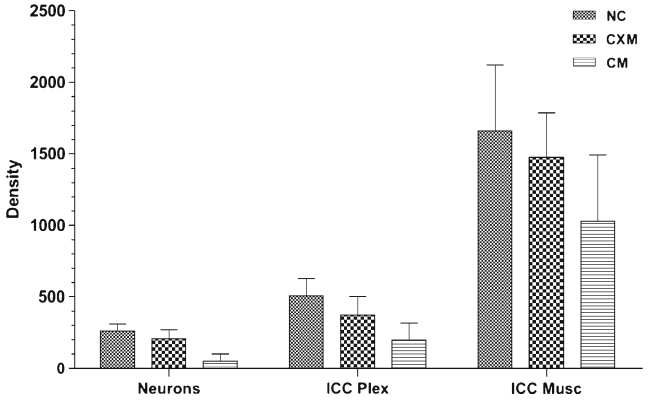

Fig. 3 Neurons and interstitial cells of Cajal density in the colon, according to the study groups. *ICC plex* ICC in level of the myenteric plexus, *ICC musc* ICC in the circular muscle layer, *NC* nonchagasic patients, *CXM* chagasic patients without megacolon, *CM* chagasic patients with megacolon

which accounted for 0.16 % of the muscle layer in the NC group, increased to 4 % in CM group [28]. Considering that, in the current study, we demonstrated a critical enlargement of 400 % in muscularis propria area in the CM group compared to the NC and CXM groups, it was predominantly due to muscular hypertrophy/hyperplasia. Had a compensatory hyperplasia of ICC occurred in the muscular layer in the CM cases, we would have detected such an increase in the number of ICC. This, however, did not occur, and we counted the ICC in half of an intestinal ring in all groups, rather than in equal areas in all three groups, consistent with the methods of other studies [17–19]. The paradoxical increase of ICC found in CM cases by Iantorno et al. [19] might be explained by mast cells, which are also c-kit positive. Mast cells progressively increase in number in CM patients [28, 29] and may have been included in the authors' ICC counts. Another explanation might be the distribution of ICC in different regions of the colon. Iantorno et al. [19] did not specify which region of the fragment was removed in cases of CM and idiopathic megacolon. They state that the distribution of ICC is relatively uniform in the human colon. However, data regarding the distribution of ICC in normal colon are contradictory; a study by Lyford el al. [30] argues for uniform distribution; however, studies by Horisawa et al. [31] and Hagger et al. [32] indicate that the distribution is heterogeneous.

Similar corrective studies could be performed to validate the results of previous studies that found a denervation and reduction of ICC in other diseases, such as idiopathic megacolon [19, 33], Hirschsprung's disease and congenital hypoganglionosis [10], or in patients with slow-transit constipation [10], as none of these studies corrected for ICC and/or neuron counts as a result of their dispersion during intestinal dilation. If the ICC reduction in these diseases is as significant as in chagasic megacolon cases, similar differences should be found. Regardless, Wedel et al. [10] highlights the overlap between the ICC values in the control group and slow-transit constipation, suggesting that the reduced ICC counts do not necessarily lead to symptoms of chronic constipation. Sanders et al. [12] suggest that the loss of ICC, which generates slow waves, reduces the myogenic regulation of motility, "but intact neural reflexes may compensate, to some extent, for loss of myogenic regulation and provide a means for propulsive behavior in tissues lacking pacemaker ICC and slow waves."

This study in chagasic megacolon indicates that diseases, which course with motility disorders, may have a reduced number of both neurons and ICC. However, the development of chagasic megacolon requires severe denervation, and the reduction of ICC may be, in part, a consequence of denervation. For this reason, we suggest that quantitative analysis of ICC should be associated to neuronal count.

Abstract ACLF is a condition with varied acute and chronic underlying etiologies and high mortality. Hepatic stellate cells (HSCs) are known to play an important role in hepatic fibrogenesis. Experimental data suggest that HSCs also display characteristics of hepatic stem/progenitor cells (HPCs). We investigated the number of activated HSC and their relationship to HPCs in ACLF in comparison to acute and chronic stages of other liver diseases. Immunohistochemical analysis of the number of activated HSCs and HPCs was performed in liver biopsies of 70 cases of ACLF and in the biopsies of patients with cirrhosis (45), acute hepatitis (25), chronic hepatitis (25), and normal live-related liver transplantation (LDLT) donor biopsies (15). The number of α-SMA-positive HSCs was assessed both quantitatively and semi-quantitatively. Keratin-19 (K19)-positive HPCs were estimated semi-quantitatively, and we looked for correlations between numbers of HSCs and HPCs. We found significantly more α-SMA activated HSCs/1,000 hepatocytes in ACLF biopsies (231±91) than in biopsies of patients with acute hepatitis (147±77), cirrhosis (73±35), chronic hepatitis (66±30), and normal LDLT donor biopsies (25±10), respectively ($p<0.0001$). A significant correlation between the presence of HPCs and ACLF versus other etiologies of liver disease was found ($p<0.001$). There was a significant correlation between the numbers of HPCs and of activated HSCs ($p<0.001$). ACLF is associated with more significant HSC activation than in acute hepatitis and other chronic liver diseases. There is a significant relationship between the presence of HSCs and that of HPCs, indicating a possible dynamic role of HSCs in liver regeneration and pathobiology of ACLF.

Introduction

Liver failure can develop either as acute liver failure in the absence of any preexisting liver disease, as chronic decompensation of an end-stage liver disease (ESLD), or as an acute deterioration of known or unknown chronic liver disease—the acute-on-chronic liver failure (ACLF) [1].

ACLF represents a newly described complication of cirrhosis that has received considerable attention recently because of its impressive presentation, high mortality, and impact on transplant allocation [2]. Due to donor scarcity, other approaches have been proposed, particularly cellular-based procedures using hepatic stem/progenitor cells (HPCs) [3]. There is paucity of histologic data in ACLF. Previous studies have emphasized the importance of liver biopsy in prognostication and determining the outcome by determining the extent of necrosis, liver damage, and fibrosis [1]. Recent focus is on the mechanisms of activation and differentiation of human HPCs and the interaction with their probable niche, and a liver biopsy can further provide vital information in this regard.

Liver fibrosis is widely acknowledged as a damaging process in long-term liver disease. Hepatic stellate cells (HSCs) are known to play an important role in the development of fibrosis and its progression to cirrhosis; however, their role in liver failure is not clear. Activated hepatic

stellate cells convert from vitamin-A-storing cells to contractile myofibroblastic cells responsible for extracellular matrix (ECM) production in the injured liver. There is growing evidence mainly from the experimental studies that HSCs possess signaling pathways required for stem/progenitor cell functions [4, 5].

To the best of our knowledge, none of the previous studies have tried to elucidate the role of HSCs in ACLF. We undertook this study to compare the number of activated HSC in ACLF with that in other acute and chronic stages of liver diseases and to determine their relationship with HPCs.

Patient selection

ACLF cases (70) were diagnosed by the APASL criteria. The APASL's definition of ACLF is "acute hepatic insult manifesting as jaundice and coagulopathy, complicated within 4 weeks by ascites and/or encephalopathy in a patient with previously diagnosed or undiagnosed chronic liver disease" [6].

Chronic hepatitis (25) included in the study was viral hepatitis, with fibrosis stage of 2–3 according to the modified Ishak's system [7]. Chronic hepatitis represents a series of liver disorders of varying causes and severity in which hepatic inflammation and necrosis continue for at least 6 months [8].

Acute hepatitis represents liver disorders in which hepatic inflammation and necrosis last for less than 6 months. Of acute hepatitis with compatible histology, 25 cases were included in the present study.

In the study were also included 45 cases of cirrhosis. Cirrhosis is a condition that is defined histopathologically by the development of fibrosis and architectural distortion with formation of regenerative nodules. It has a variety of clinical manifestations and complications [8].

Grading of necroinflammatory activity and fibrosis staging in chronic hepatitis and cirrhosis was done by a modification of the Ishak system [7].

Methods

Liver biopsy

All of the biopsies in the ACLF group were done by transjugular approach, except for two cases in which explant liver sections were available for immunohistochemistry. Mean biopsy length was 12 mm. Formalin fixed, paraffin-embedded serial sections of the liver biopsies of ACLF group were reviewed retrospectively. The pathologist was blinded to all clinical and histological findings, and liver biopsies of the five study groups (ACLF, acute hepatitis, chronic hepatitis, cirrhosis, and normal LDLT donor biopsies) were randomly numbered before immunohistochemical analysis.

Immunohistochemistry

Activated HSCs were stained by immunohistochemistry (IHC) using a monoclonal antibody for α-smooth muscle actin (α-SMA) (ready to use, clone HHF35, Biogenex, CA, USA); hepatic progenitor cells (HPCs) were assessed by anti-keratin 19 (K19) (ready to use, clone RCK 108, Biogenex, CA, USA).

Immunohistochemical staining was performed by peroxidase-enzyme-labeled streptavidin-biotin (LSAB) detection method using Polymer-HRP kit (Biogenex, San Ramon, USA) with diaminobenzidine (DAB) as a chromogen and Meyer's hematoxylin for contrasting. Muscle cells of small arterial profiles in the portal tracts served as a positive internal control. Negative control was performed by leaving out the primary antibody during the staining procedure.

Sections taken on poly-L-lysine-coated slides were deparaffinized. Endogenous peroxidase blocking was done by 3 % hydrogen peroxide in distilled water for 10 min. Heat retrieval was done in Tris buffer solution (TBS) (PH 6.0) in two cycles for 2 min half power and then full power, respectively, in microwave and cooled at room temperature. Protein block was applied for 5 min. Treatment with primary antibody with positive control was done for 1 h, secondary antibody for 20 min, and tertiary (streptavidin) for 20 min. TBS rinse was done after each step. Sections were treated with DAB for 10 min and counterstained with hematoxylin.

Assessment of activated HSCs

Both quantitative and semi-quantitative methods were used to assess the number of activated HSCs.

Quantitative assessment was expressed as the "hepatic stellate cell index" (HSCI), i.e., the number of HSCs per 1,000 hepatocytes [9]. Activated HSCs were counted using oil immersion objective (×1,000) of an Olympus BX51 microscope.

Semi-quantitative assessment was done by determining the percentage of α-SMA-positive HSCs in the perisinusoidal spaces (modification of Schmitt-Graff et al.) [10]. HSCs were counted in specific areas of liver biopsy, in ≥5 fields each of perivenular area, intermediate area, and periportal areas using ×100 and ×200 magnification.

Grading on a scale of 0–4 was performed: with 0, no staining; 1 (up to 10 % of sinusoidal surface showing activated HSCs); 2 (11–30 %); 3 (31–70 %); and 4 (71–100 %). Grades 3 and 4 were considered significant for statistical analysis.

HPCs were also semi-quantitatively estimated on a scale of 0–4, by counting HPCs at ×200 magnification in three to five

non-overlapping fields (0—no cells, 1—1–10 HPCs, 2—11–30 HPCs, 3—31–70 HPCs, 4—>70 HPCs). HPCs were distinguished from intermediate hepatocytes by their smaller size, scanty cytoplasm, and more intense K19 immunostaining [3].

Statistical analysis

Correlation of HSCs/1,000 hepatocytes was done with the etiologic groups (HBV reactivation, alcoholic hepatitis superimposed on alcoholic liver disease, acute viral infection on chronic liver disease, and cryptogenic).

The number of activated HSCs was compared between two groups by the Mann–Whitney test and among more than two groups by the Kruskal–Wallis test. HPC activation in ACLF versus other groups was determined by Pearson's Chi-square test. The relationship between HSCs and HPCs was assessed by the Kruskal–Wallis test. Correlation of HSCs with etiology in ACLF was done by Kruskal–Wallis test. A p value <0.001 was considered to indicate significant difference.

Results

Demographic and biochemical characteristics

A total of 165 liver biopsies of an equal number of patients and 15 normal living donor transplantation biopsies were included in this study.

The mean age of ACLF patients was 46.1±13.2 years (median 47 years, range 13–71 years), with male predominance (male to female 5:2). Mean serum bilirubin and albumin levels were 20.5±11.3 mg/dl and 2.2±0.4 g/dl, respectively.

The mean age of chronic hepatitis patients was 40.1±14.3 years, with a male-to-female ratio of 17:8; for acute hepatitis, the mean age was 39±17 years, and the male-to-female ratio was 18:7; for cirrhosis, the mean age was 46.4±10.4 years, and the male-to-female ratio was 24:21.

Etiology of acute insult and chronic liver disease in ACLF

Chronic liver disease was due to hepatitis B virus (n=23), alcohol (n=23), and cryptogenic (6), and HCV, NASH, PBC, and autoimmune hepatitis were the underlying etiology in the rest. Acute decompensation was due to viral etiology (n=32), alcohol (n=19), drugs (n=5), and unknown in the rest. Major etiologic groups were reactivation of chronic hepatitis B (n=19) and acute alcoholic hepatitis superimposed on alcoholic liver disease (n=19) (Table 3).

Acute hepatitis comprised of HAV (8), HEV (8), HBV (7), and drug induced (2). The chronic hepatitis group comprised HBV (17), HCV (7), and combined HBV and HCV (1), and the cirrhosis patients were of ALD (6), HBV (13), HCV (21), NASH (4), and cryptogenic (1).

Histological characteristics of ACLF

All of the cases showed histological features of acute and chronic hepatitis in variable combinations as described in our previous study [1]. Ballooning or eosinophilic degeneration of hepatocytes, cellular and canalicular cholestasis, ductular proliferation and ductular bile plugs, variable degree of parenchymal necrosis/collapse, lobular inflammation, apoptosis, sinusoidal cell activation along with the features of chronic liver disease as periportal fibrous extensions, bridging fibrosis or cirrhosis, pericellular fibrosis, and interface activity were seen in the ACLF biopsies (Fig. 1a, b).

Activated HSCs as detected by α-SMA immunohistochemistry

HSCI was highest (231±91) for the ACLF group as compared to 147±77, 66±30, 73±35, and 25±10 for acute hepatitis,

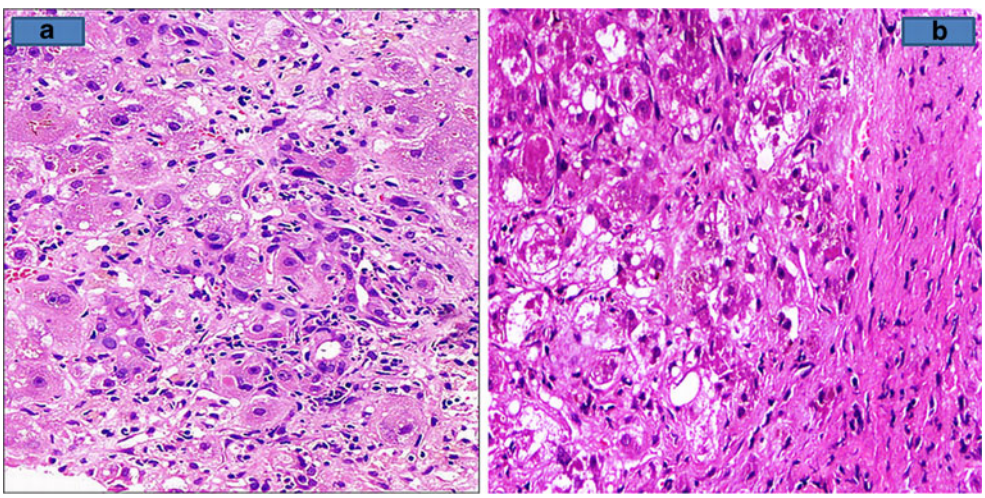

Fig. 1 **a** H&E-stained section showing periportal fibrous extensions, pericellular fibrosis and interface activity, eosinophilic degeneration of hepatocytes, and cellular and canalicular cholestasis (×200). **b** H&E-stained section showing fibrous bands, ballooning degeneration hepatocytes with Mallory hyaline bodies, cellular/canalicular cholestasis, and eosinophilic degeneration (×200)

Table 1 Hepatic stellate cell index (HSCI) in ACLF and other groups

α-SMA immunostained activated HSCs	ACLF	Acute hepatitis	Cirrhosis	Chronic hepatitis	Normal	*P* value
HSCs/1,000 hepatocytes	231±91	147±77	73±35	66±30	25±10	$P<0.0001$
Zone 1 HSCs (%)	58±12	42±17	31±17	18±10	8±4	$P<0.0001$
Zone 2 HSCs (%)	44±14	25±14	17±11	11±6	7±4	$P<0.0001$
Zone 3 HSCs (%)	50±14	39±17	23±13	15±9	8±4	$P<0.0001$

chronic hepatitis, cirrhosis, and normal LDLT biopsies, respectively ($p<0.001$). Mean HSC percentage was significantly higher in all of the three acinar areas in ACLF in comparison to the other groups ($p<0.001$) (Table 1) (Fig. 2a–d).

Semi-quantitative analysis revealed a significantly higher number of cases with activated stellate cells (high grade) in periportal, intermediate, and perivenular areas in the ACLF group ($p<0.001$) (Table 2).

In ACLF, there was no significant correlation of the number of HSCs/1,000 hepatocytes with any of the etiologic groups ($p=0.95$).

Relationship of activated HSCs with HPCs

There was a significant correlation between the number of K19-positive HPCs and ACLF in comparison with other etiologies of liver disease ($p<0.001$). There was a significant correlation between the number of HPCs and number of HSCs/1,000 hepatocytes (Table 3). Along with an increase in the number of HSCs, the number of HPCs increased significantly (Table 4).

Discussion

This is the first study to analyze HSC activation and its correlation with HPCs in ACLF. Immunohistochemical analysis of the number of activated HSCs as detected by α-SMA staining and HPC activation as detected by K19 immunostaining in ACLF was compared in biopsies of liver diseases of different stages including acute hepatitis, chronic hepatitis, cirrhosis, and normal LDLT. The number of activated HSC was significantly higher in the ACLF as compared to the other groups. Activated HSCs were observed in decreasing frequency in ACLF, acute hepatitis, cirrhosis, chronic hepatitis, and normal LDLT donor biopsies, respectively. There was a significant correlation between the number of HSCs and that of HPCs, which suggests that they play a role in liver regeneration. None of the previous studies have explored HSC activation and their correlation with liver regeneration in ACLF.

There are limited data on the entity of ACLF, but in recent years, this syndrome has gained a lot of interest, and at present, considerable efforts are ongoing to better

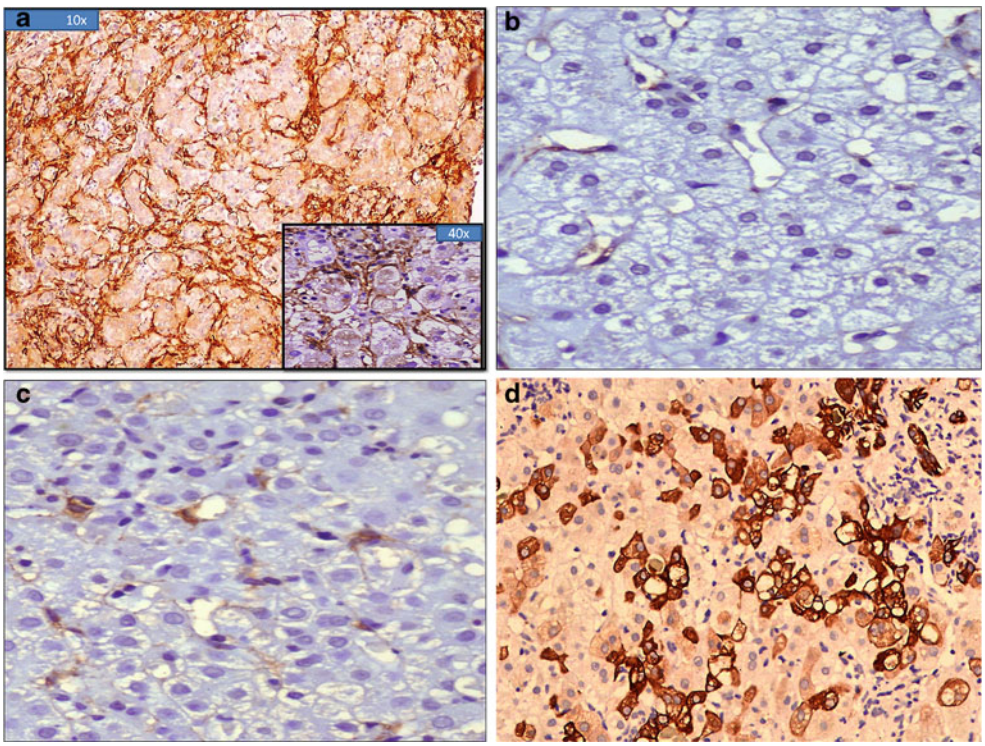

Fig. 2 **a** α-SMA immunohistochemistry showing activated HSCs in ACLF (×100), with SMA-positive stellate cell in inset (×400). **b** Minimal SMA expression seen on a biopsy of chronic viral hepatitis (×200). **c** Focal mild SMA (hepatic stellate cell activation) on a biopsy of acute viral hepatitis (×200). **d** K19 immunohistochemistry showing a fair number of HPCs and intermediate hepatocytes in ACLF (×200)

characterize the syndrome, to gain further insight into its pathophysiology, and to optimize therapy [2]. ACLF is potentially reversible, and early and accurate diagnosis and prognosis of patients are of critical importance for optimal management.

There is a paucity of literature on liver biopsy in ACLF. A recent study by our group [1] has highlighted the role of liver biopsy features as outcome predictors. Liver biopsies in ACLF display features of acute injury and chronic liver diseases with/without necrosis, in varying combinations and with variable severity. Hepatocyte ballooning, eosinophilic degeneration, rosette formation, apoptosis, fatty change, cholestasis (hepatocyte, canalicular, bile ductular, and ducts), lobular inflammation, portal inflammation, Mallory–Denk body, several foci of confluent necrosis with or without bridging necrosis with portal/periportal fibrosis, ductular proliferation, pericellular fibrosis, and cholangiolitis can all be seen in these biopsies [1]. Extensive necrosis, ductular cholestasis, eosinophilic degeneration of hepatocytes, and advanced fibrosis have been shown to be important histological predictors of poor outcome [1].

In the normal liver, HSCs comprise approximately 1.4 % of total liver volume and are present at a ratio of about 3.6 to 6 cells per 100 hepatocytes (or 1:20) [11, 12]. It is widely accepted that HSCs contribute to liver fibrosis. HSC cells reside within the perisinusoidal space of Disse in the liver that is lined by parenchymal cells and fenestrated sinusoidal endothelial cells (SECs). HSCs can develop into myofibroblast-like cells that synthesize extracellular matrix proteins and contribute to liver fibrosis [11, 13–15]. Activated HSCs loose lipid droplets stored in their cytoplasm, proliferate, and gain abundant microfilaments that consist mainly of α-smooth muscle actin (α-SMA) [16]. Activated hepatic stellate cells are identified by using a specific monoclonal antibody to detect cytoplasmic alpha smooth muscle actin (alpha-SMA), which is not present in quiescent cells [17].

Table 3 Etiological classification of ACLF patients (n=70)

Etiology of chronic liver disease	Etiology of acute insult	
Hepatitis B (n=23)	Reactivation of hepatitis B	(n=19)

	Drugs	(n=3)
	Unknown	(n=12)

There are scarce animal experimental data suggesting that mesenchymal cells such as stellate cells physically interact with oval cells and induce signals in them [18]. A recent study has shown that stellate cells of the rat liver display characteristics of stem/progenitor cells. They express CD133 (cluster designation 133) and Oct4 (octamer 4), markers expressed on pluripotent stem cells, which supports the notion that HSCs can differentiate into hepatocyte-like and endothelial-like cells in vitro and points to the role of HSCs in liver regeneration [19]. Another experimental study has provided similar information that HSCs are directly involved in restoration of liver mass even in vivo [20]. Savitza et al. have highlighted the interrelationship between stellate cells, β-catenin-dependent Wnt signaling, and the Notch signaling, which are considered to characterize the stem cell niche for HPCs. Stellate cells have also been shown to possess signaling pathways required for stem cell functions such as hedgehog and β-catenin-dependent Wnt signaling in other studies [21].

Recently, a clinical study in acute liver failure (ALF) patients has provided evidence of increased α-SMA expression, increased stiffness as measured by transient elastography, and increased serum TIMP and MMP levels [22] and has thus raised several questions regarding the role of stellate cells in liver failure such as the role of hepatocellular death in HSC activation and fibrogenesis. Also, there is a recent interest in HSCs as they display characteristics of stem cells. Our study also highlights that HSCs probably have an important role in liver regeneration.

Relevance of molecular signaling pathways for HSCs and their role on stem cell proliferation, differentiation, and their niche is unclear. It is of utmost importance to investigate the interactions of HSCs with other postulated characteristics of the stem cell niche, such as Notch and Wnt signaling in liver failure.

Future studies in a similar cohort of human liver diseases of different etiologies and stages using immunohistochemical markers and molecular studies for death signaling, HPCs, and their niche and HSCs are needed to confirm these initial observations and might provide further insight into liver injury and repair mechanisms and may help to improve therapeutic interventions in these currently untreatable human liver diseases.

Conclusion

ACLF is associated with higher numbers of activated HSC in comparison to acute hepatitis and chronic liver diseases. There is a significant relationship between the number of HSCs and of HPCs, indicating a possible dynamic role of HSCs in liver regeneration and pathobiology of ACLF.

Tumor architecture exerts no bias on nuclear grading in breast cancer diagnosis

Abstract We recently reported that nuclear grading in prostate cancer is subject to a strong confirmation bias induced by the tumor architecture. We now wondered whether a similar bias governs nuclear grading in breast carcinoma. An unannounced test was performed at a pathology conference. Pathologists were asked to grade nuclei in a PowerPoint presentation. Circular high power fields of 27 invasive ductal carcinomas were shown, superimposed over low power background images of either tubule-rich or tubule-poor carcinomas. We found (a) that diagnostic reproducibility of nuclear grades was poor to moderate (weighed kappa values between 0.07 and 0.54, 27 cases, 44 graders), but (b) that nuclear grades were not affected by the tumor architecture. We speculate that the categorized grading in breast cancer, separating tubule formation, nuclear pleomorphism, and mitotic figure counts in a combined three tier score, prevents the bias that architecture exerts on nuclear grades in less well-controlled situations.

Introduction

Despite major advances in our understanding of breast cancer biology and the advent of novel diagnostic tools to predict survival and treatment response of breast cancer patients (i.e., MIB-1, IGkG, genetic tests, etc.) [1–3], time-honored tumor grading has been confirmed as one of the most reliable prognostic and predictive markers [4]. Grading of breast carcinomas is based on three histomorphological criteria: degree of tubular differentiation, nuclear pleomorphism, and mitotic figure count [5, 6]. Recently, we found that nuclear grading in prostate cancer is subject to a strong confirmational bias induced by the tumor architecture: pathologists unconsciously assigned grades for nuclear pleomorphism that matched the Gleason grade—irrespective of nuclear morphology [7, 8]. This phenomenon is of little clinical consequence in prostate cancer, where prognosis is predicted by tumor architecture and not by nuclear grade [7]. However, we wondered whether the same heuristic phenomenon could be operative in the grading of breast cancer, potentially leading to a clinically relevant loss of prognostic/predictive information.

Methods

In analogy to the prostate cancer experiments [8], we prepared a PowerPoint presentation, where circular images of high power fields (HPF, Ø0.62 mm) of 27 invasive ductal carcinomas were superimposed over low power background images with the tumor architecture. The photographs were taken from a historical collection of cases from 1993 to 1995 at the University of Mainz [2, 4], for which specific patient consent had been obtained. No patient identifiers were known. In a random order, each HPF image was shown twice, once superimposed over a background image of a well-differentiated, tubule-rich carcinoma and once superimposed over an image of a poorly differentiated, tubule-poor carcinoma (Fig. 1a). In order to avoid recognition of the HPFs after the first presentation, the circular images belonging to the same case were rotated and flipped using Photoshop (Adobe, CS3, St. Jose, CA). With permission from the organizers of the joint annual meeting of the Austrian and the Swiss Societies of Pathology in Feldkirch in November 2010, this presentation was shown to the audience of a plenary session. Each HPF was displayed for 7 s, followed by a 1-s transition in which the background image of the next case was shown (Fig. 1b). The 7 s was chosen based on previous experience with a similar experimental setup, where nuclei were displayed on a computer screen for 8 s, and where the pathologists spoke out loud the nuclear grade at an average of 4–5 s into the 8-s interval. The presentation of the 60 HPF hence lasted exactly for 8 min. The experiment had not been announced (it "spontaneously" replaced a talk that was printed in the program book). In a brief introduction, pathologists were asked to grade nuclear pleomorphism of the projected HPFs on a five-tier scale (1, 1–2, 2, 2–3, and 3) and note the grades on a form that they found on their seats. No information was given concerning the true aim of the experiment. In particular, no mention was made of the background images. It was hence left to the "imagination" of the participants to assume that the background images belonged to the high power fields. This was the exact same experimental situation that we had used before in the prostate cancer experiments in which we had found a strong architectural bias on nuclear grading [8]. The only additional information that was asked from the participants was the number of years in practice. Statistical analyses included weighed kappa analyses and paired *t* tests (www.wessa.net).

Results

Fifty-eight of the conference attendees (70–80) participated in the experiment. Data from 14 participants were discarded since they did not rate all HPFs. Thirty-six of the remaining 44 raters indicated the number of years of experience. The reliability of nuclear grade assignment ranged from moderate to good for about half of the HPFs (n=14, weighed kappa values 0.25–0.54) and poor for the other half of the HPFs (n=13, weighed kappa values 0.07–0.25). Grading consistency was not affected by the years of professional experience (data not shown).

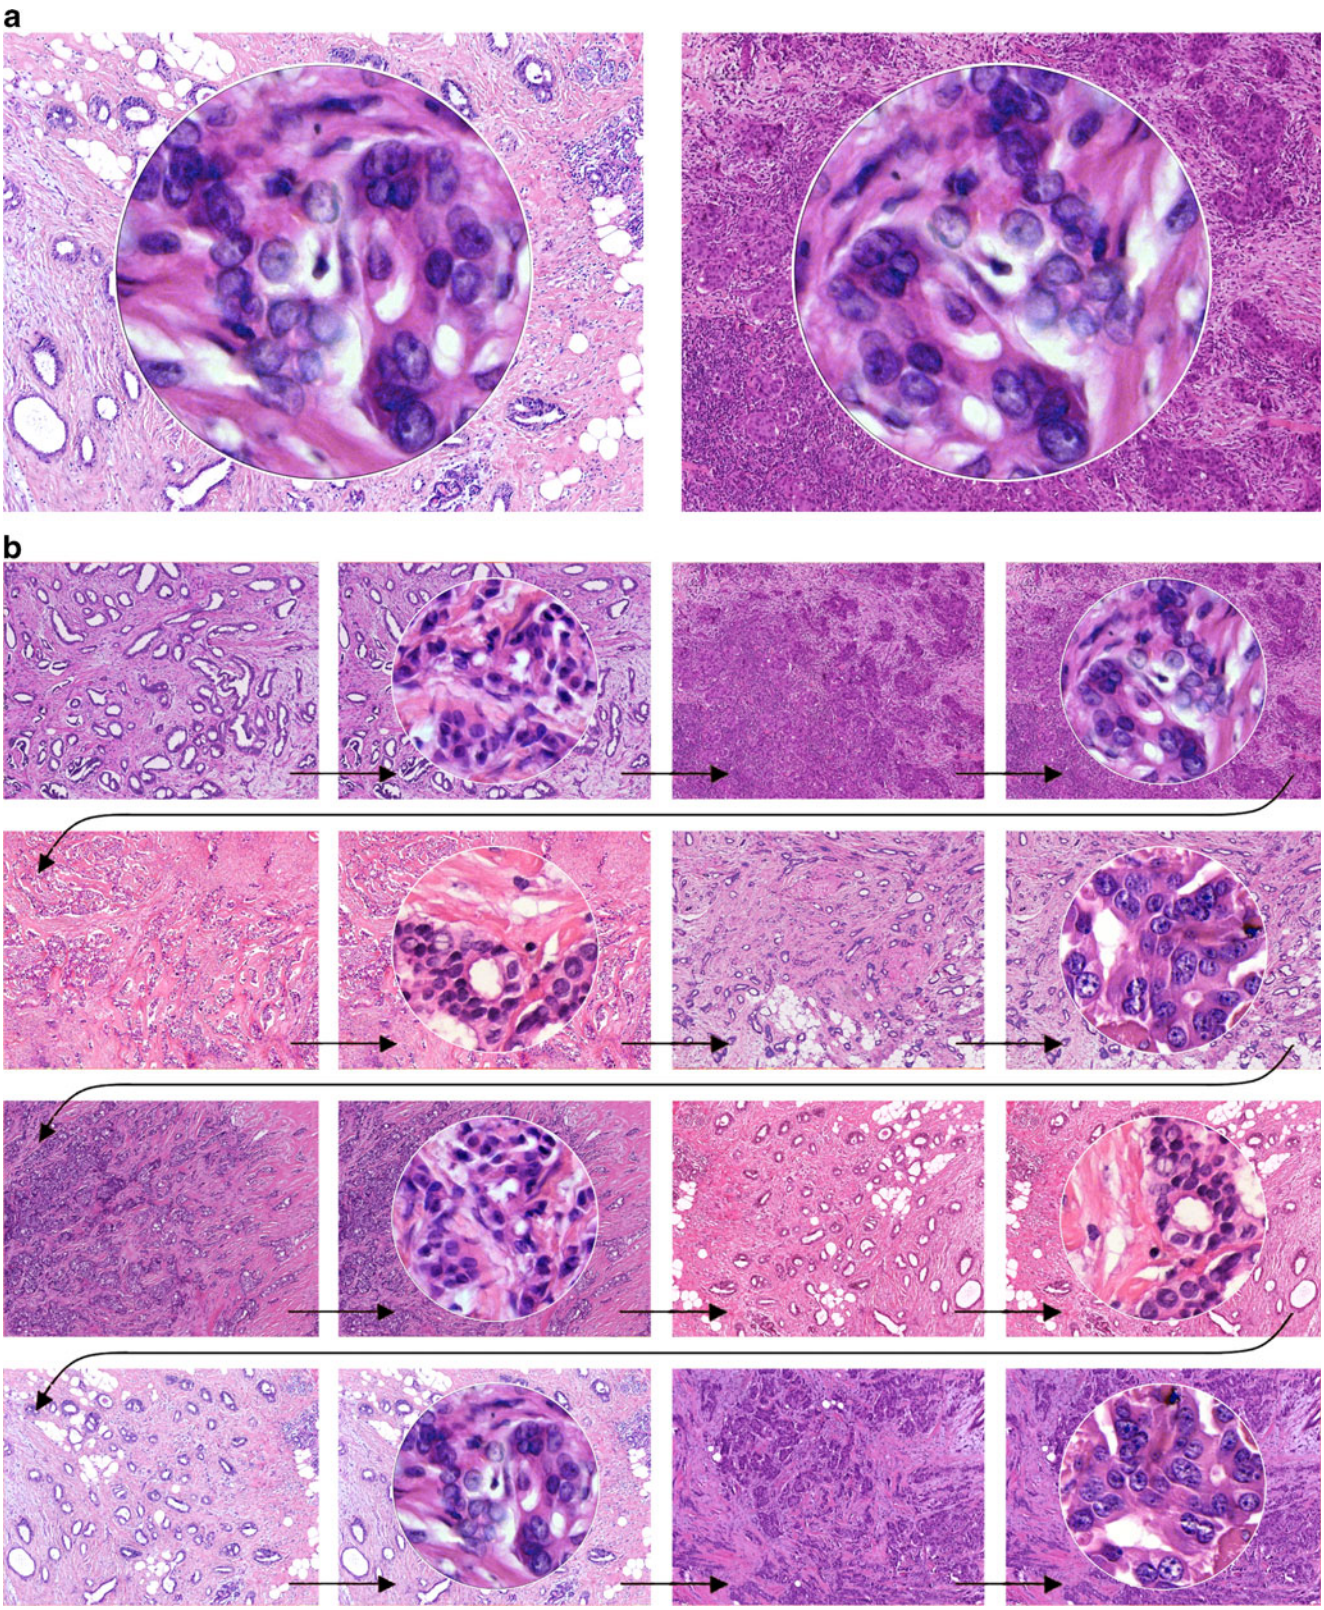
Average nuclear grades assigned to the HPFs superimposed over tubule-rich backgrounds (2.10±0.63) were comparable to average grades assigned to the same HPFs superimposed over tubule-poor backgrounds (2.15±0.62), suggesting that tumor architecture did not influence nuclear grade assignment. Also, the difference of the tubular differentiation of the background images did not influence nuclear grades (1.92±0.63 for 16 HPFs presented before pure tubular backgrounds vs. 2.00±0.67 for the same HPFs presented before solid backgrounds, n.s.).

We also found that the professional experience of the participants had no influence on the results: neither did we see any effect of tubule formation on nuclear grades in n=11 beginners (1–3 years of professional experience; 2.03±0.42 vs. 1.99±0.44), in n=13 more experienced pathologists (4–10 years of experience; 2.13±0.48 vs. 2.16±0.47), nor in n=12 "old-timers" with more than 10 years of experience (2.11±0.46 vs. 2.15±0.47). These results are shown in a graphic form in Fig. 2.

Fig. 1 PowerPoint presentation showing high power fields superimposed over different architectural backgrounds. Using a beamer, HPFs of 27 invasive ductal carcinomas were projected in the plenary lecture hall of a pathology conference. Unknown to the participants, each high power filed was shown twice, superimposed once over a well-differentiated, tubule-rich background image and once over a poorly differentiated, tubule-poor background image (**a**). In order to avoid recognition, high power fields were flipped and rotated within their circular inset (**a**). The presentation was automatically timed to show each HPF for 7 s. Between HPFs, the background image of the next case was shown for 1 s (**b**). Pathologists were asked to assign nuclear grades for each HPF and note their grade on a form that they found on their seats. The present figure was specifically created for this publication to demonstrate the principle, but using only a limited set of only four high power fields, each shown twice, superimposed over the distinct (tubule-rich or tubule-poor) background images. In the original presentation, a total of n=27 cases were randomly presented

Discussion

The principal finding of this experiment is that grading of nuclear pleomorphism in invasive ductal breast carcinoma is not affected by the tumor architecture. This finding is unexpected, as it does not confirm our prior observations in prostate carcinomas [7, 8]. In these previous studies, we found that nuclear grade assignment was unconsciously affected by a powerful confirmation bias induced by the tumor architecture. In Bombari's study [8], each of 20



pathologists was assigned lower pleomorphism grades to the nuclei of high power fields when these had been superimposed over a background of a tubule-rich carcinoma (Gleason pattern 3) and significanly higher grades when the same high power fields were shown a little later superimposed over an image of a cribriform or solid carcinoma (Gleason

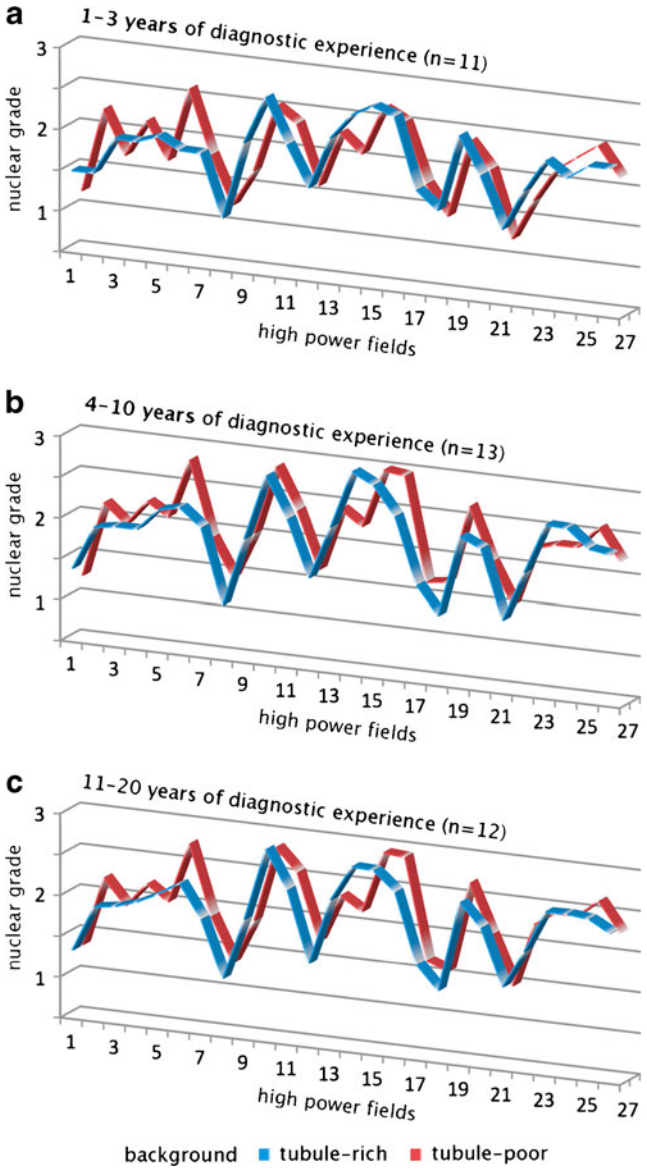


Fig. 2 Nuclear grades assigned to 27 pairs of high power fields superimposed over tubule-rich (*blue*) or tubule-poor (*red*) backgrounds. The data are shown for three subgroups of pathologists with various years of experience. **a** 1–3 years of experience, $n=11$; **b** 4–10 years of experience, $n=13$; **c** 11–20 years of experience, $n=12$. Note that for most high power fields, pathologists assigned similar nuclear grades, largely unaffected by the architecture of the background images

patterns 4 or 5). Tracking pathologists' eye fixations further showed that depending on the tumor architecture of the background image, pathologists looked at different nuclei within the high power fields: they fixated on smaller nuclei with evenly distributed, pale chromatin when the background showed a Gleason 3 pattern and on larger, hyperchromatic nuclei when the background was a Geason 4 or 5 pattern [8]. However, this selection of nuclei that "matched the expectation" accounted for only about one tenth of the total grade gravitation, suggesting that nuclear selection represents an unconscious strategy of our minds to vindicate the confirmation bias induced by the tumor architecture [8].

In the present study, we found that this powerful confirmation bias is not operative in breast cancer grading, even though the participants had exactly the same chance to explore tumor architecture and nuclear pleomorphism on the projected tumor images as they had in the previous experiments on prostate cancers [8]. In analogy to well-established modes of avoiding optical illusions by the adherence to strict guidelines and rules in aviation [9], we assume that the rigid grading system of breast cancer that was initially established by Bloom and Richardson [5] and later modified by Elston and Ellis [6] effectively prevents cross-category biases. By experience, pathologists know that in breast cancer, architecture and nuclear grade do not necessarily go along hand in hand. For instance, lobular carcinomas show no tubular differentiation (grade 3), but usually little nuclear pleomorphism (grade 1). In contrast, every pathologist has seen carcinomas with "ugly" nuclei (grade 3), but with more or less well-formed tubular architecture (grade 1). In breast cancer diagnosis, it hence poses no "conflict" for our minds to see small, round, and pale nuclei and correctly assign them a grade 1 even though the low power image in the background displays an architecturally undifferentiated (grade 3) carcinoma without any formation of tubules. In this context, it should be noticed that the pathologists who participated in the study all practice in Austria and in Switzerland, where the adherence to the three tier Bloom and Richardson grading system is generally very high. Also, it may be of interest to note that most pathologists in these two countries practice in a rather "generalist" approach, with only few departments being organized in subspeciality services, and that the session, in which the experiment was performed, had no particular breast focus. This suggests that the results of our study can be applied to most diagnostic pathologists.

In this experiment, we have focussed on the degree of tubule formation as leading architectural pattern. Another histological feature that may have potentially biased the partcipants is the relative amount of stroma between tumor cells. Pathologists tend to be quite vigilant to morphological cues that contribute, sometimes quite unconsciously, to the interpretation of the complex image on the H&E-stained slide. These cues are not always easily quantifiable, such as the percent of tubule formation or the number of mitotic figures, but are often quite subjective in nature, such as the presence and the extent of necrosis, the type and amount of peritumoral stroma, or the peritumoral lymphocytic response, to name only a few of the more obvious features. In a less well-controlled situation, as we have identified recently in prostate cancer grading [7, 8], such additional morphological features will likely affect overall cancer grading. However, the findings of the present study, where tubule formation did not affect nuclear grading (Fig. 2), suggest that in breast cancer grading, where the well-standardized and

widely applied Bloom and Richardson criteria separate architectural features from nuclear features and from mitotic figure counts, stroma will likely not affect nuclear grading.

The second observation that we made in the present study is that grade assignment to nuclei in high power fields is surprisingly inaccurate. We used weighed kappa analysis to quantify the consistency of grade assignment to the 27 pairs of high power fields. The interobserver reliability was poor in about half of the cases (weighed kappa values below 0.25) and moderate to good in the other half of the cases (kappa values between 0.25 and 0.54). We acknowledge that the experimental setup used in this study had a different primary aim. Also, grade assignment on a single projected high power field certainly does not reflect the situation that pathologists encounter during routine cancer grading, where they scan thousands of nuclei during nuclear grade assignment and not only those in one high power field. Nevertheless, our findings correlated rather well with kappa scores for interobserver reliability of nuclear pleomorphism in prior reports (range 0.3 to 0.4) that have underscored the limitations of this particular component of the grading system in breast cancer [10–12].

To conclude, we found that a cognitive bias induced by the tumor architecture does not govern nuclear grading in breast cancer diagnosis. Even though more research is needed to determine the exact conditions under which this confirmation bias unfolds, the present observation is relevant in that it suggests that adherence to strict guidelines, notably categorized grading, has the capacity to effectively counteract errors due to inconscious mental shortcuts in histological cancer grading.

Acknowledgments The study was supported by a grant of the Swiss Science Foundation (FNS 3220030–120417, to Hans-Anton Lehr and Fred Mast).

Conflict of interest The authors declare that they have no conflict of interest.

Abstract Flat epithelial atypia (FEA) may represent the earliest precursor of low-grade breast cancer and often coexists with more advanced atypical proliferative breast lesions such as atypical ductal hyperplasia (ADH) and lobular intraepithelial neoplasia (LIN). The present study aims to investigate the association between morphological parameters of FEA and presence of malignancy at surgical excision (SE) and the clinical significance of the association of FEA

with ADH and/or LIN. This study included 589 cases of stereotactic 11-gauge vacuum-assisted needle core biopsy (VANCB), reporting a diagnosis of FEA, ADH or LIN with subsequent SE from 14 pathology departments in Italy. Available slides were reviewed, with 114 (19.4 %) showing a malignant outcome at SE. Among the 190 cases of pure FEA, no statistically significant association emerged between clinical–pathological parameters of FEA and risk of malignancy. Logistic regression analyses showed an increased risk of malignancy according to the extension of ADH among the 275 cases of FEA associated with ADH (p=0.004) and among the 34 cases of FEA associated with ADH and LIN (p=0.02). In the whole series, a statistically significant increased malignancy risk emerged according to mammographic R1–R3/R4–R5 categories (OR=1.56; p=0.04), extension (OR=1.24; p=0.04) and grade (OR=1.94; p=0.004) of cytological atypia of FEA. The presence of ADH was associated with an increased malignancy risk (OR=2.85; p<0.0001). Our data confirm the frequent association of FEA with ADH and/or LIN. A diagnosis of pure FEA on VANCB carries a 9.5 % risk of concurrent malignancy and thus warrants follow-up excision because none of the clinical–pathological parameters predicts which cases will present carcinoma on SE.

Keywords Breast · Flat epithelial atypia · Stereotactic vacuum-assisted needle core biopsy · Surgical excision · Malignancy

Introduction

Widespread implementation of mammography screening programmes and the introduction of digital mammography in the pre-clinical diagnosis of breast lesions have led to an increasing number of core biopsies (CB) performed for non-palpable nodules and microcalcifications. In the diagnostic assessment of microcalcifications, stereotactic 11-gauge vacuum-assisted needle core biopsy (VANCB) has a lower underestimation rate for malignancy than stereotactic 14-gauge needle core biopsy (NCB) [1]. On CB performed for indeterminate or suspicious microcalcifications, a lesion designated as flat epithelial atypia (FEA) is frequently diagnosed.

FEA, for which the term ductal intraepithelial neoplasia grade 1a (DIN1a) is also used, was introduced by the World Health Organization (WHO) Working Group on the Pathology and Genetics of Tumors of the Breast [2] with the aim of unifying columnar cell lesions with low-grade of cytological atypia, characteristically without complex architectural atypia in the form of arcades, bars, Roman bridges, tufts or micropapillae that are essential in distinguishing this lesion from atypical ductal hyperplasia (ADH or DIN1b). For FEA, a variety of terms has been proposed [3]. Azzopardi [4] introduced the term clinging carcinoma in situ for this lesion, which can be mistaken for either normal breast tissue or fibrocystic breast change.

