LIBIDO to MARY, DUCHESS OF BURGUNDY

LIBIDO (li-bīd'o), defined by Freud as "the energy of those instincts which have to do with all that may be comprised under the word 'Love.'" Jung enlarged the concept so that for him it describes the energy resident in all instincts. Libido is usually considered to be synonymous with other such vague concepts as *élan vital* and psychophysiological energy. It is claimed that the energy of intellectual processes is measured by intelligence tests in terms of clearness and speed; but the measurement of the conative energy of a "wish" is more difficult, because the wish, which may be considered to be the inner feeling of need together with motor sets appropriate to its appeasement, may fail to find expression in measurable overt conduct on account of opposing repressive (unconscious) and suppressive (conscious) forces.

LIBITINA, Roman goddess of funerals. She had a sanctuary in a sacred grove (perhaps on the Esquiline), where, by an ordinance of Servius Tullius, a piece of money was deposited whenever a death took place. Here the undertakers (*libitinarii*), who carried out all funeral arrangements by contract, had their offices, and everything necessary was kept for sale or hire; here all deaths were registered for statistical purposes. By antiquarians Libitina was sometimes identified with Persephone, but more commonly (partly or completely) with Venus Lubentia or Lubentina, a mere confusion. Libitina may have been an earth goddess connected with luxuriant nature and the enjoyments of life (*cf. lub-et, lib-ido*); then, all such deities being connected with the underworld, she also became the goddess of death, and that side of her character predominated in the later conceptions.

LIBON, a Greek architect, born at Elis, who was employed to build the great temple of Zeus at Olympia (*q.v.*) about 460 B.C. (Pausanias v. 10. 3).

LIBOURNE, a town of southwestern France, capital of an arrondissement of the department of Gironde, at the confluence of the Isle with the Dordogne, 22 mi. E.N.E. of Bordeaux on the railway to Angoulême. Pop. (1936) 16,261. The river is tidal and vessels drawing 14 ft. can reach the town at the highest tides. Libourne stands on an ancient site. Under the Romans *Condate* stood a mile to the south of the present Libourne; it was destroyed in the 5th century. Resuscitated by Charlemagne, it was rebuilt in 1269, under its present name and on the site and plan it still retains, by Roger de Leybourne (of Leybourne in Kent), seneschal of Guienne, acting under the authority of King Edward I of England. It suffered considerably in the struggles of the French and English in the 14th century. The church of St. Jean, restored 15th-century Gothic, has a stone spire 232 ft. high. On the quay a 14th-century clock tower survives from the old ramparts, and the hôtel-de-ville is a quaint relic of the 16th century. Libourne is the seat of a sub-prefecture and of tribunals of first instance and of commerce. Trade is in local wines and brandies. Printing and cooperage are carried on.

LIBRA (The Balance), in astronomy, the 7th sign of the zodiac, denoted by the symbol ♎, resembling a pair of scales, probably to suggest that when the sun enters this part of the ecliptic, at the autumnal equinox, the days and nights are equal.

LIBRARIES. A library (from Lat. *liber*, book) is a collection of printed or written literature. The earliest libraries of the world were probably temples. The earliest collections of which we know anything were collections of archives.

Assyria.—In the course of his excavations at Nineveh in 1850, Layard came upon tablets of clay, covered with cuneiform characters. These varied in size from 1 to 12 in. square. It is estimated that this library consisted of some 10,000 distinct works and documents. The tablets appear to have been methodically arranged and catalogued, and the library seems to have been public. (*See* BABYLONIA AND ASSYRIA and NIPPUR.)

Ancient Egyptian Libraries.—At an early date Heliopolis was a literary centre of great importance, with culture akin to the Babylonian. Attached to every temple were professional scribes. We possess a record relating to "the land of the collected works (library) of Khufu," a monarch of the 4th dynasty, and a similar inscription relating to the library of Khafra, the builder of the second pyramid. At Edfu the library was a small chamber in the temple, on the wall of which is a list of books (Brugsch, *History of Egypt*, 1881, i, 240). The exact position of Ikhnaton's library (or archives) of clay tablets is known. A library of charred books has been found at Mendes (Egypt Expl. Fund, *Two Hieroglyphic Papyri*), and we have references to temple libraries in the Silsileh "Nile" stelae and, perhaps, in the Harris papyri. The most famous of the Egyptian libraries, that of King Osymandyas (Rameses II, 1300–1236 B.C.), described by Diodorus Siculus, was probably in the Ramessæum at Western Thebes. Papyri from the palace, of a later date, have been discovered by Sir W. Flinders Petrie. According to Eustathius there was a great collection at Memphis. At the Persian invasion many books were carried away by the conquerors.

Greece.—Amongst known collectors of books were Pisistratus, Polycrates of Samos, Euclid the Athenian, Nicocrates of Cyprus, Euripides and Aristotle (Athenaeus i. 41). At Cnidus there is said to have been a special collection of works upon medicine. Pisistratus is reported to have been the first of the Greeks who collected books on a large scale. Plato is known to have been a collector; and Xenophon tells us of the library of Euthydemus. The library of Aristotle was bequeathed by him to his disciple, Theophrastus, and by Theophrastus to Neleus, who carried it to Scepsis, where it is said to have been concealed underground to avoid the literary cupidity of the kings of Pergamum. It is certain that the libraries of Alexandria were the most important, as they were the most celebrated, of the ancient world.

Alexandria.—Ptolemy Soter had, it seems, already begun to collect books, but it was in the reign of Ptolemy Philadelphus that the libraries were properly established in separate buildings. There were two libraries at Alexandria; the larger, in the Brucheum quarter, was in connection with the museum, a sort of academy, while the smaller was in the Serapeum. The number of volumes was very large, although it is difficult to attain any certainty amongst varying accounts, such as those of Tzetzes (42,800 in the Serapeum and 490,000 in the Brucheum), Aulus Gellius (700,000) and Seneca (400,000). It should be observed that, as the ancient roll or volume usually contained less matter than a modern book, these numbers must be discounted for comparison with modern collections. The first five librarians appear to have been Zenodotus, Callimachus, Eratosthenes, Apollonius and Aristophanes; they cover about a century. Some of the first experiments in bibliography were the catalogues of the Alexandrian libraries. Amongst other lists, two were prepared by order of Ptolemy Philadelphus, one of tragedies, the other of comedies. The πίνακες of Callimachus formed a catalogue of all the principal books, arranged in 120 classes. After the time of Aurelian, the Serapeum became the principal library. The usual statement that the libraries continued to flourish until they were destroyed in A.D. 640 can hardly be supported.

The Pergamum.—German researches in the acropolis of Pergamum (1878–86) revealed four library rooms (Al. Conze, *Die pergamen. Bibliothek.* 1884). Despite the embargo placed by the Ptolemies upon the export of papyrus, the library, when it was transported to Egypt, numbered 200,000 volumes. We learn from Suidas that in 221 B.C. Antiochus the Great summoned the poet and grammarian, Euphorion of Chalcis, to be his librarian.

Rome.—It is not until the last century of the republic that we hear of libraries in Rome, with the exception of the writings of Mago upon agriculture. The first considerable collections of which we hear in Rome were brought there as the spoils of war. The library of Perseus was all that Aemilius Paulus reserved from the prizes of victory (167 B.C.) for himself and his sons. Next came the library of Apellicon the Teian, brought from Athens by Sulla (86 B.C.). The zeal of Cicero and Atticus in adding to their collections is well known. Tyrannion is said to have had 30,000 vols. of his own, and Cicero wrote to M. Terentius Varro: "Si hortum in bibliotheca habes, nihil deerit." The honour of being the first actually to dedicate a library to the public is said by Pliny and Ovid to have fallen to G. Asinius Pollio, who erected a library in the Atrium Libertatis on Mount Aventine. Augustus erected two libraries, the Octavian and the Palatine. The former was founded (33 B.C.) in honour of his sister, the charge of the books being committed to C. Melissus. The Octavian and Palatine libraries perished by fire; the story that the Palatine was destroyed by order of Pope Gregory the Great in the 6th century is now generally rejected. Tiberius, the immediate successor of Augustus, established on the Palatine what Gellius refers to as the "Tiberian library." Vespasian established a library in the Temple of Peace erected after the burning of the city under Nero. Domitian restored the libraries then destroyed, and he, or Hadrian, founded the Capitoline library. The most famous and important of the imperial libraries was that created by Ulpius Trajanus, known as the Ulpian library, afterwards removed to the baths of Diocletian. The library of Domitian, which had been destroyed by fire in the reign of Commodus, was restored by Gordian, who added to it the 62,000 books bequeathed to him by Serenus Sammonicus. In the 4th century there are said to have been 28 public libraries in Rome.

Roman Provincial Libraries.—The library which the younger Pliny gave to Comum cost a million sesterces; Hadrian established one at Athens, described by Pausanias, and recently identified with the Stoa of Hadrian. At Ephesus and at Timgad in Algeria, the structural plan of the library buildings is clear (R. Cagnat, "Les Bibliothèques municipales dans l'Empire Romain," 1906, *Mém. de l'Acad. des Insc.*, tom. xxxviii. pt. 1). A private library discovered at Herculaneum contained 1,756 rolls on shelves round the room, to a height of about 6 ft., with a central press. The Christian libraries closely followed the classical prototypes.

The names of several librarians (generally slaves or freedmen) are preserved to us in inscriptions, including that of C. Hymenaeus, physician and librarian to Augustus.

Constantinople.—When the seat of empire was removed by Constantine to his new capital upon the Bosporus, the emperor established a collection there. Constantine's library, which contained 6,900 vols., was perhaps mainly intended as a repository of Christian literature; it was greatly enlarged by Julian and Theodosius, at whose death it is said to have increased to 100,000 volumes. Julian not only augmented the library at Constantinople, but founded others.

As Christian literature grew, libraries became part of the ecclesiastical organization, and it became the rule to attach one to every church. The largest of these libraries, that founded by Pamphilus (d. A.D. 309) at Caesarea, and said to have been increased by Eusebius to 30,000 vols., is frequently mentioned by St. Jerome. St. Augustine bequeathed his collection to the library of the church at Hippo, which was fortunate enough to escape destruction at the hands of the Vandals. Even the hermit communities of the Egyptian deserts, out of which developed the later monastic orders, accumulated books.

With the removal of the capital to Byzantium the libraries of Rome ceased to collect the writings of the Greeks, while the Greek libraries had never cared much to collect Latin literature. The church became increasingly hostile to pagan letters. The repeated irruptions of the barbarians soon swept the old learning and libraries alike from the soil of Italy. With the close of the Western empire in 476 the ancient history of libraries may be said to cease.

MEDIAEVAL PERIOD

Gaul.—During the first few centuries after the fall of the Western empire, in the West, as in the East, few cared for learning. Sidonius Apollinaris tells us of the libraries of several private collectors in Gaul.

During the 6th and 7th centuries in the Irish monasteries there appear to have been many books. The library of York, which was founded by Archbishop Egbert, was almost more famous than that of Canterbury, and was described in verse by Alcuin. The inroads of the Northmen in the 9th and 10th centuries had been fatal to monastic libraries. The correspondence of Lupus Servatus, a pupil of Hrabanus Maurus at Fulda, and afterwards abbot of Ferrières, illustrates the paucity and dearness of books, the declining care for learning, and the increasing troubles of the time. Charlemagne collected a number of choice books for his private use. Although these collections were dispersed at his death, his son, Louis, formed a library which continued to exist under Charles the Bald. But the greatest private collector of the middle ages was doubtless Gerbert, Pope Sylvester II.

St. Benedict.—For the next four or five centuries the collecting and multiplication of books were almost entirely confined to the monasteries. In each newly-founded monastery there was to be a library, *et velut curia quaedam illustrium auctorum,* that is of religious writers. Monte Cassino became the starting point of a long tradition. Of the reformed Benedictine orders the Carthusians and the Cistercians were those most devoted to literary pursuits. The abbeys of Fleury, of Melk and of St. Gall were remarkable for the splendour of their libraries. The Augustinians and the Dominicans rank next to the Benedictines. The libraries of Ste. Geneviève and St. Victor, belonging to the former order, were amongst the largest of the monastic collections. Richard of Bury praises them for their diligence in collecting books. Sir Richard Whittington built a large library for the Grey Friars in London, and they possessed considerable libraries at Oxford.

Monastic Libraries.—In Italy, the earliest and most famous was Monte Cassino, which fell a prey to the Saracens and to fire in the 9th century. The library of Bobbio was famous for its palimpsests; the collection was mainly transferred to the Ambrosian library at Milan.

Of the monastic libraries of France the principal were those of Fleury, of Cluny, of St. Riquier and of Corbie. The library of St. Riquier, in the time of Louis the Pious, contained 256 mss., with over 500 works. Of the collection at Corbie in Picardy we have also catalogues dating from the 12th and from the 17th centuries. In 1638, 400 of its choicest manuscripts were removed to St. Germain-des-Prés. The remainder were removed after 1794, partly to the national library at Paris, partly to the town library of Amiens.

The chief monastic libraries of Germany were at Fulda, Corvey, Reichenau and Sponheim. The library of Corvey on the Weser, after being despoiled in the Reformation, was presented to the University of Marburg in 1811. The library of Reichenau fell a prey to the Thirty Years' War. The library at St. Gall, formed as early as 816 by its second abbot, still exists.

England.—In England, the principal collections were those of Canterbury, York, Wearmouth, Jarrow, Whitby, Glastonbury, Crowland, Peterborough and Durham. The library of Christchurch, Canterbury, originally founded by Augustine and Theodore, contained, in the 13th or 14th century, about 5,000 works. It was destroyed by the Danes about 867. Of Whitby there is a catalogue of the 12th century. The catalogue of Glastonbury has been printed by Hearne in his edition of John of Glastonbury. The library of Crowland perished by fire in 1091; Peterborough was rich; from a catalogue of about the end of the 14th century, it had 344 vols., with nearly 1,700 titles. The catalogues of Durham have been printed by the Surtees Society. (The oldest catalogue of a Western library is that of the monastery of Fontanelle in Normandy [8th century].) Many catalogues may be found in the collections of D'Achery, Martene and Durand, and Pez, in the bibliographical periodicals of Naumann and Petzholdt and the *Zentralblatt f. Bibliothekswesen.* The Rev. Joseph Hunter has collected some particulars as to the contents of the English monastic libraries; E. Edwards has printed a list of the catalogues (*Libraries and Founders of Libraries,* 1865, pp. 448–454. *See* also G. Becker, *Catalogi Bibliothecarum Antiqui,* [1885].) In the 14th century the Franciscans compiled a general catalogue of the mss. in 160 English libraries, and about 1400, John Boston, a Benedictine monk of Bury, catalogued the libraries of 195 religious houses in England and part of Scotland (Tanner, *Bibl. Brit. Hibern.,* 1748). Leland's list of the books he found during his visitation of the houses in 1539–45 is printed in his *Collectanea.* The identification of the early provenance of mediaeval mss. has been greatly advanced of late years, especially by the works of M. R. James, both by catalogues of existing collections and publications of surviving monastic catalogues, *e.g.,* those of Canterbury and Dover (1909). (*See,* generally, J. W. Clark, *The Care of Books* [1909], and E. A. Savage, *Old English Libraries,* 1911.) These catalogues, with many others, afford abundant evidence of the limited size and character of the monkish collections.

The Development of Library Arrangements.—Modern library methods began with the rule of St. Benedict, early in the 6th century. In the 48th chapter the monks were ordered to borrow a book apiece and to read it straight through. In many houses the treasury or spendiment contained two classes of books —one for the monks generally, one more closely guarded. A press near the infirmary contained books used by the reader in the refectory. By the end of the 15th century the larger monasteries found the necessity of a separate library apartment. Libraries were specially built at Canterbury, Durham, Citeaux, Clairvaux and elsewhere, and there grew up increased liberality in the use of books. By the 15th century, collegiate and monastic libraries were on the same plan, the books being laid on desks or lecterns, and chained to a horizontal bar. As the books increased the accommodation was augmented by one or two shelves erected above the desks. The library at Cesana is still in its original condition. The Laurentian library at Florence was designed by Michelangelo on the monastic model. There were no chains in the library of the Escorial, erected in 1584, which showed, for the first time, bookcases placed against the walls. Chains continued to be used in England in church libraries down to the early part of the 18th century, as at Wimborne. Triple desks and revolving lecterns, raised by a wooden screw, formed part of the library furniture. The English cathedral libraries were fashioned after the same principle. By the end of the 17th century the type of the public library developed from collegiate and monastic prototypes became fixed throughout Europe. The library of St. John's college, Cambridge (16th century), and the Bodleian at Oxford, are slightly developed from the mediaeval type. In that of Trinity college, Cambridge, the walls are covered with books and the windows are raised. (H. R. Tedder, "Evolution of the Public Library," in *Trans. of 2nd Int. Library Conference,* 1897, 1898.)

Arabians.—Greek manuscripts were eagerly sought for and translated into Arabic, and colleges and libraries everywhere arose, notably at Baghdad, Cordova, Cairo and Tripoli. The royal library of the Fatimites in Africa, and that collected by the Omayyads of Spain are reported, perhaps with exaggeration, to have contained 100,000 and 600,000 mss. It is said that there were no less than 70 libraries opened in the cities of Andalusia.

Renaissance.—In the 9th century, under Leo the Philosopher and Constantine Porphyrogenitus, the libraries of Constantinople awoke into renewed life. Meanwhile, in the West we find arising outside the monasteries a taste for collecting books. Charles V. of France formed a considerable library of 910 vols., including much newer literature, and had a catalogue of them prepared in 1373. Guy, earl of Warwick, formed a collection of French romances, which he bequeathed to Bordesley abbey in 1315. Richard of Bury, the doubtful author of the *Philobiblon,* amassed a noble collection. The taste for secular literature and for the classics gave a fresh direction to collectors, and a disposition to encourage literature began to show itself. Cosimo de' Medici formed a library at Venice while living there in exile in 1433, and on his return to Florence laid the foundation of the great Medicean library. Niccolo Niccoli had already, in 1436, left his library of over 800 volumes for the use of the public. Frederick, duke of Urbino, and Poggio Bracciolini, were among the chief collectors of the Latin mss. buried in monastic libraries. Beyond the Alps, Matthias Corvinus, king of Hungary, amassed a great collection of splendid manuscripts. With printing, the modern history of libraries may be said to begin.

MODERN BRITISH LIBRARIES

State Libraries, British Museum.—The British Museum ranks in importance before all the great libraries of the world, except the National Library of France, and excels in the arrangement and accessibility of its contents. The library consists of about 3,200,000 printed vols. and 56,000 mss.; the shelves measure about 55 miles. This extraordinary opulence is principally due to the enlightened energy of Sir Anthony Panizzi (*q.v.*).

The foundation of the British Museum dates from 1753, when effect was given to the bequest (in exchange for £20,000 to be paid to his executors) by Sir Hans Sloane, of his books, manuscripts, curiosities, etc., to be held by trustees for the use of the nation. A bill was passed through parliament for the purchase of the Sloane collections and of the Harleian mss., costing

£10,000. To these, with the Cottonian mss., acquired by the country in 1700, was added by George II., in 1757, the royal library of the former kings of England, coupled with the privilege of obtaining a copy of every publication entered at Stationers' Hall. A lottery having been authorized to defray the expenses of purchases, as well as for providing suitable accommodation, the museum and library were established in Montague House, and opened to the public Jan. 15, 1759. In 1763 George III. presented the Thomason collection (in 2,220 vols.) of Civil War and Commonwealth tracts. The Rev. C. M. Cracherode bequeathed his collection of choice books in 1799, and Sir Joseph Banks his library (16,000 vols.) of natural history and travels, in 1820. Of other libraries since then incorporated in the museum, the most valuable are George III.'s collection, 15,000 volumes of tracts and 65,259 vols. of printed books, which was transferred (for a pecuniary consideration) by George IV. in 1823, and that of the Right Hon. Thomas Grenville (20,240 vols. of rare books, bequeathed in 1846). The Cracherode, Banksian, King's and Grenville libraries are still preserved as separate collections.

The collections of newspapers, starting with those in the Thomason and Burney collections, are unique; provincial newspapers have, since 1906, been stored at a repository at Hendon. Of newspapers published in the United Kingdom 3,126 are annually filed and bound.

The department of mss. is equal in importance to that of the printed books. The collection of *European* mss. contains 54,000 vols., over 80,000 rolls, a rich series of charters, etc., and a vast quantity of papers, ranging from the 3rd century B.C. down to our own times, and includes the *Codex Alexandrinus* of the Bible, the old historical chronicles of England, the charters of the Anglo-Saxon kings, the Arthurian romances, and also unprinted works by English writers. The famous collections of mss. made by Sir Robert Cotton and Robert Harley, earl of Oxford, have already been mentioned, and from these and other sources the museum has become rich in early Anglo-Saxon and Latin codices, such as Beowulf, the charters of King Edgar and Henry I. to Hyde abbey, which are written in gold letters; or the Lindisfarne gospels (A.D. 700), containing the earliest extant Anglo-Saxon version of the Latin gospels. The museum can boast of an early copy of the *Iliad,* and one of the earliest known codices of the *Odyssey.* Among the unrivalled collection of Greek papyri are the unique mss. of several works of ancient literature, such as Aristotle, *On the Constitution of Athens,* the *Mimes* of Herodas, and the *Odes* of Bacchylides. Irish, French and Italian mss. are well represented. For illuminated mss. special reference may be made to the Lindisfarne Gospels, the Bedford Hours, the Sforza Book of Hours, and Queen Mary's Psalter. The collections of local and family history, of maps, and of music are very rich. Oriental printed books (116,000), and mss. (16,200) form, since 1892, a separate department. The collection includes the library formed by Mr. Rich (consul at Baghdad in the early part of the 19th century); the Chambers collection of Sanskrit mss.; and a library of Hebrew mss., including that of the great scholar, Michaelis, and codices of great age, brought from Yemen. The collection of Syriac mss. is important.

The building in which the library is housed was opened in 1857. The reading room is surrounded by book stores placed in iron stacks, the origin of the more modern steel stacks; in these are fitted hanging and rolling auxiliary bookcases. The presses inside the reading-room contain upwards of 60,000 vols.; to those on the ground floor (20,000), readers have direct access. The Natural History Museum, South Kensington, a department of the British Museum under separate management, has a library of books on the natural sciences numbering over 100,000 volumes.

Patent Office and other State Libraries.—The finest technical library in the country is that of the Patent Office in Southampton buildings, London. The library contains 220,000 volumes.

Another special library is the National Art Library, transferred to South Kensington in 1856. It contains about 150,000 vols. and 250,000 photographs. For science there is the library of the Science Museum, South Kensington, which was founded in 1857 (170,000 vols.). It is devoted to pure and applied science; it maintains, besides its own subject catalogue, an index to scientific books and periodicals.

The only other State libraries which are open to the public are those of the Board of Education (50,000 vols.), the Ministry of Agriculture, the Imperial Institute and the Imperial War Museum.

Among the other State libraries in London may be briefly noted as follows:—Admiralty (1700) 100,000 vols.; House of Commons (1818), *c.* 60,000 vols.; House of Lords (1834) 80,000 vols.; India Office (1800) 130,000 printed books and 15,000 mss. and xylographs; Kew, Royal Botanic Gardens (1853), 40,000 volumes.

Outside London the most important State libraries are the national libraries of Scotland, Wales and Ireland. Sir George Mackenzie, of Rosehaugh, may be regarded as the founder of the National Library of Scotland. In 1684 the first librarian was appointed, and in 1686 the books and furniture were valued at upwards of £11,000, exclusive of donations. The library retains the copyright privilege conferred upon it in 1709. Of the special collections the most important are the Astorga (Spanish), purchased in 1824; the Thorkelin collection, relating chiefly to the history and antiquities of the northern nations; the Dietrich collection of German pamphlets and dissertations, and the Barnbougle Scottish collection, presented in 1928 by Lord Rosebery.

Manuscripts number well over 3,000. There are 13 monastic chartularies which escaped the destruction of the religious houses to which they belonged. The mss. relating to Scottish church history include the collections of Spottiswoode, Wodrow and Calderwood. Sir James Balfour's collection and the Balcarres papers consist largely of original State papers of James V., Queen Mary and James VI. The Sibbald papers are largely topographical. The Riddel notebooks illustrate Scottish genealogy. The Magnusson Icelandic mss., purchased in 1825, and some Persian and Sanskrit, with a few classical, manuscripts may be noted. The most important mss. of old poetry are the Bannatyne ms., written by George Bannatyne in 1568, and the Auchinleck ms.

In 1922, the Faculty, finding the maintenance of the general library increasingly onerous, offered it to the Government as a national library of Scotland. The Government accepted the offer in 1923, when an institution towards which movements had been made in Scotland since 1870 received a gift of £100,000 from Sir Alexander Grant, and the necessary act was passed and the library transferred in 1925. The library now contains over 750,000 volumes. The advocates retain the law section.

The National Library of Wales at Aberystwyth, founded in 1907, was opened in 1915. It enjoys the copyright privilege, and now contains nearly 500,000 volumes, classified by the Library of Congress scheme. It is very rich in Welsh manuscripts, including the collection of Sir John Williams, and Wynn of the Gwydyr, Peniarth, Crosswood and Carreglwyd papers. Francis Bourdillon's Romances, and C. Thomas-Stanford's Euclids are among special collections of printed books. The National Library of Ireland, Dublin, was founded in 1877, and incorporates the library of the Royal Dublin Society. It contains about 300,000 volumes, classified on the decimal system, and catalogued in various forms.

University and Collegiate Libraries.—The earliest library of the University of Oxford was in existence in 1337; the second was founded by Humphrey, duke of Gloucester (d. 1447); these perished, and the Bodleian library was founded in 1598 and endowed in 1611 by Sir Thomas Bodley (*q.v.*). He opened the library in 1603 with upwards of 2,000 volumes. In 1610 he obtained a grant from the Stationers' company of a copy of every work printed in the country, a privilege still enjoyed under the Copyright Acts. Other chief benefactors have been Archbishop Laud, John Selden, Richard Gough, Francis Douce, Lord Sunderlin (brother of Edmund Malone) and Richard Rawlinson. The library now contains almost 1,250,000 printed volumes, and about 40,000 manuscripts (other than charters, rolls, etc.). In oriental manuscripts it is, perhaps, superior to any other European library; and it is exceedingly rich in other manuscripts, especially in English literary and local history, and in early printing.

The Radcliffe library of natural science, founded by Dr. John Radcliffe (d. 1714) and opened, in 1749, in the domed building known as the "Radcliffe Camera," was transferred to the new University museum and laboratories in 1860, when the trustees offered the use of the Camera to the curators of the Bodleian; the building was transferred absolutely in 1927. In the Camera are the modern books, and it also serves as a reading-room, especially for undergraduates and in the evening. Departmental libraries forming part of the Bodleian are the Indian institute, the Law library, Maitland library (social and legal history), and Rhodes house (Colonial history).

The Bodleian library is open by right to all graduate members of the university, and to other recommended students. The ordinary expenditure is about £10,000. A large repository has been arranged for book storage underground. A new building with capacity for 5,000,000 volumes has been approved (May, 1936), designed by Sir Gilbert Scott (*q.v.*).

The Taylor institution for modern languages is due to the benefaction of Sir Robert Taylor, an architect (d. 1788). The Finch collection (bequeathed in 1830), is kept with it.

The libraries of the several colleges vary considerably. That of All Souls was established in 1443 by Archbishop Chichele, and possesses 40,000 printed volumes and 300 mss., and is rich in law. The library of Christ Church is rich in divinity and topography. Corpus possesses a fine collection of Aldines, with about 400 mss. Exeter college has classical dissertations and English theological and political tracts. Jesus college has the bequest of Sir Leoline Jenkins and also Welsh mss. Keble college has the mss. of many of Keble's works. Magdalen college has about 22,500 volumes and 250 mss. with scientific and topographical collections. The old library of Merton college (*see* above) now specializes in modern foreign history and philosophy. New college has about 17,000 printed volumes and about 350 mss., including several presented by its founder, William of Wykeham. Oriel college has a special collection on comparative philology and mythology. Queen's college is strong in theology, in modern history, and in English county histories. St. John's college library is largely composed of theology and law before 1750, and medical books of the 16th and 17th centuries. Wadham college has the botanical books bequeathed by Richard Warner (1775) and Benjamin Wiffen's collection on the Spanish Reformers, Worcester college has of late specially devoted itself to classical archaeology. It is also rich in old English drama and poetry, and drawings by Inigo Jones.

The University library at Cambridge dates from the earlier part of the 15th century. Two early catalogues are preserved, the first embracing 52 vols. and dating from about 1425, the second a shelf-list, apparently of 330 vols., made in 1473. The library, which contains about 1,000,000 vols. and 19 miles of shelves, has the copyright privilege. It includes a fine series of *editiones principes* of the classics and of the early productions of English and Netherlandish presses. The mss. number over 10,000, in which are included a considerable number of adversaria or printed books with ms. notes, which form a leading feature in the collection. The most famous of the mss. is the *Codex Bezae* of the four gospels and the Acts, which was presented to the university by Beza himself.

There is a library attached to the Fitzwilliam museum, bequeathed to the university in 1816. It contains printed and ms. music, and a collection of illuminated mss., chiefly French and Flemish. Catalogues and reprints have been published.

Trinity College Library.—The library of Trinity college has over 100,000 printed and nearly 2,000 ms. volumes. Amongst special collections are the Capell collection of early dramatic and especially Shakespearian literature, German theology and philosophy, and the Grylls bequest in 1863 of 9,600 vols., including many early printed books. There are printed catalogues of the Sanskrit and other oriental mss. by Aufrecht and Palmer, of the incunabula by Robert Sinker, and of the Capell collection by W. W. Greg, 1903.

Clare college library includes George Ruggle's early Italian and Spanish plays. The library of Corpus Christi college is famous for the bequest made by Archbishop Parker in 1575. The printed books are less than 5,000 in number; the ancient mss. attract scholars from all parts of Europe. Gonville and Caius college library is of early foundation. The printed books of King's college include the bequest by Jacob Bryant (1804). The mss. are almost wholly oriental. Magdalene college is remarkable for popular literature and for naval mss., the greater portion of which is in the Pepysian library. (*See* PEPYS, SAMUEL.) The library of Peterhouse, the oldest in Cambridge, possesses a catalogue of some 600 or 700 books dating from 1418. It has a unique collection of ms. music. Queen's college library contains about 30,000 vols., and is rich in Semitic literature. The library of St. John's college is rich in early printed books and English history.

The library of the University of London, founded in 1837, now at South Kensington, has over 300,000 vols., and includes the Goldsmiths' Economic (60,000 vols.), and a musical library. Other collections are De Morgan's collection of mathematical books, Grote's classical library, etc.

University college library, Gower street, established in 1829, has 286,000 vols., including Jeremy Bentham's library, Morrison's Chinese library, Barlow's Dante library, collections of law, medicine (including medical history), mathematical, Icelandic, theological, art, oriental and other books.

King's college library, founded in 1828, has over 70,000 volumes. In close association with the University of London is the London School of Economics and Political Science (1896), in which is housed the British Library of Political Science, with 250,000 books and 500,000 pamphlets and official reports. The School of Oriental Studies was established in 1916 in the building of the London institution. The library of Sion college (1635) is rich in liturgies, Port-Royal authors, etc., and contains about 200,000 vols. classified on a modification of the decimal system. The copyright privilege was commuted in 1835.

English Provinces.—The Rothamsted Experimental Station has an agricultural library of 20,000 volumes. The other English universities and colleges have libraries; the chief are: Manchester (205,000 vols.); Birmingham (120,000 vols.); Liverpool (100,000 vols.); Leeds (98,000 vols.); Sheffield (83,000 vols.); Bristol (70,000 vols.), absorbing in 1924 the library of the Bristol Medical Chirurgical Society (1831); Durham (39,000 vols.) has many incunabula. That of Exeter is combined with the City library. The Association of University Teachers established in 1925, at Birmingham, an enquiry bureau for the University libraries, to act as a centre for mutual lending; this it is intended to transfer when possible to the central library for students. The University libraries share in the grants made by the Government's Universities Grants committee. A few of the libraries of theological colleges and public schools are important and have historical collections, incunabula, etc., such as Oscott college (1838), 36,000 vols.; Stonyhurst college (1794), *c.* 40,000 vols.; Shrewsbury school, 7,000 vols., etc.

Scotland.—The University library of Edinburgh originated in a bequest of books made to the town in 1580 by Clement Little, advocate. In 1831 the books were removed to the present building. Modern accessions have been the Halliwell-Phillips (Shakespeare), the Laing (Scottish mss.), the Baillie (oriental mss.) and the Hodgson (political economy). The library now consists of about 350,000 vols. of printed books, with over 8,000 mss.

All schools and colleges in Scotland are well equipped with libraries. The oldest University Library, St. Andrews (1456) contains well over a quarter of a million volumes. Glasgow (15th Cent.) has 255,000 volumes; Aberdeen (1500) 260,000 volumes. Among others are New College, Edinburgh (1843), 50,000 volumes, and Royal Technical College, Glasgow, 16,000 volumes.

Ireland.—In 1601 the English army, to commemorate their victory at Kinsale, subscribed £1,800 to establish a library in the University of Dublin. Later bequests and gifts have been Sir Jerome Alexander's (law books and mss.), 1674; Palliser, 1726; Gilbert, 1736; and Quin (classical and Italian), 1805. In 1802 the collection of 20,000 vols. formed by the pensionary Fagel, was acquired. The library enjoys the copyright privilege. After the recognition of the Irish Free State the right was confirmed. The library now contains 386,000 vols. and over 2,000 mss. There is no permanent endowment. There is a printed catalogue of the mss. (1900) and incunabula (1890).

Queen's college, Belfast (1849), has about 101,000 vols.; Queen's college, Cork (1849), 100,000; University college, Dublin, 65,000; and St. Patrick's college, Maynooth (1795) about 55,000. (*See* L. Newcombe, *The University and College Libraries of Great Britain and Ireland*, 1927.)

Cathedral and Church Libraries.—With one or two exceptions, libraries are attached to the cathedrals. Intended for the cathedral or diocesan clergy, they are in most cases open to persons suitably introduced. Many have valuable mss., but most were ravaged in the Civil War, and the printed collections are the work of antiquarian deans of the 18th century. That of St. Paul's cathedral was founded in very early times, and now numbers some 22,000 vols. and pamphlets, with a good collection of early Bibles and Testaments, Paul's Cross sermons, and works connected with the cathedral (catalogue 1893).

For the library of Christ Church, Oxford, which belongs alike to the college and the cathedral, *see* above. That of Durham, 20,000 vols., dates from monastic times, and possesses many of the books which belonged to the monastery. The collection is fairly general, and is kept up to date. It is especially rich in very early mss., written at Durham. The library at York is open to the public, has many valuable mss. and early printed books. It includes Edward Hailstone's topographical library (catalogue of pr. bks., 1896). The foundation of the library at Canterbury dates probably from the time of Augustine, but nothing of the pre-Conquest library survives. Many of the mss. originally here were transferred by Archbishop Parker to Corpus Christi college, Cambridge (catalogue 1743 and 1802, of mss. 1911). The present building was erected in 1867. The Lincoln cathedral library (catalogue 1859, of incunabula 1925, of mss. 1927) was refounded by Dean Honeywood, at the Restoration, in a building by Wren. Chichester dates from the Restoration only; Ely is rich in the non-jurors. Exeter possesses many Saxon mss., including the "Exeter Book" of Old English poetry, the gift of Leofric, the first bishop. At Lichfield the existing library is post-Restoration, but includes the famous Evangeliary of St. Chad. The collection at Norwich is chiefly modern. The earlier library at Peterborough being almost destroyed in the Civil War, Bishop White Kennett refounded it, but many of his books have been lost. Salisbury is rich in incunabula (catalogue 1880). Winchester cathedral library is mainly the bequest of Bishop Morley (17th century). The library at Bristol was burnt and pillaged in the riots of 1831. At Chester, in 1691, Dean Arderne bequeathed his books and part of his estate "as the beginning of a public library for the clergy and city." The library of Hereford (catalogue of mss., 1927) is a good specimen of an old monastic chained library; Worcester has fine mss. (catalogue, 1906, and of incunabula, 1910). The four Welsh cathedrals were supplied with libraries by a deed of settlement in 1709. All are small; the largest, St. Asaph, has about 1,750 volumes. That founded by Archbishop Leighton in 1684 in Dunblane cathedral (2,000 vols.), is the only cathedral library in Scotland of any historic interest. The public library established about 1694 in St. Patrick's cathedral, Dublin, by Archbishop Marsh, was incorporated in 1707, and endowed by its founder at his death in 1713. The books are chiefly theological and include the libraries of Bishop Stillingfleet and of Elias Bouhereau, the first librarian. In 1849 Beriah Botfield published *Notes on the Cathedral Libraries of England.*

The best Catholic libraries in London are those of Brompton Oratory (1849—35,000 vols., 3,000 pamph.) and Westminster cathedral (22,000 vols. and valuable archives). The archiepiscopal library at Lambeth palace (41,000 printed books and 1,300 mss.) has been enriched by the gifts of Laud, Tenison, Manners Sutton, and others of his successors. It is rich in theology and Church history. Of the illuminated mss., and early printed books, catalogues have been issued by S. R. Maitland (1792–1866). The mss. are described in H. J. Todd's catalogue, 1812, and the older volumes by M. R. James, 1900.

Endowed Libraries.—In London the Bishopsgate institute (1891), founded out of City charities, contains about 50,000 vols., and a fine collection of prints, drawings and maps of London. The Cripplegate institute (1896) in Golden lane, also founded out of charity monies, has three branches—St. Bride institute; the Queen street, Cheapside, branch; and St. Luke's institute. The St. Bride Foundation Technical Reference Library (1895) is a very complete collection of about 30,000 vols. on printing and allied arts. Dr. Williams's library (over 75,000 vols.), founded in 1716 by the will of Dr. Daniel Williams, is primarily theological, and has been enlarged to include philosophy, history and literature, with collections of theosophy and of the works of Boehme, Law, and other mystics. The mss. include the original minutes of the Westminster Assembly, letters and treatises of Richard Baxter and the journals of Crabbe Robinson.

The most notable of the English provincial endowed libraries are those of Manchester. That founded by Humphrey Chetham in 1653 is still housed in its old collegiate buildings (100,000 vols. and mss.). More important is the John Rylands. In 1928 the John Rylands had 310,000 vols. and 10,000 mss., including the 6,000 Crawford mss. from Haigh Hall, bought in 1901, and 20,000 French Revolution broadsides, etc., presented by the earl of Crawford in 1924. Other considerable endowed libraries are the William Salt, Stafford (20,000 vols. of Staffordshire history) opened 1874; the Solon Ceramic library, Stoke-on-Trent (5,500 vols. and 100 current periodicals); St. Deiniol's (1894), Hawarden, founded by W. E. Gladstone; and the Shakespeare Memorial (1879), Stratford-upon-Avon.

The oldest endowed library in Scotland is the Innerpeffray, Perthshire (1680), founded by David Drummond, 3rd Lord Madertie. The most important is the Mitchell in Glasgow, founded by Stephen Mitchell (1874), opened in 1877. It contains valuable collections of Scottish poetry, Burns' works, Glasgow printing, and art. It contains over 250,000 vols., and is the reference library for the Glasgow public library system. Glasgow also has Stirling's and Glasgow Public Library (1791), which was amalgamated with an existing subscription library (60,000 vols.) and Baillie's Institution Free Reference library (24,000 vols.) established under the bequest of George Baillie (1863), but not opened till 1887. The public library of Armagh, Ireland, was founded in 1770.

Libraries of Societies and Learned Bodies.—Full particulars of most will be found in R. A. Rye's *Libraries of London: a Guide for Students* (3rd ed., 1927), and a more summary guide, covering the whole country, in the *Aslib Directory*, 1928.

Of the law libraries, that at Lincoln's Inn, London, is the oldest and the largest (72,000 vols.). That of the Middle Temple contains 70,000 vols. The library of the Inner Temple is known to have existed in 1540. Its chief collections are William Petyt's mss., received in 1708, John Adolphus's historical pamphlets, and the Crawford collection on crime. There are about 62,000 vols. Gray's Inn library (30,000 vols.) was established before 1555. The Law Society (1828) has 62,000 volumes. The Royal Institution of Great Britain (1803), possessing a general reference subscription library of about 150,000 vols., was closed in 1916, its oriental section remaining to help found the London University School of Oriental Studies, while its Western books went to the university and college libraries.

The best library of archaeology is the Society of Antiquaries', Burlington House, 60,000 vols., many mss. and early printed books. For natural sciences there are the libraries of the Royal Society (1667), in Burlington House, which contains over 100,000 vols., mainly publications of scientific bodies (the celebrated Arundel bequest, dating from the society's infancy, has been dispersed), Geological Society (1807), 40,000 vols. and maps; the Linnean Society (1788), 50,000 vols.; the Zoological Society (1829), about 36,000 vols. The Royal Society of Medicine (1907), incorporating a number of medical societies, 120,000 vols.; the Royal College of Physicians (1525), 40,000 vols.; the British Medical Association, 20,000 vols.; the Royal College of Surgeons (1800), 60,000 vols.; the Medical Society (1773), largely historical, 20,000 vols.; the Chemical Society (1841), over 30,000 vols. Other important London society libraries are the Royal Geographical Society (1830), 80,000 vols., and numerous maps, open to the public for reference; the Royal Colonial Institute (1868), 184,000 vols. of British colonial literature; the Royal United Service institution, Whitehall (1831), 32,000 vols., belles-lettres, politics and history. The Gladstone library (31,000 vols. and pamph.) of the National Liberal Club may be used occasionally by non-members; the Garrick (a small dramatic collection), and the (Senior) United Service Club (Dugald Stewart's library) may be mentioned. Very few club libraries are supervised by trained librarians. Libraries are owned by the British and Foreign Bible Society (catalogue of Bibles, 1903–11), the Institution of Civil Engineers (53,000 vols.), the Institution of Electrical Engineers (25,000 vols.), the Royal Academy (10,500 valuable vols.), the Royal Institute of British Architects (23,000 vols.), and many others.

The library of the Writers to the Signet (1722), now contains about 150,000 vols., with early prints and other rare books, especially in British topography.

The library of the Royal Irish Academy at Dublin (1785, 50,000 vols. and over 2,000 Irish mss.), is partly supported by a Government grant and is freely open.

Among subscription libraries, the London library (300,000) stands first in order of importance. It was founded in 1841 as a lending library for the use of scholars, largely at the instance of Carlyle. Author and subject catalogues have been printed, the latter of great value.

The first circulating library in Birmingham was opened in 1757, and was followed by Liverpool Lyceum (1758) and Warrington's (1760), both merged in the museum, and by Leeds (1768).

Other proprietary libraries have been established at Leicester, Liverpool (Athenaeum, 1798), Manchester, Newcastle, Belfast (the Linen Hall library), Nottingham and elsewhere. In Scotland the first subscription library was started by Allan Ramsay, the poet, at Edinburgh in 1725. Commercial subscription libraries have increased greatly, Mudie's (1841), W. H. Smith's, and *The Times* Book Club being typical modern examples.

Many of the principal clubs possess libraries; that of the Athenaeum (London) is by far the most important. It now numbers about 75,000 vols. of choice books. The pamphlets (of which also there is a complete printed catalogue), include those collected by Gibbon and Mackintosh. Next comes the Reform club, with about 60,000 vols.

Public Libraries.—The first act of parliament authorizing the establishment of public libraries in England was obtained by William Ewart, M.P., in 1850. In 1853 the act of 1850 was extended to Ireland and Scotland.

The Public Libraries Amendment Act of 1919, besides establishing the county as a library unit, removed the rate-limit in England and Wales. The American library in 1928 was spending roughly four to five times as much per head as the average British library.

British Library Legislation.—The main points in British library legislation are as follows:—(*a*) The acts are permissive and not compulsory. (*b*) Municipal libraries are managed by committees appointed by the local authorities, who may delegate to them all their powers and duties. Glasgow has contracted them out by a special act. In Ireland, committees are appointed much as in England. (*c*) Power is given to provide libraries, museums, schools for science, art galleries and schools for art. (*d*) The regulation and management of public libraries are entrusted to the library authority, which may either be the local authority or a committee with a full or partial delegation of powers.

The London Government Act, 1899, by uniting various vestries or boards, extinguished about 23 library areas. The Metropolitan County of London in 1928 comprised 27 library areas, or, counting also the City, 28.

From 1887 progress has been rapid. An immense stimulus was given from about 1900, when Andrew Carnegie (*q.v.*) began to present library buildings to towns in England as well as to Scotland and the United States. In 1926, 57 out of 62 counties, 81 out of 82 country boroughs, all metropolitan boroughs, 232 out of 249 municipal boroughs, 732 out of 792 urban districts, and 12,660 out of 12,841 are, by adoption or inclusion, library areas under the acts. But 49 urban areas, with a population of 580,000, had then no library service, nor in 1925 had half the rural population of the country.

Building Developments and Equipment.—The Carnegie Trust, in 1917, ceased to make grants, and in 1925 decided to consider no further applications. The total sum expended by the trust on public library buildings in 1914–26 was £295,600. In every case "open access" was adopted, and stress was laid upon accommodation for children. Good specimens may be seen at Manchester and Croydon. Great improvements were effected in design. Card catalogue and subject-lists have almost entirely taken the place of printed catalogues. Library policy has, also, become far more liberal than it was before the World War. Of the greatest importance to business men has been the establishment in great city libraries, since 1919, of commercial and technical departments, notably those of Birmingham, Manchester, Liverpool and Glasgow.

There is one important municipal library which is not rate-supported under the Public Libraries Acts. This is the Guildhall reference library of the Corporation of the City of London. A library was established for London by Sir Richard Whittington between 1421–26. But it did not remain without accident; about 1549 the Lord Protector Somerset carried off three cart-loads of books, and during the great fire of 1666 the remainder together with the buildings were destroyed. Nothing was done to repair the loss until 1824; a new library was opened in 1828.

The library (nearly 200,000 printed vols. and nearly 15,000 mss. in 1928) includes a special collection of books, prints and drawings about London, the Solomons Hebrew and rabbinical library, the National Dickens library, etc., and the libraries of the Clockmakers' and Gardeners' companies and of the Old Dutch church in Austin Friars.

British Library Administration.—A brief statement of the work and methods of public libraries in the United Kingdom will help to give some idea of the extent of their activities. In 1909 60 million vols. were circulated every year for home-reading, 54% representing fiction, including juvenile literature. The reference libraries issued over 11 million vols., exclusive of books consulted at open shelves, and to the reading-rooms, 85 million visits are made per annum. It is evident, moreover, that a complete revolution in library practice has been effected since 1882. Very little had been accomplished in the way of scientific classification schemes, although the decimal method of Melvil Dewey had been applied in the United States. Dewey's system is now in use in 180 public libraries, J. D. Brown's "subject" classification in 59; the later but important library of Congress system in about five.

A complete catalogue of a general popular library contains no addition to bibliography, is costly and is out of date the moment it is printed. Modern libraries therefore compile complete catalogues only in manuscript form, and issue cheap class-lists, supplemented by lists of recent accessions.

The idea of using separate clips or cards for cataloguing books, in order to obtain complete powers of arrangement and revision, is not new, having been applied during the French revolutionary period. The card system is perhaps the most generally used, but many improvements in the adjustable binders, called by librarians the "sheaf system," already begin to make this latter form a serious rival. The card method consists of a series of cards, each bearing one entry, kept on edge in trays or drawers, to which projecting guides are added in order to facilitate reference. The sheaf method provides for slips of a uniform size being kept in book form in volumes capable of being opened by means of a screw or other fastening, for the purpose of adding or withdrawing slips. Both sides of a slip may be used, while a number of entries may be made on one slip. For great research libraries, however, the catalogue in volumes, though expensive to keep up to date, is the easiest to use.

In the United States, practically every library has its open shelf collection. On the continent of Europe, however, this method is rare. The first "safeguarded" open access municipal lending library was opened at Clerkenwell (now Finsbury), London, in 1893. Every year several municipal systems are reorganized in this way, and nothing but local lack of funds prevents the universal adoption of the system.

In America losses are sometimes enormous, one library having confessed to a loss of 35,000 volumes in a single year. The precautions of the British plan are automatic locking wickets for entrance and exit, and registration of borrowers. The great majority of British and American libraries use cards for "charging" or registering books lent to borrowers.

Various Activities of Libraries.—Other activities of modern libraries which are common to both Britain and America are courses of lectures, drawing attention to the books in the library, book exhibitions, work with children, provision of books for the blind and for foreign residents, travelling libraries and the education of library assistants. In some districts (*e.g.*, Leicester) the libraries keep public elementary schools supplied with books, over which the teachers are able to exercise supervision. Under the Law of Property Amendment Act, 1924, all manorial documents were placed under the charge of the master of the rolls, who could order their deposit in authorized repositories. Many public libraries and some of local societies were so designated, and the care of archives received a great stimulus; their study had, since 1919, been included in the curriculum of the School of Librarianship, and was added in 1927 to that of the Library Association.

Excellent work has been accomplished within recent years by the Library Association and the University of London School of Librarianship in the training of librarians.

The report of the departmental committee on public libraries, 1927, is the best survey of the field since that of 1849. The committee aimed at stimulating backward authorities by showing what is done in more favoured places. They were opposed to putting the libraries under the education authorities. The effect of the report was to outline a co-ordinated national system of public libraries, consisting of the urban libraries and the county libraries, with their village and small town branches, all these working together in regional schemes of co-operation, and beyond them the Central Library for Students acting as a reserve for out-of-the-way books, and acting as the centre for mutual loans between a large circle of special libraries, and the public libraries. The report obtained general approval, notably that of the Library Association. In the same year the Scottish Library Association appealed to the secretary of State for Scotland to appoint (and the minister of finance in Northern Ireland appointed) similar committees to make enquiry and report on the library service in those countries.

(X.; A. Es.)

COUNTY LIBRARIES

Whilst the library movement made notable headway during the last quarter of the 19th century, largely through the generous financial encouragement of Andrew Carnegie, the 28 years that followed have witnessed a greater, and, since 1918, a much more rapid advance. Before this date the service was severely handicapped by two restrictions: the one penny rate limit, which, except in the largest cities, precluded anything like adequate expenditure on books and salaries, and the almost total impossibility of applying the Public Libraries Acts in the smaller centres of population. An admirable statistical report, setting forth in detail the anomalies and difficulties of the situation, was prepared by Prof. W. G. S. Adams and published by the Carnegie United Kingdom Trust in 1915. From this it was manifest that the position in the towns could not be remedied without the removal of the rate limit, and the only hope for the rural areas was in some broad scheme of co-operation. The Library Association had persistently agitated for new legislation, with the former object as the most urgent item. Pending action by the Government, the Carnegie Trustees now set up a number of circulating systems on a regional basis, as an experiment and an object lesson to show how the rural problem should be solved.

Legislation.—The position of these rural systems was regularized in Scotland by the Education (Scotland) Act of 1918, empowering county education authorities to make book provision for children and young persons attending schools or classes, and for adults. The subject was also dealt with in an interim report by the adult education committee of the Ministry of Reconstruction; and, almost immediately, the Public Libraries Act of 1919 was passed, authorizing county councils to adopt the acts, to levy a rate, and provide a library service through their education committees. Similar powers were granted in Northern Ireland by the Public Libraries Act of 1924, and in the Irish Free State by the Local Government Act of 1925.

Success of the County Library System.—Hitherto, such rural library systems as had been established, were financed by the Carnegie Trustees, who continued to offer to defray the capital expenditure of county councils which were willing to adopt the acts. During the period 1915–27, the grants made by the trustees for this purpose in Great Britain totalled £263,785, with some supplementary grants for the period ending in 1930. Further sums are being allocated to Irish county libraries, and grants are made from time to time for special objects. In their report issued in March 1928, the trustees show that 22 English, three Welsh and six Scottish counties are now independent of their assistance, and will henceforth rely entirely on public funds. Thus it is obvious that the progress of the system has been extremely rapid, only five counties, by the end of 1926, not as yet adopted the Public Libraries Acts, one of these being London, where there is no area not already provided for by previous adoption of the acts, and the other Westmorland, which has a scheme based on the Kendal public library. The rate of this expansion is indicated by the figures given in the report of the Public Libraries Committee set up by C. P. Trevelyan, then president of the Board of Education, in 1924, which completed its proceedings in 1927. In 1911 the population in England and Wales resident in library areas amounted to 62·5% of the total. The percentage rose to 68·8 by 1921, to 90·4 by 1924, and by 1926 to 96·3. Of this last figure, the urban library service accounts for 64·1%, and the county systems for 32·2%. Thus only 3·7% of the population now reside in areas for which there is as yet no provision and none even contemplated. The committee therefore propose that the remaining county councils should be constituted library authorities for their areas; and, further, that those councils which have excluded certain populous areas, covered by towns or urban districts, should be constituted library authorities for the whole. The result would be to bring in a further population of 1,332,000. The report pointed out, however, that a library area does not necessarily imply a library service, and that, so far as they were able to ascertain, in 1925 only about one-half of the 12 millions dwelling in county library areas were actually enjoying a library service.

The system began with the periodical supply of boxes of books to village centres, usually in schools, and the boxes were sent by railway or other carriers. An increasing number of counties now have their own motor-vans, which are fitted with shelves and form small travelling libraries, affording the local volunteer librarian some opportunity of choosing books on the spot. Here and there, local interest or the philanthropy of some well-wisher has resulted in the formation of small stocks of reference books, and even the opening of a village reading-room. Special provision is usually made, so far as resources permit, for adult classes, and special collections are formed for teachers. The problem of the community of 10 to 20 million inhabitants embraced by a county area is gradually being solved by the method of differential rating, small libraries of the municipal type being established in such places. Middlesex is an excellent example of the policy of co-ordinating the municipal library and the rural system. Two other experiments that will be watched with attention are being carried out in Cornwall and Northern Ireland. In Cornwall, seven borough and two urban district libraries have been brought into a co-operative scheme for the whole county. The Belfast library has been encouraged by a liberal grant from the Carnegie Trustees to become the centre of a regional scheme of co-operation for the whole of Northern Ireland. Merely fractional rates, as low as one-tenth to one-fourth of a penny were raised by the county authorities in the first instance. In some places these have risen to a half-penny, or even more. But it is admitted that the county services are seriously under-financed, and that as the public realizes the benefits and opportunities within their scope a much more liberal provision will be demanded.

Post-war Developments.—In both county and town, progress since the act of 1919 would have been far greater but for the general anxiety to keep down the rates. That act abolished the rate limit in England and Wales, and next year the limit in Scotland was raised to threepence, and in Ireland the same, with an extension to sixpence in county boroughs. (In Northern Ireland the penny rate limit was re-established in county council areas, with a possible differential rating for urban districts, to a maximum of threepence, with Government consent.) Most of the municipal libraries proceeded to levy rates in proportion to their necessities. But, with the increase in the prices of books, other expenses, and the persistent demand for retrenchment, it has been difficult to maintain efficiency in municipal libraries at the high level desired, and the pay of the assistant is still inconsistent with the idea that he is entering a learned profession. The public libraries committee offer various recommendations for the general improvement of the service, particularly by schemes of co-operation; but they were not of opinion that the urban libraries should be transferred to the education committees, or that the numerous library districts in the metropolis should be unified under the London County Council. Only one member pressed for the latter reform.

The Central Library for Students.—Most important among these schemes for general or local co-operation was the plan for developing the Central Library for Students, as a national library forming a special department of the British Museum, to be a supplemental supply to the municipal and county libraries throughout England and Wales (Scotland and Ireland being supplied from the depôts at Dunfermline and Dublin), and to undertake such other urgent duties as the preparation of a union catalogue, the organization of an information bureau, and the issue of periodical book-lists. This library was started in 1917, largely to provide books for adult classes; but has grown from a collection of 3,000 books to a collection of 37,560, a large proportion of them costly works, supplying, in 1927, no less than 465 libraries with books they were unable to afford. The Central Library is mainly financed by an annual subsidy of £3,000 from the Carnegie Trustees. By a mutual arrangement with a large number of outlier libraries, comprising various public libraries, and such important research libraries as the Science library at South Kensington, those of the London School of Economics, the Linnaean, Folk-Lore, and Royal Asiatic Societies, the Society of Antiquaries, the Royal Colonial and Royal Anthropological Institutes, and the Royal Irish Academy, it is able to satisfy the needs, not only of students, but also of advanced research in all parts of the country. The public libraries committee outline a system of co-operation in which public libraries would be grouped round regional centres, usually the great urban libraries, with a federation of special libraries pooling their resources, and a central library acting as centre of the whole system. They recommend that an interim grant of £5,000 a year should be made by the Government to the Central library to establish it on a sound basis, and that the Science library should have an additional £3,500 a year to enable it to act in co-operation as the central supply for research students in science. The aggregate cost to the national exchequer of their proposals for the development of the Central library and of the Science library, and of the agency for central cataloguing, would not exceed £12,000 a year; and the benefit to scholarship, research, industry and commerce would be incalculable.

Co-operation with Special Libraries.—The growth in numbers and extent of special libraries of all kinds has been remarkable during the period reviewed. The valuable work of the Association of Special Libraries and Information Bureaux, established in 1925, has been a main factor in promoting this; and the publication of their Directory, "Aslib" (1928), another work financed by the Carnegie Trustees, is an immense benefit to librarians and users of libraries, since it is the first systematic survey of the special library resources of the nation. Similarly, the work of the joint standing committee on (university) library co-operation is doing much to facilitate the mobilization of the resources of university and other learned libraries, and the publication of the *World List of Scientific Periodicals* has materially contributed to the same object.

Librarianship.—The Library Association, which for many years had striven to raise the educational status of workers in libraries, and had held lectures, correspondence classes and examinations, with that purpose, appealed in 1917 for the establishment of a day school within the University of London, for the regular training of librarians. With the support of the Carnegie Trustees, who undertook to provide £1,500 a year for the first quinquennium, the School of Librarianship was opened at University college, London. A reduced grant was made for the second quinquennium, the balance required being made up by the university senate. According to the latest report, 549 students have been admitted to the school during the nine years covered, including many part-time students engaged in library work in the London area. A large and increasing number of these were already graduates of various universities. Easter and summer schools have been held both at home and abroad, with excellent results. The influence of the school in raising the educational standard of librarianship, improving salaries, and increasing the proportion of women, relatively to men, employed in libraries, has been considerable. The recent Government report is emphatic on the need for improved educational qualifications for librarians, and urges that the School of Librarianship, which is performing a national service, should be maintained, and that it "would appear to have a strong claim on the funds which the university receives from the State." An appeal for a permanent endowment fund has recently been launched. Classes in librarianship have also been started at Manchester, mainly for the benefit of assistants in that neighbourhood, and at Dublin for Irish students. Many library authorities now require a sound standard of general education from entrants to the service, and the Library Association specifies the matriculation standard for candidates for its certificates.

Other Library Developments.—The only obstacle to a general advance, after the Government report of 1927, as rapid and epoch-making as that which followed the Government report of 1919, is the present demand for economy. Great events are pending, and will probably, in a few years, be matters of history. The British Museum, in spite of the great extensions of a few years back, is still cramped for space; a large part of the interior is about to be reconstructed, and it is proposed to enlarge the Hendon repository and remove all newspapers there. Cambridge has decided to remove the University Library to a new building. Oxford is about to settle the problem of the Bodleian by erecting an additional building across Broad street and a repository at Jordan Hill for material not in constant request. What is healthiest at the moment is the intense interest aroused by the many-sided problems opened up by the growth of libraries, and by the widening consciousness of the immense part they must play in every department of life. The adoption of a more active policy by the Library Association, coupled with the appointment of a full time paid secretary and the acquisition of permanent headquarters, where they will probably soon be joined by other bodies having cognate interests, should help to a concentration of effort in the right direction. (E. A. Ba.)

BRITISH DOMINIONS

The majority of the British Dominions have permissive library laws. The rate limit is not so strict in every case. There is, for example, no rate limit in Tasmania; and South Australia may raise a library rate equivalent to threepence in the £. In Africa, Australia and Canada the Governments make grants to public libraries. The Canadian and Australian libraries are administered more or less on American, and those of South Africa, India, etc., on English lines.

Africa.—There are several important libraries in South Africa. The oldest library is the South African public library at Cape Town, established in 1818, which enjoys the copyright-privilege for the Cape (100,000 vols.). This library contains the collection of colonial books bequeathed by Sir George Grey. This and the Pretoria State library form together the National library; the legislatures have libraries, notably the Parliamentary library, Cape Town, which includes the Mendelssohn Collection of Africana. The chief public libraries are at Port Elizabeth, Kimberley, Durban, Bloemfontein, Bulawayo, Germiston, which has a country circulating system, and Johannesburg, the only really free public library. All charge a subscription for borrowing. The Education Department supports school libraries. The University library of Cape Town was being greatly developed in 1928. That at Pretoria deserves mention (40,000 vols.). (A summary of the literature of South African public libraries, by P. Freer, will be found in *The Library Assistant*, 1928.) In North Africa there are considerable collections at Cairo, especially the Royal library (1879) 107,000 vols., 23,000 mss., 500 papyri, and at Algiers, the latter under French control.

Australia.—The various States legislate for libraries independently, and maintain libraries. The Commonwealth library at Canberra was founded in 1927. The State public libraries circulate books to institutes, etc., in the country; Victoria subsidized local libraries. The local public libraries are those of Victoria at Melbourne, 1853 (421,000 vols.); of New South Wales, at Sydney, 1867 (401,000 vols., including the Mitchell library); this was an old subscription library bought by the Government; of South Australia, at Adelaide (139,000 vols.); of Queensland, at Brisbane, 1896 (34,200 vols.); and of West Australia, at Perth, 1860 (142,000 vols.). The university libraries are Sydney (180,000 vols., including the fine Fisher collection, 1885); Adelaide (70,000 vols.), which assists in control of the public library; Melbourne (60,000 vols.); and Brisbane (30,000 vols.).

Tasmania.—Only Hobart (Tasmanian Public library, 1849) had in 1925 used the large powers given by the act of 1867.

New Zealand.—In New Zealand there are 13 public libraries, established under acts dating from 1869 to 1877, which allow a penny rate. At Auckland the Turnbull Free Public library (1880) has Sir George Grey's Australasian collection and many rare books (140,000 vols.), Christchurch, 1859 (44,000 vols.) and Wellington, 1893, are the next largest. Wellington has the General Assembly library. The university library of Otago, Dunedin, 1872, is the chief academic library.

India and the East.—The chief library in India is the Imperial library at Calcutta (152,000 vols.). At Calcutta the Sanskrit college has 1,652 printed Sanskrit vols. and 4,000 Sanskrit mss., and many Jain mss.; Madras University library has a new and handsome building. The library of the Asiatic Society of Bengal was founded in 1784 (35,000 vols. and 20,000 mss.). The Geological Survey's library has 50,000 vols.

The Bombay branch of the Royal Asiatic Society (1804) has 100,000 printed vols. and 2,000 mss. The Moolla Feroze library (bequeathed 1831) is chiefly of mss., in Arabic and Persian. There are libraries attached to Elphinstone college and the Universities of Allahabad and Lahore (54,000 vols. each), Dacca (46,000 vols.), and Bombay (1864, 35,000 vols., including the Fawcett Economic library). The library of Tippoo Sahib, consisting of 2,000 mss., fell into the hands of the British (catalogue 1809).

Perhaps the most remarkable library in India is that of the raja of Tanjore, which dates from the end of the 16th or beginning of the 17th century. There are now about 18,000 mss. written in Devanagari, Nandinagari, Telugu, Kannada, Granthi, Malayalam, Bengali, Panjabi, or Kashmiri, and Uriya; 8,000 are on palm leaves. Dr. Burnell's printed catalogue describes 12,375 articles.

The Royal Asiatic Society has branches, with libraries attached, in many of the large cities of India and the Far East. At Rangoon there are several good libraries. The Raffles library at Singapore collects books relating to the Malayan peninsula and archipelago. In Ceylon there is the Museum library at Colombo (1877, with 15,000 vols.). The All-India Public Library Association, formed in 1923 to spread the public library movement throughout India, by means of provincial library associations, a quarterly journal, periodical conferences, the issue of pamphlets, and the training of librarians. In Baroda, Travancore, Pudukottai and Mysore the State helps liberally, and the movement has made progress. In British India hardly any Government help is forthcoming, save for libraries under State management in capital cities.

Palestine.—The chief library is the Hebrew National and University library (1925), 136,000 vols., which contains the Goldzieher Hebrew and Klein mathematical collections, and publishes a quarterly review, *Kiryath sefer*.

Canada.—The most important public library is that of Toronto (1883), which has over 400,000 vols., and includes a notable children's department in a separate building, and which compiles the annual *Canadian Catalogue* of new books since 1921–22 (published 1923); the central reference building was, in 1928, about to be rebuilt.

There were in 1909, 413 public libraries described as 131 free and 234 not free. The other most important libraries in Ontario are:—Queen's university, Kingston (1841), 150,000 vols., rich in Canadian history; Library of Parliament, Ottawa, about 300,000 vols., Legislative Library of Ontario, Toronto (1867), about 150,000 vols.; University of Toronto (1856), 220,000 vols. and 77,000 pamphlets.

In the province of Quebec, there are several large and important libraries, among which may be mentioned the Fraser institute, Montreal (1885), 103,000 vols.; McGill university, Montreal (1855), 268,000 vols., comprising many important collections; the Seminary of St. Sulpice, Montreal, about 223,000 vols.; Laval university, Quebec, 173,000 vols.; and the Library of the Legislature (1792).

In the province of British Columbia, under an act of 1919, a public library commission governs the six public libraries, 23 "public library associations," and 386 travelling libraries, and in 1928 was surveying the system (*Report* for 1926–27).

In Nova Scotia there is a system of circulating books among the school libraries. The Legislative library at Halifax incorporates that of the Nova Scotia Historical Society (1878). The school law of New Brunswick provides for grants to school libraries; in the West Indian islands, the Institute of Jamaica, Kingston (1879) and the Trinidad Public library (1841) should be mentioned. (X.; A. Es.)

LIBRARY SCHOOLS

The first school in the world established solely for the professional training of librarians was started at Columbia college, New York city, in 1887, by Melvil Dewey, then librarian of the college. Dewey's plan for a school for the training of librarians had been presented to the American Library Association as early as 1883, but was opposed by some of the leading librarians. Opposition gradually gave way, however, as the value of formal professional training for library workers was demonstrated, and other schools were established in various parts of the country, beginning with the Pratt Institute School of Library Science in 1890. In 1915 the Association of American Library Schools was organized, with ten charter members, for the purpose of maintaining standards of instruction. By 1921 three additional schools had been admitted to the association. Only five of these schools were conducted under the auspices of a college or university of standard grade, and with some of them the university affiliation was merely nominal. About 1920 a demand for university standards became perceptible, and culminated, in 1924, in the creation by the American Library Association of a board of education for librarianship, one of the principal functions of which was to be the formulation of minimum standards for library schools. Under the standards recommended and adopted by the American Library Association in 1925, the schools were classified as junior undergraduate, senior undergraduate, graduate and advanced graduate. All but one of the 13 schools have been accredited by the board, and, in addition, two others. About 8,500 students have completed at least the first year's work in the accredited schools.

For admission to a junior undergraduate school one year of college study is required, and three years for the senior undergraduate, while a bachelor's degree, in addition to other qualifications, is required by the graduate schools. The junior undergraduate schools grant a certificate on the completion of a one-year course. For three years of college study and one year of library school study a bachelor's degree is usually given by the senior undergraduate schools. Most of the graduate schools give a certificate for the first year's work, although two grant a second bachelor's degree for the first year of library school study. Four university schools grant the degree of M.A. or M.S. The curricula are made up of three types of subjects, the bibliographical, technical and administrative. While many other courses are given, from one-half to two-thirds of the student's time is devoted to bibliography and bibliographical method, reference service and book selection. The first year course is largely prescribed, although some of the schools offer elective courses. Specialized courses in library work with children were offered in at least five schools. (C. C. Wi.)

SPECIAL LIBRARIES

With a view to greater accessibility of special resources, the American Association of Special Libraries was formed in 1909, and has issued a directory (2nd ed. 1925). The formation of a corresponding British Association has already been recorded, and a similar directory was published by this body in 1928.

In Great Britain, during 1910–26 there was a great development of scientific, technical and commercial libraries and bureaux of information. The same movement has developed in America, probably to an even larger extent, though in that country the public library has, until recently, undertaken a larger proportion of this kind of service. Of great importance in this connection are compilations like the *World List of Scientific Periodicals* (1926–27), and the *Subject Index of Periodicals* (1915).

Mercantile Marine.—The British Sailors' Society has attempted this service for more than a century. Since 1920 it has revived and developed its arrangements under the stimulus of a Carnegie Trust subsidy. The Seafarers' Education Service (founded 1920), also with the aid of a trust grant, and contributions from the owners and the men's unions, has succeeded in placing substantial libraries of a more advanced kind upon ships. The Carnegie Corporation of New York has similarly financed the American Merchant Marine Library Association. In Great Britain a system of supply to lighthouses and lightships was initiated by the Carnegie Trust, with the aid of the public authorities concerned.

Libraries for the Blind, etc.—In Great Britain the needs of the blind have been met by the establishment of the National Library for the Blind in London, founded in 1882. It was severely damaged by the Thames flood of 1928. Books in Moon or Braille type are lent freely to public libraries, and individual readers. A sectional library for deaf education was set up in the library of the University of Manchester in 1920. Hospital collections are distributed under the auspices of the Red Cross Society. A collection for the use of nurses and health visitors has been set up by the College of Nursing (1921).

FRANCE

Besides the unrivalled libraries of the capital, France possesses a remarkable number of provincial libraries. In 1857 there were 340 departmental libraries with an aggregate of 3,734, 260 printed vols. and 44,436 mss. In 1908 the printed books had increased to over 20 million and are now probably 30 million at least.

Paris.—The Bibliothèque Nationale (formerly Bibliothèque du Roi, Royale, or Imperiale), is, perhaps, the finest library in the world. The real foundation of the institution may be said to date from the reign of King John, the Black Prince's captive, who bequeathed his "royal library" to his successor, Charles V. Charles V. removed the library from the Palais de la Cité to the Louvre, where it was arranged on desks in a large hall of three storeys by the first librarian and cataloguer, Claude Mallet, the king's valet-de-chambre. His *Inventaire des Livres du Roy nostre Seigneur estans au chastel du Louvre* is extant, as well as the inventories made by Jean Blanchet in 1380, and by Jean le Begue in 1411 and 1424. Charles VI. added some hundreds of mss. to the library, which, however, was sold to the regent, duke of Bedford, after a valuation had been established by the inventory of 1424, transferred to England, and finally dispersed at the regent's death in 1435. Charles VII. did little to repair the loss, but under Louis XI. another library was created; the first librarian was Laurent Paulmier, and Jean Foucquet of Tours was named the king's *enlumineur*. Charles VIII. enriched it with many fine mss. executed by his order, and also with most of the library of the kings of Aragon, seized by him at Naples. Louis XII. incorporated the Bibliothèque du Roi with the fine Orleans library at Blois, and further enriched it by plunder from Pavia, and by the purchase of the Gruthuyse collection; it was described at this time as one of the four marvels of France. François I. enlarged and removed it to Fontainebleau in 1534. He set the fashion of fine bindings, which was still more cultivated by Henri II., and which has never died out in France. During the librarianship of Amyot the library was transferred from Fontainebleau to Paris. Henri IV. removed it to the Collège de Clermont, but in 1604 another change was made, and in 1622 it was installed in the Rue de la Harpe. Under J. A. de Thou it acquired the library of Catherine de' Medici, and the Bible of Charles the Bald. In 1617 a decree ordered the deposit of two copies of every new publication, but this was not enforced till Louis XIV.'s time. The first catalogue worthy of the name was finished in 1622, describing some 6,000 vols., chiefly mss. Many additions were made during Louis XIII.'s reign, notably that of the Dupuy collection, but a new era dawned under Louis XIV. Colbert, one of the greatest of collectors, so enlarged the library that it became necessary to make another removal. It was therefore, in 1666, installed in the Rue Vivien (now Vivienne). The departments of engravings and medals were now created, and were soon important. Nic. Clément made a catalogue in 1684 according to the arrangement still used (in 23 classes, each designated by a letter of the alphabet), with an alphabetical index. After Colbert's death Louvois employed Mabillon, Thevenot and others to procure books, etc., from all parts of the world. A new catalogue was compiled in 1688 in 8 vols. by several scholars. Towards the end of Louis XIV.'s reign it contained over 70,000 volumes. Under the Abbé Bignon the library was removed to its present home in the Rue Richelieu. Between 1735 and 1739 a catalogue in 11 vols. was printed, and duplicates were sold. In Louis XVI.'s reign the La Vallière sale yielded many valuable accessions. A few years before the Revolution the printed books numbered over 300,000 vols. and opuscules. The Revolution increased the library, now called the Bibliothèque Nationale, and the other State libraries, with the forfeited collections of the *émigrés*, as well as of the suppressed religious communities, which by enactments of 1789–92 were gathered into "dépôts littéraires." (*See* below opening of account of provincial libraries.) In the difficulties made by such numerous acquisitions Van Praet showed himself a great administrator. Napoleon increased the Government grant; and by the strict enforcement of the law of deposits, as well as by the acquisition of collections, the library progressed, under him, towards his idea of universality. At the beginning of the century it held 250,000 printed vols., 83,000 mss., and 1,500,000 engravings. After 1815 the mss. which he had taken from conquered capitals had to be returned. After the World War, with the fall in the value of the franc, the library was seriously impoverished. A new administrator, P. Roland-Marcel, mitigated poverty by various means: (1) a "consortium," under a joint council, of the library with the other chief Parisian national libraries, *i.e.*, the Mazarine (which became the 5th department of the Nationale), the Sainte-Geneviève, and the Arsenal, and later, the University of Paris, by decrees of Aug. 29, 1923, and Dec. 28, 1926, purchases of books and periodicals being divided between them; (2) the library, and then the group, were by laws of April 28, 1927, and March 5, 1928, given the status of "civil personality," carrying the right to hold funds, (3) the loi du dépôt légal was amended, with the result of greatly enlarging the receipts of current French books; the weekly catalogue of accessions of new French books was amalgamated with the list of new publications issued by the trade ("Bibliographie de la France"); (4) the "salle ovale" or "salle de lecture publique," rendered less important by the development of the public libraries of the arrondissements of Paris, was, in 1928, being converted into a periodical room, equipped with (5) a bureau of information, the main feature of which is an index of the special collections in all French libraries; (6) a "service de prêts," or central exchange for loans of books between libraries, whether in France or between France and other countries, established in 1927; (8) an "Office de documentation et de recherches bibliographiques," established by the Society of Friends of the Bibliothèque Nationale. These developments greatly increased the library's effectiveness. But the sum available for purchases of printed books in 1927 (130,228 fr.) did not allow of any purchases of old or rare books.

Riches of the Bibliothèque Nationale.—According to the statistics for 1926–27 the riches of the Bibliothèque Nationale may be enumerated as follows:—(1) Imprimés: more than 4,400,000 vols., accessions in 1927, 13,215 vols. (apart from maps, music, periodicals, etc.); maps and plans, 500,000 in 28,000 vols. (2) Manuscrits: 122,000 mss. (3) Estampes: 3,015,000 pieces. (4) Médailles, 248,500 pieces.

Admittance to the "salle de travail" is obtained through a card procured from the secretarial office. The slip catalogue bound in volumes dates from 1882, and gives a list of all accessions since that date; it is divided into two parts, one for the names of authors and the other for subjects. Of the *Catalogue général des livres imprimés* (authors only), 91 vols., A.-Lecompte, had appeared in 1928. It is expected to be completed in 11 years. Anonyma, periodicals, etc., are reserved for later treatment. The preface to vol. i., by L. Delisle, is a valuable historical account of the library. The place of the unpublished volumes was, from 1925, supplied by a photographic issue of the ms. slips of the classed catalogue. Other exceptionally important catalogues, out of very many, are: *Catalogue de l'histoire de France* (1885–89, 11 vols.); *Table des auteurs, Catalogue général des incunables des bibliothèques publiques de France,* by M. Pellechet and L. Polain, t. i.–iii. A.–H. (1897–1909); *Livres d'Heures imprimés au XVe siècle conservés dans les bibliothèques publiques de Paris,* by P. Lacombe (1907), etc. L. Vallée's *Catalogue des cartes et plans relatifs à Paris et aux environs de Paris* (1908); *Bibliographie générale des travaux historiques et archéologiques publiés par les sociétés savantes de la France,* by R. de Lasteyrie in collaboration with d'E. Lefèvre-Pontalis, S. Bougenot, A. Vidier, t. i.–vi. (1885–1908); H. Omont's *Catalogue général des manuscrits français* (1895–1918, 13 vols., and index in the press, 1928). For the Greek collection important catalogues have been made by H. Omont, the present keeper of the manuscripts, and for the Latin by Delisle, M. Omont and others. For many oriental languages catalogues have been compiled; and those of manuscripts in modern languages are nearly all completed. The Départements des Médailles et des Estampes possess excellent catalogues. The former department includes vases, bronzes and gems; the catalogues of the Greek and Early French series are remarkable. The Département des Estampes has been described in the vicomte H. Delaborde's *Le Département des Estampes à la Bibliothèque Nationale* (1875); it includes drawings. F. Courboin's *Catalogue sommaire des gravures et lithographies composant la Réserve* (1900–01) is supported by many fine special catalogues. A list of works on and of the catalogues of the Bibliothèque Nationale, and most other French libraries, may be found in A. Vidier, *Annuaire des Bibliothèques et des Archives,* 1927, pp. 13–38. The second copy of every new French publication deposited by the printer is allotted by the Council of the National Libraries to one of the other institutions represented upon it.

The Bibliothèque de l'Arsenal was founded by the marquis de Paulmy (Antoine-René d'Argenson) in the 18th century; in 1786 it received 80,000 vols. from the duc de La Vallière's library. It contained, in 1926, about 950,000 vols., 11,462 mss., with the Bastille collection (2,500 portfolios) of which the inventory is complete, and 120,000 prints; it is the richest library for the literary history of France and has more than 30,000 theatrical pieces, including the Auguste Rondel collection, added in 1922, and, accordingly, it receives belles lettres in the allotment of deposited books.

The Bibliothèque Mazarine owes its origin to the great cardinal, who confided the direction to Gabriel Naudé; it was open to the public in 1642. Dispersed during the Fronde, it was reconstituted with 40,000 vols. after Mazarin's death, in 1661, and left to the Collège des Quatre-Nations, which, in 1691, made it again public. It is now one of the libraries of the national "consortium," and forms a 5th department of the Nationale; it has 300,000 printed vols., including 1,900 incunabula, and 4,600 mss.

The first library of the Genovéfains had nearly disappeared when Cardinal François de la Rochefoucauld, who had charge of the reformation of that order, constituted, in 1642, a new library with his own books. The Bibliothèque Ste.-Geneviève, in 1716. possessed 45,000 vols. It became national property in 1791, and was called the Bibliothèque du Panthéon and added to the Lycée Henri IV. under the Empire. In 1926 it contained 510,000 printed vols., 1,225 incunabula, 3,872 mss., 40,000 prints and 4,000 maps and plans. There is a special Scandinavian section under the patronage of the Governments of the four Scandinavian countries, which, in turn, appoint the librarian. The general catalogue of printed books (1891, and suppl. to 1910), of mss. (1894–96, and suppl. 1913), and others are printed.

Official.—The Bibliothèque du Ministère des affaires étrangères contains 90,000 vols., 300,000 pamphlets and 500,000 documents. The Bibliothèque du Ministère de la Guerre, formed by Louvois, possesses 180,000 vols. and 861 mss. The École supérieure de la Guerre (70,000 vols.) and other institutions come under this department. The Bibliothèque et Musée de la Guerre, founded after the World War, has 110,000 vols., apart from periodicals, documents, maps, etc. The Bibliothèque du Ministère de la Marine is of old formation (catalogue 1838–43); it contains 60,000 vols. and 376 mss.; the catalogue of manuscripts was compiled in 1907. The Service hydrographique has 70,000 vols., and 391 mss. The Bibliothèque de la Chambre des députés (1796) possesses 350,000 printed books and 1,622 mss. (printed catalogue of law and political economy, 1883, and of mss., 1907). The Bibliothèque du Sénat (1818) contains 170,000 vols., and 1,345 mss. There are also the following law libraries: Office de législation étrangère (80,000 vols.); Faculté de droit of the University (172,000 vols.); Cour d'appel, Ordre des avocats (1871), 80,000 vols. (printed catalogue, 1880–82); avocats de la Cour de Cassation, and Cour de Cassation. The City of Paris owns, among other libraries, the Bibliothèque Historique de la Ville de Paris, destroyed in 1871 but restored in 1872 (about half a million vols.); the Forney (industrial art), and those of prefectures, hospitals and schools. The arrondissements have each from three to six popular libraries, the stocks ranging from 2,000 to 17,000 vols., and averaging about 6,000. A few have children's libraries. The Association des Bibliothécaires Français in 1928 urged a development of popular public libraries in France generally.

Educational.—The library of the university is that of the Sorbonne (1762), originally including only arts and theology. In 1800 it was the Bibliothèque du Prytanée, in 1808 des Quatres Lycées, and in 1812 de l'Université de France. The faculty sections now are: (1) Sciences et des Lettres à la Sorbonne, (2) Médecine, (3) Droit, (4) Pharmacie. Before the separation of Church and State there was also (5) Protestant Theology. After the Bibliothèque Nationale, it is the richest, and above all in the fields of classics, archaeology and literature, philosophy, mathematics and physics. Installed since the year 1897 in the New Sorbonne, it is a library of the very first rank. The section of Sciences et Lettres has 700,000 printed books and 1,590 mss. Amongst important bequests are those of Leclerc, Peccot, Lavisse, Derenbourg and Beljame (the last including an important Shakespearian library).

At the Sorbonne are also to be found the libraries of the laboratories, notably the geological. The section relating to medicine, housed since 1891 in the new buildings of the Faculté de Médecine, includes 337,000 vols. and 85 mss. The Bibliothèque de la Faculté de Droit (1772), contains 172,000 vols. The fourth section, Faculté (formerly École supérieure) de Pharmacie, greatly developed since 1882, now contains 61,000 vols. The section of art and archaeology contains 100,000 vols., recently enriched by the gift of the Jacques Doucet library.

The other libraries connected with higher education include that of the École des Beaux-Arts (40,000 vols., 100,000 reproductions, 14,000 drawings); École normale supérieure (1794), has a portion of Cuvier's library, there are 400,000 vols.; École des Chartes (50,000 vols.). The library of the Muséum d'histoire naturelle (18th century) has 225,000 vols., 2,300 mss., 8,600 original drawings on vellum from 1631. The Bibliothèque de l'Office et Musée de l'Instruction publique (formerly Musée pédagogique), 1880, has 100,000 volumes. The other principal museums (Louvre, Cluny, Guimet, etc.) have large working libraries for the curators and students. In 1760 was founded the Bibliothèque de l'Institut de France, which is very rich; its acquisitions come particularly from gifts and exchanges (600,000 vols., 4,369 mss.), especially the modern one, the Fondation Thiers (75,000 vols. and 1,000 mss.), is attached to the Institut. Among other libraries may be mentioned those of the Conservatoire National de Musique et de Déclamation (1775); Observatoire (25,000 vols.); Institut Catholique (180,000 vols.); Conservatoire national des arts et métiers (60,000 vols.); Polonaise (attached to the Académie polonaise des sciences et lettres) containing the musée Adam Mickiewcz (120,000 vols., 12,000 mss. and autographs, 30,000 prints); and the Comédie Française (30,000 vols. and 1,700 mss.).

Before the Revolution there were, in Paris alone, 1,100 libraries with two million volumes. In 1791 more than 800,000 vols. were seized in Parisian religious houses and transferred to eight "dépôts littéraires," while, in the provinces, six million vols. were seized and transferred to similar local depositories. The organization of the central libraries (decree of 3 Brumaire An IV.–Oct. 25, 1795), came to nothing, but the consular edict of Jan. 28, 1803, organized the local depots, and the library system was reconstituted, alike in Paris and the provinces. Many precious books and mss. were burnt, since by the decree of 4 Brumaire An II. (Oct. 25, 1793) the Committee of Instruction ordered, on the proposition of its president, the deputy Romme, the destruction or modification of supposedly feudalist books and objects of art.

The books in public provincial libraries, numbered, in 1910, over 9,200,000 vols., 15,540 incunabula and 93,986 mss., and the number of printed books was probably nearly doubled by 1928. The number in the colonies and protected States outside France is uncertain, but in 1910 was over 200,000 vols.; to this must be added the 2,428,954 vols. then contained in the university libraries, now, doubtless, more than doubled, even without reckoning that of Strasbourg, transferred from Germany. There are over 300 departmental libraries, and as many belong to learned societies. Nearly all are administered under State control by municipalities. The collections distributed from the depots after 1803 remain State property, and the 42 libraries in which these "fonds d'État" preponderate are "classed" by the Ministry of Public Instruction; the librarians of these have higher qualifications and are less subject to local control than those of the "unclassed." They are organized by a law of 1897, and, like the universities, are subject to the inspectorate of the Ministry and its consultative commission, established in 1909. This body controls professional qualifications, and publishes collective catalogues (as of mss. and incunabula) and technical instructions.

Old Municipal Libraries.—In most towns there are, besides the learned and historical "bibliothèque de la ville," popular lending libraries, privately founded, but since 1874 subsidized, supplied with books and inspected by the Ministry. In one or two departments there is the beginning of a rural circulating system. Most municipal libraries date but a short time before the Revolution, but there are exceptions. Thus Angers owes its first collection to Alain de la Rue about 1376; it now contains 92,170 vols., 71 incunabula and 2,120 mss. That of Bourges dates from 1466 (45,900 vols., 325 incunabula, 485 mss.). That of Carpentras was established by Michel Anglici between 1452 and 1474 (83,000 vols., 184 incunabula, 2,154 mss.). Mathieu de la Porte is said to be the founder of the library at Clermont-Ferrand, at the end of the 15th century; it contained rather more than 49,000 vols. at the time of its union with the Bibliothèque Universitaire.

Amongst the libraries which date from the 16th century must be mentioned that at Lyons, founded by François I. in 1527; it possesses 600,955 vols., 897 incunabula and 9,730 mss. (many catalogues printed).

In the 17th century were established the following libraries: Abbeville, by Charles Sanson in 1685; Besançon, by Abbé Boisot in 1696; La Rochelle, by the Consistoire Réformé in 1604; St. Etienne, by Cardinal de Villeroi.

The principal libraries founded during the 18th century are the following: Aix-en-Provence (1705); Bordeaux (1738); Chambéry (1736); Dijon (1701); Grenoble (1772); Marseilles (1799); Nancy (1750); Nantes (1758); Nice (1786); Nîmes (1778); Niort (1771); Perpignan (1759); Rennes (1733); Toulouse (1782). The World War wrought very great havoc among the libraries of the northern departments. The libraries of Arras, Douai, Péronne, Rethel, Saint-Quentin, Compiègne, Noyon, Verdun, and many other places were wholly or largely destroyed; that of Reims was mainly removed to safety.