Although the biological and clinical significance of FEA is still far from completely understood, emerging histological and molecular evidence suggests that FEA may represent the earliest morphologically identifiable non-obligatory precursor of low-grade breast cancer [5, 6]. In fact, FEA often coexists with more advanced atypical proliferative breast lesions such as ADH and atypical lobular hyperplasia (LIN1/ALH) or low-grade ductal carcinoma in situ (DCIS, particularly micropapillary and cribriform type), lobular carcinoma in situ (LIN2/LCIS), tubular carcinoma and invasive lobular carcinoma (ILC) [7–12]. Otherwise, the possibility that columnar cell lesions in general and FEA in particular significantly elevate breast cancer risk is at the moment not well supported [13, 14].

From a clinical point of view, a diagnosis of FEA on CB, pure or in association with more advanced atypical proliferative breast lesions, impacts on the management of these patients. Based on the underestimated malignancy rates of patients with a CB diagnosis of FEA, the prevailing recommendation remains surgical excision (SE) [15].

The aims of our study were to evaluate: (1) if morphological parameters of pure FEA can predict malignancy (DCIS or invasive carcinoma) in subsequently performed SE, (2) the frequency of association of FEA with more advanced atypical proliferative breast lesions such as ADH and/or lobular intraepithelial neoplasia (LIN) and (3) the clinical significance of ADH and or LIN associated with FEA in terms of finding DCIS or invasive carcinoma in subsequently performed SE.

Materials and methods

The study population of a large Italian multi-institutional series of stereotactic VANCB, performed using an 11-gauge stereotactic vacuum-assisted device (Mammotome®, Ethicon Endo-Surgery, Breast Care, Norderstedt, Germany), has been previously reported [1]. Of 22 institutions participating in that study, 14 agreed to proceed with a histological review of all VANCB and SE specimens: eight from Northern Italy, three from Central Italy and three from Southern Italy. Institutional review board approvals were obtained for the study from each participating centre.

Pathology departments participating in the study were asked to retrieve from their archival files all available slides of consecutive B3 cases from VANCB specimens related to the study period [1] and reported in the original histological diagnosis as FEA, atypical epithelial proliferation of ductal type/ADH and LIN. In all participating pathology departments, once a

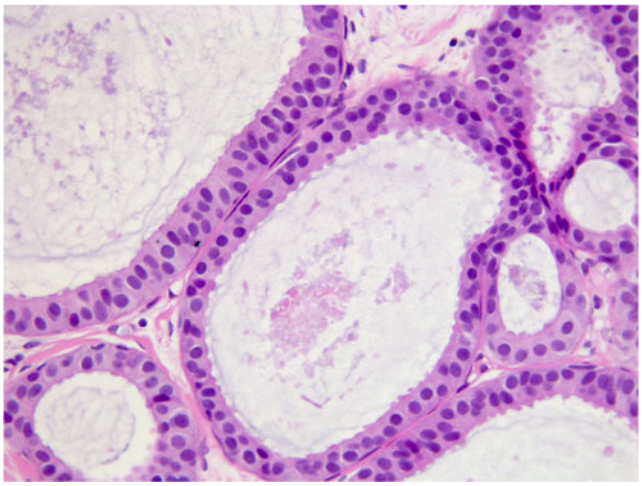

Fig. 1 Pure flat epithelial atypia: dilated acinar unit lined by a single cell layer of columnar epithelial cells that show mild cytological atypia characterized by relatively round and monotonous nuclei

diagnosis of FEA was considered, at least three additional levels of sectioning of VANCB, generally taken approximately at 25 μm apart, were routinely performed in view of the possibility of coexisting more advanced atypical proliferative breast lesions such as ADH and LIN1/ALH. Only VANCB cases with subsequent SE were included in this study.

Radiology departments participating in the study were asked to provide for each case the age of patient, mammographic pattern (microcalcifications versus other patterns), mammographic category according to BI-RADS (Breast Imaging Reporting and Data System) five-point (R1-R5) classification system [16], number of tissue cores obtained (12, 13–20, 21+) and presence of residual microcalcifications on post-stereotactic VANCB radiograms.

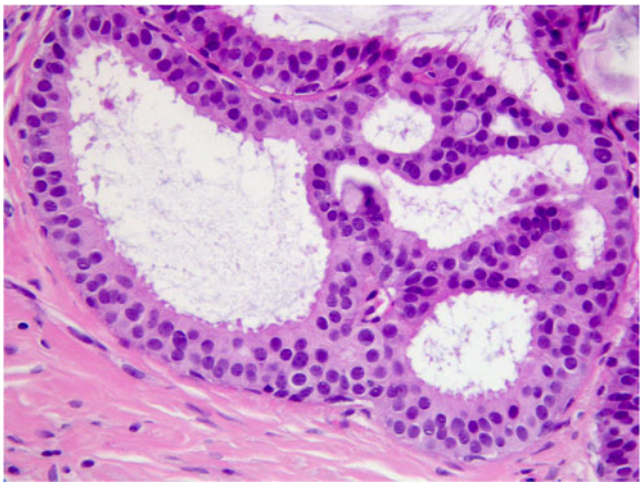

Fig. 3 Atypical ductal hyperplasia arising in a background of flat epithelial atypia: part of the acinus is lined by only a few layers of atypical cells (*left*); on the *right*, the acinus shows a more complex architectural atypia with formation of bridges and fenestrations. Atypical ductal hyperplasia is composed of cells cytologically identical to those in the areas of flat epithelial atypia

An electronic spreadsheet to record clinical, radiological and histological data was used. Each pathologist participating in the study reviewed all haematoxylin & eosin (H&E) and immunohistochemically stained slides, when routinely obtained, of his/her own VANCB cases. The following morphological parameters were evaluated: (a) presence of determinant microcalcifications within the index lesion, (b) presence of unrelated microcalcifications, (c) patterns of FEA (cystically dilated glands, blunt duct adenosis (BDA) resembling pattern on low power, presence of apocrine features as reported by Kunju et al. [11]), (d) grade of cytological atypia of FEA: mild atypia (characterized by relatively round or ovoid rather than elongated nuclei with

a slight increase in the nuclear/cytoplasmic ratio, finely dispersed chromatin or slight margination of chromatin, variably prominent nucleoli and loss of polarity) or moderate atypia (characterized by enlarged, more oval nuclei with cytologically atypical features including mild to moderate pleomorphism, prominent nucleoli, some clumping of chromatin and increased nuclear/cytoplasmic ratio) as described by Pinder et al. [17, 18], (e) patterns of ADH (cribriform, micropapillary, solid or with presence of apocrine features) according to Kunju et al. [11], (f) patterns of LIN (LIN1/ALH or LIN2/LCIS), (g) presence of chronic inflammation and (h) presence of stromal changes including fibrosis and myxoid change.

FEA was diagnosed according to strict morphological criteria [2, 19]: variably distended acini lined by one to several layers of monotonous, mildly or moderately atypical, cuboidal to columnar cells growing in an exclusively flat pattern in the complete absence of architecturally atypical intraluminal proliferations. The presence of a single atypical intraluminal structure as arcade, bar, Roman bridge, tuft or micropapillary formation was considered enough for a diagnosis of FEA associated with concomitant ADH.

ADH was diagnosed using combined histological and cytological criteria as established by Page and Rogers [20]: a proliferative lesion that fulfils some but not all qualitative criteria for a diagnosis of intraductal carcinoma, i.e. evenly spaced cells with hyperchromatic nuclei coexisting with patterns of usual ductal hyperplasia or columnar cell changes, producing a partial involvement of glandular structure by neoplastic cells. In CB histology, technical issues hamper the application of quantitative criteria in diagnosing ADH [21].

In the histological revision, LIN was subdivided into atypical lobular hyperplasia (LIN1/ALH) and lobular carcinoma in situ (LIN2/LCIS). LIN1/ALH was defined by filling and distension of fewer than half of the terminal duct units of a lobule with uniform small dyscohesive cells, evenly spaced, with round nuclei and minimal pleomorphism. LIN2/LCIS was diagnosed when more than half of the acini in the terminal duct units were completely filled or distended [22]. The presence of a single lobule with morphological characteristics of LIN1 or LIN2 was considered sufficient for a diagnosis of FEA associated with LIN. The extent of involvement was determined by evaluating the number of large ducts and/or terminal duct lobular units affected by FEA, ADH and LIN as described by Ely et al. [23] and Wagoner et al. [24]. Cases were divided according the number of foci affected in: (a) cases confined to one focus, (b) cases limited to two foci, (c) cases limited to three foci and (d) cases with four or more foci. The reviewed VANCB final diagnoses were coded into seven categories as follows: pure FEA, pure ADH, pure LIN, FEA + ADH, FEA + LIN, ADH + LIN, FEA + ADH + LIN.

[a] R2 mammographic category was reported in 1 case (0.5 %) and R5 mammographic category was reported in 4 cases (2.1 %)

[b] In 48 cases (25.9 %), complete removal of microcalcifications was obtained; among them, two cases of malignancy were assessed at surgical excision

[c] *p* values from Fisher exact tests

[d] Variable included as an ordinal term in the logistic model.

In each pathology department participating in the study, histology reports and slides of subsequent SE were collected. Each local pathologist reviewed all H&E slides of subsequent SE of his/her VANCB cases included in the study and reported them as: (a) malignant lesions specifying histotype, histological grade, size and lymph node status for invasive carcinoma, nuclear grade and size for DCIS and size for pleomorphic lobular carcinoma in situ, (b) atypical lesions specifying if FEA, ADH, ALH, LCIS were pure or in association and (c) benign lesions. Pathologists were asked to select for each VANCB case one or more representative H&E-stained slides and, where appropriate, IHC-stained slides of the lesion to be reviewed jointly by the panel of 14 pathologists participating in the study. The selected slides of all VANCB cases included in the study were reviewed during a meeting organized at the Division of Pathological Anatomy of the University of Florence in September 2010 to obtain concordance on the diagnosis on each VANCB. Slides were reviewed using the Leica

[e] *p* values from Fisher exact test

DMD108 digital microscope (Leitz Microsystems, Wetzlar, Germany) connected to a high-resolution data projector. In cases for which concordance was not reached, a majority diagnosis was established. No information about SE follow-up was provided during the panel revision. For the present analyses, only cases with a VANCB diagnosis of FEA (pure FEA, FEA + ADH, FEA + LIN, FEA + ADH + LIN) were considered.

Statistical analysis

The distribution of the histological diagnoses reported for the 859 VANCB specimens was calculated. The distribution of the histological diagnoses after SE (benign, atypical or malignant lesion) was also established as well as the percentage of cases with malignancy (according to each specific diagnosis at VANCB).

For all cases with a diagnosis of FEA (pure or associated with other lesions), the distribution according to the following variables was calculated: mammographic category (R2–R3, R4–R5), mammographic pattern (microcalcifications, other), determinant microcalcifications (yes, no), number of cores (12, 13–20, >20), chronic inflammation (yes/no), stromal changes (yes/no), pattern of FEA (blunt duct adenosis resembling pattern, cystically dilated glands, apocrine features), extension of FEA (one focus, two foci, three foci, four foci or more), grade of cytological atypia of FEA (mild, moderate), pattern of ADH (cribriform, micropapillary, solid or with presence of apocrine features), extension of ADH (one focus, two foci, three foci, four foci or more), pattern of LIN (ALH/LIN1 or LCIS/LIN2), extension of LIN (one focus, two foci, three foci, four foci or more). *P* values from chi-square test or Fisher exact test were also calculated. Mean age at VANCB diagnosis according to malignant outcome (*p* values from between-mean comparison *t* tests) was also calculated. Logistic regression models were used to compute odd ratios (ORs) and 95 % confidence intervals (95 % CIs) for each FEA-related variable as estimate of malignant breast cancer risk. Logistic regression analyses were performed separately for a diagnosis on VANCB of pure FEA, of FEA + ADH, of FEA + LIN and of FEA + ADH + LIN. Logistic models were adjusted for age at VANCB diagnosis of the cases, grade of cytological atypia of FEA, pattern and extension of ADH or LIN or both, respectively.

Logistic regression analyses were also performed for all cases including a VANCB diagnosis of FEA (pure FEA or FEA + ADH or FEA + LIN or FEA + ADH + LIN). Logistic models were adjusted for age at VANCB diagnosis, grade of cytological atypia of FEA and co-presence of ADH or LIN.

Results

A total of 859 histologically reviewed VANCB cases with a subsequent SE were available including pure FEA (Figs. 1 and 2) (*N*=190, 22.1 %), pure LIN (*N*=149, 17.3 %), pure ADH (*N*=108, 12.6 %), FEA associated with ADH (Fig. 3) (*N*=275, 32.0 %), FEA associated with LIN (Fig. 4) (*N*=90, 10.5 %), ADH associated with LIN (*N*=13, 1.5 %) and FEA associated with both ADH and LIN (*N*=34, 4.0 %).

Of 589 (68.6 %) cases with FEA (190 pure FEA and 399 FEA associated with ADH or LIN or ADH + LIN), 167 (28.3 %) had a benign, 308 (52.3 %) an atypical (including LIN1 and LIN2) and 114 (19.4 %) a malignant outcome diagnosed on subsequent SE. A total of 18 malignancies among pure FEA, 75 malignancies among FEA + ADH, 13 malignancies among FEA + LIN and 8 malignancies among FEA + ADH + LIN were diagnosed on SE, resulting in underestimation rates of 9.5, 27.3, 14.4 and 23.5 % respectively (Table 1; heterogeneity *p* value <0.0001). As shown in Fig. 5, DCIS was the most frequent malignancy at SE among all the types of VANCB diagnosis. The median age of patients with pure FEA was 50.7 years, 51.9 years for FEA + ADH, 49.9 years for FEA + LIN and 52.6 years for FEA + ADH + LIN (data not shown).

In Tables 2, 3, 4 and 5, the distribution of cases with a VANCB diagnosis of pure FEA, FEA + ADH, FEA + LIN and FEA + ADH + LIN, respectively, according to malignancy upon SE, and several FEA and/or ADH and/or LIN-related variables is reported together with the results of multivariate analyses. The risk of malignancy in women with moderate cytological atypia showed a trend towards being increased (Table 2) compared with that of women with mild cytological atypia (χ^2 test, p=0.06). The suggestion was confirmed by logistic regression analysis (OR 2.41; p=0.08). The suggestion that complete removal of microcalcifications was less frequently associated with malignancy (two cases out of 48 or 4.2 % showing malignancy at surgery) than incomplete removal was not statistically significant (16 out of 142 or 11.3 %).

In Table 3 (FEA + ADH), an increased risk of malignancy according to the extension of ADH emerged in a model adjusted for age, grade of cytological atypia of FEA and pattern of ADH (OR 1.45, *p* value 0.004). In Table 4 (FEA + LIN), an increased risk of malignancy in patients with a moderate grade of cytological atypia of FEA compared to patients with a mild grade of cytological atypia emerged (OR 5.22, *p* value 0.03). In Table 5 (FEA + ADH + LIN), an increased risk of malignancy according to the extension of ADH emerged (OR 6.71, *p* value 0.02).

According to Table 6, women in the mammographic category R4–R5 had an increased risk of malignancy compared with those in R2–R3 category (OR 1.56, 95 % CI

[e] *p* values from Fisher exact tests

1.01–2.39, *p* value 0.04). Women with an extension of FEA of three foci or more had an increased risk of malignancy compared with those with one or two foci (OR 1.73, 95 % CI 1.10–2.73, *p* value 0.02). Women with moderate grade of cytological atypia had an increased risk of malignancy compared with those with mild grade of cytological atypia (OR 1.94, 95 % CI 1.24–3.04, *p* 0.004). While the association of LIN with FEA at VANCB (FEA + LIN or FEA + ADH + LIN) did not modulate the risk of a malignant outcome, the association of ADH (FEA + ADH or FEA + ADH + LIN) was a strong predictor of malignancy at SE (OR 2.85, 95 % CI 1.78–4.58, $p<0.0001$). The mean age of women with malignancy at SE was significantly higher than that of women with a non-malignant outcome (53.4 vs 50.7 years, $p=0.001$).

Discussion

Our study, although limited by its retrospective design, to the best of our knowledge, represents the largest series published to date of FEA, pure or in association with more advanced lesions such as ADH and or LIN, diagnosed on stereotactic 11-gauge VANCB with subsequent follow-up surgical excision. It may contribute to the assessment of the clinical and biological significance of pure FEA and to the management of patients with VANCB diagnosis of pure FEA. All VANCB cases were histologically reviewed and diagnoses were agreed by the panel of 14 pathologists participating in the study using non-ambiguous terminology [25, 26].

Pure FEA

On CB performed for indeterminate or suspicious microcalcifications, a lesion designated as flat epithelial atypia is increasingly recognized and diagnosed [1]. The preoperative histological diagnosis of FEA poses a management dilemma for the clinician. Although there is no definitive agreement at present on the clinical management of FEA (underestimation rates for CB diagnosis of pure FEA reported in the literature vary from 0 to 67 % [13]), the currently prevailing recommendation is that it warrants follow-up surgical excision [1, 27]. A few studies in the published literature support the follow-up observation for the management of pure FEA [26, 28, 29]. A recent review [15] reported a pooled underestimation rate of 12 % for FEA in VANCB (in good agreement with our 12.7 % [1]) compared to 17 % in studies restricted to NCB (difference not statistically significant). Consequently, the authors concluded that surgical excision should be considered. On the other hand, the data reported mostly concern small series (range 1–60 cases), partly published only in abstract form, mostly lacking standardized terminology (including pure FEA and FEA with ADH and or LIN). No single or a combination of clinical, radiological or pathological criteria clearly identified a subset of pure FEA cases at low risk of malignancy. Thus, our results and other recent data [27] justify the conclusion that the presence of pure FEA on VANCB warrants follow-up excision.

The identification of FEA also poses a diagnostic challenge to the pathologist, particularly in CB, because FEA with mild cytological atypia may be subtle and care should be taken not to overlook the lesion or to

Table 6 Frequency of several FEA-related variables among 589 patients with a mention of FEA in the VANCB diagnosis (pure FEA or FEA associated with ADH or LIN or ADH + LIN) according to histological outcome after surgical excision (malignant yes/no). ORs from logistic analyses (95 % CIs and *p* values) for each variable as estimate of malignant breast cancer risk are also reported

[e] *p* values from Fisher exact tests

over-diagnose it and reporting as atypical any columnar cell lesion [17, 18].

Our results confirm previous reports [11, 25–27] that almost all patients (185/190, 97.4 %) with pure FEA are

asymptomatic and that microcalcifications are the main determinant in 91 % (173/190) of cases. As earlier studies reported [11], we found moderate to severe chronic inflammation in 12 % of pure FEA cases (23/190) and stromal changes, including myxoid change and fibrosis in 36.3 % (69/190), of which the significance remains to be clarified.

FEA associated with ADH

Although FEA may occur as pure lesion, a large proportion (275/589 or 46.7 %) is associated with ADH, in agreement with earlier reports [11, 12, 26, 27, 30]. The association of FEA with ADH has an important impact on clinical management as for ADH on CB the need for surgical excision is unanimously recognized [31]. The positive predictive value for malignancy of FEA associated with ADH on CB significantly increases when compared to that of pure FEA [11, 26]. We found that 27.3 % (75/275) of FEA associated with ADH showed a malignancy at follow-up SE. Our study confirms the strong association between FEA and ADH on CB. Our data, together with data from other observational [26] and molecular studies [5–6] support the hypothesis that FEA represents the earliest precursor of low-grade ductal carcinoma, both in situ and invasive [19].

FEA associated with LIN

Some investigators have reported the coexistence of FEA and LIN in the same surgical specimen, particularly in cases of tubular carcinoma [7, 32, 33]. Recently, Abdel-Fatah et al. [8] found that columnar cell lesions, predominantly FEA, and LIN coexist in 60 % of cases of ILC, suggesting that the loss of E-cadherin expression may switch on the development of lobular differentiation, and proposed an evolutionary pathway of ILC through columnar cell lesions on the basis of histological evidence and common genetic changes.

We found FEA associated with LIN in 15.3 % (90/589) of cases, in agreement with data reported by Levoue et al. [27], which results in a malignancy underestimation rate of 14.4 %.

FEA associated with ADH and LIN

In 5.8 % (34/589) of our cases, we found FEA associated both with ADH and LIN, resulting in an underestimation rate of malignancy of 23.5 %, which is closer to the underestimation rate of FEA + ADH (27.3 %) than that of FEA + LIN (14.4 %). This indicates that ADH determines the natural history of the lesion. In FEA associated with both ADH and LIN, the extension of ADH seems to be strongly associated with the risk of malignancy.

Taken together, in our series 19.4 % (114/589) of cases with a mention of FEA (pure FEA and/or FEA associated to ADH and/or LIN) showed a malignancy at subsequent SE. The risk of malignancy increased along with the mammographic category, the extension of FEA and the grade of cytological atypia of FEA, while the association with ADH was a strong predictor of malignancy. The median age of patients with pure FEA was slightly younger than that of patients with FEA + ADH and FEA + ADH + LIN (50.7, 51.9 and 52.6 years, respectively) but slightly older compared to those with FEA + LIN (49.9 years, as reported earlier) [11, 26].

Conclusion

None of the studied parameters of pure FEA can predict the risk of malignancy in a subsequent SE. A trend was found only for the grade of cytological atypia (mild versus moderate) and incomplete removal of microcalcifications.

In FEA associated with ADH or ADH and LIN, the risk of malignancy increases along with increasing extension of ADH. In FEA associated with LIN, the risk of malignancy is higher in case of moderate cytological atypia of FEA. The risk of malignancy in FEA increased according to mammographic category, extension of FEA and grade of cytological atypia of FEA.

A diagnosis of pure FEA on VANCB warrants SE because, on the basis of clinical–pathological parameters, it is impossible to predict which cases are associated with carcinoma. The absence of residual microcalcifications on post-VANCB mammography does not exclude the presence of an associated malignancy at SE: we found malignancy in 4 % (2/48), 10 % (5/50) and 16.7 % (2/12) of cases with complete removal of microcalcifications by VANCB in pure FEA, FEA + ADH and FEA + ADH + LIN, respectively.

We therefore confirm the frequent association of FEA with more advanced atypical proliferative breast lesions such as ADH and/or LIN [17–19, 34] and support the recommendation proposed by several authors [25, 30] that deeper levels of CB with pure FEA should be examined in order to detect or exclude the co-existence of more advanced breast lesions. The findings concerning the frequent association of FEA with more advanced atypical proliferative breast lesions support the hypothesis that FEA, together with ADH and LIN, belongs to the family of precursor lesions of low grade in situ and invasive breast cancer [5, 8] as the earliest precursor recognized to date.

Abstract Flat epithelial atypia (FEA) of the breast have a tendency to calcify and, as such, are becoming increasingly detected by mammography. There is no consensus yet on whether to excise these lesions or not after diagnosis on core needle biopsies (CNB). We reviewed 3,948 cases of breast CNB between June 2004 and June 2009 correlating histomorphologic, radiological, and clinical features. There were 3.7 % (145/3,948) pure FEA and 1.5 % (58/3,948) concomitant FEA and atypical ductal hyperplasia (ADH). In the pure FEA population, 46.2 % (67/145) had microcalcifications on mammography with 65.5 % (95/145) of patients undergoing subsequent excisional biopsies with the following findings: benign 20 % (19/95), ADH 37.9 % (36/95), ductal carcinoma in situ (DCIS) 1.1 % (1/95), and DCIS and invasive ductal carcinoma (IDC) 2.1 % (2/95). In the concomitant FEA and ADH group, 86.2 % (50/58) patients had microcalcifications on radiograph with 74.1 % (43/58) of patients undergoing subsequent excisions with: benign 23.3 % (10/43), DCIS 9.3 % (4/43), DCIS and IDC 4.7 % (2/43), DCIS + lobular carcinoma in situ + invasive lobular carcinoma 2.3 % (1/43), and tubular carcinoma 2.3 % (1/43). The incidence of carcinoma in the FEA + ADH group is 18.6 % (8/43) and 3.2 % (3/95) for the pure FEA group. This difference is statistically significant (p=0.0016). The relative risk of carcinoma in the ADH + FEA group versus the pure FEA group is 6.4773, with 95 % CI of 1.8432 and 22.76 24. Five-year mean follow-up in the unexcised pure FEA did not show any malignancies. These findings suggest that pure FEA has a very low association with carcinoma, and these patients may benefit from close clinical and mammographic follow-up while the combined pure FEA and ADH cases may be re-excised.

Introduction

Flat epithelial atypia (FEA), as defined by the World Health Organization (WHO), is an intraductal alteration of the terminal duct lobular units characterized by replacement of the native epithelium by one layer or three to five layers of mildly atypical cells [1]. The affected ducts are often dilated and contain flocculent material or microcalcifications. It is believed that FEA is the same lesion originally described in 1979 by John G. Azzopardi as "clinging carcinoma (CC), monomorphous type" [2]. However, in recent times, FEA is becoming increasingly recognized due to greater awareness of its morphological features and the increased use of mammographic breast screening. Moreover, FEA has been shown to be a neoplastic lesion at the molecular level [3, 4]. FEA as defined by the WHO encompasses a variety of atypical beast lesions previously known by various appellations including atypical cystic lobules [5], small ectatic ducts lined by atypical cells with apocrine snouts [6], atypical cystic duct [7, 8], columnar alteration with prominent apical snouts and secretions [9–11], DIN flat type [3, 12,

This work was presented in part as an abstract poster at the San Antonio Breast Cancer Symposium on December 12, 2010 in San Antonio Texas, USA.

13], and columnar cell change with atypia [14–16]. The contentious issue with FEA is what to do with it after a diagnosis on core needle biopsy (CNB) since there is no consensus yet whether to re-excise these lesions or not. We report herein our findings in a review of 3,948 cases of consecutive breast core needle biopsies between 2004 and 2009 carrying diagnoses of FEA, columnar change/hyperplasia with atypia, combined FEA and atypical ductal hyperplasia (ADH), and their corresponding excisional biopsy findings.

Methods

Beginning January 2004, the pathologists in the Department of Pathology at Carle Foundation Hospital, Urbana, Illinois, USA adopted the policy of group review of breast biopsies. Particular emphasis was placed on FEA and other atypical breast lesions. These cases were reviewed by at least two pathologists and in most cases, by all pathology staff around a six-headed microscope (Olympus BH51®). These cases were then logged into the laboratory information system database (Softpart ©). The database was queried in the latter part of June 2009 to determine the number of cases of pure FEA and FEA plus ADH on CNBs. The findings on CNBs are correlated with the corresponding excisional biopsies where available. All CNBs showing ductal carcinoma in situ (DCIS), invasive ductal carcinoma (IDC), invasive lobular carcinoma (ILC), or other forms of breast cancer were excluded from the study. Diagnosis of FEA was made based on the 2003 WHO definition [1]. The medical records were also reviewed, and patients who had any previous breast cancer were eliminated from the study. Demographic and clinical information including age, mammographic/radiologic information, and findings of the subsequent excisional biopsies whenever available were also obtained from the medical records. The CNBs were grouped into two: (1) pure FEA where FEA was the most advanced atypical lesion in the breast core biopsy; and (2) FEA plus ADH group with ADH as the most advanced atypical lesion. The subsequent excisional biopsy findings whenever available were correlated with the corresponding CNB cases in the two groups. Some cases, where additional levels were obtained that resulted in an upgrade to a more atypical lesion or carcinoma, were eliminated from this study.

The core needle biopsy processes are as follows: For calcifications as well as masses not seen on ultrasound, the area is sampled via 9-gauge ATEC system (Hologic Corp., Indianapolis, IN©) and a Lorad Table (Hologic Corp, Indianapolis, IN©). After written informed consent and local anesthesia, the area of interest is targeted under stereotactic guidance, and correct needle is documented on both pre- and post-fire stereo pair images. Several (usually 5–12) cores are obtained. For calcifications, the core samples are radiographed during the procedure to ensure target calcifications have been sampled. A metallic microclip marker is placed at the site of biopsy. Post clip placement mammography is obtained following the procedure to document correct clip position. For masses sampled under ultrasound, the lesion is sampled either using vacuum-assisted technique or not. For both modalities, written informed consent is obtained and local anesthesia is used. For vacuum-assisted technique, an 11-gauge ATEC (Hologic Corp., Indianapolis, IN©) system is used with several (usually 5–12) cores being obtained. For non-vacuum-assisted technique, a 14-gauge Achieve (CareFusion, San Diego, CA) needle system is used with usually 5–7 core samples obtained. Metallic microclip markers are placed at the areas of biopsy and confirmed with post clip placement mammography.

Clinical and mammographic follow-up in the 50 unexcised pure FEAs was obtained from the electronic medical records of these patients.

Results

A total of 3,948 breast CNBs were performed and evaluated between June 2004 and June 2009. There were 3.7 % (145/3,948) cases of pure FEA (age range 33–82 years, median 49 years, mean 54 years) (Fig. 1) and 1.5 % (58/3,948) cases of concomitant FEA and ADH (age range 34–83 years, median 51.5 years, mean 54 years). In the pure FEA group, 65.5 % (95/145) patients had subsequent excisional biopsies. Of these 95 patients, 71 % (67/95) had microcalcifications and the rest had mammographic densities/masses.

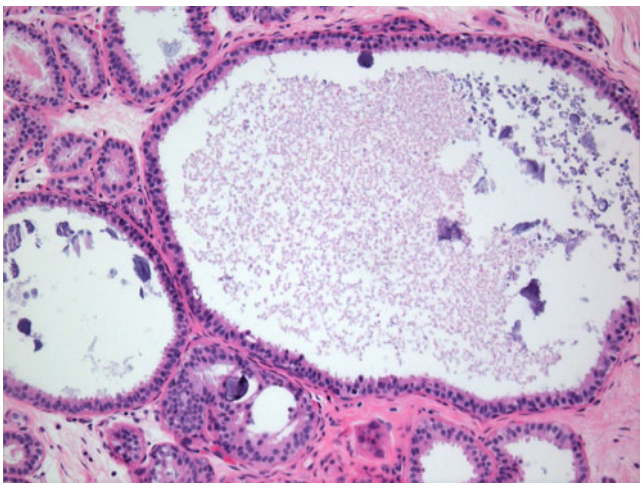

Fig. 1 CNB of breast showing FEA with dilated ducts lined by ovoid atypical cells containing flocculent material and calcifications. H&E ×200

Excisional biopsy findings in this group included: benign/fibrocystic changes 20 % (19/95), FEA 35.8 % (34/95), ADH 37.9 % (36/95), low nuclear grade DCIS1.1 % (1/95) (Fig. 2), and DCIS and well-differentiated IDC 2.1 % (2/95) (Fig. 3).

In the concomitant FEA and ADH group (n=58), 86.2 % (50/58) had microcalcifications and 74.1 % (43/58) of the patients underwent subsequent excisional biopsies with the following findings: benign/fibrocystic changes 23.3 % (10/43), DCIS 9.3 % (4/43), DCIS and IDC 4.6 % (2/43), DCIS and ILC 2.3 % (1/43), and tubular carcinoma 2.3 % (1/43). The mean ages of the pure FEA and the FEA plus ADH group are homogeneous with no statistical difference (p=0.3446) using t test. The incidence of carcinoma in the ADH plus FEA and pure FEA group is 18.6 % (8/43) and 3 % (3/95), respectively. The relative risk of carcinoma findings in the ADH plus FEA group versus the pure FEA group is 6.4773 (95 % CI 1.8432, 22.7624), p=0.0016 (Fisher's exact test). Women in the ADH plus FEA group are six times more likely to be diagnosed with carcinoma compared to the pure FEA group.

The DCIS seen in the excision of one of the cases of pure FEA measured 4.0 mm with low nuclear grade and cribriform architecture without necrosis. The other two cases of invasive ductal carcinoma were both of low grade (grade 1/3 Nottingham Histologic Score) and measured 0.8×0.8 cm and 1.3×0.7 cm, respectively. The decision to re-excise in the pure FEA patients was mainly from the preference of the patient. Follow-up in the unexcised pure FEA cases in the form of yearly mammograms was available in 33 patients. Seventeen patients were lost to follow-up. The follow-up period ranged from 3 to 8 years with a mean of 5 years. The 33 patients for whom follow-up studies were available did not show any evidence of malignancy.

Discussion

Our study shows a pure FEA rate of 3.7 % and a combined FEA and ADH rate of 1.5 % of which there were 3 and 20 % carcinoma rates, respectively. Puibello and colleagues [17] found a similar rate of 3.7 and 1.2 % for pure FEA and combined FEA plus ADH, respectively, in a retrospectively review of 875 core needle biopsies performed using the 11-gauge biopsy gun. Puibello and associates also found a younger median age group for the pure FEA group compared with the combined FEA plus ADH group, an observation reported by Kunju and Kleer[18]. We did not see any statistical difference between the age groups of patients with pure FEA and those in the combined FEA and ADH groups in our study.

It is now generally accepted that FEA is the earliest morphologic precursor of breast cancer and, together with ADH and DCIS, is the non-obligate precursor of invasive and metastatic ductal carcinoma. Morphologic and epidemiologic factors appear to support this hypothesis [19–21]. More light has been shed on the evolutionary relationship between FEA, ADH, DCIS, and invasive ductal carcinoma. Moinfar and associates in the first ever study of genetic abnormalities in FEA showed a high rate of loss of heterozygosity (LOH) at chromosomes 16q in FEA which is also manifested in the adjacent low-grade in situ lesions and low-grade invasive ductal carcinoma [3]. Dabbs and associates also showed LOH in FEA (columnar cell change with atypia/atypical columnar cell hyperplasia) [4]. Similarly, Buerger et al. [22] showed frequent loss of 16q in low-grade DCIS and 13q loss including amplifications of 17q12 and 11q13 in high-grade DCIS. O'Connell and colleagues [23] demonstrated loss of 16 q as a hot spot in ADH which is most frequently related to low-grade rather than high-grade DCIS. More recently, Simpson and colleagues

[24] in a comprehensive CGH based study showed that FEA, ADH, DCIS, and invasive ductal carcinoma (low and intermediate nuclear grade) are an evolutionary continuum in the breast cancer tumorigenesis and progression of the molecular luminal A and B categories [25, 26]. In our study, no high-grade DCIS or IDC was seen in the patients who had cancer on subsequent excisional biopsies in the pure FEA and FEA plus ADH groups.

Moinfar [27] has recently proposed adopting the DIN terminology (low or high grade) as the all encompassing term for all the flat lesions of the breast that had enjoyed various appellations. Interestingly, the WHO classification [1] uses DIN1a as a synonym for FEA. Moinfar [27] argues that the DIN terminology points out the flat, ductal phenotype and neoplastic nature of the lesions with no significant intraluminal proliferations. Furthermore, the term DIN eliminates the use of the alarming term of "cancer" or "carcinoma in situ" in flat lesions including DCIS, and unifies the intraepithelial neoplasia of the breast as commonly seen in other organ systems. Our cases of FEA showed mild nuclear atypia. However, there were cases that looked more atypical than others with more prominent nucleoli without intraluminal proliferations or frankly high-grade nuclei.

What still remains a contentious issue with FEA is the lack of a generally accepted mode of treatment of patients after a diagnosis is made on CNB. Kunju and Kleer [18], in a review of 60 core biopsies, found carcinoma rates of 21 and 38 % in the pure FEA and pure ADH groups, respectively. They concluded that FEA shows a risk of upgrade to carcinoma similar to that of ADH and a follow-up excision in FEA cases. Piubello and associates [17] found no evidence of carcinoma in 20 excisional biopsies of the 33 pure FEA in their review. They recommended close radiologic follow-up in these patients diagnosed with pure FEA. Jara-Lazaro and associates [28] recommended excisional biopsy for pure FEA after a review of several published cases in the literature showing up to 22 % of ductal carcinoma after excisional biopsies. Senetta et al. [29] and de Mascarel et al. [30] did not find any cancer associated with pure FEA in their studies and did not recommend excisional biopsies. All these cases are limited by their small sample sizes. Verschuur-Maes et al. [31] in a retrospective review of 4,164 breast CNBs found 311 columnar cell lesions consisting of 221 columnar lesions without atypia, 69 with atypia, and 21 mixed columnar cell lesions and ADH. Their progression risks were 2 % for columnar cell lesions without atypia, 18 % for columnar cell lesion with atypia, and 22 % for columnar cell lesions and ADH. In a cohort-retrospective review of 80 cases of in situ carcinoma with a mean follow-up period of 17.5 years, Eusebi and associates [32] found only two cases of recurrent well-differentiated DCIS in 32 CC with monomorphous nuclei 3 and 9 years, respectively, after the initial breast biopsies. Both recurrences showed no evidence of disease after subsequent re-excisions 19 and 26 years, respectively, after the initial biopsies. Similarly, Bijker et al. [33], with a median follow-up of 5.4 years, found no recurrences in 59 cases of well-differentiated DCIS with clinging architecture. They recommended close follow-up of these patients after local excisions. More recently, Yamaguchi et al. [34], in a retrospective review of 2,358 breast CNB spanning 4 years, found a pure FEA rate of 0.72 % (17/2,358) and combined FEA + ADH rate of 0.76 % (18/2,358). Subsequent excisions performed in 53 cases revealed malignancy rates in the pure FEA and combined FEA + ADH groups of one out of eight (1/8) and seven out of ten (7/10), respectively, with recommendation to re-excise the combined FEA + ADH and watch the cases of pure FEA. These findings in the rates of malignancy on re-excision of the CNBs are similar to our cases where ADH was the most common finding after excisional biopsies of pure FEA (38 %), and a 3 % ductal carcinoma rate and the FEA plus ADH group, on the other hand, showed a carcinoma incidence of 20 %. Greater than 90 % of our patients who had subsequent excisional breast biopsies had their lesions removed less than 80 days after the original CNBs. This suggests that the FEA most likely coexisted with the more atypical lesions that were found on subsequent excisional biopsies. The tumors found on excision of the pure FEAs were small and of low grade, and whether to subject patients to excisional biopsies for small low-grade tumors that may progress slowly and may not have a fatal course is debatable. Furthermore, the available follow-up in the unexcised pure FEA cases failed to show any malignancies albeit with a short follow-up period. However, the possibility of selection bias in favor of less extensive/less suspicious lesions cannot be completely excluded due to small population size and variability of method of follow-up.

In conclusion, FEA on CNB has a low predictive value for breast carcinoma on subsequent surgical excisional biopsy, and it is more often associated with ADH. FEA appears to have a natural sequential progression to ADH and subsequently to frank breast carcinoma. Women in the FEA plus ADH group were six times more likely to be diagnosed with carcinoma compared to the pure FEA group. It might be prudent for these patients to have clinical and mammographic follow-up and re-excise those cases that have concomitant ADH. Further studies with larger sample sizes and longer follow-up periods may be needed to further determine what management steps to undertake in patients diagnosed with pure FEA.

Acknowledgments The authors wish to thank Dr. Maria Muyot for help with the statistical analyses.

Abstract Poly(ADP-ribose) polymerase 1 (PARP) is a key element of the single-base excision pathway for repair of DNA single-strand breaks. To compare the cytoplasmic and nuclear poly(ADP-ribose) expression between familial (BRCA1, BRCA2, or non BRCA1/2) and sporadic breast cancer, we investigated 39 sporadic and 39 familial breast cancer cases. The two groups were matched for hormone receptor status and human epidermal growth factor receptor 2 status. Additionally, they were matched by grading with a maximum difference of ±1 degree (e.g., G2 instead of G3). Cytoplasmic PARP (cPARP) expression was significantly higher in familial compared to sporadic breast cancer (P=0.008, chi-squared test for trends) and a high nuclear PARP expression (nPARP) was significantly more frequently observed in familial breast cancer (64 %) compared with sporadic breast cancer (36 %) (P=0.005, chi-squared test). The overall PARP expression was significantly higher in familial breast cancer (P=0.042, chi-squared test). In familial breast cancer, a combination of high cPARP and high nPARP expression is the most common (33 %), whereas in sporadic breast cancer, a combination of low cPARP and intermediate nPARP expression is the most common (39 %). Our results show that the overall PARP expression in familial breast cancer is higher than in sporadic breast cancer which might suggest they might respond better to treatment with PARP inhibitors.

Introduction

In the USA in 2012 about 226,870 women will be diagnosed with breast cancer, which makes breast cancer the most common cancer in women, and with 39,510 estimated deaths, breast cancer is the second most frequent cause of cancer death in women [1]. About 5–10 % of these cases can be related to a hereditary or familial form of breast cancer

[2]. There are several types of mutation found in this type of breast cancer, but the best studied are the BRCA1 and BRCA2 mutations, which were discovered in the 1990s and are located on chromosome 17q and 13q, respectively [3], and account for about 20–50 % of all familial breast cancers [4].

The proteins encoded by the BRCA1 and BRCA2 genes play an important role in the repair of double-strand breaks and initiation of homologous recombination in damaged DNA. Carriers of a mutated form of BRCA are heterozygous for this gene and have a higher susceptibility for carcinogenesis through loss of heterozygosity. The susceptibility for carcinogenesis further increases as BRCA-associated tumors more often seem to express mutated versions of the tumor suppressor genes TP53 and c-erbB2 [5, 6].

BRCA-mutated tumors are often histologically poorly differentiated (grade 3) and show a more aggressive phenotype, for example, high mitotic counts and decreased tubular formation. This may explain the poor prognosis of patients carrying the mutated gene in the germ line [7].

Furthermore, the majority of BRCA1-mutated breast cancers is triple negative, i.e., no expression of estrogen- and progesterone receptor and no amplification of the Her2 gene, and highly proliferative, which leads to a comparably high response rate to certain kinds of chemotherapy. Nevertheless, there is a high recurrence rate [8].

Current therapeutic strategies for triple-negative breast cancer are focused on chemotherapy, in some cases augmented with radiotherapy or treatment with biologicals [9]. Because the overall prognosis is not very promising, there is a need for new treatment approaches, which should be selective for the tumor and have an acceptable side effect pattern. Beside other agents like platinum in neoadjuvant chemotherapy [10], poly(ADP-ribose) polymerase (PARP) inhibitors seem to be highly effective agents for tumors in patients with BRCA-mutated genes [11].

PARP-1 (PARP) is the most studied and founding member of the PARP family which contains 17 other proteins that are present in various cell compartments. It is located primarily in the nucleus and its functions range from regulation of gene expression and chromatin structure to an important role in metabolism. But the most important function, which is the reason PARP inhibitors were developed, is the role of PARP-1 in the repair of DNA single-strand breaks via the single-base excision pathway [12, 13].

Inhibition of PARP will lead to an accumulation of single-strand breaks, which would turn into double-strand breaks after cell division. Because tumor cells of patients with a BRCA mutation are BRCA deficient, they would not be able to repair these double-strand breaks. Finally, this would lead to apoptosis of the tumor cells [14]. This mechanism is thought to be highly selective and would not affect normal tissues of the patients because only tumor cells are completely BRCA deficient [15].

In vitro studies showed a more than 1,000-fold higher sensitivity for PARP inhibitors in the cell lines with BRCA1 and BRCA2 mutations compared to wild-type breast cancer cells [11]. In phases 1 and 2 trials, PARP inhibitors have proven to be effective in women with BRCA1 and BRCA2 mutations who were resistant to normal chemotherapy [11, 16]. But the first PARP inhibitor to enter a clinical phase 3 trial, iniparib, failed to meet the goals of the trial. Subsequent research implied that iniparib might not be a PARP inhibitor but seems to non-selectively modify cysteine-containing proteins in tumor cells [17].

In the light of these studies, more basic research studies needs to be done to improve our knowledge of PARP and its localization in order to allow the development of more PARP-specific inhibitors. This study focuses on possible differences in PARP localization between hereditary and non-hereditary breast cancer tissue samples.

Materials and methods

Study population

To determine the PARP expression in familial breast cancer, we analyzed formalin-fixed paraffin-embedded tissue of 47 patients from the Department of Pathology of the Radboud University Nijmegen Medical Centre.

The core biopsies were arranged in two tissue microarrays, together with samples of liver tissue for adequate orientation. We had to exclude eight cases from the final analysis due to lack of tumor in the tissue microarrays. The final cohort consisted of 24 BRCA1-mutated-, 8 BRCA2-mutated-, 2 non-BRCA-mutated cases, and 5 cases in which mutation analysis had not been yet performed at the moment of study inclusion.

The sporadic breast cancer tissue samples were provided by the Institute of Pathology of the Charité University Hospital. They were matched with the 39 familial cases by hormone receptor status and human epidermal growth factor receptor 2 (HER2) status. Additionally, they were matched by grading with a maximum difference of ±1 degree (e.g., G2 instead of G3). Matching between cohorts was executed using the statistical language R [18]. Of the tumors, 30 matched exactly with respect to grading, while there was a difference of ±1 for the other nine.

Immunohistochemical staining and histopathological examination

Immunohistochemical staining on the tissue microarrays was performed using standard procedures. To detect PARP

residues in the samples, a monoclonal-purified mouse anti-human PARP antibody (1:1,500; clone 7D3–6; BD Pharmingen, San Diego, CA) was used. As detection system, a peroxidase/DAKO system (Dako REALTM Detection System, peroxidase/3,3-diaminodbenzidine positive, rabbit/mouse; Dako, Glostrup, Denmark) was used.

Stained slides were digitized and virtually examined with the VM Slide Explorer 2009 (VMscope GmbH, Berlin, Germany). Nuclear PARP (nPARP) and cytoplasmic PARP (cPARP) expression patterns were evaluated in terms of the nuclear and cytoplasmic intensity (negative, weak, moderate, and strong) and the percentage of stained tumor cells (0 to 100 %, with 10 % intervals).

The intensity and percentage of positive tumor cells were used to calculate an immunoreactivity score (IRS), which was divided into three subgroups defined as low (IRS 0–2), intermediate (IRS 3–4), and high (IRS 6–12) expression [19]. To get an impression of the overall PARP staining, nuclear and cytoplasmic PARP expression patterns were combined. Nuclear and cytoplasmic PARP expression received one point for an IRS of 0–2, two points for an IRS of 3–4, and three points for an IRS of 6–12. In order to determine the overall PARP expression, the points given for nPARP and cPARP expression were added and the result was defined as low (0–2 points), intermediate (3–4 points), and high (5–6 points) overall PARP expression.

Information about the histological grading was extracted from the pathology reports. If the information was not available, the tumor tissue was regraded on the TMA.

Statistical evaluation

Statistical analysis was carried out using the PASW Statistics 18 program (IBM, Armonk, New York). For the evaluation, the familial and sporadic subgroups were compared regarding the cytoplasmic, nuclear, and overall PARP expression. Differences between the subgroups were assessed using the chi-squared test and the chi-squared test for trends. P values <0.05 were considered statistically significant.

Results

Study cohort

The clinicopathological characteristics of the cohort are listed in Table 1. The mean age at diagnosis of patients with familial breast cancer was 45±11 years and of patients with sporadic breast cancer was 65±12 years.

The tumor samples showed different cytoplasmic and nuclear PARP expression patterns, which were categorized as low, intermediate, or high, as recently described [19]. Figure 1a shows tumor tissue with a negative (low) cytoplasmic and negative (low) nuclear PARP expression, Fig. 1b shows tumor cells with intermediate cytoplasmic and low nuclear PARP expression, and Fig. 1c shows a high cytoplasmic and low nuclear PARP expression.

Table 1 Tumor characteristics (including histological grading, tumor size, nodal status, hormone receptor status, HER2 status, histological tumor type, and mutation status) of the familial and sporadic breast cancer samples

	Familial BC	Sporadic
Histological grading		
G1	3 (7.7 %)	4 (10.3 %)
G2	27 (69.2 %)	18 (46.2 %)
G3	9 (23.1 %)	17 (43.6 %)
Tumor size pT		
pT 1	22 (56.4 %)	15 (38.5 %)
pT 2	10 (25.6 %)	20 (51.3 %)
pT 3	4 (10.3 %)	3 (7.7 %)
pT 4	1 (2.6 %)	0
Missing	(5.1 %)	1 (2.6 %)
Nodal status		
N0	20 (51.3 %)	28 (71.8 %)
N+	15 (38.5 %)	8 (20.5 %)
Missing	4 (10.3 %)	3 (7.7 %)
Hormone receptor status		
HR+	21 (53.8 %)	21 (53.8 %)

ILC	3 (7.7 %)	4 (10.3 %)
Mutation status		
BRCA 1	24 (61.5 %)	–
BRCA 2	8 (20.5 %)	–
Non-BRCA1/2	2 (5.1 %)	–
Mutation not known	5 (12.9 %)	–

Comparison of cPARP expression in familial and sporadic breast cancer

As shown in Fig. 2, the cytoplasmic PARP expression in familial breast cancer was low in 33 %, intermediate in 26 %, and high in 41 % of cases. In contrast, cPARP in sporadic breast cancer was low in 59 %, intermediate in 26 %, and high in 15 % of cases. Statistical analysis showed that cPARP expression was significantly higher in familial compared to sporadic breast cancer (P=0.008, chi-squared test for trends).