Nearly all the other municipal libraries date from the distribution of the dépôts littéraires in 1803. Those of Avignon, Montpellier, Caen, Rouen, Tours, and Versailles are specially important; in a second rank come Amiens, Auxerre, Beaune, Brest, Douai, le Havre, le Mans, Orleans, Pau, Poitiers, Toulon.

The Ministry of Public Instruction has published joint catalogues of certain classes, e.g., *Catalogues des mss. des bibliothèques de Paris et des Départements* (1885), and the *Catalogue Général des Incunables des Bibliothèques Publiques de la France,* by Marie Pellechet and M. L. Polain (vols. i.–iii., A. H.). The old university libraries, scattered and thrown into the depôts at the Revolution, were re-established by acts of 1875, 1879 and 1882, when Jules Ferry united the faculty libraries in each of the 17 academic districts in one university; civil personality, carrying financial autonomy, followed in 1896. The Bibliothèque Nationale et Universitaire, formerly the Universitäts und Landesbibliothek, of Strasbourg, founded in 1871 to replace that burned in the Franco-Prussian war, is the largest provincial university library (1,700,000 vols., 1,900 incunabula, 4,759 mss., 5,000 papyri), Others are: Aix, Algiers, Besançon, Bordeaux, Caen, Clermont, Dijon, Grenoble, Lille, Lyons, Marseilles, Montpellier, Poitiers, Rennes, Toulouse. That of Nancy was totally burned ten days before the Armistice of 1919. The library profession is organized by central legislation, starting from a royal ordinance of 1839, which assigned one-third of the higher posts to trained "archivistes-paléographes." Municipal librarians are appointed by the mayors. The prefect of the Seine appoints those of the City of Paris, since 1904 exacting certain technical training. The "classed" libraries are seeking complete nationalization, on the lines of the organization of the archives, and the establishment of a single certificate of training (Ch. Mortet, "The Public Libraries of France," in *Library Assoc. Record,* 1925, pp. 145–159).

The Association des Bibliothécaires Français (founded in 1906, its bulletin, 1907, now forming part of the *Revue des Bibliothèques*) actively promotes library reform.

GERMANY (WITH AUSTRIA AND SWITZERLAND)

Germany is emphatically the home of large libraries; there is no law of deposit wider than the individual States, and Saxony and some less important parts of the Reich have no law of deposit at all. To supply the lack of a single library, where all German books may be preserved, the national book-trade union, the Börsenverein der Deutschen Buchhändler, established one, the Deutsche Bücherei, in Leipzig in 1913; this is subsidized by the Reich, the Saxon State, and the city, and the books are deposited freely by a voluntary agreement of the publishers. It had 675,000 vols. in 1928. There is an active professional body, the Verein deutscher Bibliothekare, which, since 1902, has published a valuable year book. In 1921 the Austrian association joined the German. The number of German universities has tended to multiply considerable collections; 1,617 libraries were registered by P. Schwenke in 1891. The *Jahrbuch der deutschen Bibliotheken* for 1927, which gives statistics and administrative details of 395 German libraries, makes a total of 41,000,000 vols.; in 1909 W. Erman had reckoned 190 libraries and 23,500,000 volumes.

The State and university libraries are under State control. The earlier distinction between these two classes has become less and less marked; thus the university libraries are widely used and books are borrowed extensively, especially in Prussia. In 1924 was promulgated the Leihverkehrsordnung für die deutschen Bibliotheken, which authorized and organized mutual lending between all libraries in the country. Owing to financial exhaustion and the depreciation of the currency under 1918, German libraries were unable to acquire foreign publications, and in 1920 there was founded the Notgemeinschaft der deutschen Wissenschaft (emergency union of German learning); to secure files of recent foreign journals, to organize exchange, and to distribute foreign publications among the German libraries. By edict of Jan. 5, 1926, a national exchange bureau (Reichaustauschstelle) was formed in the Ministry of the Interior, to serve the same purposes as the Smithsonian institution.

Popular libraries (Volksbüchereien) exist in most towns, Karl Preusker formed a plan for setting them up in 1839, and four were founded in Berlin in 1850. After 1890 a number of popular libraries were established, some by municipalities, but many by associations and firms. In 1907 the Berlin City library was founded; it now has 20 districts and 90 branches, with 400,000 books. Hamburg also has a large system.

Most of the States have a consultative office for popular libraries, and the Deutsche Zentralstelle für Volkstümliches Büchereiwesen acts as a centre. The Verband Deutscher Volksbibliothekare (founded in 1922 as the Deutscher Büchereiverband) publishes an annual directory (1926). Very few Volksbuchereien, however, attempt the work of the public library of English-speaking countries, and the expenditure on them is only a halfpenny per head. In Prussia since 1907, and in Baden since 1928, a council deals with library matters at the Ministry of Public Instruction. Generally, the State does not concern itself with the town libraries and the popular libraries, but there is much in common between these two classes. Sometimes popular libraries are under the supervision of a scientifically administered town library, as in Berlin, Danzig, etc; elsewhere, as at Magdeburg, we see an ancient foundation take up the obligations of a public library. In Prussia from 1893, and in Bavaria, regulations are in force as to the professional education of librarians. This regulation has been in force as regards librarians in Bavaria from 1905. Throughout Germany librarians are divided by qualifications into three grades. There are schools of librarianship at Berlin (1921, founded at Göttingen in 1886), Munich, Leipzig, Freiburg and Bonn.

Libraries in Berlin.—Berlin is well supplied with libraries, 268 being registered by P. Schwenke and A. Hortzschansky in 1906, with about five million printed volumes. The largest of them is the State (formerly Royal) library, which was founded and made public by the "Great Elector," Frederick William, in 1661. From 1699 the library became entitled to a copy of every book published within the royal territories, and it has received many valuable accessions by purchase and otherwise. It now includes 2,128,707 printed vols. and 56,810 mss. Current catalogues of accessions since 1892, and of the Prussian University libraries, also since 1898, of academic publications of German universities, etc., are printed. The catalogues of mss. are mostly in print, vols. 1–13, 16–23 (1853–1905). The library is specially rich in oriental mss. The musical mss. are very remarkable and form the richest collection in the world as regards autographs. The building, erected about 1780 by Frederick the Great, rebuilt in 1909 and since added to, houses the University library and the Academy of Sciences. There is a regular system of mutual lending, established by ministerial edict of Jan. 27, 1893, between the State library and a great number of Prussian libraries. This is the same in Bavaria, Württemberg and Baden; the oldest system is that between Darmstadt and Giessen (dating from 1837).

Conducted by the State library are the *Gesamtkatalog der Preussischen wissenschaftlichen Bibliotheken* (describing the printed books in the Royal library and the Prussian University libraries in one general catalogue upon slips), the Auskunftsbüro der Deutschen Bibliotheken (founded in 1905 to give information where any particular book may be consulted), and the Kommission für den Gesamtkatalog der Wiegendrucke (a complete catalogue of books printed before 1500), of which 3 vols. out of 12 or more, appeared by 1928. For most of these improvements and for many others credit is due to Friedrich Althoff, for 25 years Prussian minister for education.

The University library (1831) numbers 381,000 vols., exclusive of dissertations. The library possesses the right to receive a copy of every work published in the province of Brandenburg.

Some of the governmental libraries are important, mostly those of Berlin, especially those of the War Office (363,000 vols.), Statistisches Landesamt (260,344 vols.); Reichstag (277,500 vols.); and Patent-Amt (257,000 vols.).

The Prussian University libraries outside Berlin include Bonn (511,380 printed vols., 2,140 mss.), Breslau (545,305 printed vols., 4,570 mss.), Göttingen, from its foundation, in 1736–37, the best administered library of the 18th century (734,949 vols., 8,134 mss.), Kiel, Königsberg, Marburg, Münster. Largely in consequence of the impoverishment of the years after 1918 the university libraries practise a division of the field of knowledge: according to Dr. Balcke. (C. Balcke "The German Library World," in *The Library Association Record*, 1927, pp. 101–121, the only recent general account of German libraries; this section is in part based upon it.) Bonn collects Romance, Göttingen English, Kiel Scandinavian, Breslau Slavonic, Heidelberg art and archaeology, Königsberg philosophy, Leipzig Italian and oriental, Tübingen theology and oriental, Berlin German and foreign academica, and Griefswald Low German. Under provincial administration are the (formerly) Königliche und Provinzialbibliothek at Hanover (232,000 printed vols., 4,083 mss.), and the Landesbibliothek at Cassel (230,000 printed vols., 4,400 mss.). Frankfurt a/M., Cologne and other large towns possess excellent municipal libraries.

Munich.—The libraries of Munich include two of great importance. The State (formerly Royal) library was founded by Duke Albrecht V. of Bavaria (1550–79), who made numerous purchases from Italy, and incorporated the libraries of the Nuremberg physician and historian Schedel, of Widmannstadt, and of J. J. Fugger. The number of printed vols. is estimated at 1,580,000 and about 50,000 mss. The library has 16,000 incunabula, many from the monastic libraries closed in 1803. The oriental mss. are numerous and valuable, and include the library of Martin Haug. The catalogue of the printed books are in manuscript; printed catalogue of mss. (1858). The University library (850,000 vols., 4,000 incunabula, 4,000 mss., 45,000 vols. on reference shelves) was originally founded at Ingolstadt in 1472, and removed with the university to Munich in 1826. After these two the most noteworthy is the Bayrische Armee-Bibliothek (156,950 vols.).

The chief Bavarian libraries outside Munich are the State (formerly Royal) library at Bamberg (400,000 vols., 4,320 mss.) and the University library at Würzburg (600,000 vols., 1,750 mss.). The University of Erlangen, Augsburg and Nuremberg have large libraries; at the last is also that of the Germanisches National museum (300,000 vols., 4,000 mss.).

Dresden.—In 1906 there were in Dresden 78 public libraries with about 1,495,000 volumes. The Sächsische (formerly Königliche) Landes-bibliothek in the Japanese palace was founded in the 16th century, specializes in history and literature, and has 694,800 vols. and 460,000 pamphlets, with 7,000 mss.

Leipzig University library has 675,000 vols.; the Pädagogische Central-Bibliothek der Comenius-Stiftung (283,010 vols.) is perhaps the largest educational library in the world. The Deutsche Bücherei has already been mentioned. The University library of Tübingen (713,589 vols. and 4,409 mss.) is the largest library in Württemberg.

Stuttgart.—The Royal Public Library of Stuttgart (1765) possesses 481,236 vols., 263,041 pamphlets, and 6,797 mss., with a famous collection of Bibles. The library also enjoys the copy-privilege in Württemberg. The former Royal private library, founded in 1810, contains about 105,000 vols.

Darmstadt.—The former Grand-ducal library of Darmstadt, now the Hessische Landesbibliothek, was established by the grand duke Louis I. in 1819, on the basis of a 17th century library, and includes 678,651 vols. and 3,857 mss.

Among the other libraries of Hesse the chief are the University library at Giessen and the Stadtbibliothek at Mainz (including the Gutenberg museum).

In the Grand Duchy of Baden are the Badische (formerly Hof- und) Landes-Bibliothek at Carlsruhe (276,947 vols., 4,830 mss.), the University libraries at Freiburg i./B. (420,000 vols., 700 mss.), and Heidelberg (1386), the oldest of the German University libraries. In 1623 the whole collection of the last named was given to the pope, and only the German mss. were returned. The library was re-established in 1703, and after 1800 enriched with monastic spoils; it now contains 928,301 vols., apart from dissertations etc., 3,721 mss., and about 5,200 papyri, for the most part of great value.

In other German States should be mentioned Jena, Rostock, Schwerin, Weimar, all possessing rich collections of mss.

The Ducal library of Gotha was established by Duke Ernest the Pious in the 17th century, and contains many valuable books and mss. from monastic collections. It numbers about 250,000 vols., with 7,728 mss. The catalogue of the oriental mss., chiefly collected by Seetzen, and forming one-half of the collection, is one of the best in existence.

The Herzog August (formerly Landes) library at Wolfenbüttel, founded in the second half of the 16th century by Duke Julius, was made over to the university of Helmstedt in 1614, whence the most important treasures were returned to Wolfenbüttel in the 19th century; it now numbers 350,000 vols., and 8,400 mss., and is exceptionally rich in incunabula.

The chief libraries of the Hanse towns are those of Bremen, Lübeck and Hamburg (Staats- und Universitats- formerly Stadtbibliothek), made public since 1648 (680,000 vols., 12,652 mss., among them many Mexican). Hamburg has also, in the Kommerzbibliothek (175,000 vols.), a valuable trade collection.

Austria.—The *Adressbuch der Bibliotheken der Oesterreichungarischen Monarchie,* by Bohatta and Holzmann (1900), described the libraries of the Austro-Hungarian empire. The largest library in Austria, and one of the chief in Europe, is the Nationalbibliothek (before 1920 Hofbibliothek) (1440), including a portion of the library of Matthias Corvinus. Since 1808 the library has also been entitled to the copy-privilege. The number of printed vols. is 1,210,000; 9,000 incunabula. The mss. amount to 27,000 (2,360 oriental), with 100,000 papyri of the collection of Archduke Rainer. The main room is one of the most splendid in Europe. The collection of prints was separated from the books in 1921 and annexed to the Albertina. The University library of Vienna (1775) 1,050,000 vols., was established by Maria Theresa, and is open to all; this library also lends.

The number of libraries in Vienna enumerated by Bohatta and Holzmann is 165; 25 of the chief are described by R. Teichl, *Wiener Bibliotheksführer und Plan* (1926).

The number of monastic libraries in Austria is very considerable. They possess altogether more than 2,500,000 printed vols., 25,000 incunabula and 25,000 mss. The oldest library in Austria is that of the monastery of St. Peter at Salzburg (785–821), 70,000 vols., nearly 1,500 incunabula. Kremsmünster (100,000), Admont (86,000) and Melk (70,000), date from the 11th century. Account of their mss. appear from time to time in *Zentralblatt für Bibliothekswesen.* Many of their librarians are trained in the great Vienna libraries.

Switzerland.—Among the Swiss libraries, which numbered 2,096 in 1868, there is none of the first rank. The University library at Basle (1460) the Cantonal library at Lausanne, and the Stadtbibliothek at Berne, which, since 1903, is united to the University library of that city, the Landes-Bibliothek (Bibliothèque Nationale) at Berne, and the City library of Geneva, are considerable. All the Swiss literature since 1848 is collected by the Landes-Bibliothek at Berne, established in 1895 for this special object. There is now no legal, but only a voluntary, deposit of Swiss books. Older Helvetiana are collected in the subsidized Bürgerbibliothek at Lucerne. The monastic libraries of St. Gall (830) and Einsiedeln (946), are of great historical interest. The League of Nations has its library at Geneva; The Rockefeller foundation made, 1927, a large gift to the League for a library building.

OTHER EUROPEAN COUNTRIES

Hungary.—Information about the chief libraries in Hungary under the dual monarchy was given annually up to 1911 in the Hungarian *Statistical Year Book.* The largest library in Hungary is the Széchenyi-Nationalbibliothek at Budapest, founded in 1802 by the gift of the library of Count Franz Széchenyi. It contains 400,000 printed vols. and 16,000 mss., and has 11 lending and four reference branches. The University library of Budapest (1635) includes 543,572 printed books and 3,401 mss. Since 1897 there has been in Hungary a chief inspector of museums and libraries. He has charge of a general catalogue of all the mss. and early printed books in Hungary.

After the war, the central bureau of public libraries organized exchange, distributing the literature received in this way from abroad. It also produces a general catalogue of accessions (which serves as a current national bibliography).

The library of the Benedictines at St. Martinsberg (11th century) is the central library of the order in Hungary, and contains nearly 170,000 vols. Its principal treasures were, on the secularization of the monasteries, distributed among the State libraries in Budapest.

Czechoslovakia.—The most considerable libraries in the Republic are the University library, Prague (1366:1773) with 591,245 vols., the National library at Prague (1918) with over 70,000 vols. and many State documents, and the Central library (1891) with 378,562 volumes.

During the 19th century, free libraries were founded by the clergy and school teachers, while the library periodical, *Česká Osvěta* (1904), helped to spread a knowledge of Anglo-American popular library methods. By this each community was to establish a public library, administered by special locally-elected bodies; a minimum library tax of 50, 60, 70 or 80 hellers (0.75d., 0.9d., 1.05d., or 1.2d.) per head is levied in towns of less than 5,000, 10,000 or 100,000, or of over 10,000 inhabitants respectively. All libraries thus established are controlled by the Ministry of Education, which issues statistics. In 1920 there were 3,343 libraries with 1,644,558 vols., 310,880 borrowers, 3,180,509 issues for home use, and a total income of 3,211,026 Czech crowns; in 1927 there were 15,355 libraries with 5,444,844 vols., 880,326 borrowers, 14,440,593 home issues, and income 16,275,308 Czech crowns. The average of readers to a library was 860, and one book to every two readers. The expenditure per head was 1.55 Czech crown (2.33d.) as against the sum of one Czech crown (1.5d.) laid down by the law of 1919.

Italy.—As the former centre of civilization, Italy is the home of the oldest libraries. The Vatican at Rome and the Laurentian at Florence are sufficient in themselves to give Italy primacy in respect of rare and valuable mss., and for antiquity there are the venerable relics at Vercelli, Monte Cassino and La Cava. The local rights which so long impeded the unification of Italy created and preserved many libraries which would have been lost under a Central State. Italy is still, in spite of war and collectors, rich in books. Official statistics of 1896 gave particulars of 1,831 libraries, of which 419 are provincial and communal. In 1893 there were 542 popular and circulating. A *Bollettino* for these *biblioteche popolari* was commenced in 1907, and a congress held at Rome in 1908.

Governmental Libraries.—Governmental libraries (*biblioteche governative*) are under the minister of public instruction. The pre-Fascist *Regolamento* controlling them was issued in the *Bollettino Ufficiale,* Dec. 5, 1907. They consisted of the national central libraries of Rome (Vittorio Emanuele) and Florence, of the national libraries of Milan (Braidense), Naples, Palermo, Turin and Venice (Marciana); the Biblioteca governativa at Cremona; the Marucelliana, the Mediceo-Laurenziana and the Riccardiana at Florence; the governativa at Lucca; the Estense at Modena; the Brancacciana and that of San Giacomo at Naples; the Palatina at Parma; the Angelica, the Casanatense, and the

Lancisiana at Rome; the university libraries of Bologna, Cagliari, Catania, Genoa, Messina, Modena, Naples, Padua, Pavia, Pisa, Rome and Sassari; the Ventimiliana (with the university library at Catania); the Vallicelliana and the musical library of the R. Acad. of St. Cecilia at Rome; the musical section of the Palatine at Parma; and the Lucchesi-Palli (added to the national library at Naples). The minister of public instruction is assisted by a technical board. Each library was to possess a general inventory, an accessions register, an alphabetical author-catalogue and a subject-catalogue. Catalogues of the special collections were next to be compiled. A general catalogue of the mss. was, in 1910, being issued together with catalogues of oriental codices and incunabula; books are chosen by the librarians in Government libraries, and in the university libraries partly by a professional council. The rules (*Boll. Ufficiale,* Sept. 17, 1908) allow lending to other countries under special circumstances.

The 36 *biblioteche governative* annually spent, in 1908, about 300,000 lire in books. Their accessions were 142,930; there were 1,176,934 readers. Out of 1,700 libraries confiscated from suppressed monasteries, containing two million and a half volumes, about 650 were added to public libraries already in existence; the remainder served to form new communal libraries.

The Fascist Government supervises, not only the libraries dependent upon it, but also communal, provincial, special and corporation libraries, by means of 12 *Sopraintendenze bibliografiche,* with headquarters at the chief libraries of each region, and inspectors in all library centres.

Two publications, the *Bollettino delle pubblicazioni italiane* and *Bollettino delle opere moderne straniere acquistate dalle biblioteche governative,* for many years issued from the national libraries of Florence and Rome respectively, take the place of a collective catalogue of accessions. The former is the current national bibliography.

The Vittorio Emanuele library at Rome acts as an information bureau, as it is especially well equipped with works of reference.

Vatican.—The Biblioteca Vaticana (now in the newly created Vatican State [1929]) stands in the very first rank among European libraries as regards antiquity and wealth of mss. We can trace it back to the earliest records of the *Scrinium Sedis Apostolicae,* kept first at the Lateran, and later on partly in the Turris Chartularia; but one, the doubtful survival, is the Codex Amiatinus now in the Laurentian library. There remains an inventory made under Boniface VIII. The library was moved to Avignon, where it was renewed and was increased, but this collection has only in part, and in later times, been taken into the Library of the Vatican. The latter is a new creation of the 15th century. Eugenius IV. planted the first seed, but Nicholas V. was the real founder of the library, to which Sixtus IV. consecrated an ornate abode, in the Court of the Pappagallo. Sixtus V. erected the present magnificent building in 1588, and greatly augmented the collection. The most noteworthy librarians were Marcello Cervini (the first *Cardinale Bibliotecario,* later Pope Marcel II.), Sirleto and A. Carafa. In 1600 it was further enriched by the acquisition of the library of Fulvio Orsini. Pope Paul V. (1605–21) separated the library from the archives and added the two "Pauline" halls, for the new codices. Under him and under Urban VIII. many mss. were purchased from the Convent of Assisi, the Minerva at Rome, the Capranica college, and above all the Rossano, of Bobbio (*q.v.* above, under "Mediaeval Period"). Gregory XV. (1622) received from Maximilian I., duke of Bavaria, the valuable library of the Elector Palatine, seized by Count Tilly at the capture of Heidelberg. Alexander VII. (1658) added the mss. of the dukes of Urbino. The *Libreria della Regina, i.e.,* of Christina of Sweden, of ancient mss., some from French monasteries, from St. Gall and elsewhere, and others of importance for French literature from the collection of Petau, was in great part presented by Alexander VIII. in 1689. Under Clement XI. were purchased 54 Greek mss. which had belonged to Pius II., and also oriental mss. Under Benedict XIV. was bequeathed the Capponi library, rich in Italian books; and by purchase, the Biblioteca Ottoboniana, which, in Greek, Latin and Hebrew mss. was, after the Vatican, the richest in Rome. Clement XIII. in 1758, Clement XIV. in 1769, and Pius VI. in 1775, were also benefactors. After three centuries of uninterrupted growth the Vaticana was to undergo a severe blow. In 1798, after the Treaty of Tolentino, 500 picked mss. were sent to Paris. These, however, were chiefly restored in 1815, though most of the Palatine mss. found their way back, not to Rome, but to Heidelberg. Pius VII. acquired the library of Cardinal Zelada in 1800, and among important purchases of the 19th century were the splendid Cicognara (archaeology and art, 1823); Cardinal Mai, 40,000 vols. (1856), some 300 Borghese mss. from the papal library of Avignon, the Barberini library and the Borgia collection, *De Propaganda Fide.*

The printed books in the Vaticana number some 350,000, the mss. about 53,000, and the incunabula about 6,000 with many vellum copies; 500 Aldines and a great number of bibliographical rarities, including very many presentation copies. Among the Greek and Latin mss. are some of the most ancient and valuable in the world; *e.g.,* the famous biblical *Codex Vaticanus* of the 4th century, the two Virgils of the 4th and 5th centuries, the Bembo Terence, and the palimpsest *De Republica* of Cicero.

Many important catalogues of special classes of mss. and important single volumes have been published in facsimile. A new catalogue of the printed books was made in 1927–29 to make easily available the library's rich treasures. This catalogue, made possible by the aid of the Carnegie Endowment, was worked out mainly according to the code of the American Library Association by four Vatican librarians and four American librarians.

Other Roman Libraries.—The most important library in Italy for modern requirements is the Nazionale Centrale Vittorio Emanuele (1875) (495,000 vols., 300,000 pamphlets and 5,223 mss.). This contains the *biblioteca maior o secreta* of the Jesuit college of Rome and the cloister libraries of the Provincia Romana, and has the right to copies of new Italian books. Noteworthy among the mss. are the Farfensi and the Sessoriani of Santa Croce in Jerusalem, some of these last being of the 6th to the 8th centuries. The library was reorganized in 1910. It is rich in the renaissance, in Roman topography, and generally in books of reference and in journals. A monthly *Bollettino* is issued of modern foreign literature received by the libraries of Italy. The library acts as the central bureau of bibliographical information for Italy.

The Biblioteca Casanatense, founded by Cardinal Casanate in 1698 (131,778 printed vols., 2,086 incunabula, with many Roman and Venetian editions, and 6,124 mss., some of the 8th–10th centuries), is rich in theology, mediaeval history, law and the social sciences. An incomplete catalogue of the printed books by A. Audiffredi (1761–88) still remains a model.

The Biblioteca Angelica, founded in 1614 by Angelo Rocca (120,000 printed vols. and 3,000 mss.) was the first library in Rome to be opened to the public. The library of the University of Rome is the Alessandrina, founded by Alexander VII. in 1661, with the greater part of the printed books belonging to the dukes of Urbino, and opened in 1676. In 1815 Pius VII. granted to it the right to receive a copy of every book printed in the States of the Church, which grant was continued by Italian law but limited to the province of Rome. The library possesses 200,000 printed books.

The library of the Senate, established at Turin in 1848, contains 130,289 vols. rich in the history and statutes of Italian cities. That of the Chamber of Deputies (1848) contains 250,000 vols., and specializes in more modern history, law and politics. The Vallicelliana (1581), controlled by the R. Societá Romana di Storia Patria has some important mss., including one attributed to Alcuin; the Lancisiana (1711), is valuable for its medical collections; the Accademia di San Luca possesses a good art library; the Biblioteca Militare Centrale (1893) has 100,000 printed vols. and 72,000 maps; and the Biblioteca della R. Accad. di S. Cecilia (1875), a musical collection of 150,000 vols. and 6,000 mss.; the Corsiniana, founded by Clement XII., is rich in incunabula and prints, and, since 1884, belongs to the Accademia dei Lincei. The Deutsches Institut, École Française and British and American Schools, and the International Institute of Agriculture may be mentioned. All these and many other Roman libraries are open, at least to advanced students.

Subiaco.—At Subiaco, about 40 m. from Rome, the Benedictine monastery of Santa Scolastica has only 6,000 printed vols. and 400 mss., but it is remarkable as having been, in 1465, the first seat of typography in Italy, and students may inspect the series of Sweynheim and Pannartz's original editions preserved in their first home.

Florence.—The Biblioteca Nazionale Centrale of Florence, formed from the union of Magliabechi's library with the Palatina, is the largest after the Vittorio Emanuele at Rome. The Magliabechiana became public in 1714, and in 1861 Palatina (formed by Ferdinand III., grand duke of Tuscany), was joined with it. It had long had a right to a copy of every work printed in Tuscany, a right maintained more rigorously since 1860. Since 1870 the Nazionale receives, by law, a copy of every book published in the kingdom. Its monthly *Bollettino* is the current bibliography of the national literature. The mss. include the most important extant *codici* of Dante and later Italian poets and historians. The Galileo collection numbers 308 mss. Of the 25 mss. portolani, the oldest is dated 1417, and several seem to be the original charts executed for Sir Robert Dudley (duke of Northumberland) in the preparation of his *Arcano del Mare.* Amongst the early printed books is a great number of 16th century *Rappresentazioni,* books printed on vellum, municipal histories and statutes, *testi di lingua* and maps. The library contains 750,000 printed vols., 22,207 mss., and 3,601 incunabula, besides prints and maps. A new building was completed on the Corso dei Tintori in 1929.

Milan.—The Biblioteca Nazionale of Milan, better known as the Braidense, founded in 1770 by Maria Theresa, has 500,000 printed vols., 2,000 mss., 2,500 incunabula and 913 Aldines. Amongst the mss. are letters of Galileo, poems in Tasso's autograph, and a fine series of Italian illuminated service-books, 12th to 16th centuries.

Naples.—The Biblioteca Nazionale at Naples (founded in 1734 and opened in 1804) is the largest library of that city, and has recently been splendidly re-housed. To the collection of Cardinal Seripando were added, especially in 1848 and 1860, many private and conventual libraries. The biblical section is rich. Other features are the collections of *testi di lingua,* and of books on volcanoes, the best in existence of the publications of Italian learned societies and a nearly complete set of the Bodoni press. The mss. include many illuminated books, the autographs of Leopardi, and portolani. The library contains about 1,000,000 printed vols., 11,868 mss. and 4,625 incunabula. Annexed to it is the Officina dei Papiri Ercolanesi.

The Biblioteca Nazionale of Palermo, founded from the Jesuits' libraries, is rich in 15th century books (catalogue printed in 1875), in Aldines, and Sicilian 16th century books, many being unique. The library contains 283,227 printed volumes.

Turin.—The Biblioteca Nazionale Universitaria of Turin took its origin in the private library of the House of Savoy, given in 1720 to the university by Vittorio Amedeo II. The fire of 1904 destroyed about 24,000 out of 300,000 vols., and of the 4,138 mss. there survive but 1,500, and those in a damaged condition. Among those that perished were the palimpsests of Cicero, Cassidorus, the Codex Theodosianus and the famous *Livre d'Heures.* The 1,095 incunabula escaped. Since the fire the library has been enriched by new gifts, notably Baron A. Lumbroso's of 30,000 vols., principally on the French Revolution and Empire. The library was, in 1910, transferred to the premises of the Palazzo of the Debito Pubblico.

Venice.—The Biblioteca Marciana, or library of St. Mark, at Venice, was traditionally founded in 1362 by Petrarch's gift of mss. (all now lost) and opened by Cardinal Bessarione in 1468. It has 330,000 printed books, 12,106 mss. of great value (more than 1,000 Greek codices given by Bessarione), collections on Venetian history, music and theatre, and on early geographical research, a codex of the laws of the Lombards, and the autograph ms. of Sarpi's *History of the Council of Trent.* Since the fall of the republic and the suppression of the monasteries, many private and conventual libraries have been incorporated first in the Libreria del Sansovino, from which the library was transferred in 1812 to the Palazzo Ducale, and in 1904 to the Palazzo della Zecca (the Mint).

University Libraries.—Among the university libraries under Government control some deserve special notice. First in historical importance comes that of Bologna, founded by U. Aldrovandi (1605). Count Luigi F. Marsili in 1712 increased the library and established an Instituto delle Scienze, reconstituted as a public library by Benedict XIV. in 1756. The printed books number 214,991 vols., and the mss. 5,400, the oriental being noteworthy. The grand hall, with its fine furniture in walnut wood, merits particular attention. The Biblioteca della Universita at Naples, established by Joachim Murat in 1812 in the buildings of Monte Oliveto, and thence sometimes called the "Biblioteca Gioacchimo," was transferred to the Royal university and opened in 1827. It is strongest in medicine and science; its chief mss. and early printed books were transferred about the middle of the 19th century to the Nazionale. Other important university libraries are those of Catania (1755); Genoa (1773); Pavia (1763); Padua (1629) (314,000 vols.), which in 1910 was housed in a new building; Cagliari and Sassari. Messina was destroyed in the earthquake of 1908, but the more important part of the furniture was saved, and by 1910 the library was already restored to active work.

Chief among the remaining Government libraries comes the world-famed Biblioteca Mediceo Laurenziana at Florence, formed from the collections of Cosimo the Elder, Pietro de' Medici, and Lorenzo the Magnificent. It was made public by Clement VII., who charged Michelangelo to construct a suitable edifice for its reception. Opened by Cosimo I. in 1571, it has steadily grown. The accessions in the 18th century alone were enough to double it. Its printed books number probably only 11,000, and though almost all of the highest rarity and interest, the 10,017 mss. give its chief importance to this library. More than 700 are earlier than the 11th century. Some of them are the most valuable codices in the world—the famous Virgil of the 4th or 5th century, Justinian's *Pandects* of the 6th, a Homer of the 10th, and several other very early Greek and Latin classical and biblical texts, as well as copies in the handwriting of Petrarch, about 100 codices of Dante, a *Decameron* copied by a contemporary from Boccaccio's own ms., and Benvenuto Cellini's ms. of his autobiography. Administered with the Laurentian is the Riccardiana, rich in mss. of Italian, and especially the Florentine literature. The Biblioteca Marucelliana (founded 1703, opened 1753) is remarkable for its early woodcuts and engravings; the printed volumes number 310,000 and the mss. 2,000.

Modena.—At Modena is the Biblioteca Estense, founded by the Este family at Ferrara in 1393; it was transferred to Modena by Cesare D'Este in 1598. Muratori, Zaccaria and Tiraboschi were librarians here. The printed vols. number 151,057, the incunabula 1,600, the mss. 8,567, besides the 4,958 mss. and the 100,000 autographs of the Campori collection.

The oldest library at Naples is the Brancacciana, founded in 1647 by Cardinal F. M. Brancaccio, and opened by his heirs in 1675. The Regia Biblioteca di Parma was founded definitely in 1779 by the grand-duke Philip, who employed Paciaudi to organize it. It contains 323,208 vols. and 5,290 mss., including De Rossi's biblical and rabbinical mss. Also worthy of note are the Bibl. Pubblica or governativa of Lucca, and that of Cremona.

The Ambrosiana.—Among the great libraries not under Government control, the most important is the Ambrosiana at Milan, founded in 1609 by Cardinal Fed. Borromeo. It contains 400,000 printed vols., 3,000 incunabula and 10,000 mss. Amongst the mss. are a Greek Pentateuch of the 5th century, the famous Peshito and Syro-Hexaplar, a Josephus on papyrus, supposed to be of the 5th century, several palimpsest texts, and a 7th century copy of St. Jerome's commentary on the Psalms, full of contemporary glosses in Irish, Gothic fragments of Ulfilas, and a Virgil with notes in Petrarch's handwriting. Cardinal Mai and Pope Pius XI. were former custodians here. At Genoa the Biblioteca Franzoniana (40,000 vols.), founded about 1770 for the instruction of the poorer classes, is noteworthy as being the first European library lighted up at night for the use of readers.

Monte Cassino.—The monastery of Monte Cassino (529) is due to St. Benedict, and is the prototype of all Western religious houses. The library now extends to about 70,000 vols., and that belonging to the monks contains about the same number. But the chief glory of Monte Cassino consists of the *archivio*, which is quite apart; and this includes more than 30,000 bulls, diplomas, charters and other documents, besides 1,000 mss. dating from the 6th century downwards. There are good written catalogues, and descriptions with extracts are published in the *Bibliotheca Casinensis*. The monastery was declared a national monument in 1866. At Ravenna the Biblioteca Classense has a 10th century codex of Aristophanes. At Vercelli the Biblioteca dell' Archivio Capitolare comprises nothing but mss., all of great antiquity and value, amongst them an Evangeliarium S. Eusebii, supposed to be of the 4th century; also a famous codex of Anglo-Saxon homilies.

La Cava.—The Monastero della S. Trinità, at La Cava dei Tirreni, in the province of Salerno (beginning of the 11th century), has only some 10,000 vols., but these include mss. from the 8th to the 14th century, amongst them a Codex Legum Longobardorum, dated 1004, besides a well-known geographical chart of the 12th century, over 100 Greek mss., and about 1,000 charters beginning with the year 840, more than 200 of which belong to the Lombard and Norman periods. The library is now national property, the abbot holding the office of keeper of the archives.

Not a few of the communal and municipal libraries are of great extent and interest: Bologna (1801); Brescia, Civica Quiriniana (1747); Ferrara (1753); Macerata, the Mozzi-Borgetti (1783–1835, united 1855); Mantua; Novara, Negroni e Civica (1847 and 1890); Padua; Palermo (1760); Perugia (1852), founded by P. Podiani; Siena (1758), founded by S. Bandini, fine art collection; Venice, Museo Civico Correr (1830); Verona (1792, public since 1802); Bertoliana (1708). Italian librarians are organized and there is a school for professional training in the Archiginnasio at Bologna.

Spain and Portugal.—Most of the royal, State and university libraries of Spain and Portugal have Government control and support.

The chief library in Spain is the Biblioteca Nacional (formerly Real) at Madrid (1716), with 1,210,520 printed books, including 2,412 incunabula, 30,172 mss. and 120,000 prints. Theology, canon law, history, etc., are very complete. The collection of prints was principally bought from Don Valentin Carderera in 1865. Other Madrid libraries are Biblioteca de la Real Academia de la Historia, 1738 (50,000 vols., and 8,400 mss.), which contains Spanish books of great value, including the Salazar collection. In 1808, the year the Escorial contained approximately 30,000 printed vols. and 3,400 mss., Joseph removed the collection to Madrid, but when it was returned by Ferdinand 10,000 vols. were missing. There are now about 40,000 printed volumes. The Biblioteca Provincial y Universitaria of Barcelona (1841) contains about 100,000 vols., and that of Seville (1767) has 110,000 volumes. Among other provincial and university libraries is that of Salamanca (1254).

Among the libraries of Portugal the Biblioteca Nacional at Lisbon (1796) naturally takes the first place. In 1841 it was largely increased from the monastic collections, and now has 800,000 vols. of printed books, largely on theology, canon law, history and Portuguese and Spanish literature, 16,000 mss., and 40,000 coins and medals. The Academia das Sciencias (1779), in the suppressed convent of the Ordem Terceira da Penitencia, in 1836 acquired the library of that convent (30,000 vols.) which has since been kept apart. The Archivo Nacional was brought here in 1749.

The Biblioteca Publica Municipal at Oporto, founded during the siege of 1833, and till 1874 styled the Real Biblioteca do Porto, is one of the largest in Portugal (about 300,000 vols.). The regent gave to the town the libraries of the suppressed convents in the northern provinces. The important Camoens collection is described in a printed catalogue (1880), and the mss. by H. da Cunha Rivara (1850–70). The University Library of Coimbra (1591) 300,000 vols., the Instituto Juridico, Coimbra (1912) 53,000 vols., and the Biblioteca Provincial, Cadiz 40,000 vols., may be mentioned.

Much interest in libraries has not been shown in Latin America. Most of the libraries which exist are national or legislative libraries.

Cuba.—The chief are in Havana, and the best is the Biblioteca Nacional (1901), 256,000 vols., the Biblioteca Publica. The Biblioteca Publica is one of the most actively-managed libraries in Latin America.

Mexico.—Of the 29 States the territories of the Mexican republic, many possess rare and valuable books from the libraries of the suppressed religious bodies, but few have much modern literature. Many scientific and literary associations in the republic possess books. The Society of Geography and Statistics in Mexico City (founded 1833, reorganized 1851), the most important of them, owns a fine museum and library. The ecclesiastical libraries of Mexico City were amalgamated as the Biblioteca Nacional; this now possesses over 200,000 volumes. Two copies of every book printed in Mexico must be deposited in it. Most of the libraries of Mexico, city or provincial, are subscription, and belong to societies and schools of various kinds. The American Library Association is spreading Anglo-American library technique in Mexico, and also in the Philippines.

Argentina.—There are more than 200 public libraries in Argentina. They are due to benefactions, but the Government adds an equal sum to endowments. A central commission exists to facilitate the acquisition of books and to secure good administration. The most considerable is the Biblioteca Nacional at Buenos Aires (1810), which is passably rich in mss. concerning the early history of the Spanish colonies and has 350,000 printed volumes. The Biblioteca Popular del Municipio (1879) has about 80,000 volumes. There are also libraries attached to colleges, churches and clubs.

Brazil, Chile and Peru.—The chief library in Brazil is the Biblioteca Nacional at Rio de Janeiro (1810), now comprising over 488,000 printed vols., with many mss., largely on South America. Other libraries of the capital are those of the Faculty of Medicine, Marine library, National museum, Portuguese Literary club, Biblioteca Fluminense, Benedictine monastery, and the Biblioteca Municipal (60,000 vols.). There are provincial and town libraries throughout Brazil.

The Biblioteca Nacional at Santiago (1813) is the chief library in Chile. It possesses about 232,000 volumes. There is also a university library at Santiago (40,000 vols.) and the Biblioteca Publica at Valparaiso (50,000 vols.).

The Biblioteca Nacional at Lima was founded by a decree of the liberator, San Martin, in 1820, from those of the university of San Marcos and of several monasteries, and books presented by the liberator; it is rich in the history of Peru.

Netherlands.—Since 1900 there has been considerable progress made in both Belgium and Holland in the development of public libraries, and many towns in the latter country have established popular libraries after the fashion of the municipal libraries of the United Kingdom and America.

Belgium.—The national library of Belgium is the Bibliothèque Royale at Brussels, based on the Bibliothèque des ducs de Bourgogne, the library of the Austrian sovereigns of the Low Countries in 1772. In 1794 a number of volumes were transferred to Paris, the majority being returned in 1815; in 1795 the remainder were formed into a public library under the care of La Serna Santander, who was also town librarian, and who was followed by van Hulthem. At the end of the administration of van Hulthem a large part of the precious collections of the Bollandists was acquired. In 1830 the Bibliothèque de Bourgogne was added to the State archives. Van Hulthem died in 1832; his private library (catalogue printed 1836), mostly relating to Belgian history, was purchased in 1837, and, having been added to the Bibliothèque de Bourgogne and the Bibliothèque de la Ville (open since 1794), formed the Bibliothèque Royale de Belgique. The printed volumes now number over 800,000, with 31,200 mss., 34,600 maps, 1,267,700 prints and 80,000 coins and medals. There are printed catalogues of special collections of mss., of accessions, etc. There is no free legal deposit of books in Belgium; the Government purchases new books from the publishers and deposits them in the

Royal library. The financial crisis after 1918 led to proposals, by a governmental committee of economics, to divide the foreign accessions of the library among those of various ministries; but in 1928 the scheme had been severely animadverted on and seemed unlikely to be pressed. There are libraries attached to most of the departments of the Government. Other important libraries are the Bibliothèque Collective des Sociétés Savantes (1906), with a union catalogue on cards, and the Bibliothèque du Conservatoire Royal de Musique (1832) with 31,000 volumes. The popular or communal libraries of Brussels (1842) and of the suburbs are distributed through the schools. At Antwerp the town library (1505) has now 500,000 volumes. The valuable collection of books in the Musée Plantin-Moretus (1640) should also be mentioned. It contains 427 mss. and 20,000 printed books, comprising the works issued by the Plantin family and many 15th century books, besides the archives of the firm.

The university library of Ghent (declared public in 1797, opened in 1798), was known successively as the Bibliothèque de l'École Centrale and Bibliothèque Publique de la Ville. On the foundation of the university in 1817 the town placed the collection at its disposal, but it has since remained under State control. The printed volumes now amount to 450,000 and the mss. to 2,650. The Bibliothèque de l'Université Catholique of Louvain (1636) is based upon the collections of Beyerlinck, bequeathed in 1627, and of Jacques Romain, professor of medicine. There were over 211,000 vols. in 1914, when the library was totally destroyed by fire at the German occupation. On the foundation of the University of Liége (1817) the old Bibliothèque de la Ville was added to its library (now 454,000 printed vols., 184,500 pamphlets, and 2,140 mss.). The Liége collection, bequeathed by M. Ulysse Capitaine and the Bibliothèques Populaires of Liége (1862), are circulated among the school children. The Bibliothèque publique of Bruges (1798) contains 145,000 printed books and mss. housed in the old Tonlieu (1477). Every town has a communal library, mostly small and open only part of the day; the chief are those of Alost, Arlon (1842), Ath (1842), Courtrai, Malines (1864), Mons (1797), Namur (1800), Ostend (1861) and Tournai (1794, housed in the Hotel des Anciens Prêtres, 1755); those of Ypres and other towns in the war area were destroyed in 1914–18. A complete list will be found in the *Annuaire de la Belgique scientifique, artistique et litteraire* (1908).

By a law of Oct. 17, 1921, communes may singly or in conjunction establish public libraries, and if complying with certain conditions receive State subsidies.

The "Union des villes et communes belges" at Brussels is planning a national scheme of federation and mutual lending between public libraries; and similar associations at Louvain, Antwerp, Bruges, Ermeton, near Namur (for the Walloon districts) are similarly engaged. Rural circulating libraries are brought by the law of 1921 under the same control as those of the communes. (*See* J. van Meel, *Bibliothèques publiques,* 192.)

Holland.—Information on Dutch libraries can be obtained from J. D. C. von Dukkum and G. A. Evers, *Nederlandsche Bibliotheekgids,* 2nd ed., 1924.

The national library of Holland is the Koninklijke Bibliotheek at The Hague (1798). The library of the princes of Orange was then united with those of the defunct Government bodies to form the national Bibliotheek. In 1805 the present name was adopted; and since 1815 it has become the national library. In 1848 the Baron W. Y. H. van Westreenen van Tiellandt bequeathed his library and antiquities to be preserved in his former residence as a branch of the royal library. There are now about one million printed books and over 6,000 mss. Books are lent all over the country. The library is the richest in the world in books on chess, Dutch incunabula, Elzevirs and in Spinozana. In 1800–11 a printed catalogue was issued, and since 1866 a yearly list of additions.

The next largest library is that of the Academia Lugduno-Batavia, which dates from the foundation of the University of Leyden in 1575. Valuable additions include those from the libraries of Golius, Joseph Scaliger, Isaac Voss, Ruhnken and Hemsterhuis. The library of the Society of Netherland Literature, placed here in 1877, Legatum Warnerianum of oriental mss., and the collection of maps bequeathed in 1870 by J. J. Bodel Nyenhuis, are noteworthy. Published catalogues are: books and mss., 1716; supplements of books added in 1814–47, and of mss., 1850; and oriental mss., 1851–77. The Bibliotheek der Rijks Universiteit (1575) at Leyden contains about 800,000 vols. and 3,400 oriental mss., many of value.

The University library at Utrecht (292,500 vols.) is based on conventual collections brought together in 1581. The public library thus formed was soon enriched by books bequeathed by Hub. Buchelius and Ev. Pollio, and was transferred to the university on its foundation in 1636. Among the mss. is the famous "Utrecht Psalter," which contains the oldest text of the Athanasian creed. Printed catalogues are of printed books of 1834 (supplement 1845, index from 1845–55, and additions 1856–1870), and of mss., 1887. Titles of accessions are printed.

The University library at Amsterdam is based on a 15th century collection. Since 1877 the collection has been known as the University library, and in 1881 it was removed to a building modelled on the British Museum library. It includes the best mediaeval collection in Holland, and the Bibliotheca Rosenthaliana of Hebraica (30,000 vols., catalogue 1875). The libraries of the Dutch Geographical and other societies are preserved here. The library contains about 800,000 volumes. There are popular subscription libraries with reading-rooms in all parts of Holland, and in Rotterdam there is a society for the encouragement of social culture which has a large library. At The Hague, Leyden, Haarlem, Dordrecht and other towns popular libraries have been established, but ecclesiastical divisions hamper free development. Dutch librarians are organized in a professional body.

The library of the Genootschap van Kunsten en Wetenschappen at Batavia contains books printed in Netherlandish India, or relating to the Indian archipelago.

Denmark.—Owing largely to so many Scandinavian librarians having been trained and employed in American libraries, a greater approach has been made to Anglo-American library ideals in Norway, Sweden and Denmark than anywhere else on the continent of Europe.

A survey of 384 Danish libraries in 1915 (*Dansk Biblioteksfoerer*) was published by Svend Dahl; and a statistical list of popular libraries appears yearly in *Bogens Verden.*

The beginning of the national library, the great Royal library (Kongelige Bibliothek) at Copenhagen may be credited to Christian III. (1533–59); but to Frederick III. (1648–70) is mainly due the collection of Icelandic literature and the acquisition of Tycho Brahe's mss., and also the present building (in the Christiansborg castle), begun in 1667. In 1793 the library was opened as the national library. Two copies of every book published in Denmark must be deposited here. The incunabula and block books form an important series. In foreign literature it specializes in the humanities. There are printed catalogues of the de Thott collection (1789–95); French mss., Oriental mss. (1846); the Danish collection (1875), etc. There are now 850,000 printed books and 30,000 mss. The Royal library has nearly completed publication of *Bibliotheca Danica,* a bibliography of Danish books, 1482–1830.

The University library (1482), destroyed by fire in 1728, but soon re-established, receives, since 1894, a copy of every Danish publication, and has 430,000 vols. and 7,000 mss., including the Arne-Magnean collection, specializing in the natural sciences. The Statsbiblioteket of Aarhus (1894) possesses about 270,000 vols. and the Landsbokasafn Islands (National library) of Reykjavik, Iceland, about 118,000 printed books and 7,830 Icelandic mss. A State library commission supervises the State-supported libraries. An association for promoting public libraries was formed in 1905, and in 1909 the minister of public instruction appointed a special adviser.

Modern developments show, perhaps more clearly than elsewhere in Europe, a tendency to co-ordinate all the libraries.

Norway.—The Norsk Bibliotekforening in 1924 published a statistical account of 266 libraries (*Handbok over norske Biblioteker*).

The chief library in Norway is the University library at Oslo (Christiania), founded in 1811 by Frederick VI., with a large donation of duplicates from the Royal Library at Copenhagen. There are now over 700,000 vols. in the collection. The Deichmanske Bibliotek at Oslo was founded by Carl Deichmann in 1780 as a free library, and is maintained by endowments and by the city. It now contains about 195,000 volumes. The Free library at Bergen (1874) has 163,758 vols. and has been re-housed. The Kongelige Norske Videnskabers Selskab at Trondhjem has also a large library.

Sweden and Finland.—Swedish libraries were surveyed in 1924 in Einar Sundstrom's *Svenska Bibliotek.*

The first Royal library at Stockholm, established in 1585, was given to the University of Uppsala by Gustavus II. Charles X.'s library was burned in 1697, and the present library was organized shortly afterwards. The Benzelstjerna-Engestrom library (rich in Swedish history) is now annexed to it. Natural history, medicine and mathematics are left to other libraries. Among the mss. the *Codex Aureus* of the 6th or 7th century, with an Anglo-Saxon inscription, is noteworthy. The library contained, in 1924, 460,000 printed books and over 12,000 mss. The Karolinska Institutet, in Stockholm, contains a library of medical books numbering over 60,000.

The University library at Uppsala was founded as mentioned above by Gustavus Adolphus in 1620, from the remains of convent libraries, and endowed. The mss. chiefly relate to the history of the country, but include the *Codex Argenteus* of the Gothic gospels of Ulfilas, published in facsimile by the library in 1928. Printed catalogues are: general (1814), foreign accession lists (annually from 1850), and Arabic, Turkish and Persian mss. (1846). The library now contains about 600,000 printed books and mss. The University library at Lund (1668) was based upon the old cathedral library. The mss. include the de la Gardie archives, acquired in 1848. There are about 145,385 vols. in the library. The Stadsbibliotek of Gothenburg (1890) contains about 240,000 vols., and has a printed catalogue.

Finland has the University library of Helsingfors (1640–1827), about 500,000 vols., and the parliamentary library (1872), 58,500 volumes.

Russia.—The Gosudarstvennaya Publichnaya Biblioteka at Leningrad, formerly the Imperial public library at St. Petersburg, the State library of the Union of Soviet Socialist Republics, is perhaps the largest library in the world. In 1910 it had about 1,800,000 printed vols. and 34,000 mss., as well as large collections of maps, autographs, photographs, etc. It is now said to contain 4,566,645 printed books and 240,000 mss., and autographs. It originated in the books seized by Peter the Great in Courland in 1714; the library, however, only attained to the first rank in 1795, by the acquisition of the famous Zaluski collection. The Zaluski library was formed by the Polish count, Joseph Zaluski, who collected 200,000 vols., added to by his brother Andrew, bishop of Cracow. At his death it was left to the Jesuit college at Warsaw; on the suppression of the order it was taken by the Commission of Education; and in 1795 it was transferred by Suvarov to St. Petersburg as a trophy of war. It then had 260,000 printed vols. and 10,000 mss., but in consequence of the dispersal of many works among other institutions, hardly 238,000 vols. remained in 1810. After the World War the Zaluski collection was returned to Poland. By a law passed in 1810 two copies of every Russian publication must be deposited in the library. Very many valuable special collections have been added, such as the Tolstoy Slavonic collection (1830), Tischendorf's mss. (1858), the Dolgorousky oriental mss. (1859), and the Firkowitsch Hebrew (Karaite) collection (1862–63), and the national mss. of Karamzin (1867). Some departments are thus exceedingly rich, while others are comparatively meagre.

The glory of the mss. is the *Codex Sinaiticus* of the Greek Bible, brought from the convent of St. Catherine on Mount Sinai by Tischendorf in 1859. Other important biblical and patristic codices are to be found among the Greek and Latin mss.; the Hebrew mss. include some of the oldest extant, and the Samaritan collection is one of the largest; the oriental mss., and the French mss. (notably the historical) are of great value. The Biblioteka Vsemirnoj Literatury (1919) has about 90,000 and the University library (1925) 711,000 volumes.

The library at the Hermitage was founded by the empress Catherine II.'s purchase of Voltaire's and Diderot's books and mss. In 1861 it possessed 150,000 vols., of which nearly all but those on the history of art were then transferred to the Imperial library. There are many large and valuable libraries attached to the Government departments in Leningrad, and most of the academies and colleges and learned societies are provided with libraries. The national library published in 1928 material for a directory of the learned libraries of the city.

The second largest library in Russia is the Lenin Memorial Library in Moscow (formerly Rumyantzov Museum collection, renamed after Lenin's death in 1924). It has over three million volumes, is rich in early printed books, Russian history, and mss. The latter number 5,000, including many ancient Slavonic codices, historical documents and the archives of the masonic lodges in Russia between 1816 and 1821; catalogues of the mss. and of some special collections are printed. The University at Moscow (1755) has a library of over 310,000 vols., and the Duchovnaja academy has 120,000 volumes. The (formerly Imperial) Russian Historical museum (1875–83) in Moscow contains nearly 200,000 volumes. Among Russian university libraries mention may be made of Kazan (1804), Kharkov (1805), Kiev (1832) and Odessa (1865). There are also communal or public libraries at Kharkov (1886), Odessa (1830) in the Ukraine, and many other towns. The Soviet Government has established many popular libraries. The Lenin Institute of Library Science at Moscow trains librarians and has published text-books.

Poland.—The Jagiellonska library at Cracow (1400) 524,000 vols. and 6,711 mss., at present serves as national library for Poland. As the headquarters of the Government is at Warsaw, however, it is now debated whether all publications concerning Poland should be housed in the National Library there (1917) 91,532 vols., or whether they should be divided between the two cities. It is suggested that the Jagiellonska library be made into a historical collection containing books to the year 1918, the date of the reconstitution of the Polish State, and that the Warsaw library be confined to accessions since that date, and organized on the lines of the Deutsche Bücherei at Leipzig. A bibliographical institute will be attached to the Warsaw collection and will disseminate information through a special bureau, the functions of which are at present fulfilled by the Jagiellonska and by the Warsaw section of the libraries of the Ministry of Public Instruction. The National Library at Warsaw has also been enriched by the famous Zaluski collection, described in the paragraph on Russian libraries. The Warsaw university library (1817) has 730,000 volumes. Besides the Cracow and Warsaw libraries, that of Posen (formerly Kaiser Wilhelm Bibliothek) may be mentioned. Lemberg (Lwow) has three noteworthy collections housed in the University library, the Ossolinsky library and Museum and the Bavorovsky library. Chwalewik's *Les Collections polonaises* (2 vols.) gives a complete list of Polish libraries, and 427 libraries are listed in the Mianowski Foundations Year Book (1927), pp. 162–221. There is no general catalogue, but its place is taken at present by Charles Estreicher's *Bibliografia Polska* (1870–). The Lett city of Vilna also has a public library (1856).

Elsewhere in Eastern Europe.—Latvia has the city and university libraries of Riga (with 375,000 and 60,000 vols.). Estonia has the university library of Tarfu (Dorpat 1806) with 270,000 vols., and the city library of Tallinn.

The university libraries of Belgrade and Sofia (1888), 192,039 vols., and the national library at Sofia (1924), over 200,000 printed books and 5,500 mss., are the chief in the Balkans. There is a Bulgarian State Library Commission, which organizes local libraries and trains librarians.

At Athens the national library (1842) possesses about 400,000 vols., 3,800 mss., and 200,000 historical documents.

Constantinople has a National library (1925) and a public library, the Oumoumiye, of about 300,000 volumes. There are over 120,000 vols. in the University library (1910), and there are also libraries at the Greek literary society and the Theological school. The mosque of St. Sophia contains a library of some thousands of mss., of which a printed catalogue is obtainable, consisting mostly of Korans and service books. The old Seraglio contains many important books.

THE FAR EAST

China.—The earliest notice of a library in China is that of the imperial Chou dynasty whose capital was at Loyang in the modern province of Honan. According to a tradition preserved in Ssu-ma Ch'ien's "Historical Record" the philosopher Lao-tse, who lived in the seventh century before Christ, was keeper of books in this library. National collections of books in the modern sense, however, originated with the attempts made to recover the books scattered or destroyed by the so-called "First Emperor" in 220 B.C. Hence the earliest catalogue of Chinese books is preserved in the "History of the Former Han Dynasty" (206 B.C.–23 A.D.) and written in the first century of our era. The histories of nearly all succeeding dynasties have likewise left catalogues of books preserved in their libraries or known to their times. After the invention of printing in China private libraries became increasingly numerous. From time to time these were destroyed or dispersed, but catalogues of many of them remain. There are still some fourteen large private libraries in various parts of China some of which contain as many as two hundred thousand volumes.

According to a survey made by the Library Association of China in 1927 there were then 503 public and private libraries in China proper and Manchuria. Of this total the province of Kiangsu has 145; the city of Shanghai 60, Peking 42, and Nanking 20. The largest single collection of books is found in the Metropolitan Library, Peking. Each provincial capital also has its own library. The following universities boast large and rapidly growing collections of both Chinese and western books: Peking National University, Sun Yat Sen University (Canton), Tsinghua University (Peking), Yenching University (Peking), Amoy University, and Nanking University. The most common classification of books in Chinese libraries—the so-called *Ssu K'u* system which has been in vogue for fifteen centuries—divides all Chinese literature into four classes: classics, history, philosophy, and belles lettres. A few of the modern Chinese libraries have discarded this system entirely, but most of them combine with it a modified Dewey or Library of Congress classification. (*See* the files of the Library Science Quarterly, *T'u Shu Kuan Hsüeh Chi K'an,* the official organ of the Library Association of China which was founded in 1925.)

Japan.—The ancient history of libraries in Japan is analogous to that of China.

Perhaps the most extensive library of the empire is that of the Imperial Cabinet (1885) at Tokyo with 507,600 vols., consisting of the collections of various Government departments.

The Imperial library at Uyeno Park (1872) contains 387,208 vols., of which some 297,000 are in Japanese or Chinese. At Tokyo there is also the Ohashi library (1902), 81,154 vols., the Hibiya library (1908), 153,000 vols., and the Nanki library (1899), 87,000 vols. The library of the Imperial University of Kyoto (1899) contains nearly 650,000 vols., of which a large proportion are in European languages. Kyoto and other towns have considerable municipal libraries. Kasan in Korea has a library (1804) of about 250,000 vols.

LIBRARY ASSOCIATIONS AND TRAINING

The first and largest association established for the study of librarianship was the American Library Association (1876), which includes Canada. The Library Association of the United Kingdom was formed in 1877, as an outcome of the first International Library Conference, held at London, and in 1898 it received a royal charter. It publishes a *Year Book,* the quarterly *Library Association Record.* It also holds examinations. The Library Assistants' Association was formed in 1895 and has branches in different parts of England, Wales and Ireland. It issues a monthly magazine entitled *The Library Assistant.* The Association des Bibliothécaires Français was founded in 1906 and publishes an important journal. There are two associations in Germany, the Verein deutscher Bibliothekare, and the Verein deutscher Volksbibliothekare, which issues a year-book giving information concerning the libraries of the country; a similar organization in Austria-Hungary is now merged into the former. An Association of Archivists and Librarians was formed at Brussels in 1907, and there are similar societies in France, Italy, Spain, Holland, Denmark, Norway, Sweden, and, since 1927, in China also. In every country there is now some kind of library association.

The movement, since the World War, partly because of the financial crisis in Europe, and partly because of the increased consciousness of each other among the nations, has been one of co-operation and closer organization, so that the world's library resources are far better utilized.

Two agencies further international co-operation between libraries: (1) The Institut International de Bibliographie, founded in 1897 at Brussels by Paul Otlet and Henri Lafontaine, but shortly to be moved to Geneva, aims at amalgamating the catalogues of the world's chief libraries into an universal card bibliography. It has also produced a more thorough (decimal) classification for books and papers. (2) The Institut International de Co-opération Intellectuelle at Paris, an institution of the League of Nations, by its committee of library experts (mostly the heads of the great national libraries), has brought into mutual relations the national bureaux of bibliographical information, and publishes reports from them.

It has been calculated by E. Sparn (*El Crecimiento de las grandes Bibliotecas de la Tierra*) that the larger libraries of the Old World were doubled, and those of North America trebled, in content in the first quarter of the 20th century.

BIBLIOGRAPHY.—There is no considerable bibliography of libraries or librarianship. Current lists appear in *Zentralblatt für Bibliothekswesen* (Leipzig), and annual bibl. from these by R. Hoecker and J. Vorstius, *Internationale Bibliographie der Bibliothekwissenschaft* (1926, etc.); previous vols. as *Beihefte* of the Z. f. B., by J. Vorstius alone. A very full bibl. of articles in periodicals in English only is H. G. T. Cannon, *Bibliography of Library Economy, 1876–1920* (1927). Directories (*see* also under the various countries); *Minerva: Jahrbuch der Gelehrten Welt* (1890, etc.), the source of many of the statistics for particular libraries in the foregoing article. A supplement for libraries is now appearing. *See* also L. Haffkin-Hamburger, "Library Directories" (annotated list) in *The Library Journal* (Nov. 1, 1928); *Index Generalis: Annuaire Général des Universités, Bibliothèques, etc.* (1926–27); E. Sparn, *Las Bibliotecas con 50,000 y mas volumenes y su distribución geografica sobre la Tierra* (Cordova, 1924), and *El Crecimiento de las grandes Bibliotecas de la Tierra durante el primer cuarto del Siglo XX.* (1925–26); Institut International de Co-opération Intellectuelle, *La Co-ordination des bibliothèques: rapports sur les centres nationaux de renseignements* (1928).

THE UNITED STATES

The earliest libraries in the colonial period of America were private. Among the notable libraries of this kind were those of Elder William Brewster of Plymouth, Gov. Winthrop of Connecticut, Dr. Cotton Mather of Boston, Col. Ralph Wormeley of Virginia and the Rev. John Harvard. Toward the end of the 17th century the so-called Bray parish libraries began to appear. These were collections mainly of religious books sent to America through the efforts of the Rev. Dr. Thomas Bray of London, designed particularly for the use of the clergy, though open to the public. The first subscription library in the colonies was projected by Benjamin Franklin in 1731 in Philadelphia. Many of the early subscription and proprietary libraries have become the foundations of public libraries. A few of them, however, still flourish. The Boston Athenaeum (1807) had in 1928 a collection of 305,000 volumes and was especially rich in historical material. The Providence Athenaeum (1753) had 104,000 volumes. The New York Society library (1754) had a general collection of 125,000 volumes. its special strength being in fine arts, early fiction and Americana.

Endowed Libraries.—The gift or bequest of great private libraries or large sums of money for the erection of library buildings and the organization and maintenance of libraries for free public use has been a favourite form of philanthropy in America. In New York the Astor library, founded by a bequest of John Jacob Astor, was incorporated in 1849 and opened to the public in 1854 as a reference library of the most valuable books on all subjects. The Lenox library was established in 1870 by James Lenox, a New York merchant and one of America's greatest book collectors. In addition to funds for a library building and endowment amounting to $1,247,000, he gave his valuable collection of books and art treasures. From the estate of Samuel J. Tilden, the City of New York in 1892 received the private library of the former governor of the State and about $2,000,000 for library purposes. In 1895 the Astor library, the Lenox library and the Tilden Trust were consolidated under the name of the New York Public library, Astor, Lenox and Tilden Foundations, which was soon to become the largest public library system in the world (2,971,209 volumes and pamphlets). In 1901 the New York Free Circulating library, with 11 branches, and later other circulating libraries, were consolidated with the new system as the Circulation Department of the New York Public library. In 1901 also Andrew Carnegie gave $5,200,000 for the construction and equipment of free circulating libraries in Greater New York. Chicago has two important endowed reference libraries, the Newberry library (1887), with 443,757 volumes and pamphlets, and the John Crerar library (1894), with 820,000. The Enoch Pratt Free library (1886) of Baltimore and the Providence (R.I.) Public library (1878) are typical of the numerous endowed public libraries, many of which are supported in part by municipal appropriations.

At the head of the list of library benefactors stands the name of Andrew Carnegie, whose first library gift was made in 1881 to Dunfermline, his native town in Scotland. His second gift of a library was made in 1890 to Allegheny, Pa. Pittsburgh received a large central building in 1895 and later eight branches. The total amount given by Carnegie and the Carnegie Corporation for library building in the United States and Canada was $43,665,000. In its gifts for library buildings the corporation, organized in 1911, followed the wishes of its founder, until its gifts for libraries were discontinued in 1917.

College and University Libraries.—The history of college and university libraries is also a record of generous gifts from private collectors and friends of education. Harvard college library dates from 1638, when John Harvard bequeathed to it his collection of 330 volumes. By 1764 the library had grown to 5,000 volumes, when all but one of the original volumes were destroyed by fire. The library of Yale college was founded in 1700, but grew so slowly that even with the 1,000 volumes received from Bishop Berkeley in 1733 it had only 4,000 volumes in 1766, and some of these were lost in the Revolutionary War. The library of King's college, renamed Columbia college after the Revolutionary War, dates from 1756, when Joseph Murray, a governor of the college, bequeathed to it his private library. It is estimated to have had only about 2,000 volumes at the outbreak of the Revolution. Though stored in the city hall for safe keeping, many of the books were carried off by British soldiers and the rest scattered and never recovered except for a few volumes which are now in the library of Columbia university. The rehabilitation of the library after the Revolution was accomplished very slowly. In 1863 it had only 14,941 volumes.

The Harvard college library has about doubled in size every 20 years for over a century, and this rate of growth has been equalled or exceeded by most of the larger college and university libraries, especially in recent decades. In 1927 the number of volumes in these libraries were: Harvard, 2,622,400; Yale, 1,838,099; Columbia, 1,092,343; University of California, 665,680; University of Chicago, 768,559; Cornell university, 787,127; University of Illinois, 708,850; University of Michigan, 649,912; University of Minnesota, 501,507; University of Pennsylvania, 635,070; Princeton university, 594,195.

Library of Congress.—The Library of Congress has become in fact if not in name the national library of the United States. It was established in 1800 by Act of Congress as a legislative library and was housed in the Capitol until 1897 when it was moved to its own building which is the largest, most ornate and most costly library building in the world. It occupies $3\frac{3}{4}$ ac. of ground, contains over 10,000,000 cu.ft. of space, and has a floor area of over $13\frac{1}{2}$ acres. The original cost was $6,347,000—including the site, close to $7,000,000.

On June 30, 1927, the Library of Congress contained 3,556,767 books and pamphlets, making it the third largest library in the world. The principal sources of growth have been deposits under the copyright law, exchanges of official publications with foreign Governments, and the Smithsonian exchanges which add extensive files of the transactions of foreign learned societies. The main collections are strongest in bibliography, history, political and social sciences, public law and legislation, the fine arts, American local history, biography and genealogy.

Besides its research and other services for members of Congress and the Government Departments, it offers excellent facilities for serious scholars. It is also performing the functions of a national library by extending bibliographic and other services to all the libraries of the country. It stands at the head of a recognized inter-library loan system, by lending to college, university, State, municipal and other libraries books which they do not possess and cannot obtain elsewhere.

Public Libraries.—The modern public library, maintained by the municipality or some other unit of local government from the proceeds of taxation, was scarcely known before 1850 and has developed for the most part since the formation of the American Library Association in 1876. The earliest tax-supported library is supposed to have been the town library of Salisbury, Conn., established in 1803. The oldest existing library of this kind is said to be the one at Peterborough, N.H., which dates from 1833. Legislative sanction for the use of taxation to maintain public libraries was given in New York in 1835, the school district being the library area. By the Michigan Constitution of 1835 the legislature was given power to establish a library in every school district. In 1848 the Massachusetts general court authorized the city of Boston to raise $5,000 a year to maintain a public library, and in 1851 this Act was applied to all towns in the State. Similar laws were soon passed in other States. In 1928 legislation authorizing the establishment and maintenance of municipal public libraries was found in every State except Delaware, where the school district was the only unit recognized for this purpose.

The latest statistics show about 6,000 public libraries in the United States, with an average *per caput* income of $0.33 and an annual *per caput* circulation of 2·13 volumes. It is estimated, however, that 5% of the urban population and 82% of the rural population live in areas with no local public library service at all. Most of the well organized city library systems spend from $0.75 to $1.00 or more *per caput*. In 1926 Cleveland led all other cities, with a *per caput* library expenditure of $1.69, followed by Boston with $1.42, Indianapolis with $1.14, Los Angeles with $1.05 and Minneapolis with $1.00.

One of the ways in which the modern public library attempts to make its service of value to the community is by specialization in its service and organization. Specialization by subject is frequently represented by separate departments, in charge of specialists, of business, technology, art, music, education, etc. In some of the recent central library buildings book stacks and reading rooms are arranged to facilitate departmental organization. Specialized service such as work with children and co-operation with schools is usually not confined to the central library but operates also through different kinds of distributing agencies. Branch libraries and sub-branches have their own collection of books and are located near the centre of the local business or residence area to be served. It is assumed in the best library systems that there should be one branch to every 25,000 to 40,000 population. In less densely populated districts a branch cannot effectively serve so large a number. Deposit stations are located in stores, schools, factories, clubs, etc., and are provided with collections of from one to several hundred volumes which are changed frequently. Delivery stations have no books on hand but fill orders from a central stock. Travelling libraries consist of small collections of books, 25 or 50 to several hundred, lent to factories, stores, clubs, etc. In many communities the public library has undertaken to supply books needed in the public schools by furnishing classroom libraries. In some cities the school and library authorities co-operate in providing what are known as school libraries, and in a few cities branch libraries are established in school buildings.

The governing body of the municipal public library supported wholly or in part by public funds is usually a board of trustees, appointed by the mayor or some other official or body designated by law. In a few cases the library board is self-perpetuating. In some States the public library is operated under the board of education, and in certain cities which are under the city manager or the commission form of government there is no library board at all, the public library being administered as a department of the city government with the librarian directly responsible to the mayor or city manager.

A special library for children was established in New York city as early as 1885. In 1890 a separate room for children was opened in the public library at Brookline, Mass., and in the next few years public libraries began generally to provide special rooms or other facilities for children. By 1900 a separate children's room, with specially trained children's librarians to give skilled and sympathetic guidance in the use of books and periodicals, had come to be considered an essential part of every well conducted public library. To-day in public libraries in which organized work with children is carried on the juvenile circulation amounts to from 30 to 50% of the total. From one-quarter to one-third of its total book fund is considered a reasonable proportion for the average public library to devote to children's books. In libraries which combine the children's department and work with schools, the children's librarians select books to be sent to classrooms, visit schools to talk to the children, give talks to parents and teachers, and give instruction in the use of books and libraries to classes sent to them regularly from the schools.

State Libraries.—In the beginning the State library was essentially a law and legislative library for State officials. The State library of New Hampshire was started in 1770 as a colonial library. The New Jersey State library dates back to 1796. A legislative library was established in South Carolina in 1814. The largest and best State library, that of New York at Albany, was founded in 1818. While the State library is primarily a special reference library for the legislative or executive departments of the State Government, or for both, it is generally open to the public for reference purposes. About 1887 State libraries began to assume leadership of the State commission movement and in 13 States library extension work is now a function of the State library. In 13 States the State law library is separate from the State library. In nine States the legislative reference bureau is also separate. In certain States miscellaneous functions have been assumed, such as historical research and the care of museums.

The term library extension is usually applied to the efforts of some State authority to aid in providing local public library service, or some substitute for it, in the smaller towns and rural districts. Over 90% of the population living in towns and cities of more than 2,500 population in the United States enjoy the service of a local public library of some sort, while less than 20% of the population in the smaller towns and in the open country have any kind of local public library service. The first State to attack this problem was Massachusetts, which in 1890 created a State board known as the Free Public Library Commission, whose function was to aid in establishing and developing free libraries throughout the State. New Hampshire followed in 1891. In 1892 the New York State library was made a central bureau for promoting, stimulating, aiding and directing local libraries. A commission similar to that in Massachusetts was created in Connecticut in 1893, in Vermont in 1894 and in Wisconsin in 1895. Other States quickly followed their examples. In 1904 the League of Library Commissions was organized "to promote by co-operation such library interests as are within the province of library supervision by the State." In 1928 39 States had a library extension agency in operation, three more had laws providing one, leaving seven States that had no extension agency nor legal provision for one. In 13 States, as noted above, the State library is the extension agency; in 12 the function is performed by the State board or department of education; and in 14 there is an active library commission. The functions actually performed by library commissions or other State agencies responsible for library extension include aid in improving local public library service; establishment of new libraries where needed; promotion of co-operation between libraries; assistance in providing library service for schools, and for State charitable, penal and reformatory institutions; provision for library service where local service is impracticable; distribution of State documents; library service for the blind; and legislative reference work.

The travelling library represents one of the earliest forms of State library extension. In 1892 a system of travelling libraries was created in New York under the leadership of Melvil Dewey. Travelling collections of books were used in 1928 in 35 States. The State travelling library is a collection varying from 50 to several hundred volumes for general reading, although special collections are sent out in some States. "Package libraries," consisting of pamphlets and magazine and newspaper clippings on current events and topics on which there are no books, are sent out through the mail by some extension agency in several States for the use of high school debaters, club women, discussion groups, etc. Nearly all the extension agencies make a practice of mailing one or several volumes directly to individuals.

County Libraries.—The most effective form of library extension being carried on is the development of county library systems. The county library is a tax-supported library serving an entire county (excluding in some cases the larger towns and cities which have their own library service) through a central library, usually located at the county seat, and a system of branches and deposit stations, all served and directed by skilled librarians. To reach the more isolated sections book automobiles are used by some county libraries. From the middle of the 19th century sporadic efforts were made to establish county libraries, and some of them met with a fair degree of success; but it was in California beginning about 1909 that the first real system of county libraries developed. The California library law of 1911 gave that State the leadership in the county library movement and has had much influence on county library legislation in other States. Thirty-three States have laws authorizing county library service in some form. Management is usually in the hands of a county library board. In a few States, California for example, the county library system is managed directly by the county supervisors. To maintain the highest standard of service the county library system should be under the supervision of some State agency. In 1928 public funds were being appropriated for county public library service in only 251 out of the 2,806 counties in the United States. California headed the list of States with 46 counties out of a total of 58, less than 3% of the population being outside public library service areas.

School Libraries.—The new curriculum of the high school and the newer methods of teaching have made the school library a necessity. The first modern high school libraries were started by the librarians of public libraries, and all of them have appeared since 1905, when full time high school librarians began to be appointed. Strictly speaking, a library even though located in a school building is not a school library unless maintained and administered primarily for the benefit of pupils and teachers. Administration of school libraries of this kind may be undertaken by the school authorities themselves or turned over to the public library. The importance attached to the school library in modern education is reflected in the State laws and the regulations of State education authorities. The standards prescribed usually apply only to high schools and cover such matters as the annual appropriation, the initial cost or value of the books, the expenditure per pupil, the number and kind of books selected, the housing and equipment of the library and the qualifications, education, training and duties of the librarian. In some States the standards adopted are not compulsory but are merely recommended to local school boards. It is usually assumed that a full time librarian is required in schools of 500 or over. In the smaller high schools a teacher—most frequently the teacher of English—serves as teacher-librarian.

Special Libraries.—Specialization in all fields of endeavour necessarily has its counterpart in library service. A very large tax-supported public library can specialize its collections and service to some extent, particularly in the direction of some dominant industrial or other interest of the community. Endowed public libraries have more freedom to neglect certain fields and concentrate their efforts on others. Public libraries, on the other hand, may build up special collections in various subjects and provide specialized service for schools, for children, for the blind, for business men, for Government officials, etc., but it is seldom possible for them to carry specialization in either collections or service to the extent that is required by the educational, business, professional and other interests of the community. Professional and other groups, therefore, find it desirable to organize and maintain their own libraries so that in populous centres are to be found privately supported libraries of law, medicine, engineering, etc. Some of these are for the use of members or subscribers only; others are open to the public. Educational institutions require libraries that are built up and administered to meet the special needs of students and teachers. With the development of the modern business corporation the need arose for a specialized library service which could not ordinarily be furnished by the public library. The result has been the rapid development since about 1910 of collections of printed matter in special fields, in charge of persons familiar with the subject matter, for the use of a more or less limited group. In 1909 a Special Libraries Association was organized and began publishing the monthly journal *Special Libraries*. While the association draws its membership from many types of special libraries, the business interests predominate. It has now become quite common to find special libraries maintained by banks and investment houses, insurance companies, advertising agencies, newspaper offices, public service corporations and a great variety of industrial and commercial companies.

The American Library Association, organized in 1876, is an association of libraries, librarians, trustees and other friends of libraries, pledged to carry out the purpose of its founders "by disposing the public mind to the founding and improving of libraries." It had in 1927 a membership of more than 10,000. Its total budget in the fiscal year 1927 was more than $325,000, the largest items of expenditure being for the promotion of professional library education and the publication of text-books, professional literature and aids to book selection. Headquarters are located in Chicago. During the World War, the association provided libraries for soldiers, sailors and marines, sending more than 2,000,000 books overseas from 1917 to 1920. Other associations affiliated with the A.L.A. are the American Association of Law Libraries, the League of Library Commissions, the National Association of State Libraries, and the Special Libraries Association. Nearly every State has its own library association or joins with neighbouring States in a regional association. Library clubs are found in many of the larger cities. (C. C. Wi.)

E. Bostwick, *The American Public Library* (1923); H. C. Long, *County Library Service* (1925); D. A. Plum, *A Bibliography of American College Library Administration, 1896–1926* (1926); J. L. Wheeler, *The Library and the Community* (1924); G. A. Works, *College and University Library Problems* (1927).

Administration.—In the United States details of administration differ because of varying requirements from local and State governments, with marked tendency toward uniformity due to the influence of library schools and the A.L.A.

In general the public library is administered by a board of trustees or directors elected by the community or chosen or appointed by the mayor, city manager, council, or some similar officer or board. A few libraries are controlled by the local school boards, and fewer by self-perpetuating boards related to the city by contract or agreement. That in 13 cities of over 30,000 inhabitants boards of trustees have been discontinued, is an indication of a growing trend under city commission or city manager control. State aid—and therefore control—is a growing factor. Growth in county library service (even super county libraries) is noteworthy. The trustees are charged with the duty of fixing the policy for the institution, establishing principles governing the staff, determining the kind of library best fitted for the community. They usually work through committees. Tenure of office and length of service may differ in detail, but the aim and intent generally seem to be the choice of a middle ground between changes so frequent and rotation in office so constant as to make impossible continuity of policy, and so infrequent as to suggest danger of dry rot.

The librarian is usually recognized as executive officer of the board.

Current rules seem to emphasize fair play for all users of books, equitable treatment for the public, rather than convenience for the staff. How many volumes may be taken at one time, length of withdrawal before renewal, fines for failure to return books for renewal, regulations for summer or vacation privileges, special consideration for teachers or other classes of readers, these and similar administrative controls differ widely because of varying local conditions. Most libraries limit loans for ordinary books to two weeks, set fines of one or two cents a day for books not renewed, grant special privileges when general harm or inconvenience will not follow.

Support usually comes from public funds granted by the committee or board fixing the local tax levy. Money thus granted is turned over to the library board for spending under proper accounting, or is paid from the office of the local disbursing agent when warrants are presented bearing proper authorization.

Book selection through librarian and staff is increasing, decreasing through trustees. Occasionally books must be bought by public bids and tenders, but the tendency seems towards giving the librarian greater discretion as to purchase of books and supplies. Preliminary steps and details are in many cases regulated by statute, but once the books have passed this stage their administrative processes are fairly uniform, thanks to standardizing of methods and processes resulting from the influence of the library schools and the training classes. Cataloguing, accessioning, subject heading, classifying, charging to borrowers, registration of borrowers, inventory work, reading the shelves are all coming to show little variation. One important element in uniformity of cataloguing is the growing use of printed cards supplied by the Library of Congress. Several classification schemes had ardent advocates a generation ago; today the Dewey decimal system is almost universal among the more popular libraries, and the Library of Congress system bids fair to equal it among the larger college, university, and reference libraries. A similar tendency toward uniformity in the reporting of activities is shown by the growing use of the system recommended by the A.L.A.

LIBRARY ARCHITECTURE. Architecturally, the library is a modern problem. There were, of course, many famous libraries before modern times, but from the description that we have of those of antiquity, and from the examples still existing of libraries of the Renaissance on to the end of the 18th century, it is clear that the great collections of books were kept simply in rooms or galleries furnished with shelves or cupboards, and sometimes with heavy, pulpit-like counters on which the ponderous folios could be rested. Aesthetically, the treatment of these rooms was often masterful, as in the Vatican, the Biblioteca Lorenziana in Florence and the old Ste. Geneviève library (now in the Lycée Henri IV.) in Paris; but not until the 19th century were buildings or portions thereof designed to solve the special problems encountered in the cataloguing and storing of printed material and its use by readers. For private libraries, or libraries open only to a selected public, such as those of clubs, scientific

FIRST FLOOR PLAN OF THE BIBLIOTHÈQUE NATIONALE, PARIS

institutions and special departments in our modern universities, the old scheme, in which the shelves of books provide a decoration for the walls rivalling the finest tapestries, is likely to continue. But for the requirements of the modern *public* library, which has to meet demands peculiar to modern conditions, the old plan cannot serve.

A scientific approach to library planning first became necessary during the tremendous growth in the number of books published and the development of the democratic desire to place well-classified collections at the service of the general public. The mere extension of the type of libraries as then existed was found to be no solution. We have the record of such a scheme in the library project of Boulée (1729–99), entitled *Memoir on the Means to Secure for the King's Library the Advantages Required for this Monument* (1785). This memoir is accompanied by a drawing showing a gigantic gallery covered by a barrel vault, supported on two colonnades which vanish in the distance at a terminal apse, and admitting the light only through a rectangular opening in the centre. Under the colonnades there are three platforms, each supporting a tier of books. Aesthetically, the design is not without merit in its severity, and it shows, moreover, an appreciation of the magnitude of the new problem. But the solution was not to be found in a mere increase in size; rather in a frank segregation of the public in reading rooms and of the creation of separate store-rooms for the books. These store-rooms are what we now call the "stacks," where in general the public is not admitted and an intensive use of space can be made.

As early as 1835, the French architect, Benjamin Delessert, suggested for the proposed Bibliothèque Nationale in Paris, a circular reading room, with the book-stacks surrounding it, lying radially to the centre. The old Wolfenbuttel library (1706), and its derivative, the Radcliffe library at Oxford, had already been built on a circular plan, but without the separate book-stacks. This circular reading room recommended itself by allowing the librarian (installed on a raised platform in the centre) an easier supervision of the readers. Delessert's plan probably suggested that of the reading room of the British Museum (R. and S. Smirke, architects, 1852) where, however, the stacks are rather awkwardly arranged around the central dome.

When Henri Labrouste was appointed architect for the new Ste. Geneviève library in Paris (1843) the site selected, being long and narrow, almost forced the solution of a reading room occupying the entire upper floor of the building and containing many of the books, as in the old libraries, but with other spaces for books beneath,—a scheme that in recent years has been used in many important libraries. Although the shape of the lot unfortunately made it necessary to divide the book storage into two sections, Labrouste had, nevertheless, evolved a masterly solution of his problem, a solution so daring in his frank treatment of structural elements that this building remains one of the prototypes of modern architecture.

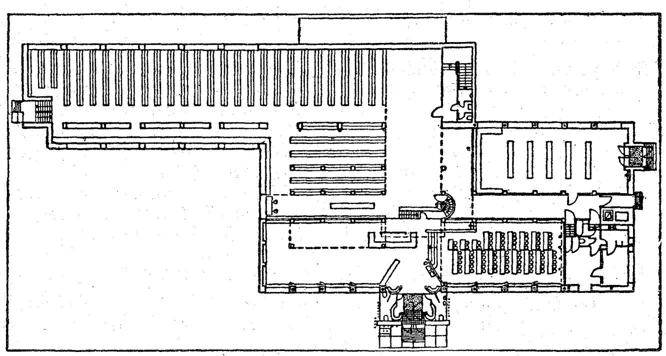
Later, in the plans for the Bibliothèque Nationale in Paris (1854), where he was less hampered by the exigencies of space, Labrouste gave another remarkable building. The main reading room is square, with an apse, where the librarians are installed, facing its entrance and commanding that to the stacks. The reading room is surrounded by three tiers of shelves, with the light coming through a large opening on the north side, and from nine domes which each rest on four light steel columns. The atmosphere of the rooms is quiet and restful and the light is excellent. The most remarkable part of the composition, however, is the book-stack (*magasin des imprimés*), a huge room, 90 ft. by 120 feet. Here the principle of the modern book-stack is first evolved. The shell of masonry is covered by a glass skylight, which allows daylight to penetrate every corner, while inside this shell, the metal framework of the book tiers and the passages between is an entirely independent construction resting on the basement floor. These are the essentials of the modern book-stack, the invention of which has been attributed quite incorrectly to W. H. Ware and Bernard Green; the only improvement contributed by these gentlemen, many years later, was the closer packing of the shelves and the elimination of such woodwork as remained.

LIBRARY PLANNING

The three types of libraries represented by the two works of Labrouste and the British Museum, furnished the patterns for most large libraries of late 19th and early 20th centuries. To the type of the Ste. Geneviève; *i.e.*, with a reading room lighted on both sides, with books along the walls or in alcoves, and with a storage under the reading room, belong the New York public library (Carrère and Hastings, architects, 1897), the library of the University of Chicago (Shepley, Rutan and Coolidge, architects, 1910) and the Philadelphia free library (H. Trumbauer, architect, 1915–27). To the type of the Bibliothèque Nationale; *i.e.*, with a reading room parallel or perpendicular to the stacks, belong the project for the library of Berlin by Hosfield (1875), the Widener Memorial library at Harvard, the Toronto library and many university libraries. To the type of the British Museum; *i.e.*, with a circular reading room surrounded by the book-stacks and lighted by high windows or skylights, belong the Columbia university library, New York (McKim, Mead and White, architects, 1897), the library of Strasbourg (Hartel and Neckelmann, architects, 1895) and the library of Congress, Washington, D.C. (Smighmeyer, Pelz and Casey, architects, 1886–97). The original scheme for this last library had radiating book-stacks, like the Delessert scheme, but it was abandoned for a block entirely filling the light courts.

The economy of space which this effects cannot be questioned, but opinions differ widely as to the advisability of packing the book-stacks so closely without allowing other than artificial light.