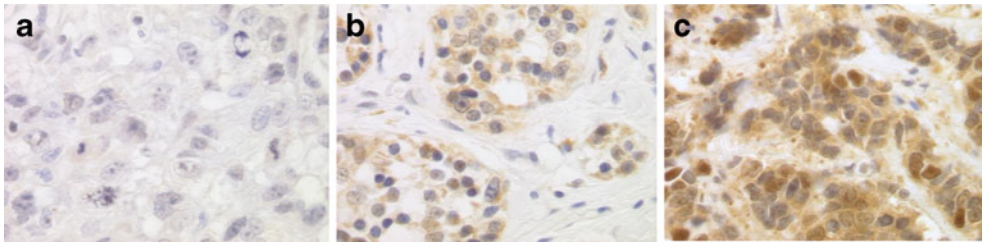

Fig. 1 Tumor cells with different PARP expression patterns: **a** negative (*low*) cytoplasmic and negative (*low*) nuclear PARP expression; **b** intermediate cytoplasmic and low nuclear PARP expression; and **c** high cytoplasmic and low nuclear PARP expression

Comparison of nPARP expression in familial and sporadic breast cancer

Figure 3 shows that the nuclear PARP expression in familial breast cancer was low in 13 %, intermediate in 23 %, and high in 64 % of cases. Compared to that, the nPARP expression in sporadic breast cancer was low in 5 %, intermediate in 59 %, and high in 36 % of cases. Familial breast cancer showed a significant higher nPARP expression than sporadic breast cancer (P=0.005, chi-squared test). In comparison, non-familial breast cancer showed more intermediate nPARP expression (59 %) than familial breast cancer (23.1 %).

Comparison of the overall PARP expression in familial and sporadic breast cancer

The overall PARP expression, a combination of cPARP and nPARP expression, in familial breast cancer was low in 8 %, intermediate in 41 %, and high in 51 % of cases. In sporadic breast cancer, the overall PARP expression was low in 5 %, intermediate in 69 %, and high 26 % of cases (Fig. 4). Familial breast cancer showed a significantly higher overall PARP expression (P=0.042, chi-squared test). There was no significant correlation between cPARP, nPARP, or the overall PARP expression and other clinicopathological parameters (results not shown).

Correlation of cPARP and nPARP expression in familial and sporadic breast cancer

Figure 5 shows that familial breast cancer samples exhibited low PARP expression pattern in 11 cases, in 15 cases either cPARP or nPARP was high and in 13 cases cPARP and nPARP were high. On the contrary, sporadic breast cancer showed low PARP expression in 23 cases, in 12 cases either cPARP or nPARP was high and only in 4 cases cPARP as well as nPARP expression was high. Table 2 compares cPARP and nPARP expression in breast cancer, regardless of familial or sporadic origin. It shows that 17 % of cases had high nPARP but low cPARP expression and 7 % had high cPARP but low to intermediate nPARP expression.

Taken together, the results suggest that sporadic breast cancer more often exhibits a low PARP expression pattern, whereas in familial breast cancer, high PARP expression is more common (P=0.009, chi-squared test). No significant correlation between the clinicopathological parameters or the BRCA mutation status and PARP expression patterns (data not shown) was found.

Discussion

Our study shows that cPARP expression is significantly higher in familial than in sporadic breast cancer. In familial

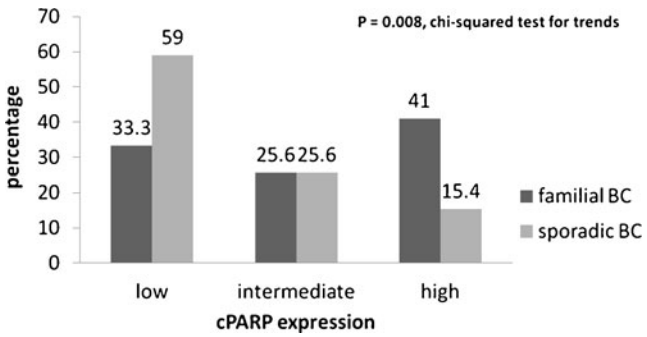

Fig. 2 cPARP expression (*low*, *intermediate*, and *high*) in familial and sporadic breast cancer. cPARP expression was significantly more often high in familial breast cancer and more often low in sporadic breast cancer (P=0.008, chi-squared test for trends)

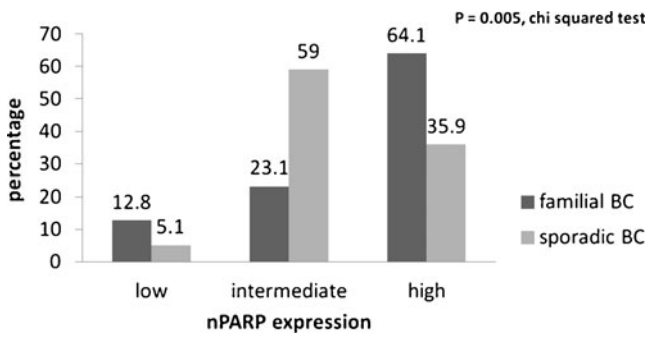

Fig. 3 nPARP expression (*low*, *intermediate*, and *high*) in familial and sporadic breast cancer. nPARP expression was significantly higher in familial breast cancer than in sporadic breast cancer (P=0.005, chi-squared test)

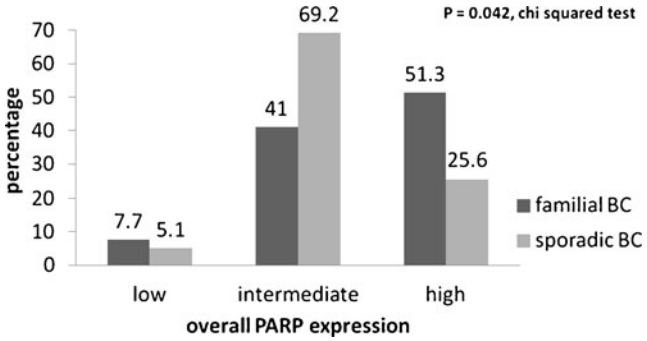

Fig. 4 Overall PARP expression (*low*, *intermediate*, and *high*) in familial and sporadic breast cancer. The overall PARP expression was significantly higher in familial breast cancer than in sporadic breast cancer (P=0.042, chi-squared test)

breast cancer, the number of samples with intermediate nPARP expression was lower, but cases with low or high nPARP expression were more frequent. The overall PARP expression was significantly higher in familial breast cancer. Additionally in familial breast cancer, a combination of high cPARP and high nPARP expression is most common, whereas in sporadic breast cancer, a combination of low cPARP and intermediate nPARP expression is most common.

PARP expression in familial and sporadic breast cancer has been investigated by several others. Domagala et al. included 130 BRCA1-associated and 594 BRCA1 non-related breast cancer tissue samples in their study. Immunohistochemical staining and evaluation showed that the BRCA1-associated tumor samples more often exhibited a low nPARP expression. cPARP expression was low in most cases, but more frequent in the BRCA1-associated group, similar to our results [20]. The differences in cPARP and

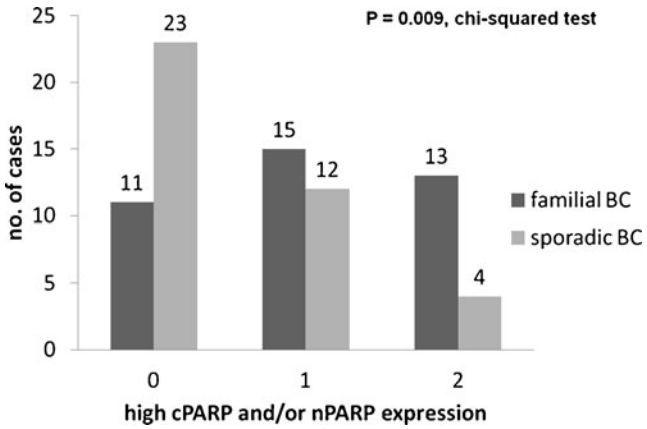

Fig. 5 Combined cPARP and nPARP expression defining three different groups in which either none (0) of the two, one (1), or both (2) were highly expressed, showing that in familial breast cancer more often one of the two or both were highly expressed and in sporadic breast cancer mostly neither cPARP nor nPARP were highly expressed (P=0.009, chi-squared test)

Table 2 Comparison of cPARP and nPARP expression levels

nPARP	cPARP			
	Low	Intermediate	High	Total
Low	5 (6.4 %)	1 (1.3 %)	1 (1.3 %)	7 (9 %)
Intermediate	18 (23.1 %)	10 (12.8 %)	4 (5.8 %)	31 (41 %)
High	13 (16.7)	9 (11.5 %)	17 (21.8 %)	39. (50 %)
Total	36 (46.2 %)	20 (25.6 %)	22 (28.2 %)	78 (100 %)

nPARP expression are evident but cannot be explained with our study design.

Another study done by Ozretić et al. included tissue samples from 93 BRCA1/2-associated and 53 sporadic breast cancers [21]. Consistent with our findings, Ozretić et al. found high nPARP expression more frequently in BRCA1/2-associated cases. In contrast to our results, they did not observe cytoplasmic staining. They also observed significantly higher nPARP expression in hormone receptor-positive cases, whereas other studies showed higher PARP expression in hormone receptor negative samples than in hormone receptor-positive samples [19, 22]. Our study did not show any correlation between PARP expression and hormone receptor status or other clinicopathological parameters.

The differences in results between those two studies and ours may be due to different PARP antibodies used. Domagala et al. also used a different scoring system (multiplicative quickscore) than Ozretić et al. and us (immunoreactivity score). Another difference between the studies is that we included different kinds of familial breast cancer cases (BRCA1, BRCA2, and non-BRCA1/2) while Domagala et al. and Ozretić et al. only included BRCA1- and BRCA2-mutated tumors. In addition, we used a case–control approach, matching cases according to size, grade, HR status, and HER2 status, whereas Ozretić et al. and Domagala et al. used different selection criteria.

In a recent review on the various functions of PARP-1, its dominant role in DNA repair is highlighted [23]. In response to genotoxic stress, PARP relocates to the site of DNA damage to induce DNA repair in several different ways, e.g., PARylation and subsequently p53 activation. BRCA-mutated cases might have more DNA damage. This might explain why cPARP and nPARP expression is higher in familiar breast cancer cases. This hypothesis is supported by Ossovskaya et al. who demonstrated that loss of a DNA repair pathway can be compensated by upregulation of alternative DNA repair mechanisms. We contend that also the PARP pathway may be upregulated due to the loss of a DNA repair pathway [22]. The resulting higher PARP levels in turn induce downregulation of, e.g., BRCA2 expression, through interaction with the BRCA2 promoter [24]. Newer

data suggest that PARP inhibition can also downregulate BRCA1, which in turn downregulates homologous recombination. Cells which show low BRCA expression, e.g., BRCA-mutated breast cancer cells, have defects in the homologous recombination pathway [25]. A study by Patel et al. showed that PARP-1 plays an important role in nonhomologous end joining in these cells, which finally contributes to the genomic instability arisen from the use of PARP inhibitors [25–27].

In a recent study of sporadic breast cancer in the neoadjuvant setting, we reported a correlation between high cPARP expression and high-grade histological characteristics, unfavorable long-term prognosis, and better response to neoadjuvant chemotherapy [19]. In our present study, cPARP expression was higher in familial breast cancers. As breast cancer prognosis depends on parameters such as estrogen receptor expression, tumor size, and nodal status [28, 29], which were different between the patient groups in these studies, the lack of consistency between these studies does not come as a surprise. In order determine the potential of PARP as a prognostic factor in hereditary and non-hereditary breast cancer, a large case–control study will be necessary.

Patients with a higher PARP expression might also respond better to neoadjuvant chemotherapy. This idea might be supported by a study from Arun et al. which showed that hereditary breast cancer, especially BRCA1, is associated with higher pCR rates after neoadjuvant systemic chemotherapy [30]. In order to confirm this hypothesis, studies including PARP expression and response to neoadjuvant chemotherapy in hereditary and non-hereditary breast cancer are needed.

Although our study showed promising results, there are still some limitations to it. In order to make a statement about the long-term prognosis in the two groups, it would have been beneficial to include survival data and probably even larger group sizes. As the genetic testing has not been performed for the cohort of clinically sporadic breast cancer cases, it might be possible that a few familial breast cancer cases are present in this group. In addition, the cohort of familial breast cancer was not homogenous, and BRCA testing had not been performed for five cases. It might therefore be interesting for further study purposes to differentiate between different types of familial breast cancer, especially in the context of a study from Kurian et al. that showed that women who tested negative for an BRCA1 or BRCA2 mutation are not at high enough risk to be kept under routine surveillance [27]. But in combination with the PARP expression and the probable prognostic implication of that, it might be interesting to further investigate differences in PARP expression between hereditary and familial breast cancer.

In conclusion, our results show that the overall PARP expression is higher in familial breast cancer than in sporadic breast cancer, which suggests that they might respond better to treatment with PARP inhibitors. In order to reveal the potential of PARP as a prognostic factor and predictor of response to PARP inhibitors, further research needs to be done.

Abstract We identified a group of melanocytic lesions with an architectural pattern very similar to that of a junctional nevus: cells mostly grouped in distinct nests, more or less of the same size and shape, and regularly distributed along the dermoepidermal junction. In contrast with these nevus-like features, these neoplasms display additional details which are incompatible with a diagnosis of junctional nevus. These include areas of lentiginous array with focal pagetoid spread of melanocytes above the junction; marked cytological atypia, such as nuclear enlargement, hyperchromasia, nuclear membrane thickening and with a mild degree of cellular pleomorphism. Moreover, these lesions mostly developed on severely sun-damaged skin of old patients. Using a four-probe fluorescence in situ hybridization (FISH) assay targeting RREB1, MYB, Cep6, and CCND1, we found that seven of the eight propositus cases showed chromosomal aberrations consistent with the standardized FISH diagnostic criteria for melanoma. Instead, the five junctional nevi that served as controls were negative in this test. These findings underline the utility of correlating clinical–pathological observations with FISH analysis for diagnosing correctly as melanoma these malignant neoplasms, which closely simulate a junctional nevus.

Introduction

We have identified a group of melanocytic lesions of which the architectural pattern strikingly resembles that of a common junctional melanocytic nevus. The neoplastic cells are predominantly organized in nests, mostly roundish and discrete, more or less of the same size and shape, and evenly scattered along the dermoepidermal junction. These reassuring architectural features give a first impression at scanning magnification of a junctional nevus, but these lesions display other details which are unquestionably in conflict with the seemingly benign nature of these tumors [1–7]. Significant cytological atypia is observed: cells are either hyperchromatic, with small lymphocyte-like nuclei and barely distinguishable cytoplasm or large-sized, with a thick and irregular nuclear membrane, coarse chromatin, and prominent nucleoli. Occasionally, areas of lentiginous melanocytic proliferation are noted, along with focal pagetoid spread of atypical cells within the epidermis [8–11]. Moreover, a closer view at higher magnification shows the presence of a subtle but indisputable cellular pleomorphism. Finally, these lesions have mostly developed on severely sun-damaged skin of old patients. We present in this paper eight cases with the above-mentioned cytoarchitectural features, which we investigated from a morphological point of view but also with the Vysis LSI RREB/LSI MYB/LSICCND1/CEP6 fluorescence in situ hybridization (FISH) in order to confirm a diagnosis of melanoma of these lesions. This four-probe multicolor FISH assay detects genetic abnormalities in chromosomes 6 and 11 and currently provides a means to discriminate melanoma from nevi with a sensitivity of 86.7 % and a specificity of 95.4 %. The four chromosomal loci and the specific genes targeted by the

FISH assay include 6p25 (RREB1), 6q23 (MYB), 11q13 (cyclin D1), and Cep6 (the centromeric portion of chromosome 6) [12–14].

Materials and methods

We selected eight propositus cases of melanocytic neoplasms containing the following conflicting histological characteristics:

1. Prevalence of a nested pattern, with mostly roundish and clear cut nests, regularly shaped and sized, evenly scattered along the dermoepidermal junction. In some cases, however, focal areas with large, bizarrely shaped, and irregularly confluent melanocytic nests could be found as well.
2. Sharp circumscription by discrete nests at both extremities of the lesions.
3. The presence of focal areas with lentiginous proliferation of melanocytes at the dermoepidermal junction.
4. Occasional pagetoid scattering of melanocytes both at the center and the edges of lesions and also above areas in which single melanocytes predominated.
5. Presence of features of marked cytological atypia, namely, either hyperchromatic cells, with small lymphocyte-like nuclei and an almost undetectable rim of cytoplasm or large cells, with thick and irregular nuclear membranes, prominent nucleoli, and clumped chromatin. A mild degree of cellular pleomorphism was detectable, too.
6. Absence of epidermal atrophy, expansive nodules, and significant mitotic activity.
7. Presence of a variable degree of solar elastosis in all but one case.
8. All lesions were more than 5 mm in diameter and less than 1 mm in thickness.
9. Adult/old age of patient (range 37–90 years).

Control cases

Five cases of junctional nevi without any hints of malignancy were used as controls.

Fluorescence in situ hybridization (FISH)

FISH analysis on the eight propositus cases and five controls was carried out on 3–4 μm thick sections from formalin-fixed, paraffin-embedded tissue samples. From each specimen, two slides were obtained, one for H&E staining, the other for FISH analysis. On the H&E stained sections, regions with predominance of melanocytic cells over stromal cells were marked using a diamond-tipped scribe. The same areas were scribed on the corresponding unstained slides. Deparaffination was carried out by baking the unstained slides for 4–5 h at 75 °C and subsequently immersing them in Coplin jars containing xylene, first at 60 °C for 1 h and then at room temperature for 20 min. Slides afterwards underwent two passages in absolute alcohol, each time for 20 min. Before hybridization, sections were pretreated with 1× SSC pH 6.3 at 80±1 °C for 35 min and digested with 25 mg/ml protease at 37 °C for 10 min. Slides were then rinsed in purified water for 3 min and immersed three times in 70 %, 85 %, and 100 % ethanol, respectively, each time for 2 min. The following DNA probes (Abbott Laboratories) were used: the RREB1 (6p25) probe, labeled with Spectrum Red; the MYB (6q23) probe, labeled with SpectrumGold; the CCND1 (11q13) probe, labeled with SpectrumGreen; and the CEP 6 probe, labeled with SpectrumAqua. Hybridization was performed using the HYBrite machine (Abbott Laboratories). Ten microliters of probe in hybridization buffer was applied to each slide which was subsequently covered with a coverslip and sealed with rubber cement. The slides were codenatured with the probe mixture at 73 °C for 5 min and then hybridized for ≥16 h at 37 °C. Slides were then washed in 2× SSC/0.3 % NP40 for 2 min at room temperature, counterstained with 10 μl of DAPI 1 (Abbott) and finally examined under a fluorescence microscope (Olympus BX61), equipped with appropriate excitation and emission filters, allowing visualization of aqua, green, gold, and red fluorescent signals and DAPI counterstaining. For each case, 30 cells from a minimum of three different regions previously located within the tumor were scored for the four FISH probes. To determine melanoma status, four parameters were calculated:

1. Average CCND1 signals per nucleus,
2. Average MYB signals per nucleus,
3. Percentage of nuclei with abnormal RREB1, and
4. Percentage of nuclei with loss of MYB relative to CEP6.

Specimens were defined as “Melanoma FISH positive” if one of the following from the manufacturer's established criteria was fulfilled:

1. Average CCND1 signals per nuclei or average MYB signals per nuclei ≥2.5,
2. Percent loss of MYB relative to CEP6 ≥31 %, and
3. Percentage of abnormal nuclei for RREB1 ≥63 %.

Specimens were classified as “FISH negative” if none of the criteria mentioned above were met.

DNA extraction and BRAF mutational analysis

Two or more sections of paraffin-embedded tissue (the number varied depending on the concentration of tumor

cells in the sample) were manually microdissected by an expert pathologist with a sterile razor and genomic DNA was extracted with a QIAamp DNA mini extraction kit following the manufacturer's protocol (Qiagen). Amplification of BRAF was performed by PCR with the AmpliTaq kit (Applied Biosystems) using the following primers: BRAF F: 5′-CCTAAACTCTTCATAATGCTT-3′ BRAF R: 5′-ATAGCCTCAATTCTTACCAT-3′. The PCR products were treated with exonuclease/shrimp alkaline phosphatase (Exo/Sap USB) and sequenced with the same PCR primers using the 3.1 BigDye Terminator Cycle Sequencing Ready reaction kit (Applied Biosystems). The sequencing reactions were purified with the XTerminator solution (Applied Biosystems) and run by capillary gel electrophoresis in an ABI PRISM 310 Genetic Analyzer (Applied Biosystems). PCR reactions were performed at least twice and sequence analyses were performed in forward and reverse orientations.

Immunohistochemistry

Immunohistochemical staining for cyclin D1 (clone SP4-R), S-100 (clone 4C4.9), p16, Melanoma Associated Antigen (clone KBA.62), and Anti-Human Melanosome (Clone HMB-45) was performed using the Ventana BenchMark XT (Ventana, Tucson, AZ) (Fig. 3a, b, c).

Results

Clinical characteristics

All the eight propositus cases occurred in females, with a median age of 65.6 years (range 37–90 years). Four of the eight cases were on the trunk, three on the lower extremities, and one on the forearm. Of the five control cases of junctional nevi, four were from females, with a median patient age of 34.8 years (range 26–53 years). Three cases were from the trunk and two from the extremities.

Histological findings

Histologically (Table 2), all lesions were mostly well-circumscribed with sharp margins and characterized by a striking nested pattern (Fig. 1), suggesting at scanning magnification a diagnosis of junctional nevus. Nests were mostly small, nevus-like, clear cut, and evenly spaced along the junction. However, a few alarming details indicative of malignancy were present as well. All cases but one showed a mild to severe degree of solar elastosis, with even confluent masses of elastotic fibers replacing the normal collagen bundles. A few areas of lentiginous proliferation with focal pagetoid ascent of melanocytes, more consistent with a diagnosis

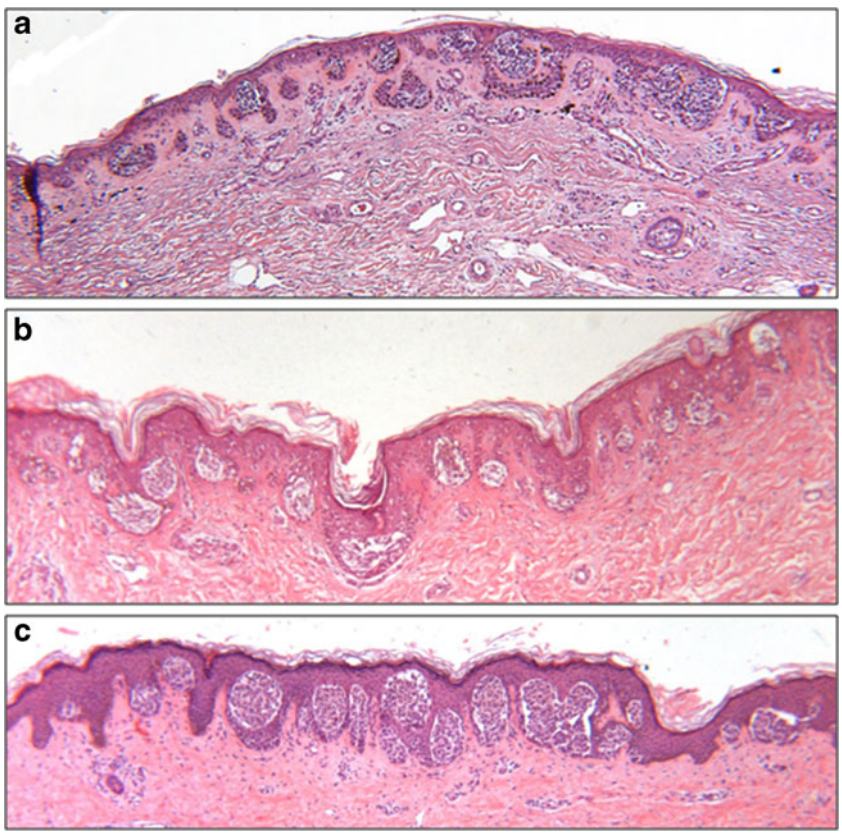

Fig. 1 A panel showing the striking nested pattern throughout the entire span of the lesion

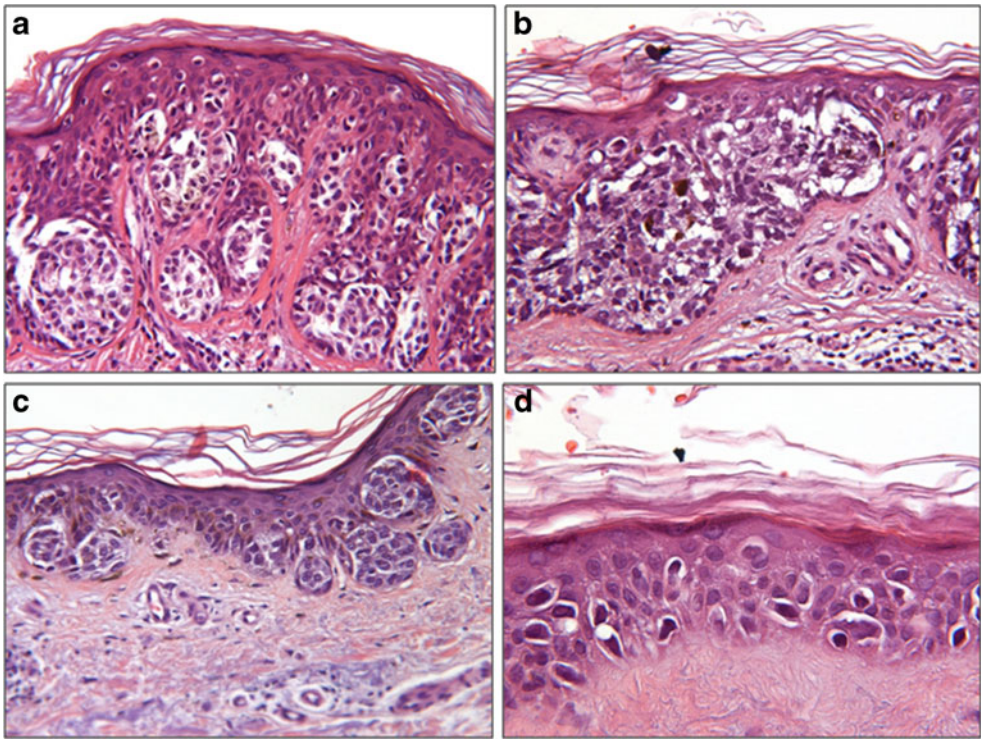

Fig. 2 Some of the hints of malignancy observed in the lesions (see text for details)

of melanoma in situ, were found as well. Some cytological atypia along with mild cellular plemorphism was also present. Cells were small, lymphocytic-like, highly hyperchromatic with barely distinguishable cytoplasm (Fig. 2). In some cases, a second population of large melanocytes with vesicular nuclei, irregularly thickened nuclear membranes, and prominent nucleoli was also found. Occasionally, nests were larger and widely confluent in bizarrely shaped masses of cells. Moreover, they sometimes varied significantly in size, shape, and content of pigment. No or scant inflammatory infiltrate was seen in the cases. In case no. 3 additional serial sections were made revealing a clear-cut invasive malignant melanoma of about 0.3 mm in thickness.

FISH results

Regarding FISH analysis, results were obtained using an Excel-based analysis algorithm for data elaboration supplied by the producing company and are plotted in Table 1. Seven of the eight cases proved positive in the test (Fig. 3d). The alteration in the RREB1 site was the most frequently observed abnormality in our nested melanoma cases (Table 1). In contrast, the five cases of junctional melanocytic nevus used as control were all negative by FISH, no genome anomalies were registered, and reference values were always well below cutoff values.

Table 1 Clinical data and FISH results

Case	Age	Sex	Dim (mm)	RREB1 percentage of nuclei with signal ≠ 2≥63	MYB ≥2.5 amplification (average)	CCND1 ≥2.5 amplification (average)	Percentage loss of MYB ≥31	FISH results
1	90	F	10	88.1	4.1	3	33	Positive
2	61	F	7	50	1.9	1.5	2	Negative
3	37	F	8	50	2.7	2.5	5.6	Positive
4	49	F	12	78	2.5	1.9	49	Positive
5	67	F	>30	87.8	2.1	2.1	24.2	Positive
6	76	F	10	88.9	1.5	1.7	41.5	Positive
7	80	F	6	78	2.8	2.2	25	Positive
8	65	F	10	63.8	2.4	2.1	19.6	Positive

BRAF results

Cases no. 1, 2, and 7 showed the BRAF V600E mutation, whereas all the others were normal.

Discussion

The cases of our study have in common a striking nested junctional pattern highly suggestive at scanning magnification of a diagnosis of a benign nevus. Cells are mostly arranged in roundish nests evenly aligned at the dermoepidermal junction. Nests are mostly clear-cut and regularly sized and shaped. There is no doubt that in routine histological examination these lesions might be misdiagnosed as junctional nevi. However, the clinical setting is definitely not compatible with a junctional nevus. Patients are old and the neoplasms appear on severely sun-damaged skin. Moreover, the lesions are unusually large in most of the cases. Furthermore, from a histological point of view, major cytological details conflict with a diagnosis of

Table 2 Histological characteristics

No.	Shoulders	Elastosis	Atrophy	Lentiginous array[a]	Cytological atypia	Confluence of nest	Pagetoid spread[b]	Inflammatory infiltrate	Pigment distribution
1	Lentiginous	++	No	++	++	Yes	+	+	Irregular
2	Nested	++	No	++	+	Yes	+	+/−	Irregular
3	Nested	+	No	−	+	Yes	+	+/−	Regular
4	Nested	No	No	−	+	Yes	++	No	Irregular
5	Lentiginous	+	No	++	+++	Yes	++	+	Irregular
6	Nested	+++	No	+/−	+	Yes	+	No	Regular
7	Nested	++	No	+	++	Yes	+	No	Regular
8	lentiginous	++	No	+	+++	Yes	+	No	Regular

The values reported (insignificant or not detectable finding −, low +, moderate ++, and severe +++) were independently assessed by 2 different observers (IP-VA) and confirmed by a senior pathologist (GM)

[a] Lentiginous arrangement was considered (+) when present for a third of the span of the lesional epidermis, (++) for half of the span, and (+++) for more than half

[b] Pagetoid spread was judged as (+) when 1–3 melanocytes were present for 1 mm of epidermis, (++) for 3–5 melanocytes, and (+++) for more than 5. Other cytological or architectural details were judged simply presence or absence

junctional nevus [1–3, 5, 7]. The most important of these is the presence of diffuse hyperchromasia of the cells inside the nests. Nuclei are small, lymphocyte-like, hyperchromatic as well as clumped. In some cases, a second population of large cells with a thickened nuclear membrane and large and basophilic nucleoli is found as well. At high power, a subtle but unquestionable cellular pleomorphism is also present. A further aspect contradicting a diagnosis of benign melanocytic nevus is the presence of a few cells with atypical features scattered above the junction. The pagetoid spread involves not only the center of the lesions but also the lateral portion of the neoplasms and even areas where junctional nests are not present at all. In some cases, a major feature is the presence of a lentiginous pattern of growth alternating with a nested one [8–10]. Melanocytes are aligned in single units along the junction with skip areas of irregular distribution. In all, these junctional lesions fulfill most criteria for a diagnosis of melanoma despite their striking nested pattern. Obviously, these lesions have to be distinguished from a form of junctional or compound dysplastic nevus, which can also occur in older patients and is usually larger than 5 mm in diameter [15–17]. However, in the cases we present, a diagnosis of malignant melanoma rather than dysplastic nevus was favored mostly on the basis of the following histological features: (1) predominance of melanocytic cells with a significant cytological atypia; (2) absence of lamellar fibroplasia in the papillary dermis which is typical of Clark nevus; and (3) presence of severe solar elastosis, which makes the diagnosis of dysplastic nevus highly improbable. This notwithstanding, in order to corroborate the diagnosis of melanoma, we further evaluated these lesions with a FISH assay for diagnosis in melanoma which currently provides a sensitivity of 86.7 % and a specificity of 95.4 % in discriminating benign and malignant melanocytic neoplasms [12–14, 18–20]. This assay revealed chromosomal alterations indicative of melanoma in all but one of our cases, whereas all control cases were negative. In our opinion, the subset of melanoma we presented here represents an evolved stage of the so-called lentiginous melanoma, an entity which was firstly described by King et al. in 2005 [8–10]. The term "lentiginous melanoma" defines a group of slowly progressing melanoma typically found on the trunk and proximal extremities of middle-aged and older patients. Its histological pattern is characterized by a broad lentiginous proliferation of atypical melanocytes occasionally gathered in nests, with focal pagetoid spread and nonsignificant dermal fibroplasia. In the paper by Newman et al. [11], a FISH study was conducted on 19 cases of lentiginous melanoma, of whom 16 (84 %) were positive by the test. Hence, in the same way, we propose to label as nested melanoma the subgroup of neoplasms closely mimicking a junctional nevus that we first described here. We firmly believe these lesions should be studied carefully through serial sections as they might not only reveal areas of more conventional melanoma but also an invasive component into the papillary dermis, as happened in one of our lesions. Regarding clinical treatment, reexcision of these lesions is highly recommended (Table 2).

Conclusions

Our observations support the notion that a small but distinct group of melanomas closely simulate junctional nevi because of their nested architecture. The striking nested pattern which characterizes this new entity, compared with the prominent lentiginous proliferation with only focal nesting of lentiginous melanoma, makes it a very dangerous diagnostic trap. In view of the strong similarity to a junctional nevus, these lesions are more likely to be misinterpreted as benign than cases of lentiginous melanoma, given that the lentiginous growth pattern itself represents a major hint of malignancy. A diagnosis of nested melanoma can be suspected when considering some additional clinical and histological clues, namely, old age of the patient, large lesion, presence of severe sun damage, atypical cytological features, focal pagetoid spread, and lentiginous pattern of melanocytic proliferation. These clues should induce the pathologist to perform additional evaluation with FISH technique with which we found chromosomal alterations consistent with melanoma in all but one of our cases. All the lesions consisted of junctional melanocytic proliferations in the initial sections, but additional serial sections showed an invasive component in one case. Making the correct diagnosis of melanoma in these cases is not only an academic matter as the misinterpretation of these lesions could have serious implications for treatment and prognosis.

Conflict of interest None.

Abstract Loss of E-cadherin expression in melanoma correlates with increased tumor thickness and reduced disease-free survival. The molecular mechanisms underpinning its differential expression in melanoma tissue remain elusive. MicroRNAs (miRNAs) have been implicated in tumor progression and regulation of E-cadherin expression. Here, we demonstrate a significant correlation between tumor thickness and loss of expression of miR-200a, miR-200c, and miR-203 in a series of 23 frozen primary melanomas, where it was confirmed in two subsequent validation series (series 1: six nevi, 15 primary

melanomas, and 16 metastases; series 2: 11 matched pairs of primary melanomas and metastases). Decreased levels of miR-200a, miR-200c, and miR-203 correlated with increasing thickness in the combined validation series (P=0.024, 0.033, and 0.031, respectively). In addition, progressive loss of miR-200a expression with disease progression was observed in series 1 (P<0.001) and in series 2 (P=0.029). MiR-200 in situ hybridization and E-cadherin immunohistochemistry demonstrated reduced expression of both at the deep invasive margin of the tumor. Furthermore, a functional validation study using an anti-miR200 strategy demonstrated that loss of miR-200 expression in melanoma cell lines reduced E-cadherin expression. Collectively, our data point towards an important role for miR-200 and miR203 expression in regulating E-cadherin during melanoma progression.

Introduction

Epithelial–mesenchymal transition (EMT) is associated with increased malignancy of carcinomas [1]. EMT increases migratory and invasive capacities of tumor cells and can prevent apoptosis and senescence. Dissolution of E-cadherin-mediated adhesion is a key preliminary step in EMT. Throughout tumor progression, melanoma cells accumulate mesenchymal characteristics [2–4]. In culture, loss of E-cadherin correlates with the metastatic potential of melanoma cells and with the ability of keratinocytes to modulate expression of melanoma progression markers like MelCAM [5]. Accumulation of mesenchymal traits by melanoma cells in tissue is not as evident as in cell lines. This is not only because of the enormous cytological variation between primary cutaneous melanomas, but also because phenotypic differences within a given melanoma in which mesenchymal-like spindle cell areas may alternate with areas in which the melanoma cells assume a more epithelial-like aspect. Furthermore, invasive melanoma cells in tissue commonly lack spindle morphology [6]. Loss of E-cadherin expression has been reported to correlate with increased thickness [7] and reduced survival [8]. However, E-cadherin expression in melanoma may be quite heterogeneous [9].

Canonical and noncanonical Wnt signaling modulate E-cadherin expression [10]. Fibroblast growth factor, Hedgehog, transforming growth factor β (TGFβ), and noncanonical Wnt signals synergistically induce EMT regulators, such as, Snail, Slug, TWIST, and the E-cadherin repressors ZEB1 and 2. High Snail protein expression is observed in melanoma [11] and can induce immune suppression via induction of regulatory T cells and impairment of dendritic cell function [12]. Our previously published gene expression study in primary melanoma demonstrated a correlation between overexpression of Snail and poor 4-year distant metastasis-free survival (DMFS) [13] and supported the hypothesis that mesenchymal traits of melanoma cells is associated with poor prognosis.

In addition to Wnt signaling, E-cadherin expression can be modulated by differential expression of microRNAs (miRNAs). MiR-9 directly targets the E-cadherin encoding messenger, CDH1 [14]. Conversely, miR-200 family members (miR-141; miR-200a, b and c; and miR-429) target transcriptional repressors of E-cadherin, i.e., ZEB1 and ZEB2, in breast, ovarian, and pancreatic cancers [15–17] and various tumor cell lines [18]. Although target prediction algorithms predicted little overlap in the targets of miR-200 family members, experimental approaches suggested that their sets of targets are highly overlapping [18].

Using a large set of fresh frozen nevi, primary melanomas, and melanoma metastases, we demonstrate that expression of miR-200a and miR-200c correlate with melanoma thickness and metastasis. These findings were validated by quantitative PCR, miRNA in situ hybridization, and functional validation studies. Collectively, our data support the hypothesis that loss of miR-200 and miR-203 expression in melanoma increases mesenchymal characteristics and that this can contribute to progression.

Materials and methods

Tissues

All tissue samples were retrieved from the pathology archives at the University Hospital Leuven, Leuven, Belgium. The pertinent histological and clinical features are listed in Supplemental Tables S1–S3. Representative tissue parts were snap frozen in liquid nitrogen-cooled isopentane and stored at −80 °C until used. Sampling, storage, and use of these samples were performed according to requirements of the Local Ethical Committee. For miRNA in situ hybridization, formalin-fixed and paraffin-embedded tissue blocks were retrieved from pathology archives of the Radboud University Nijmegen Medical Centre. Tissues were obtained according to local ethical guidelines and approved by the local regulatory committee.

Preparation of total RNA and cDNA for miRNA profiling

Depending on the size of the sample, 20 to 40 sections (10 μm) were cut from frozen tissue blocks containing more than 75 % melanoma or nevus cells as evaluated from hematoxylin and eosin-stained sections. Sections were lysed immediately in 1 ml TRIzol (Invitrogen) and RNA was extracted subsequently according to the manufacturer's protocol. Absence of DNA contamination and RNA integrity

were analyzed on a Bioanalyzer (Agilent Technologies). RNA integrity number (RIN) higher than 7.5 and, in most cases, higher than 9 were obtained.

Total RNA (8 ng) was reverse transcribed using 50 nM stem–loop RT primer and MultiScribe Reverse Transcriptase (Life Technologies) according to the manufacturer's protocol. The expression of total 158 mature human miRNAs was analyzed using specific miRNA primers available from Life Technologies (Supplemental Table S4).

Real-time quantitative PCR

Real-time PCR was performed using the standard TaqMan protocol using Applied Biosystems reagents and an Applied Biosystems 7900 High Throughput Sequence Detection System. All reactions were run in duplicate. Mean Treshold Cycle (Ct) value was determined as median of two reads. In order to provide robust data, only values below 32 Ct were considered as specific and values above 32 CT were considered as missing data. This resulted in the exclusion of 29 miRNAs for further analyses, leaving a total of 129 miRNAs in the discovery phase of the study (Supplemental Table S4). Change in expression was determined by calculating the 2^{-ddCt} value [19]. MiRNA expression was normalized to let-7a expression. Normalization to any calibrator sample had very low influence on the overall data (data not shown), demonstrating high quality total RNA purification.

Statistical analysis

The Pearson correlation coefficient between the normalized Ct value of a miRNA and primary tumor thickness was determined. A stratified correlation coefficient was calculated for the analysis of association between expression and tumor thickness after combining all data from the two validation series, thereby controlling for possible batch effects [20]. DMFS was defined as the time interval between the diagnosis of the primary cutaneous melanoma and a distant metastasis and statistical differences assessed by a logrank test. Patients alive without distant metastasis or who died of causes not related to melanoma were censored at the date of last follow-up or at the date of death, respectively. An analysis of variance was applied to test for the difference in expression between nevi, tumors, and metastases. The paired *t* test was used for paired analysis of miRNA expression in the matched series of primary melanomas and metastases. Because of multiple testing, *p* values were adjusted for the False Discovery Rate (FDR) criterion [21]. *P* values from the stratified correlation analyses are based on an empirical permutation distribution and were not further adjusted. The *t* test for equality of means for independent samples (equal variance not assumed, two-tailed) was used to determine the difference in CDH1 expression in cell lines after miR-200c silencing.

In situ hybridization for miR-200c and E-cadherin immunohistochemistry

Consecutive tissue sections of formalin-fixed and paraffin-embedded primary melanomas ($n=10$) were prepared. MiRNA in situ hybridization was performed on 6-μm sections according to our previously described protocol [22] with minor modifications. A 5′- and 3′-end digoxigenin-labeled LNA/DNA oligonucleotide designed to hybridize to miR-200c ([18]; 5′-CCATCATTACCCGGCTGTATTA, underlined nucleotides indicate LNA bases, Exiqon, Vedbaek, Denmark) was hybridized to the tissue section overnight at 55 °C. MiR-200c was visualized using alkaline phosphatase-conjugated anti-digoxigenin Fab fragments (Roche), nitro blue tetrazolium, and 5-bromo-4-chloro-3′-indolyphosphate. The consecutive 4-μm sections were stained for E-cadherin as described previously [23].

MiR-200c silencing

E-cadherin-expressing human melanoma cell lines 888Mel, 1 F6, and SK-Mel28 were cultured as described previously [23, 24]. Exponentially growing cells were transfected with 20 nM thioacetylated LNA–DNA oligo towards miR-200c (5′-CCATCATTACCCGGCTGT ATTA) or a thioacetylated LNA–DNA scrambled oligo (Exiqon) using X-tremeGENE siRNA transfection reagent (Roche) according to the supplier's protocol. Two days after transfection, cells were harvested and plated in a 6-well plate at 60 % confluence and the transfection protocol repeated. The remaining cells were used for total RNA extraction (NucleoSpin RNA II, Macherey-Nagel, Düren, Germany). A total of three transfections were performed. cDNA was prepared using 0.5 μg total RNA, oligo-dT primers, and Moloney Murine Leukemia Virus Reverse Transcriptase (Promega) according to the supplier's protocol. cDNA was diluted five times and 5 μl was used for qPCR using Power SYBR Green Universal Master Mix (Applied Biosystems), and a CDH1-specific primer pair (NM_004360.3, 5′-ATGAGTGTCCCC CGGTATCTT and 5′-CAGCCGCTTTCAGATTTTCATC) in 25 μl. All samples were normalized for GAPDH expression (NM_002046.3, 5′-GAACCTGACCTGCCGTCTAG, 5′-CCTGCTTCACCACCTTCTTGA). A preliminary primer validation study revealed that the slope of the standard curves for both CDH1 and GAPDH was between 2.9 and 3.2. Normalized Ct values for CDH1 expression for scrambled and anti-miR-200 oligo-transfected cells at $t=0$ was set at 100 % and used to calculate change in CDH1 expression for all other time points. The experiment was performed three times in triplicate.

Table 1 Pearson correlation coefficient between normalized Ct values and tumor thickness

Name	*p* value[a]	FDR[b]	Correlation[c]
miR-203	0.000	0.002	0.788
miR-205	0.000	0.018	0.713
miR-200b	0.001	0.026	0.698

Results

Discovery phase for miRNAs associated with progression

For the discovery phase of the study, miRNAs were isolated from fresh frozen primary cutaneous melanomas from 23 different patients (median Breslow thickness 3.68 mm; range 0.44–15.64; Table S1). Of these patients, 12 patients did not develop distant metastases during a follow-up of at least 4 years. Expression of 159 different miRNAs was measured in triplicate by qPCR. Thirty miRNAs were subsequently excluded from further analyses because reproducible quantification failed. Statistical analyses of the remaining 129 miRNAs (Supplemental Table S4) identified 11 miRNAs which expression strongly correlated with tumor thickness ($p<0.01$ and FDR<0.08, Table 1). The most significant miRNA was miR-203: its expression strongly decreased with increasing tumor thickness ($p<0.001$, FDR<0.002).

Two miRNAs demonstrated a significant correlation with DMFS or death due to the disease. Loss of miR-203 expression was associated with reduced DMFS (logrank $p=0.006$), whereas increased expression of miR-130b was associated with better DMFS (logrank $p=0.008$). However, for both miRNAs, the FDR was high (FDR=0.25).

Validation phase: unmatched and matched series

To replicate the possible associations with progression, we subsequently analyzed expression of nine miRNAs (miR-17.5p, 106a, 130b, 150, 200a, 200c, 203, 205, and 335) in a second unmatched series of melanocytic lesions (six acquired nevi, 15 primary melanomas (median thickness 4.20 mm, range 0.94–9.28), and 16 melanoma metastases). qPCR analyses revealed significantly different expressions of miR-200a, miR-200c, and miR-203 (Fig. 1; ANOVA, $p<0.001$, FDR<0.001), with miR-203 being the most significant. To confirm the progressive decrease in expression with progression to metastasis, their expression was determined in a third matched set of 11 primary cutaneous melanomas (median thickness 4.27 mm, range 0.59–5.57) and their corresponding locoregional ($n=10$) or distant ($n=3$) metastases (Supplemental Table S3). A paired *t* test confirmed a significant difference for miR-200a ($p=0.029$, FDR<0.08), but not for miR-203 ($p=0.08$) and miR-200c ($p=0.07$). However, the expressions of the three miRNAs were very highly correlated between each other (all three pairwise correlation coefficients>0.84, $p<0.002$).

We next analyzed whether expression of the three miRNAs correlated with tumor thickness by combining the two validation studies (26 primary melanomas, median thickness 4.1 mm (range 0.59–9.28)). For each miRNA, a correlation coefficient stratified by series was calculated in order to control possible batch effects [20] and found a significant correlation with tumor thickness for each miRNA ($p=0.024$, 0.033, and 0.031 for miR-200a, miR-200c, and miR-203, respectively).

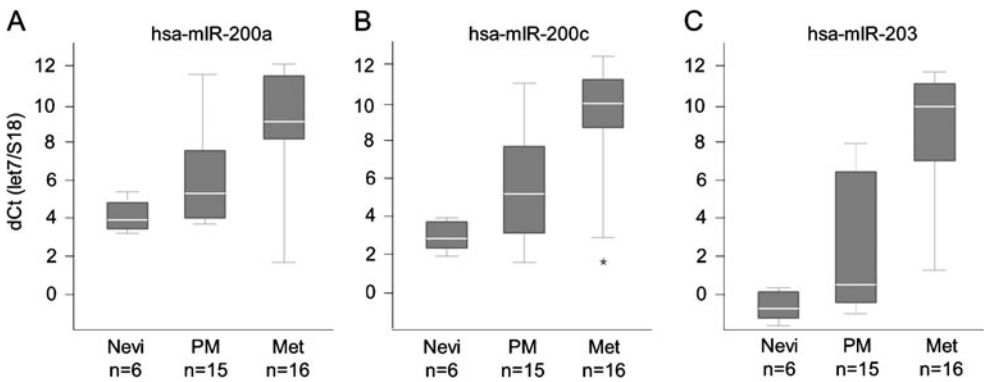

Fig. 1 Box plot presentation of miR-200a, miR-200c, and miR-203 expression in nevi, melanoma, and melanoma metastases. Ct values for the miRNAs in nevi, melanoma, and melanoma metastases were normalized to Let7 and 18S and expressed as 2^{-Ct}

In situ detection of miR-200c and E-cadherin expression in primary melanoma

It has been established previously that downregulation of miR-200a and miR-200c increases ZEB1/2 expression and that it downregulates E-cadherin expression in vitro [25]. To demonstrate this correlation in melanoma tissue, a chromogenic in situ hybridization assay for miR-200c was performed using a LNA–DNA oligo [18]. A total of ten superficial spreading primary melanomas with clear vertical growth phase were analyzed. Consecutive tissue slides were stained for E-cadherin. Strong miR-200c and E-cadherin expressions were observed in epidermis and hair follicles of the skin and served as an internal positive control. This strong and positive correlation between miR-200c and E-cadherin expressions in nontumor tissue strongly suggests specific hybridization signals. These analyses demonstrated that loss of miR-200c expression coincides with loss of E-cadherin expression in all tumors analyzed. The weakest hybridization signal at the deep invasive margin of the melanoma (Fig. 2, representative staining) confirmed the progressive loss of miR-200c with increasing thickness. Loss of miR-200c and E-cadherin expression did not correlate with clear mesenchymal cell morphology: cells lacking E-cadherin did not display an obvious spindled shape. However, a case of spindle cell melanoma was entirely negative (Supplemental Fig. S1).