A marked progress in library design was noticeable around 1930. In the design of the Bibliothèque Nationale Suisse in Berne (1931, Oeschger, Kaufmann and Hostettler, architects), a straightforward functional solution of library needs expressed itself in



FLOOR PLAN OF MUNICIPAL LIBRARY, VIIPURI (VIBORG). ALVAR AALTO, ARCHITECT the plans and elevations. Emphasis within was laid on clarity of vision, ease of access to books and uniform day and night lighting facilities. The library of the League of Nations, Geneva (Nénot and Flengenheimer, architects), has gained international recognition as a reference library.

The municipal library at Viipuri (Viborg) (1934, Alvar Aalto, architect), shows a departure from the formality of axial relationships and symmetry hitherto employed in library planning. The technical requirements for shadowless lighting, mechanical ventilation and acoustical treatment influenced the shape of rooms and contributed the interest in the wall and ceiling surfaces formerly supplied by surface decoration. The storage annex at Versailles of the Bibliothèque Nationale in Paris solves the problem caused by the immense accumulation and continuing growth of material to be stored by libraries. A separate building was built for newspaper storage 15 km. from the central library and well outside city congestion.

At the Library congress held in 1937 at the Paris exposition, the use of miniature photographs to reduce storage space was discussed. Printed material photographed on 35 mm. film, on an average diminishes the bulk and weight of material by 95%. Branch libraries and reference libraries specializing in particular fields likewise tend to overcome the unwieldiness of the central libraries.

American Libraries.—In the United States the number of people who borrow books for home reading exceeds the number of those who use the reading rooms in the library. This has given rise to a new service, the essential feature of which is the delivery room with its desk in direct communication with the stacks, and its catalogues and open shelves so arranged that the readers in the reading rooms need not be disturbed.

In the larger libraries, the card-catalogue has developed to such an extent as to require a special room. In the New York public library the catalogue room is on the third floor where readers must pass it on their way to the reading room.

Excellent examples of public libraries with the delivery room as the central feature and the reading rooms secondary to it, are best seen in those by Albert R. Ross at Washington, D. C., and Denver, Colo., and even possibly more so in those at St. Louis, Mo., and Detroit, Mich., both by Cass Gilbert.

A special type of university library was evolved for Johns Hopkins university, Baltimore, Md., by Parker, Thomas and Rice (1914).

In this case, special emphasis was laid on affording the small groups of advanced students working in classes in the building (seminar groups) an easy access to the stacks. For this purpose the stacks, in two units, are placed in the centre of the block opening into the corridors of the seminar rooms, which are on the outer sides of the building. The main reading room is at the end of the composition.

In the first quarter of the 20th century, a standard type was evolved for the libraries of smaller communities or for the branch libraries in the cities (*e.g.,* branch libraries in Detroit and Philadelphia, and Carnegie libraries in England).

Although the plan of such may vary slightly to admit some special requirement such as a lecture or picture gallery, it is generally that of a one-story, rectangular building over a basement and standing free on a lot, in order to ensure lighting from every side.

The entrance, on the long side, leads directly to the delivery desk, while the spaces to right and left are devoted to the adult reading room and to the children's reading room, separated, in the majority of cases, only by a low enclosure, to afford general supervision by a small staff from the delivery desk.

EXTERIOR AND INTERIOR TREATMENT

Recognition of the need for a logical expression in the elevations of the functional requirements of the plans did not come until the end of the third decade of the 20th century. Before this, libraries were treated in the modernized classic tradition or, as in some American university libraries, in the general style of collegiate Gothic architecture adapted for the group. As remarkable studies for elevations may be mentioned the Ste. Geneviève library, the library of the École de Médecine, by Ginain, both in Paris, the New York public library, the Boston public library and the Columbia university library, the last two by McKim, Mead and White, and the Detroit public library. In the smaller libraries in the United States, there is a wider range in the styles of the façades, which are often inspired by the dominant note in the suburban architecture (*e.g.,* colonial types or Spanish mission).

The technical equipment of libraries has followed the general trend of the times in the progressive elimination of all woodwork in the shelving, unless kept for decorative reasons, in the effort to utilize a maximum of space for storing books, and in the simplification of service by book-lifts, conveyors, etc.

(P. P. Cr.; W. F. B.)

LIBRATION, a slow oscillation, as of a balance; in astronomy especially the seeming oscillation of the moon around her axis, by which portions of her surface near the edge of the disc are alternately brought into sight and swung out of sight.

LIBRETTO (It., dim. of *libro,* a book), term for the text, or "book" of an opera.

LIBYA, Greek name for northern Africa (Λιβύη) and modern name for the Italian colony comprising Tripolitania and Cyrenaica (*qq.v.*). Ancient Libya did not include Egypt, then part of Asia and first assigned to Africa by Ptolemy, who made the isthmus of Suez and the Red Sea the boundary between the two continents. The name Africa came into general use through the Romans.

The old name was reintroduced by Diocletian, by whom Cyrenaica was divided into Marmarica (Libya inferior) in the east and Cyrenaica (Libya superior) in the west. A further distinction into Libya interior and exterior is also known. The former (ἡ ἐντός) included the interior (known and unknown) of the continent, as contrasted with the N. and N.E. portion; the latter ἡ ἔξω was called simply Libya. *See* Africa, Roman.

Modern Libya, comprising 679,183 sq.mi., was organized on Jan. 1, 1934, into four provinces: Bengasi, 58,684 sq.mi., pop. (1936 census) 113,744; Derna, 43,143 sq.mi., pop. 46,788; Misurata, 38,191 sq.mi., pop. 215,877; and Tripolitania 73,803 sq.mi., pop. 392,564; and a military territory in the south of 465,362 sq.mi. and a pop. of 48,403. In 1938 the population of Libya was estimated at 888,401. By a decree of Jan. 9, 1939, the four provinces were incorporated into the national territory of Italy, but the Libyan Sahara territory was not affected.

Crop production in 1937 included barley 42,500 short tons; wheat 17,500 tons; olives 16,300 tons; and grapes 7,000 tons. In 1938 sponge fisheries yielded 107 tons and tunny fisheries 1,022 tons. Over 40,000 tons of salt were produced. Livestock in 1938 included 726,000 goats, 890,000 sheep, 70,000 cattle and 90,000 camels. Imports in 1938 were valued at $46,400,600, exports $5,731,900. Nearly 90% of the trade was with Italy. Italian forces were driven out of Libya in World War II, and a British military government was set up.

LICATA, seaport, Sicily, province of Agrigento, 24 mi. S.E. of Agrigento direct; 54 mi. by rail. Pop. (1936) 30,641 (town), 31,611 (commune). The river Salso, east of the town, is the ancient *Himera meridionalis.* On the promontory, which has the town at its foot, and is called the Poggio di Sant' Angelo, the Ecnomus of the Greeks, is the site of the town Phintias of Aeragas built after the Mamertines destroyed Gela (281 B.C.). It was off this promontory that the Romans defeated the Carthaginian fleet in the spring of 256 B.C., while in the plain to the north, Hamilcar defeated Agathocles in 310 B.C.

The modern port refines and exports sulphur. It was bombed by the Allies in World War II.

LICENCE, permission, leave, liberty, hence an abuse of liberty; in particular, a formal authority to do some lawful act Such authority may be either verbal or written; when written, the document containing the authority is called a "licence." Many acts, lawful in themselves, are regulated by statutory authority, and licences must be obtained. (*See* Liquor Laws and Liquor Control, etc.)

LICENSED VICTUALLER. A "licensed victualler," in the original English meaning of the term, was the keeper of what the old licensing statutes called a "victualling house." As a descriptive term the name is one of considerable historical interest and importance. It bears clear witness to the intention and purpose of the State in the institution of the liquor licensing system, and also to the character of the social service which the licensee was expected and required to render to the community. He was not, and was not intended to be, a mere dram-seller, *i.e.,* a retailer whose primary and practically exclusive business it was to supply alcoholic liquors to the public, but a *victualler, i.e.,* a retailer of food and drink other than, and in addition to, the alcoholic beverages commonly consumed, the sale of which by the licensed victualler was merely an ancillary part of his victualling trade.

The idea, like other institutional ideas, did not long endure in practice, although until the 17th century at least it continued to represent the intention and object of the State. Lax and negligent administration and—much later—fiscal and legislative changes obscured the idea until it ceased to govern or even to influence the trading methods of the licensee. The "licensed victualler" became a publican whose primary and practically sole business was and is the retailing of alcoholic beverages. The name has lost its ancient and specific meaning. In modern (and accepted trade) usage it applies only to the holder of an ordinary "full" (publican's) licence, and is so restricted in the rules of the Incorporated Society of Licensed Victuallers, the oldest and most prosperous of "trade" benevolent societies. Changes in the connotation of names and terms are not uncommon in the history of social institutions, but such changes are usually changes of expansion, involving an enlargement and improvement of the scope of the service rendered. In the case of the public-house (the licensed "victualling house") the change has been of a different kind. It has not been, in the strict sense, an evolutionary change, but a departure from a governing idea which was the *raison d'être* of the institution itself, and it has involved not an enlargement, but an unhappy restriction, of the social service which the institution was intended to render. In the process of the change the "victualling house" became, against law and State intention, a "drinking house." That the State subsequently, but not until the beginning of the 18th century, accepted and accelerated the change by legalizing the worst form of dram-shop is true, but the "victualling house" by that time had disappeared, and the name alone survived in the statute-book. It is only in recent years that the name itself has fallen into legal (legislative) disuse.

Why "Victualling" Disappeared.—This was not, as is sometimes assumed, due to changes in social and economic conditions. These emerged as co-operating causative factors at a much later stage in British social history. It was due primarily to the play and pressure of commercial motives and was made possible by the default of the controlling authority. The incentives were plain. The victualling trade was, in the nature of things, a limited trade with natural bounds set to its expansion. It ministered to a limited demand. Profits were relatively small and not easily earned. The sale of liquor, on the other hand, was a simple trade; the expenses were small, the profits ample and quickly earned, and the demand was one which was easily fostered and dependable. The liquor business drew a larger, surer, more profitable patronage than a strictly victualling business. Given facilities, it provided a livelihood for a much greater number of sellers.

Even so, the incentives, powerful as they were, could not, unless tolerated and encouraged, have prevailed over the intention of the law. They found their opportunity in lax administration of the law. Licences were granted by justices in many districts with a careless and often a shameless disregard of local needs which drew upon them repeated admonitions from the Privy Council and from judges of assize, and required frequent resort to summary measures of licence suppression. These suppressions were sporadic and intermittent and they had no appreciable effect in re-establishing the public-house as a "victualling house." The intention of the law, nevertheless, remained clear and it was the reassertion of this intention in the notorious Tippling Acts of James I. (1603–4 and 1623–24) and Charles I. (1625) that gives these futile acts their historical significance. The object of this special legislation was made plain in the preamble to the first of the Tippling Acts. It was to restore the "ancient, true and principal use of inns, ale-houses, and victualling houses" as places "for the receit, relief and lodging of wayfaring people travelling from place to place, and for such supply of the wants of such people as are not able by greater quantities to make their provision of victuals and not meant for entertaining and harbouring of lewd and idle people to spend and consume their money and time in lewd and idle manner."

The Tippling Acts notoriously failed. Prolonged inefficiency in regulative control and widespread maladministration of the licensing statutes had gone too far to make a summary cure possible; but the clearly avowed object of the Tippling Acts is of great historical importance in a survey of the original purpose and intention of the English licensing system. The ultimate responsibility for the final departure from the original idea of a victualling house rests, however, with the State, which, by its unhappy fiscal and legislative policy at the end of the seventeenth and in the early decades of the eighteenth century, took the first of two steps, each of which had demoralizing social effects, which finally sealed and disastrously aggravated a departure in aim and policy which heretofore had casually developed from administrative negligence.

The Gin Shops.—The economic and fiscal policy of William and Mary at the end of the 17th century, continued as it was by Anne in 1704, brought in its train a flood of gin shops which established in England a new and immeasurably worse type of "tippling" house whose increase and activities put a vicious stamp upon the character of the English public-house which it has never wholly lost. In the Gin Acts, the old idea and ideal of the "victualling house" was not merely ignored but destroyed. The evil wrought by these acts was further aggravated, a century later, by the Act of 1830, which established the beer-houses—a new form of drinking saloon—which, although subsequently restricted, but endowed with a vested interest, still exist in large numbers.

It is to these departures from the original aim and purpose of the English licensing system that we owe the difficulties and complexities of the public-house problem as it exists in England to-day. It is these departures, due partly to negligence and partly to lamentable mistakes in fiscal and legislative policy, that have saddled Great Britain with a "drink problem." Their effects are manifest. They have created a problem of redundancy which is not disputed but which is buttressed and beset by legal interests which make an equitable adjustment of facilities for sale to public need and demand difficult and slow. A return to the idea of the "victualling house," which, if preserved, would automatically have determined and controlled the supply of facilities, is not easy. Modification of the original requirement and long permitted departure from the "victualling house" idea have stimulated and fostered a habit of dram and "bar" drinking which cannot be summarily suppressed. Sweden is the one country in Europe which has slowly but progressively retraced its steps and, by eliminating private profit interests in the sale of spirits (the national beverage), has been able to substitute the "victualling house" for the dram-shop by compulsorily coupling the "on" sale of spirituous liquors with the sale of food.

The British Parliament in 1910 made it a ground of refusal of the renewal of an "old on-licence" (other than an ante-1869 beer-house licence) that the holder of the licence has persistently and unreasonably refused to supply suitable refreshment (other than intoxicating liquor), at a reasonable price. The Act of 1921 went a step further. By abolishing the old-time "closing-hour," but limiting the sale of intoxicants to what are called "permitted hours," it leaves the publican free to keep his premises open for the sale of food and non-intoxicants at any hour of the day or night. The privilege has not so far (1928) been used. (A. Sh.)

LICHENS constitute a class of small plants, in common speech included usually under the mosses, but actually belonging with the fungi, from which they differ in that they contain and live upon cells of living algae, in a relation more symbiotic than parasitic, as explained later.

Lichens are seen in waste places unsuited to other vegetation, also covering the ground, the bark of trees, rock surfaces and logs, in woods and fields untouched by fire and otherwise undisturbed. They are most plentiful in exposed, little-shaded places, mountain tops, bogs, arctic tundra, where atmospheric moisture is supplied by frequent fogs or by proximity to large bodies of water. Few of them thrive on fertile soils where vegetation is rank, while none at all grow in the neighbourhood of large cities, where they are killed by smoke and gases.

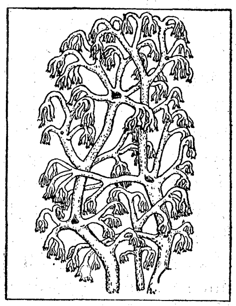

FIG. 1.—REINDEER MOSS (CLADONIA RANGIFERINA) (AFTER "THE LICHEN BOOK")

From true mosses, which are usually bright green or dark green, clothed with small green leaves, lichens are distinguished by the absence of leaves, except that some are covered with leaf-like or fin-like scales thicker and more opaque than leaves, and by the colour, which when dry is rarely bright green. Prevailing shades are pale gray, greenish gray and white, with yellow, olive, black, brown, orange and red less frequent. When moist many lichens turn dull green or olive, sometimes bright green.

Among the most familiar lichens are the stalked forms of the large genus Cladonia, which form extensive sods of closely packed flakes, or in some species flakeless incrustations, from which arise fruit-stalks called podetia, extremely variable in shape, often capped by the fruits (apothecia), which may be red, brown or variously coloured. Cladonia includes the Reindeer Moss (fig. 1), covering large areas of ground with tangled, gray tufts as much as 6 in. high. Other stalked lichens grow upright, not from a sod, but from a single point of attachment, and some hang down from the branches of trees, a striking feature in the landscape, familiarly called Old Man's Beard (fig. 2).

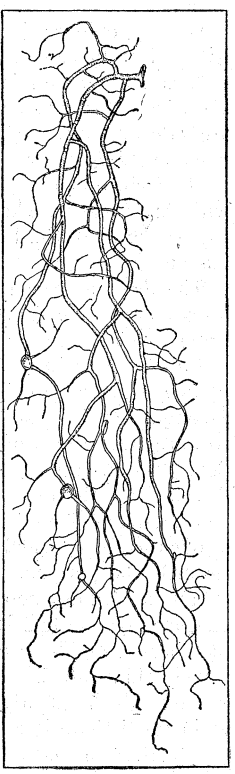

FIG. 2. — OLD MAN'S BEARD (USNEA TRICHODEA) (AFTER "THE LICHEN BOOK")

The larger rosette lichens form conspicuous, target-like mats on tree-trunks and rocks, spreading circularly to a diameter of a foot or more, plainly visible from a distance. These belong chiefly to the genera Parmelia and Sticta, with many of smaller dimensions, especially Physcia. Even more numerous are the crust lichens which cling to the surface of rock or tree, often as a mere discoloured area, studded with disk-shaped or pimple-like fruits. The colour of age in rocks commonly referred to as weathering may be due in large part to the presence of these small lichens.

The commoner lichens are distributed throughout most of the world, the same or closely related species occurring in the arctic, antarctic and both temperate zones. In the tropics and warmer regions of the temperate zones, however, specialized lichens rare in colder climates appear in great numbers, including the leaf lichens and numerous graphids, in some of which the fruits resemble Arabic script.

Lichens exhibit a considerable choice of habitat and form more or less constant associations of lichens only or with other plants. They are the pioneers of vegetation and soil-formation. By their delicate filaments they cling to the rock surfaces which they gradually penetrate and disintegrate. By mechanical action due to alternate wetting and drying of the gelatinous hyphae a sucker-like detachment of minute rock particles is constantly taking place (Fry 1924; 1926); by chemical action the acids discharged by the hyphae (carbonic, oxalic or lichen acids) dissolve the hardest rocks and even old window glass. The detached particles and the humus of cast-off portions of the thallus, together with blown dust, form a nidus for other vegetation—mosses and flowering plants—and mixed associations arise. The chief ecological factors are the types of substratum: the associations or communities are therefore naturally divided into:—1, arboreal and lignicolous, 2, terricolous, 3, saxicolous and 4, localized communities such as maritime lichens. Within these great groups there are minor associations influenced by the kind of bark, the nature of the soil (sand, clay or humus), the character of the rock (siliceous or calcareous) and also by conditions of temperature, moisture and exposure. A very distinct association is that of nitrophilous lichens: it constantly occurs on any kind of habitat in places frequented by birds and small mammals, and near to farmyards or on roadsides where the dust is mixed with nitrogenous animal matter. As in other plant communities there is a struggle for place and light. Crustaceous species are invaded and ousted by those of thicker or squamulose thallus or by the larger foliose species. Some mischance may in time dispossess them all and colonization begins afresh.

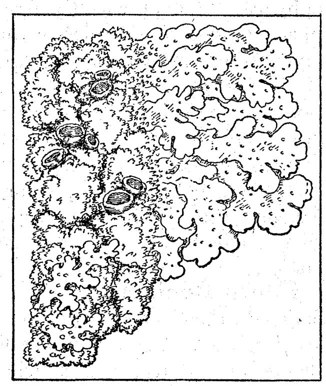

FIG. 3. — PARMELIA RUDECTA (AFTER "THE LICHEN BOOK")

ECONOMIC AND TECHNICAL

Lichens occupy an important place in the economic field. Mites and other small insects, caterpillars and slugs feed on them especially when they are moist and the acids not too pronounced. Petch has stated that they are the staple food of the black termites in Ceylon. Abbé Hue considered that the abundance and perfect development of lichens in the antarctic was due to the absence of insect life. In northern latitudes several kinds, for example *Cladonia alpestris*, are of great service as provender for domestic animals. *Cladonia rangiferina*, the reindeer moss (fig. 1), is the special food of the reindeer. In times of scarcity it has been found advantageous to grind up lichen thalli after elimination of acids, and to mix the powder with meal for human consumption. *Lecanora esculenta*, a rock lichen and often erratic, is abundant in eastern deserts and has been similarly used: it has been considered that that lichen was the manna of the Israelites. Species of *Umbilicaria* and *Gyrophora* called *tripe de roche* have been used by arctic explorers to stay the pangs of hunger. *Gyrophora esculenta*, an eastern maritime rock lichen is greatly esteemed as an edible plant both in Japan and in China.

Their value in medicine rested in the past on a somewhat fanciful basis—that of the "doctrine of signatures": certain characteristics of form by their resemblance to organs of the body, were considered to indicate curative properties. Some very bitter species such as *Pertusaria faginea* served as a substitute for quinine. *Cetraria islandica*, the "Iceland Moss" (*q.v.*), owing partly to its gelatinous consistency has been used with good effect in chest troubles, and is now the only lichen recognized in the British Pharmacopeia.

Their use as dye-plants has been known from the earliest times, and before the discovery of aniline dyes the rich and varied colours obtained from lichens were highly valued. The colouring principle of the dyes is contained in the peculiar lichen-acids. Treatment with an alkali is generally necessary to extract the colour; mordants are frequently used. With some lichens, boiling the plants with the material to be dyed is sufficient to secure the desired colour. The dyes can be used only on animal fibres such as wool and silk; they have no effect on linen or cotton. Purple lichen dyes—orchil, litmus or cudbear—are obtained from *Roccella tinctoria,* a maritime lichen, *Lecanora tartarea* and a few others. Other serviceable colours are the varied yellows and browns so much used in home or village industries. But abundant though dye lichens are, they can only furnish a limited quantity and could never meet any large demand.

About 1900 the use of *Evernia prunastri* and other lichens in the manufacture of perfume was revived after having lapsed since ancient times. The lichen and the perfume derived from it are both called Oakmoss (*q.v.*).

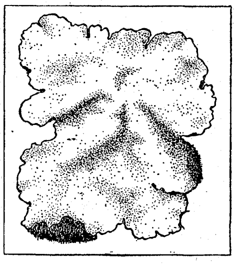

FIG. 4. — UMBILICARIA DILLENII (AFTER "THE LICHEN BOOK")

Lichens are of unusual interest in that the vegetative body or thallus is a composite plant formed by the interdependent growth of unicellular or filamentous green or blue-green algae Myxophyceae or Chlorophyaceae (fig. 5), with the filaments (hyphae) of one of the higher fungi—Ascomycetes or, in one or two genera only, Basidiomycetes. On this basis of combination or symbiosis there has been evolved a great series of distinctive plants, capable of vigorous life and of reproduction from generation to generation. Phycolichens signify those that contain blue-green, Archilichens those with bright-green algae, designated as lichen gonidia. The fungus is the dominant partner as it provides the fruiting bodies.

Lichen Gonidia.—For long it was accepted that the green bodies in the lichen plant were cells budded off from the colourless hyphae that gradually acquired a green colour. It was known that minute portions of a lichen plant—the soredia—each composed of a few green cells with entangled colourless filaments were agents of propagation. Wallroth (1835), for that reason, coined for the green cells the term *gonidia* to signify their reproductive function (fig. 6). In most lichens there is a gonidial zone near the surface and to that he gave the name *stratum gonimon.* In a lesser number the gonidia are distributed through the thallus (fig. 7). These two types he distinguished as *heteromerous* with distinctive layers, and *homoimerous* where there is no such diversity.

The belief in the genetic origin of the green cells within the thallus held sway for many years, though observations of a disturbing character were not lacking. Agardh (1821) had suggested that they were transformed algae as he had followed the development of the blue-green alga, *Nostoc,* to the complete thallus of the lichen, *Collema.* The view gradually gained ground that the bright-green gonidia of many lichens were comparable to the alga *Protococcus.* The explanation given was that these free growing algae were lichen gonidia escaped from the thallus that had continued independent growth. Wallroth spoke of them as "unfortunate brood cells" that could not again form a lichen plant. Finally in 1867 Schwendener published his bold theory that lichen gonidia were true algae imprisoned and parasitized by fungal hyphae. The statement was welcomed by many as enlightening and convincing. Others, among whom were the renowned Finnish lichenologist, W. Nylander and the British J. M. Crombie, scornfully rejected the new view. The theory was, however, successfully tested by cultures of lichen spores with free-growing algae—first by Rees (1871), then by Bornet (1872) and others who followed the development from spore to fruiting stage, a slow growth of several years' duration.

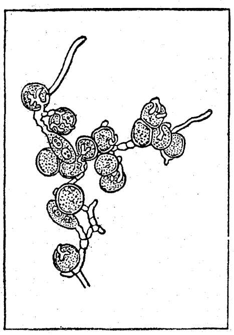

FIG. 5.—LICHEN HYPHAE AND GONIDIA. ASSOCIATION OF LICHEN HYPHAE AND GONIDIA X 250. (AFTER BONNIER)

Symbiosis.—The relation between the two organisms was regarded at first as a parasitism of the fungus on the alga, or as *helotism.* Reinke (1873) pointed out the insufficiency of a condition of parasitism to explain the healthy lichen, and he therefore proposed the term *consortium* as a truer conception. A few years later de Bary (1873) suggested *symbiosis* as an adequate term and it is now generally accepted as a *mutual symbiosis.* This view has been confirmed by culture experiments. In general the alga supplies carbohydrates by photosynthesis, the fungus provides salts and water storage. Symbiosis in lichens is a fairly stable life-balance which may tip, however, to the detriment of one or other of the organisms: there are instances, perhaps more frequent than we have supposed, of gonidia perishing in the grip of the fungi, but there are also cases where owing to some unfavourable condition, the fungus has succumbed while the algae increased enormously. There is no doubt as to the normal healthy condition of the thallus and of both symbionts. The interest in lichen gonidia has of late centred in the globose bright-green alga considered to be a species of Protococcus, said by Paulson and Somerville Hastings (1920) to have a massive parietal chromatophore, and to multiply freely and abundantly in the thallus by the free cell formation of aplanospores. The season of greatest increase was from February to April, or after heavy rain following a season of drought; zoospores were not seen in the gonidial state. The sporulating gonidia were most abundant in the actively growing regions. More recently Puymaly (1924) has proposed a new genus, *Trebouxia,* for the alga without and within the lichen thallus. He describes it, however, as possessing a massive stellate chromatophore. In view of Paulson's observations, again renewed, it is impossible to regard the gonidium chromatophore as of stellate form.

Lichen Algae.—The algal constituents of the thallus belong to two classes. I. Myxophyceae (blue-green algae) and II. Chlorophyceae (bright-green algae). They are, in general, aerial forms and in a free condition inhabit moist shady situations. Though the determination of algal species is somewhat uncertain, the genus can be more easily recognized.

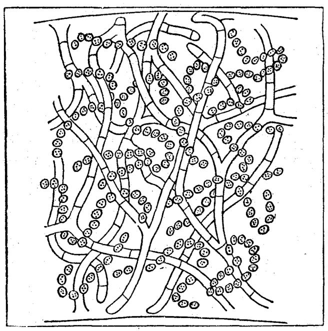

FIG. 6.—THALLUS WITH GONIDIAL ZONE. SECTION OF HETEROMEROUS THALLUS X 500. (AFTER SCHWENDENER)

I. Myxophyceae associated with Phycolichens in Collemaceae and other families. The algae of most frequent occurrence are *Gloeocapsa, Nostoc, Scytonema* and *Stigonema.*

II. Chlorophyceae associated with Archilichens. Those of most importance are the globose algae belonging to the Protococcaceae and *Trentepohlia,* a filamentous alga.

The alga may become modified in the gonidial state: *Gloeocapsa* loses colour, *Nostoc* chains, and *Trentepohlia* filaments may be broken up into cell units.

Lichen Hyphae.—These undergo considerable modification as lichen symbionts. The fruiting form indicates their origin as ascomycetous or basidiomycetous, and their affinity can be traced to ancestral groups of fungi. Bonnier (1889) in describing their development from the spores in synthetic cultures noted three distinct types:—(1) clasping filaments with repeated branching which surround and secure the alga; (2) filaments with short swollen cells destined to form several lichen tissues and (3) towards the periphery, searching filaments that form the hypothallus and annex new algae. In five days after germination the clasping hyphae had laid hold of the alga and symbiotic growth had begun. In the growing regions the hyphae remain comparatively thin-walled. In other parts—especially in the cortex, etc. —the walls frequently become thick and gelatinized. In lichens as in fungi there is no true cell structure or parenchyma, but in the cortices of many lichens a pseudo-parenchyma or plectenchyma arises by the closely packed growth of the septate tips of the hyphae. Plectenchyma also occasionally appears in other parts of the thallus.

Cultures in artificial media apart from gonidia have been made by several workers: by Möller (1887) with *Lecanora subfusca;* by F. Tobler (1909) and by Killian (1925) with *Xanthoria parietina* (fig. 8). Also by Killian and Werner (1924) with the spores of *Cladonia squamosa*. In all cases the results were fairly similar: growth was slow and finally ceased—in *Xanthoria parietina* in eight or ten months. A series of tissues was however observed in the last culture: (1) a dense layer of filaments representing the medulla; above that (2) a looser tissue in the position of the gonidial layer and (3) a second dense tissue representing the cortex from which arose aerial hyphae. Tobler further records that growth became more lichenoid when the gonidial alga was introduced and the yellow acid parietin appeared in the tissues. Werner (1927) tested hyphal growth on various media and found that galactose was the most advantageous food supply. Organic nitrogen was added as peptone and asparagin, inorganic as nitrate

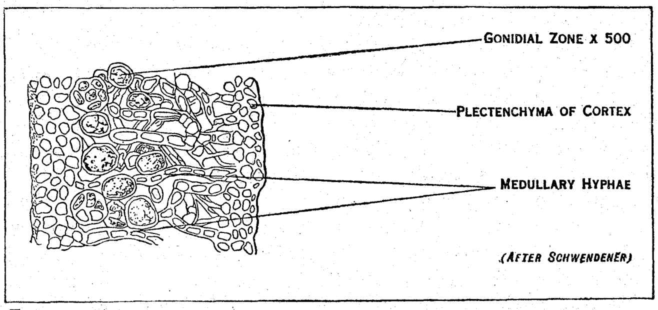

FIG. 7.—THALLUS WITH DISPERSED GONIDIA. SECTION OF HOMOIOMEROUS THALLUS X 250. (AFTER "B. M. HANDBOOK OF BRITISH LICHENS")

of ammonium. Growth was slow, but the addition of gonidia to the culture retarded it yet more, so that the algae gained in numbers.

MORPHOLOGY

The main interest in morphology lies in tracing the effect of symbiosis on development. The fungus as the dominant partner provides the structure of the thallus but the variety of forms evolved is due to the necessity of securing light and air to enable the alga to carry on the work of photosynthesis.

General Structure of Ascolichens.—In these there are two main types of thallus:—(1) the *stratose* which includes flat spreading plants, crustaceous or foliose, in which the upper surface alone is exposed to light; and (2) the *radiate* which in the lichen competition for sunlight and space has developed upwards from a rooting base to shrub-like branching fronds or pendulous filaments.

(1) The simplest stratose lichens consist of a film of loose hyphae with scattered gonidia. In further advanced species there is a more bulky thallus formed of an upper cortical protecting layer, generally of dense hyphae with more or less swollen walls and with the lumen of the cells almost obliterated (decomposed cortex); beneath the cortex a gonidial zone of massed gonidia and intermingled slender hyphae, the latter passing downwards to form a loose medulla. Projecting hair-like hyphae anchor the plant to the rock, tree or soil. The upper surface may be smooth or uneven, or seamed and cracked into small compartments called areolae. Not infrequently the crustaceous thallus is wholly embedded in the substratum as in Graphidaceae. In contrast to the surface or *epiphloeodal* forms, such lichens on trees are termed *hypophloeodal,* a stain on the bark usually indicating their presence; the fructifications are formed on the surface. Similarly rock lichens are *epilithic* or *endolithic*. The latter live in limestone, which they penetrate to various depths. Friedrich (1906) noted in an immersed species, *Biatorella simplex,* a slight cortical layer, below that a zone of gonidia 600–700 μ in thickness, while the medullary hyphae reached a depth of .47 in. An instance has been recorded of a lichen penetrating to 1.2 in. below the surface. Still higher in development are the squamulose thalli of tiny leaflets and the larger foliose (fig. 10) forms in both of which the thallus is raised from the substratum

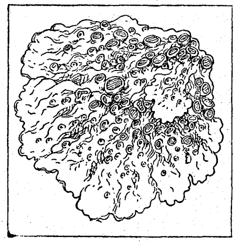

FIG. 8. — XANTHORIA PARIETINA (AFTER "THE LICHEN BOOK")

partly or entirely and in which the free under-surface also acquires a protecting cortex which generally repeats that of the upper-surface—either of decomposed cells, of plectenchyma or of hyphae parallel with the surface (fibrous cortex). Stratose lichens start from a centre, the growing tissue is situated in the gonidial zone and the greatest increase is at the periphery, the lichen gradually enlarging on all sides, in some to a size of one foot or more in diameter. Growth is continuous, but divisions may arise that are imbricate and leaf-like. In squamulose forms the squamules arise in succession from the spreading hypothallus—the travelling ground hyphae. Foliose forms are attached at irregular intervals by rhizinae.

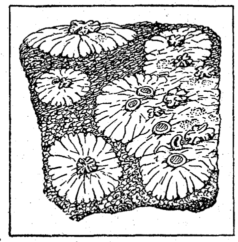

FIG. 9. — CRUSTACEOUS LICHEN (LECANORA GELIDA) WITH CEPHALODIA (AFTER "THE LICHEN BOOK")

(2) Radiate lichens, upright fruticose forms (fig. 11), start from a rooting base; the fronds are exposed to sun and air on all sides and the structure is alike round the whole surface. The cortex is of several types:—of decomposed cells, of densely packed, fastigiate hyphae or of longitudinal, thick-walled fibres. All these variations give strength and pliancy to the fronds. Other strengthening structures are the "sclerotic" fibres which extend up the frond either just within the gonidial zone as in *Ramalina* or, as in *Usnea,* in one strong chondroid central strand of great toughness and strength. Growth in radiate lichens is apical or intercalary. Fronds of *Rocellae, Ramalinae,* etc., reach a height of several inches; pendulous lichens often grow in long streamers: a length of 11 yd. has been recorded for *Usnea longissima* in the tropics.

In *Cladoniae,* the cup lichens, there is a double thallus: leaflet squamules of stratose structure, with upright stalks or *podetia,* frequently widening to a cup or *scyphus* at the top (fig. 13). The podetium becomes hollow in time but is firm and strong owing to the sclerotic fibres that line the central tube. Fructifications are borne on the tips of the podetia or on the edges of the scyphus, which seems to indicate that the podetium originated as a fruit stalk. There is great variety of form, texture and colour in each of these main groups.

Special Lichen Structures.—*Cyphellae.* There are no stomata in lichens, but ample provision is made for aeration and for gaseous exchange. Definite aeration structures (fig. 14), cyphellae or pseudo-cyphellae pierce the thick under-cortex of the Stictaceae. They are small and cup-like, in cyphellae with an overarching margin; the base rests on the medulla and the cup is filled with small loose cells. Pseudo-cyphellae lack the cup margin. In other lichens there occur dot-like openings; the lines between the areolae admit air, or the surface is seamed by cracks and delicate reticulations; soredial openings are present in many species, and in *Parmelia exasperata* there are true breathing-pores — minute cone-like outgrowths, open at the summit.

Cephalodia. These occur as excrescences on the thallus of Archilichens (with bright green gonidia), and always contain blue-green cells, mostly *Nostoc* or *Scytonema*. They are small bodies of various form and size from the minute pustules on the surface of *Peltigera aphthosa* (fig. 15) to the coralloid masses on *Lobaria laciniata*. Blue-green cells alight by chance on the thallus and the cortical hairs grow out and gradually form a cortex round them. In a few instances there are groups of blue-green cells which are absorbed into the thallus by the under-surface, and a layer of blue-green algae, below the normal bright green zone in *Solorina crocea,* also rank as cephalodia. These alien bodies seem to indicate an ancestral association of the particular lichen with blue-green gonidia, the power to combine having persisted along

FIG. 10.—FOLIOSE LICHEN (PARMELIA TILIACEA) (AFTER "THE LICHEN BOOK")

with the presumably more recent symbiosis with the bright green alga.

Soredia. As already indicated these are minute portions (hyphae and gonidia) that break away from the parent thallus and serve for propagation of species. The simplest types are diffuse soredia that in certain conditions of shade or moisture cover the surface of the plant. More defined forms are termed *soralia* which arise by the upward push of hyphae in the gonidial zone, and emerge as roundish or oblong bodies packed with soredial granules. These multiply and, as they become detached, are easily dispersed. Soralia are more or less specifically constant in form and size and in their position on the surface or margins of the lobes.

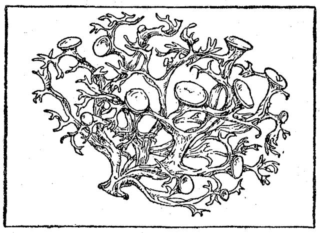

FIG. 11. — FRUTICOSE LICHEN (RAMALINA CALICARIS) (AFTER "THE LICHEN BOOK")

Isidia. Many lichens are rough on the surface owing to small outgrowths called isidia. So noticeable are they that Acharius established the genus *Isidium* to include isidiose lichens. They are cortical structures and begin generally as a small swelling or wart: they are upward extensions of the tissues and the cortex is continuous over their surface; sometimes they are darker in colour than the normal thallus as in *Evernia furfuracea* (fig. 12).

Structure of Basidiolichens.—There are three genera recorded in this group of tropical lichens: *Cora, Corella* and *Dictyonema.* The gonidia, *Chroococcus* or *Scytonema* are Myxophyceae. *Cora* and *Dictyonema* are of a thin bracket-like form; they grow on the trunks and branches of trees, very rarely on the ground, and are attached by rhizinae. No proper cortex is formed, but in *Cora* the hyphae take an upward direction towards the surface where they become horizontal, so that a compact protective tissue lies over the top; the gonidia (*Chroococcus*) form a zone at the base of the upward hyphae. In *Corella* and *Dictyonema* the *Scytonema* trichomes retain their form and are surrounded by the lichen hyphae.

Basidiolichens are related to the fungal family Thelephoraceae: the fructification is by basidiospores borne on the under-surface of the thallus.

REPRODUCTION

Lichens with few exceptions (Basidiolichens and primitive indeterminate forms) are Ascolichens, their method of reproduction corresponding to that of Ascomycetes, *i.e.*, by the production of ascospores in open or closed ascophores—apothecia or perithecia. In the slow-growing symbiotic plants these fruit bodies have been provided with special protective tissues that secure prolonged spore formation, differing in this respect from the fugitive ascophores of fungi.

Apothecia.—In lichens these are of several forms to which special names have been given:—ardellae, the irregular spot-like fruit of Arthoniaceae; lirellae, elongate, slit-like, dark-coloured bodies in Graphidaceae; in the larger majority of lichens open discoid apothecia. Those surrounded by a protective thalloid margin are called lecanorine (fig. 16), such as occur in the genus *Lecanora.* Those consisting solely of hyphal tissue surrounded by a hyphal or "proper margin" only as in *Lecidea* are described as lecideine (fig. 17). If that margin is obscure with the disk often brightly coloured they are biatorine, as in the sub-genus, *Biatora.* These are true distinctions, and are of value in the determination of genera and species. The difference is due to their origin in the thallus: in the lecanorine series gonidia are carried up with the developing fruit, and algal cells extend along the base and, entering into the "thalline margin," surround the apothecium. The lecideine tissues, solely hyphal, pass up through the gonidial zone, pierce the cortex and expand above it, the outer sterile hyphae forming the protective "proper margin." Minor differences in growth occur, with different types of apothecia—sessile or stalked, etc., and in size from a minute body to one of over 1.2 in. in width according to the genus or species of lichen. The disk or thecium is composed of a compact series of filamentous upright simple or branched paraphyses and of asci—club-like structures within which eight spores (fewer or more numerous) are produced by free cell formation. These, constituting the hymenium, are subtended by a layer of tissue, the hypothecium; the tips of the paraphyses projecting above the asci form the epithecium, generally coloured; the surrounding sterile filaments represent the parathecium; the thalline margin when present forms the amphithecium.

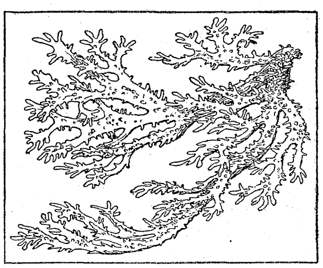

FIG. 12. — EVERNIA FURFURACEA (AFTER "THE LICHEN BOOK")

Perithecia.—These differ from the apothecia in being comparatively small, globose or pear-shaped, closed bodies immersed or semi-immersed in the thallus, and opening above by a pore, the ostiole. When the outer dark wall is continuous it is described as entire, and when absent at the base as dimidiate. In some genera the paraphyses dissolve as the asci mature.

Apothecia and perithecia are long lived like the thallus and may produce spores continuously or at definite seasons for several years, in *Solorina saccata,* for instance, over a period of two to four years, as observed by Hilitzer (1926).

Spermogonia or Pycnidia.—These are small closed bodies outwardly resembling perithecia; the hyphae that line the interior walls bud off minute pycnidiospores. As spermogonia they were considered of great importance as the male organs that produce the spermatia. There is no reliable evidence of their sexual nature and they are now generally classified as pycnidia resembling similar bodies that form a secondary stage in the fruit cycle of the Ascomycetes. It has been proved that the spermatia germinate and produce hyphae, a characteristic of spores.

FIG. 13.—SQUAMULES AND PODETEA OF CLADONIA VERTICILLATA (AFTER "THE LICHEN BOOK")

Cytology.—This aspect of reproduction has excited great interest since Fuisting (1866) observed in a crustaceous *Lecidea* the fruit primordium or ascogonium as a coiled hypha. Stahl (1877) announced the further discovery in a *Collema* of a trichogyne, a filament that travelled upwards from the ascogonium and emerged above the surface. He noted also an empty spermatium (pycnidiospore) adhering to the tip of the trichogyne after presumed fertilization. Other workers made similar observations both in gelatinous and in non-gelatinous lichens, and in open and closed fruits. Copulation with the spermatium has also been demonstrated but the behaviour of the spermatial nucleus has escaped observation. The ascogonium may be a coiled hypha or simply a complex of cells distinguished by their richer contents, and changes in these cells have been observed that seem to imply spermatial fertilization. It may be that in some lichens fusion takes place between neighbouring cells in the ascogonium: F. Bachmann (1912) found that copulation took place deep down in the thallus of *Collema* sp. between an internal trichogyne and a free spermatial cell. Apogamy, however, undoubtedly prevails in many lichens: either no trichogynes are formed or they fail to reach the surface and fertilization by spermatia is doubtful. Zahlbruckner (1924) has expressed the opinion that reproduction by sexual organs—present in the more primitive lichens—tends to die out in more developed forms. The whole subject bristles not only with the difficulties of observation in these slow growing plants, but also with the perplexities of interpretation: the function of the lichen trichogyne, a multiseptate hypha of vigorous growth, is not understood; but it may be of some service to the deep seated ascogonium. From the ascogonium arise the hyphae that are destined to form the asci. As in fungi the nuclei of two adjacent cells at the tips of these hyphae fuse and become the definitive nucleus of the ascus. There are normally eight spores, but the number varies in different genera and species from one, as in *Varicellaria,* to the large numbers in *Acarospora.* They are colourless or brown, and simple, variously septate or muriform, and they differ in size from a few microns in *Acarospora,* etc., to the large one-septate spore in *Varicellaria* ($350\times115\ \mu$). Large simple spores, as in *Pertusaria,* are multinucleate. Spore ejection is brought about by pressure of the paraphyses when moistened.

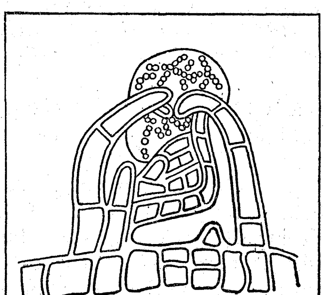
FIG. 14.—SECTION OF THALLUS OF STICTA, WITH CYPHELLA ON UNDER-SURFACE MUCH MAGNIFIED

PHYSIOLOGY AND BIONOMICS

Cells and Cell-contents.—In the study of lichen physiology attention must be given to the activities of the symbionts as well as to those of the symbiotic plant. Gonidia do not greatly differ from the allied algae growing in the open: they possess chloroplasts and form starch by photosynthesis. Mameli (1920) and Tobler (1923) demonstrated minute granules of starch on the outside of the gonidia—a ready food for the fungus. The hyphal cells have been more affected by symbiosis, and a much slower growth than in fungi has become a fixed character as proved by artificial cultures. The cell-walls, as in fungal tissues, are formed of hemi-celluloses, chitin being present in nearly all lichens. There is no true cellulose, but a substance, lichenin ($C_6H_{10}O_5$), allied to starch, has been demonstrated as well as a slightly different substance, isolichenin, the latter proved by Ziegenspeck (1924) to be a reserve material. Amyloid hyphae giving a blue reaction with iodine are present in the medulla of several species. Swollen cells filled with oil, probably an excretory substance, occur in many lichens, especially in limestone species. Oxalic acid is also frequently found in lichen tissues in the form of crystals, small granules, or in large clear masses as in *Pertusaria communis.*

Lichen Acids.—These are the most interesting and characteristic of lichen products. They are deposited on the outside of the hyphal cells as minute coloured specks or as colourless substances, and show a wide range of chemical formulae and a great variety of crystalline form. They are the product of the symbiotic plant as was proved by Tobler (1909) in his cultures of lichen tissues. Many of them are bright yellow, orange or red, and give the clear pure tone of colour to many familiar lichens. They are strongly influenced by light: *Xanthoria parietina* (fig. 8), a brilliant yellow plant in full exposure, becomes gray-green in the shade, with a small acid content. Some of these acids are rare, others are widely distributed, *e.g.*—usninic acid, found in some 70 widely diverse species; atranorin, first discovered in *Lecanora atra,* in about 70 species; salazinnic acid is equally common. They are abundant chiefly on well-aerated portions of the thallus—the soredial hyphae, the outer cortex, the loose medullary tissue and on the disk of the apothecia.



FROM J. BABIKOFF, "DU DÉVELOPPEMENT DES CÉPHALODIES SUR LE THALLUS DU LICHEN PELTIGERA APHTHOSA," HOFFIN BULLETIN (ACADEMY OF SCIENCE, U.S.S.R.)

FIG. 15.—CEPHALODIUM OF PELTIGERA APHTHOSA EARLY STAGE, MUCH MAGNIFIED

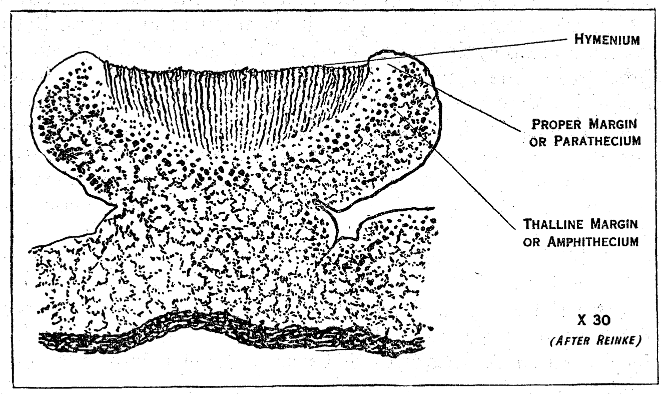
Chemical Grouping. The acids have been arranged by Zopf (1907) in 1, the fat series and 2, the benzole series.

1. The fat series. Zopf includes five groups in this series: three of the series are colourless substances, the coloured include vulpinic acid from the yellow lichen, *Letharia vulpina,* stictaurin deposited in orange-red crystals on the hyphae of *Sticta aurata* and rhizocarpic acid obtained from the yellow lichen *Rhizocarpon geographicum.*

2. The benzole series, with two sub-series—orceine and anthracine derivatives. The colourless orceine contains the colouring principle of commercial orchil. In the anthracine derivatives some of the acids are also coloured, such as parietin from *Xanthoria parietina* and solorinic acid from *Solorina crocea.* Asahina (1936) listed 19 lichen acids found in the genus Cladonia.

The question has been debated as to the service rendered by the acids: to some extent they protect the plants from wholesale destruction by snails, insects, etc., as they render the thallus more or less unpalatable. Goebel (1927) demonstrated that they are also a protection against water-logging. He found that outgrowths of hyphal hairs, cilia, etc., formed efficient water conductors, but if acids were abundant they remained dry: when the acids were removed by chemical means saturation was easily achieved. As acids are present on all aerated portions, they must be a powerful aid in keeping the air-channels open and thus serve a useful purpose.

General Nutrition.—Water is supplied by rain, mist or dew, mist being the most favourable for lichen requirements (Stocker 1927). Dew is important in extremely dry localities such as deserts. Inorganic substances are obtained to some extent from the substratum but mainly from air borne particles. Organic food is



BY COURTESY OF MESSRS. BORNTRAGER

FIG. 16.—SECTION OF LECANORINE APOTHECIUM (LECANORA SUBFUSCA)

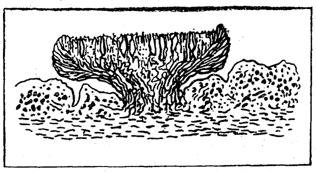
provided by the algae or may be procured by the hyphae from humus, etc.

Lichens show marvellous resistance as regards heat or cold. They survive the high temperatures of direct illumination and they endure seasons of extreme cold on mountains or in the polar zone. It is to their power of drying up to a condition of latent vitality that they owe this resistance. Light that can penetrate the thickened cortex and reach the gonidial zone is essential, but the same dense cortex protects the gonidia from too intense sunlight as do the acids and pigments. Light is of first importance in fruit formation, and the fruit bodies are therefore situated on well lighted portions of the thallus.

Bionomics.—The response of lichens to their environment is intimately associated with their physiological properties. Their scanty subsistence entails slow development though a few may be ranked as relatively quick growers—mostly soil lichens in touch with moisture. Such are *Peltigera canina* (fig. 18) that spreads over damp lawns, etc., and crustaceous forms such as *Baeomyces* spp., *Lecanora tartarea,* and *Lecidea uliginosa;* the latter has been known to spread over an area several feet in diameter in one season, and has been reported as a pioneer plant forming a dark film over sand dunes in Alberta. But in many lichens growth is often almost stationary: the large foliose *Lobaria pulmonaria* (fig. 19) and the crustaceous *Rhizocarpon geographicum* have been observed to make practically no advance during a period up to 50 years. Accurate measurements of more active *Parmeliae,* etc., have given a general increase of .39 in. per annum; their fruiting bodies require in general four to eight years to develop.

Lichens do not grow on friable rocks or on peeling bark. They require, for the first stages at least, a substratum to which they can be firmly attached by filaments or by rhizinae. In fruticose branching and straggling forms compactness is often secured by *haptera,* which form a bridging connection between the fronds of the same lichen or to other vegetation, as for instance, *Cladonia sylvatica,* which becomes detached from the soil and adheres to the growing heather, thus securing not only attachment but light and air. Some few species become loose and continue growth while they drift about as erratic lichens. Several *Parmeliae, Alectoriae* and *Lecanora esculenta,* etc., are erratic forms.

PHYLOGENY AND CLASSIFICATION



FROM A. L. SMITH, "LICHENS" (UNIVERSITY PRESS, CAMBRIDGE)
FIG. 17.—SECTION OF LECIDEINE APOTHECIUM (LECIDEA PARASEMA) (AFTER "B. M. HANDBOOK OF BRITISH LICHENS")

Phylogeny.—It would be interesting to know when the symbiotic plant originated and whether the first association of the fungus was with Myxophyceae or Chlorophyceae; but lichens, owing to the gelatinous nature of the thallus, become soft in water and there is little or no evidence in the rocks as to their antiquity: there is only a doubtful record of an *Opegrapha* in Mesozoic chalk. It is concluded from their elaborate morphology and physiology that they are very old plants, but the symbiotic organism—the lichen—is obviously of more recent descent than its component ancestors. Both symbionts are polyphyletic in origin: the algae are blue-green or bright green; the hyphae belong to various phyla of the fungi from which they are late derivatives. Basidiolichens are related to one fungus family, Telephoraceae; Ascolichens to Ascomycetes and to several distinct phyla within that class. The ascophore, which marks the phylum, has undergone considerable alteration which is recognized in classification. Phylogenetic development has, however, mainly taken place in the thallus which presumably began as a loose association of straggling hyphae with algal cells. It progressed to the definite crustaceous structure, and finally to the foliose and fruticose lichen. The greatest advance must have occurred when the thalline particle took an upward direction—a small outgrowth that was to develop into numerous forms.

The intimate relation between lichens and fungi is evident in the species that have remained on the border line. Some with scanty thallus appear to lose the algal symbiont as the ascophore matures, and the hyphae apparently revert to saprophytism as exemplified, for instance, in *Calicium,* a lichen genus, with *Mycocalicium,* the fungal counterpart. Others classified now as lichens and now as fungi live on an alien lichen thallus though not always as simple parasites; in a number of cases their hyphae penetrate the thallus and draw sustenance by symbiosis with the algal cells: these have been designated half-parasites. Lichen thalli are, however, a favourite host for many micro-fungi.

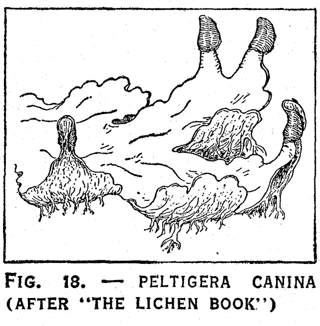


FIG. 18. — PELTIGERA CANINA (AFTER "THE LICHEN BOOK")

Classification. — Before the true nature of lichen plants was understood, many attempts had been made to classify them in relation to each other and to other members of the plant kingdom—to mosses, hepatics or algae. Tournefort (1700) placed them all in one genus *Lichen,* and was followed by Linnaeus (1753). Knowledge of their number and variety increased, and Acharius (1803) gave diagnoses of 23 genera with their included species. Nylander (1854) issued what he considered a final statement on lichen families and genera and of their relationships. His arrangement began with those nearest akin to algae, gelatinous blue-green forms, and wound up with those he considered to be most like fungi—the Pyrenocarpineae. Later students have worked from this basis.

Of the various systems proposed for showing the relationship of the lichens to each other and to the fungi, none is entirely satisfactory. Fink (1935) published an arrangement probably acceptable currently to a majority of lichenologists:

Class Ascolichenes
  Subclass Pyrenocarpeae
    Order Pyrenulales
  Subclass Gymnocarpeae
    Order Caliciales
    Order Hysteriales
    Order Lecanorales
Class Hymenolichenes
Class Lichenes Imperfecti

The exact arrangement of families and genera in this scheme is not yet well agreed upon. The best known genera in the Pyrenulales are Verrucaria, Endocarpon, Pyrenula, Trypethelium. The Caliciales, a small order, include Calicium and Sphaerophorus. Arthonia, Graphis and Roccella are typical of the Hysteriales. The Lecanorales include most of the common lichens, Lecanora, Lecidea, Parmelia, Usnea, Physcia and many others. The Hymenolichenes are few and unimportant, while the Lichenes Imperfecti embrace common forms so little understood that it can hardly be said they are classified.

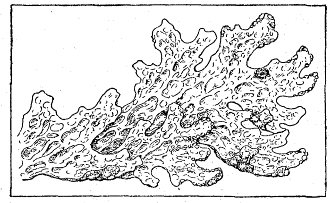

FIG. 19. — LOBARIA PULMONARIA (AFTER "THE LICHEN BOOK")

In all, more than 200 genera have been named and an incalculable number of species. It cannot be said, however, that any such number of distinct forms actually exist. The names await simplification, following more thorough studies of the true relationships.

BIBLIOGRAPHY.—Lichens are discussed in general text-books, especially in those devoted to cryptogamic botany. Only the publications concerned exclusively with lichenology are cited here. In most of these will be found lists of books and papers that deal with various aspects of the subject as outlined above.

General: M. Fünfstück, *Lichenes, A, Allgemeiner Teil,* in Engler and Prantl's *Die Naturlichen Pflanzenfamilien* VIII (Leipzig, 1926); G. G. Nearing, *The Lichen Book* (Ridgewood, N. J., 1943 in course of publication); Albert Schneider, *Text-book of Lichenology* (1897); A. Lorrain Smith, *Lichens* (Cambridge Botanical Handbooks, Camb., 1921); F. Tobler, *Biologie der Flechten* (Berlin, 1925); W. Zopf, *Die Flechten Stoffe* (Jena, 1907).

Floristic: Incomplete Floras. Among these may be cited Th. Fries, *Lichenographia Scandinavica* (Uppsala, 1871); J. Harmand, *Lichens de France,* five fascicles (Paris, 1905–13); W. Migula, *Flora Deutschlands, Osterreichs und der Schweiz, Abt. II Krypt, Flora XII Die Flechten. Lief. I* (in course of publication); Edward Tuckerman, *A Synopsis of the North American Lichens* (1882).

Complete Floras.—Bruce Fink, *The Lichens of Minnesota* (Washington, 1910), *Lichen Flora of the United States* (1935); A. Jatta, *Flora Italica Botanica, Pars. III, Lichenes* (1909–11); H. Olivier, *Exp. Syst. Descr. Lich. de l'Ouest et N. Ouest de France,* 2 fasc. (Paris, 1897–1903); A. Lorrain Smith, *Monogr. Brit. Lichens* (London, 1918–26); P. LICHFIELD, a city, county of a city, and municipal borough in Staffordshire, England, 115¾ mi. N.W. from London. Pop. (est. 1938) 8,760. Area 5.6 sq.mi. The town is on a stream with low hills to the east and south. There is a tradition that "Christianfield" nearby was the site of the martyrdom of 1,000 Christians during the persecutions of Maximian about 286. At Wall, 3 mi. distant, there was a Romano-British village of Letocetum ("gray wood"), from which the first half of the name Lichfield is derived. The first authentic notice of Lichfield occurs in Bede's history, where it is mentioned as the place where St. Chad fixed the episcopal see of the Mercians. At the time of the Domesday survey Lichfield was held by the bishop of Chester, who held the lordship and manor of the town until the reign of Edward VI, when they were leased to the corporation. Richard II gave a charter (1387) for the foundation of the gild of St. Mary and St. John the Baptist; this gild obtained the whole local government, which it exercised until its dissolution by Edward VI, who incorporated the town (1548). The only existing fair is a small pleasure fair of ancient origin held on Ash-Wednesday; the annual fête on Whit-Monday claims to date from the time of Alfred. King Edward VI's grammar school was founded in 1495.

The cathedral dates from the 13th and early 14th centuries. Its fine exterior has a lofty central and two lesser western spires, of which the central, 252 ft. high, is a restoration attributed to Sir Christopher Wren after its destruction during the Civil Wars. Among numerous monuments are memorials to Samuel Johnson (born at Lichfield, 1709), and to David Garrick, who spent his early life and was educated there. The bishop's palace (1687) is adjacent to the cathedral. There are many old houses, among which is that in which Johnson was born. Brewing is the principal industry, but there is some metal-working, and in the neighbourhood are large market gardens. The borough was extended in 1934 and is in the Lichfield parliamentary division.

LICH-GATE or LYCH-GATE, the roofed-in gateway to churchyards (O.E. *lic*, "a body, a corpse"). Lich-gates existed in England 13 centuries ago, but comparatively few early ones survive, as they were almost always of wood. One at Bray, Berkshire, is dated 1448. Here the clergy meet the corpse and some portion of the service is read. The gateway served to shelter the pall-bearers. The most common form of lich-gate is a simple shed composed of a roof with two gabled ends, covered with tiles or thatch.

LICHNOWSKY, KARL MAX, PRINCE (1860–1928), German diplomatist, was born at Kreuzenort, Upper Silesia, on March 8, 1860, the son of the 6th Prince Lichnowsky and of Princess Marie de Croy. He entered the German foreign office in 1884, and served in various legations until 1889 when Bülow recalled him to the foreign office. In 1912 he became ambassador in London. During his stay in London he worked hard for pacific relations between England and Germany; and the colonial agreement which was ready for signature in 1914 was largely his work. When the Serbian crisis arose in the summer of that year Lichnowsky urgently recommended the acceptance in Berlin of Sir E. Grey's mediation proposals. He had repeatedly warned Berlin of the dangers underlying the Anglo-German rivalries, but his warnings were neglected. On the outbreak of war he returned to Berlin a broken man, and found that in some quarters he was held guilty of not having done his utmost to prevent British intervention. He wrote an apologia, *Meine Londoner Mission,* of his conduct of affairs in London for private circulation, which fell into the hands of German pacifists who printed it in 1918. He was then excluded from the Prussian upper house. In 1925 he published an appeal against this exclusion, *Flugschriften des Bundes Neues Vaterland;* and in 1927 wrote *Auf dem Wege zum Abgrund* (Eng. trans. 1928), dealing with the origins of World War I. He died at his estate of Kuchelna on Feb. 27, 1928.

LICHTENBERG, GEORG CHRISTOPH (1742–1799), German satirical writer and physicist, was born at Oberramstadt, near Darmstadt, on July 1, 1742. In 1763 he entered Göttingen university, where in 1775 he became ordinary professor of physics. This post he held till his death Feb. 24, 1799. As a physicist he is best known for his investigations in electricity, more especially as to the so-called Lichtenberg figures. As a satirist and humorist, Lichtenberg takes high rank among the German writers of the 18th century. His biting wit involved him in many controversies with well-known contemporaries, such as Lavater, whose science of physiognomy he ridiculed, and Voss, whose views on Greek pronunciation he satirized in *Über die Pronunciation der Schöpse des alten Griechenlandes* (1782). He resided for some time in England; his *Briefe aus England* (1776–78), with admirable descriptions of Garrick's acting, are the most attractive of his writings. He contributed to the *Göttingisches Magazin der Literatur und Wissenschaft,* of which he was co-editor (1780–82). He also published in 1794–99 an *Ausführliche Erklärung der Hogarthschen Kupferstiche.*

Lichtenberg's *Vermischte Schriften* were published by F. Kries in 9 vols. (1800–05; new editions in 8 vols., 1844–46 and 1867). Selections by E. Grisebach, *Lichtenbergs Gedanken und Maximen* (1871); by F. Robertag in Kürschner's *Deutsche Nationalliteratur* (vol. 141, 1886); and by A. Wilbrandt (1893). Lichtenberg's *Briefe* have been published in 3 vols. by C. Schüddekopf and A. Leitzmann (1900–02); his *Aphorismen* by A. Leitzmann (3 vols., 1902–06). *See* also R. M. Meyer, *Swift und Lichtenberg* (1886); F. Lauchert, *Lichtenbergs schriftstellerische Tätigkeit* (1893); and A. Leitzmann, *Aus Lichtenbergs Nachlass* (1899).

LICHTENBERG, formerly a small German principality on the Rhine, now belonging to the district of Trier, Prussian Rhine province. The principality includes parts of the electorate of Trier, and Nassau-Saarbrücken. Originally called the lordship of Baumholder, it owed the name of Lichtenberg and its elevation in 1819 to a principality to Ernest, duke of Saxe-Coburg, to whom it was ceded by Prussia, in 1816. The duke restored it to Prussia in 1834. The area is about 210 sq.mi.

LICINIANUS, GRANIUS, Roman annalist, probably lived in the age of the Antonines (2nd century A.D.). He wrote a brief epitome of Roman history based upon Livy. Accounts of omens and portents apparently took up a large portion of the work.

Editions by C. A. Pertz (1857); seven Bonn students (1858); M. Flemisch (1904); *see* also J. N. Madvig, *Kleine philologische Schriften* (1875), and the list of articles in periodicals in Flemisch's edition (p. iv).

LICINIUS (FLAVIUS GALERIUS VALERIUS LICINIANUS), Roman emperor, A.D. 307–324, of Illyrian peasant origin, was born probably about 250. He was elevated to the rank of Augustus by Galerius, his former friend and companion in arms, on Nov. 11, 307, receiving as his immediate command the provinces of Illyricum. On the death of Galerius, in May 311, he shared the entire empire with Maximinus, the Hellespont and the Thracian Bosporus being the dividing line. In April 313 he inflicted a decisive defeat on Maximinus at Heraclea Pontica, and established himself master of the east while his brother-in-law, Constantine, was supreme in the west. In 314 his jealousy led him to encourage a treasonable enterprise against Constantine. When his perfidy became known a civil war ensued, in which he was twice severely defeated. The outward reconciliation left Licinius in possession of Thrace, Asia Minor, Syria and Egypt, but added numerous provinces to the western empire. In 323 Constantine again declared war against him, and, having defeated his army at Adrianople, succeeded in shutting him up within the walls of Byzantium. The defeat of Licinius' fleet compelled his withdrawal to Bithynia, where a last stand was made; the battle of Chrysopolis, near Chalcedon, finally resulted in his submission. He was executed in the following year.

See Zosimus ii 7–28; Zonaras xiii 1; Victor, *Caes.* 40, 41; Eutropius x 3; Orosius vii 28.

LICINIUS CALVUS STOLO, GAIUS: *see* ROME: *Ancient History.*

LICINIUS MACER CALVUS, GAIUS (82–47 B.C.), Roman poet and orator, the son of the annalist Licinius Macer. As a poet he followed his friend Catullus in style and choice of subjects. As an orator he was the leader of the opponents of the florid Asiatic school, who took the simplest Attic orators as their model and attacked even Cicero as wordy and artificial. Twenty-one speeches by him are mentioned, among which the most famous were those delivered against Publius Vatinius. Calvus was very short of stature, and is alluded to by Catullus (Ode 53) as *Salaputium disertum* (eloquent Lilliputian).

For Cicero's opinion see *Brutus,* 82; Quintilian x 1. 115; Tacitus, *Dialogus,* 18. 21; the monograph by F. Plessis (Paris, 1896) contains a collection of the fragments (verse and prose).

LICTORS [Lat. *lictores*], in Roman antiquities, a class of the attendants (*apparitores*) upon certain Roman and provincial magistrates. As an institution they went back to the regal period and continued to exist till imperial times. The majority of the city lictors were freedmen; they formed a corporation divided into decuries, from which the lictors of the magistrates in office were drawn; provincial officials had the nomination of their own. In Rome they wore the toga; on a campaign and at the celebration of a triumph, the red military cloak (*sagulum*); at funerals, black. As representatives of magistrates who possessed the *imperium,* they carried the fasces (*see* FASCES). They were exempt from military service; received a fixed salary; theoretically they were nominated for a year, but really for life. They were the constant attendants of the magistrate to whom they were attached. They cleared a passage for him (*summovere*) through the crowd, and saw that he was received with the marks of respect due to his rank. They stood by him when he took his seat on the tribunal; mounted guard before his house, against the wall of which they stood the fasces; summoned offenders before him, seized, bound and scourged them, and (in early times) carried out the death sentence. Directly a magistrate entered an allied, independent state, he was obliged to dispense with his lictors. Each of the consuls had 12 lictors; the dictator, as representing both consuls, 24; the emperors 12, until the time of Domitian, who had 24. The Flamen Dialis, and each of the Vestals were also accompanied by lictors. These lictors were probably supplied from the lictores curiatii, 30 in number, whose functions were specially religious, one of them being in attendance on the pontifex maximus. They originally summoned the comitia curiata, and when its meetings became merely a formality, acted as the representatives of that assembly.

Bibliography.—For the fullest account of the lictors, *see* Mommsen, *Römisches Staatsrecht*, i. 355, 374 (3rd ed., 1887), *cf.* J. E. Sandys, *Companion to Latin Studies* (1921).

LIDCOMBE: *see* Sydney (New South Wales, Australia).

LIDDELL, HENRY GEORGE (1811–1898), English scholar and divine, was born at Binchester, near Bishop Auckland, on Feb. 6, 1811. He was educated at Charterhouse and Christ Church, Oxford, became a college tutor, and was ordained in 1838. In 1846 he became headmaster of Westminster school. Early in 1834 he and Robert Scott began the great *Lexicon* (based on the German work of F. Passow) which became his life work, and the 1st edition was published in 1843. It is still the standard Greek-English dictionary (revised ed. by H. S. Jones in 1925). In 1855 he became dean of Christ Church, and took an active part in the first Oxford University Commission. He resigned the deanery in 1891 and retired to Ascot, where he died on Jan. 18, 1898.

See H. L. Thompson, *Henry George Liddell* (1899).

LIDDESDALE, the valley of Liddel Water, Roxburghshire, Scotland, extending 21 mi. from the Peel Fell to the Esk. The Waverley route of the L.N.E.R. runs down the dale, and the Catrail, or Picts' Dyke, crosses its head. At one period points on the river were occupied with freebooters' peel-towers, but many have disappeared. Larriston Tower belonged to the Elliots, Mangerton to the Armstrongs and Park to "little Jock Elliot," the outlaw who nearly killed Bothwell in 1566. Hermitage castle, a massive H-shaped fortress and one of the oldest baronial buildings in Scotland, stands on a hill overlooking Hermitage Water, a tributary of the Liddel. It was built in 1244 and captured by the English in David II's reign. It was retaken by Sir William Douglas, who received a grant of it from the king. In 1492 Archibald Douglas, 5th earl of Angus, exchanged it for Bothwell castle on the Clyde with Patrick Hepburn, 1st earl of Bothwell. It passed to the duke of Buccleuch. It was there that Sir Alexander Ramsay of Dalhousie was starved to death by Sir William Douglas in 1342, and that James Hepburn, 4th earl of Bothwell, was visited by Mary, queen of Scots, after the assault referred to.

LIDDON, HENRY PARRY (1829–1890), English divine, was the son of a naval captain and was born at North Stoneham, Hampshire, on Aug. 20, 1829. He was educated at King's College school, London, and at Christ Church, Oxford. As vice-principal of the theological college at Cuddesdon (1854–59) and as vice-principal of St. Edmund's Hall, Oxford, he withstood the liberal reaction against Tractarianism, which had set in after Newman's secession in 1845. In 1864 he became prebendary of Salisbury cathedral. In 1866 he delivered his Bampton Lectures on the *Divinity of Our Lord* (13th ed., 1889), which established his fame. In 1870 he was made canon of St. Paul's Cathedral, London, where his preaching attracted vast crowds. In 1870 he had also been made Ireland professor of exegesis at Oxford. His position gave him extensive influence over the Church of England. In 1886 he became chancellor of St. Paul's. He died on Sept. 9, 1890.

See J. Johnston, *Life and Letters of Dean Liddon.*

LIDICE, a mining village in Czechoslovakia, near the coal fields of Kladno. This unknown village sprang into world fame at the very day of its complete destruction, announced officially by the Germans on June 10, 1942. The Germans suspected that some inhabitants had supported the patriots who killed the German police general, Reinhard Heydrich, reichsprotektor for Bohemia and Moravia. According to official German statements, all the male inhabitants, irrespective of age, and 56 women were immediately executed. The other women were put into concentration camps; the children were carried off to correction schools, "all buildings of the village were levelled to the ground and the name of the village was immediately abolished." These actions aroused world-wide sympathy and protest. Towns in several countries were renamed to commemorate the Czech village, among them Lidice, Illinois, near Joliet, U.S.A., inaugurated July 12, 1942, and Lidice, Mexico, formerly known as San Geronimo, near Mexico City.

LIE, JONAS LAURITZ EDEMIL (1833–1908), Norwegian novelist, was born on Nov. 6, 1833, close to Hougsund (Eker), near Drammen. In 1838, his father being appointed sheriff of Tromsö, the family removed to that Arctic town. Here Lie gained acquaintance with the wild seafaring life which he was afterwards to describe. He studied at Christiania (Oslo), where Ibsen and Björnson were among his fellow-students. On completing his studies he began to practise as a solicitor at Kongsvinger. In 1860 he married his cousin, Thomasine Lie, who collaborated with him in his works. In 1866 he published his first book, a volume of poems. Financial embarrassment drove him to Christiania to try his luck as a man of letters. As a journalist he had no success, but in 1870 he published a melancholy little romance, *Den Fremsynte* (Eng. trans., *The Visionary*, 1894), which made him famous. Lie proceeded to Rome, and published *Tales* in 1871 and *Tremasteren "Fremtiden"* (Eng. trans., *The Barque "Future,"* Chicago, 1879), a novel, in 1872. *Lodsen og hans Hustru* (*The Pilot and his Wife*, 1874) placed him at the head of Norwegian novelists, and brought him a small government stipend. Lie spent the next few years partly in Dresden, partly in Stuttgart. He then returned to Norway for a short time, and there wrote some novels of contemporary Norwegian life. But he was back in Germany very soon. From 1882 to 1891 he made Paris his headquarters. His later years were spent in Norway, and he died at Christiania on July 5, 1908. Two of the most successful of his numerous novels were *The Commodore's Daughters* (1886) and *Niobe* (1894), both of which were included in the International library. In 1891–1892 he wrote, under the influence of the new romantic impulse, twenty-four folk-tales, printed in two volumes entitled *Trold.* Some of these were translated by R. N. Bain in *Weird Tales* (1893), illustrated by L. Housman. His *Samlede Vaerker* were published at Copenhagen in 14 vols. (1902–1904). As a novelist Jonas Lie stands with those minute and unobtrusive painters of contemporary manners who defy arrangement in this or that school. He is with Mrs. Gaskell or Ferdinand Fabre; he is not entirely without relation with that old-fashioned favourite of the public, Fredrika Bremer.

LIE, MARIUS SOPHUS (1842–1899), Norwegian mathematician, was born at Nordfjordeif, near Bergen, on Dec. 17, 1842, and was educated at the University of Christiania (now Oslo). In 1869 he went to Berlin and there met Klein, in conjunction with whom he afterwards published several papers. In 1871 he was appointed assistant tutor in Christiania university, in the same year submitting for his doctor's degree his famous memoir *Ueber Complexe, insbesondere Linien- und Kugel-Complexe, mit Anwendung auf die Theorie partieller Differential-Gleichungen*, in which he advanced the theory of tangential transformations. He was appointed extraordinary professor in 1872, and the following year began his researches on continuous transformation groups, and discovered his transformation, making a sphere correspond to a straight line (*Comptes Rendus*, vol. lxxi.). In 1884 Engel went to assist Lie, and after nine years' work was published *Theorie der Transformationsgruppen* (3 vols., Leipzig, 1893), a work of wide range and great originality. In 1886 Lie succeeded Klein in the chair of mathematics at Leipzig, Engel being appointed his assistant. In 1898 he returned to Christiania to accept a special post created for him, but his health was already broken and he died on Feb. 18, 1899. Besides his development of transformations, Lie made contributions to differential geometry, but his primary aim was the advancement of the theory of differential equations.

An analysis of Lie's works is given in the *Bibliotheca Mathematica* (Leipzig, 1900).

LIEBER, FRANCIS (1800–1872), German-American publicist, was born at Berlin on March 18, 1800. He served with his two brothers under Blücher in the campaign of 1815, fighting at Ligny, Waterloo and Namur, where he was twice dangerously wounded. Shortly afterwards he was arrested for his political sentiments, the chief evidence against him being several songs of liberty which he had written. After several months he was discharged without a trial, but was forbidden to pursue his studies at the Prussian universities. He accordingly went to Jena, continuing his studies at Halle and Dresden. He subsequently took part in the Greek War of Independence, publishing his experiences in his *Journal in Greece* (Leipzig, 1823, and under the title *The German Anacharsis,* Amsterdam, 1823). In 1827 he went to the United States and as soon as possible was naturalized. He settled at Boston, and for five years edited *The Encyclopaedia Americana.* From 1835 to 1856 he was professor of history and political economy in South Carolina college at Columbia, S.C., and during this period wrote his three chief works, *Manual of Political Ethics* (1838), *Legal and Political Hermeneutics* (1839) and *Civil Liberty and Self Government* (1853). In 1857 he was elected to a similar post in Columbia college, New York, where in 1865 he became professor of constitutional history and public law. During the Civil War Lieber rendered services of great value to the Government. Upon the requisition of the president, he prepared the important *Code of War for the Government of the Armies of the United States in the Field.* This code suggested to Bluntschli his codification of the law of nations, as may be seen in the preface to his *Droit International Codifié.* During this period also, Lieber wrote his *Guerilla Parties with Reference to the Laws and Usages of War.* He died Oct. 2, 1872.

His *Miscellaneous Writings* were published by D. C. Gilman (Philadelphia, 1881). *See* T. S. Perry, *Life and Letters* (1882), and biography by Harby (1899). Consult also Ernest Nys, "Francis Lieber, His Life and Work," *Am. Jour. Internat. Law,* vol. v., pp. 84–117, 335–393 (1911); Chester Squire Phinmy, *Francis Lieber's Influence on American Thought* (1918); and Louis Martin Sears, "The Human Side of Francis Lieber," *So. Atlantic Quar.,* vol. xxvii., p. 42–61 (1928).

LIEBERMANN, MAX (1847–1935), German painter and etcher, was born in Berlin on July 20, 1847. After studying under Steffeck, he entered the school of art at Weimar in 1869. Though the straightforward simplicity of his first exhibited picture, "Women plucking Geese" (Berlin, National gallery) in 1872, presented already a striking contrast to the conventional art then in vogue, it was heavy and bituminous in colour. In his course he was confirmed by Munkacsy's influence in Paris in 1872. A summer spent at Barbizon in 1873, where he became acquainted with Millet and studied the works of Corot, Troyon and Daubigny, resulted in the clearing and brightening of his palette. He subsequently went to Holland, where the example of Israels confirmed him in the method he had adopted at Barbizon; on his return to Munich in 1878 he caused much unfavourable criticism by his realistic painting of "Christ in the Temple," which was condemned by the clergy as irreverent. Henceforth he devoted himself exclusively to the study of light and to the painting of the life of humble folk. He found his best subjects in the orphanages and asylums for the old in Amsterdam, among the peasants in the fields and village streets of Holland, and in the beer-gardens, factories and workrooms of his own country.

Liebermann did for his country what Millet did for France. His pictures hold the fragrance of the soil and the breezes of the heavens. His people move in their proper atmosphere and their life is stated in all its monotonous simplicity. His work being at variance with the academic tradition he became the leader of the Secession. His first success was a medal awarded him for "An Asylum for Old Men" at the 1881 salon. Then followed "The Cobbler's Shop" (1881) and "The Flax Spinners" (1887) both of which are now in the National gallery, Berlin. In 1884 he settled in Berlin, where he became president of the Academy. Liebermann is represented in most of the German and other continental galleries. His etchings are to be found in the leading print rooms of Europe. In 1933 he elected, as a Jew, to leave Germany.

LIEBIG, JUSTUS VON, Baron (1803–1873), German chemist, was born at Darmstadt on May 12, 1803. His father, a drysalter and dealer in colours, used sometimes to make experiments in the hope of improving his processes and thus the son early acquired familiarity with practical chemistry. For the theoretical side he read all the textbooks which he could find. At the age of 15 he entered the shop of an apothecary at Heppenheim near Darmstadt; but he soon found how great is the difference between practical pharmacy and scientific chemistry. He next entered the university of Bonn, but migrated to Erlangen with the professor of chemistry, K. W. G. Kastner (1783–1857). He then went to Paris, where by the help of L. J. Thénard he gained admission to the private laboratory formerly used by Vauquelin and occupied by H. F. Gautier de Glaubry (1792–1873), professor of chemistry at the École de Pharmacie, Paris. Soon afterwards, by the influence of A. von Humboldt, he was given quarters in the laboratory of Gay-Lussac. He attended lectures of Gay-Lussac, Thénard, Dulong, Petit, Laplace and Cuvier. There he concluded, in 1824, his investigations on the composition of the fulminates. On Humboldt's advice he determined to become a teacher of chemistry, and after overcoming many difficulties he was appointed extraordinary professor of chemistry at Giessen in 1824, becoming ordinary professor two years later. His most important work was accomplished at Giessen. He persuaded the Darmstadt government to provide a chemical laboratory in which the students might obtain a proper practical training. This laboratory, unique of its kind at the time, in conjunction with Liebig's unrivalled gifts as a teacher, soon rendered Giessen the most famous chemical school in the world. In it were trained many accomplished chemists and it gave a great impetus to the progress of chemical education throughout Germany. Liebig remained at Giessen for 28 years, until, in 1852, he became professor of chemistry at Munich university. He died at Munich on April 18, 1873. His grave is in the Alt Süd Friedhof.

Work on Pure Chemistry includes improvements in technique of organic analysis, his method for determining the natural alkaloids and for ascertaining the molecular weights of organic bases by means of their chloroplatinates, his process for determining the quantity of urea in a solution, and his invention of the potash bulb, formerly known in every laboratory. He did not invent the condenser commonly known as the "Liebig" condenser, but popularized its use. His contributions to inorganic chemistry were numerous, including investigations on the compounds of antimony, aluminum, silicon, etc., on the separation of nickel and cobalt, and on the analysis of mineral waters, but they are outweighed in importance by his work on organic substances. In this domain his first research was on the fulminates of mercury and silver, and his study of these bodies led him to the discovery of the isomerism of cyanic and fulminic acids. Further work on cyanogen and connected substances yielded a great number of interesting derivatives. He described an improved method for the manufacture of potassium cyanide and for the analysis of cyanides by titration with silver nitrate.

In 1832 he published, jointly with Wöhler (*q.v.*), one of the most famous papers in the history of chemistry, that on the oil of bitter almonds (benzaldehyde), wherein it was shown that the radicle benzoyl might be regarded as forming an unchanging constituent of a long series of compounds. Berzelius hailed this discovery as marking the dawn of a new era in organic chemistry. A continuation of their work on bitter almond oil by Liebig and Wöhler resulted in the elucidation of the mode of formation of that substance and in the discovery of the ferment emulsin as well as the recognition of the first glucoside, amygdalin. Another and not less important and far-reaching inquiry in which they collaborated was that on uric acid, published in 1837. About 1832 he began his investigations into the constitution of ether and alcohol and their derivatives. These on the one hand resulted in the enunciation of his ethyl theory, by the light of which he looked upon those substances as compounds of the radical ethyl (C_2H_5); on the other they yielded chloroform, chloral and aldehyde, as well as other compounds, and also the method of forming mirrors by depositing silver from a slightly ammoniacal solution by acetaldehyde. In 1837, with Dumas, he published a note on the constitution of organic acids, and in the following year an elaborate paper on the same subject appeared under his name alone; by this work T. Graham's (*q.v.*) doctrine of polybasicity was extended to the organic acids. Liebig also did much to further the hydrogen theory of acids.

Animal and Vegetable Physiology.—These and other studies in pure chemistry mainly occupied his attention until about 1838, but the last 35 years of his life were devoted more particularly to the chemistry of the processes of life, both animal and vegetable. In animal physiology he attempted to trace out the operation of chemical and physical laws in the maintenance of life and health. To this end he examined such vital products as blood, bile and urine; he analyzed the juices of flesh, establishing the composition of creatin and investigating its decomposition products, creatinin and sarcosin; he classified the various articles of food in accordance with the special function performed by each in the animal economy and expounded the philosophy of cooking. In opposition to many of the medical opinions of his time he taught that the heat of the body is the result of the processes of combustion and oxidation performed within the organism. A secondary result of this line of study was the preparation of his food for infants and of his world-famous extract of meat.

Vegetable physiology he pursued with special reference to agriculture. His first publication on this subject was *Die Chemie in ihrer Anwendung auf Agricultur und Physiologie* in 1840, which was at once translated into English by Lyon Playfair. Rejecting the old notion that plants derive their nourishment from humus, he taught that they get carbon and nitrogen from the carbon dioxide and ammonia present in the atmosphere, these compounds being returned by them to the atmosphere by the processes of putrefaction and fermentation, while their potash, soda, lime, sulphur, phosphorus, etc., come from the soil. Of the carbon dioxide and ammonia no exhaustion can take place, but of the mineral constituents the supply is limited because the soil cannot afford an indefinite amount of them; hence the chief care of the farmer, and the function of manures, is to restore to the soil those minerals which each crop is found, by the analysis of its ashes, to take up in its growth. On this theory he prepared artificial manures containing the essential mineral substances together with a small quantity of ammoniacal salts, because he held that the air does not supply ammonia fast enough in certain cases, and carried out systematic experiments on ten acres of poor sandy land which he obtained from the town of Giessen in 1845. But in practice the results were not wholly satisfactory, and it was a long time before he recognized one important reason for the failure in the fact that to prevent the alkalis from being washed away by the rain he had taken pains to add them in an insoluble form, whereas, as was ultimately suggested to him by experiments performed by J. T. Way about 1850, this precaution was not only superfluous but harmful, because the soil possesses a power of absorbing the soluble saline matters required by plants and of retaining them, in spite of rain, for assimilation by the roots.

Liebig's literary activity was very great. The Royal Society's *Catalogue of Scientific Papers* enumerates 318 memoirs under his name, exclusive of many others published in collaboration with other investigators. In 1832 he founded the *Annalen der Pharmazie,* which became the *Annalen der Chemie und Pharmazie* in 1840 when Wöhler became joint editor with him, and *Annalen der Chemie* in 1874. In 1837 with Wöhler and Poggendorff he established the *Handwörterbuch der reinen und angewandten Chemie.* After the death of Berzelius he continued the *Jahresbericht* with H. F. M. Kopp.

The following are his most important separate publications, many of which were translated into English and French almost as soon as they appeared: *Anleitung zur Analyse der organischen Körper* (1837); *Die Chemie in ihrer Anwendung auf Agrikultur und Physiologie* (1840); *Die Thier-Chemie oder die organische Chemie in ihrer Anwendung auf Physiologie und Pathologie* (1842); *Handbuch der organischen Chemie mit Rücksicht auf Pharmazie* (1843); *Chemische Briefe* (1844); *Chemische Untersuchungen über das Fleisch und seine Zubereitung zum Nahrungsmittel* (1847); *Die Grundsätze der Agrikultur-Chemie* (1855); *Über Theorie und Praxis in der Landwirthschaft* (1856); *Naturwissenschaftliche Briefe über die moderne Landwirthschaft* (1859). A posthumous collection of his miscellaneous addresses and publications appeared in 1874 as *Reden und Abhandlungen,* edited by his son George (b. 1827). His criticism of Bacon, *Über Francis von Verulam,* was first published in 1863 in the *Augsburger allgemeine Zeitung,* where also most of his letters on chemistry made their first appearance. His autobiographical notes appeared in *Berichte der deutschen chemischen Gesellschaft* (1890).

See also *The Life Work of Liebig* (London, 1876) by his pupil A. W. von Hofmann, which is the Faraday lecture delivered before the London Chemical Society in March 1875, and is reprinted in Hofmann's *Zur Erinnerung an vorangegangene Freunde;* also W. A. Shenstone, *Justus von Liebig, his Life and Work* (1895); Tilden's *Famous Chemists* (1921); A. Kohut, *J. Liebig, Sein Leben und Werken* (1903); J. Volhard, *Justus von Liebig,* 2 vols. (1909); R. Blunck, *Justus von Liebig* (1938); R. Winderlich, Essay in Bugge's *Das Buch der grossen chemiker* (1930); R. E. Oesper, *Journal of Chemical Education* (1927); etc. His extensive correspondence with Wöhler, Schönbein, Mohr, Berzelius, etc. has been published, likewise his letters to his parents. The laboratory at Giessen and the birth house at Darmstadt have been made into museums. Imposing monuments were erected at Giessen and Munich.