Downregulation of miR-200 in melanoma cell lines

To demonstrate a possible causal relation between loss of miR-200c and E-cadherin expressions, E-cadherin expressing melanoma cell lines 888Mel, 1 F6, and SKMel28 were transfected with a LNA–DNA oligo that was previously shown to antagonize miR-200c [18]. Three rounds of transfection with anti-miR-200c resulted in decreased CDH1 expression in all three cell lines, whereas transfection with the scrambled control LNA–DNA oligo did not (Fig. 3). At 6 days post-transfection, mean CDH1 expression was reduced to 43 % (SEM=5.8, n=3, P=0.008) in 1F6 cells compared to scrambled control (Fig. 3a), 44 % for 888Mel cells (SEM=6.9, n=3, P=0.014, Fig. 3b), and 60 % in SKMel28 cells (SEM=6.9, n=3, P=0.031, Fig. 3c). These data suggest a causal relationship between miR-200c and E-cadherin expressions in melanoma. Additional transfections did not further decrease CDH1 expression and expression returned to normal levels within 1 week after the last transfection (data not shown).

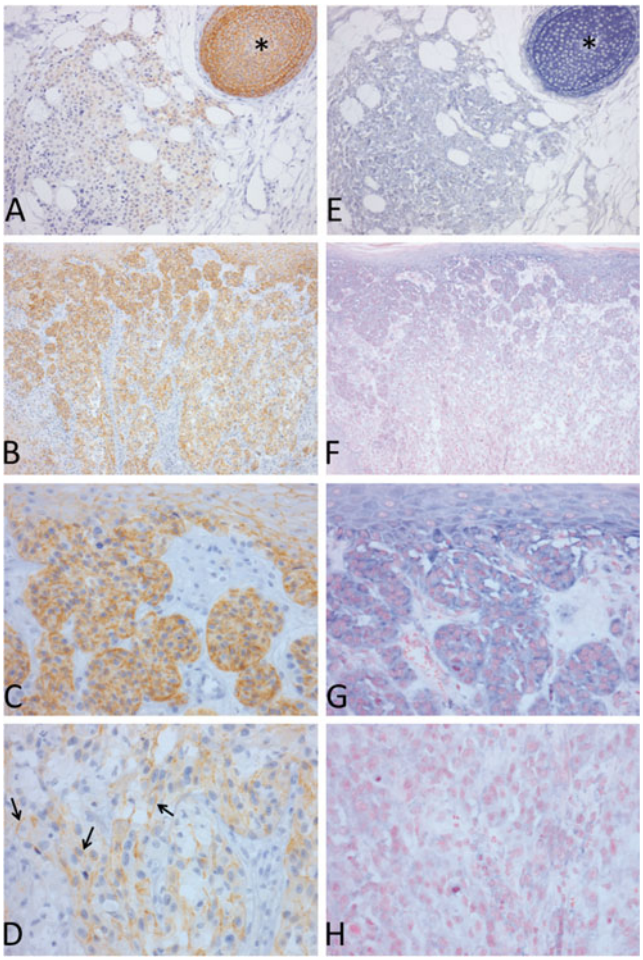

Fig. 2 In situ detection of miR-200 and E-cadherin. Consecutive tissue sections were subjected to E-cadherin immunohistochemistry (**a**–**d**) and miR-200c in situ hybridization (**e**–**h**). A subcutaneous metastasis (**a**, **e**) displays no E-cadherin (**a**) and miR-200c (**e**), whereas high E-cadherin (*red AEC staining*) and miR-200 expression (*blue NBT-BCIP staining*) was observed in the adjacent hair shaft (*asterisk*). In primary melanoma (**b**–**f**), a progressive loss of both E-cadherin (**b**) and miR-200c (**f**) can be seen with increasing thickness. At higher power view of the subepidermal component (**c**, **g**), clear membranous E-cadherin staining of the overlying epidermis and strong membranous staining of melanoma cells can be seen (**c**). Strong miR-200c expression was observed in epidermis and melanoma cells (**g**). In the deep dermal component, low and predominantly membranous E-cadherin expression was detected (**d**, *arrow*) but miR-200c expression was not observed (**h**)

Discussion

In this study, we demonstrate that loss of miR-200a, miR-200c, and miR-203 expression in melanoma correlates with tumor thickness, and their progressive loss in a series of matched primary tumors and associated metastases strongly suggest a possible association with disease progression. Loss of miR-200c and E-cadherin expression was exclusively observed that the invasive front and in in vitro experiments support a causal relation between loss of miR-200c and E-cadherin expression.

Loss of miR-200 family members in melanoma has been described previously [26], but not in the context of tumor thickness, localization of expression with the tumor, and

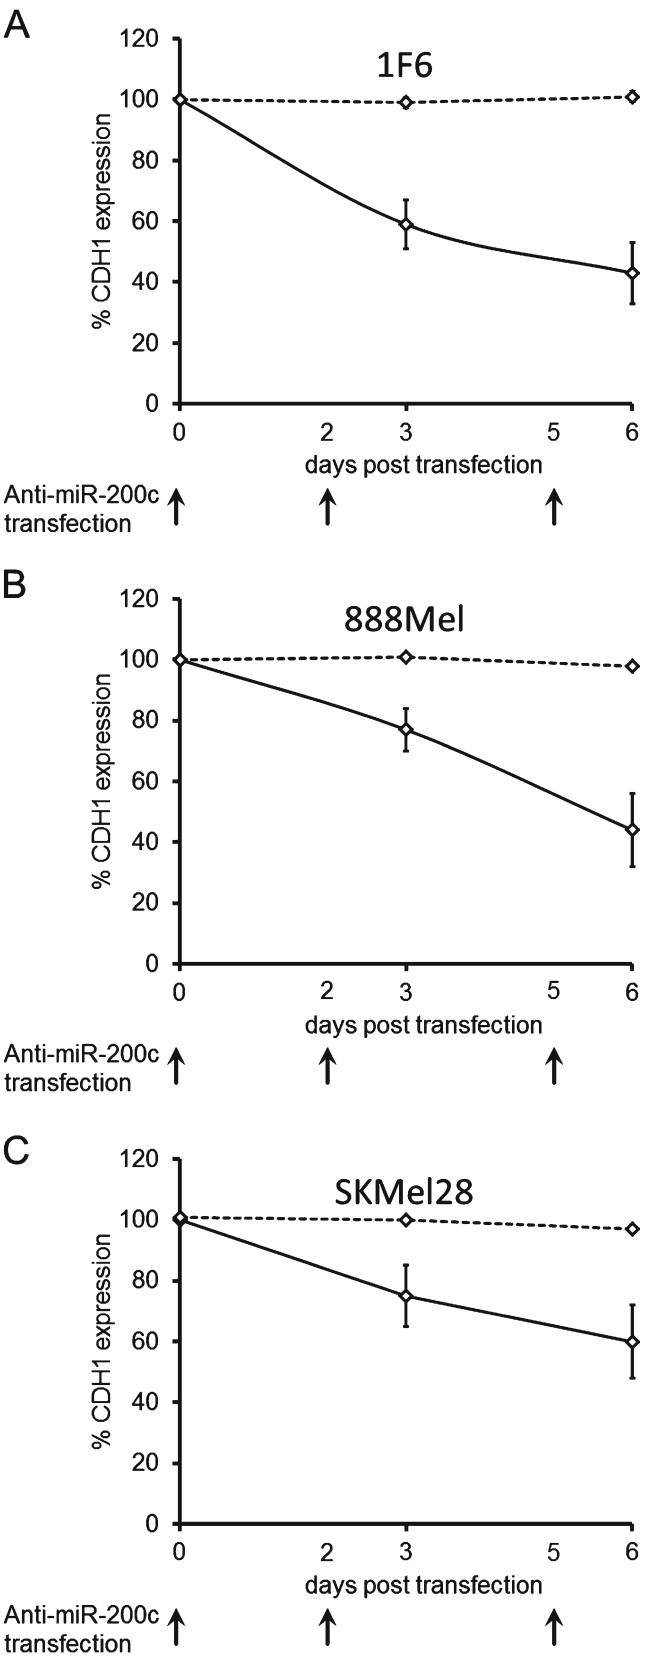

Fig. 3 Anti-miR-200c reduced E-cadherin expression in melanoma. Consecutive rounds of transfection of three different E-cadherin-expressing melanoma cell lines 1F6 (**a**), 888Mel (**b**), and SKMel28 (**c**) with the LNA–DNA oligo-targeting miR-200c resulted in a progressive decrease in E-cadherin (CDH1) expression as measured by qPCR in all cell lines (*solid line*) compared to scrambled control transfected cells (*dashed line*).Six days after transfection, mean CDH1 expression levels in 1F6, 888Mel, and SKMel28 cells were reduced to 43 % (P=0.008), 44 % (P=0.014), and 60 % (P=0.031) of that of control cells, respectively. *Arrows* indicate time points of transfection. Data is expressed as the percentage of expression of scrambled control transfected cells. *Error bars* indicate the standard deviation of three different experiments, each in triplicate

progression towards a metastatic melanoma phenotype. Recently, reduced expression of miR-200 family members was observed in a series of melanoma metastases compared to a series of unrelated primary melanoma [27]. Our work significantly refines these observations by visualizing the gradual loss of miR-200c and E-cadherin expression in primary melanoma, with maximal loss of expression at the most invasive component of the tumor. Furthermore, using pairs of melanoma metastases and the primary melanomas from which they originated, we could demonstrate loss of miR-200a, c, and miR-203 expression with advanced stages of disease for individual. Therefore, our data support the hypothesis that loss miR-200a, c, and miR-203 correlates with melanoma progression towards metastases.

The mechanism by which loss of miR-200a, c, and miR-203 contributes to melanoma metastasis remains elusive and their role in metastasis is subject of debate. Previous observations suggest that miR-200c expression can suppress migration of carcinoma cells [18, 25, 28, 29]. However, in melanoma cell lines, miR-200 family members do not inhibit cell migration but have profound effects on melanoma cell morphology and mode of melanoma cell invasion in 3D matrices [30]. MiR-200c overexpression drives the nonmesenchymal amoeboid form of invasion in type I collagen gels [30]. A different study demonstrated that melanoma cells can express markers of amoeboid invasion at the invasive front of melanomas, which most often consists of cells without a spindled morphology [6]. In that study, miR-200c expression was not analyzed. Our data, however, demonstrate that loss of miR-200c expression occurs at the invasive front and argues that miR-200c-mediated ameboid invasion in 3D culture models with its known limitations [31] is not representative for melanoma invasion in tissue. A recent study using a breast cancer cell line suggests a biphasic role of miR-200 family members in metastasis in which their expression can hinder tumor cell dissemination and entry into circulation but that it can support outgrowth at a secondary site [32]. Our data, however, demonstrate that loss of miR-200c expression occurs at the invasive front and that its expression in metastases is significantly lower compared to primary lesion from which it originated. This may suggests that the metastases originated from the miR-200-negative cells at the invasive front. The discrepancies between our data, miR-200c-mediated mode of invasion in 3D culture models, and the

possible biphasic effect of the expression of miR-200 family members in melanoma warrants further investigations.

The contribution of miR-200 a and c to tumor progression most likely extends beyond its ability to modulate invasion via the ZEB/miR-200/E-cadherin axis. Our data demonstrate a very strong correlation between miR-200a, c, and miR-203 expressions. ZEB1, in addition to repressing E-cadherin transcription, also represses miR-203 expression [17]. It has been proposed that miR-203 is a key molecule repressing expression of epithelial differentiation by 'stemness'-related genes [33, 34], such as, the stem cell-related transcription factors *BMI1* [35] and *SOX2* [17]. Expression of Sox2 has been documented in melanoma cells with presumed stem cell or tumor-initiating characteristics, in particular, at the invasive front of primary cutaneous melanoma [36, 37]. A stem cell-like phenotype is associated with the cell's ability to grow in an anchorage-independent manner. Loss of miR200a and c may, therefore, be important for cells to acquire this ability. Although we were not able to maintain long-term down regulation of miR200c expression using anti-miR-200c that allowed us to test if loss of miR-200c loss increased colony formation in soft agar (data not shown), others have demonstrated that forced expression of miR-200c in A375 melanoma cells reduced their capacity to grow in soft agar [27]. This suggests that loss of miR-200c could indeed promote anchorage-independent growth. The observations that ZEB1 expression is necessary for TrkB-mediated suppression of anoikis in rat intestinal epithelial and kidney cells [38] and that TrkB expression is predominantly observed in the invasive growth component of melanoma [39] lend further support to additional effects of disturbing the ZEB-miR200 equilibrium beyond that of modulating E-cadherin-mediated cell adhesion in melanoma cells.

Our results demonstrate a clear and highly significant correlation between loss of miR-200a, c, and miR-203 expression at the invasive front of melanoma, which is casually related to loss of E-cadherin expression. Expression of these miRNAs is strongly reduced in melanoma metastases compared to the matched primary tumors. Several lines of research point to a variety of effects of miR-200 activity in different tumor types and cell lines. If and how these are relevant for melanoma progression warrants further investigations.

Conflict of interest None.

Abstract Acquired immunodeficiency syndrome (AIDS) is characterized by decreased immunity, making a patient more susceptible to opportunistic infections which can have cutaneous manifestations. The aim of this study was to evaluate the local immunity of the skin through morphological and immunohistochemical analysis. Skin samples of 52 women, 27 without AIDS and 25 with AIDS, autopsied in an academic referral hospital in Brazil were evaluated. The autopsy reports and medical records were reviewed, and histochemical Hematoxylin–eosin, Picrosirius red, and Verhoeff stains as well as morphometric (Image J and KS-300 Kontron-Zeiss) and immunohistochemical (S-100 and anti-IgA) analyses of the skin were performed. Women with AIDS presented a thinner epidermis than women without AIDS (33.33 [12.00–317.66] vs 67.42 [12.00–530.02] μm; $p<0.001$), with a lower number of epithelial cell layers (4.00 [2.00–11.00] vs 4.00 [2.00–16.00]; $p<0.001$), a smaller cell diameter (12.92 [6.00–28.87] vs 24.32 [6.00–33.12] μm; $p<0.001$), and a lower number of Langerhans cells (LC) (12.58 [0.00–81.74] vs 31.44 [0.00–169.77] LC/mm^2; $p<0.001$). The dermis contained more collagen fibers (8.20 % [2.40–19.40] vs 6.30 % [0.40–13.90]; $p<0.001$). Some of these parameters were negatively correlated with viral load and positively correlated with the number of CD4+ T-lymphocytes. We conclude that a decrease of the local skin immunity in women with AIDS may contribute to the development of skin lesions.

Introduction

Acquired immunodeficiency syndrome (AIDS) is characterized by decreased immunity, making the patient more susceptible to opportunistic infections and cutaneous manifestations, especially in countries where the availability of antiretroviral therapy is limited [1, 2]. Skin involvement in AIDS comprises neoplasia, infections, and inflammatory disorders [3].

The immune response to infectious agents occurs through two mechanisms known as innate immunity and adaptive immunity. The first is provided by natural barriers such as the skin tissue, mucosa, and lymphoid tissue; the latter is related to the production of antibodies and cytokines by B lymphocytes and CD4+ and CD8+ T-lymphocytes [4]. In this context, morphological and immunological alterations of the skin may indicate a decrease of both innate and adaptive immunity of the skin. Therefore, the study of skin samples of autopsied patients presents an opportunity to gain knowledge of this organ and its changes in patients with AIDS.

The epidermis is a continuously renewed stratified epithelium. It is mostly composed of keratinocytes, but 5 to 10 % of the cells are Langerhans cells (LC) and melanocytes [5]. The LC found in the epidermis have functions which include antigen presentation and the stimulation of a T-cell response. During AIDS, there is a decrease of LC in the epidermis [6] and in other stratified epithelia such as the esophagus [7–9], uterine cervix [10], and the oral mucosa [11].

Keratinocytes represent the body's "first line of defense" from the outside environment, and as such they are the first responders to injury. After injury, keratinocytes become activated, secreting various cytokines and growth factors as well as responding to cytokines and growth factors as part of the mounting inflammatory response [12]. Several adhesion molecules are involved in the migration of circulating T cells to the tissues, but the memory lymphocytes which infiltrate the skin express the cutaneous lymphocyte antigen, a surface glycoprotein that allows the arrival of lymphocytes in the skin [13]. Both Th1 and Th2 responses are well developed in the skin, but in most inflammatory cutaneous diseases the predominant response is Th1 [14]. Despite humoral immunity being less active in the skin, it is relevant to evaluate the influence of AIDS on the expression of immunoglobulins in the epidermis.

Epidemiological data have shown a progressive incidence of the infection caused by the human immunodeficiency virus (HIV), and in most cases, the disease is associated with heterosexual transmission [15], which results in a substantial increase of cases in women [16]. Studies of women with AIDS have demonstrated a reduction in the thickness of the cervical [10, 17] and esophageal epithelia [8, 9], which suggest altered innate immunity since the epithelial cells constitute a physical barrier important to the defense against pathogens [18]. As the skin contains a stratified squamous epithelium [19], similar to the one which covers the external portion of the uterine cervix and of the esophagus, we expected to find in our study a thinner epidermis in women with AIDS.

Patients with advanced HIV infection frequently have a CD4+ T-lymphocyte count of <200 cells/mm^3, high levels of RNA virus in the plasma, and clinical manifestations indicating severe immunodeficiency [20]. The higher the level of the viral load, the lower the CD4+ T-lymphocyte count and the greater the risk of developing AIDS [21]. Therefore, our study intended to verify whether the morphological and immunological alterations described in other organs [8–10, 17] also occur in the skin of AIDS patients, as well as the influence of the viral load and the CD4+ T-lymphocyte count on these alterations.

Methods

This study was approved by Triângulo Mineiro Federal University Research Ethics Committee on 06/08/07 (approval number 902). The reports of 330 autopsies, conducted between 1984 and 2008 at the General Hospital of Triângulo Mineiro Federal University in the state of Minas Gerais, Brazil, were reviewed. We selected those from 52 women aged between 16 and 54 in order to compose two groups: (1) women without AIDS (n=27) and (2) women with AIDS (n=25). Although Triangulo Mineiro Federal University offers services for various regions of Minas Gerais state and also to other states, all patients in this study, with and without AIDS, were from Minas Gerais state. Cases with an incomplete autopsy report or with chronic metabolic or infectious diseases that might influence the findings were excluded. Data concerning age, body mass index (BMI), cause of death, and macroscopic alterations of the skin were collected from the autopsy reports, whereas the use of antiretroviral therapy and the values of the last viral load tests and CD4+ T-lymphocyte cell count were collected from medical records.

We recovered the results of these exams from only 11 patients with AIDS since they started being taken care of in this hospital only in 1998. Moreover, some patients requested care only in the terminal phase of their disease, leaving insufficient time to conduct these tests. Patients with and without AIDS were matched according to age, BMI, and cause of death in order to avoid the confounding effects of these variables.

All patients with AIDS observed in this study died during the post-highly active antiretroviral therapy (HAART) era (after 1996) [20]. Some patients autopsied before 1997 were assigned to the group without AIDS because the number of patients without AIDS autopsied in post-HAART era, with age, BMI value, and cause of death matching our patients with AIDS, was insufficient.

AIDS diagnosis was made by evidence of at least one AIDS-defining disease presented by a patient [22]. All patients without AIDS were HIV-negative. In this study, the causes of death were grouped into cardiovascular, infectious, digestive, neoplastic, and others [23].

Skin fragments from the anterior thoracic region of women selected for this study were obtained from the General Pathology Division archives. This region was chosen because it is an area protected from the harmful effects of ultraviolet irradiation. The skin samples were macroscopically and microscopically normal. They had been submitted to histological processing, and for the study, we cut serially sections from the available paraffin blocks at 4 μm for histochemical and immunohistochemical studies. In order to account for tangential cutting, the morphology of dermal papillae and of cell layers (basal, spindle, granular, and corneal) was observed. Cases in which the epidermal morphology indicated that the sections were not perpendicular to the surface were excluded. Hematoxylin–eosin (H&E) staining was carried out for the morphometric analysis of epidermis thickness, Picrosirius red was used for the quantitative analysis of collagen fibers, and Verhoeff stain was used for the measurement of elastic tissue.

Image J Program (an interactive analysis system) was used to measure epidermal thickness, which was measured by tracing five straight lines on different parts of each field

to be analyzed [8–10, 17] Along each line, the number of keratinocyte nuclei was counted in order to determine the number of cell layers in the epidermis. The average cell diameter was obtained by dividing the epidermal thickness by the number of keratinocyte nuclei in each measure.

To investigate the amount of collagen fibers in the dermis, Picrosirius red stained fragments were examined under polarized light and quantified by Image J software. To analyze elastic fibers, skin samples stained with Verhoeff stain were examined under a conventional light microscope and quantified by an image analysis system, KS-300 (Kontron-Zeiss®).

To evaluate the number of Langerhans cells, antibody Anti-S100 (Dako®) was used at a concentration of 1/400; IgA was quantified using antibody anti-IgA (Erviegas®) at a concentration of 1/1,000. For antigen retrieval, heating in sodium citrate buffer was utilized for the antibody Anti-S100 and trypsin digestion for anti-IgA. For blocking of non-specific staining, bovine serum albumin was used. The primary antibodies were incubated for 2 h and processed through LSAB+System-HRP (DAKO®); diaminobenzidine (DAB) was used as substrate-chromogen.

Immunostained LC were quantified by conventional light microscopy along the length of the specimen and the number expressed/area (mm^2). To determine the quantity of immunostained IgA in the dermis, the DAB-stained area was measured using KS-300 (Kontron-Zeiss®) software.

Statistical analysis was carried out using the SigmaStat 2.03® program. In cases of normal distribution and similar variances, Student's *t*-test was employed; otherwise, we used Mann–Whitney (*T*) test. Correlation between both variables with abnormal distribution was determined through Spearman (rS) tests, respectively. We considered statistically significant values at $p<0.05$.

Results

The age range of both groups was 30–39 years. The average BMI in the non-AIDS group was 23.22±6.82 kg/m^2 and in the AIDS group it was 21.67±5.24 kg/m^2 ($p=0.364$). The frequency of causes of death from cardiovascular, infectious, neoplastic, and other causes in women without AIDS and with AIDS were nine (33.33 %), 11 (40.74 %), two (7.40 %), and five (18.51 %) versus nine (36.00 %), nine (36.00 %), two (8.00 %), and five (20.00 %), respectively.

Macroscopic alterations in the skin were observed in four (14.80 %) women without AIDS and in seven (28.00 %) women with AIDS. Among these changes, eschar, ulcer, crusted lesion, scaly lesion, verrucous lesion, and nocardiosis in skin were reported in the autopsy records of one (3.70 %), two (7.40 %), one (3.70 %), 0, 0, and 0 patient without AIDS and of two (8.00 %), one (4.00 %), 0, 2 (8.00 %), one (4.00 %), and one (4.00 %) patient with AIDS, respectively.

Antiretroviral therapy was taken by 14 (56.00 %) women with AIDS, but in most cases, the treatment compliance was insufficient.

Women with AIDS showed significantly reduced epidermal thickness, number of keratinocyte layers, and keratinocyte diameter than women without AIDS (Table 1; Fig. 1).

Women with AIDS had a significantly higher percentage of dermal collagen fibers than women without AIDS, but the density of elastic fibers was not different (Table 2).

The number of LC was significantly smaller in patients with AIDS. A lower IgA-immunoreactive area was observed in the dermis in the group with AIDS, but this did not reach statistical significance (Table 3; Fig. 2).

In the group of patients with AIDS, the mean CD4+ T-lymphocyte count was 43.00 cells/mm^3 (7.00–517.00), and the mean viral load was 595.00 copies/ml (233.00–15,019.00) of blood. A significant negative correlation was observed between the viral load and the thickness of the epidermis (rS, −0.157; $p<0.001$), the number of cell layers (rS, −0.0618; $p=0.00986$), the average cell diameter (rS, −0.144; $p<0.001$), the IgA-immunoreactive area (rS, −0.243; $p<0.001$), and the LC number (rS, −0.484; $p<0.001$) in the epidermis of patients with AIDS. There was a significant positive correlation between the number

Discussion

Women have been more intensely infected by AIDS in the 25 to 39 age range and still show increasing indices of incidence in practically every age range, but the incidence rates have stabilized during the last decade [24]. The average age in both groups observed in this study represents the age at which women are mostly infected by the syndrome.

There was no significant difference in BMI values between the groups of women with and without AIDS, which avoided a possible influence of this parameter on the thickness of the epidermis.

Causes of death were similar in patients with and without AIDS, which is important because some causes of death, such as neoplastic, are related to weight loss [25, 26], which might influence the thickness of the epidermis.

Skin changes were more frequent in patients with AIDS, in agreement with the literature. The decrease in immunity, caused by this syndrome, makes the patient more susceptible to opportunistic infections and cutaneous manifestations [1].

Epidermal thickness was significantly reduced in patients with AIDS, which is in agreement with the results obtained in studies on cervical [10, 17] and esophageal [8, 9] epithelia in women with AIDS. This atrophy of the epidermis is caused by a significant reduction in the number of cell layers, which may be related to the cytopathogenic effect of HIV infection, which induces apoptosis [27]. HIV cytopathogenesis is associated with the entrance of osmotically active monovalent cations, K+and Na+, into the infected cells since the virus is capable of disturbing the transport of ions through the plasma membrane [28, 29]. The most common HIV cytopathogenic effect, in vitro, is called ballooning degeneration, in which cells swell beyond the limits of membrane integrity, hence suffering cell lysis [30]. Another contributing factor to epidermis atrophy was the reduction of cell diameter, which indicates that the virus might compromise the synthesis and/or the function of cell components.

The percentage of collagen fibers in the dermis was significantly increased in patients with AIDS compared with patients without AIDS. The HIV cytopathogenic effect, immunodepression, and occurrence of co-infections might induce alterations in the tissue microenvironments, including changes in cytokine production, increasing the inflammatory and fibrogenic activities [31].

The elastic fibers are responsible for skin contraction and their quantity is likely to diminish with age, exposure to solar radiation, and other factors [32]. AIDS-related parameters did not influence the quantity of elastic fibers in the dermis.

Women with AIDS presented a significantly lower number of LC in the epidermis than those not infected by the retrovirus, which is in agreement with the literature [33, 34]. Several hypotheses attempt to explain the LC loss during viral infections. LCs may be infected directly by HIV, causing cellular death, which is related to the immediate cytopathogenic effect of the virus [35, 36]. Alternatively, the antigen presenting LC may migrate from the epithelium to regional lymphoid tissues to mount an immune response [37], reducing the density of the epithelial LCs.

[b] T=530,580.500, p=0.462

HIV infection induces activation and dysfunction of B cells, resulting in hypergammaglobulinemia [38–40]. However, the resulting antibodies are not HIV antigen specific [38, 41, 42]. Although we expected an increase of IgA in the dermis, lower but not statistically significant values were found in the group with AIDS. This reduction of IgA in the dermis might contribute to the occurrence of opportunistic cutaneous infections in patients infected with AIDS because the high amount of immunoglobulin secreted during AIDS is not specific, although some retain neutralizing functions [43].

Increase of viral load precedes the decrease of the number of CD4+ T-lymphocytes as high plasma HIV RNA levels indicate worse prognosis [44, 45]. The possible relationship between viral load and dermatological alterations in patients with AIDS is not entirely clear, but it is thought that HIV may alter LC and keratinocytes, which may increase skin vulnerability to several diseases [46, 47]. We observed a significant negative correlation between the viral load and epidermal thickness, the number of cell layers, the average cell diameter, and the IgA and LC in the epidermis of patients with AIDS, which suggests that the higher the viral load, the lower the local skin immunity.

Advanced stages of cutaneous diseases in AIDS are associated with very low CD4+ T-lymphocyte count. [32]. Moreover, several studies show a negative correlation between CD4+ T-lymphocyte count and dermatological diseases [48–50]. However, we found in the epidermis of AIDS patients a significant positive correlation between the CD4+ T-ymphocyte count and epidermal thickness, number of cell layers, and number of LC. These data suggest that the higher the CD4+ T-lymphocyte count, the higher the local skin immunity is.

Our data suggest that AIDS reduces local skin immunity. This might interfere with the constitution and the natural immune function of the skin, enhancing the impact of harmful agents during the course of the disease. A better understanding of silent skin changes during AIDS would be valuable not only for the production of cosmetics, topical therapeutic applications, and external physical therapeutic modalities but also to better understand how to cure a wide variety of dermatological lesions in patients with AIDS.

Abstract Emmprin is a transmembrane glycoprotein known as a matrix metalloproteinase inducer and is highly up-regulated in malignant cancer cells. The monocarboxylate transporters (MCTs) are responsible for H^+-linked transport of monocarboxylates across the cell membrane. It was recently demonstrated that proper plasma membrane localization and activity of MCTs require the presence of emmprin as a chaperone and that MCT-1 also acts as chaperone for emmprin. The objectives of this study were to clarify emmprin and MCT-1 expression patterns in ovarian epithelial tumors and to elucidate the clinicopathological significance of co-localization of the two molecules. Immunohistochemical analysis of 205 epithelial tumors indicated that emmprin is always localized in cell membranes but its distribution differs according to tumor type: in lateral membranes in 89 % of adenomas, in lateral and basal membranes in 76 % of borderline tumors, and in membranes surrounding the entire cell in 98 % of carcinomas. Most carcinomas in situ also showed a lateral and basal expression pattern. In only 21 % of the carcinomas, the cells expressing membranous MCT-1 showed co-localized emmprin expression. Poor co-localization of the two molecules was more frequently found in serous carcinomas. However, the overall survival was not significantly different for the good and poor co-localization carcinoma groups. These findings indicate that the emmprin expression pattern might discriminate between invasive carcinomas and borderline tumors including carcinoma in situ. Moreover, there may be an as yet unidentified regulatory mechanism(s), for localization of MCT-1 and emmprin in cell membranes in vivo.

Keywords Emmprin · MCT-1 · Expression pattern · Ovarian epithelial tumors · Immunohistochemistry

Introduction

Epithelial ovarian cancer is a frequent cause of cancer death in women because it is usually first detected in the metastatic phase of the disease [1]. Matrix metalloproteinases (MMPs), which comprise a family of zinc-dependent proteolytic enzymes, have a central role in the progression of tumors, and degradation of the extracellular matrix by MMPs and energy production via glycolysis are both critical for tumor invasion and growth.

Emmprin is a transmembrane glycoprotein known as an MMP inducer [2], which stimulates peritumoral fibroblasts to produce MMP. Emmprin, also known as basigin and CD147, is a cell surface glycoprotein of the immunoglobulin superfamily that is highly up-regulated in malignant cancer cells [3, 4]. Emmprin is functionally associated with monocarboxylate transporters (MCTs). The MCT family has 14 members, including isoforms 1, 2, 3, and 4, which are responsible for the H^+-linked transport of monocarboxylates such as lactic acid across the membrane. The underlying molecular events involved in MCT regulation are poorly understood; however, it was recently demonstrated that the

proper plasma membrane expression and activity of MCTs, particularly MCT-1 and MCT-4, in vitro require the presence of emmprin as a chaperone [5]. Interestingly, silencing of MCT-1 led to maturation arrest of CD147 in its core glycosylated form, demonstrating that MCT-1 also acts as chaperone for CD147 [6]. However, the clinicopathological significance of co-localization of emmprin and MCTs in ovarian epithelial tumors has been hardly explored [7]. The objectives of this study using ovarian epithelial tumors were to clarify the expression patterns of emmprin and MCT-1 and to elucidate the clinicopathological significance of co-localization of the two molecules.

Material and methods

Tissue samples

The study material comprised a total of 205 patients with ovarian epithelial tumors including 48 ovarian adenomas (age range, 10–83 years; mean, 45.2 years), 48 ovarian borderline tumors (age range, 17–86 years; mean, 48.3), and 109 ovarian carcinomas (age range, 29–86 years; mean, 55.8) obtained from the ovarian tumor files kept at the Department of Pathology, Fukuoka University Hospital. The 205 patients had been treated at the Department of Obstetrics and Gynecology, Fukuoka University Hospital between April 1993 and April 2005. Six normal ovarian control specimens were obtained from early stage cervical cancer patients and leiomyoma patients with a mean age of 58 ± 9 years (range 46–67), who underwent surgery during the same period. Anonymous use of redundant tissue is part of the standard treatment agreement with patients at our hospital when no objection is expressed. The study protocol was approved by the Ethics Committee of Fukuoka University. Tumor tissue specimens for laser capture microdissection or western blotting were frozen in liquid nitrogen and kept at −80 °C until use.

Pathological evaluation

The surgically resected specimens were fixed routinely in 10 % formalin and processed into paraffin blocks for histopathological examination. The histopathological type was determined according to the 2003 World Health Organization classification [8]. The histological grading of carcinomas was determined according to the Silverberg grading system [9].

Immunohistochemistry

For immunoperoxidase staining of formalin-fixed, paraffin-embedded tissue sections, a dextran polymer-based method (for emmprin) and a standard biotin–streptavidin method (for MCT-1) were used. Briefly, after nonspecific protein binding sites were blocked with 5 % nonfat dry milk in Tris-buffered saline, pH 7.6 (TBS) for 1 h at room temperature (RT), sections were incubated with mouse anti-emmprin monoclonal antibody (R&D Systems, Minneapolis, MN, USA) used at a 1:100 dilution overnight at 4 °C or with anti-MCT-1 goat polyclonal antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA) used at a 1:20 dilution for 1 h at RT. The sections were then washed in TBS and incubated with Histofine reagent (Nichirei Biosciences, Tokyo, Japan) for 1 h for emmprin or with biotinylated anti-goat rabbit IgG (Vector Laboratories, Burlingame, CA, USA) for 30 min at RT for MCT-1. The sections were then washed in TBS and incubated with streptavidin-horseradish peroxidase pre-diluted (BD Pharmingen™, Franklin Lakes, NJ, USA) for 30 min at RT for MCT-1. The reaction was visualized by using horseradish peroxidase and 3,3′-diamino-benzidine (DAKO, Carpinteria, CA, USA) or alkaline phosphatase and naphthol AS-BI phosphate (Sigma, St Louis, MO, USA).

The immunohistochemical specificity of the emmprin antibody was confirmed by two types of negative controls: substituting mouse non-immune IgG for the primary antibody and omitting the primary antibody in the staining protocol. Antigen competition controls using anti-MCT-1 antibody absorbed with a fivefold excess of MCT-1 N-terminal peptide antigen (Santa Cruz Biotechnology) were also performed. Epithelioid sarcoma and malignant mesothelioma tissues were used as positive controls for emmprin and MCT-1, respectively (Supplementary Fig. 1).

Stained sections were evaluated semiquantitatively by two independent observers (M.F. and K.N.), who were blinded to the clinical data. Immunostaining was considered negative if less than 10 % of the tumor cells were stained. In specimens considered positive, staining of the tumor was quantitated on a scale from 1 to 4 based on the percentage of positively stained tumor cells, as described previously [10]. The scale was structured as follows: 1+=10–24%; 2+=25–49%; 3+=50–74%; and 4+=≥75 %. As to the localization of reactivity, a membranous or a combined membranous and cytoplasmic reactivity was interpreted as positive. The emmprin expression patterns and co-localization of emmprin with MCT-1 were also evaluated.

Protein extraction from frozen tissue samples and western blotting

Western blotting was performed using frozen tumor tissues, not identical but closely matched in the subtypes of tumors, including ovarian carcinomas from 12 patients (age range, 49–80 years; mean, 58) and ovarian adenomas from 6 patients (age range, 27–82 years; mean, 54.8). Proteins

including emmprin and MCT-1 were extracted from tissue samples using a homogenizer (Polytron-aggregate; Kinematica, Lucerne, Switzerland) in a lysis buffer containing 10 mM Tris HCl (pH 7.5), 15 mM NaCl, 2 mM ethylenediaminetetraacetic acid, 1 % Triton X-100, and protease inhibitors (Complete Mini; Roche Applied Sciences, Penzberg, Germany) on ice for 30 min. The extracts were clarified by centrifugation at 14,000 rpm for 10 min and subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis after measurement of their protein concentrations with the Bio-Rad Protein Assay (Bio-Rad, Hercules, CA, USA). After electrophoresis, the proteins were transferred electrophoretically to an Immobilon membrane (Millipore, Bedford, MA, USA), as described previously [11]. Nonspecific protein binding sites were blocked with 5 % non-fat dry milk in 0.05 % Tween-20/TBS, pH 7.6 (TBS-T) at 37 °C for 1 h, and the membrane was incubated overnight at 4 °C with mouse anti-emmprin monoclonal antibody (R&D Systems) or rabbit anti-MCT-1 polyclonal antibody (Alpha Diagnostic International, San Antonio, TX, USA). After washing with TBS-T, the membrane was incubated for 1 h with peroxidase-conjugated anti-mouse (for emmprin) and anti-rabbit (for MCT-1) IgG. Color was developed with chemiluminescence reagents according to the instructions supplied by the manufacturer (DuPont NEN, Boston, MA, USA). The bands on the film were subjected to image analysis with NIH ImageJ version 1.44. Student's *t* test was used for all statistical analyses.

Laser capture microdissection

Laser capture microdissection (LCM) was performed with the Pixcell IIe LCM system (Arcturus Engineering Inc., Mountain View, CA, USA) as described previously [12]. Frozen sections were cut and attached to uncharged microscope slides for each sample. Immediately after dehydration and staining (HistoGene; Arcturus), slides were processed with the Pixell IIe LCM system, followed by collection of microdissected cells with CapSure Macro LCM Caps (Arcturus Engineering Inc.).

RNA extraction, cDNA synthesis, and real-time quantitative RT-PCR

Total RNA was isolated from frozen tissue specimens, with the illustra RNAspin Mini RNA Isolation Kit (GE Healthcare Bio-Sciences, Piscataway, NJ, USA), according to the instructions supplied by the manufacturer. Next, the cDNA was synthesized from 1 μg of total RNA, with the First-Strand cDNA Synthesis Kit (GE Healthcare Bio-Sciences). Three gene-specific oligonucleotide primer pairs were purchased for emmprin, MCT-1, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Takara Bio, Otsu, Japan). The primer pairs used for RT-PCR analysis were intron-spanning—for emmprin: 5′-TGTCACTGACTGGGCCTGGTA-3′ (forward) and 5′-GCCTCCATGTTCAGGTTCTCAA-3′ (reverse); for MCT-1: 5′-TGTGGAATGCTGTCCTGTCCTC-3′ (forward) and 5′-TGATGCCCATGCCAATGAA-3′ (reverse); and for GAPDH: 5′-GCACCGTCAAGGCTGAGAAC-3′ (forward) and 5′-TGGTGAAGACGCCAGTGGA-3′ (reverse). Real-time monitoring of PCR reactions was performed with the Light-Cycler system (Roche Applied Science, Indianapolis, IN, USA) and SYBR® Premix Ex Taq™II (Takara Bio), according to the instructions supplied by the manufacturers. Each assay was performed three times to verify the results. Student's *t* test was used for statistical analysis of the normalized values for ovarian cancers and adenomas.

Statistical analysis

Associations between categorical factors were evaluated with the χ^2 test or Fisher's exact test. Survival curves were plotted with the Kaplan–Meier method, and *P* values were calculated with the log rank test. Univariate analysis was performed by using Cox's proportional hazards regression analysis. Statistical comparison between clinical stage and pathological grades was performed with the Kruskal–Wallis test. A *P* value of <0.05 was considered to denote a statistically significant difference. All statistical evaluations were performed with the Stat View statistical software for Windows version 5.0 (SAS Institute Inc., Cary, NC, USA).

Results

The clinicopathological characteristics of patients with ovarian carcinomas

Table 1 summarizes the clinicopathological characteristics of the 109 patients with ovarian carcinomas. The pathological diagnosis identified 39 cases of serous cystadenocarcinoma, 16 of mucinous cystadenocarcinoma, 27 of endometrioid adenocarcinoma, 18 of clear cell adenocarcinoma, 3 of squamous cell carcinoma, and 6 of malignant mixed epithelial tumors. Lymph node metastasis and recurrence were found in 18 cases (19 %) and 30 cases (28 %), respectively, in a follow-up period of 1–115 months (mean, 51.2 months). The residual tumor size after primary debulking surgery was 0 in 76 cases (70 %), less than 1 cm in 3 cases (3 %), and more than 1 cm in 30 cases (28 %). Advanced stages (III, IV), high grade (3), and the presence of residual tumor, peritoneal dissemination, and lymph node metastasis were significantly associated with shorter survival. Adenomas comprised 33 cases of mucinous cystadenoma and 15 cases of serous cystadenoma, and borderline tumors

comprised 36 cases of mucinous, 9 cases of serous, 1 case of endometrioid, and 2 cases of mixed tumor.

Immunohistochemical expression of emmprin

Emmprin expression was positive in 27/48 (56 %) of adenomas, 45/48 (94 %) of borderline tumors, and 108/109 (99 %) carcinomas (Table 2). Emmprin was localized in the cell membranes of all positive tumors, but its distribution was quite different according to the tumor type. It was present in only the lateral membranes in 24/27 (89 %) of adenomas (Fig. 1a) and in the lateral and basal membranes in 34/45 (76 %) of borderline tumors (Fig. 1b), while 98 % (107/109) of carcinomas showed emmprin immunoreactivity surrounding all the cells (Fig. 1c; Table 2). The difference in expression patterns in these three types of tumors was significant ($P<0.01$, Kruskal–Wallis test; Table 2). In 15 cases of carcinoma in situ, only one tumor showed emmprin expression surrounding all the cells (Fig. 1d), while the others exhibited its reactivity in lateral and basal membranes as was seen in most borderline tumors (Fig. 1e). Moreover, most of the emmprin-expressing carcinomas

Table 2 Expression patterns of emmprin in ovarian epithelial tumors

	Number of cases		Expression pattern (% positive)		
	Total	Positive	Lateral	Basolateral	Surrounding
Adenoma	48	27	24 (89)*	3 (11)	0
Borderline tumor	48	45	7 (15)	34 (76)*	4 (9)
Carcinoma	109	108	0	1 (1)	107 (98)*

*$P<0.01$ by Kruskal–Wallis test

(104/109, 95 %) were scored 3+ or 4+ (high expression group), while 25 % (12/48) and 65 % (31/48), respectively, of emmprin-expressing adenomas and borderline tumors belonged to the high expression group; the differences among these three different types of tumors were statistically significant ($P<0.01$, Fisher's exact test; Fig. 2a). As a nonspecific membrane protein control, epithelial membrane antigen (EMA) expression was also examined in carcinomas and its expression pattern was focal and irregular, quite different from that of emmprin (Fig. 1f). No emmprin immunoreactivity was found in normal ovarian tissues except for granulosa cells (data not shown).

Immunohistochemical expression of MCT-1

Positive MCT-4 immunoreactivity was observed in none of the ovarian epithelial tumors including adenomas, borderline tumors, and carcinomas (data not shown). Most adenoma cells were also negative for MCT-1 (Fig. 1g), whereas borderline tumors (Fig. 1h) and carcinomas (Fig. 1i) exhibited positive membrane and cytoplasmic reactivity to MCT-1. MCT-1 reactivity was also detected in the tumor stroma in 40 % (19/48) of adenomas (Fig. 1g). Panels b and c of Fig. 2 show a summary of MCT-1 immunostaining results for ovarian epithelial tumors. Positive MCT-1 expression in cell membranes was seen in 4 % (2/48) of adenomas, 21 % (10/48) of borderline tumors, and 41 % (45/109) of carcinomas, and the difference between adenomas and carcinomas was statistically significant ($P<0.01$, Fisher's exact test; Fig. 2b). Tumors with high MCT-1 expression (scores 3 and 4) were identified in 2 % (1/48) of adenomas, 13 % (6/48) of borderline tumors, and 19 % (21/109) of carcinomas, and the difference between adenomas and carcinomas was statistically significant ($P<0.01$, Fisher's exact test; Fig. 2c). No MCT-1 immunoreactivity was found in normal ovarian tissues except for granulosa cells (data not shown).

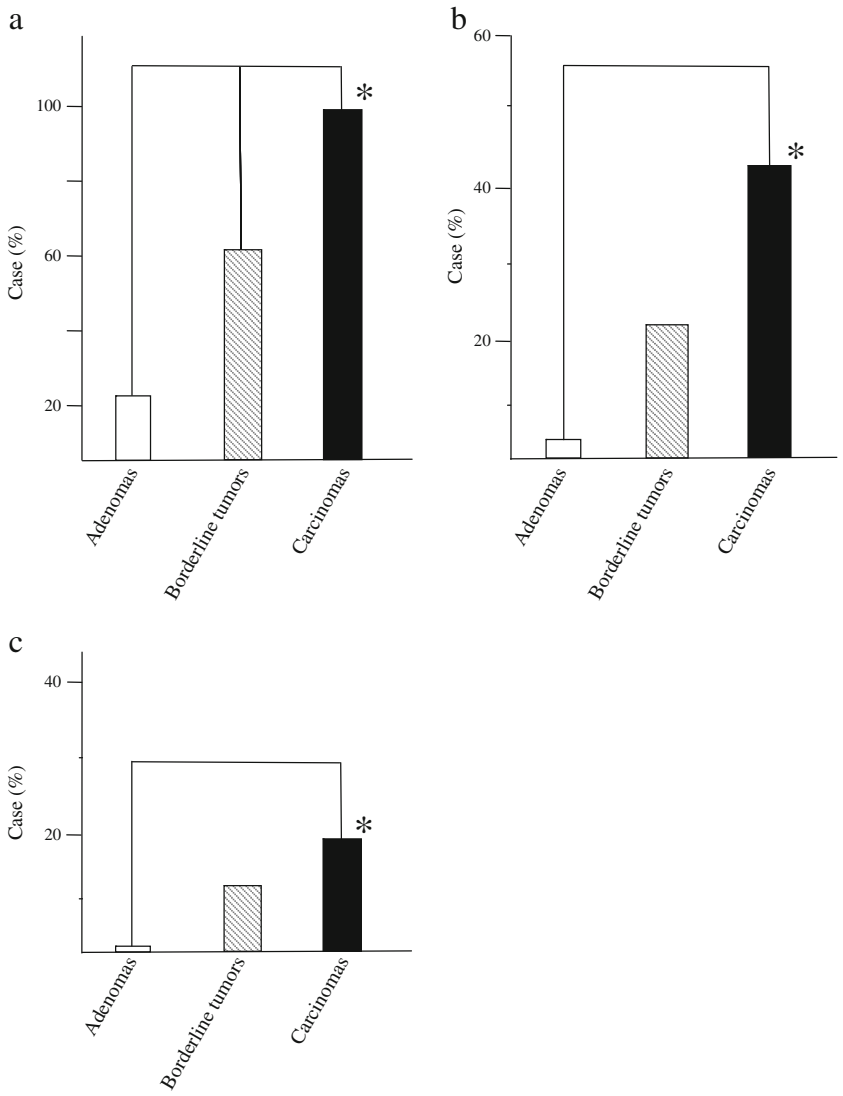

Fig. 2 Semiquantitative analysis of emmprin and MCT-1 expression in adenomas, borderline tumors, and carcinomas. Numbers of tumors with high levels of emmprin expression (scores 3 and 4) (**a**) are shown for adenomas, borderline tumors, and carcinomas. Numbers of MCT-1 positive tumors (**b**) or those of tumors expressing high levels of MCT-1 (**c**) are shown for adenomas, borderline tumors, and carcinomas. *$P<0.01$ by Fisher's exact test

Co-localization of emmprin and MCT-1

Co-localization of emmprin and MCT-1 in carcinomas was analyzed next. Some carcinomas expressed both emmprin and MCT-1 in the same parts of the tumors, as was demonstrated immunohistochemically in serial sections (Fig. 1j, k), while others showed expression of only emmprin but not of MCT-1 (Fig. 1l, m). Parts which expressed MCT-1 but not emmprin were extremely rare. Figure 3a summarizes the results of this co-localization analysis. Good co-localization of emmprin and MCT-1, which was defined by identical immunostaining scores for emmprin and MCT-1 or with a difference of only 1 and shown as black columns in Fig. 3a, was observed in 23 carcinomas (21 %), whereas 86 carcinomas (79 %) showed poor co-localization. The two groups of carcinomas, expressing good or poor co-localization of emmprin and MCT-1, showed no statistical differences in overall survival of patients (Fig. 3b), nor in clinicopathological parameters except for the histological type (Table 1). Serous carcinomas were significantly more associated with carcinomas showing poor co-localization, while 30 cases of recurrent carcinomas also showed a similar rate (8/30, 27 %) of co-localization of emmprin and MCT-1 (Table 3). In 95 % (21/22) of the cases with poor co-localization, a different expression pattern of emmprin and MCT-1 was found with emmprin expressed in cell membranes, while MCT-1 was found diffused in the cytoplasm.

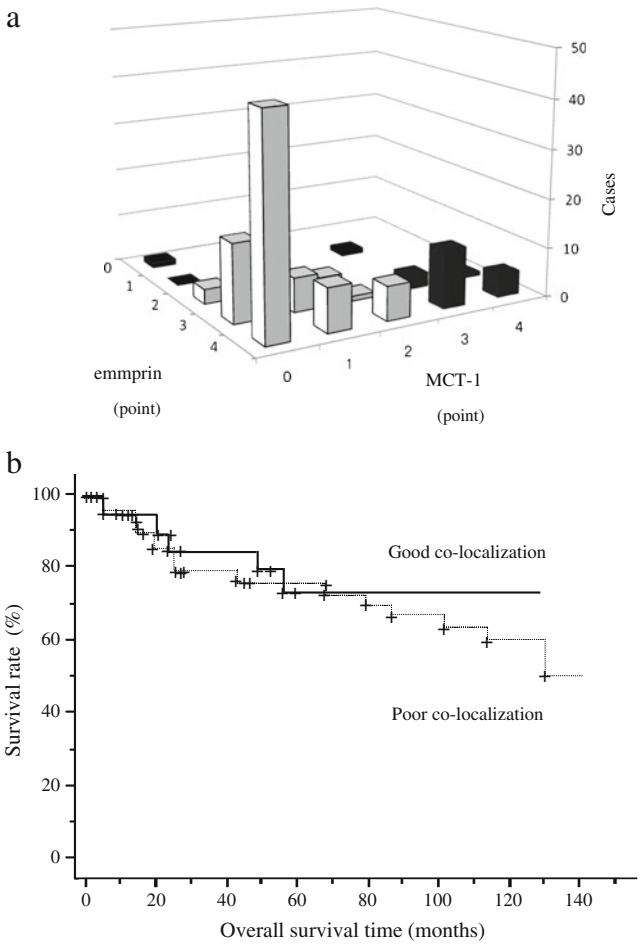

Fig. 3 Co-localization of emmprin and MCT-1 (**a**). *Black columns* show tumors with good co-localization of emmprin and MCT-1, while *white columns* represent tumors with poor co-localization. Overall survival of patients with tumors showing good or poor co-localization of emmprin and MCT-1 (**b**). No significant difference was found between the two groups of patients

Expression of emmprin and MCT-1 mRNAs and proteins in ovarian epithelial tumors

Expression levels of emmprin and MCT-1 mRNA were also examined in 14 frozen tissue samples (4 or 5 adenomas and 10 carcinomas) by means of real-time RT-PCR. The expression levels of emmprin and MCT-1 mRNA, although higher in ovarian carcinomas than in adenomas, were not statistically significantly different (Fig. 4a).

Expression levels of emmprin and MCT-1 proteins were also examined in 18 frozen tissue samples (6 adenomas and 12 carcinomas) by means of western blotting. MCT-1 was expressed as a 48-kDa band, while emmprin appeared as 58 and 45 kDa bands, possibly due to different levels of glycosylation or proteolytic degradation [11, 13]. All carcinomas expressed both emmprin and MCT-1 proteins (Fig. 4b), with expression levels that were both higher than those of adenomas, although the differences were not statistically significant between the two types of tumors (Fig. 4c).

Discussion

To the best of our knowledge, this study is the first to show that immunohistochemical expression patterns of emmprin might be useful for differentiating invasive carcinomas from borderline tumors including in situ adenocarcinomas. Moreover, in regard to co-localization of emmprin and MCT-1, we found that ovarian carcinomas could be divided into two groups. One comprises tumors that co-express these two molecules in the cell membrane of most of the carcinoma cells (the good co-localization group). The others consist of tumors with more than 50 % of the carcinoma cells expressing only emmprin and not MCT-1 (the poor co-localization group). Although the two groups did not show significant differences in overall survival, our findings indicate that emmprin expression in cell membranes in vivo does not always need co-expression of MCT-1 but that MCT-1 expression in membranes may need the co-expression of emmprin.

We also found that emmprin is differently expressed in cell membranes depending on the type of tumor.

Table 3 Expression of emmprin and MCT-1 in recurrent ovarian tumors

Expression	No. of patients (%)
Total	30
Emmprin	
High expression	26 (87)
Low expression	4 (13)
MCT-1	
High expression	7 (23)
Low expression	23 (77)
Co-localization	
Good	8 (27)
Poor	22 (73)

Furthermore, the expression pattern in most of the in situ carcinomas was the same as that in borderline tumors. Thus, emmprin expression surrounding the entire cell membrane was almost always restricted to invasive carcinomas. This pattern of expression was due not only to loss of cellular polarity in carcinoma cells, but possibly also to a mechanism specific to emmprin, since a mucin-like glycoprotein, EMA, was expressed irregularly and focally in cell membranes, especially around the apical membranes, even in carcinomas. A similar occurrence of differences in localization in ovarian tumors according to tumor type was also reported for aquaporin-5 (AQP5), a family member of small membrane transport proteins that act primarily as water selective pores [14]. AQP5 is mainly localized in the basolateral membrane of benign tumor cells, the apical and

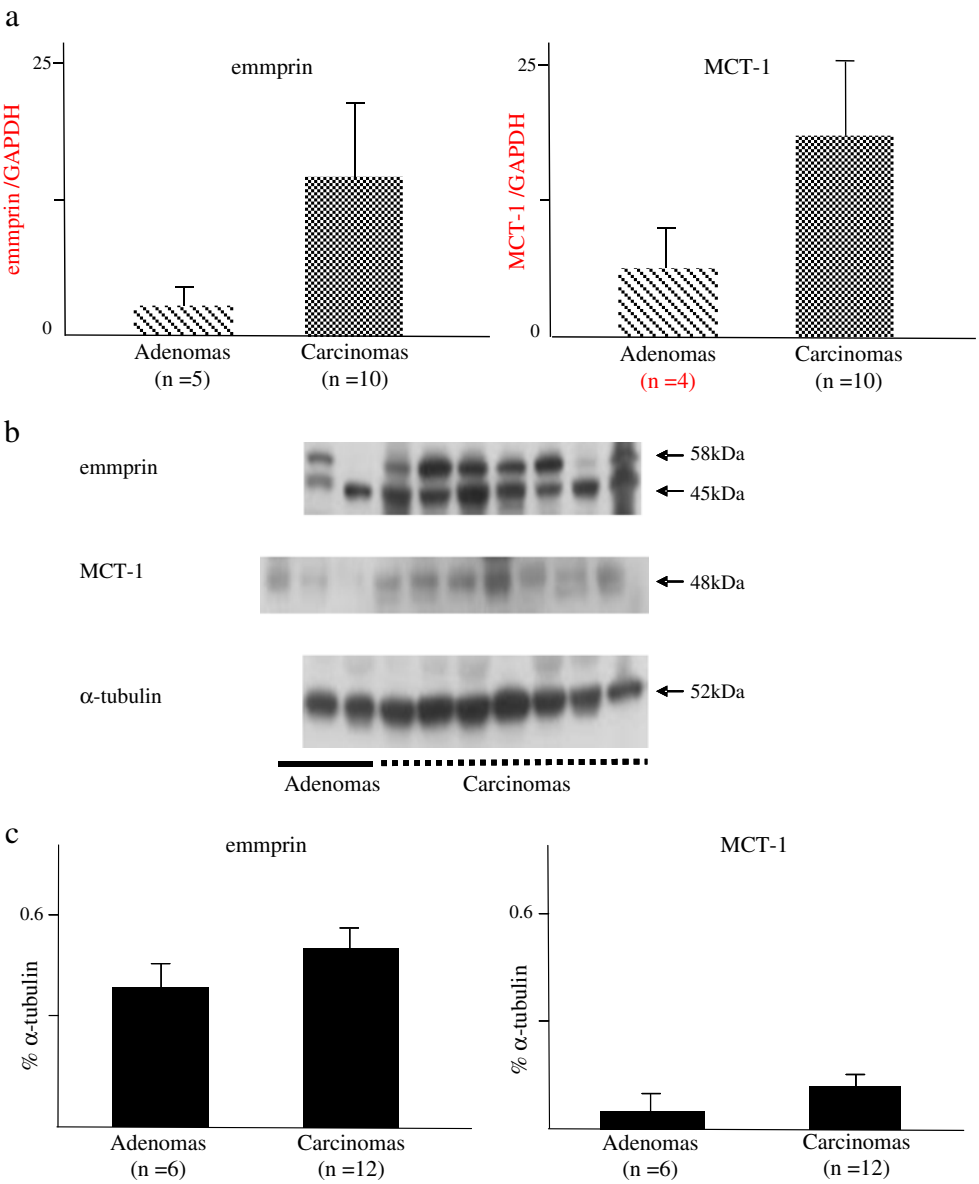

Fig. 4 Detection by real-time RT-PCR and western blotting of emmprin and MCT-1 in tissue extracts from adenomas and carcinomas. **a** Emmprin and MCT-1 mRNAs were both expressed at higher levels in ovarian carcinomas than in adenomas. **b** The 45- and 58-kDa bands of emmprin and the 48-kDa band of MCT-1 can be seen in both tumor extracts, although their intensities were stronger in carcinomas than adenomas. **c** Semiquantitative analysis of emmprin and MCT-1protein expressions by means of image analysis

basolateral membrane of borderline cells and scattered in the membrane of malignant cells, while the normal ovarian epithelium shows almost no or weak staining for this protein. However, the mechanism involved in this difference in localization of AQP5 is still unknown [14]. As for emmprin localization within cells, a sorting signal consisting of Leu-252 in its C-terminal domain has been identified by using extensive mutagenesis [15]. This signal dictates basolateral localization of emmprin in MDCK cells but is not recognized by the retinal pigment epithelium, resulting in a reversed apical localization of emmprin in this epithelium [15, 16]. These findings suggest the presence of a cell type-specific recognition mechanism for the Leu-252-based signal. It seems that this recognition mechanism is maintained or somewhat altered in ovarian adenomas and borderline tumors, respectively, and probably malfunctions in carcinomas.

In vitro studies have demonstrated that the co-presence or co-expression of emmprin is critical for cell membrane localization and activity of MCTs. On the other hand, maturation and cell surface expression of emmprin depends on MCT expression [6, 17]. In COS and HeLa cells, MCT transfection caused accumulation of expressed protein in a perinuclear compartment, whereas co-transfection with emmprin enabled expression of active MCT-1 and MCT-4 in the cell membrane [17]. In Lovo cells, emmprin and MCT-1 co-localized on the cell surface, and anti-human CD147/emmprin mouse monoclonal antibody (MEM-M6/1) inhibited the association of these molecules, resulting in the prevention of lactate uptake and release and a reduction in intracellular pH [18]. Emmprin/basigin co-localized with MCT-1 and MCT-4 on the A375 melanoma cell membrane, while silencing of emmprin/basigin in A375 cells by siRNA clearly eliminated the expression of MCT-1 and MCT-4 and their co-localization with emmprin/basigin and dramatically reduced the glycolysis rate, the level of extracellular pH, and the production of ATP [19]. Co-expression of emmprin and MCT-1 was also observed in vivo and was significantly associated with lymph node and/or distant metastases in cervical adenocarcinomas (P=0.033). However, no statistically significant associations with survival data were found [20]. In gastric carcinomas, MCT-1/emmprin co-expression was associated with advanced gastric carcinoma, Lauren's intestinal type, TNM staging, and lymph node metastasis [21]. Co-expression of emmprin with MCT-1 in ovarian carcinomas was reported by two groups [5, 7]. In one of these studies, a substantial number of MCT-1-positive cases were negative for emmprin, prompting the authors to suggest that MCT-1 plasma membrane expression in tumors may depend on an as yet unidentified regulatory protein [5]. In our study, however, emmprin was highly expressed in cell membranes in 95 % of carcinomas, while in about 80 % of carcinomas, MCT-1 was much less highly expressed in the cell membrane than was emmprin (poor co-localization group). Carcinoma cells expressing emmprin in cell membranes and MCT-1 in the cytoplasm were also observed (data not shown). There may thus be a mechanism by which emmprin is expressed in cell membranes independently of MCT-1, as well as a mechanism to prevent the translocation of MCT-1 from the cytoplasm to cell membranes even in the presence of emmprin. A study by another group showed frequent co-expression of emmprin with MCT-1 in both primary and metastatic epithelial ovarian cancer cells by immunofluorescence labeling [7]. In their study, emmprin expression was mainly cell membrane-associated, but also with distinct positive cytoplasmic staining, and MCT-1 immunostaining was mainly cytoplasmic. These staining patterns were interpreted as co-expression. However, in our study, we focused on membranous expression of emmprin and MCT-1, and a membranous or a combined membranous and cytoplasmic reactivity was interpreted as positive. Our study is the first to examine in ovarian carcinomas whether co-localization of emmprin with MCT-1 is associated with overall survival and other clinicopathological parameters. Poor co-localization occurred significantly more frequently in serous carcinomas, but overall survival and progression-related parameters were not different between the good and poor co-localization groups of carcinomas.

The relationship between emmprin expression and patient survival has remained controversial. Increased expression of emmprin in colorectal carcinomas showed a significant correlation with poor disease-specific survival [22]. Similarly, positive emmprin expression in bladder carcinomas was significantly associated with stage, grade, recurrence, progression, and death of patients [23]. However, it was also reported that low membranous emmprin expression in high grade ovarian carcinomas or low cytoplasmic staining in serous carcinomas is an independent predictor of poor 10-year disease-related survival [24]. More interestingly, it has been shown that emmprin expression in carcinoma cells in effusions and solid lesions does not correlate with disease outcome for ovarian carcinomas, but that emmprin expression in stromal cells of primary tumors and in endothelial cells of all solid tumors correlated with poor survival [25]. In our study, most of the carcinomas (95 %) expressed high levels of emmprin, and thus the emmprin expression level did not correlate with patient survival. Emmprin was also sometimes expressed in tumor stroma, which might have reduced the difference in emmprin protein expression between carcinomas and adenomas in whole tissue extracts, but the stromal expression level was not associated with patient outcome or tumor progression (data not shown). While emmprin expression seems to be involved in tumor progression in view of its diverse biological functions and high levels of expression in both

primary and recurrent ovarian tumors, its association with survival of patients with ovarian carcinomas needs to be further explored.

Acknowledgments We wish to thank Ms. K. Yano, Ms. H. Fukagawa, and Ms. M. Onitsuka for their expert technical assistance with immunohistochemical staining and in vitro studies. This work was supported in part by a grant from the Research Center for Advanced Molecular Medicine, Fukuoka University.

Conflict of interest The authors declare that they have no conflict of interest.

Abstract A range of studies have analyzed prognostic factors in bladder cancer. However, prior cohorts have included heterogeneous pT classification at biopsy and others were derived from large, multi-institutional clinical trials over the span of many years. Our objective was to analyze prognostic factors in a recent radical cystectomy (RC) cohort at a single institution and evaluate outcomes based on current practice patterns. A retrospective analysis of overall survival (OS) was conducted on 180 RC patients with biopsy proven pT2 disease between 2007–2010. Increasing pT classification was a negative predictor of survival. pT was grouped into three categories with pT0/a/is/1/2a surviving longer than pT2b/3a/3b, and pT4 having the worst prognosis. Subclassifying pT2 and pT3 showed no statistically significant difference in survival. Lymphovascular invasion (LVI) and node positivity correlated with decreased OS. Patients treated with neoadjuvant chemotherapy (NAC) had a higher incidence of pT0, yet pN1+ was more common and NAC was not associated with improved OS. This investigation provides reference OS values for patients with pathologically diagnosed muscle-invasive bladder cancer based on current medical guidelines outside the context of a clinical trial. pT4 was the strongest negative predictor of survival, followed by pN1+, the group pT2b/3a/3b, and presence of LVI. NAC patients were noted to have a higher frequency of low pT classification, yet more frequent node positivity, suggesting that pT classification in NAC patients may not accurately reflect remaining tumor burden.

Keywords Bladder cancer · Survival · Stage · Lymph node · Neoadjuvant

A portion of the content of this study was presented as a platform presentation at the annual USCAP meeting in Vancouver, Canada in March 2012.

Introduction

Bladder cancer is the second most common genitourinary malignancy in the United States [1]. It is estimated that 69,250 people will be diagnosed and 14,990 will die of bladder cancer in 2011 [2]. While only approximately one third of patients have muscle-invasive disease, these patients have a significantly greater risk of metastasis, progression, and death [3].

Radical cystectomy (RC) with pelvic lymphadenectomy is currently the standard of care for treating muscle-invasive disease. However, with persistent failure rates of 30-45 % from surgery alone, interest in neoadjuvant chemotherapy (NAC) arose [4]. The poor survival in muscle-invasive disease may be attributed to micrometastasis already present at the time of diagnosis, which NAC could possibly treat. Level 1 evidence for NAC is based on methotrexate, vincristine, doxorubicin, and cisplatin (MVAC), with cisplatin described as the single most effective chemotherapeutic agent against urothelial carcinoma of the bladder [5, 6].

A range of studies have analyzed prognostic factors in bladder cancer. Canter et al. [7] illustrated that increasing age, advanced pathological classification, and positive lymph nodes (LN) were adversely associated with cancer-specific survival. The Southwest Oncology Group Intergroup trial concluded that increased survival was associated with cisplatin based NAC, completion of RC, and removing a minimum number of LN [3]. However, much of the data are from large, multi-institutional clinical trials over the span of many years while others cohorts include patients with both muscle-invasive and non-muscle invasive disease [5–7]. The study is unique in that we analyzed a recent, large, single institution RC cohort restricted to pathologically proven muscle-invasive disease at biopsy to assess survival outcomes in current day practice.

Materials and methods

Data were collected from all patients who had a RC at this institution from 2007 to 2010. Pathology reports from RC and bladder biopsy/transurethral resections (TUR) were reviewed. Parameters obtained included gender, age, cT classification prior to RC, NAC usage, regimen, and number of cycles received, pT classification at TUR and RC, grade at RC and TUR, number of nodes resected, nodal status, presence of lymphovascular invasion (LVI) and/or carcinoma in situ (CIS) at TUR and RC, surgical margin status, and date of death. LVI information was available for all but three patients due to inaccessible TUR reports. Patients that received NAC regardless of number of cycles or regimen were designated as having received NAC. Exclusion criteria for NAC included renal insufficiency precluding treatment with cisplatin and Eastern Cooperative Oncology Group performance status ≥3. NAC was given at our hospital or an outside facility. RC was offered to almost all patients with pT2 disease (tumor invasive into the muscularis propria) with very few determined to be non-surgical candidates.

Pathologic classification was based upon AJCC seventh edition definitions [8]. The cohort for analyses was restricted to patients with TUR of pT2 to ensure consistency. A central review of all 180 RC cases was completed by one pathologist (D.L.Z.). Stage-based response (SBR) was defined as a decrease in pT between TUR (pT2) and RC (<pT2). Nodal involvement was recorded as pN0 if all nodes were negative or pN1+ if any nodes were positive. Patients with no nodes removed (pNX) were excluded from survival analysis using nodal involvement as a factor.

Overall survival (OS) was defined as time from RC to date of death due to any cause or date of last chart review. Surviving subjects were censored at the time of last chart review in time-to-event analyses. Kaplan–Meier survival curves were used to evaluate differences in OS between groups. Cox regression models were used to model OS based on RC pT classification, nodal involvement, NAC use, and SBR. Survival analyses included univariate and multivariable modeling. Due to limited numbers in some subgroups, 95 % confidence intervals (CI) for survival estimates at given time points were used to assess variability and differences between groups in lieu of formal comparisons. Prognostic utility of collapsed subgroups based on RC pT classification were explored and analyzed in a similar manner. Comparisons between groups were evaluated using chi-square tests or Fisher exact tests if fewer than five subjects in a cell. Differences in continuous measures between groups were evaluated using two-sample *t* tests or Kruskal–Wallis tests if comparing across more than two subgroups. Logistic regression was used to measure significance of prediction factors against binary response variables. Given the hypothesis-generating nature of these analyses for potential prospective studies, multiple comparison corrections were not used, and statistical significance was declared at $P<0.05$.

Results

The study reviewed all patients who had RC for primary bladder carcinoma at our institution between 2007–2010 ($n=305$). At TUR, 180 patients were pT2. All statistics were performed on these 180 patients.

Table 1 outlines the clinicopathological characteristics of the cohort. In 2007, 7.1 % (2/28) of patients received NAC, which increased to 40.8 % (20/49) in 2008, 53.1 % (26/49) in 2009, and 59.3 % (32/54) in 2010 as in recent years use of NAC is strongly encouraged for every candidate patient.

Figure 1a depicts OS by RC stage ($P<0.00001$). pT4a (invasion of prostatic stroma, uterus, or vagina) was comparable to pT4b (invasion of pelvic or abdominal wall) and pT0 (no evidence of tumor) similar to pTis (carcinoma in situ), therefore these groups were combined (pT4a/pT4b and pT0/is) and are each reflected by only one curve. OS rate (1.5 years) (95 % CI) based on stage was pT0/pTis, 80 % (65–98 %); pT1 (subepithelial invasion), 77 % (54–100 %); pT2a, 80 % (62–100 %); pT2b, 61 % (43–87 %); pT3a (microscopic perivesicular fat invasion), 58 % (42–81 %); pT3b (macroscopic perivesicular fat invasion), 43 % (25–72 %); pT4, 12 % (4–35 %). Estimates are not given for pTa (noninvasive papillary carcinoma) given that there was only one pTa patient. Based on the World Health Organization/International Society of Urologic Pathology grading system included in the seventh edition of AJCC, 139 patients (77.2 %) were high grade at RC. Five patients (2.8 %) were low grade at RC and 36 patients (20 %) did not have a grade given due to no residual tumor or predominance of glandular/squamous differentiation.

Table 1 Cohort characteristics of patients receiving RC between 2007 and 2010 for pT2 bladder cancer

	Number (%)
Total	180 patients
Mean age (years)	67.1 (range 23–87)
Sex	34 F (18.9 %), 146 M (81.1 %)
NAC	81 (45.0 %)
Gemcitabine/cisplatin	41
MVAC	22
Other	18
Mean number of completed cycles	3.9
LVI	78 (44.1 %)
Mean LN count at RC	31.3 (range 0–77)
Positive margin at RC	24 (13.3 %)
Deaths	76 (42.2 %)
Mean surviving follow-up (days)	406.4 (range 207–1,619)
pT at RC	
pT0	27 (15.0 %)
pTa	1 (0.6 %)
pTis	7 (3.9 %)
pT1	12 (6.7 %)
pT2a	18 (10.0 %)
pT2b	23 (12.8 %)
pT3a	33 (18.3 %)
pT3b	28 (15.6 %)
pT4	31 (17.2 %)
pN at RC	
pN0	123 (68.3 %)
pN1+	54 (30.0 %)
pNX	3 (1.7 %)
SBR	45 (25.0 %)

Subclassifying pT2 revealed no difference in OS (P=0.18). Subclassifying pT3 showed a non-statistically significant separation in curves (P=0.09). Restricting subclassification to the pN0 population did not yield a significant difference among pT2 and pT3 subcategories (P=0.8 and P=0.57, respectively). OS (1.5 years) (95 % CI) based on substage for pN0 patients was pT2aN0, 84 % (65–100 %); pT2bN0, 74 % (55–100 %); pT3aN0, 59 % (40–86 %); pT3bN0, 63 % (41–96 %). Median OS (95 % CI) in months was pT3a, 28.3 (15.3—not applicable (NA)); pT3b, 13.0 (7.9—NA); and pT4, 8.4 (4.0–13.9). Sufficient deaths did not occur in the remaining stages to calculate median OS with CI.

Graphically, there were noted similarities in survival distribution, with certain pT classifications having comparable survival rates across different time points. pT was collapsed into three groups for additional analysis, with pT0/a/is/1/2a surviving longer than pT2b/3a/3b and pT4 having the worst survival (P<0.00001) (Fig. 1b). OS (1.5 years) (95 % CI) were pT0/a/is/1/2a, 79 % (68–92 %); pT2b/3a/3b, 53 % (41–67 %); pT4, 12 % (4–35 %).

SBR was shown to have improved OS (P=0.00043) with a 1.5-year OS (95 % CI) of 79 % (67–95 %) vs. 45 % (37–56 %) without SBR (Fig. 1c).

Nodal involvement was strongly associated with poor outcome (P<0.00001) (Fig. 1d). OS (1.5 years) (95 % CI) were 66 % (56–76 %) for pN0 and 30 % (19–48 %) for pN1+. Median OS (95 % CI) was 11 months (9.2–17.8) in pN1+ and could not be calculated for pN0 due to insufficient deaths. pN1+ was not restricted to high pT, as 4.5 % of the cohort and 14.8 % of the pN1+ group were pT0 (n=1), pTis (n=1), pT1 (n=2), and pT2a (n=4).

Of the patients, 44.1 % had LVI. Figure 1e demonstrates OS based on presence of LVI (P<0.0001). OS (1.5 years) (95 % CI) was 70 % (60–82 %) without LVI versus 33 % (23–48 %) with LVI. When analyzing LVI and nodal status together, 50.0 % (87/174) of patients had no LVI/pN0, 6.3 % (11/174) no LVI/pN1+, 19.0 % (33/174) LVI/pN0, and 24.7 % (43/174) LVI/pN1+ with 1.5-year OS (95 % CI) of no LVI/pN0, 78 % (68-89 %); LVI/pN0, 38 % (23-61 %); no LVI/pN1+, 28 % (9-82 %); and LVI/pN1+, 30 % (17-51 %). Distribution of number of LN for the subgroups showed no statistical significant difference (P=0.28) (mean number of LN: no LVI/pN0, 31.8; LVI/pN0, 29.9; no LVI/pN1+, 37.3; and LVI/pN1+, 28.3). Number of LN removed was not a significant predictor of nodal status (P=0.65) or LVI (P=0.14).

Of the patients, 38.2 % (68/178) had CIS on TUR or RC. OS (95 % CI) in months was 22.7 (14.9—NA) without CIS verses 19.9 (13.9—NA) with CIS (P=0.889), demonstrating no statistically significant difference.

Tables 2 and 3 reveal characteristics of patients that received NAC verses immediate RC. More NAC patients were cT3/4 (42/81, 51.9 % vs. 45/99, 45.5 %). More frequent decrease in T classification comparing cT prior to RC versus pT at RC in the NAC group was observed (45.7 % vs. 24.2 %). There was a higher incidence of NAC patients with pT0 (23.5 % vs. 8.1 %) and the low pT group pT0/a/is/1/2a (45.7 % vs. 28.3 %). However, in each cT group, there were more pN1+ patients with a history of NAC, although this difference was not statistically significant (P=0.63 for cT2; P=0.21 for cT3; P=0.24 for cT4). Of note, all eight patients that had low RC pT (pT0/a/is/1/2a) with pN1+ disease were in the NAC group (representing 9.9 % of the NAC group). Of these eight patients, three have died with a median follow-up in the remaining five living patients of 14 months. There was no significant difference in OS (P=0.746) based on use of NAC (Fig. 1f) with median OS (95 % CI) in months as 24.0 (15.6—NA) with NAC and 22.2 (14.0—NA) for RC alone. OS (1.5 years) (95 % CI) was 58 % (46–72 %) in the NAC group and 50 % (40–63 %) with no NAC and the 3-year OS (95 % CI) was 31 % (15–63 %) with

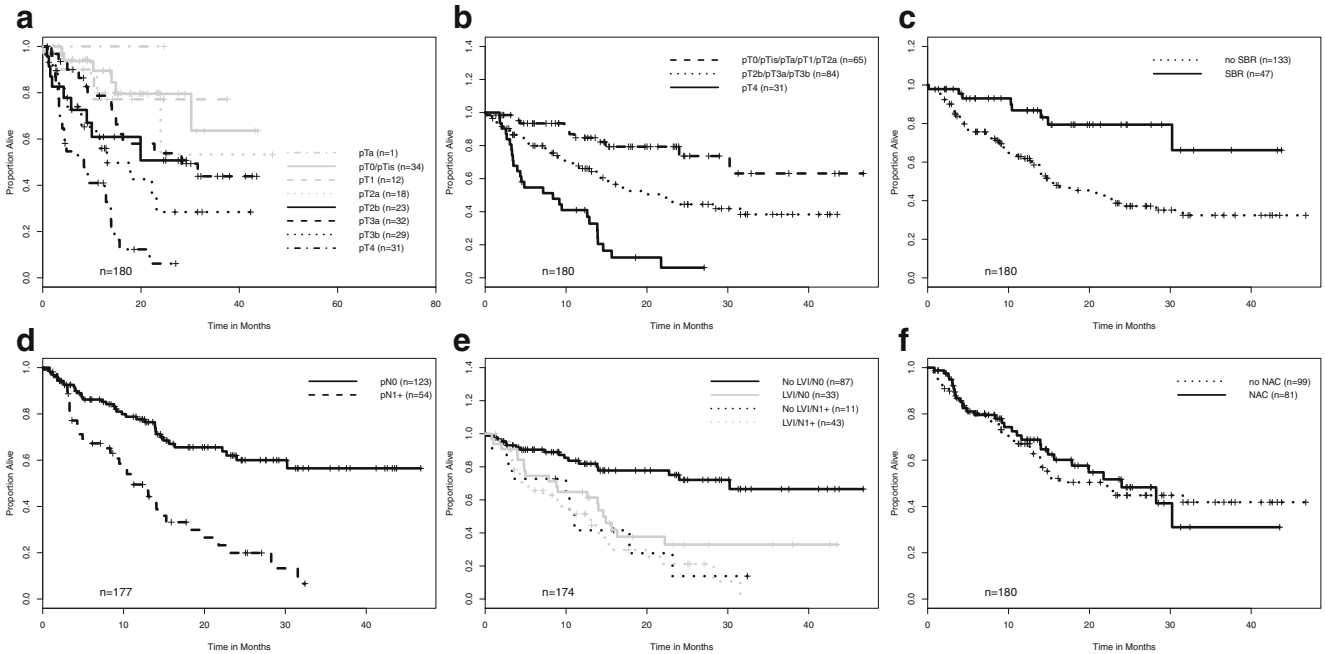

Fig. 1 Survival analysis showing survival time in months for the proportion of patients remaining alive. **a** OS for RC pT classification ($P<0.00001$). **b** OS by collapsed RC pT classification ($P<0.0001$). **c** OS by SBR ($P=0.000426$). **d** OS by RC Nodal status (three patients were pNX and were not included) ($P<0.00001$). **e** OS by LVI and node status ($P<0.0001$) status. **f** OS by NAC status ($P=0.746$)

NAC compared to 42 % (31–56 %) without NAC. An additional consideration when interpreting OS is the time interval from TUR to RC which was on average 56.6 days longer for patients receiving NAC. We also attempted to see if there was a survival benefit with NAC for certain stage groups, with no benefit identified.

On multivariable analysis, pT4 followed by high RC pT group and positive nodes were negative prognostic factors (Table 4). SBR was not significant in the multivariable setting. Although SBR was a significant prognostic univariate factor, it was actually the RC pT0/a/is/1/2a group that conferred an improved OS. SBR was a surrogate of this pT group, without the inclusion of pT2a. When LVI was combined with RC pT, it was a significant prognostic factor, but nodal status was a stronger predictor of OS. This was confirmed looking at all subsets models. NAC was not a significant factor of OS across all pT classifications, collapsed pT groups, nodal status, SBR, and did not impact the other prognostic indicators. Thus, only RC pT, pT groupings, and nodal status remained significant in multivariable analysis.

Discussion

Muscularis propria-invasive bladder cancer has been associated with significant risk of progression, metastasis, and death [3]. Standard of care for ≥ pT2 disease is RC with lymphadenectomy, with increasing usage of NAC [4, 5, 9]. Past studies have evaluated different prognostic markers in order to stratify survival. Factors such as use of NAC, completion of RC, and extended LN dissection have been shown to improve survival, whereas advanced pT and LN metastases were linked to poor outcomes [3, 7]. Our aim was to analyze prognostic factors of bladder cancer in RC. This study is relevant in that it reflects a contemporary cohort at a single institution with similar surgical practices. Unlike previous reports, analysis was restricted to patients with TUR proven pT2 disease to ensure consistency within the cohort. The data provide reference OS values for patients with pathologically diagnosed muscle-invasive bladder cancer based on current medical guidelines outside the context of a clinical trial.

Over 50 % of patients at our institution had pT3/4 disease at RC. Not surprisingly, the OS of 57.8 % for the cohort was low. Incidence of pT3/4 disease from other single institutions ranged from 30 % to 53 % [10–13]. Of note, these studies had widely variable accrual lengths and included all RC patients, compared to only pT2 disease at TUR in our cohort [10–13]. We demonstrated a statistically significant relationship between pT classification at RC and OS. Similar to previous publications, pT4 had the worst OS (12 % at 1.5 years), with T4a and T4b disease behaving comparably [14, 15]. There was a non-statistical separation in survival

Table 2 NAC versus immediate RC

	NAC (n=81)	Immediate RC (n=99)
Mean age (years)	65.6	68.3
Mean LN count at RC	33.1	29.4
Positive margin at RC	11 (13.6 %)	13 (13.1 %)

curves between pT3a and pT3b and no difference in OS for pT2a and pT2b. Limiting analysis to the pN0 population did not show a difference in survival. Prior investigations have found no difference in recurrence free survival (RFS) for pT3 substages except within pN0 in which pT3aN0 had improved RFS compared to pT3bN0 [16, 17]. The literature

reports conflicting results regarding RFS for pT2 subcategories [18, 19]. A limitation of subclassifying pT3 tumors is that it is based on gross impression of fat invasion, making standardization difficult. Similarly, subclassifying pT2 is somewhat subjective because it reflects an estimation of the depth of muscularis propria invasion. Demonstrating a survival benefit within these substages was also limited by the number of patients and number of deaths that occurred, especially within the pT2 population. We found OS between pT0, pTa, pTis, and pT1 to be comparable, although analysis was limited by small numbers and few deaths. There is contradictory published data comparing pT0 to pTa/Tis [20, 21]. Nonetheless, pT0 has improved survival compared to ≥pT1 at RC [20]. Based on similarities in survival distribution, pT were collapsed into pT0/a/is/1/2a, pT2b/3a/3b, and pT4 groups, representing a novel simplified model for bladder cancer OS. There was a statistically significant difference between these three groups, with pT0/a/is/1/2a patients surviving longer than pT2b/3a/3b, and pT4 disease having the worst survival. Moreover, on multivariable analysis, RC pT group pT2b/3a/3b remained a strong negative predictor of OS.

Our investigation indicates that patients with SBR (pT2 at TUR and <pT2 at RC) have improved OS, with a 1.5-year survival rate of 79 % vs. 45 % without SBR. There is limited data regarding the prognostic implications of SBR as most studies focus on complete pT response (pT0). When comparing SBR as a potential prognostic factor versus a three-tiered RC pT group, the collapsed pT group was a stronger indicator of OS. This illustrates that SBR is a surrogate to analyze lower RC pT, without the inclusion of pT2a. Thus, our data indicate that a stage of ≤pT2a is a stronger prognostic factor and may be more relevant to describe the effectiveness of a treatment than SBR and/or complete pT response. It is also interesting to note that presence of SBR is not specific to patients with NAC: 18.2 % of the RC cohort also had a decrease from pT stage at TUR to pT stage at RC. This illustrates that use of BCG therapy as well as physically debulking the tumor during TUR may play a role in downstaging tumors. While previous studies have used downstaging or a complete pT response as an indicator of successful use of NAC, our study demonstrates that

downstaging is not limited to this population of patients and may be relevant in the immediate RC cohort.

Of our cohort, 30 % was pN1+ at RC and represented a significant negative predictor of survival. Nodal status impacting prognosis has been well illustrated in the literature [3, 7, 10, 15, 22, 23]. At 1.5 years after RC, 66 % of our patients with pN0 were alive versus 30 % with pN1+, consistent with published outcomes [3, 7, 10, 15, 22, 23]. Abdel-Latif et al. [23] demonstrated a 3-year RFS of 78 % with pN0 versus 38 % with positive nodes. Moreover, Stein et al. [10] found a 69 % 5-year OS with pN0 verses 31 % with pN1+. One limitation in the ability to compare our results with other institutions is that as a tertiary care center, we treat more patients with high stage and positive nodal disease. Our institution also routinely uses extended lymph node dissection, which is not practiced in all hospitals. While pN1+ was a predictor of poor outcome, an important finding of our analysis was that positive nodes were not limited to high pT disease, with 4.5 % of patients having pN1+ with ≤pT2a disease.

Almost half of the cohort had LVI. LVI did not impact survival in node positive patients; however, LVI was a negative predictor of survival in the pN0 group. There is data illustrating LVI at RC as an independent predictor of survival and recurrence in bladder cancer [24, 25]. Shariat et al. [26] studied pN0 RC patients and demonstrated that LVI was strongly associated with clinical outcome. The finding of pN0 patients with LVI and poor survival raises the possibility that the nodal resection was less substantial in this group. However, our data showed that LN number was comparable. A second possibility is that the LN metastases may not have been present for histologic assessment, in that either the tumor was cut through and discarded during processing or that the metastatic deposit is still embedded in paraffin and was not available for microscopic examination. A third possibility is that a diagnostic error occurred in which the pathologist did not identify the positive LN. A past article compared histologic impression versus keratin immunohistochemistry to detect micrometastasis in node negative bladder cancer, with no identified missed metastases [27]. We hypothesize that these patients may have a different path of tumor spread, for example, directly to non-regional lymph nodes or bone marrow. Future research is required to understand the mechanism by which patients come to have pathologically identified LVI and negative nodes and the biologic relevance of these findings.

Between the NAC vs. non-NAC groups, age and surgical parameters such as number of LN and margin status were comparable. However, there was extensive heterogeneity in type of NAC given, number of cycles, medical setting (tertiary care center vs. community practice) and time between NAC and RC, reflecting the current variable practice patterns. With NAC, we observed more frequent decrease of T classification comparing cT prior to RC and pT at RC (45.7 % vs. 24.2 %), increased pT0 (23.5 % vs. 8.1 %) and a higher rate of SBR (33.3 % vs. 18.2 %). High pT (≥pT2b) at RC occurred less often with NAC (34.6 % vs. 56.6 %). Similarly, previous authors have demonstrated that NAC is associated with more frequent complete pathologic response than RC alone (33–38 % vs. 5–15 %) [3, 12, 20, 28, 29]. However, we did not identify a statistically significant increase in OS in NAC patients (NAC OS 22 vs. 24 months without NAC). Literature regarding the survival advantage of NAC is controversial, but evidence from clinical trials suggests a benefit of up to 5.5 % [3, 28–34]. Perhaps to achieve this benefit, NAC must be better standardized as is done in a clinical trial and therefore our data does not discredit the use of neoadjuvant chemotherapy in patients with muscle-invasive bladder cancer. Surprisingly, pN1+ was more common in NAC patients (39.5 % vs. 22.2 %). For each cT classification, more node positivity was seen in the NAC cohort, although this difference was not statistically significant. Moreover, we identified a group of pN1+ patients with a low pT (≤pT2a). All patients in this group received NAC, with deaths observed. These findings suggest that focusing on pT classification or the frequency of decreased cT to pT at RC without the corresponding node status in NAC patients may not be fully indicative of a tumor's potential lethality, a concept not discussed in the literature. As NAC has consistently been shown to decrease pT at RC, systemic chemotherapy could have utility in the treatment of non-muscle-invasive, BCG refractory patients that are not ideal surgical candidates or have limited life expectancy.

Limitations of this investigation included its retrospective nature, short follow-up, limited number of patients, and multiple surgeons. Another consideration was potential bias between NAC and non-NAC groups. Poor renal function and performance status excluded patients from NAC. Age was slightly higher in the non-NAC group, which in conjunction with the NAC exclusionary criteria should help eliminate a bias of unhealthier patients receiving NAC. NAC was heterogeneous, as previously discussed. Other histopathological factors which may have prognostic significance, such as tumor multifocality and grade, were not analyzed. Lastly, being a tertiary care center with potentially higher cT/pT tumor, more positive nodes, routine use of extended LN dissection, and frequent use of NAC, our data may not be representative of other patient cohorts.

Conclusions

We performed a retrospective single institutional study of muscle-invasive bladder cancer at RC. Negative prognostic factors in bladder cancer included pT4, pT2b/3a/3b disease,

pN1+, and LVI. Collapsing pT into pT0/a/is/1/2a, pT2b/3a/3b, and pT4 was a stronger predictor of survival than SBR. pN0 patients with LVI had decreased OS. The presence of positive nodes at RC was not limited to high pT disease with pN1+ seen in NAC patients with low RC pT. pT0 and SBR were more common in patients with a history of NAC, although use of NAC was not associated with increased OS. Our findings may be more indicative of outcomes outside the context of a clinical trial and highlight the variability of multidisciplinary management in bladder cancer in its current usage today.

Abstract Chondrosarcomas are malignant cartilage-forming tumours that can arise centrally (in the medulla) or peripherally (at the surface) of the bone. They are classified into three histological grades which correspond to the clinical severity. Previous studies by our group have shown altered signal transduction of the fibroblast growth factor and Wnt signalling pathways during peripheral chondrosarcoma progression. Heparan sulphate (HS) is a glycosaminoglycan that facilitates receptor binding of multiple growth factors, in which the sulphation of 6*O* position plays a pivotal role. 6*O*-Sulphation occurs through three HS 6*O*-sulphotransferases (HS6ST1-3) and is fine-tuned by two endosulphatases (SULF1-2) that remove 6*O*-sulphate groups. We have investigated whether the expression of HS6STs and SULFs changes during chondrosarcoma progression and have determined 6*O*-sulphation levels in two chondrosarcoma cell lines. Immunohistochemistry on tissue microarrays of chondrosarcomas showed that HS6ST3 and SULF1 were highly expressed in most chondrosarcomas, whereas SULF2 expression was absent in most cases. HS6ST1 and HS6ST2 expression are significantly increased during chondrosarcoma progression, which suggest that 6*O*-sulphation is increased during progression. This was confirmed in one grade III chondrosarcoma cell line, which showed a dramatically increased 6*O*-sulphation compared to an articular chondrocyte cell line by HPLC; another cell line showed an increased expression of one 6*O*-sulphated HS disaccharide. In conclusion, our results show increased HS6ST1 and HS6ST2 expression during chondrosarcoma progression and increased HS 6*O*-sulphation in vitro. As 6*O*-sulphation plays an important role in signal transduction, altered HS6ST expression might be associated with changes in signal transduction pathways in chondrosarcoma progression.

Introduction

Chondrosarcomas (CS) are malignant cartilage-forming tumours that can arise centrally (in the medulla) or peripherally (at the surface) of the bone. Both types can originate from benign precursor lesions, called enchondromas (central) or osteochondromas (peripheral). Chondrosarcomas are histologically classified into three grades which correspond to the clinical severity [1]. We have previously shown altered signal transduction during chondrosarcoma progression. Fibroblast growth factor (FGF) signalling positively correlates with

increasing histological grade in peripheral cartilage tumours, whereas Wnt signalling is attenuated in both central and peripheral tumours [2–4].

Osteochondromas are caused by inactivation of one of the exostosin (*EXT*) genes [5, 6]. EXT is involved in the biosynthesis of heparan sulphate proteoglycans (HSPGs), elongating the heparan sulphate (HS) chains attached to proteoglycan cores. HSPGs are present on the cell surface and in the extracellular matrix, where they, among other functions, act as co-receptors for growth factors [7, 8]. HS chains consist of alternating units of an uronic acid (UA) which can be sulphated on the 2*O* position and a glucosamine (GlcNAc) which can be sulphated on *N*, 3*O* and 6*O* positions. Each modification of the chain only occurs on some of the disaccharides and results in a domain structure with regions high in sulphation that interact with protein ligands, interspersed with less-sulphated regions.

EXT inactivation is absent in central cartilaginous tumours [4]. Instead central tumours carry heterozygous mutations in isocitrate dehydrogenase (*IDH*) 1 or *IDH2* in more than 50 % of all cases, while peripheral cartilage tumours do not carry *IDH* mutations [9, 10]. Both IDH1 and IDH2 are involved in cellular metabolism. Recent studies suggest that while *IDH* (in the case of central tumours) and *EXT* (peripheral tumours) cause the formation of benign cartilaginous tumours, malignant transformation is a process unrelated to these mutations, and the mechanisms underlying this process are as yet unknown but might be similar [10–12].

In other tumour types, it has been found that HS chain modifications can play a role in tumour progression by influencing HS-ligand binding [13, 14]. One of these modifications is 6*O*-sulphation which is mediated by three HS 6*O*-sulphotransferases (HS6ST1-3) that attach sulphate groups to the 6*O* position of glucosamine groups in the HS chain [15]. In addition, two endosulphatases, SULF1 and SULF2, play a role in fine-tuning the 6*O*-sulphation pattern by removing 6*O*-sulphate groups [16, 17].

The level and pattern of 6*O*-sulphation of HS chains have been shown to affect their binding capacity to different growth factors (as reviewed by Lamanna et al. [18]). For example, 6*O*-sulphation inhibits the binding of Wnt and BMP to their respective receptors but, on the other hand, is a requisite for the binding of FGF to its receptor. Altered signal transduction during chondrosarcoma progression might therefore be (partially) mediated by the changes in HS 6*O*-sulphation.

Therefore, we investigated whether the expression of the HS6STs and SULFs differs with increasing histological grade in cartilage tumours and whether the levels of HS 6*O*-sulphation are altered in high-grade chondrosarcoma cell lines in order to elucidate the role of HS 6*O*-sulphation in chondrosarcoma progression.

Materials and methods

Construction of TMAs

The tissue microarrays (TMAs) used in this study were constructed as described [19]. A total of 153 formalin-fixed, paraffin-embedded enchondroma (six), osteochondroma (11), central chondrosarcoma [91 samples, composed of 42 grade I (CCSI), 36 grade II (CCSII) and 13 grade III (CCSIII)] and peripheral chondrosarcoma samples [45, composed of 31 peripheral chondrosarcomas grade I (PCSI), 11 grade II (PCSII) and three grade III (PCSIII)] diagnosed between 1985 and 2008 were retrieved from the archives of the departments of pathology at Leiden University Medical Center (Leiden, The Netherlands) and Onze Lieve Vrouwe Gasthuis (Amsterdam, The Netherlands). Diagnosis was re-evaluated before inclusion. Three representative 2-mm cores were punched from every tumour sample and transferred to the recipient block using TMA Master (3DHISTECH, Budapest, Hungary). In addition, cores from skin, colon, tonsil, prostate, breast carcinoma, spleen and liver were included for control and orientation purposes. Follow-up data on metastasis-free and overall survival were collected. The mean follow-up period was 9 years. On a total of 153 patients in our sample set, 11 patients developed metastases, 28 presented with local recurrences and 22 died. In order to compare protein expression to normal cartilage, separate paraffin sections of articular cartilage ($n=5$) and growth plate (four post-natal and one foetal) were included as well. Articular cartilage and growth plates were acquired from pathological specimens that are not related to cartilaginous tumours. All samples were handled according to the ethical guidelines as described in the Code for Proper Secondary Use of Human Tissue in The Netherlands of the Dutch Federation of Medical Scientific Societies (www.federa.org).

Immunohistochemistry

Immunohistochemistry was performed and the slides were scanned using Mirax Desk instrument (3DHISTECH) as described in [19]. An overview of the used antibodies, positive controls, antigen retrieval and dilution is given in Table 1. The staining of the TMAs was scored on a 0–7 scale based on staining intensity (1=weak, 2=moderate and 3=strong) added to the percentage of the positive cells (1=0–24 %, 2=25–49 %, 3=50–74 % and 4=75–100 %) by two independent observers (CJFW and CEdA) [20].

Cell culture

The articular chondrocyte cell line LBPVA [21] and chondrosarcoma cell lines CH2879 [22] and OUMS27 [23] (both CCSIII) were cultured in RPMI 1640 (Invitrogen, Breda, The Netherlands) supplemented with 20 % foetal calf serum

Table 1 Overview of used antibodies

Antigen	Species and clone	Positive control	Antigen retrieval	Dilution	Manufacturer
HS6ST1	Mouse monoclonal, 9L832	Kidney	Citrate pH 6.0	1:200	US Biological
HS6ST2	Rabbit polyclonal	Prostate	Citrate pH 6.0, 5 % elk milk	1:200	Sigma Aldrich
HS6ST3	Rabbit polyclonal	Kidney	Citrate pH 6.0, 5 % elk milk	1:50	Abcam
SULF1	Goat polyclonal	Testis	Citrate pH 6.0	1:50	Abcam
SULF2	Mouse monoclonal, 2B4	Squamous cell lung carcinoma	Citrate pH 6.0	1:100	AbD Serotec

(Invitrogen), 2 % P/S (Invitrogen) and 1 % GlutaMAX (Invitrogen). At 70–80 % confluency, the cells were harvested and HS disaccharide analysis was performed as described in [24].