LIEBKNECHT, KARL (1871–1919), German socialist, was born in Leipzig on Aug. 13, 1871. The son of Wilhelm Liebknecht (*q.v.*), he qualified as a lawyer, and became a prominent member of the extreme left wing of the Social Democrat party. After serving a sentence of 18 months' imprisonment for high treason, in 1908 he was elected to the Prussian chamber of deputies, and in 1912 entered the reichstag as a Social Democrat. He was one of a small group who refused to vote war credits in 1914. He violently opposed the war and the successive votes of credit. He organized antiwar demonstrations, and in 1916 gave the police the desired opportunity for arresting him by shouting "down with the war" to some troops passing through the Potsdamer Platz. He was condemned to two years' penal servitude, and was released only on Oct. 22, 1918. Before his imprisonment he had founded the international group, later the Spartacus Union, the policy of which was based on the full execution of the Erfurt programme. Liebknecht's condemnation was the signal for a strike of the metal workers in Berlin organized by the Spartacists independently of the trade unions. On his release in 1918 he placed himself at the head of the Spartacists and demanded a "free socialist republic," but the independent socialists had joined hands with the Ebert party, and Liebknecht's efforts failed. During the insurrection of the Spartacists in Jan. 1919 Liebknecht was arrested; while being conveyed from military headquarters in the west end of Berlin to the prison at Moabit on Jan. 15, he was brutally murdered, on the usual pretext of attempted escape. His comrade, Rosa Luxemburg, perished the same night. Their bodies were thrown into the canal; Liebknecht's was recovered and received a public funeral.

See his *Militarismus und Antimilitarismus* (1908, Eng. trans. 1918); *Briefe aus dem Felde, aus der Untersuchungschaft und aus dem Zuchthaus* (1919); H. Schumann, *Karl Liebknecht, ein unpolitisches Bild* (1919).

LIEBKNECHT, WILHELM (1826–1900), German socialist, was born at Giessen on March 29, 1826, and educated at the universities of Giessen, Bonn and Marburg. His political activities, which resulted from socialistic convictions acquired in his youth, led to his expulsion from Berlin, and in 1846 he left Germany for Switzerland where he earned his living by teaching. Returning in 1848, he endeavoured to found a republic in Baden and after suffering eight months' imprisonment was again forced to flee the country. He went to Geneva, where he came into intercourse with Mazzini; but being expelled from Switzerland he went to London, where he lived for 13 years in close association with Karl Marx. He endured great hardships, but secured a livelihood by teaching and writing; he was a correspondent of the *Augsburger Allgemeine Zeitung.* The amnesty of 1861 opened for him the way back to Germany, and in 1862 he accepted the post of editor of the *Norddeutsche Allgemeine Zeitung.* Only a few months elapsed before the paper passed under Bismarck's influence, but Liebknecht remained faithful to his principles and resigned his editorship. He became a member of the *Arbeiterverein,* and after the death of Ferdinand Lassalle he was the chief Socialist leader in Germany and was instrumental in spreading the influence of the newly-founded *International,* which stood under the leadership of Karl Marx. Expelled from Prussia in 1865, he settled at Leipzig, and it is primarily to his activity in Saxony among the newly-formed unions of workers that the modern Social Democrat party owes its origin. Here he conducted the *Demokratisches Wochenblatt.* In 1867 he was elected a member of the North German reichstag, where he opposed the policy of compromise of Lassalle's followers.

Liebknecht was strongly influenced by the "great German" traditions of the Democrats of 1848, and distinguished himself by his attacks on the policy of 1866 and the "revolution from above," and by his opposition to every form of militarism. His adherence to the traditions of 1848 are also seen in his dread of Russia, which he maintained to his death. His opposition to the War of 1870 exposed him to insults and violence, and in 1872 he was condemned to two years' imprisonment in a fortress, for treasonable intentions. The union of the German Socialists, which was achieved by a fusion of the groups under Liebknecht's leadership and the Lassalleans, in 1874 at the congress of Gotha was a triumph of his influence, and from that time he was regarded as founder and leader of the combined party. From 1874 till his death he was a member of the German reichstag, and for many years also of the Saxon diet. He was one of the chief spokesmen of the party, and he took an important part in directing its policy. In 1881 he was expelled from Leipzig, but took up his residence in a neighbouring village. After the lapse of the Socialist law (1890) which had made socialist organizations, publications and propaganda illegal, he became chief editor of the *Vorwärts* and settled in Berlin. If he did not always find it easy in his later years to follow the new developments, he preserved to his death the idealism of his youth, the hatred both of liberalism and of state socialism; and though he was to some extent overshadowed by Bebel's greater oratorical power, he was the chief support of the orthodox Marxian tradition. Liebknecht wrote numerous pamphlets and books, among which were: *Robert Blum und seine Zeit* (Nuremberg, 1892); *Geschichte der Französischen Revolution* (Dresden, 1890); *Die Emser Depesche* (Nuremberg, 1899) and *Robert Owen* (Nuremberg, 1892). He died at Charlottenburg on Aug. 7, 1900.

LIECHTENSTEIN, one of the smallest independent sovereign states of Europe (*see* SAN MARINO and MONACO), 65 sq.mi. in extent, and bounded by the right bank of the Rhine a few miles above Lake Constance. Westward lies the canton of St. Gallen (Switzerland). To the east lies the former Austrian Vorarlberg, and southward are the western crests of the Rhätikon, between Liechtenstein and Graubunden (Switzerland). The country, geographically, is more German-Austrian than Swiss—politically its interests have oscillated between both. The major physical divisions are: (1) A small narrow strip along the Rhine valley, widening northward into the triangular lowland of the confluence of the Rhine and the tributary Ill. (2) The larger upland area, practically bisected by the Samina which feeds the Ill. The highest peaks lie southward, with Falkais (8,401 feet), central south, and Naafkopf (8,432 feet), southeast, at the meeting points of the three frontiers. The chief settlements are at the western foot of the uplands and not on the Rhine itself. In order from the south, they are Balzers, Triesen, Vaduz (capital and seat of government, pop. 2,020), Schaan and Nendeln. They are linked by the road joining Ragaz (Switzerland) with Feldkirch (Germany). Two small settlements, Eschen and Mauern, lie in the northern triangular lowland. Liechtenstein's only railway crosses the centre of the western frontier from Buchs (Switzerland) and then parallels the road through Schaan and Nendeln. Pop. (1941) 11,102, is largely German in origin and speech, Roman Catholic in religion and agricultural in interest. Corn, wine and fruit are grown and cattle are reared. There are also small manufactures of cotton, leather and pottery.

The principality, founded in 1719, consisted of the lordships of Schellenburg and Vaduz, and formed part of the Holy Roman empire. From 1806–15 it was included in the Rhine confederation, and from 1815–66 in the German confederation. Since 1866 it has been independent. Prince Johann II (1840–1929) succeeded his father in 1858. The constitution after 1921, provided a *Landtag* of 15 members elected by direct vote; suffrage is universal. The standing army was abolished in 1868. Public debt (Jan. 1, 1940), 5,600,000 francs. Until 1919 Liechtenstein was closely allied with Austria; in 1921 it adopted Swiss currency, and after 1924 it was included in the Swiss Customs union. Switzerland administers its telegraph and postal services. Franz I (1853–1938) succeeded his brother in 1929, and was in turn succeeded by his great-nephew, Franz Josef, in 1938.

Heer, *Vorarlberg und Liechtenstein Feldkirch* (1906); A. Helbock, *Quellen zur Geschichte Vorarlbergs und Liechtenstein* (Berne, 1920).

LIEDERTAFEL (Ger., lit. "song table"), a type of musical society formerly very popular and numerous in Germany, devoted to four-part singing for male voices, and combining refreshments and social intercourse with its music, whence the name. In recent years the older Liedertafeln have been more or less superseded by the larger male voice choirs, though the name has been retained for the public invitation concerts given by the latter.

LIÉGE, one of the nine provinces of Belgium, the successor of the old prince-bishopric, touching on the east Dutch Limburg and Rhenish Prussia. Its towns are Liége, Verviers, Spa, Seraing, Huy, etc. The Meuse flows through the centre, and its valley from Huy to Herstal is one of the most productive mineral districts in Belgium. Agriculture in the Condroz district south of the Meuse has been much developed. There are three administrative arrondissements, 28 cantons and 373 communes, and the districts of Eupen, Malmédy, St. Vith and the former neutral district of Moresnet after 1919 became part of the province. Area 1,525 sq.mi. Pop. (est. 1939) 969,948 or 636 per square mile.

LIÉGE (Flemish, *Luik,* Ger. *Lüttich*), capital of the Belgian province of Liége, on the Meuse, long the seat of a prince-bishopric, the centre of the Walloon country.

The great cathedral of St. Lambert was destroyed in 1794, and in 1802 the church of St. Paul, dating from the 10th century but rebuilt in the 13th, was declared the cathedral. The law courts are installed in the old palace of the prince-bishops, constructed between 1508 and 1540. The university has separate schools for mines and arts and manufactures.

Liége had a population of (est. 1939) 161,187, and is the centre of the iron and armament manufacture of Belgium and of a coal-mining district. The production of zinc and of motorcars has also become important. There is also a large cattle market. Suburbs have arisen on the heights to the north, and a circular boulevard has been laid out with connecting roads.

HISTORY

Liége first appears in history about the year 558, at which date St. Monulph, bishop of Tongres, built a chapel near the confluence of the Meuse and the Legia. A century later the town, which had grown up round this chapel, became the favourite abode of St. Lambert, bishop of Tongres, and here he was assassinated. His successor, St. Hubert, raised a splendid church over the tomb of the martyred bishop about 720 and made Liége his residence. It was not, however, until about 930 that the title bishop of Tongres was abandoned for that of bishop of Liége. The episcopate of Notger (972–1008) was marked by large territorial acquisitions, and the see obtained recognition as an independent principality of the empire. The popular saying was "Liége owes Notger to God, and everything else to Notger." By the munificent encouragement of successive bishops Liége became famous during the 11th century as a centre of learning, but the history of the town for centuries records little else than the continuous struggles of the citizens to free themselves from the exactions of their episcopal sovereigns, the aid of the emperor and of the dukes of Brabant being frequently called in to repress the popular risings.

The long episcopate of Eberhard de la Marck (1505–38) was a time of good administration and of quiet, during which the town regained something of its former prosperity. The outbreak of civil war between two factions, named the *Cluroux* and the *Grignoux,* marked the opening of the 17th century. Bishop Maximilian Henry of Bavaria (1650–88) at last put an end to the eternal strife and imposed a regulation (*règlement*) which abolished all the free institutions of the citizens and the power of the guilds. The French revolutionary armies overran the principality in 1792, and from 1794 to the fall of Napoleon it was annexed to France, and was known as the department of the Ourthe. The Congress of Vienna in 1815 decreed that Liége, with the other provinces of the southern Netherlands, should form part of the new kingdom of the Netherlands under the rule of William I., of the house of Orange. The town of Liége took an active part in the Belgian revolt of 1830, and after that date the ancient principality was incorporated in the kingdom of Belgium.

Heavily fortified, Liége was the scene of intense fighting between Belgian and German armies in both World Wars I and II. The town itself was occupied by German troops Aug. 7, 1914 while the 12 surrounding forts held out for several more days. (*See* Belgium, Invasion of, 1914.)

In World War II, the surprise capture on May 11, 1940, of Fort Eben Emael, strongest link in Liége's defenses, hastened the collapse of Belgian arms.

LIEGE, an adjective of uncertain derivation which seems originally to have meant "simple," "unconditioned." The word is historically important because it was early used as a qualification of legal terms such as homage. In feudal law, liege homage is the homage due from a tenant to his chief lord. In course of time the idea prevailed that liege homage was due to the king, above and beyond the homage done to any immediate lords. From this idea is ultimately derived the employment of the abstract noun "allegiance," to denote the subject's duty to his sovereign.

See Pollock and Maitland, *History of English Law* (2nd ed., 1898), i. 298–300.

LIEGNITZ, a town in the Prussian province of Silesia, Germany, on the Katzbach, just above its junction with the Schwarzwasser, and 40 mi. W.N.W. of Breslau, on the main line of railway to Berlin via Sommerfeld. Pop. (1939) 83,000. Liegnitz is first mentioned in an historical document in the year 1004. In 1163 it became the seat of the dukes of Liegnitz, who greatly improved and enlarged it, and who are buried in the church of St. John. On the death of the last duke of Liegnitz in 1675, the duchy came into the possession of the Empire, which retained it until the Prussian conquest of Silesia in 1742. On Aug. 15, 1760 Frederick the Great gained a decisive victory near Liegnitz over the Austrians. It consists of an old town, and several suburbs. The palace, formerly the residence of the dukes of Liegnitz, and rebuilt after a fire in 1835, is used as the administrative offices of the district. The Ritter Akademie, founded by the emperor Joseph I., was reconstructed as a gymnasium in 1810. The church of SS. Peter and Paul (restored in 1892–1894) dates from the 14th century. The manufactures are considerable, the chief articles made being cloth, wool, leather, tobacco, pianos, clogs, sugar, carriages and machinery. Its trade in grain and its cattle-markets are likewise important. There are large market gardens in the suburbs.

LIEN. The word lien signifies the right of a person in possession of property belonging to another to detain such property until some debt or demand in connection with the property detained is satisfied. This right of lien arises either by implication of law or by express contract. Where, however, an express contract for security is made between parties such agreement excludes, to the extent of the express contract, any lien upon property to which it might otherwise have been subject. The possessory right conferred by lien is not a right *ad rem,* that is to say it does not convey to the person in possession of goods any property in them, it merely gives him a legal right to retain them until his demand is satisfied. Consequently, apart from statute or legal process authorizing him so to do, he is not entitled to sell the goods to recover what is due to him.

If the goods be not in possession of the claimant of lien, as in the case of the furniture of a tenant owing rent to a landlord, the law will indeed assist the landlord to seize the property and enable him to sell it in due course in order to pay himself out of the proceeds, but it will not give him any property in the furniture itself.

There are two descriptions of lien recognized by the English law: particular and general. Particular liens exist where persons have a right to retain possession of property in respect of labour or money expended by them on the identical chattel which constitutes the *res gestae* or subject matter of the dispute. Liens of this description are usually favourably regarded by the court. General liens are claims made in respect of a general balance of account between the parties.

Liens are created in three ways, either (1) by express contract, (2) by usage of trade, or (3) by some legal relation between the parties, where there is no express contract, nor any usage of trade. The term legal relation applies either to those persons on whom the law throws an obligation to perform certain services whenever required so to do by any member of the public, such as an inn-keeper or a common carrier, or else to a person who usefully expends time, work or money on the reparation of the chattel of another, such as a jobbing tailor, a boot repairer, a furrier, a calico printer, or indeed any person to whom goods are delivered in order to have some service performed in connection with them for which such delivery is necessary. But the mere safeguarding of the article, apart from work done upon it, will convey no right to lien in this particular form of deposit.

Again, a ship-master (on behalf of the owner) has a lien upon cargo for freight; and if, upon landing, notice of such lien is given to the wharfinger or warehouseman, the cargo is bound thereby in his hands, and may be subsequently sold by him upon compliance with statutory conditions (Merchant Shipping Act, 1894, secs. 494–498). And a like rule applies to passengers' luggage (except wearing apparel actually in use) for unpaid passage money.

A claim to general lien, though, as already stated, not regarded with favour by the courts, may be established by special or necessarily implied agreement, or by the custom of a certain trade. By virtue of accepted custom of trade or profession, wharfingers, bankers, insurance brokers and solicitors have a lien upon the property of their employers, not only for debts arising out of the particular transaction for which the property was delivered to them, but also for a general balance of account between the parties, and this rule has been held to apply to statute barred debts (*Courtenay* v. *Williams,* 3 Hare at p. 552).

A similar principle as to general balance of account has been held applicable to the lien of calico printers and packers, and locally (by the custom of Exeter) to fullers. The right to general lien is, however, incapable of transference.

Maritime Lien differs from all other forms of lien in that it neither includes nor requires actual physical possession of the ship in respect of which a maritime lien arises. It presupposes the giving of a credit coupled with a postponement intentionally made of the right to enforce it. It follows as a necessary consequence that unless the creditor has forfeited the right because of his own laches he can take legal proceedings against the ship notwithstanding any change there may have been in the ownership, and he has priority over all other titles to the ship which are not based on superior or equal liens, including mortgages already existing. It is otherwise with an existing possessory lien of a ship repairer. (Carver's *Carriage by Sea,* 55. 320, 692.)

The principal instances in which the law recognizes maritime liens are bottomry (*q.v.*) (*i.e.,* mortgage of ship's keel), salvage wages, master's wages, disbursements, liabilities, damage from collision, in which case the lien attaches to the wrong-doing ship.

Right of Sale or Transference of Lien.—Apart from statute a mere lien confers no right of sale on the party entitled to retain the chattels against the true owner, even if the detention be attended with trouble and expense (*Thames Iron Company* v. *Patent Derrick Company*, 1860, 29 L.J., Ch. 714). A statutory right of sale, however, of any goods left by a guest in his custody enures, after six weeks, to an innkeeper for the amount of his bill, by virtue of the Innkeepers Act, 1878 (sec. 1). By the Merchant Shipping Act, 1894 (secs. 497–498), a wharfinger or warehouseman, at the expiration of 90 days from the time when goods are placed in his custody (or a shorter time if the goods be perishable) is entitled to sell them by public auction; and sec. 97 of the Railway Clauses Act, 1845, authorizes railway companies to detain and sell any goods delivered to them for carriage upon default of payment of their tolls. Neither the custody of the chattel nor the accompanying lien is capable of legal transference to a third party, who is consequently, after demand and refusal, liable in trover to the true owner of the goods.

The lien of an unpaid vendor for the price of the article which he has sold to an insolvent purchaser subsists until the chattel has either been actually or constructively delivered into the hands of the latter. This lien for the price of specific goods is not determined by the mere delivery of the chattels to a carrier for the purpose of conveyance. Consequently, if the vendor can arrest the goods at any stage of the transit before they reach the hands of the purchaser or his agent the vendor reverts to the same position as if he had not parted with the possession of the goods.

The right is not de-vested by the purchaser endorsing over a bill of lading of the goods by way of security or for valuable consideration to a third party, with notice of the consignee's insolvency, or by a purchaser's sub-sale of the goods before the termination of the *transitus*, without delivery of the documents of title to an innocent third party.

Waiver and Determination of Lien.—A lien may be waived, and the right to assert the claim lost, by conduct on the part of the holder of the goods obviously inconsistent with the existence of such a right. A lien is determined by actual payment or tender of the full amount of the legal claim for which the goods are detained, but part payment of such demand is not sufficient, neither is a general tender or offer to discharge the claim without actual tender or what, in point of law, is equivalent thereto.

(W. W.-P.)

U.S. Differences.—In the United States, speaking generally, the law relating to liens is that of England, but there are some considerable differences occasioned by three principal causes. (1) Some of the Southern States, notably Louisiana, have never adopted the common law of England. When that State became one of the United States of North America it had (and still preserves) its own system of law. In this respect the law is practically identical with the Code Napoleon, which, again speaking generally, substitutes privileges for liens, *i.e.*, gives certain claims a prior right to others against particular property. These privileges being *strictissimae interpretationis*, cannot be extended by any principle analogous to the English doctrine of equitable liens. (2) Probably in consequence of the United States and the several States composing it having had a more democratic government than Great Britain, in their earlier years at all events, certain liens have been created by statute in several States in the interest of the working classes which have no parallel in Great Britain, *e.g.*, in some States workmen employed in building a house or a ship have a lien upon the building or structure itself for their unpaid wages. This statutory lien partakes rather of the nature of an equitable than of a common-law lien, as the property is not in the possession of the workman, and it may be doubted whether the right thus conferred is more beneficial to the workman than the priority his wages have in bankruptcy proceedings in England. Some of the States have also practically extended the maritime lien to matters over which it was never contended for in England. (3) By the constitution of the United States the Admiralty and inter-State jurisdiction is vested in the Federal as distinguished from the State courts, and these Federal courts have not been liable to have their jurisdiction curtailed by prohibition from courts of common law, as the court of Admiralty had in England up to the time of the Judicature Acts; consequently the maritime lien in the United States extends further than it does in England, even after recent enlargements; it covers claims for necessaries and by material men, as well as collision, salvage, wages, bottomry and damage to cargo.

Difficulties connected with lien occasionally arise in the Federal courts in Admiralty cases, from a conflict on the subject between the municipal law of the State where the court happens to sit and the Admiralty law; but as there is no power to prohibit the Federal court, its view of the Admiralty law based on the civil law prevails. More serious difficulties arise where a Federal court has to try inter-State questions, where the two States have different laws on the subject of lien; one for example, like Louisiana, following the civil law, and the other the common law and equitable practice of Great Britain. The question as to which law is to govern in such a case can hardly be said to be decided. "The question whether equitable liens can exist to be enforced in Louisiana by the Federal courts, notwithstanding its restrictive law of privileges, is still an open one" (Derris, *Contracts of Pledge*, 517; and see *Burdon Sugar Refining Co.* v. *Payne*, 167 U.S. 127).

LIEPĀJA (*Libau*), a seaport of Latvia in 56° 32′ N., 21° 2′ E., at the northern extremity of a narrow sandy peninsula which separates Lake Libau (12 mi. long and 2 mi. wide) from the Baltic sea. Pop. (1939) 57,098. There are four harbours: the Commercial, with stone quays, storehouses for merchandise and three grain elevators; the Winter, with numerous timber yards round the quays; the Avant pier or New harbour, where regular passenger steamers berth; and the War harbour (closed shortly after the start of World War II) with two dry docks, each 600 ft. Vessels drawing more than 28 ft. cannot enter the port. It is open practically the year round with the help of icebreakers.

The chief imports are coal, iron, salt, herrings, grain, cotton, machinery, chemical manure and phosphates. The exports include rye, barley, oats, wool, linseed, sleepers, deals, pitprops, pulpwood, skins and hides, wheat and eggs. The port also serves as a coaling and oiling station.

Primarily because of the loss of Russian commerce, trade fell in 1920 to approximately 20% of the 1913 level. Industries before 1913 included iron and steel works and engineering yards, veneering, flour-milling, bacon-curing, tobacco manufacture, the extraction of vegetable oils, the making of colours and varnishes, brewing, distilling and leather work. Many of the factories ruined during the conflict, 1914–19, were never repaired and put into production. An immense state-owned factory, dominating the water front, produces agricultural and other heavy machines.

The port of Libau, Lyra portus, is mentioned in 1263, when it belonged to the Livonian order or Brothers of the Sword. In 1418 it was burned by the Lithuanians and in 1560 mortgaged by the grandmaster of the Teutonic order, to which it had passed, to the Prussian duke Albert. In 1701 it was captured by Charles XII of Sweden, and in 1795 annexed to Russia. After 1872, when it was brought into railway connection with Moscow, Orel and Kharkov, Liepāja became an important port and developed rapidly. The Russians constructed an extensive naval port, protected by moles and breakwaters in 1893–1906. The Latvian government removed here when Riga was in German occupation in 1917–19, and Liepāja itself was occupied by German troops in 1919. Certain areas were still in ruins in 1941, when the Germans again re-occupied the town, following the Russian occupation of 1940–41.

LIERNE, in architecture, a small, subordinate vaulting rib, which runs between the more important structural ribs. With the English tendency to sub-divide vaulting areas during the 14th century, the invention and development of the lierne was a necessary consequence. Used more for decorative than for structural reasons, liernes are especially grouped near the vault ridges, where they form extremely rich and complicated intersecting patterns. These generally fall into two types, that known as reticulated, or net-work patterns, as in the choir of Gloucester (completed 1377); and star patterns, as in the nave of Canterbury cathedral (*c.* 1400). The intersections of liernes with each other or of liernes with the major ribs, are usually decorated with carved, projecting bosses.

LIERRE (French for Lier), a town in the province of Antwerp, Belgium, 9 mi. S.E. of Antwerp. Its church of S. Gommarus (completed 1557) has three fine windows, given by Archduke Maximilian to celebrate his wedding with Mary of Burgundy. The cutlery and beads industries are very important and a little silk is manufactured. Pop. (est. 1939), 28,604.

LIESTAL, the capital of the half canton of Baselland, Switzerland. Population 6,698.

LIEUTENANT, one who takes the place, office and duty of and acts on behalf of a superior or other person. The word in English preserves the form of the French original (from *lieu,* place, *tenant,* holding), which is the equivalent of the Lat. *locum tenens,* one holding the place of another. The usual English pronunciation appears early, the word being frequently spelled *lieftenant, lyeftenant* or *luftenant* in the 14th and 15th centuries. The modern American pronunciation is *lewtenant,* while the German is represented by the present form of the word *Leutnant.* In French history, *lieutenant du roi* (*locum tenens regis*) was a title borne by the officer sent with military powers to represent the king in certain provinces. With wider powers and functions, both civil as well as military, and holding authority throughout an entire province, such a representative of the king was called *lieutenant général du roi.* The first appointment of these officials dates from the reign of Philip IV. the Fair (*see* CONSTABLE). In the 16th century the administration of the provinces was in the hands of *gouverneurs,* to whom the *lieutenants du roi* became subordinates. The titles *lieutenant civil* or *criminel* and *lieutenant général de police* have been borne by certain judicial officers in France (*see* CHÂTELET and BAILIFF AND BAILIE: *Bailli*). As the title of the representative of the sovereign, "lieutenant" in English usage appears in the title of the lords lieutenant of the counties of the United Kingdom. (*See* COUNTY; MILITIA: *Militia of England.*)

The most general use of the word is as the name of a grade of naval and military officer. In Italy and Spain the first part of the word is omitted, and an Italian or Spanish officer bearing this rank is called *tenente* or *teniente* respectively. In the British and most other navies the lieutenants are the commissioned officers next in rank to commanders, or second class of captains. Originally the lieutenant was a soldier who aided, and in case of need replaced, the captain, who, until the latter half of the 17th century, was not necessarily a seaman in any navy. At first one lieutenant was carried, and only in the largest ships. The number was gradually increased, and the lieutenants formed a numerous corps. Lieutenants now often qualify for special duties such as navigation, or gunnery, or the management of torpedoes. In the British army a lieutenant is a subaltern officer ranking next below a captain and above a second lieutenant. In the United States of America subalterns are classified as first lieutenants and second lieutenants. In France the two grades are *lieutenant* and *sous-lieutenant,* while in Germany the *Leutnant* is the lower of the two ranks, the higher being *Ober-leutnant* (formerly *Premier-leutnant*). A "captain lieutenant" in the British army was formerly the senior subaltern who virtually commanded the colonel's company or troop, and ranked as junior captain, or "puny captain," as he was called by Cromwell's soldiers.

LIFE, the kind of activity characteristic of living creatures. No doubt this activity is, in its objective aspects, an integration of numerous chemical and physical processes, and there is no warrant for postulating any mysterious "vital force." On the other hand, it must be allowed that life is a unique kind of activity, for the formulae of matter and energy, electrons, protons and electro-magnetic radiations or ether-waves, as at present understood, do not suffice to describe (*a*) the everyday functions of the body in their orchestration, (*b*) the self-preservative activities of any organism at any grade of being, (*c*) the purposive behaviour of higher animals well-endowed with brains, (*d*) the phenomena of development and heredity or (*e*) the facts of evolution. Everyone allows that living is in part analysable into chemical and physical processes, yet these are modified by their occurrence in the colloidal medium of the chemically very complex protoplasm. In conditions of extreme complexity, a new aspect of reality—Life—emerges. Moreover, when the chemical and physical ledger is added up, it does not give a unified description of what has actually occurred when, *e.g.,* a migrant bird makes its journey. For to describe this it is necessary to introduce concepts beyond physics and chemistry, such as enregistration of the past, awareness of the present and purposiveness towards the future. In at least the higher reaches of the animal kingdom, behaviour is correlated with psychical activity, incommensurable with physical processes. Thus life is an activity of organisms which requires for its description concepts transcending those of mechanism. This view does not in any way contradict the theory that living organisms may have arisen on the earth from nonliving materials. When the materials were complex enough and in an appropriate collocation, living organisms may have emerged.

Characteristics of Organisms.—(*a*) The self-preservative persistence of an organism is associated with the building-up and breaking-down of proteins, which have large complex molecules, representing an accumulation of potential chemical energy. Anabolic processes counterbalance the katabolic, repair counteracts waste; rejuvenescence wards off senescence. The organism is like a clock that winds itself up as it runs down. No doubt this quality is to be analysed as far as may be,—in terms, for instance, of the characteristic fermentations and their reversibility. Much depends on the fact that the proteins are always colloidal, admitting of intensity and rapidity of chemical reactions on the surface of the multitudinous ultra-microscopic particles or droplets suspended in the liquid phase. Another feature is the chemical individuality everywhere manifest, for each distinct type of organism seems to have some distinctive protein of its own, and some characteristic rate or rhythm of metabolism. Thus under the general quality of persistence amid unceasing metabolism, there is a triad of facts: (1) the building-up that compensates for the breaking-down of proteins, (2) the occurrence of these proteins in a colloidal state and (3) their specificity from type to type.

(*b*) A second triad of qualities includes the organism's characteristic powers of *growing, multiplying* and *developing.* A surplus of income over expenditure is the primal condition of organic growth. As contrasted with the growth of a crystal, an organism can grow at the expense of materials more or less different from those of the growing body; it implies active assimilation, not mere passive accretion; and it is a definitely regulated process—regulated from within. Growth naturally leads to the simplest forms of multiplication or reproduction, for persistent growth tends to bring about organic instability, which may be intracellular as in unicellular organisms and in ordinary cell-division, or localized along a line of weakness or low vitality, as in the fragmentation of some lower multicellular animals. Asexual multiplication is a regularized form of discontinuous growth, and sexual reproduction by liberated germ-cells is a secondary specialization, anticipated in the spore-formation of many of the Protozoa and Protophyta (*see* REPRODUCTION).

Development is the progressive attainment of full-grown complexity from comparatively undifferentiated simplicity, whether that be in stump or fragment, in leaf or bud, in spore-cell or germ-cell. It implies an expression of hereditary initiatives in appropriate nurture, and often in such a way that the individual stages in the ontogeny can be correlated with great steps in the racial history or phylogeny. Development, with its central fact of progressive differentiation and integration, is particularly to be thought of in connection with the building up of the embryo, but it cannot be separated from the everyday repair of worn-out tissue, the replacement of periodically deciduous structures (like leaves and hair), and the frequent regeneration (*q.v.*) of lost parts, thus linking back with reproduction and growth.

(*c*) In the third place living creatures stand apart from nonliving things in their purposive behaviour, in their power of enregistering experience, and in their capacity for giving rise to the new—a third triad. Many non-living things, such as explosives, react forcefully to outside stimulus, but organisms are marked by the self-preservative efficiency of their reactions. Only the higher big-brained animals can be credited with perceptual purpose, but the quality of purposiveness seems to be co-extensive with life. The organism is an agent that gets things done, at various levels of behaviour—intelligent, instinctive, tropistic, reflex, and so forth. The mental aspect may in many cases be subordinated to the bodily, but in the majority there is the bent bow of endeavour, even though the creature's awareness of that endeavour may be dim. The mental aspect seems to be struggling for expression throughout, and the organism appears as a psycho-physical being, now (mind)-BODY and again (body)-MIND (*see* BIOLOGY).

A bar of iron is never quite the same after it has been severely jarred; a violin suffers from mishandling. But these are hardly more than vague analogies of the distinctive power that living creatures have of enregistering the results of their experience, of establishing internal rhythms, of forming conditioned reflexes and habits, and of remembering. Individual experience is built into the individual organism and influences subsequent reactions.

Finally, it must be recognized as characteristic of organisms that they give origin to what is new; they have evolved in the past, and the evolution of many is still going on. Variability and evolvability must be ranked as fundamental characteristics of living beings. The organism selects stimuli from its environment and often moves from one environment to another; the organism is often experimental, moulding itself by its efforts; it tests the newness of its inheritance in its ceaseless trafficking with circumstances. The central secret of life is missed if the organism is not recognized as in some measure a struggling sub-personality.

To sum up, the characteristics of organisms are:—(*a*) *Persistence of integrity amid ceaseless change,* there being (1) a self-preservative compensation of down-breaking by up-building, (2) a metabolism of proteins and other complex substances in a colloidal state, (3) a chemical individuality; (*b*) *a triad of linked capacities,* namely, (4) growth, (5) multiplication, (6) development; and (*c*) the crowning triad of (7) effective behaviour, (8) enregistration of experience, (9) evolvability.

Aspects of Life.—The biologist works with three co-ordinates—the organism, its functions and the environment. These are the three sides of the biological prism. At times what is observed is the insurgent organism acting on its environment, both animate and inanimate; and this may conveniently be summed up by using the first letters, $O \longrightarrow f \longrightarrow e$, giving the Organism a capital. But at other times, and just as familiarly, the Environment closes in upon the organism, stimulating and inhibiting, fostering and weathering, warming and cooling, feeding and starving. This may be formulated again $E \longrightarrow f \longrightarrow o$, reversing the capitals. Thus, as Patrick Geddes points out, living implies an ever-changing ratio $\frac{Ofe}{Efo}$. Most animals are less in the grip of their environment than most plants, and sedentary corals more than pelagic medusae, the very young more than the resiliently mature, and the summer hedgehog more than the hibernater. In the article BIOLOGY it has been suggested that since an organism without its everyday functions is rather an empty abstraction, the term function in the $O \longrightarrow f \longrightarrow e$: $E \longrightarrow f \longrightarrow o$ formula, should rather read "functionings," *i.e.*, the work or on-goings, the actions and reactions of the organism as a whole.

The Drama of Life.—What has been said gives too cold an impression of life, which must be envisaged as a drama on a crowded stage. (1) Whatever the secret of vital activity may be, it must be thought of as an overflowing spring. Organisms accumulate energy acceleratively and must multiply. Life is like a river that is often in flood. (2) From the ant-hill, the bee-hive, the rookery, the rabbit warren, there comes the impression of urge and endeavour. Whether the urge be vegetative, appetitive, tropistic, instinctive or intelligent, organisms are almost always after something—never satisfied. The more they get the more they want. (3) But the quality of life rises to what may be called insurgence. Animals in particular are full of daring and adventure. As Goethe said, they are always attempting the next to the impossible and achieving it. This is well illustrated by gossamer-spiders making aerial journeys, or by Arctic terns within the Antarctic Circle; but it finds many an unsensational expression. (4) Another quality, so universal that it must be called characteristic, is adaptiveness. Practically every organism is a bundle of adaptations or fitnesses. As Weismann said, "If all the adaptations are taken away from a whale, what is there left?" (5) It is perhaps an expression of this adaptiveness that so many living organisms form linkages with others. There is no aloofness in the realm of organisms; nothing lives or dies to itself. Thus animate nature is characteristically a system,—a fabric that changes in pattern and yet endures. Though the individual threads of the web are always dying, they are replaced without a discontinuity. There is wear, but no tear, except when man carelessly interferes with the loom, or when some physical violence, like flood or fire, causes an inevitable rent. (6) But this leads to another characteristic of the biosphere that marks it off from the cosmosphere: there is continual sifting. A new star often appears in the sky, but there is no indication of any struggle for existence or selection of the relatively more fit. But who can describe the advancement of life and leave out winnowing? There is cosmic flux and there is organic flux, but only in the latter is there discriminate elimination. (7) Another characteristic of living creatures is their beauty. All independently-living organisms are artistic unities, with protean wealth of beauty in form and colour, in pose and movement, expressing a harmonious life from which the discordant has been more or less completely eliminated. Apart from exceptions, like parasites, which prove the rule, organisms are like works of art. (8) Nothing can be said as to the mental aspect of a wood-anemone and only a little about that of a sea-anemone, but a picture of life must include the fact that in organisms there is the promise and potency—and in higher animals the epiphany—of "Mind." Perceptual inference is a relatively late achievement; conceptual inference or reason is man's prerogative; but throughout the animal kingdom there is a stream of inner life, of feeling and purpose, even when there is not very much in the way of intelligence. The probability is that "Life" and "Mind" are co-extensive. (9) But the crowning characteristic of life is its progressiveness. No doubt there have been eddies and stagnant pools, but on the whole there has been a flow in the stream of life, and it has been uphill! As epoch has succeeded epoch for inconceivably long ages, life has been slowly creeping—sometimes swiftly leaping—upwards, towards greater fullness and freedom. The whole process must be envisaged in the light of its outcome, organic evolution in the light of man.

LIFE-BOAT AND LIFE SAVING. The article on DROWNING AND LIFE SAVING (*q.v.*) deals generally with the means of saving life at sea, but under this heading it is convenient to include the appliances connected specially with the life-boat service. The ordinary open boat is unsuited for life saving in a stormy sea, and numerous contrivances, in regard to which the lead came from England, have been made for securing the best type of life-boat.

The first experimenter in England was Lionel Lukin, a London coach-builder, later Master of the Worshipful Company of Coach-makers. Encouraged by the prince of Wales (George IV.), he converted a Norway yawl into what he called an "unimmergible" boat, which he patented. Buoyancy he obtained by means of a project-

FIG. 1.—TYPES OF MODERN LIFE-BOATS

Top: self-righting life-boat, 40 ft. by 10 ft. 6 in., with 40 h.p. motor, also fitted with rowlocks for oar propulsion. Below: Watson type cabin motor life-boat, with 80 h.p. motor

ing gunwale of cork and air-chambers inside—one of these being at the bow, another at the stern. Stability he secured by a false iron keel. The self-righting and self-emptying principles he seems not to have thought of; at all events he did not compass them. Lukin was thinking rather of making all boats safer than of constructing a boat for the special purpose of life saving, but he was associated with the earliest known attempt at establishing a Life-Saving Service when, in 1786, he converted a coble into a "safety-boat" for Archdeacon Sharp. This boat was employed for some years at Bamborough in saving life from shipwreck, the village becoming thereby the first life-boat station.

Public apathy in regard to shipwreck was temporarily swept away by the wreck of the "Adventure" of Newcastle at the mouth of the Tyne in 1789. This vessel was stranded only 300yd. from the shore, and her crew dropped, one by one, into the raging breakers in presence of thousands of spectators, none of whom dared to put off in an ordinary boat to the rescue. An excited meeting among the people of South Shields followed; a committee was formed, and premiums were offered for the best models of a life-boat. This called forth a number of plans, among those who submitted them being William Wouldhave, a house painter and a teacher of singing, and Henry Greathead, a boat builder, both of South Shields. Wouldhave's model was so constructed that, if capsized, it would immediately right itself, and Wouldhave is entitled to be considered the discoverer of that principle, which is now used in more than half the life-boats round the British coasts. But the committee did not adopt this principle, nor was it entirely satisfied with Wouldhave's design. It gave him half the reward and then, from this and the other designs submitted, prepared a model of its own from which Greathead built the first life-boat.

The First Life-boat.—This boat was rendered buoyant by nearly 7cwt. of cork, and had very raking stem and stern-posts, with great curvature of keel. The total cost was just under £150. This life-boat, the "Original," served until 1830 and rescued hundreds of lives. No other life-boat was launched till 1798, when the duke of Northumberland ordered Greathead to build him a life-boat which he endowed. This boat also did good service, and its owner ordered another in 1800 for Oporto. In the same year Mr. Cathcart Dempster ordered one for St. Andrews, where, two years later, it saved twelve lives. Thus, the value of life-boats began to be recognized, and before the end of 1803 Greathead had built thirty-one boats—eighteen for England, five for Scotland and eight for foreign lands. In this work he was materially helped by Lloyds. Four years later Lukin, the coach-builder, again appeared on the scene, being invited by the Suffolk Humane Society to superintend the building of the first sailing life-boat. This boat, launched at Lowestoft at the end of 1807, was the forerunner of the Norfolk and Suffolk type of life-boat still used on that part of the coast.

In spite of these efforts, however, by individuals and local societies acting independently of one another, public interest in life-boats was not thoroughly aroused until 1823, when an appeal to the nation was made by Lt.-Col. Sir William Hillary, Bt., a resident in the Isle of Man. It is to him that we owe the establishment of a national life-boat service. He saw many terrible wrecks on the stormy coasts of the Isle of Man, and he helped to save no fewer than 305 lives. His appeal was a carefully thought out plan of what a life-boat service should be, of those to whom it should look for support, and how it should carry on its work. As Sir William Hillary planned the service more than a century ago so, in all the main features of its work, it is to-day. These main features were: That a life-boat service must be a matter for national concern; that those who carried out the dangerous work of rescue should not only be rewarded, but should be certain that, if they lost their lives, their dependents would be provided for; that the life-boats should be at the service of all in peril round the coasts, whatever their nationality; and that the service should be maintained by voluntary contributions. Within a year, and with the help of two members of parliament—Mr. Thomas Wilson and Mr. George Hibbert—Hillary had founded the "Royal National Institution for the Preservation of Life from Shipwreck."

The Royal National Life-boat Institution.—This, perhaps the grandest of England's charitable societies, and now named the "Royal National Life-boat Institution," was founded on March 4, 1824. It began its career with a sum of only £9,826. In the first year twelve new life-boats were built and placed at different stations, besides which thirty-nine life-boats had been stationed on the British shores by benevolent individuals and by independent associations over which the institution exercised no control, though it often assisted them. In its early years the institution placed the mortar apparatus of Captain Manby at many stations, and provided for the wants of sailors and others saved from shipwreck,—a duty subsequently discharged by the "Shipwrecked Fishermen and Mariners' Royal Benevolent Society." At the date of the institution's second report it had contributed to the saving of three hundred and forty-two lives, either by its own life-saving apparatus or by other means for which it had granted rewards.