Statistical analysis

Results were analysed by the PASW 17.0 for Windows software package (SPSS Inc., Chicago, IL, USA). The differences in relative HS disaccharide expression as measured by SAX–HPLC were analysed by independent samples Student's *t* tests. Trends in immunohistochemical scores between histological grades were evaluated by ANOVA followed by post-hoc test for linear trend. Survival (metastasis-free, disease-free and overall survival) was compared between a high and low expression group using Kaplan Meier survival analysis. High expression was defined as a score of the median or higher and low expression as a score below the median. P values<0.05 were considered significant for all analyses.

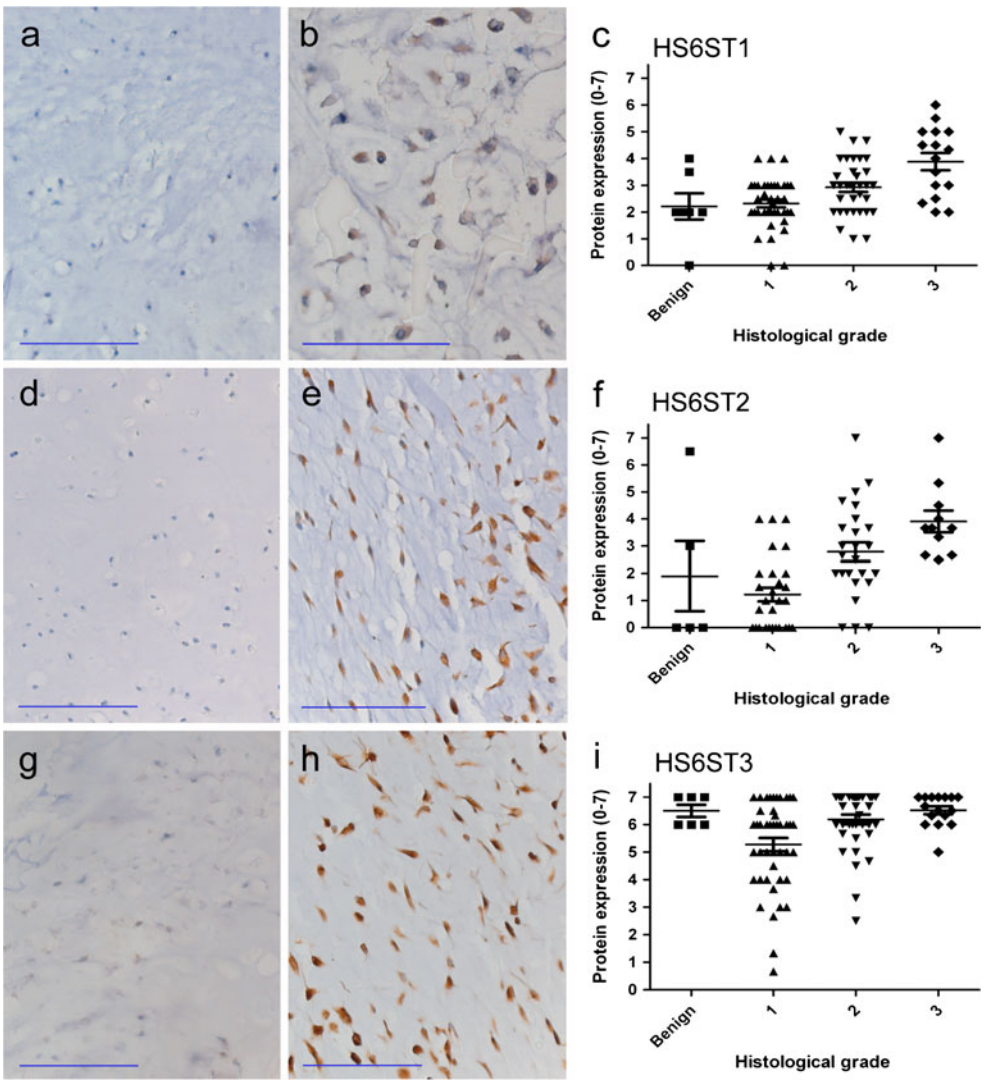

Fig. 1 HS6ST protein expression in cartilage tumour tissue shows a correlation of HS6ST1 and HS6ST2 expressions with histological grade. **a** Grade I central chondrosarcoma negative for HS6ST1. **b** Moderately strong HS6ST1 expression in a grade II peripheral chondrosarcoma. **c** HS6ST1 expression grouped by histological grade shows a strong correlation between expression and histological grade ($p<0.001$). **d** Grade I central chondrosarcoma negative for HS6ST2. **e** Strong HS6ST2 expression in grade II central chondrosarcoma. **f** HS6ST2 expression is correlated with increasing histological grade ($p=0.033$). **g** Weak HS6ST3 expression in grade I central chondrosarcoma. **h** Strong HS6ST3 expression in grade II central chondrosarcoma. **i** High HS6ST3 expression in most cases. *Blue bars* indicate 10 μm; *error bars* represent standard error of the mean (SEM)

Results

Expression of heparan sulphate 6*O*-sulphotransferases

We performed immunohistochemistry to assess the expression of the HS6STs, which attach sulphate groups to the HS chain on the 6*O* position of glucosamine. As the expression of all enzymes was highly similar between central and peripheral cartilage tumours, the results of central and peripheral tumours were combined (data not shown).

In general, while HS6ST3 was expressed strongly in almost all cartilage tumours, HS6ST1 and HS6ST2 were expressed at lower levels, although some, especially high-grade tumours, showed high expression (Fig. 1a–f). Expression in normal cartilage was absent or low, similar to the expression detected in low-grade samples (data not shown). For HS6ST1 and HS6ST2, a trend for an increased score with increasing histological grade was present ($p<0.001$ and $p=0.033$, respectively). Although on average HS6ST3 expression was reduced in grade I chondrosarcomas compared to the other grades, immunohistochemical scores did not show a significant trend with increasing histological grade (Fig. 1g–h). Normal cartilage samples showed moderately strong expression of HS6ST3 (data not shown).

As histological grade is negatively correlated with survival in chondrosarcoma patients [1], we assessed whether there were differences in survival (metastasis-free, disease-free and overall survival) between patients with high expression of HS6ST1 and HS6ST2 and patients with low expression. However, no correlation with metastasis-free, disease-free or overall survival was found (data not shown).

Expression of endosulphatases

We examined the expression of SULF1 and SULF2, the two endosulphatases that are able to remove 6*O*-sulphate groups after they have been attached to the HS chain by HS6STs. Whereas SULF1 was expressed strongly in almost all cartilage tumours, SULF2 expression was rare (Fig. 2). Although the median expression of SULF1 seemed to increase with increasing histological grade, no significant trend was observed ($p=0.193$). SULF2 was expressed only in a small number of tumours, and expression was highly focal (Fig. 2d–f). SULF2 expression was absent in normal cartilage (data not shown).

HS disaccharide analysis of chondrosarcoma cell lines

To further study 6*O*-sulphation in chondrosarcomas, the relative HS disaccharide content of two high-grade central chondrosarcoma cultures and one articular chondrocyte cell line was analysed. The results showed an increased expression of 6*O*-sulphated HS disaccharides (UA-GlcNAc 6S and UA-GlcNS 6S) in CH2879 (CCS grade III) in comparison to the articular chondrocyte cell line (Fig. 3a). Another CCS grade III cell line, OUMS27, showed an increased UA-GlcNAc 6S expression, although the change was not as large as in CH2879. After regrouping the disaccharide distribution by its sulphation type, CH2879 showed a significantly increased

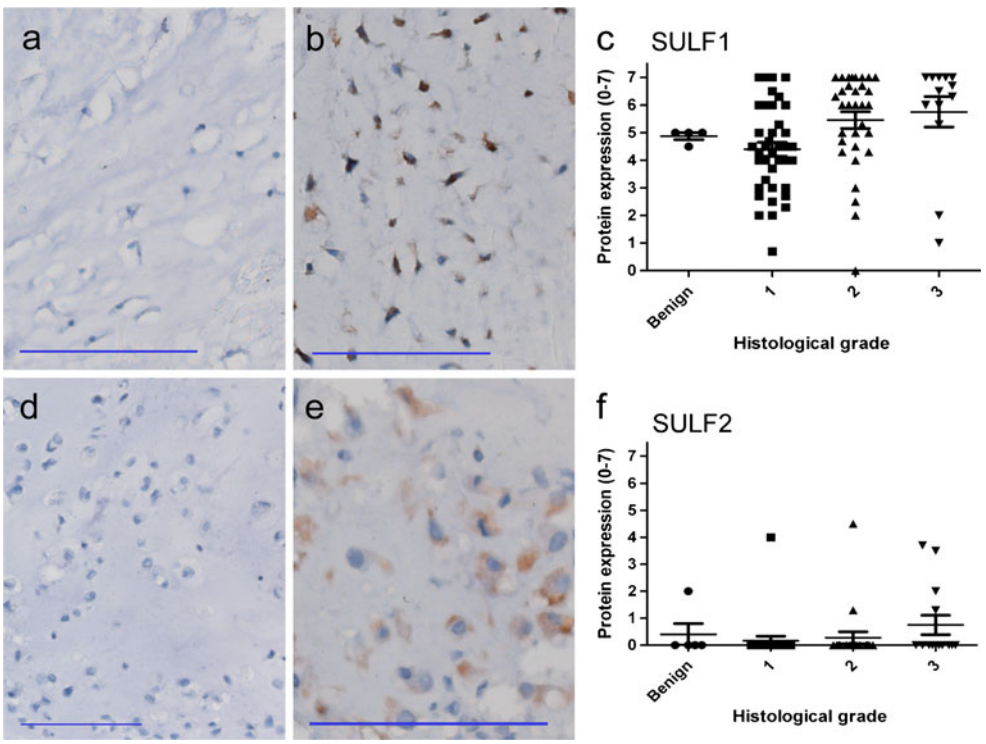

Fig. 2 High SULF1 and low SULF2 protein expression in cartilage tumours. **a** Grade I central chondrosarcoma negative for SULF1. **b** Moderate to strong expression of SULF1 in a grade III central chondrosarcoma. **c** SULF1 expression is not significantly correlated to histological grade. **d** Grade III central chondrosarcoma negative for SULF2. **e**) Grade II central chondrosarcoma showing focal expression of SULF2. **f** Most cartilage tumours are negative for SULF2. *Blue bars* indicate 10 μm; *error bars* represent SEM

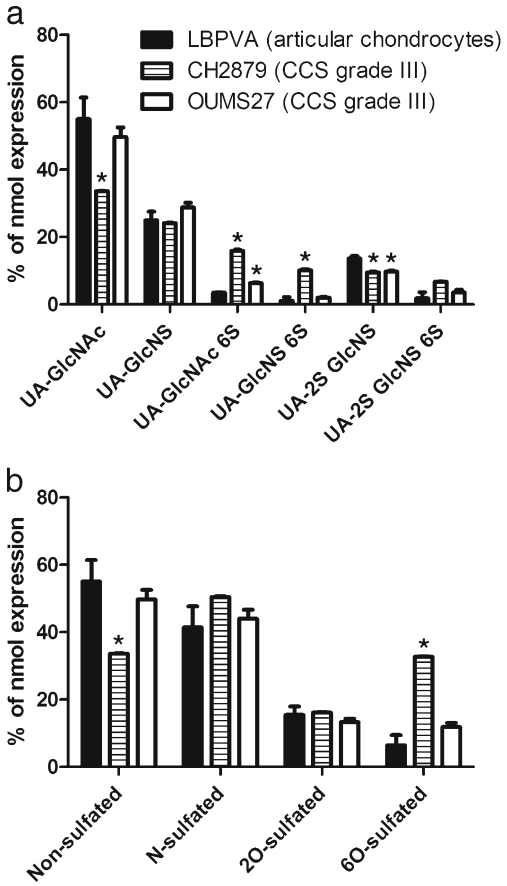

Fig. 3 Increased 6*O*-sulphation in a grade III central chondrosarcoma cell line compared to articular chondrocytes. **a** Relative HS disaccharide expression as determined by SAX–HPLC in CH2879 (cell line CCS grade III), OUMS27 (cell line CCS grade III) and LBPVA (cell line normal articular chondrocytes) shows significantly increased relative expression of the 6*O*-sulphated UA-GlcNAc 6S and UA-GlcNS 6S disaccharides and simultaneous decreased expression of the UA-GlcNAc and UA-2S GlcNS disaccharides in CH2879, and the significantly increased expression of UA-GlcNAc 6S and decreased expression of UA-2S GlcNS in OUMS27, compared to the relative disaccharide expression in the LBPVA cell line. **b** HS 6*O*-sulphation level is markedly increased in the CH2879 cell line compared to the LBPVA articular chondrocyte cell line, but not in the OUMS27 chondrosarcoma cell line. *Asterisks* denote a p value<0.05 compared to normal articular chondrocytes; *error bars* represent SEM

total 6*O*-sulphation compared to the articular chondrocytes (Fig. 3b). In OUMS27, the total 6*O*-sulphation levels were not significantly increased. In both cell lines, the expression of the *N*- and 2*O*-sulphated UA-2S-GlcNS disaccharide was reduced compared to the articular chondrocytes (Fig. 3a). In addition, the total relative expression of non-sulphated disaccharides was reduced in CH2879 (Fig. 3b).

Discussion

Previously, our group has reported increased FGF signalling and decreased Wnt signalling with malignant progression of chondrosarcoma [2–4]. The degree and the pattern of 6*O*-sulphation of HS chains play an important role in determining the capacity of HS chains to facilitate growth factor-receptor binding [14, 15]. In the case of 6*O*-sulphation, this is achieved by a delicate balance of heparan sulphate 6*O*-sulphotransferases (HS6ST1-3) attaching sulphate groups to the 6*O* position and 6*O*-endosulfatases (SULF1-2) removing some of these sulphate groups. Different studies have highlighted the importance of 6*O*-sulphation in tumourigenesis, especially by examining the role of SULF expression in tumours [13, 25, 26].

Our study showed that the expression of HS6ST1 and HS6ST2 was increased in chondrosarcoma with increasing histological grade. This suggests that 6*O*-sulphation also increases during chondrosarcoma progression. Conversely, HS6ST3 is generally highly expressed in most chondrosarcoma samples, so 6*O*-sulfotransferase activity is likely to be present in most chondrosarcomas. However, the HS6STs have been shown to have different substrate preferences for trisulphated sequences on one hand and disaccharides lacking 2*O*-sulphate groups on the other [27, 28]. Therefore, changes in the expression of one HS6ST could lead to distinct differences in the structure of the HS chain, even though another HS6ST is ubiquitously present. The 6*O*-sulphation can be modified by endosulphatases (SULF1 and SULF2) that can, in turn, remove 6*O*-sulphate groups after addition to the HS chain by HS6STs. SULF1 expression was high in almost all samples. Conversely, SULF2 was not expressed in most cases. Although the expression of HS6ST1 and HS6ST2 increased with increasing histological grade [1], the expression was not correlated to metastasis-free, disease-free or overall survival. This is probably due to the relatively small disease-related morbidity and mortality in chondrosarcoma and, therefore, also in our set of patients [1].

The combination of positive correlation of both HS6ST1 and HS6ST2 with histological grade raises the question as to whether 6*O*-sulphation is increased during malignant progression as well. As the isolation of HS disaccharides from cartilage cryosections proved to be technically unfeasible, cell lines were used even though they may be a sub-optimal biological model because HS sulphation is very tissue- and environment-specific [29–31]. Disaccharide analysis of two high-grade chondrosarcoma cell lines showed the increased expression of two 6*O*-sulphated disaccharides in one high-grade CS cell line and of one 6*O*-sulphated disaccharide in the other cell line. The total 6*O*-sulphation was markedly increased in the former high-grade CS cell line, but the latter cell line did not show this pattern. The relative expression of *N*- and 2*O*-sulphated disaccharides was reduced in both cultures, which is likely due to the relatively increased expression of 6*O*-sulphated disaccharides. In conclusion, the results suggest that 6*O*-sulphation could be upregulated in high-grade chondrosarcomas, although the degree of 6*O*-sulphation is variable.

Studies on the role of HS 6*O*-sulphation in growth factor-receptor binding have shown that an increase in 6*O*-sulphation leads to increased FGF and decreased Wnt receptor binding [18]. We here show increased HS6ST expression and increased 6*O*-sulphation during malignant progression of chondrosarcoma, which might underlie the previously reported increased FGF and decreased Wnt signalling during chondrosarcoma progression [2, 3].

In conclusion, this study shows that with malignant progression in chondrosarcoma, there is an increased expression of two HS 6*O*-sulphotransferases, HS6ST1 and HS6ST2. Our results point to an increased 6*O*-sulphation during the process of progression, which might act as an upstream mechanism influencing the activity of signalling pathways such as FGF and Wnt pathways and, in this way, play a role in chondrosarcoma progression.

Acknowledgments We thank Andrea Facchini (Istituto Ortopedico Rizzoli, Bologna, Italy) for the donation of the LBPVA cell line, Antonio Llombart-Bosch (Valencia University, Spain) for the CH2879 cell line and Toshiyuki Kunisada (Okayama University Medical School, Japan) for the OUMS27 cell line. We would also like to thank Armin Walter (Onze Lieve Vrouwe Gasthuis, Amsterdam, The Netherlands) for kindly providing patient samples. We would also like to gratefully acknowledge Pancras Hogendoorn, Christianne Reijnders, Steve Rosen (University of California, San Diego, CA, USA) and Jacob van den Born (University Medical Center Groningen, The Netherlands) for their fruitful discussion. Lastly, we would like to thank Klaas van der Ham for his photographic assistance and Inge Briaire-de Bruijn and Dorien van der Geest for their expert technical assistance. Abstract We wish to highlight the unusual occurrence of gastric neuroendocrine cell hyperplasia and type I neuroendocrine tumours within three hyperplastic polyps. In all cases, the neuroendocrine component was present within and between the hyperplastic foveolar glands of the polyps and overall formed the minor part of the polyps. Two of the patients presented with epigastric pain and the other with fatigue from anaemia, and on endoscopy, all three were found to have superficially ulcerated gastric polyps in the body (cases 1 and 2) and fundus (case 3). Two of the cases had serologically proven autoimmune atrophic gastritis, while the third case had histological evidence of an atrophic gastritis, most likely also autoimmune in aetiology. Cases 1 and 3 had single hyperplastic polyps, while case 2 had three polyps. All polyps showed linear neuroendocrine cell hyperplasia within hyperplastic foveolar epithelium both at the surface and within deeper-situated glands. Neuroendocrine immunohistochemistry highlighted the neuroendocrine cell hyperplasia. The bulk of the neuroendocrine component was restricted to hyperplastic mucosa forming the polyps. Non-hyperplastic adjacent mucosa showed less prominent neuroendocrine cell hyperplasia. It is unclear whether the two pathologies occurred simultaneously or independently. The common feature and causal link is atrophic gastritis, which predisposed the gastric mucosa to the development of both neuroendocrine cell hyperplasia and tumours, and hyperplastic polyps.

Gastric hyperplastic polyps are relatively common and are usually encountered as a reactive condition to mucosal injury and/or inflammation. This is noted particularly in association with autoimmune atrophic gastritis and, less commonly in *Helicobacter pylori* chronic gastritis and in post-antrectomy stomachs. Hyperplastic polyps are also encountered infrequently in rare forms of chronic gastritis such as cytomegalovirus gastritis, lymphocytic gastritis, amyloid deposition, Zollinger–Ellison syndrome and gastric antral vascular ectasia [1–3]. While they represent a discrete entity, gastric hyperplastic polyps have been associated with both adenomatous/flat dysplasia, and adenocarcinoma usually within the adjacent non-polyp mucosa [1–3].

Although uncommon, neuroendocrine cell hyperplasia and tumours are well described in the stomach. Clearly defined clinicopathological associations exist for the different types of gastric neuroendocrine tumours [4–6]. Linear neuroendocrine hyperplasia and tumours (so-called type I tumours) are pathognomonic of atrophic gastritis.

Both hyperplastic polyps and neuroendocrine cell hyperplasia and tumours thus occur in the milieu of gastric atrophy and injury and are well recognised in this context as separate entities.

We present three cases with atrophic gastritis and gastric hyperplastic polyps associated with neuroendocrine cell hyperplasia and an accompanying neuroendocrine tumour both within the hyperplastic polyps. Adjacent non-hyperplastic

gastric mucosa did not show prominent neuroendocrine cell hyperplasia as compared to the hyperplastic foveolar epithelium. The occurrence and coexistence of hyperplastic neuroendocrine cells and type I tumours within gastric hyperplastic polyps have not been described previously, to the best of our knowledge.

Materials and methods

Cases 1 and 2 were referred for a second opinion to one of the authors (RC). All materials were received in 10 % neutral buffered formalin, processed routinely, and hematoxylin and eosin (H&E)-stained sections were produced. Immunohistochemistry was performed on the paraffin-embedded, formalin-fixed tissue for the following: chromogranin (Dako-Cytomation, Ely, UK; dilution 1/50), synaptophysin (Dako; 1/200), gastrin (Leica/Novocastra, Newcastle-on-Tyne, UK; 1/200), serotonin (Leica/Novocastra; prediluted), somatostatin (Leica; 1/2,000), CD56 (Leica; 1/80), pan-cytokeratin (Dako; 1/40) and Ki-67 (Leica; 1/200).

In addition to the three study cases, five other random gastric hyperplastic polyps were examined morphologically and immunohistochemically for neuroendocrine cells.

Results

Results of clinicopathological assessment are presented in Table 1.

Clinical information

Case 1 A 45-year old male complained of epigastric pain and, on endoscopy, was found to have an ulcerated mucosal polypoid lesion in the body of his stomach, measuring 25 mm that was snared and submitted for pathological evaluation. The patient was also found to have a microcytic anaemia due to blood loss from the gastric ulcerated area. He had autoantibodies to parietal cells, but gastrin levels were not determined.

Case 2 This was a 72-year-old man who also had epigastric pain, melaena and anaemia. He was found to have a large polypoid mass together with two smaller polyps, in the fundus and body. He underwent a partial gastrectomy because of the clinical suspicion of malignancy and the multiplicity of polyps and, 1 year post-operatively, is well and disease-free. Autoimmune serology and serum gastrin levels were not performed.

Case 3 This was a 33-year-old female who presented with fatigue and found to have a microcytic anaemia and vitamin B12 deficiency. In the investigation of the cause of the anaemia, endoscopy revealed marked gastric atrophy in the body and fundus together with a small polyp in the fundus.

She had positive serology for anti-parietal cell antibodies; however, anti-intrinsic factor antibodies were negative. She was also noted to have hypergastrinaemia at this time (gastrin level >400 units). Endoscopy showed a normal antrum and a fundic polyp. The polyp was removed, and the fundus, body and antrum were biopsied.

None of the patients had Zollinger–Ellison syndrome or multiple endocrine neoplasia type I (MEN-I), clinically and by relevant imaging. They also did not have a family history of any polyposis syndrome.

Gross findings

Case 1 The submitted polyp was tan-coloured, measured 23×15 mm and showed surface ulceration.

Case 2 A partial gastrectomy excised a large polypoid lesion measuring 25×18 mm, and two smaller polyps, 13×8 and 12×7 mm, respectively, were also noted. The surface of the largest polyp showed pinpoint hemorrhagic foci but no obvious ulceration. Deep to this polyp, the gastric wall appeared firmer and thickened. This area was sampled extensively.

Case 3 The polyp that was submitted for histological evaluation along with the biopsies, measured 10×10 mm and appeared tan-coloured.

Microscopy

All three cases had features typical of hyperplastic polyps (Fig. 1a–c). There was foveolar hyperplasia with irregular cystic dilatation of glands. Foci of intestinal metaplasia were

Table 1 Clinicopathological features

Case	Age	Gender	Site	Polyp size (mm)	NET size (mm)	Resection	Autoantibodies	Gastrin levels
1	45	Male	Body	23	20	Polypectomy	Anti-parietal cell	Not done
2	72	Male	Fundus/body	25	4	Partial gastrectomy	Not done	Not done
3	33	Female	Fundus/body	10	5	Polypectomy	Anti-parietal cell, anti-intrinsic factor	>400 units

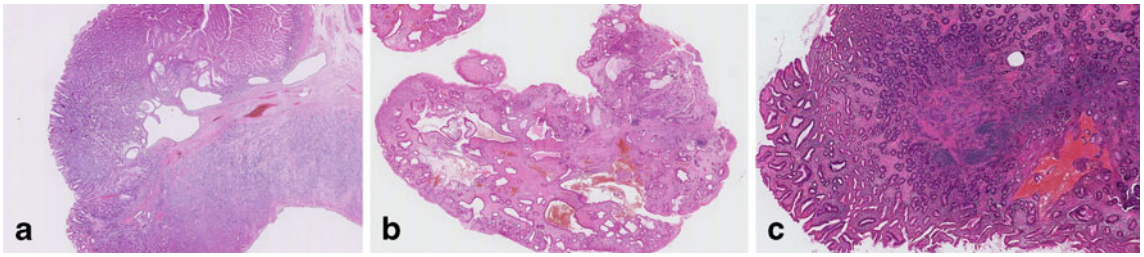

Fig. 1 **a**–**c** Low power images of the polyps from the three cases. There is surface ulceration and dilated tortuous glands typical of hyperplastic polyps. The neuroendocrine component is within the hyperplastic polyp as aggregates between the hyperplastic tubules

noted in all three hyperplastic polyps but most prominent in cases 2 and 3. The stroma appeared acutely inflamed with oedema; granulation tissue and evidence of chronic inflammation with lymphoid aggregates were also present. Several prominent ectatic vessels were also present in the lamina propria. Several (but not all) hyperplastic glands within the polyps and surface mucosa showed linear neuroendocrine cell hyperplasia (Fig. 2a–c). The neuroendocrine cells were clearly visible as linear runs or rows along the abluminal aspect of the hyperplastic glands in both superficial and deep aspects of the polyps. Although not every hyperplastic gland showed neuroendocrine cell hyperplasia, the majority of glands directly above and within the neuroendocrine tumours showed the most obvious linear neuroendocrine cell hyperplasia. Immediately adjacent mucosa did not show the same striking neuroendocrine cell hyperplasia (in case 1, non-hyperplastic mucosa was present at the base of the polypectomy specimen; in the remaining two cases, ample adjacent mucosa was available from the gastrectomy specimen and biopsy material). The neuroendocrine hyperplasia in adjacent mucosa was more evident in sections stained with neuroendocrine markers. Within the lamina propria, micronodules, trabeculae and sheets of neuroendocrine cells were noted between hyperplastic, dilated glands. These cells were uniform with eosinophilic cytoplasm and monotonous nuclei with typical "salt and pepper" chromatin distribution. The neuroendocrine tumours extended into the submucosa in cases 1 and 2. In case 3, oblique sectioning precluded definitive comment on submucosal penetration. The neuroendocrine component occupied 90 % of the polyp in case 1, 10 % in case 2 and 50 % in case 3.

In addition in case 2, the adjacent mucosa showed mainly low-grade dysplasia with focal areas of high-grade dysplasia. The dysplastic epithelium contained occasional neuroendocrine cells, but there was no linearity to the arrangement and

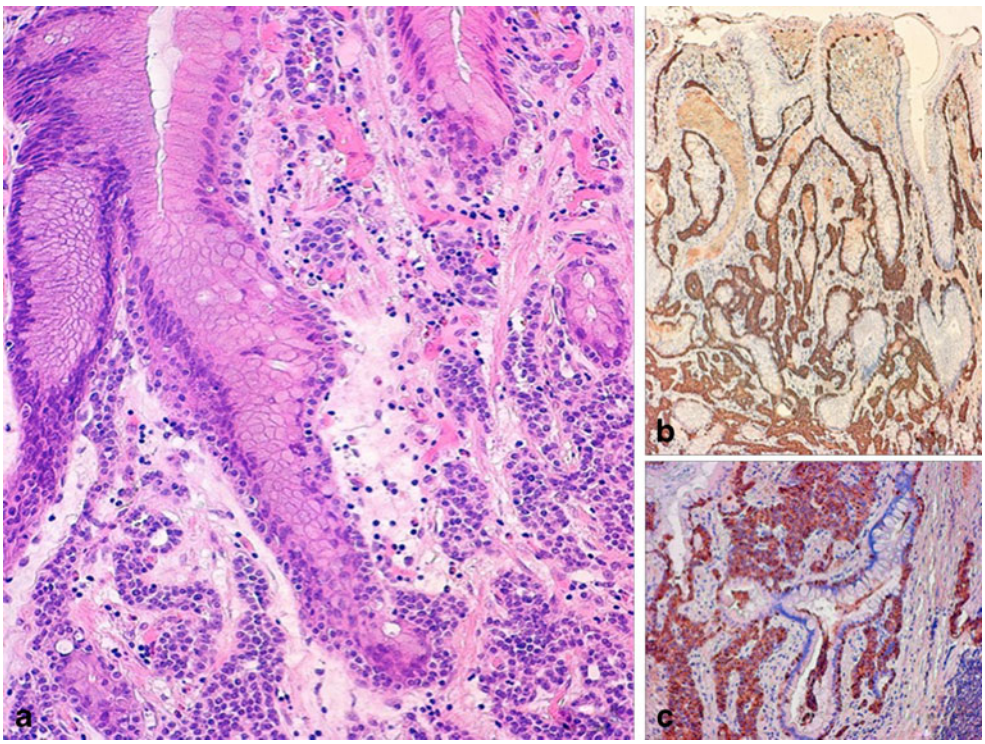

Fig. 2 **a**–**c** The hyperplastic glands display single cell, linear neuroendocrine hyperplasia in both cases (**a**, from case 1). Neuroendocrine tumour cells are present within the lamina propria between hyperplastic glands. Chromogranin stain highlights the extent of neuroendocrine cell hyperplasia within the hyperplastic polyps (**b**, from case 1; and **c**, from case 3)

was not interpreted as hyperplastic. An adenocarcinoma was not present.

The adjacent, non-polyp/non-hyperplastic mucosa in all three cases showed evidence of atrophic chronic gastritis with loss of and/or very occasional parietal cells. There was an associated chronic inflammation with lymphoid aggregates, intestinal metaplasia and so-called "antralization" of the body and fundus because of the absence of oxyntic mucosa. *H. pylori* organisms were not identified in all three cases. The neuroendocrine cell hyperplasia was predominantly noted in areas containing hyperplastic polyps and was not prominent in normal non-hyperplastic-appearing gastric mucosa remote to the polyps, either on H&E or neuroendocrine immunohistochemical markers.

In case 1, there were three mitoses per 10 high-power fields (HPF), and the Ki-67 proliferation index was 16 %, making this a grade 2 neuroendocrine tumour.

Case 2 contained one mitotic figure per 10 HPF and a Ki-67 index of less than 2 % and was therefore a grade 1 neuroendocrine tumour.

Case 3 was graded as a grade 2 neuroendocrine tumour with one mitotic figure per 10 HPF but a Ki-67 index of 4 %.

The neuroendocrine component of both polyps was strongly positive for chromogranin (Fig. 3a, b), synaptophysin, CD56 and cytokeratin. Gastrin, serotonin and somatostatin were all negative.

The five control hyperplastic polyps did not show any evidence of linear neuroendocrine cell hyperplasia on H&E sections or with neuroendocrine cell markers. In fact, fewer neuroendocrine cells were identified within the hyperplastic foveolar glands of the polyps compared to normal adjacent gastric mucosa.

Discussion

Neuroendocrine tumours of the stomach are said to be of three types. Type I occurs in the presence of achlorhydric, atrophic body gastritis or autoimmune gastritis associated with pernicious anaemia. This represents the most common type of gastric neuroendocrine tumour and is gastrin-dependent. Type II occurs in the setting of Zollinger–Ellison syndrome that is associated with MEN-I and is gastrin-dependent, and type III is a sporadic form that develops without antecedent specific gastric pathology and is gastrin-independent. It is also well known that there is a temporal sequence or evolution from neuroendocrine hyperplasia through to tumour, especially in types I and II [4–6]. Enterochromaffin–like cell hyperplasia occurs in the body and fundus of the stomach and is seen either autoimmune chronic atrophic gastritis or in patients with MEN-I. Thus, types I and II gastric neuroendocrine tumours are associated with precursor neuroendocrine cell hyperplasia. In both these clinical contexts, there are definite provoking circumstances for neuroendocrine cell hyperplasia. Two of the three patients in this paper had both serologic evidence of autoimmune atrophic gastritis, but all three patients had histological features consistent with atrophic gastritis. Although case 2 did not have appropriate autoimmune serology performed, the histological features (including neuroendocrine cell hyperplasia and the absence of *H. pylori* organisms) favoured an autoimmune aetiology. None of the patients reported herein had any evidence of MEN-I clinically or histologically. The unusual feature of the neuroendocrine tumour in case 2 was the high Ki-67 index (16 %). In general, type I gastric neuroendocrine tumours have a low proliferation index although, in rare cases, it may be high and the tumours maybe of grade 2 lesions [7]. Type III neuroendocrine tumour is not usually accompanied by neuroendocrine cell hyperplasia and is usually a low- to high-grade tumour.

There is a report of a case of juvenile polyposis of the stomach with accompanying hypergastrinemia [8]. The gastrectomy specimen of this case showed multiple hyperplastic-type polyps with G cell hyperplasia in the polyp and in adjacent normal mucosa (in antral glands).

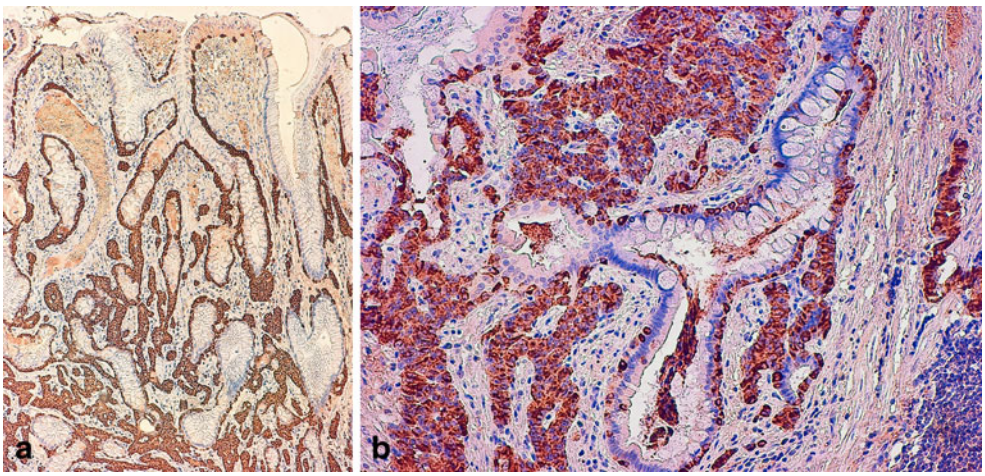

Fig. 3 **a**, **b** The neuroendocrine component of both polyps was strongly positive for chromogranin

The authors ascribed the increase in G cells to changes in cell migration patterns [8]. While this argument is appealing, neuroendocrine cell hyperplasia does not appear to be part of the same hyperplastic/reactive process involving both foveolar epithelium in gastric hyperplastic polyps since the five random polyps selected as "control" cases failed to show any neuroendocrine hyperplasia.

In a recent study on patients with autoimmune metaplastic atrophic gastritis, Park and colleagues demonstrated that hyperplastic polyps occurred in 57.5 % of patients while 19 % of patients had well differentiated neuroendocrine tumours [9].

Any proposed pathogenetic mechanism linking hyperplastic polyps with neuroendocrine cell hyperplasia is speculative and conjectural. While there does not appear to be an obvious direct causal link between the two pathologies, it is likely that they both arose within atrophic gastric mucosa that is stimulated by hypergastrinaemia. It should also be noted that the hyperplastic polyp can predominate, and the neuroendocrine component may be masked, especially in biopsy samples. The neuroendocrine hyperplasia may have preceded, occurred concurrently or even appeared after the hyperplastic polyps. Some glands may have contained linear neuroendocrine cell hyperplasia as a result of the atrophic gastritis, and the foveolar hyperplasia occurred as a secondary phenomenon. It may also be possible that the neuroendocrine cell hyperplasia or tumour stimulated the foveolar epithelium in a paracrine fashion.

This paper highlights the unusual coexistence of gastric hyperplastic polyps and neuroendocrine cell hyperplasia together with an underlying neuroendocrine tumour within the hyperplastic glands of the polyp. Surrounding mucosa that was not hyperplastic did not show as prominent neuroendocrine cell proliferation as within the hyperplastic mucosa. Although it is unclear precisely how these two pathologies are pathogenetically linked, it is likely that gastric atrophy and hypergastrinaemia are important. The novel aspect of this report is the coexistence of the hyperplastic polyp, neuroendocrine hyperplasia and neuroendocrine tumour within the same lesion, a phenomenon that has not, to the best of our knowledge, been described before.

Conflict of interest We declare that we have no conflict of interest.

Abstract The recognition and removal of apoptotic inflammatory cells by tissue macrophages and non-professional phagocytes, in a process called efferocytosis, is required for resolution of inflammation and is actively anti-inflammatory. We have previously demonstrated phagocytosis of apoptotic neutrophils by tumor cells in human gastric carcinoma, but to date, there have been no studies investigating this process in chronic active *Helicobacter pylori* gastritis. Biopsy specimens from 28 subjects with or without *H. pylori* infection and active inflammation were examined and graded according to the updated Sydney system. Light microscopy, electron microscopy, and Terminal Deoxynucleotidyltransferase-Mediated UTP End Labeling staining were used to identify apoptosis. *H. pylori* infection was detected by histology and by molecular assay in 16 out of 28 cases. DNA from paraffin-embedded gastric biopsies was amplified using primers specific for cagA, for the cag "empty site" as well as for the s and m alleles of vacA. The more virulent cagA-positive strains were found in five out of nine patients with chronic active gastritis. The vacA s1/m1 and s2/m1 genotypes were more common in nine patients with chronic active gastritis, while the vacA s2/m2 genotype was more frequent in seven patients with chronic inactive gastritis. Apoptotic neutrophils were also detected within the cytoplasmic vacuoles of the foveolar cells of nine cases with chronic active gastritis. Transmission electron micrographs revealed further apoptotic neutrophils within spacious phagosomes of foveolar cells in a similar manner to those described in late-phase efferocytosis both in vivo and in vitro. These new observations expand the morphological spectrum of gastritis in patients infected with more virulent *H. pylori* strains, compatible with an anti-inflammatory role for the gastric epithelial cells in their removal of apoptotic neutrophils during active chronic gastritis.

Introduction

Helicobacter pylori colonizes the human stomach and establishes a long-term infection of the gastric mucosa [1]. The persistent colonization induces gastritis and is associated with the development of peptic ulcer disease, atrophic gastritis, and gastric cancer [2]. The pathobiology of *H. pylori* gastritis is peculiar in many aspects. *H. pylori* gastritis is characterized by severe, acute, and chronic inflammation, which might last for decades if not treated properly [2, 3]. Persistent active inflammation with neutrophil infiltration is exceptional in other organs or biological systems. Activated neutrophils generate reactive oxygen and nitrogen species, which are mutagenic and carcinogenic, therefore having serious biological implications [4].

Phagocytosis of apoptotic cells, also known as efferocytosis, is an essential feature of immune responses [5, 6]. Failure to do so will result in disintegration of the apoptotic cell via a process called secondary necrosis and subsequent uncontrolled leakage of the contents of dying cells, resulting

in a propagated inflammatory response [7]. While the macrophage and dendritic cells are considered to be the most important cells involved in apoptotic cell removal, including that of apoptotic neutrophils, many lines of evidence suggest an important role for non-professional "neighboring" cells with phagocytic capacity (such as epithelial cells, endothelial cells, and fibroblasts) [7–10].

Although neutrophils are well known to play an important role in *H. pylori* gastritis, of which their presence marks the activity and severity, few data are available regarding the clearance mechanism of apoptotic neutrophils in *H. pylori* gastritis.

In the present study, using Terminal Deoxynucleotidyltransferase-Mediated UTP End Labeling (TUNEL) assay and electron microscopy, we showed intrafoveolar apoptotic neutrophils in *H. pylori* chronic active gastritis. These results are discussed in relation to recent studies on efferocytosis, in vivo and in vivo.

Subjects and methods

Study subjects and sampling

Twenty-eight patients scheduled for upper endoscopy were enrolled prospectively from the Department of Internal Medicine between December 2006 and February 2007 at the University Hospital of Messina. The study protocol was approved by the ethics committee of the University Hospital of Messina (Messina, Italy). None of the subjects had taken any antibiotics, proton-pump inhibitors, H2 antagonists, non-steroidal anti-inflammatory drugs, or corticosteroids 2 months prior to this study. After obtaining a written informed consent, upper endoscopy was performed, and endoscopic findings were recorded. The protocol included the collection of six biopsy specimens (four for diagnosis and two for electron microscopy) from the gastric antrum and corpus.

For light microscopy, four biopsy specimens were fixed in 10 % buffered formalin and embedded in paraffin. We graded the histopathological findings of gastritis (glandular atrophy, intestinal metaplasia, mononuclear cells, neutrophils, *H. pylori* density) on a scale of 0 (normal), 1 (mild), 2 (moderate), and 3 (marked) using the visual analog scale of the updated Sydney system [3]. All cases were histologically examined by two of the authors (RAC and FF). If their opinions differed, the specimens were jointly reconsidered until a consensus was reached.

TUNEL assay

TUNEL assay was conducted by using a TUNEL detection kit according to the manufacturer's instruction (Apotag, HRP kit DBA, Milan, Italy). Briefly, sections were incubated with 15 μg/ml proteinase K for 15 min at room temperature and then washed with PBS. Endogenous peroxidase was inactivated by 3 % H2O2 for 5 min at room temperature and then washed with PBS. Sections were immersed in terminal deoxynucleotidyltransferase (TdT) buffer containing deoxynucleotidyl transferase and biotinylated dUTP in TdT buffer, incubated in a humid atmosphere at 37 °C for 90 min, and then washed with PBS. The sections were incubated at room temperature for 30 min with anti-horseradish peroxidase-conjugated antibody, and the signals were visualized with diaminobenzidine. Sections of human tonsil and human small intestine, as well as a control tissue provided with the ApoTag kit, were the positive controls.

Genomic DNA extraction from paraffin-embedded gastric biopsies

DNA was extracted from formalin-fixed, paraffin-embedded tissue blocks. Sections of a total of 30–60 μm thickness were deparaffinized with xylene as previously described [11]. Then, total DNA was extracted using the QIAamp Tissue kit (Qiagen, Hilden, Germany) with standard protocols.

PCR amplification

PCR was performed to detect the cagA and cag empty site, and the signal sequence (s1 and s2) and middle region (m1 and m2) alleles of the vacA gene, as previously described [12] using the primers listed in Table 1 and the following conditions: 30 cycles of 94 °C for 1 min, 55 °C for 1 min, and 72 °C for 1 min. The amplified genes were analyzed by electrophoresis in a 2 % gel with ethidium bromide.

Electron microscopy

For electron microscopy, two biopsies (one from the gastric antrum and one from the corpus) were immediately fixed in 3 % phosphate-buffered glutaraldeyde pH 7.4 and post-fixed in 1 % osmium tetroxide. Semi-thin araldite-embedded sections were stained with toluidine blue for selection of fields. For

electron microscopy, ultrathin sections were double-stained with uranyl acetate and lead citrate; they were then examined and photographed in a Zeiss EM 902 electron microscope.

Statistical analyses

To examine the relationship between *H. pylori* genotypes and gastritis activity, Fisher's exact test was performed owing to the small sample size in some groups. A p value <0.05 was considered statistically significant.

Results

H. pylori colonization and histopathological diagnosis

Of the 28 patients with gastric symptoms, 16 were positive for *H. pylori*, detected by histology as well as by PCR. Seven out of 16 positive cases revealed chronic gastritis without activity, characterized by mononuclear cell infiltration consisting of various amounts of lymphocytes, plasma cells, mast cells, and macrophages in the lamina propria but without the presence of neutrophils. Nine out of the 16 positive cases revealed active gastritis. In these cases, mucosal biopsies revealed a regenerative epithelium, with neutrophil infiltration of the lamina propria around non-colonized renewal zone epithelium of gland necks or beneath infected epithelium (Fig. 1). Neutrophils were also found inside the epithelium and formed small collections (microabscesses) in the lumen of the foveolae. Some intraepithelial neutrophils exhibited apoptotic changes such as chromatin condensation and cell shrinkage (Fig. 2) and were TUNEL positive (Fig. 3). One to three apoptotic neutrophils were found within the cytoplasmic vacuole of a foveolar cell (Fig. 2). This phenomenon was particularly extensive in four out of nine cases (Figs. 2 and 3) and was accompanied by cytoplasmic mucin depletion, nuclear pseudostratification, and occasional mitoses (Fig. 2). Of the nine patients with chronic active gastritis, five harbored cagA-positive strains (Table 2). *H. pylori* strains belonged to the vacAs1/m1 genotype in seven cases and vacAs1/m2 genotype in two cases (Table 2). The vacA s1/m1 and s2/m1 genotypes were significantly more common in nine patients with chronic active gastritis, while the vacAs2/m2 genotype was more frequent in seven patients with chronic inactive gastritis (Table 3).

Twelve patients with non-ulcer dyspepsia showed histologic normal mucosa and were not infected with *H. pylori*.

2	Negative	s1/m1
3	Positive	s1/m1
4	Negative	s1/m1
5	Positive	s1/m1
6	Positive	s1/m1
7	Positive	s1/m1
8	Negative	s2/m1
9	Negative	s2/m1

No granulocytes and only sparse mononuclear cells (mostly lymphocytes and macrophages) were observed in the lamina propria by both light and electron microscopies, while virtually no imononuclear cells were detected inside the epithelium apart from occasional lymphocytes.

Electron microscopy

By electron microscopy, interepithelial neutrophils exhibited the characteristic equipment of discrete primary and secondary granules, glycogen, and lipid bodies. Other neutrophils were present within spacious phagosomes of epithelial cells and showed apoptotic changes. Ultrastructural signs of early apoptotic changes included nuclear chromatin separation into dense and electron-lucent areas, rounded nuclear profiles, preservation of cytoplasmic granules, and maintenance of cell membrane integrity (Fig. 4). Late apoptotic morphology was characterized by cell shrinkage, tightly packed cytoplasmic granules, and uniform collapsed nucleus (Fig. 5). Several cytoplasmic organelles including lysosomes were found in the vicinity of phagosomes (Fig. 5).

Discussion

Our histologic data show apoptotic neutrophils within cytoplasmic vacuoles of foveolar cells in chronic active *H. pylori* gastritis. To investigate neutrophil apoptosis, we chose three independent techniques: light microscopy with H & E staining, TUNEL staining, and electron microscopy. At the light microscopic level, apoptotic cells may be recognized by their typical condensed chromatin and reduced cell volume [13]. Electron microscopy is still considered the "gold standard" for the identification of apoptotic cells [14]. Moreover, the inter- or intraepithelial localization of neutrophils is easily recognized by electron microscopy, whereas this recognition is difficult by light microscopy. At the electron

microscopy level, neutrophils showed tightly packed cytoplasmic granules, condensed nuclear chromatin, and, especially, uniform and collapsed nucleus, which has been outlined as the defining morphological feature of an apoptotic cell [14]. Furthermore, the tissue specimens in our study were put into formalin or glutaraldehyde for fixation immediately after endoscopic biopsy so that no accumulation of apoptotic cells after removal from the organism was possible. Several molecular approaches have been devised for detection of apoptotic neutrophils in tissues. The TUNEL technique, which is based on enzymatic incorporation of labeled nucleotides at sites where DNA fragmentation has occurred, is commonly used [14]. However, the TUNEL staining is not specific to apoptotic cells (e.g., necrotic cells also exhibit DNA fragmentation) [14]. Hence, in this study, our ultrastructural analysis served as complement to, as well as validation of, the TUNEL technique.

Emperipolesis has been defined as a random passage of different types of cells through the cytoplasm of another cell without any important change on either the host or invading cells [15]. It differs from phagocytosis in that an engulfed cell only temporarily exists within another cell [16]. We rule out the possibility that the presence of neutrophils within foveolar cell is merely due to emperipolesis, because these neutrophils were apoptotic, as revealed by electron microscopy and TUNEL assay.

The pattern of apoptotic neutrophils within vacuoles of foveolar cells most closely resembles that seen in efferocytosis: a dynamic process characterized by phagocytosis of apoptotic cells [5, 6, 17, 18]. Our ultrastructural data, such as spacious phagosomes containing apoptotic neutrophils and concentration of lysosomes around the phagosomes, are also morphologic hallmarks of late-phase efferocytosis described in vivo and in vitro [18].

In our previous studies, we also showed apoptotic neutrophil phagocytosis by tumor cells in human gastric carcinomas [19]. Taken together, our results confirm and extend earlier findings demonstrating intraepithelial apoptotic neutrophils, likely due to efferocytosis, not only in foveolar epithelium in chronic active *H. pylori* gastritis, but also in neoplastic epithelial cells of human gastric carcinomas.

Our data, resulting from *H. pylori* genotype analyses from paraffin-embedded biopsies, showed a significative association between neutrophil activity and more virulent *H. pylori* strains such as cagA-positive as well as vacAs1/m1 and vacAs2/m1 strains. These distinct *H. pylori* genotypes were also associated with the neutrophil efferocytosis phenomenon.

There are conflicting data both in vitro and in vivo regarding the mechanisms leading to the induction of neutrophil apoptosis by *H. pylori*. Neutrophils are constitutively programmed to undergo apoptosis, and such a process limits their pro-inflammatory potential and leads to rapid and non-phlogistic recognition by macrophages [8]. The possibility that *H. pylori* increases the lifespan of neutrophils, by preventing the natural occurring apoptosis, thus causing the prolongation of the phlogistic process, has been recently suggested [20, 21]. However, there are a few studies regarding the clearance mechanism of apoptotic neutrophils in *H. pylori* gastritis. Therefore, the exact mechanisms involved in mediating neutrophil efferocytosis by foveolar cells observed in vivo during infection with more virulent *H. pylori* strains remain not well determined to date. Our findings, however, suggest that foveolar epithelium might be an active participant in the removal of apoptotic neutrophils and therefore plays an important role in the modulation of neutrophil inflammation in patients infected with more virulent *H. pylori* strains.

One of the hallmarks of chronic active gastritis caused by *H. pylori* infection is the infiltration of neutrophils into the gastric mucosa [22]. However, other infections and inflammatory conditions (e.g., syphilis and Crohn's disease, reactive gastropathy with focal activity) may be responsible for the presence of neutrophils in gastric mucosa [22]. A complete understanding of neutrophil efferocytosis phenomenon by gastric foveolar cells will require further studies to assess its specificity among the different forms of gastritis.

In summary, through the use of light and electron microscopies and TUNEL staining, the present study provides evidence of intrafoveolar apoptotic neutrophils in chronic active *H. pylori* gastritis. These findings are compatible with a late phase of neutrophil efferocytosis by foveolar cells and suggest a role in the removal of apoptotic neutrophils during active gastritis caused by more virulent *H. pylori* strains. Further studies will be required to fully evaluate the clinical significance of our findings and to determine the specificity of this morphologic change.

Conflict of interest statement The authors declare that they have no conflict of interest.

Abstract For several years, the lack of consensus on definition, nomenclature, natural history, and biology of serrated polyps (SPs) of the colon has created considerable confusion among pathologists. According to the latest WHO classification, the family of SPs comprises hyperplastic polyps (HPs), sessile serrated adenomas/polyps (SSA/Ps), and traditional serrated adenomas (TSAs). The term SSA/P with dysplasia has replaced the category of mixed hyperplastic/adenomatous polyps (MPs). The present study aimed to evaluate the reproducibility of the diagnosis of SPs based

on currently available diagnostic criteria and interactive consensus development. In an initial round, H&E slides of 70 cases of SPs were circulated among participating pathologists across Europe. This round was followed by a consensus discussion on diagnostic criteria. A second round was performed on the same 70 cases using the revised criteria and definitions according to the recent WHO classification. Data were evaluated for inter-observer agreement using Kappa statistics. In the initial round, for the total of 70 cases, a fair overall kappa value of 0.318 was reached, while in the second round overall kappa value improved to moderate (kappa=0.557; $p<0.001$). Overall kappa values for each diagnostic category also significantly improved in the final round, reaching 0.977 for HP, 0.912 for SSA/P, and 0.845 for TSA ($p<0.001$). The diagnostic reproducibility of SPs improves when strictly defined, standardized diagnostic criteria adopted by consensus are applied.

Keywords Serrated polyp · Diagnosis · Criteria · Kappa statistics

Introduction

The term "serrated polyp" is used as a generic name for polyps demonstrating saw tooth-like infolding of the surface and crypt epithelium. The family of serrated polyps (SPs) comprises hyperplastic polyps (HPs), sessile serrated adenomas/polyps (SSA/Ps), and traditional serrated adenomas (TSAs) according to the latest WHO classification [1], in which the term "SSA/P with dysplasia" is preferred instead of the category of mixed hyperplastic/adenomatous polyps (MPs) [2]. The most common members of the SP family, HPs, comprise 80–90 % of all serrated polyps and are found throughout the colon and rectum, yet with distal predominance. Histologically, HPs are characterized by simple elongated crypt architecture and narrow crypt bases resembling normal mucosa, with proliferative activity confined to the basal third of the crypts [1, 3–6]. SSA/Ps, on the other hand, account for 8–20 % of serrated polyps with a predilection for the right colon. Their diagnosis is based mainly on crypt architectural features including serration, dilatation, horizontal orientation, L-shape or inverted T-form at the base of the crypts [1, 3–9], which furthermore show an asymmetrical proliferation zone and goblet cell or gastric foveolar cell differentiation [10]. The rarest type of SPs, TSA, has a protuberant growth pattern with a complex villiform configuration and premature crypt formation, defined as "ectopic crypt" [1, 5, 9, 11].

Lack of consensus in pathological diagnosis and classification in the past two decades resulted in publications in which polyps with almost identical morphology were reported with different diagnostic terms [12–15]. Hence, the molecular data that were created on the "serrated neoplasia" pathway have been rather inconsistent [16–21]. An accurate diagnosis of SPs is, therefore, crucial for a better understanding of the biology of the different entities, their specific molecular characteristics, and a better definition of the risk for malignant neoplasia that they incur. Only when this has been clarified can accurate risk assessment and adequate surveillance approaches be adopted. In daily practice, reproducibility of histopathological lesions in the serrated polyp family has been perceived as less than optimal [22–30]. We therefore designed a European study aiming to find answers to the following questions:

1. How reproducible are the diagnoses of serrated polyps?
2. What is the impact of a standardized classification (i.e., WHO classification) on diagnostic reproducibility?
3. Which criteria are used for diagnosis, how reproducible are they, and what is their discriminative value?

Materials and methods

Twenty European pathologists, all members of the Digestive Diseases Working Group of European Society of Pathology and all with special interest and experience in gastrointestinal pathology, were invited to participate in the study. Cases diagnosed as SPs (28 HPs, 25 SSA/Ps, 11 TSAs, and six MPs) in the original sign-outs were retrieved from the pathology archives of Ankara, Graz, and Warsaw. None of the features as size, location, or biopsy orientation was

considered in the selection of cases in order to simulate a real-life experience for participating pathologists. Thus, the cases comprised a mixture of polyps with characteristic features and those with features hampering an ambiguous diagnosis. The aim was to assess the histological criteria and classification without any supportive information to avoid bias in morphological assessment. Consequently, the original sign-out diagnoses, size, and location of the polyps were not provided on the worksheet.

We used the definitions and diagnostic criteria available in the literature by 2008 [3–9] when the study was initiated, prior to the last edition of the WHO blue book [1]. Thus, diagnostic categories comprised of HP, SSA/P, TSA, and MP when a final diagnosis could be made, while a category of unclassified polyp (UCP) was used for a case for which a participant could not make a final diagnosis, e.g., due to inadequate sampling or poor orientation [31, 32]. Diagnostic categories are presented in Fig. 1. The participants were requested to provide a diagnosis and to indicate which of the nine categories of diagnostic criteria, comprising epithelial serration (surface/upper crypt/lower crypt), crypt dilatation (upper/lower crypt), crypt architectural changes (horizontal crypts, crypt branching, inverted crypts), mitotic activity (upper/lower crypt), mature goblet cell distribution (upper/lower crypt), gastric epithelium (lower crypt), nuclear features (hyperchromasia, elongation, pseudostratification, vesicular nucleus, prominent nucleolus), cytoplasmic eosinophilia, and dysplasia (low/high grade), were present in the lesion. The final diagnosis (HP, SSA/P, TSA, MP, or UCP) was determined according to the diagnoses made by the majority of participants for each case.

The study was designed to allow an assessment of diagnostic reproducibility before and after introduction of the latest WHO classification [1]. The initial round of observations included 20 pathologists and a total of 70 cases. To initiate this process, the group first evaluated 15 cases of SPs retrieved from the files of the Department of Pathology, Ankara University Medical School, including round table discussions based on the initial observations and focusing on diagnostic criteria and terminology in order to establish a common language and a standardized diagnostic approach. A further 55 cases were then provided by three centers (Ankara, Graz, and Warsaw) to allow in-depth analysis of reproducibility and diagnostic criteria on a total of 70 cases, permitting reliable Kappa analysis. Subsequent to the publication of the 4th edition of WHO Classification of Tumors of the Digestive System [1], the same group (four members could not participate, leaving a total of 16 assessors) reassessed the 70 case series using the WHO diagnostic categories and proposed criteria, which constituted the second round. The worksheets for the second round contained the initial diagnostic categories of HP, SSA/P, TSA, and MP in order to allow comparisons between the two rounds, but the participants were informed that the category of MP in their previous assessment corresponded to the new category of SSA/P with dysplasia, in line with the WHO classification. The participants were requested to diagnose such cases as SSA/P with dysplasia, including a qualification of the

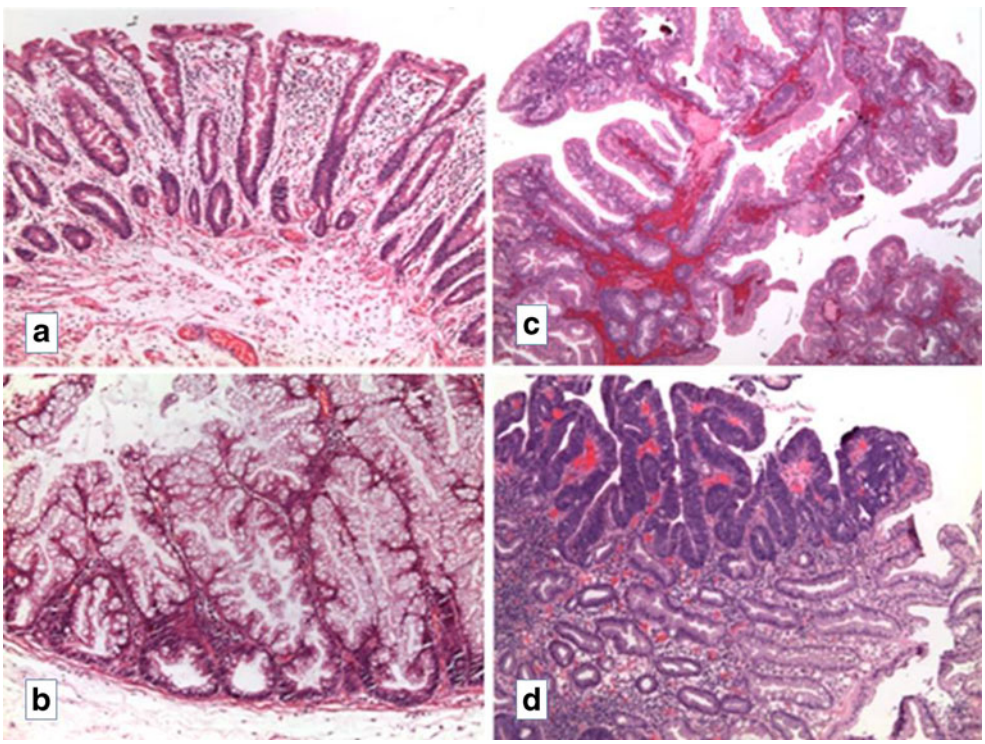

Fig. 1 SP categories including **a** HP (H&E, ×200), **b** SSA/P (H&E, ×200), **c** TSA (H&E, ×100), and **d** MP (H&E, ×100)

degree of dysplasia (low or high grade). Dysplasia was not further classified as adenomatous or serrated, although nuclear features comprising hyperchromasia, elongation, and pseudostratification are considered as diagnostic for "adenomatous" dysplasia, while vesicular nucleus, prominent nucleolus, and cytoplasmic eosinophilia are indicative of "serrated" dysplasia according to the WHO [1].

To define the most reproducible and discriminative criteria for each diagnostic category of SPs, all participants registered on the excel sheets as to which of the predefined diagnostic criteria they regarded as the most relevant.

Statistical analysis

Kappa statistics was performed in the Department of Biostatistics, Ankara University Medical School, by the same biostatistician (NK) for each round using SPSS for Windows 15.0 for paired (between two observers) and overall (group) inter-observer agreement and for intra-observer agreement. Comparisons between the initial and the second round were assessed using the Wilcoxon signed ranks tests. Analysis of the criteria was performed using chi-square tests and by means of proportions of positive judgements method for agreement levels [33]. Kappa values were grouped as poor (<0.2), fair (0.21–0.40), moderate (0.41–0.60), good (0.61–0.80), and perfect (>0.80). A p value less than 0.05 was considered as significant.

Results

Initial round: how reproducible are the diagnoses of SPs?

In the initial round, 44 % (n=31) of the 70 cases were diagnosed as HP, 40 % (n=28) as SSA/P, 10 % (n=7) as TSA, and 6 % (n=4) as MP by the majority of the observers.

The overall kappa value for the first 15 cases was poor with a kappa value of 0.202 (CI lower 0.147–CI upper 0.256; p<0.001), while overall kappa values for each diagnostic category were 0.315 for HP, 0.223 for SSA/P, 0.181 for TSA (p<0.001), and 0.107 for MP (p>0.05).

Following consensus discussions, on the additional 55 cases a fair inter-observer agreement was achieved with an overall kappa value of 0.349 (CI lower 0.320–CI upper 0.377; p<0.001). Kappa values for each diagnostic category were 0.443 for HP, 0.323 for SSA/P, 0.512 for TSA (p< 0.001), and 0.235 for MP (p=0.01), respectively.

Finally, on the full 70-case set, a fair overall kappa of 0.318 (CI lower 0.293–CI upper 0.343; p<0.001) was reached; also, for each diagnostic category, kappa values were fair, reaching to 0.415 for HP, 0.301 for SSA/P, 0.433 for TSA (p<0.001), and 0.221 for MP (p=0.01).

Second round: the impact of WHO classification on reproducibility

In the second round, a re-evaluation of all 70 cases was performed by 16 of the initial 20 participants using WHO criteria. A diagnosis of HP was made on 43 % (n=30), SSA/P on 46 % (n=32), TSA in 10 % (n=7), and MP on 1 % (n=1) of the cases. One HP was diagnosed as SSA/P and three MPs as SSA/P with dysplasia, while the diagnoses of 30 HPs, 28 SSA/Ps, seven TSAs, and one MP remained unchanged (Fig. 1d). No case was classified as UCP by the majority in either round, but 49 % (n=33) of the cases received this diagnosis from between one to three observers.

Overall kappa value was moderate (kappa=0.557; CI lower 0.532–CI upper 0.612, p<0.001), while kappa values were significantly higher than the previous observations for each diagnostic category: 0.977 for HP, 0.912 for SSA/P, 0.845 for TSA, and 0.158 for MP (p<0.001). Paired and overall agreements for all rounds and diagnostic categories are summarized in Table 1.

Intra-observer agreement for each diagnostic category was evaluated with respect to the initial and final rounds of assessments made by each of the 16 observers for the total of 70 cases. Kappa values ranged between 0.013 and 1.00 (Table 2). The overall agreement between the initial and second round of diagnoses for all cases was 0.79 (p< 0.0001), while the kappa value was 0.855 for HP, 0.767 for SSA/P, 0.841 for TSA, and 0.386 for MP (p<0.001). Kappa analysis was not performed for UCP as this cannot be considered as a diagnostic category. Examples of cases which were renamed after the final round are presented in Fig. 2.

How reproducible and discriminative are the histologic criteria?

Firstly, the analysis of histological criteria revealed perfect and near-perfect agreement on epithelial serration in the upper crypts (kappa=0.97), serration of the surface epithelium (kappa=0.83), mitosis in the lower crypts (kappa= 0.79), goblet cells in the upper crypts (kappa=0.77), and dilatation of upper crypts (kappa=0.72) in contrast to crypt architectural features, which yielded fair to moderate agreement and to nuclear features that resulted in only fair agreement between the observers (Table 3).

Secondly, the association of the criteria to each diagnostic category was analyzed by recording the frequencies of the criteria selected by the observers for each diagnostic category in every case using proportions of positive judgements method [33]. The presence of dilatation, mature goblet cells in upper crypts (p=0.01), and epithelial serration (p<0.05) were significantly associated with a diagnosis of HP, while epithelial serration, crypt dilatation, presence of mature

Table 1 Paired and overall agreement for all cases and for each diagnostic category

	All cases	HP	SSA	TSA	MP
Initial round (total, n=70)					
Overall kappa	0.318	0.415	0.301	0.433	0.221
Paired kappa (min–max)	0.03–0.93	0.08–0.75	0.05–0.82	0.09–0.93	0.03–0.88
p value	<0.001	<0.001	<0.001	<0. 001	0.014
Second round (total, n=70)					
Overall kappa	0.557	0.977	0.912	0.845	0.158
Paired kappa (min–max)	0.09–1.00	0.11–1.00	0.09–1.00	0.21–1.00	0.09–1.00
p value	<0.001	<0.001	<0.001	<0.001	0.014

goblet cells in lower crypts (p<0.001), crypt architectural changes (p<0.001), vesicular nucleus (p<0.001), and prominent nucleolus (p<0.01) were significantly associated with a diagnosis of SSA/P. TSA, on the other hand, was determined by the presence of epithelial serration in lower crypts (p< 0.001), mitotic activity in upper crypts (p<0.001), nuclear features of atypia (p<0.001), cytoplasmic eosinophilia (p< 0.001), presence of low-grade dysplasia (p<0.001), crypt branching (p<0.01), ectopic crypts (p<0.05), and gastric epithelium in lower crypts (p<0.05) (Table 4). Most discriminatory criteria for each diagnostic category are presented in Fig. 3. Low-grade dysplasia was diagnosed in 3.2 % of HP, 24.4 % of SSA/P, 81.3 % of TSA, 22.4 % of MP, and 27.3 % of UCP, while high-grade dysplasia was found in 2.2 % of SSA/P, 3.1 % of TSA, 22.5 % of MP, and 5.5 % of UCP. Among SSA/Ps with dysplasia, 69.8 % showed "serrated" dysplasia, while 30.2 % had "adenomatous" dysplasia as determined by the associated cytological features. Adenomatous dysplasia was more frequent in TSAs (59.7 %) in comparison to "serrated" dysplasia (40.3 %), similar to MPs of which 26.1 % had "adenomatous" and 17.96 % had "serrated" dysplasia.

Discussion

This study presents a European initiative aiming to improve the reproducibility of histological diagnoses of SPs. The poor overall inter-observer agreement for 15 cases studied initially led us to repeat the assessment after a consensus discussion on 70 cases, which improved the agreement from poor to fair, highlighting the significance of a standardized approach supported by a consensus discussion.

Introduction of the WHO classification through a second consensus meeting led to a further improvement in overall agreement for the whole group, and perfect agreement was achieved for the categories HP, SSA/P, and TSA.

Few studies [22–30] have addressed the question of reproducibility in the diagnosis of SPs (Table 5). Those that evaluated inter-observer agreement had a major drawback as they used the term "serrated adenoma" for all serrated polyps except HP, possibly due to the poorly defined criteria to distinguish SSA from TSA, available at time of publication [22, 24]. However, Farris et al. [23], in an approach similar to ours, evaluated the diagnostic concordance of five GI pathologists on 185 SPs comprising 92 HPs, 74 SSAs, and 19 TSAs. The observers were provided with a list of criteria for SSA and TSA in the first round, which revealed moderate overall agreement, while clinical information including size and localization of the polyps caused no change on the level of agreement in the second round. Following a consensus conference, the agreement was evaluated on a different but smaller series and revealed moderate agreement for HP and SSA and near-perfect agreement for TSA. Their

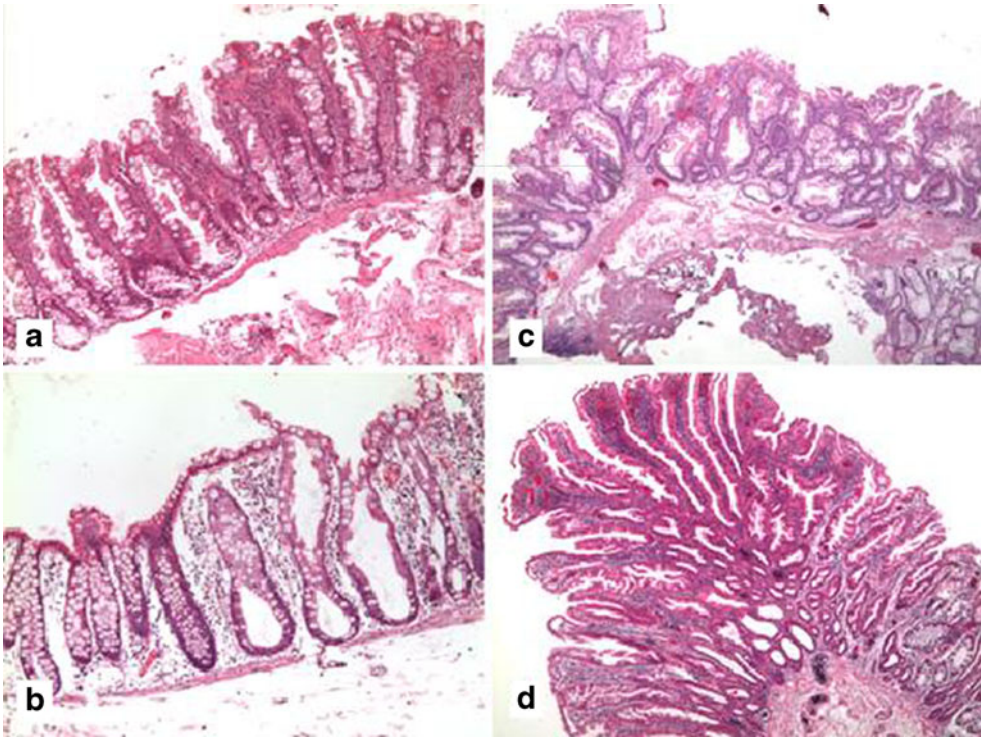

Fig. 2 Examples of cases which were renamed after the final round. **a** HP renamed as SSA/P (H&E, ×200), **b** HP renamed as SSA/P (H&E, ×200), **c** SSA/P renamed as TSA (H&E, ×100), **d** MP renamed as SSA/P with dysplasia (H&E, ×100)

study design is similar to ours with respect to the consecutive rounds of evaluation followed by consensus discussions to achieve the best possible agreement between the observers. In contrast to our study, they did not evaluate the reproducibility of the diagnostic criteria.

Table 3 Agreement of observers for diagnostic criteria

Diagnostic criteria	Kappa value
Epithelial serration in upper crypts	0.9661

Mitosis in upper crypts	0.2533
Ectopic crypts	0.2104
Gastric epithelium in lower crypts	0.2044
Inverted crypts	0.1745
Dysplasia—high grade	0.0405

Our study was conducted in a blind fashion regarding the size and localization of the polyps in order to analyze the morphological criteria in a more stringent way, devoid of any bias. It is, on the other hand, generally accepted that diagnosis of polyps with intermediate features that lie on a continuum between HP and SSA/P may require clinical information, and for such polyps, pathologists may be more inclined to make a diagnosis of SSA/P when the polyp is large and localized in the right colon. However, additional clinical information failed to have any effect on the diagnostic accuracy of the observers in two previous studies [23, 27]. We believe that the histopathological diagnosis of a polyp should not depend upon the size or the localization of the lesion. However, for unclassified non-dysplastic serrated polyps with intermediate features or in case of sampling error, pathologists need to know the size and localization of the lesion before making a diagnosis. Although a diagnosis of serrated polyp "unclassified" is recommended by WHO [1], improvement in our diagnostic skills together with the use of standardized criteria will help to better classify such borderline cases and avoid unnecessary utilization of the unclassified category.

The third issue that was raised by the initiative was to define the most reproducible and discriminative criteria for each type of serrated polyp. Although many publications utilize similar criteria in the diagnosis of SPs, there are considerable variations in histologic features as well as

Table 4 Diagnostic criteria discriminative for each SP category

Criteria	HP (%)	SSA/P (%)	TSA (%)	MP (%)

definitions and terminology in many others, particularly for SSA/P [4, 10, 18]. The first approach of standardization came from Bariol et al. [22], who evaluated the diagnostic utility of histologic criteria attributed to serrated adenomas in a series of cases including hyperplastic polyps, serrated adenomas, admixed polyps, and conventional adenomas. In their study, surface epithelial dysplasia, surface epithelial tufting, increased surface mitosis, and epithelial serration in more than 20–50 % of crypts were the criteria with the highest kappa values for the diagnosis of serrated adenoma. They did not, however, assess how consistently different observers could distinguish serrated adenoma from other polyps, nor did they further classify their cases as sessile and traditional serrated adenomas.

In a more recent attempt to distinguish HP from SSA, Sandmeier and colleagues [27] assessed 102 SPs and tested the reproducibility of Snover's criteria [5]. They, too, blinded the observers to the clinical information in order to avoid any bias in the histopathological interpretation. As in our study, they found architectural changes together with the various cell types including goblet cells, undifferentiated cells, and gastric foveolar cells in basal crypts to be the most useful criteria to distinguish SSA from HP. Also, Farris et al. [23] concluded that architectural rather than cytological features are most helpful in distinguishing SSA from HP, whereas cytological features like nuclear elongation and stratification are more useful in distinguishing TSA from other serrated lesions. Of the WHO criteria, the most discriminatory for HP were serration, dilatation, and presence of mature goblet cells in the upper crypts, whereas the presence of these features in the lower crypt zone was significantly consistent with a diagnosis of SSA/P together with the architectural features, such as horizontal crypts and crypt branching, and nuclear features, including vesicular nucleus and prominent nucleolus. TSA, on the other hand, was associated with ectopic crypts and crypt branching as well as nuclear features comprising hyperchromasia, elongation, pseudostratification, and cytoplasmic eosinophilia. These findings confirm that architectural rather than cytologic features are diagnostically useful and also that nuclear features are more reproducible than architectural criteria.

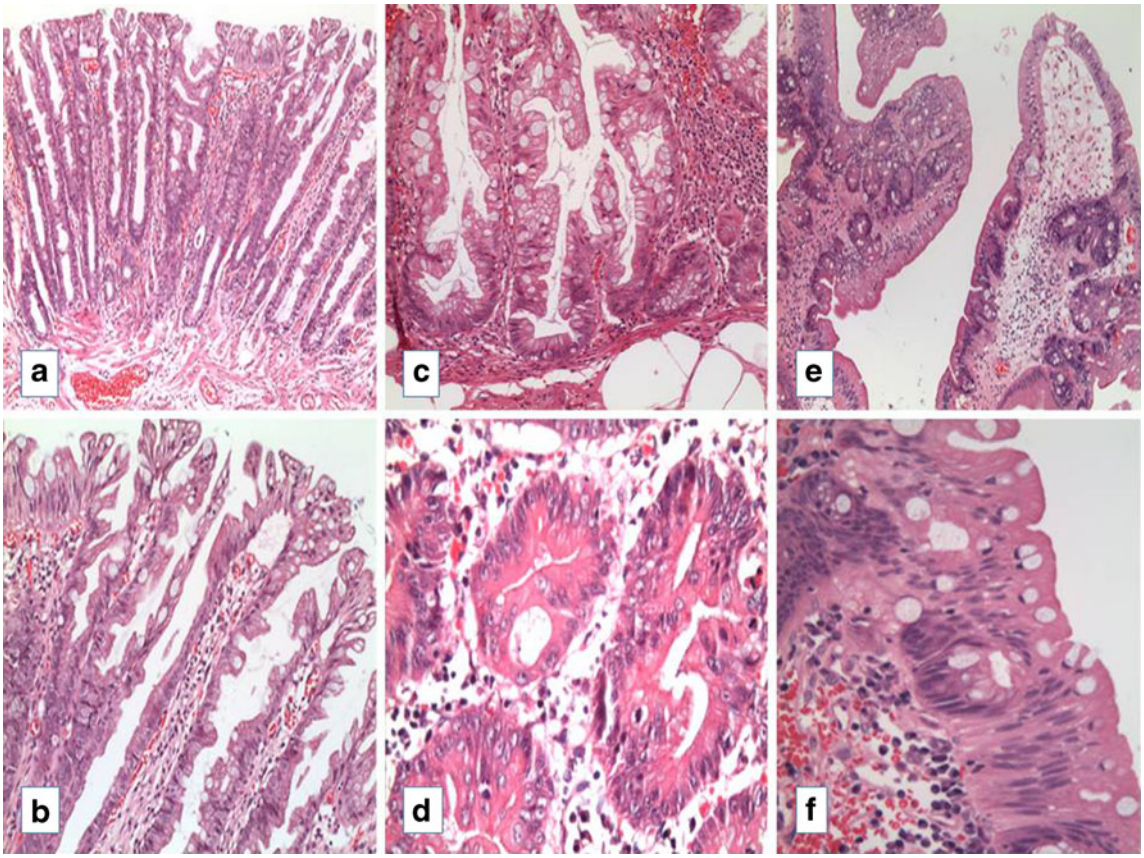

Fig. 3 Most discriminatory criteria for each diagnostic category. **a**, **b** Serration, dilatation, and mature goblet cells in upper crypts in HP (H&E, ×100 and×200, respectively). **c**, **d** Serration, dilatation, horizontal shape in lower crypts and vesicular nuclei with nucleoli in SSA/P (H&E, ×200 and×400, respectively). **e**, **f** Ectopic crypts, cytoplasmic eosinophilia, pseudostratification, nuclear elongation and hyperchromasia in TSA (H&E, ×100 and×400, respectively)

On similar grounds, the Working Group on Gastrointestinal Pathology of the German Society of Pathology [34] proposed that the SSA/P architectural features should be present in at least two different crypts, not necessarily adjacent, although the new WHO definition of SSA/P requires two or three contiguous crypts with these features [1]. There is no evidence base for either view, but it is safe to postulate that several crypts close together should be a

Table 5 Summary of publications on reproducibility of the diagnoses of SPs

Publication (reference number)	Cases	Results
Bariol et al. 2003 [22]	255 polyps (72 HPs, 9 SAs, 4 MPs, 170 conventional adenomas), 2 observers	Kappa for diagnostic criteria ranging from −0.029 to 0.852
Sandmeier et al. 2007 [27]	102 SPs (58 HPs, 7 SSAs, 5 TSAs, 3 MPs, 29 UCPs)	Criteria for HP vs. SSA, no kappa
Glatz et al. 2007 [26]	20 SPs (8HPs, 4 TSAs, 4 SSAs, 4 tubulovillous adenomas), 168 participants (Internet-based quiz)	High variation in SSA, no kappa
Farris et al. 2008 [23]	185 SPs (92 HPs, 74 SSAs, 19 TSAs), 5 observers	Kappa=0.55

minimal criterium, which was however not assessed in our study.

Two types of dysplasia have been observed in SSA/Ps: "adenomatous" dysplasia and "serrated" dysplasia, the latter characterized by round cells with eosinophilic cytoplasm, vesicular nuclei, and prominent nucleoli [1, 20, 35]. SSA/Ps with dysplasia were probably classified as "mixed polyps" in the past [2, 5, 6, 32, 36], a term used for lesions with distinct foci of adenomatous epithelium and hyperplastic/serrated architecture. WHO [1] recommends the term "SSA/P with dysplasia" in order to emphasize that the dysplastic part of the lesion never shows APC mutations as found in adenomatous epithelium but rather presents with MSI resulting from methylation of MLH-1. In our study, a small number of cases, almost half of which showed dysplastic foci, were diagnosed as MP in the first round, whereas a diagnosis of SSA/P with high-grade dysplasia was made for these cases in the second round. Surprisingly, however, there was one particular case which was persistently diagnosed as MP in both rounds by the majority of the participants who apparently felt that dysplastic SSA/P category does not always coincide with polyps showing truly and distinctly mixed features. For the latter ones, a category of MP would seem legitimate.

In the present study, although dysplasia was graded as low and high without further classification into adenomatous or serrated types, the histological criteria used in the study already comprised features of serrated dysplasia such as vesicular nuclei, prominent nucleoli, and eosinophilic cytoplasm, as well as features of adenomatous dysplasia characterized by pseudostratification, nuclear byperchromasia, and elongation [1]. An evaluation of these criteria demonstrated that the majority of SSA/Ps possessed features of "serrated" dysplasia. Although their original description involves dysplastic epithelium, TSAs lack mitotic activity in the tall columnar epithelial cells with pencillate nuclei and eosinophilic cytoplasm and are therefore not truly dysplastic in the sense of tubular or villous adenomas [1]. The high rate of low-grade dysplasia in the TSA group suggests that the epithelial lining of TSAs was misinterpreted as low-grade dysplastic by the majority of the observers due to its resemblance to adenomatous epithelium. The low-grade dysplasia observed in a small percentage of HPs seems to correspond with a mucin-poor variant of HP presenting with regenerative epithelium that can be misinterpreted as dysplasia.

In conclusion, the results of the study show that consensus discussions on a sufficiently large SP collection improve inter-observer agreement, which was further improved when the new WHO classification was introduced. Furthermore, architectural criteria appear as most reliable for an accurate diagnosis of a SP. However, even when a consensus classification such as that provided by the WHO is applied, the reproducibility of the histopathological diagnosis on a SP remains imperfect.

Conflict of interest The authors declare that they have no conflict of interest.

Abstract Endobronchial ultrasound-guided transbronchial needle aspiration has demonstrated its accuracy in the diagnostic workup of enlarged mediastinal lymph nodes. In addition to conventional smears, the use of liquid-based cytology (LBC) and cell block preparations (CBP) has been introduced more recently. The aim of our study was to determine the performance of each of the different techniques, separately and combined, in terms of diagnostic yield and sensitivity. A total of 290 consecutive patients were included. The pathological examination was based on smear cytology, LBC, and CBP. Adequate sampling was defined by the presence of pathological material or lymphocytes. The global diagnostic yield was 82.7 % and the sensitivity was 89.1 %. The diagnostic yield was 72.8 % for smears, 78.8 % for LBC, and 69.9 % for CBP. The combination of smears with CBP significantly increased diagnostic yield (p=0.01) and sensitivity (p=0.006), but not the combination of smears with LBC (yield: p=0.07; sensitivity: p=0.13). The combination of the three techniques further increased yield (p=0.007) and sensitivity (p=0.006), compared with smears alone. CBP were more sensitive than smears for both diagnoses of carcinoma (p=0.01) and granulomatous inflammation (p=0.048). Conversely, LBC was less sensitive than smears for granulomatous inflammation (p=0.004), but the difference was not significant for carcinoma (p=0.42). CBP, as a complement to smears, increases diagnostic yield and sensitivity for both diagnoses of carcinoma and granulomatous inflammation. LBC, if used alone, increases the risk of a false-negative result.

Introduction

Lung cancer is the leading cause of cancer death in France with a 5-year survival rate of 15 %. Only 20 % of cases of lung cancers benefit from curative surgical treatment. Precise staging has great importance to decide the best therapeutic strategy. Mediastinoscopy [1] has been the gold standard for a long time in the diagnosis of enlarged mediastinal lymph nodes but explores a limited number of lymph node stations. More recently, endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) has demonstrated its usefulness in the diagnosis of benign

as well as malignant mediastinal or hilar lymph nodes and in lung cancer staging [2–6].

EBUS-TBNA is an accurate, minimally invasive, and cost-effective method for the diagnosis of mediastinal or hilar adenopathy and staging in lung cancer [7]. It has been shown to be equivalent to classical mediastinal biopsy [8], with a sensitivity ranging from 81 % to 98 % [7–9]. The specimens collected during EBUS-TBNA were classically limited to conventional smears, providing good inter-observer reproducibility [6]. Liquid-based cytology (LBC) was reported as a promising alternative to conventional cytology [10]. With the EBUS-TBNA method, small tissue cores can also be obtained. These fragments are paraffin-embedded and analyzed on cell block preparations (CBP). An efficient analysis can be carried out using this method, conserving histological architecture and allowing immunohistochemical and molecular analysis [10, 11].

We hypothesized that combining smears, LBC, and CBP would improve the sensitivity of EBUS-TBNA. The aim of this study was therefore to determine the performance of each of the different techniques (smears, LBC, and CBP), separately and combined, in terms of yield and sensitivity.

Methods

Patients

Between July 2009 and July 2011, 290 consecutive patients were included in the study at the Respiratory Department of the Medical University Hospital of Nancy (France). EBUS-TBNA was performed for the diagnosis of enlarged mediastinal nodes or for the staging of lung cancer in the presence of enlarged (by computed tomography, CT) and/or hypermetabolic (positron emission tomography/computed tomography, PET/CT) lymph node(s). The patients provided written consent after receipt of information about the benefits and the risks of this method (institutional review board approval: number DC2008-459, Comité de Protection des Personnes Est-III).

EBUS-TBNA and sampling

All exams were performed by the same operator (OM). Conventional flexible bronchoscopy was first performed. Then, EBUS was started using the Olympus BF UC160F-OL8. Each nodal station was located using ultrasound imaging. Lymph nodes with a short axis larger than 10 mm were sampled. Three punction biopsies were performed at each level with a dedicated 22-gauge needle. On-site adequacy assessment was not performed during EBUS-TBNA. Half of the aspirate was expelled onto glass smears. Alternatively, one slide was air-dried, and the following slide was immediately fixed with CytoRAL (RAL; Marcillac, France). For each aspirate, an average of eight smears was obtained. Smears were available for all patients. The residue of the needle content of each aspirate was expelled in CytoRich (Thermo Fisher Scientific; Waltham, USA), an ethanol-based fixative. This allowed performing LBC on 193 patients and cell blocks/CBP on 276 patients. At the end of EBUS-TBNA, bronchial aspirates were systematically collected for bacteriological analysis.

Sample analysis

Air-dried smears were stained with May–Grunwald–Giemsa (MGG), and fixed smears were stained with Harris–Shorr coloration (Harris hematoxylin, Oxoid, Basingstoke, UK; Shorr staining solution, Merck KGaA, Darmstadt, Germany). LBC was performed from a CytoRich-fixed material with an Autocyte automate (Tripath; Burlington, VT, USA). In the presence of tissue microfragments in CytoRich fixative, 5-μm paraffin-embedded tissue sections were processed from cell blocks and stained with hematoxylin and eosin. Grocott's methenamine silver stain and Ziehl–Neelsen stain were used in case of granulomatous inflammation. The cases were reviewed by two experienced pathologists (JMV, GG).

Statistical analysis

The diagnostic yield was defined by obtaining adequate material, consisting of either pathological material or a significant number of lymphocytes, indicating adequate sampling of a lymph node. The diagnostic yield was calculated for the whole series, considering each cytological and histological method, and each lymph node station.

Sensitivity and negative predictive value (NPV) were calculated, globally and for each technique. True positivity was defined by the assessment of a diagnosis with EBUS-TBNA; false negativity was defined by the absence of diagnosis during a contributive EBUS-TBNA (presence of lymphocytes), when a different diagnostic method resulted

in a diagnosis. True negativity was defined by the absence of a diagnosis and the absence of evolution within a 6-month clinical and radiological follow-up. The diagnosis was not verified by other methods in order to avoid unnecessary invasive exams; therefore, no false positive cases were identified, resulting in 100 % specificity and positive predictive value.

Statistical analysis was performed using R-project software, version 2.11.1 (R Development Core Team, http://www.R-project.org), using 95 % confidence interval (CI 95 %). Chi-square test was used for qualitative variables and Wilcoxon–Mann–Whitney test was used for quantitative variables. A p-value$\leq$0.05 was considered as statistically significant.

Results

Clinical data

A total of 290 patients were included in our study, corresponding to the sampling of 493 lymph node stations (1.7 stations for each EBUS-TBNA). The mean age was 61.6 years (20–89). The indications for performing an EBUS-TBNA were a suspicion of lung cancer with mediastinal or hilar metastatic lymph nodes (159 patients, 54.8 %), isolated enlarged mediastinal lymph nodes (126 patients, 43.4 %), and mediastinal tumors (four patients, 1.4 %). No data were available for one patient (0.3 %).

Global diagnostic yield and diagnoses

For the 240 patients examined, the analysis showed either pathological material (147 patients, 50.7 %) or normal lymphocytes (93 patients, 32 %), resulting in a diagnostic yield of 82.7 %. The average size of lymph nodes was 29.8 mm (min, 10 mm; max, 60 mm). The yield correlated positively with the size of lymph nodes (p=0.004).

EBUS-TBNA diagnosed carcinoma in 118 patients (40.8 %), comprising of small-cell lung carcinoma (SCLC; 9.7 %), non small-cell lung carcinoma not otherwise specified (7.6 %), adenocarcinoma (13.8 %), squamous cell carcinoma (9.7 %), lymphomas (0.7 %), granulomatous inflammation (9.0 %), and non-specific inflammatory tissue (0.3 %) (Fig. 1).

A significant number of lymphocytes were observed in the smears of 93 patients, confirming the successful sampling of lymph nodes, but without any pathological material. Follow-up was available for 63 of these 93 patients. Eighteen false-negative cases were identified, which were assessed by a second EBUS-TBNA in two cases, lobectomy with mediastinal lymph node dissection in five cases, mediastinal biopsy in four cases, computed tomography-guided biopsy in one case, three biopsies of other organs in three cases, two bacteriological samples in two cases, and biopsy during flexible bronchoscopy in one case. These 18 false-negative cases comprised of nine carcinomas, eight granulomatous inflammations, and one lymphoma. This resulted in a global sensitivity of 89.1 % and a negative predictive value of 71.4 %. In these false-negative cases, EBUS-TBNA provided only lymphocyte-containing cytological samples (smears and/or LBC) in six cases, only CBP in one case, and both cytological samples and CBP in 11 cases.

In the 50 remaining cases, neither pathological material nor lymphocytes were found, with only blood and/or bronchial cells, indicating the failure of lymph node sampling.

Lymph node stations

The yield sorted by lymph node station was 76.3 % (95 % CI, 72.3–80.0). Of the 172 punction biopsies, seven were performed at the subcarinal station, 94 at the 4R station, 41 at the 4L station, and 41 at the 10R station (Table 1).

Comparison of the technical methods

Smears were performed in all cases, LBC in 193 cases, and CBP in 276 cases. The yield sorted by cytological or histological methods was as follows: 72.8 % (95 % CI, 77.5–86.7) for smears, 78.8 % (95 % CI, 72.3–84.3) for LBC, and 69.9 % (95 % CI, 64.1–75.3) for CBP (Table 2). The combination of the three techniques significantly increased the yield compared to smears or CBP alone (p=0.007 and p=0.0007, respectively). In addition to smears, the use of CBP significantly increased the yield (p=0.01), but not the use of LBC (p=0.07).

Tables 3 and 4 show the comparison of sensitivity and negative predictive value between smears, LBC, and CBP and for each diagnostic category. The combination of the three types of samples significantly increased sensitivity compared with smears or LBC alone (p=0.006 and p=4.10^{-5}, respectively). Most notably, the combined use of smears and CBP significantly increased sensitivity compared with smears taken alone (p=0.0006), but not the combined use of smears and LBC (p=0.13). CBP were significantly more sensitive than smears both for the diagnoses of carcinoma (p=0.01) and granulomatous inflammation (p=0.048). LBC was less sensitive than smears for the diagnosis of granulomatous inflammation (p=0.004), but without a significant difference for carcinoma (p=0.42).

Discussion

EBUS-TBNA is a safe and effective method for the exploration of mediastinal adenopathies

EBUS-TBNA was proven to be an efficient, safe, and cost-effective method to explore mediastinal and hilar enlarged

lymph nodes [2–6, 12]. This method is presently replacing classical mediastinoscopy [8]. In our study, EBUS-TBNA was performed in 54.8 % of the cases in the context of a lung tumor in order to determine lung cancer stage or to obtain a diagnosis for a lung tumor when the tumor was not accessible to classical endobronchial or transparietal biopsy. The global diagnostic yield was higher than 80 %, in line with the data available in the literature [10, 13], underlining the conclusion that it is not necessary to use more invasive diagnostic methods. For 43.4 % of patients, EBUS-TBNA was performed to explore enlarged isolated mediastinal lymph nodes, mostly leading to a diagnosis of granulomatous inflammation (suggestive of sarcoidosis or tuberculosis) and also lymphoma and rare metastatic carcinoma (colonic and kidney). No complications occurred in our series, confirming the safety of this method.

Global sensitivity was high, about 90 %. The highest sensitivity was obtained for carcinoma (91 %) and the lowest for granulomatous inflammation (77 %) and lymphoma (67 %). False-negative diagnoses were assessed in most cases through standard histological examination of mediastinal lymphadenectomy samples, during surgical treatment, or by mediastinal biopsy. In the literature, sensitivity ranges from 81 % to 98 % for a diagnosis of carcinoma [7, 8, 14–18] and 83 % for sarcoidosis [19]. For lung carcinoma staging, maximal sensitivity is obtained by combining EBUS-TBNA with mediastinal biopsy, the former allowing sampling of lymph node stations difficult to access through mediastinoscopy [12]. The combination of EBUS-TBNA and mediastinal biopsy, which is more invasive and expensive, should be limited to selected indications, depending on pre-operative radiological data. Wallace et al. have reported an alternative method, combining endobronchial with transesophageal fine-needle aspiration. With this method, they reported 93 % sensitivity [18].

Table 2 Diagnostic yield comparison between smears, liquid-based cytology, and cell block preparations

Procedure	% vs %	*P*-value

[a] Exclusion of exams 1–95, for which no LBC was performed

The combination of CBP with conventional cytology increases diagnostic yield

We show that combining CBP and smears, but not LBC and smears, increases the diagnostic yield versus smear cytology alone. Fragments of lymph node tissue, although very small, allow a comfortable and reliable histological analysis. Our results are in line with the study of Sanz-Santoz et al., who reported a nearly 7 % increased yield using CBP ("cyto-blocks") [20]. In our study, the combination of the three techniques increased the yield up to 10 %. However, the diagnostic yield of CBP only was lower than that of conventional smears. Consequently, CBP is an efficient complement to conventional cytology but cannot replace it. A higher yield might be obtained in the future with the development of optimized dedicated needles for EBUS. Indeed although some lymph nodes are easily targeted, aspirates can be low on diagnostic material, most notably concerning tumors containing an abundant fibrous stroma or for fibrosing inflammatory processes. In contrast, it is worth noting that the sensitivity of

cytology in EBUS-TBNA is very high for SCLC (Table 3). This might be explained by its high cellularity, the absence of fibrous stroma, and the poor cohesiveness of the tumor cells, which facilitates their aspiration. The use of larger needles might increase the diagnostic yield. However, Nakajima et al. showed that the yield of a 21G needle is equivalent to that of a 22G needle; moreover, it led to more contamination of the sample with blood [21]. An alternative approach was reported by Franke et al., who used a 21G forceps introduced in the orifice obtained after sampling with a 22 G needle, resulting in a higher diagnostic yield, with minimal hemorrhagic complications [22].

CBP are more sensitive than conventional and liquid-based cytology

To our knowledge, the expected sensitivity gain by using other methods than conventional cytology in EBUS-TBNA has not yet been reported. Relative to the yield, sensitivity is a more accurate means of evaluating the diagnostic performance of a diagnostic method as yield does not take into account the potential risk of a false-negative result. We show here that the combination of the three sample types significantly increases sensitivity compared with smears only. This sensitivity gain cannot be attributed to LBC use but is due to the possibility to analyze tissue micro-fragments fixed in CytoRich. LBC did not significantly increase sensitivity, even if fragments were picked from the same container. CBP sensitivity was significantly higher than cytology both for the diagnoses of carcinoma and granulomatous inflammation. Thus, although the diagnostic yield of histological samples is not very high, they provide a real gain in terms of sensitivity. Due to a higher risk of a false-negative result, a negative EBUS-TBNA without CBP should be interpreted more carefully than a case for which paraffin-embedded fragments of normal lymph node parenchyma are present. An additional advantage is that immunohistochemistry can be performed on paraffin-embedded tissues, a very useful tool to make an accurate diagnosis. This material can also be used successfully for molecular biological studies, screening for *EGFR* and *ALK* mutation, a major parameter for the treatment of lung adenocarcinoma [11, 23]. Samples from our EBUS-TBNA were successfully used for molecular analyses in 90 % of cases (data not shown).

Cytology without CBP incurs an increased risk of a false-negative result

We show that smears not combined with CBP run a higher risk of a false-positive result upon a diagnosis of carcinoma and even more so in granulomatous inflammation (Table 4). Moreover, it must be underlined that LBC resulted in very low sensitivity for the diagnosis of sarcoidosis and other types of granulomatous inflammation (sensitivity of smears, 50 %; LBC, 4.5 %). This might be explained by the relative lack of cellular cohesiveness in granulomas and the difficulty in identifying single epitheloid cells on such a preparation. Conversely, epithelioid cells are easily identified on CBP, in which the granulomatous architecture is conserved. Even though EBUS-TBNA has been shown in a randomized trial to be an efficient method for the diagnosis of granulomatous inflammation [19], the risk of a false-negative result should be kept in mind when interpreting an EBUS-TBNA case. When CBP are not available in case of a suspicion of sarcoidosis or tuberculosis, a new EBUS-TBNA or other investigations should be considered before excluding these diagnoses.

Conclusion

In conclusion, the combination of conventional cytology with histological sections from paraffin-embedded samples significantly increases diagnostic yield and sensitivity, both for carcinoma and granulomatous inflammation. Conversely, smears and LBC, used without CBP, increase the risk of a false-negative result, most notably in the case of a granulomatous inflammation. Our results should incite operators to systematically collect material in liquid fixative milieu in addition to conventional smears.

Abstract Visceral pleural invasion (VPI) is defined as penetration by cancer cells of the elastic layer of the pleura. The purpose of this retrospective study was to compare the effect of invasion of the inner elastic layer of the pleura on survival to that of invasion of the outer elastic layer. One hundred twenty-four pT1 size lung adenocarcinomas were examined for visceral pleural invasion, which was classified into three types: no pleural invasion (NPI), invasion of the inner elastic layer only (IEL), and invasion of both inner and outer elastic layers (OEL). The relationship between the types of VPI and the prognosis was analyzed by univariate and multivariate analyses. Seventy-three (59 %) cancers showed NPI, while 51 cancers showed invasion of the pleura [(IEL) in 26 (21 %), OEL in 25 (20 %)]. The 5-year survival was 81, 60, and 37 % for patients with NPI, IEL, and OEL, respectively. Survival was poorest in patients with OEL ($P<0.01$). Invasion of the outer elastic layer was also significantly associated with lymph node metastasis and frequent lymphatic involvement, micropapillary pattern, higher stromal invasion grade, and presence of small cluster invasion within tumors. Univariate analysis showed a significant relationship between invasion of the outer elastic layer and poor prognosis. However, multivariate analysis identified lymph node metastasis as the most significant predictor of poor prognosis. Analysis of invasion of the inner and outer visceral pleura is important; invasion of the outer elastic layer correlates with poor prognosis in pT1 size lung adenocarcinomas.

Background

Visceral pleural invasion (VPI) increases the T category of lung cancers and is one of the most important prognostic factors in lung cancer [1–5]. Both tumor–node–metastasis (TNM) staging systems of the International Union Against Cancer (UICC, seventh edition) [6] and the Japan Lung Cancer Society (JLCS, sixth edition) classify VPI into the following stages: pl0, lung tumor with no pleural involvement beyond its elastic layer; pl1, lung tumor that extends beyond the elastic layer of the visceral pleura but is not exposed on the pleural surface; and pl2, lung tumor that is exposed on the pleural surface but does not involve adjacent anatomic structures. Anatomically, however, the visceral pleura comprises two elastic layers: one is the thick elastic layer beneath the submesothelial layer (the outer elastic layer), and another is the thin elastic layer in close to the pulmonary parenchyma (the inner elastic layer) [6]. Both the UICC and JLCS TNM staging systems do not mention the exact elastic layer for the above definitions of VPI and staging of lung cancer. Infiltration of the most prominent elastic layer has been introduced as the international recommendation [6]. The outer elastic layer is more easily recognized than the inner elastic layer, because no elastic fibers are located between the pleural surface and the outer elastic

layer. Several studies reported that VPI represented the unequivocal penetration of tumor cells beyond the elastic layer [4, 5, 7]. In this regard, the prognostic difference of penetration of the two elastic layers has not been investigated even in the above articles. There is only one study that intended to standardize or establish internationally acceptable guidelines for the diagnosis of VPI with respect to the two elastic layers [8]. However, the authors could not find any significant difference in the patients' survival based on the invasion of the elastic layers, and their conclusion was that differential evaluation of the tumor infiltration depth according to the elastic layers is not practical. In the present study, we evaluated VPI for each elastic layer and correlated these with the survival of patients with pT1 size lung adenocarcinomas.

Materials and methods

Patients

We reviewed 126 pT1 size lung adenocarcinomas (≤3 cm) that had been surgically resected at the Department of Thoracic Surgery, Fukuoka University Hospital, between January 1993 and December 2002. The study protocol was approved by the Ethics Committee of Fukuoka University. Anonymous use of redundant tissue is part of the standard treatment agreement with patients in our hospital when no objection is expressed. The pathological stage was determined according to the TNM classification of malignant tumors, seventh edition (International Union Against Cancer). We excluded two patients with tumors, in which pleural invasion was difficult to diagnose because of artificial damage of tissue associated with the preparation of intraoperative frozen diagnosis. Thus, 124 cases were available for investigating the relationship between pleural invasion and survival.

Pathologic evaluation

The surgically resected specimens were fixed routinely in 10 % formalin, and the whole tumor nodules were processed into paraffin blocks for histopathological examination. Tissue sections were cut 4 μm thick, including the largest cut surface of the tumor and stained with hematoxylin and eosin, elastica-van-Gieson, and orcein stains. The tumors were histopathologically classified according to the novel IASLC/ATS/ERS consensus classification [9]. Lymphatic and vascular involvements were immunohistochemically confirmed using D2-40 and anti-CD31 antibodies, which detect lymph and vascular

NPI no pleural invasion, *IEL* invasion of the internal elastic layer, *OEL* invasion of the outer elastic layer

[a] Pleural invasion was determined histopathologically in 124 tumors as described in "Materials and methods"

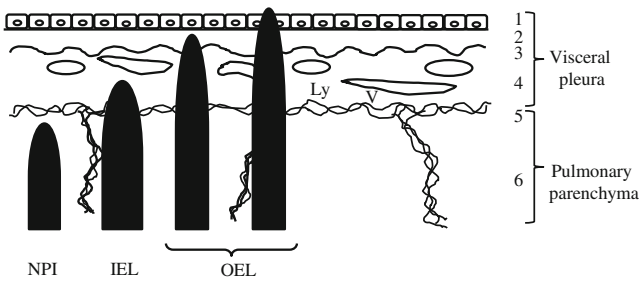

Fig. 1 Scheme diagram illustrating the different types of visceral pleural invasion (VPI) in lung cancers based on the two elastic layers of the pleura. The pl0 tumors show NPI and IEL, which do not penetrate the outer elastic layer, while pl1 tumors show OEL, which penetrates the outer elastic layer. The pl2 tumors represent those with invasion of the visceral pleural surface, but no involvement of the parietal pleura. *1* Mesothelial layer, *2* submesothelial layer, *3* outer elastic layer (superficial elastic layer), *4* subpleural layer, *5* inner elastic layer (deep fibroelastic layer), *6* pulmonary parenchyma. *Ly* lymphatics, *V* blood vessels, *NPI* no pleural invasion, *IEL* invasion of the inner elastic layer only, *OEL* invasion of both inner and outer elastic layers (modified from [8])

endothelial cells, respectively. Immunohistochemical staining was performed as described previously [10].

The clinicopathological parameters analyzed in this study included age, gender, tumor size, lymph node metastasis, stromal invasion grade (SIG), micropapillary pattern (MPP), small cluster invasion (SCI), lymphatic and vascular permeation, and pleural invasion. SCI was defined as single or small clusters of invading carcinoma cells seen at the invasive margin of the tumor within the fibrotic focus [10, 11]. The small clusters appear to have separated from acinar or papillary structures of

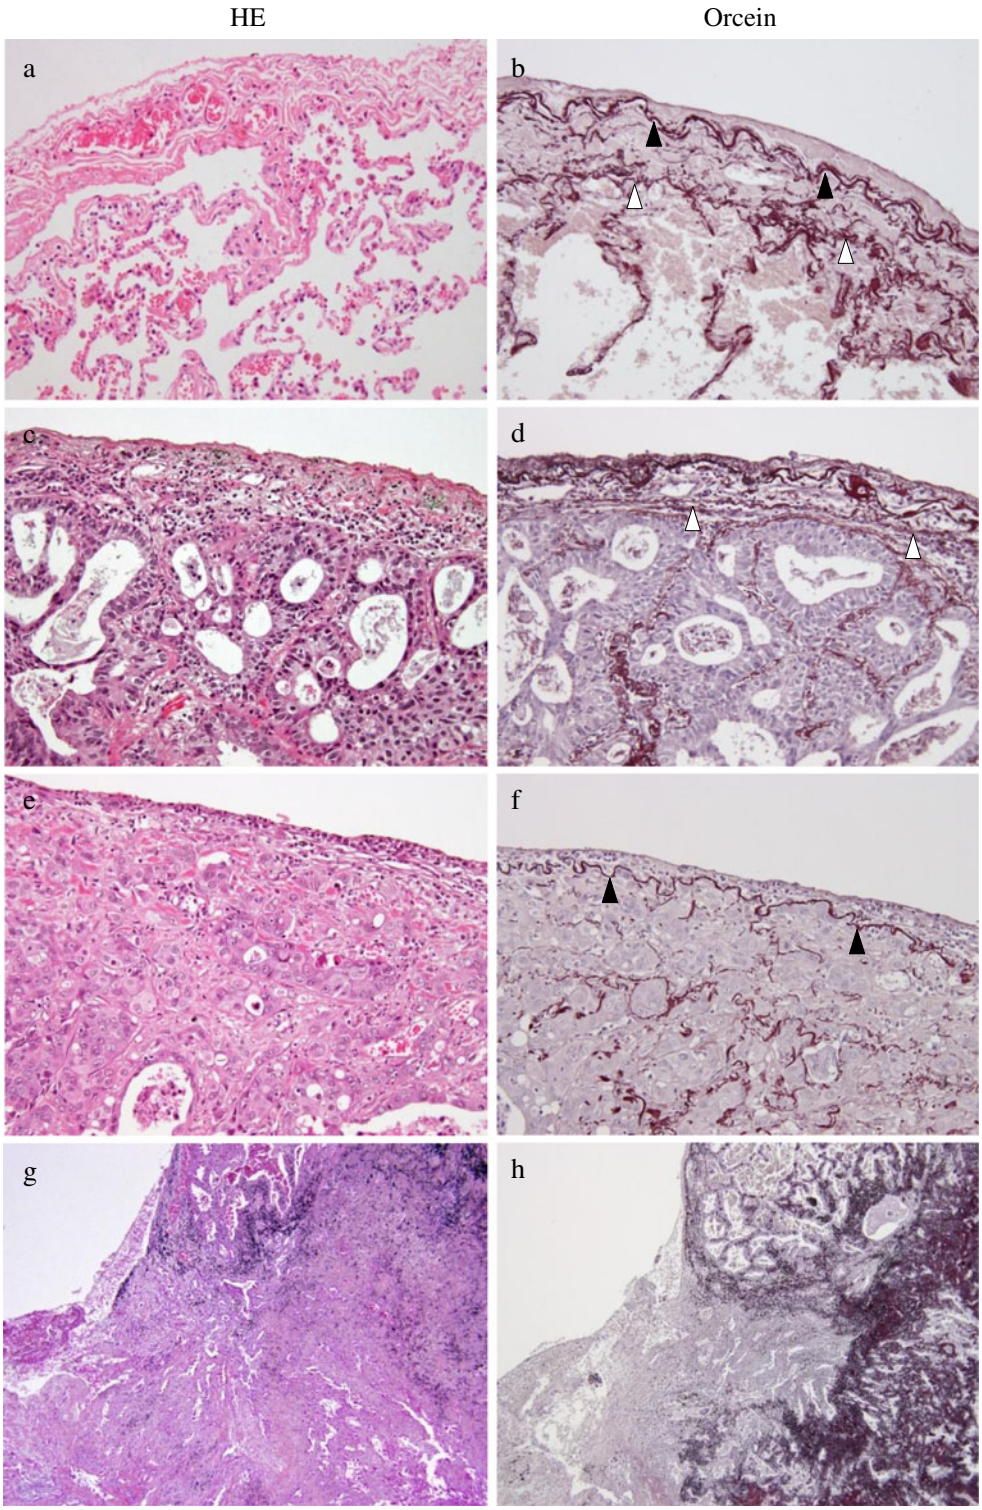

Fig. 2 Morphology of visceral pleura and pleural invasion. The slightly thickened pleura contains fibrocollagenous layer and lymphatic and blood vessels (**a**). The two elastic layers are stained with orcein. The outer elastic layer is thick and continuous (*black arrowheads*) while the inner elastic layer is thin and occasionally discontinuous (*white arrowheads*). Note the presence of lymphatic and blood vessels between these two elastic layers (**b**). Carcinoma cells do not invade the inner elastic layer (*white arrowheads*) (**c**, **d**). Carcinoma cells invade the inner elastic layer but do not penetrate the outer elastic layer (*black arrowheads*) (**e**, **f**). Carcinoma cells penetrate the outer elastic layer and are present on the pleural surface (**g**, **h**)

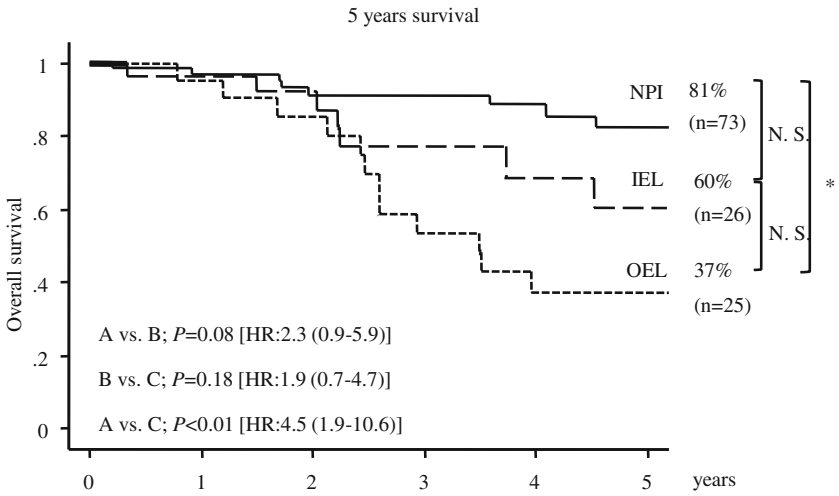

Fig. 3 Five-year overall survival curves for patients with lung adenocarcinoma according to the type of visceral pleural invasion (NPI, IEL, and OEL). Survival is poorest in patients with the outer layer penetration, and difference in survival between NPI and OEL was statistically significant. There was no significant difference in survival of patients with types (NPI and IEL) and (IEL and OEL). *NPI* no pleural invasion, *solid line*; *IEL* invasion of the internal elastic layer, *dashed line*; *OEL* invasion of the outer elastic layer, *dotted line*; *N.S.* not significant

tumors due to dedifferentiation. The details of the scoring system of SIG and MPP were described previously [11].

Statistical analysis

Summary statistics were obtained using standard methods and statistical analysis software StatView for Windows version 5.0 (SAS Institute Inc., Cary, NC, USA). The relationships between several clinicopathological parameters and histopathological subgroups were evaluated using the χ^2 test and Fisher's exact test. Survival curves were plotted using the Kaplan–Meier method, and differences in survival were determined by log-rank analysis. Univariate analysis was conducted for each clinicopathological parameter. Multivariate analysis with the Cox proportional hazard model was used to determine the independent prognostic factors. A P value less than 0.05 was considered statistically significant.

Results

Table 1 summarizes the clinicopathological characteristics of patients. This study included 126 patients (55 men and 71 women) with a mean age of 64 years (range, 28–85 years), and 60 patients (48 %) were less than 65 years old. Histopathological subtypes included adenocarcinoma in situ (4/126, 3 %), minimally invasive adenocarcinoma (2/126, 2 %), lepidic predominant (3/126, 2 %), acinar predominant (21/126, 17 %), papillary predominant (73/126, 58 %), micropapillary predominant (11/126, 9 %), solid predominant (5/126, 4 %), and invasive mucinous adenocarcinoma (7/126, 6 %). The subtypes of invasive adenocarcinoma showed no significant differences in terms of the extent of pleural invasion. Lobectomy was performed in 93 patients (74 %), and limited surgery was performed in 33 cases (26 %). Regional lymph node dissection was performed in all patients, and lymph node metastasis was diagnosed in 23 patients (18 %). The pleura has two elastic layers (Fig. 2a, b): the outer (Fig. 2b, black arrowheads) and inner (Fig. 2b, white arrowheads) layers, which can be identified with elastic fiber stains. VPI was classified into three types [no pleural invasion (NPI), invasion of the internal elastic layer (IEL), and invasion of the outer elastic layer (OEL)] according to modification of the scoring system by Warth et al. [8] (Figs. 1 and 2). NPI showed no invasion of pleural elastic layers; the tumor cells were adjacent to the inner elastic layer (deep fibroelastic layer) but did not penetrate it (Fig. 2c, d). IEL represented invasion of the inner elastic layer by tumor cells, but no penetration of the outer elastic layer (superficial elastic layer) (Fig. 2e, f). OEL represented invasion of the outer elastic layer by tumor cells (Fig. 2g, h). Of the 124 cases, 73 cases were classified as NPI (Figs. 1 and 2c, d, 59 %), 26 cases as IEL (Figs. 1 and 2e, f, 21 %), and 25 cases as OEL (Figs. 1 and 2g, h, 20 %). The latter group included four cases in which the tumor cells extended on to the surface of the visceral pleura.

The survival rates at 5 years for patients with NPI, IEL, and OEL were 81, 60, and 37 %, respectively (Fig. 3). Invasion of the inner elastic layer did not influence overall survival in pT1 size lung adenocarcinomas [hazard ratio

Table 2 Relationship between pleural invasion and lymph node metastasis

	Lymph node metastasis		
	n	(+)	(−)
NPI	73	9 (12.3 %)	64 (87.6 %)*
IEL	26	3 (11.5 %)	23 (88.4 %)**
OEL	25	11 (44.0 %)	14 (56.0 %)

NPI no pleural invasion, *IEL* invasion of the internal elastic layer, *OEL* invasion of the outer elastic layer

*P=0.003, compared with OEL, by χ^2 test; **P=0.01, compared with OEL, by χ^2 test

Table 3 Relationship between pleural invasion and lymphovascular involvement

	n	Pleura				Tumor			
		Lymphatic invasion		Blood vessel invasion		Lymphatic invasion		Blood vessel invasion	
		(+)	(−)	(+)	(−)	(+)	(−)	(+)	(−)
NPI	73	0 (0 %)	73 (100 %)	0 (0 %)	73 (100 %)	16 (22 %)	57 (78 %)*	8 (11 %)	65 (89 %)#
IEL	26	1 (4 %)	25 (96 %)	0 (0 %)	26 (100 %)	5 (19 %)	21 (81 %)$	6 (23 %)	20 (77 %)
OEL	25	4 (16 %)	16 (64 %)	2 (8 %)	23 (92 %)	20 (80 %)	5 (20 %)	10 (40.0 %)	15 (60 %)

NPI no pleural invasion, *IEL* invasion of the internal elastic layer, *OEL* invasion of the outer elastic layer

*$P<0.01$, compared with lymphatic invasion in tumor of OEL, by χ^2 test; #$P<0.01$, compared with tumor vessel invasion in tumor of OEL, by χ^2 test; \$$P<0.01$, compared with lymphatic invasion in tumor of OEL, by χ^2 test

(HR) 2.3, 95 % confidence interval (CI) 0.9–5.9, $P=0.08$]. However, invasion of the outer elastic layer correlated more significantly with shorter survival than of the internal elastic layer (HR 4.5, 95 % CI 1.9–10.6, $P<0.01$) (Fig. 3).

Table 2 shows the relationship between the type of VPI and lymph node metastasis. Lymph node metastasis was more common in patients with tumors of type OEL than those with NPI or IEL type tumors. Furthermore, lymphatic involvement within the tumor, especially in or around the fibrotic foci, was significantly more frequent in patients of OEL than NPI and IEL, while that in the pleura did not show significant differences between the two types (Table 3). Vascular involvement in the tumor was also significantly different between NPI and OEL. Furthermore, in IEL and OEL, lymphatic involvement within the tumor correlated significantly with more frequent lymph node metastasis, while vascular involvement did not ($P=0.002$) (Table 4). However, no significant differences were found between patients with N1 and N2 metastasis in terms of pleural invasion and lymphatic involvement. MPP, SIG (grade 3), and SCI were significantly more frequently observed in tumors with VPI of OEL than NPI (Table 5). No significant differences were found between NPI and IEL and IEL and OEL (Table 5).

Univariate analysis showed significant relations between survival of patients with pT1 size lung adenocarcinoma and lymph node metastasis ($P<0.01$), SIG ($P=0.01$), MPP ($P=0.03$), SCI ($P<0.01$), and VPI with penetration of the outer elastic layer ($P<0.01$). Multivariate analysis that included clinicopathological parameters identified lymph node metastasis ($P=0.02$) as independent and significant prognostic factors (Table 6).

IEL invasion of the internal elastic layer, *OEL* invasion of the outer elastic layer

Discussion

So far, only one report by Warth et al. has analyzed the significance of pleural invasion in relation to invasion of the inner versus the outer elastic layers [8]. The authors used a new scoring system to define tumor infiltration depth in each elastic layer. However, in their study, no significant relationship was found between the patients' survival and the tumor infiltration depth [8]. Our study is the first to report that prognosis was significantly poorer for patients with pT1 size lung adenocarcinomas invading the outer elastic layer of the pleura than those invading the inner elastic layer. The different outcomes in internal and external elastic invasion subgroups between the study of Warth et al. and ours can be explained at least in some parts by the completely different methodology. Their methodology different from ours includes (1) no lymph node metastasis was

admitted to the case selection; 2) tumor size was not a selective criterion; 3) not only adenocarcinoma but also squamous cell carcinoma and other histological types of NSCLC were included; (4) the median follow-up was 40.6 months; and (5) no other clinicopathological factors except for the depth of pleural invasion were analyzed for a correlation with survival.

VPI is ordinarily defined as tumor extension beyond the elastic layer of the visceral pleura, regardless of its invasion of the pleural surface [4, 12]. The visceral pleura comprises two elastic layers that are easily recognized with elastic stains: one is the thick and continuous elastic layer beneath the submesothelial layer (the outer elastic layer), and the other is the thin and discontinuous elastic layer, which attaches to the alveolar septal elastic fibers (the inner elastic fiber) [6, 13]. It is a well-known fact that elastic layers are frequently duplicated or even triplicated, making it quite hard to recognize them. Furthermore, lung cancers, especially subpleural tumors, often cause pleural puckering, and the visceral pleural elastic layer could be invaded in three patterns: (1) without eliciting any secondary changes, (2) with prominent elastic reduplication and inflammatory infiltrates, and (3) with thick fibroblastic proliferation [6, 14]. In our study, the inner elastic layer sometimes became ill-defined and difficult to recognize even in sections prepared with elastin staining mostly due to the fibrous thickening of the visceral pleura and collapsed alveolar septal elastic fibers (Fig. 2g, h). Even in such occasions, the outer elastic layer could be recognized more easily than the inner elastic layer, because the former was thicker, continuous, and located close to the pleural surface. Moreover, in the tumor with entirely fused thick elastic layers, invasion of the outer elastic layer could be assessed by detecting carcinoma cells, which completely penetrated the elastic layer and reached outside of it. Therefore, the outer elastic layer is the more convenient and efficient landmark than the inner elastic layer.

The reported incidence of VPI in resected nonsmall cell lung carcinomas (NSCLCs) is between 16.2 and 26.8 % [3, 15–17]. VPI is an important prognostic factor in stage I and stage II NSCLCs [3, 5, 16]. However, it is not clear why VPI is associated with a poor prognosis. Previous studies indicated that VPI was significantly correlated with more extensive mediastinal lymph node involvement [3, 17]. Also, several studies reported that VPI is associated with N2 lymph node metastases [3, 16, 18]. These reports support the notion that VPI correlates with tumor invasion and metastasis through the subpleural lymphatics into the mediastinal lymph nodes. Anatomically, the visceral pleura contains many lymphatic and blood vessels sandwiched between the inner and outer elastic layers (subpleural layer) (Fig. 1). Based on these results, we speculated that adenocarcinomas with VPI penetrate the inner elastic layer and invade the lymphatic and blood vessels in the subpleural layer, leading to frequent lymph node metastasis compared with adenocarcinomas without VPI. In our study, however, the frequency of lymphovascular involvement in the pleura was not significantly different among the three types of VPI. In contrast, the frequency of lymphatic involvement in the tumor (in or around the central scar) was significantly higher in OEL than NPI and IEL (Table 3). Lymph node metastasis was found mostly in intrapulmonary and hilar nodes, and only five patients had skip metastasis to the mediastinal nodes. Furthermore, in VPI-positive cases (IEL and OEL), presence of lymphatic involvement in the tumor was also significantly associated with lymph node metastasis (Table 4). Thus, VPI might reflect poor prognosis not by pleural lymphatic involvement but by the presence of lymphatic involvement within the primary tumor itself. The lymphatic involvement in patients with stage I NSCLC is

reported to be indicative of tumor invasiveness [16, 19]. Furthermore, we divided tumors in our study into pT1a and pT1b size and analyzed them about the VPI, frequency of lymphovascular involvement in the pleura or in the tumor, and survival. Significantly more tumors with NPI (no pleural invasion) were found in pT1a tumors than pT1b tumors ($P<0.01$). The lymphatic involvement tended to be found more frequently in pT1b tumors than pT1a tumors, but their difference was not significant. Moreover, the depth of VPI was not significantly different between pT1a and pT1b tumors (data not shown).

We reported previously that high grade stromal invasion significantly correlated with shorter overall survival in patients with pT1 size adenocarcinomas and that MPP-positive tumors with stromal invasion grade 3 (SIG 3) were significantly associated with poorer prognosis than MPP-negative tumors with SIG 3 [10, 11]. Moreover, the presence of SCI also correlated with high grade stromal invasion, MPP, lymphatic involvement, and lymph node metastasis, leading to shorter survival. These results suggested that MPP, SIG, and SCI reflect tumor aggressiveness and invasiveness in pT1 size lung adenocarcinoma. In the present study, the presence of MPP, SIG, and SCI was significantly associated with invasion of the outer elastic layer of the pleura (OEL). Moreover, univariate analysis indicated that lymph node metastasis ($P<0.01$), SIG ($P=0.01$), MPP ($P=0.03$), SCI ($P<0.01$), and VPI ($P<0.01$) were related with shorter survival (Table 6). Considered together, invasion of the outer elastic layer seems to reflect high tumor invasiveness and aggressive behavior of pT1 size lung adenocarcinoma.

In conclusion, the present study demonstrated that the outer elastic layer of the pleura is a more useful landmark for the diagnosis of VPI than the inner elastic layer: (1) it is easier to recognize the outer layer of the pleura than the inner layer with elastic stain. (2) Invasion of the outer elastic layer of the pleura correlates with shorter survival and seems to reflect the invasiveness and aggressiveness of pT1 size lung adenocarcinomas. Thus, the routine use of elastic stains is suggestive in case of questionable pleural invasion in daily practice.

Acknowledgments We thank Ms. M. Onitsuka for the excellent technical assistance in immunohistochemical staining. This work was supported in part by a grant from the Research Center for Advanced Molecular Medicine, Fukuoka University.

Conflict of interest The authors declare no conflict of interest.

Abstract Members of the HER (ERBB) receptor protein tyrosine kinase family play an important role in regulating cellular division, proliferation, differentiation, and migration and have prognostic significance in a number of cancers. Here, we sought to define their role in extrahepatic cholangiocarcinoma (EHCC). HER2 and HER3 protein expression was studied in 230 EHCC cases using a tissue microarray and compared with clinicopathological variables, including the survival of EHCC patients. HER3 was predominantly localized to the cytoplasm, whereas HER2 exhibited a membranous expression pattern. Overexpression of HER2 and HER3 was observed in 6 % (13/224) and 39 % (90/230) of EHCCs, respectively. Membranous HER2 overexpression occurred more frequently in intraductal papillary neoplasms with an associated invasive carcinoma than in tubular adenocarcinomas (P=0.02). HER3 protein was more commonly overexpressed in nodular and infiltrative than in papillary tumors (P=0.03). HER3 overexpression was associated with decreased survival in both univariate (P=0.01) and multivariate (P=0.008) analyses, whereas HER2 overexpression was not associated with survival. HER2 and HER3 are overexpressed in subsets of EHCC patients. Notably, HER3 overexpression is correlated with decreased patient survival, suggesting that HER3 constitutes a prognostic factor as well as a potential candidate for targeted therapy.

Introduction

Extrahepatic cholangiocarcinoma (EHCC) is a malignant epithelial neoplasm of the biliary tract, from the hepatic hilum to the distal bile duct, that accounts for 70–90 % of all cholangiocarcinomas [1]. EHCC is a relatively uncommon cancer in Western countries but is more prevalent in Eastern Asian countries, including Korea [1–3]. Surgical resection of the tumor is the only curative therapeutic modality for patients with EHCC but can be applied only in a limited number of patients with localized or locally advanced disease [4]. The 5-year survival rate of EHCC patients following surgical resection is approximately 20 % [5]. Several neoadjuvant therapies, including chemotherapy, radiation therapy, and photodynamic therapy, have been extensively studied, but none have yielded significant survival advantages for EHCC patients [1, 6]. Therefore, identification of new biomarkers for early detection and/or development of new therapeutic regimens based on a better understanding of the biological mechanisms of this deadly disease are essential for decreasing mortality among EHCC patients.

Epidermal growth factor receptors (EGFRs) are members of a membrane receptor protein tyrosine kinase family that includes HER1 (ErbB1/EGFR), HER2 (ErbB2), HER3 (ErbB3), and HER4 (ErbB4). After binding ligands, EGFRs are activated by receptor homo- or heterodimerization, resulting in the phosphorylation of various downstream substrates, which mediate intracellular signal transduction. EGFR signaling pathways play an important role in regulating cell division, proliferation, differentiation, and migration [7]. The EGFR family member HER3 lacks intrinsic protein tyrosine kinase activity [8]. However, binding of

neuregulin family ligands enables HER3 to form functional heterodimers with EGFR or HER2 that act through the cytoplasmic domain of HER3 to exert tyrosine phosphorylation activity [9]. Thus, by heterodimerizing with other EGFR proteins, HER3 can participate in diverse signal transduction cascades and regulate various cellular processes [7, 9]. The development of tyrosine kinase inhibitors of EGFR or HER2 was initially considered a promising strategy for blocking EGFR or HER2 pathways in several solid cancers, including breast and lung cancers. However, evidence suggests that HER3 may be responsible for the resistance to these therapeutic regimens, which often develops [10]. Overexpression of HER3 has been reported in several malignant neoplasms in gastrointestinal tract organs, including gastric [11–13], colorectal [14–19], and ampulla of Vater [18] cancers. Although a few studies have demonstrated HER2 expression in cholangiocarcinoma, showing that it is relatively infrequent in these tumors [20–23], there have been no comprehensive studies of HER2 and HER3 expression in EHCCs. In the current study, we analyzed HER2 and HER3 protein expression in 230 EHCC cases using tissue microarray immunohistochemistry. We demonstrate that HER3 expression in EHCC constitutes a prognostic factor.

Materials and methods

Patients and tumor samples

The study population consisted of 230 patients with surgically resected EHCCs treated at Asan Medical Center, University of Ulsan College of Medicine, in Seoul, South Korea, between 1991 and 2005. Carcinomas with an epicenter in the extrahepatic bile duct were included in this study, whereas carcinomas from the ampulla of Vater or pancreas were not. Carcinomas arising in the gallbladder or intrahepatic bile duct with extension to the extrahepatic bile duct were also excluded. Information regarding the age and gender of patients, surgical procedure, survival time, and survival status was obtained by reviewing EHCC patients' medical records. Data pertinent to location, size, and growth pattern of the tumor were obtained from surgical pathology reports. Materials were obtained with appropriate human protection approval from the Institutional Review Board of the Asan Medical Center (Project Number 2011–0734). Information regarding post-operative radiation, chemotherapy, and performance status of patients was not analyzed in this study.

Tissue microarray construction

Tissue microarrays were constructed from archival formalin-fixed, paraffin-embedded tissue blocks as previously described [24]. Briefly, 230 extrahepatic cholangiocarcinoma cases and 12 normal extrahepatic bile ducts were included. A representative area was carefully selected for each tumor or normal biliary epithelia from a hematoxylin-and-eosin-stained section of a donor block. Each case was represented by two to four 1.5-mm-diameter cores.

Immunohistochemistry and scoring

Immunohistochemistry was performed on 4-μm-thick tissue microarray sections as previously described [25]. Briefly, tissue sections were deparaffinized and hydrated in xylene and serially diluted ethanol, respectively. Endogenous peroxidase was blocked by incubation in 3 % H_2O_2 for 10 min. Antigen retrieval was performed in a steam pressure cooker using preheated antigen retrieval buffer, pH 6 (Dako, Glostrup, Denmark), at 95 °C for 10 min. Non-specific binding of antibodies was minimized by incubating sections with Protein Block (Dako) for 15 min. Microarrays were incubated at room temperature for 30 min with rabbit polyclonal anti-HER2 (c-erbB2, A0485; 1:750 dilution; Dako) or overnight at 4 °C with mouse monoclonal anti-HER3 (RTJ.2, 1:500 dilution; Santa Cruz, CA, USA). Antigen–antibody reactions were detected with an LSAB+peroxidase kit (Dako) and 3,3′-diaminodbenzidine (Dako). Negative controls were composed of identically treated histologic sections with the omission of primary antibodies. Immunostained sections were lightly counterstained with hematoxylin, dehydrated in ethanol, and cleared in xylene. We did not perform immunohistochemistry for Her2 and Her3 on full sections. Tissue core representativity might be a concern, but certainly for 1.5-mm cores previous studies have demonstrated that two to four tissue cores are representative with 95–97 % concordance rate [62].

HER2 protein expression was scored on a scale of 0 to 3 using the following gastric cancer staging system [26]: 0, no reactivity or membranous reactivity in less than 10 % of cells; 1+, faint/barely perceptible membranous reactivity in ≥10 % of cells or reactivity in only part of the cell membrane; 2+, weak to moderate complete or basolateral membranous reactivity in ≥10 % of tumor cells; 3+, strong complete or basolateral membranous reactivity in ≥10 % of tumor cells. Cases receiving a HER2 score of 3+ were considered positive for HER2 expression.

The results of immunohistochemical staining for HER3 were scored based on the intensity of staining as 0 (negative), 1 (weak), or 2 (strong), and the percentage of positive epithelial cells as 0 (<5 %), 1 (6–25 %), 2 (26–50 %), 3 (51–75 %), or 4 (>76 %). A Histo-score was generated as the product of intensity and area. The Histo-score was then dichotomized into no/lower expression (Histo-score, 0–6) and overexpression (Histo-score, 8).

Statistical analysis

Statistical analyses were performed using SPSS version 17 (SPSS Inc., Chicago, IL, USA). Associations between categorical variables were examined using Pearson's chi-square and Fisher's exact tests. Survival curves were calculated by the Kaplan–Meier method, and statistical significance was evaluated using the log-rank test and the Cox proportional hazards regression model. $P<0.05$ was considered as statistically significant.

Results

Clinicopathological characteristics of cases

The clinicopathological characteristics of cases are summarized in Table 1. Patient age ranged from 30 to 84 years (mean, 60.9 years). Of the 230 patients, 164 were men and 66 were women. Tumor size ranged from 0.5 to 6 cm (mean, 2.5 cm). Thirty-one cases were pT1 tumors, 84 were pT2, 91 were pT3, and 24 were pT4. The length of patient follow-up time ranged from 1 to 127 months, and median survival time at last follow-up was 22 months.

HER2 and HER3 expression

HER2 protein expression patterns were analyzed in tumors from a total of 224 EHCC patients using tissue microarray immunohistochemistry. Information regarding six patients was excluded from the HER2 analysis because their tissue microarray cores were either detached or folded during the HER2 immunohistochemical staining procedure. Representative images of the expression of HER2 and HER3 in EHCC tumors and normal biliary epithelial cells are shown in Fig. 1. All 12 samples of normal biliary epithelial cells did not show immunoreactivity for either HER2 or HER3. HER3 was predominantly distributed in a cytoplasmic pattern, whereas HER2 was mainly localized to the cell membrane in EHCC cases. HER2 and HER3 overexpression was observed in 6 % (13/224 cases) and 39 % (90/230 cases) of EHCCs, respectively. Only the histological subtype was significantly associated with HER2 overexpression ($P=0.02$). Specifically, intraductal papillary neoplasms with associated invasive carcinoma cases showed significantly more HER2 overexpression than other histological subtypes, including tubular adenocarcinoma, adenosquamous carcinoma, intestinal type adenocarcinoma, and mucinous carcinoma, which did not express HER2 (Table 2). HER3 protein was more commonly overexpressed in nodular and infiltrative tumors than in papillary tumors ($P=0.03$). HER3 overexpression was more frequent in cases without than in cases with invasion of the pancreas ($P=0.02$).

Among 13 HER2-overexpressing EHCCs, seven (54 %) showed HER3 overexpression. There was a significant

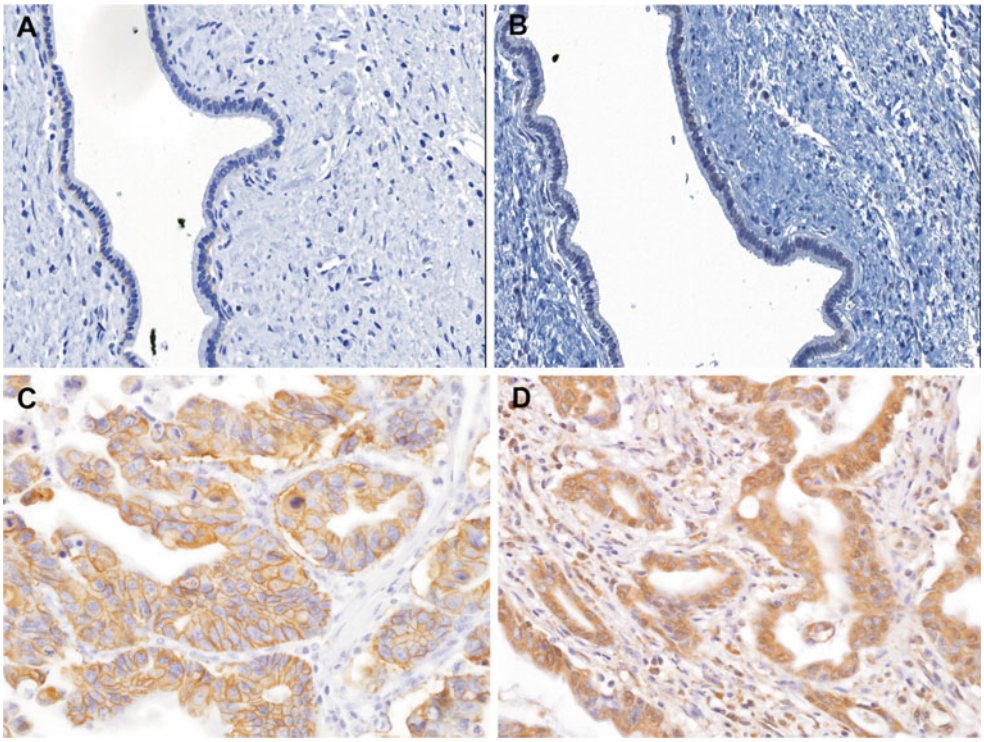

Fig. 1 Representative immunohistochemical staining of HER2 and HER3 in EHCC. Normal bile duct epithelia show negativity for HER2 (**a**) and HER3 (**b**). Cholangiocarcinoma show strong and complete membranous expression of HER2 (**c**) and diffuse and strong cytoplasmic HER3 immunopositivity (**d**)

correlation between cases with HER2 overexpression and those with HER3 overexpression (R=0.24, P<0.001) but not between HER2 and HER3 co-overexpression and clinicopathological parameters (Table 3).

Survival analysis

Median survival of patients with HER3 overexpression (24.0 months) was significantly worse than that of patients with no/lower HER3 expression (31.9 months; P=0.01, log-rank test; Fig. 2a). The 1-, 3-, and 5-year survival rates in the HER3-overexpression group were 82.2, 22.6, and 13.9 %, respectively, whereas the corresponding rates in the no/lower HER3-expression group were 82.6, 40.5, and 31.2 %.

There was no significant difference in survival between patients with HER2 overexpression (median survival, 25.9 months) and those without HER2 expression (median survival, 27.8 months; P=0.17, log-rank test; Fig. 2b).

Median survival of EHCC patients with both HER2 and HER3 overexpression (24.8 months) tended to be lower than that in patients without HER2 and HER3 co-overexpression (28.0 months; P=0.08; Fig. 2c), but this did not reach statistical significance.

Association between survival and other clinicopathological factors

The relationships between other clinicopathological variables and survival are summarized in Table 4. Of these additional clinicopathological variables, tumor differentiation status (P<0.001), pT classification (P=0.01), lymph node metastasis (P<0.001), liver invasion (P=0.01), and vascular invasion (P=0.02) were also significantly associated with survival. In contrast, survival was not associated with gender (P=0.38), tumor location (P=0.47), growth pattern (P=0.09), pancreatic invasion (P=0.24), duodenal invasion (P=0.07), perineural invasion (P=0.36), or resection margin status (P=0.10).

Multivariate analysis of clinicopathological factors

The independent prognostic significance of HER3 expression as well as of other clinicopathological parameters was determined by applying the Cox proportional hazards model (Table 5). HER3 overexpression (P=0.007), differentiation (P=0.002), liver invasion (P=0.03), and lymph node metastasis (P=0.002) remained as prognostic factors.

Discussion

In this study, we observed overexpression of HER2 and HER3 protein in a subset of EHCCs, with about 6 % of EHCC cases overexpressing HER2 (13/224) and 39 % (90/230) overexpressing HER3. In addition, we found HER3 overexpression to be an independent prognostic factor in EHCC patients. HER3 is unique among members of the

HER receptor tyrosine kinase family in that it lacks intrinsic tyrosine kinase activity but it does contain six consensus phosphotyrosine sites, which bind the SH2 domain of the three regulatory subunits of phosphoinositide-3-kinase (PI3K) [27, 28]. Binding of HER3 can activate the PI3K/Akt signaling pathway, which is a critical regulator of many cellular processes. HER2-mediated transformation of epithelial cells is associated with the activation of the PI3K/Akt signaling pathway in breast cancer. Several targeted therapeutics, including trastuzumab, a monoclonal antibody against the extracellular domain of HER2, and lapatinib, an EGFR/HER2 tyrosine kinase inhibitor, have been approved for use in the treatment of HER2-overexpressing breast cancers. It has been proposed that inhibition of HER3 phosphorylation and blockade of the PI3K/Akt signaling pathway are required in order to obtain a tumor suppression effect despite differences in the operating mechanisms of these therapeutic agents [29]. HER2–HER3 heterodimerization plays a key role in HER2-mediated transformation, tumor progression, and drug resistance [29]. Previous studies on loss of HER3 expression in HER2-dependent cells have demonstrated reduced PI3K signaling and decreased cell proliferation, suggesting that HER3 is essential for HER2-driven carcinogenesis [30, 31]. Treatment of HER2-amplified tumors with tyrosine kinase inhibitors results in a compensatory increase in HER3 expression, membranous HER3 localization, and decreased HER3 dephosphorylation [32]. MET-dependent phosphorylation of HER3 has been identified as one mechanism of resistance to EGFR inhibitors in lung cancer [33]. A recent study demonstrated that blocking both HER2 and HER3 inhibits the PI3K/Akt pathway more effectively than blocking HER2 or HER3 alone, suggesting that also HER3 should be inhibited in patients with HER2- and PI3K-dependent cancers in order to completely block the PI3K/Akt pathway [29]. Our group previously demonstrated that the Akt pathway is activated in a large proportion of EHCCs (84 %) [24]. In the present study, we demonstrate that HER3 is overexpressed in 39 % of EHCC cases. Considering the current study and the results of previous studies of breast cancers and EHCCs, we hypothesize that application of a therapeutic regimen for blocking HER3, such as AMG888, together with HER2 inhibitors and PI3K inhibitors might be effective in a subset of EHCC patients with activated Akt and HER3.

HER3 overexpression has been identified in malignant neoplasms from several organs, including melanoma, and prostate, colorectal, lung, ovarian, and gastric cancers [17, 30, 34–38]. In addition, HER3 overexpression has been reported to be associated with a worse outcome in melanomas and lung and gastric cancers [34, 38, 39]. Although HER3 is specifically required for HER2-driven tumorigenesis and has been extensively studied in the HER2-amplified subtype of breast cancers, other types of cancer also show higher HER3 expression without accompanying HER2 overexpression [30, 40]. In these tumors, HER3 may function as an allosteric activator of other members of the HER receptor tyrosine kinase family, such as EGFR [41–43]. EGFR expression has been reported in 8–57 % of cholangiocarcinomas, and patients with EGFR-positive tumors showed worse clinical outcome than those with EGFR-negative cancers [20, 23, 44, 45]. The absence of a survival difference in patients with HER2 overexpression and the significantly shorter survival in patients with HER3 overexpression, as demonstrated in this

study, suggest a possible link between shorter survival time in the HER3-overexpression group and EGFR–HER3 heterodimerization in a subset of these patients. These patients may benefit from a therapeutic regimen that includes other types of HER inhibitors, including erlotinib, cetuximab, and lapatinib, which have been investigated recently in cholangiocarcinomas [46–50].

HER2 overexpression in cholangiocarcinomas has been explored in various studies and has shown to vary widely (between 5 and 76 %) [20, 51–57]. These discrepancies might be explained by the lack of a standardized methodology, different standards of interpretation, or differences in tumor location. In recent reports, the HER2 expression rate in resected EHCCs was reported to be 5 to 10 % [20, 23, 45, 52]. The approximately 6 % HER2 expression rate identified in the current study is in agreement with these previous studies. Consistent with some previous reports, we found a higher HER2 overexpression rate in intraductal papillary neoplasm with an associated invasive carcinoma than in other histological types [20, 45, 54]. Although the HER2 overexpression rate is not exceptionally high in EHCCs, a subset of patients with HER2 overexpression might benefit from HER2-targeted monoclonal therapy.

The recently updated (7th edition) American Joint Committee on Cancer Staging Manual divided EHCCs into perihilar and distal bile duct cancers [58]. The term “distal bile duct cancers” was applied to cancers distal to the insertion of the cystic duct. This division reflects the growing evidence for distinct biological patterns in perihilar and distal EHCCs

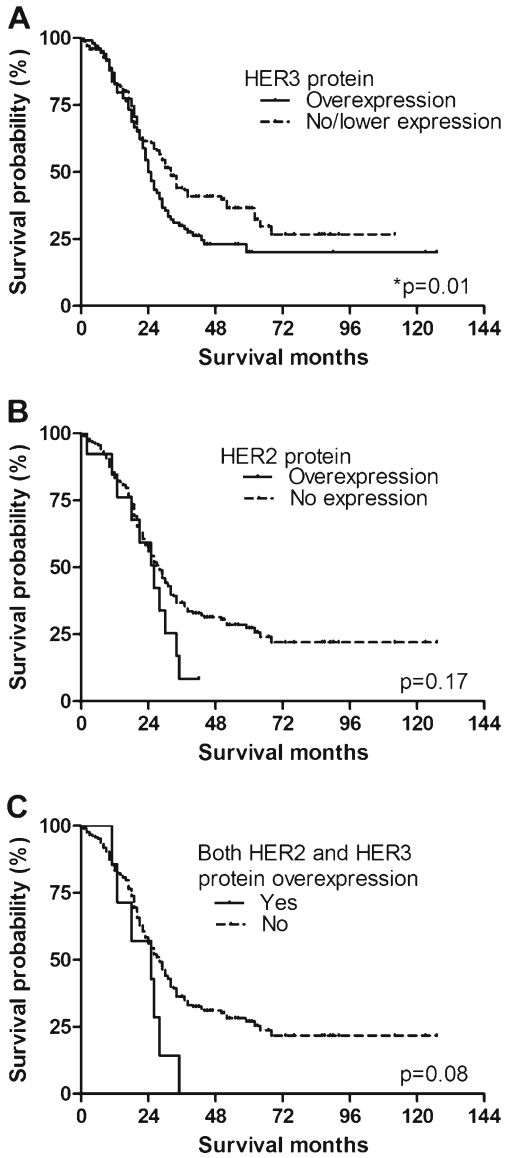

Fig. 2 Survival curves stratified by HER2 and HER3 expression in EHCC patients. **a** Median survival in patients in the HER3-overexpression group (24.0 months) was significantly shorter than that for patients in the no/lower HER3-expression group (31.9 months; P=0.01, log-rank test). **b** Survival was not significantly different between patients in the HER2-overexpression group (25.9 months) and the no/lower HER2-expression group (27.8 months; P=0.17, log-rank test). **c** Median survival in EHCC patients with both HER2 and HER3 co-overexpression (24.8 months) was marginally different from that in patients without HER2 and HER3 co-overexpression (28.0 months; P=0.08)

[59–61]. However, in our study, the proportions of HER2 and HER3 overexpression were similar in perihilar and distal bile duct cancer groups.

In conclusion, HER2 and HER3 proteins are overexpressed in subsets of EHCCs. HER3 overexpression is correlated with decreased patient survival and therefore constitutes a prognostic factor and a potential therapeutic target in patients with EHCCs.