In the year 1849, came another tragedy at the mouth of the Tyne. The life-boat "Providence," when out on service, capsized, and of her double crew of 24 no fewer than 20 were drowned. Tragic though this event was, it yet served to re-direct public attention to the needs of the life-boat service, and as such marks a turning point in its history. These first twenty-five years of the institution's history had been years of great national stress, and the institution had inevitably suffered. In 1849–50 its income had fallen as low as £354, and the majority of the life-boats were

UNITED STATES COAST GUARDSMEN USING FLARES AND LAUNCHING LIFEBOATS FOR RESCUE WORK

1. Hauling surfboat to beach abreast of wreck for launching. Boat is mounted on a specially constructed cradle chassis, and is hauled by a tractor, or ordinary truck, horses, or members of the crew
2. Launching the surfboat. Steersman (extreme left) is the last to enter the boat when it is afloat and the oarsmen in their places. Every member of the crew is required to wear a lifebelt
3. Surfboat at Rockaway Point station, New York, just after launching through the surf
4. Surfboat just entering the surf, the men in their places and the captain in the act of leaping aboard. Skill and strength, with steady nerves and trained teamwork, are required to launch or land a boat through a surf such as that shown
5. Surfman, upon discovery of a vessel in distress burning a rocket flare, answering with the Coston light or beacon signal, to let the sailors know that help is at hand
6. A life-saving crew burning flares to illuminate the scene of a wreck. Stations are supplied with powerful acetylene searchlights for this purpose, which are practically wind and waterproof, and afford an intense diffused light over the entire field of operations at a wreck. The hand lights are generally used only for signalling to warn vessels standing into danger, or to notify a stranded vessel that it is discovered and help is at hand

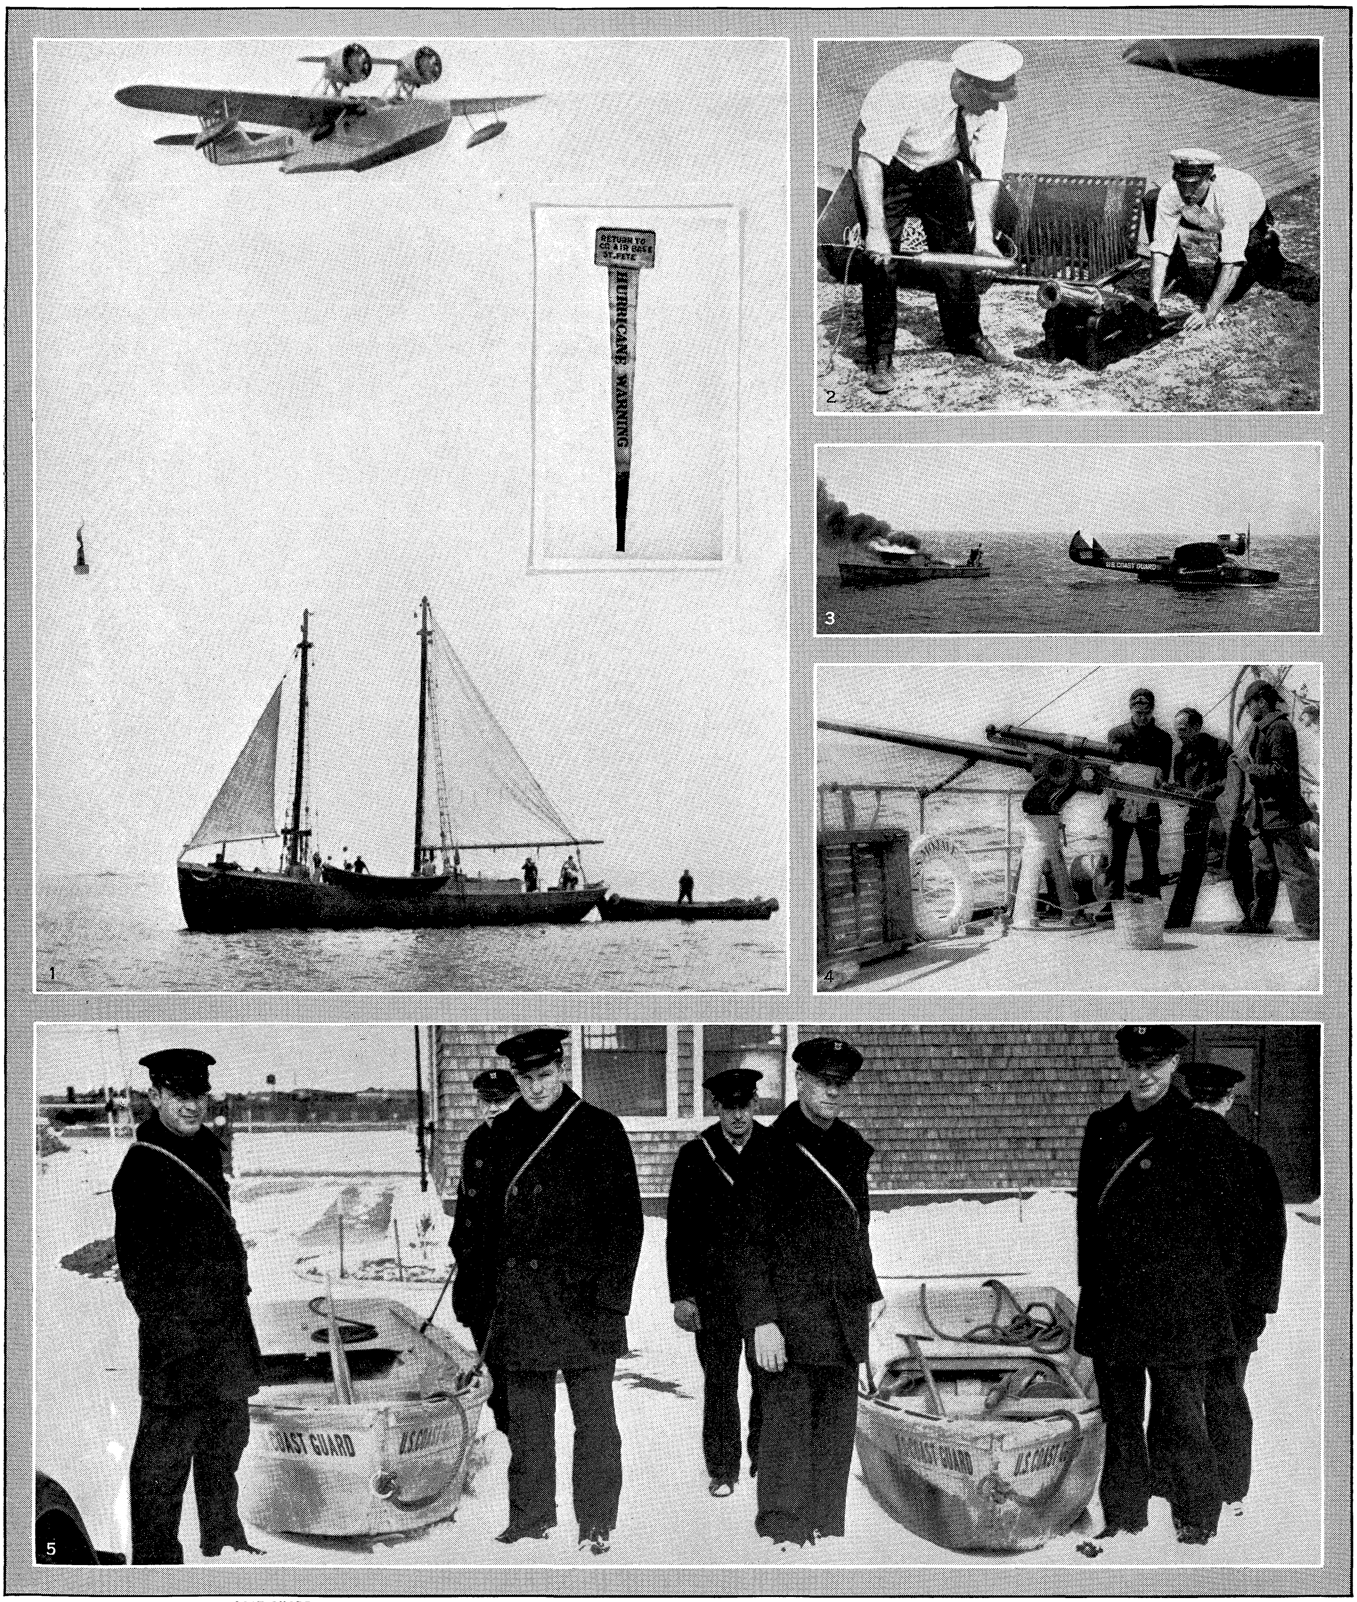
RESCUE WORK IN PROGRESS AND VESSELS ASHORE AND AFIRE AFTER LIFE SAVING

1. The British steamer "Thistlemore" ashore, Peaked Hill Bar, Cape Cod, Mass., Feb. 1922. Coast guardsmen on the beach have shot a lifeline to the ship by means of the Lyle line-throwing gun. Persons are taken from the ship in life car or breeches buoy (*see* fig. 3)
2. Full-rigged British ship "Glenesslin" ashore on Oregon coast. Many vessels were lost along dangerous coasts during earlier days before the establishment of life saving stations. Sailing vessels were particularly liable to disaster on a lee shore because of difficulty in manoeuvring
3. The breeches buoy, a life-saving device which travels on a hawser rigged between the disabled vessel and the shore. The buoy consists of a cork life-preserver having breeches attached. Suspended by a pulley on the lifeline, the apparatus holds occupant securely. Ropes to ship and shore control passage
4. Schooner "Annie C. Ross" stranded on sandy beach near Pensacola, Florida. Hull of ship rests on sand, lessening chance of breaking up
5. A steam trawler or fishing vessel ashore, resting on her port side. This type of vessel operates largely outside of regular ship lanes, where the danger of running ashore is increased by the absence of lighthouses
6. Steam freighter "Cabo Hatteras" afire at sea. Crew was rescued and the ship, which had become a menace to navigation, was later sunk by gunfire and mines from U.S. Coast Guard Cutter "Seminole"



BY COURTESY OF THE U. S. COAST GUARD

THE AEROPLANE AND OTHER MODERN LIFE-SAVING DEVICES

1. Coast Guard plane dropping message block to warn fishermen of approaching hurricane. Insert shows close-up of message block, with streamer attached. At the first notice of approaching hurricane, Coast Guard planes take off with a number of these hurricane warning blocks and drop them near small fishing boats, which are not equipped with radio or other means of communication
2. Drill with Lyle line-throwing gun, Rockaway Point Station, New Jersey. This gun is used by shore stations for firing a line to stranded or distressed vessels
3. Coast Guard plane making preparations to rescue the crew of a burning craft at sea
4. The Camden line-throwing projectile about to be fired from the 6-pounder. This projectile and gun are used in extremely bad weather for throwing a line to a distressed craft, where the shoulder line-throwing gun would be inadequate
5. Specially constructed boats, used mostly on Great Lakes, where it is often necessary to haul the boats for miles over rough ice before reaching water where they can be launched.

no longer seaworthy. Public interest in it had almost ceased. The Tyne disaster helped to recall the public to the importance of their life-boat service and the need to support it. In 1850 the Prince Consort became vice patron of the institution in conjunction with the king of the Belgians, and Queen Victoria, who had been its patron since her accession, became an annual contributor to its funds. In 1851 Algernon, fourth Duke of Northumberland, became the institution's president. He was known as the "Sailor Duke." He entered the Navy in the year of Trafalgar, was now a Rear Admiral, and a little later became First Lord of the Admiralty. He brought a new spirit to the work, and from that day to this the institution has never looked back. It has gone from strength to strength, and it is many years now since it was first able to say that a life-boat had been stationed at every point on the coast where it was required, and where an efficient crew could be found.

In 1850 its committee undertook the immediate superintendence of all the life-boat work on the coasts, with the aid of local committees. Periodical inspections, quarterly exercise of crews, fixed rates of rewards for coxswains and men, on a sliding scale according to the season of the year, and the day or night, were instituted; and the duke of Northumberland, realising that the "first and most obvious step was to endeavour to introduce an improved life-boat," offered a prize of one hundred guineas for the best model, and appointed a committee of experts to report on those sent in. In reply to the offer no fewer than two hundred and eighty models were sent in, not only from all parts of Great Britain but from France, Germany, Holland and the United States. The prize was gained by Mr. James Beeching of Great Yarmouth, whose model, slightly modified by Mr. James Peake, one of the committee of inspection, was adopted by the Institution. Mr. Beeching's model embodied most of Wouldhave's ideas with improvements of which he had never dreamed, and, coming sixty-two years later, was the model for the first genuine self-righting boat ever built. This boat, with minor alterations, is practically the type of the self-righting life-boat of to-day.

The Watson Life-boat.—Another important step was taken in 1887, following on an accident at the end of 1886 to two self-righting life-boats on the Lancashire coast, in which twenty-seven out of twenty-nine of the two crews were drowned. A permanent technical sub-committee was appointed by the Institution whose object was, with the help of an eminent consulting naval architect —a new post created—and the Institution's technical officials, to give its careful attention to the improvement of the design of life-boats. The immediate result was the designing of a new type of life-boat, by Mr. G. L. Watson, the famous yacht designer, who had been appointed consulting naval architect, and held that post for many years. The Watson life-boat did not self-right. It was a larger and more stable boat than the self-righter, had beautiful lines, was safe, weatherly, quick in stays and with a good turn of speed. With the design of this type a new principle was introduced, the principle on which the Institution's life-boats are still built. Broadly speaking, it is that with large life-boats intended to go well out to sea, it is better to set aside the self-righting principle and aim at great buoyancy and stability. Besides the Watson boats there are six other types of life-boat which do not self-right, in the Institution's fleet. More than half the fleet consists of self-righters, more than a quarter of Watson boats, and the remainder of these other types. The choice of boat is largely determined by the conditions of the coast on which it will be placed, but the crews are always consulted, and no crew is given a new life-boat unless it has already inspected it and expressed itself as satisfied. The first of the Watson life-boats was designed in 1890, and in the same year the first steam life-boat, named "Duke of Northumberland," was stationed at Harwich.

The Motor Life-boat.—The first experiments with an internal combustion engine were made during the year 1903. With these experiments began the modern era of life-boat work. To design an engine which should comply with the stringent requirements of the service might well seem an insoluble problem. Such an engine had to be water-tight but not air-tight, and able to run under all conditions of night and storm without attention. It had to have controls not only simple but easy to distinguish by touch, so that they could be worked in the darkness. It had to run and to lubricate itself with certainty at any angle. At the same time, when the capsizing point was reached it had to cut itself off automatically, for, otherwise, if the boat were of the self-righting type, she would right herself and be carried away by her engine, leaving the crew in the water. In addition to all this, the engine must interfere neither with the self-righting quality of the boat, nor with its sailing powers. The first life-boat to be converted to motor power was completed in 1904, and sent to Tynemouth. She had a 12 h.p. two-cycle motor. The Institution has now sixty-five motor life-boats in its fleet, and it is hoped in the next few years to increase this number to over a hundred. By its ability to attain a speed and to cover distances impossible for boats which depend upon sails and oars; by its power to force its way in the face of winds and seas, before which rowing and sailing boats would be helpless, and, above all, by its great manoeuvring power when close to the wreck, the motor life-boat can save lives which, without it, would be beyond the reach of human aid.

Greathead's life-boat was an open rowing boat, 30 feet long. She had no other source of buoyancy than cork could give her, no other means of ridding herself of water than by baling, no other means of propulsion than by oars. That the largest of the modern motor life-boats are twice as long is the smallest part of the difference. Instead of baling tins they have automatic valves which empty out the water as fast as the sea can pour it in. Instead of cork they have as many water-tight compartments as a modern battle-cruiser. Twenty holes might be knocked in each side, and they could still go on with their work. They are practically unsinkable. Instead of oars they have engines so designed that they can go on running when completely submerged, so long as the air-intake is above water. They have cabins; electric searchlights; line-throwing guns, with a range of 80 yards; and oil-sprays for spraying oil on heavy seas. The largest of these life-boats, the Barnett Twin Screw type, has two engines, each of 76 h.p. She has 15 main and 100 minor water-tight compartments, and two cabins with accommodation for between 50 and 60 people. In a calm sea she could take 300 people on deck. Under most conditions of bad weather she could in safety carry 150 people in addition to her crew. She carries enough petrol to be able to travel 500 miles at a cruising speed of 8 knots, and her maximum speed is $9\frac{1}{2}$ knots. This may not seem a high speed, but a life-boat is not built for high speed, but so that she can maintain her speed under practically any conditions of weather.

All the Institution's engines for motor life-boats use petrol for fuel in order to obtain the greatest power for a given weight. The earliest types were adaptations of various designs of commercial engines, the most successful being an adaptation of an engine built by Messrs. Tylor and Company for lorries. It was, however, soon found that a water-tight engine was essential in order that it might continue to work even when the life-boat had been holed in the engine-room. As there was no such engine on the market the Institution produced a design of its own for a six cylinder 76 h.p. engine, and the first was built in 1923. This has been followed by an improved type, of which there are two variants, one being a four cylinder engine producing 40 h.p. and the other a six cylinder engine producing 60 h.p., one, or two, of these engines being installed in a life-boat, according to its size and type. A light 35 h.p. engine has also been adapted to the Institution's requirements for use in the specially light type of life-boat built for launching from the beach.

Life-boat Houses and Slipways.—The largest type of motor life-boats lie afloat, and in one or two cases the life-boats lie on the open beach, but for the most part they are kept in houses, various methods of launching being used according to the type of foreshore. The most effective, because the quickest, is down a slipway. For a slipway to be built, however, it is necessary that the shore should be steep enough to give a sufficient depth of water for launching the boat at any state of the tide. Slipways, for the most part, are built of reinforced concrete, the longest, at Porthdinllaen, Carnarvonshire, being 351 feet in length. The usual slope is 1 in 5. The great majority of houses with slipways for motor life-boats are provided with power winches for hauling up the boats. On flat sandy beaches life-boats are still launched off a carriage which is taken out into the sea, until a sufficient depth is reached to float the boat, and a specially light type of motor life-boat is built for such stations. Instead of horses, motor caterpillar tractors are now used at an increasing number of stations; these tractors not only drag the life-boat down to the water's edge, but push it out into the sea.

Modern Life-Boat Equipment.—All motor life-boats are provided with a line-throwing gun, specially designed for the Institution by the Birmingham Small Arms Company. The gun is similar to a carbine, with Martini Henry breech action. The line is coiled up in a tin cylinder which fits over the barrel. One end of it is attached to a hollow steel projectile, and this projectile has a rod down the centre, the rod having the diameter of the bore of the gun. The gun is "loaded" by slipping the projectile over the muzzle so that the rod goes inside the barrel, while the rest of the projectile fits outside it, in the space between the barrel and the cylinder holding the line. The projectile is fired with a small cordite cartridge, which has a very small recoil, and as the weight of the gun, complete with projectile and line, is only 14lb. it can be easily handled. There is no need for firing sights, and the correct angle at which the gun should be held is automatically obtained by a small plumb-bob suspended from a leaf-sight fixed at an angle of 30 degrees. The line used is $\frac{3}{16}$in. in diameter, and it can be thrown a distance of sixty to eighty-five yards, according to the conditions of the weather.

FIG. 2.—PROFILE AND MIDSHIP SECTION OF 26-FT. SURF BOAT

The majority of motor life-boats are provided with electric searchlights, specially designed to be water-tight and simple to manipulate. They are of two kinds, a portable searchlight of 100 candle-power, and a mounted searchlight of 2,000 candle-power, the latter being used only on the largest type of boats. The largest type of life-boat, the Barnett twin-screw, is provided with a net, stretched amidships, into which those on board the wreck can jump as the life-boat lies alongside.

The Crew.—All pulling and sailing life-boats are launched for an exercise once a quarter, and all motor life-boats once a month, for testing the machinery and once a quarter for drilling the crew. A crew varies in number from 6 and 8 in the case of motor life-boats to 13 and 17 in the case of pulling and sailing life-boats.

The Life-boats in the World War.—At the beginning of the World War there were already nineteen motor life-boats on the British coast. For four and a half years all construction was suspended. Boats already begun were left unfinished until the war was over. Even the work of repairing damaged boats was sometimes impossible. But though the war came at a time of critical development in the life-boat service, and delayed that development for over four years, it found the service ready for every emergency. The brief chronicle of its war-rescues is that from the outbreak of war in Aug. 1914, to the signing of peace in July 1919, the life-boats were launched 1,808 times and 5,322 lives were rescued. The boats were launched 552 times to the help of ships or aircraft of the navy, or to merchant vessels wrecked or in distress on account of the war. Besides those 5,322 lives the life-boat saved 186 boats and vessels. The bulk of the crews who did such fine work in the mine-sweepers, trawlers and drifters were drawn from the fishing population which, for generations, has manned the life-boats. On one occasion, of a crew of eighteen, twelve were over fifty years of age and two of the twelve were men of seventy-two.

Relations with the Government.—In 1893 a representative of the Institution moved a resolution in the House of Commons that, in order to decrease the serious loss of life from shipwreck on the coast, the British Government should provide either telephonic or telegraphic communication between all the coast-guard stations and signal stations on the coast of Great Britain; and that where there are no coast-guard stations the post offices nearest to the life-boat stations should be electrically connected, the object being to give the earliest possible information to the life-boat authorities at all times, by day and night, when the life-boats are required for service; and further, that a Royal Commission should be appointed to consider the desirability of electrically connecting the rock lighthouses, lightships, etc., with the shore. The resolution was agreed to without a division, and though its intention has never been entirely carried out, the development of wireless should, in due course, provide a simple and efficient means by which, eventually, all lighthouses and lightships will be connected with the shore.

Finance.—When the Institution was founded, it was laid down as one of its chief objects to reward those who rescued life from shipwreck, and give relief to the widows and families of those who lost their lives in attempting to save others. In carrying out these objects the Institution has long since worked on a carefully prepared scheme of rewards and pensions. In 1898 a pension and gratuity scheme was introduced by the committee of management, under which life-boat coxswains, bowmen and signalmen of long and meritorious service, retiring on account of old age, accident, ill-health or abolition of office, receive special allowances as a reward for their good services. This was followed in 1917 by a pension scheme for the widows and dependent children of life-boatmen who lose their lives as a result of rescuing or attempting to rescue life from shipwreck. For many years before that date it had been the practice of the Institution to pay a gratuity of at least £100 to the widow, and £25 for each dependent child. The financial obligation assumed by the Institution towards those who risk their own lives in attempting to rescue life from shipwreck may be summarised as follows:—It gives retaining fees to coxswains, second coxswains, etc., and wages to motor mechanics; it gives rewards for every rescue or attempted rescue from shipwreck round the coasts of Great Britain and Ireland by whomsoever performed; it compensates life-boatmen injured on service. It pays pensions or gratuities to coxswains, bowmen and signalmen of long and meritorious service; it pensions the widows and dependent children of life-boatmen who lose their lives on service.

The 40 years after the duke of Northumberland reorganized the Institution were years of many experiments and immense developments. In 1851 there were only 30 life-boats on the coast, and the Institution's income was under £800. In 1890 there were 300 life-boats, and the ordinary income of the Institution was over £42,000. Unfortunately, developments outstripped the increase in income, great as this had been, and in the year, 1891, the total expenditure was over £75,000, nearly double the income. Once again the life-boat service was in the greatest need of increasing public interest in its work, and it found the means in the Life-boat Saturday Fund, which was founded by Sir Charles W. Macara, Bt., in 1891. This fund was started as a result of the public interest aroused by the disaster, already mentioned, to the two life-boats on the Lancashire coast in 1886. It remained in existence until 1910, when its work and organization were taken over by the Institution, and during those 19 years it raised nearly £300,000.

The use of mechanical power wherever possible, while it has greatly increased the efficiency of the service, has necessarily increased its cost. At the end of the 19th century a thousand pounds was sufficient not only to build but to endow a life-boat, so that, out of that sum, it could be replaced in perpetuity. To-day a motor life-boat costs, to build alone, from £4,500 to £14,000, while the boat house and launching slipway cost, on an average, as much as the boat. At the beginning of the century the Institution required annually, to provide and maintain the service,

£100,000. It now requires £250,000. In order to obtain this much larger sum it has greatly extended its methods of appeal. In 1921 the Ladies' Life-boat Guild was formed, to unite in one body the many hundreds of women who were working for the Institution. In addition to over 200 life-boat stations, the Institution has over a thousand financial branches and guilds, with thousands of voluntary workers attached to them. It is one of the remarkable features of the Institution's work that, in spite of the great changes and developments which have been made in the course of over a century, it is still maintained by voluntary means.

National and International Aspects.—It is still more remarkable that even those who believe in nationalization would not nationalize the life-boat service, and one of the best tributes to its success as a voluntary organization was paid by a leading exponent of socialist theory, Mr. Sidney Webb, when he was president of the Board of Trade. He said that "one of the Institution's glories is that it is entirely voluntary," and to that he added an interesting analysis of the reasons why the Institution has succeeded as a voluntary body. "One of the advantages of voluntary organization is that it can initiate and experiment, which is very difficult for a Government department."

The British life-boat service has been the acknowledged model of the other life-boat services of the world, and of the fourteen other countries which have national services, Holland, Belgium, the United States, Germany, Denmark, Norway, Sweden, France, Russia, Spain, Japan, Portugal, Latvia and Iceland, only four are maintained by the State, those in the United States, Belgium, Denmark and Russia. Four of the remaining nine—those in Germany, Norway, Sweden and Spain—were originally State-services, but they have since been handed over to voluntary organizations, or such organizations have been set up to supplement the State-service.

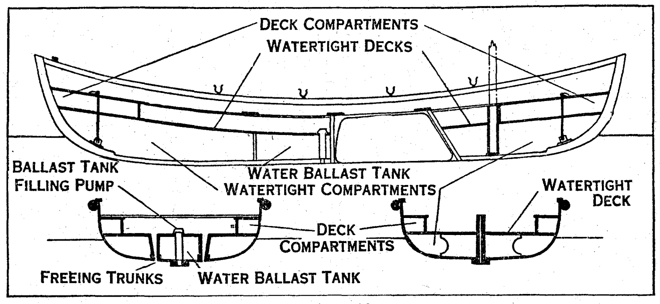
In 1924, by which year it had given rewards for the rescue of nearly 60,000 lives, the Institution celebrated its centenary, and those celebrations showed what a secure place it holds in the pride and affection of the British people. The King personally decorated with the Medal of the Order of the British Empire the eight men still living out of the eighty-seven who during the century had won the Institution's Gold Medal, the Victoria Cross of the Life-boat Service. On its hundredth birthday, March 4, the Institution held a centenary meeting at the Mansion House. Shortly afterwards an international conference was held in London, attended by delegates from eight foreign countries, while five of them sent life-boats, so that, for the first time, an international life-boat fleet lay on the Thames. At this conference it was unanimously decided that an international life-boat organization, on the lines of the Red Cross Society, ought to be formed, and that it was desirable to have some organization for saving life from shipwreck in all the maritime countries of the world. This resolution was brought to the notice of the governments of all maritime countries and of the League of Nations. It was discussed at a meeting of the League's sub-committee on Ports and Maritime Navigation in the following year, at which the Institution was represented by its secretary, and the sub-committee decided that it could best encourage the promotion of life-boat services by asking governments to induce their national life-boat organizations to keep in constant touch with one another. For this purpose the sub-committee placed its own secretariat at their disposal. Thus, a little more than a century after Sir William Hillary launched his appeal for a national life-boat service, the international value of such services, and the duty of all maritime countries to provide them for the succour of the seafarers of their own and other nations, were fully and formally recognized.

For the use of rockets in life saving, *see* ROCKET AND ROCKET APPARATUS. (G. F. SH.)

THE UNITED STATES

Life-saving work upon the coast of the United States is a function of the United States Coast Guard, the former Life-Saving Service having been merged with the Revenue Cutter Service in 1915, the combined service taking the name of the Coast Guard (*q.v.*).

Extent of Operations.—In the extent of coast-line covered, the magnitude of operations, and the extraordinary success which has crowned its efforts, the life-saving work of the United States Coast Guard is not surpassed by any other institution of its kind in the world. Notwithstanding the exposed and dangerous nature of the coasts stretching between the approaches to the principal seaports, and the immense amount of shipping concentrating upon



BY COURTESY OF THE UNITED STATES COAST GUARD

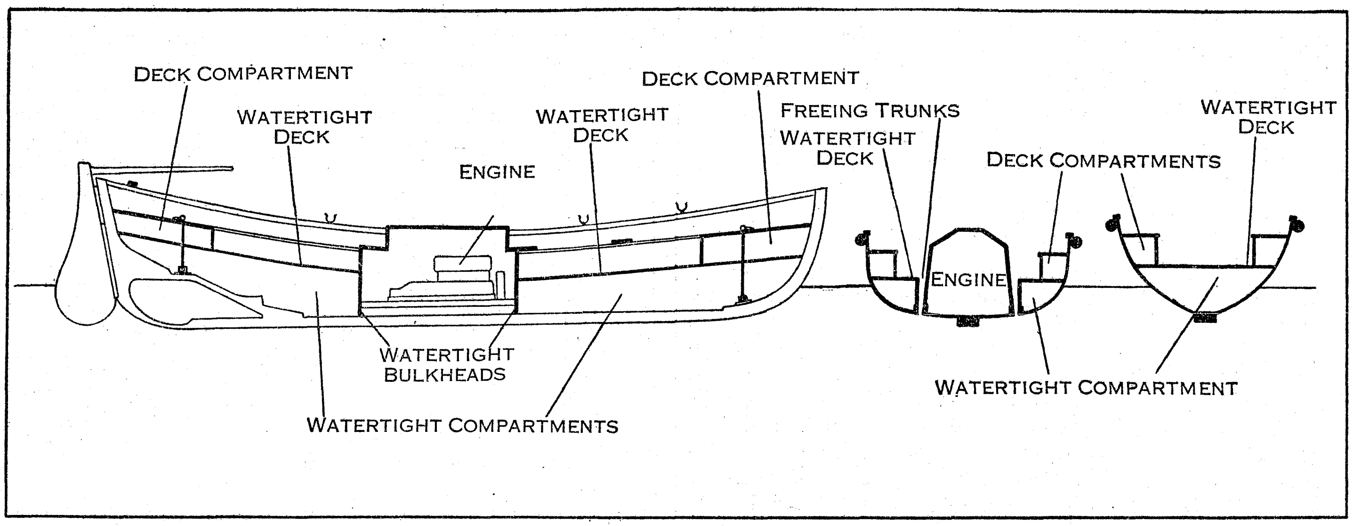
FIG. 3.—PROFILE AND TWO SECTIONS OF 25-FT. 6-IN. SELF-BAILING SURF BOAT (MODEL H)

them, the loss of life of persons imperilled by marine casualty within the scope of operations of the service is less than 1%, and even this small total is made up largely of persons washed overboard immediately upon the striking of vessels and before any assistance from shore could possibly reach them, or lost in attempts to land in their own boats, and persons thrown into the sea by the capsizing of small craft.

In the service, next in importance to the saving of life is the saving of property from marine loss.

The Massachusetts Humane Society, as early as 1789, began the erection of rude huts along the coast of Massachusetts for the shelter of any destitute persons who might escape death in the sea. At first no attempt was made to provide means of rescue, but in 1807 a station, equipped with a boat for use by volunteer crews, was erected at Cohasset, Mass., and additional stations were placed at exposed points along the coast from time to time. The Federal Government, soon after its organization at the close of the Revolutionary War, commenced the erection of lighthouses, which were placed under the charge of the Treasury department; but it was not until 1838 that it was suggested, by two officers of the navy who had been assigned to make a general inspection of the lighthouse system, that life-boats be added to the equipment of seven of the lighthouses, and it is not recorded that this suggestion bore any immediate fruits. However, on March 3, 1847, Congress appropriated the sum of $5,000 "for furnishing the lighthouses on the Atlantic coast with means of rendering assistance to shipwrecked mariners." No steps having been taken to expend this sum, the Massachusetts Humane Society in the following year made application to the secretary of the Treasury and was granted the use thereof. The society at that time represented that it was maintaining "16 or more life-boats on the coast at the most exposed places, also a number of houses on exposed beaches." During the period from 1849 to 1870 this society secured additional appropriations aggregating $40,000 from Congress for the prosecution of its work.

First Government Efforts.—The first Government life-saving stations were plain boat-houses, a few of which were erected along the coast of New Jersey in 1848, each equipped with a fisherman's surf-boat, a mortar for firing a line across a stranded vessel, a life-car or enclosed metallic boat to be hauled between the shore and a wreck, and a few simple accessories. In 1849 the service was extended to the coast of Long Island, and in 1850 one station was placed on the Rhode Island coast, thus protecting the coasts converging on the principal American seaport, New York city. No provision was made for crews or even for responsible caretakers, and as a result the buildings and equipment rapidly deteriorated from the ravages of the elements, and much of the equipment was stolen or destroyed. In 1854 provision was made for the appointment of paid keepers for the New Jersey and Long Island stations, and a superintendent for each of these coasts, marking the begin-



BY COURTESY OF THE UNITED STATES COAST GUARD

FIG. 4.—PROFILE AND TWO SECTIONS OF 26 FT. MOTOR SELF-BAILING SURF BOAT (MODEL H)

ning of an organized, effective governmental life-saving service. Volunteer crews were depended upon until 1870, when Congress authorized crews at each alternate station for the three winter months.

The present extensive and thoroughly organized system was inaugurated in 1871 by Sumner I. Kimball who in that year was appointed chief of the Revenue Cutter Service which, some years earlier, had been given charge of the embryo system. He secured from Congress an appropriation of $200,000, and authority for the employment of crews for all stations for such periods during the year as were deemed necessary. The existing stations were thoroughly overhauled and put in condition for the housing of crews; the best available boats and equipment were provided; inefficient station keepers, who had secured appointment through political influence, were succeeded by men carefully selected for their skill and experience; additional stations were established, and all were manned by capable surfmen; the merit system of appointments and promotions was inaugurated, and effective regulations for the government of the service and training of the crews were adopted and enforced. A beach patrol maintained throughout the hours of darkness and in thick and stormy weather in the daytime, for the warning of vessels standing into danger and the prompt discovery of such as were cast ashore, was instituted. The result of this transformation was immediate and striking. At the end of the year not a life had been lost within the domain of the service; and during the next year but one life was lost although the service now embraced the dangerous coast of Cape Cod.

Establishment of Regular Service.—The service continued to grow rapidly in extent and importance until, in 1878, Congress established the Life-Saving Service as a distinct and independent organization, operating under the Treasury department. The Life-Saving Service became the United States Coast Guard in 1915.

Organization.—The Coast Guard in 1939 embraced 13 districts, with shore stations of which 197 were active, situated at selected points upon the sea and lake coasts. Five districts on the Atlantic and Gulf coasts contained 128 stations, including three houses of refuge on the coast of Florida, each in charge of a keeper only, without crews; two districts on the Great Lakes contained 52 stations, including one at the falls of the Ohio river at Louisville, Ky.; and three districts on the Pacific coast contained 23 stations, including one within the Arctic circle at Nome, Alaska.

Each Coast Guard district is in charge of a district commander, who is a commissioned officer. The district commander has immediate supervision over the operation of the stations, the selection and enlistment of the crews and their assignment, the enforcement of discipline, the procurement of supplies and equipment, and the payment of compensation. He is held responsible for the efficiency of the stations in his district.

The maintenance of the property, buildings, wharves, launchways, sea walls, etc., is in the hands of a civil engineer attached to headquarters in Washington, with a number of assistants in immediate personal charge of extensive sections of the coast. The general administration of the service is conducted by the commandant of the Coast Guard with headquarters at Washington.

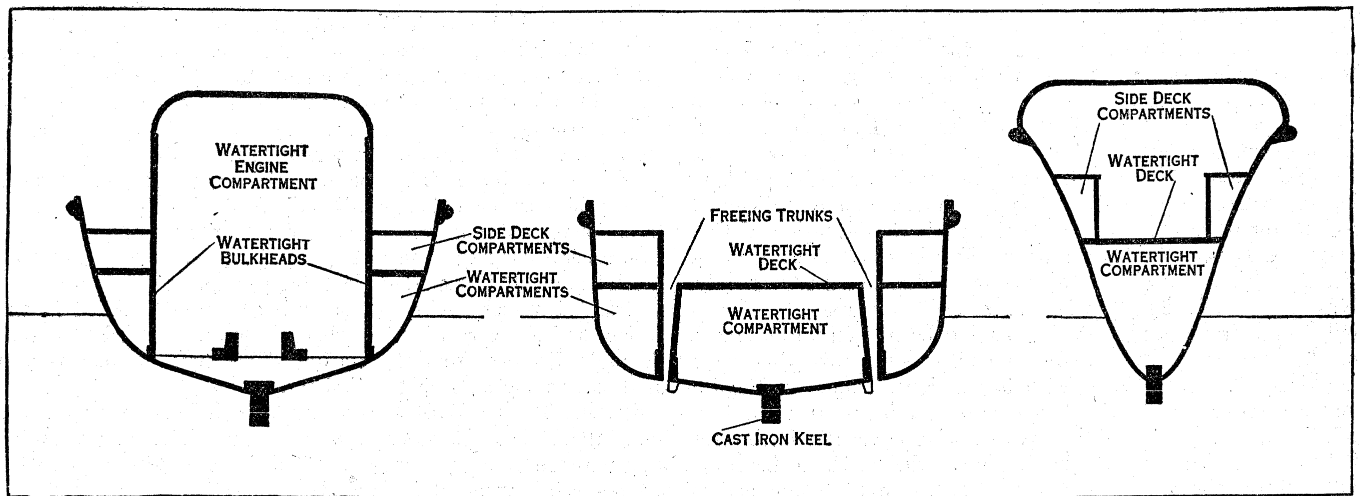
FIG. 5.—PROFILE OF 36 FT. SELF-BAILING AND SELF-RIGHTING MOTOR LIFE-BOAT



BY COURTESY OF THE UNITED STATES COAST GUARD

FIG. 6.—THREE SECTIONS OF A 36 FT. SELF-BAILING, SELF-RIGHTING MOTOR LIFE-BOAT

Station crews are composed of an officer in charge holding the rank of a boatswain, and, at a majority of the stations, from six to eight surfmen, with a larger number, up to as many as fifteen, at certain stations where the service is particularly arduous. The number of men in each crew is determined principally by the number and kind of boats, the extent and nature of the coast-line to be served, the climatic conditions at various seasons, and the amount of shipping in the locality. Nearly all stations are now equipped with motor-powered boats. One or more of the members of the crew are trained in the care, operation and repair of these engines, those so qualified being rated motor machinists.

For this purpose there is maintained, at the ship repair and boat building yard of the service, at Baltimore, Md., a school for the special instruction of men who show an aptitude for this work. The surfmen are enlisted for periods of from one to three years, after a thorough medical examination. All stations on the ocean coasts are in commission and fully manned throughout the year. The floating station at Louisville, and a number of stations on the Great Lakes situated at harbours where shipping is in operation during the winter months, are in continuous commission.

Stations.—The stations contain, as a rule, suitable living quarters for the officer in charge and members of the crew, and a boat and apparatus room. Many of the stations, particularly on the Lakes, have living quarters for the family of the officer in charge. Each station has a look-out tower for the day watch, on the station building proper, or separately placed at a point of vantage. In some places the dwelling and boat-house are built separately, and a number of stations also have additional boat-houses situated at danger points distant from the main station. Those equipped with the larger life-boats have launchways or marine railways for the launching of the boats directly into deep water, with power winches and cradles for launching and hauling out. The Louisville station guards the falls of the Ohio river, where life is much endangered from accidents to vessels passing over the falls, and to small craft which are liable to be drawn into the chutes. It consists of a dwelling with look-out tower, apparatus room, and ways for small boats, the whole mounted on a scow-shaped hull. Its equipment includes several river skiffs which can be quickly launched directly from the ways at one end of the station. These skiffs are modelled much like surf-boats, designed to be rowed by one or two men.

Equipment.—The equipment of the stations consists of the beach apparatus—line-throwing guns, hawsers, breeches-buoys and life-car—flag and pyrotechnic signals, heaving sticks and lines, life-preservers and life-boats, surf-boats and other special types of boats. The outfits are practically the same at all stations, but the boats are of various types, depending upon their suitability for rescue work on the different coasts. The larger life-boats are too heavy to be launched from the beach into the surf, and launching ways are provided for them where comparatively smooth water prevails—on rivers, bays and inlets. The surf-boats are mounted on boat-wagons by which they are drawn to a point abreast of a wreck and launched directly from the beach.

Beach Patrol.—The system of beach patrols maintained at all stations is of distinctly American origin, and has proved of great value in the saving of life and property. A fixed beat or patrol is laid out in each direction along the shore, varying according to the conformation of the coast with respect to inlets, headlands, etc., from one-half to two, three or four miles in length. The station crew is divided into regular watches of two men each, who during the hours from sunset to sunrise, and during thick and foggy weather in the daytime, patrol these beats, keeping a sharp look-out seaward. The usual schedule is: first watch, sunset to 8 P.M.; second watch, 8 P.M. to midnight; third watch, midnight to 4 A.M.; fourth watch, 4 A.M. to sunrise.

Positive evidence of the integrity of the patrol and watch is required. Where stations are sufficiently close to one another to permit the entire intervening distance to be patrolled, a half-way point is established, at which point each patrol-man must deposit a brass check bearing the name of his station and his number in the crew. This is taken up on the next visit by the patrol-man from the adjacent station, who in turn leaves his check. The first patrol-man at night returns all checks of the previous night. Where the patrols do not connect the patrol-man carries a watchman's clock or time detector, in which there is a dial that can be marked only by means of a key which registers the exact time of marking. This key is secured in a safe embedded in a post at the limit of the patrol, and the patrol-man must reach that point in order to obtain the key with which to register his arrival.

In some cases telephones are placed in half-way houses or at the end of patrols, by means of which the patrol-man reports to his station. In other cases the patrol-man is provided with a small portable telephone set with which he can communicate with the station from any point along his patrol. The Coast Guard owns and operates a telephone line system consisting of 183 separate lines, with a total mileage of approximately 2,650, including 500 m. of submarine cable. Practically all of its shore stations, 160 lighthouses, and a number of other Government agencies such as naval radio compass stations, weather bureau stations, etc., are served by these lines, which are connected with commercial exchanges for both local and long distance service.

Assistance and Rescue.—On discovering a vessel standing into danger the patrol-man burns a pyrotechnic signal which emits a brilliant red flare, to warn the vessel of her danger. The number of vessels thus warned averages over 200 annually. The extent of the loss of life and property thus averted can never be known. When a stranded vessel is discovered, the patrol-man's Coston signal apprises the crew that they are discovered and assistance is at hand. He then notifies his station, either by telephone or by an electric hand flash using the telegraphic code. When such notice is received at the station, the officer in charge determines the means by which to attempt a rescue, whether by boat or beach apparatus. If the beach apparatus is chosen, the apparatus cart is hauled to a point directly opposite the wreck by motor tractor or truck, by horses, or by the members of the crew. The breeches-buoy gear is unloaded and while it is being set up the officer in charge fires a line over the wreck with the Lyle gun, a small bronze cannon weighing, with its 18 lb. elongated iron projectile to which the line is attached, slightly more than 200 lb., and having an extreme range of about 700 yd., though seldom available at wrecks for more than 400 yd. This gun is the invention of Col. David A. Lyle, retired, U.S. army. Shotlines are of three sizes, $\frac{4}{32}$, $\frac{7}{32}$, and $\frac{9}{32}$ of an inch in diameter, designated respectively, Nos. 4, 7 and 9. The two larger are ordinarily used, the No. 4 only for extreme range. A line having been fired within reach of the persons on the wreck, an endless rope rove through a tail-block is sent out by it with instructions, printed in English and French on a tallyboard, to make the tail fast to a mast or other elevated portion of the wreck. This done, a 3 in. hawser is bent on to the whip and hauled off to the wreck, to be made fast a little above the tail-block, after which the shore end is hauled taut over a crotch by means of tackle attached to a sand anchor.

From this hawser the breeches-buoy or life-car is suspended and drawn between the ship and shore by means of the endless whip-line. The life-car can also be drawn like a boat between ship and shore without the use of a hawser. If any of the rescued persons are frozen, as often happens, or injured, first aid and simple remedies are furnished. Dry clothing, supplied by the Women's Nat. Relief Assn., is also furnished to survivors.

Boat Equipment.—All stations are equipped with boats adapted to the special requirements of the different localities and occasions. The three principal types of life-boats used in rescue work are a self-righting and self-bailing motor life-boat, a self-bailing motor surf-boat and self-bailing pulling boat.

The motor life-boat is 36 ft. in length with an overall beam of 9 ft. $5\frac{1}{4}$ in., and an approximate draft of 2 ft. 8 inches. Its weight with full equipment, not including fuel and crew, is about 14,300 pounds. It is constructed of wood with $1\frac{1}{8}$ in. planking. It is fitted with numerous water-tight compartments and has a water-tight deck, end compartments and a house over the engine. A cast iron keel weighing 1,800 lb. extends the full length of the bottom and protects the propeller and rudder from injury. A semi-tunnel for the propeller is provided in order to obtain shallow draft. This boat develops to the highest degree the self-bailing and self-righting qualities so essential to a life-boat. It is equipped with a 44 h.p. gasolene engine, driving a 3-bladed propeller of 22 in. diameter, and 16 in. pitch, and has a speed of about 9 m. p.h. under usual service conditions. Sails and oars are also provided for auxiliary use when needed. This type of boat is used at practically all stations on the Great Lakes, and along the ocean coasts in localities where sheltered inlets are available in which it can be safely launched or moored. It is an extremely able craft and will go through practically any surf and live in any sea.

The power surf-boat has a length of 26 ft., a beam of 7 ft., and is equipped with a 20 h.p. gasolene engine. Like the larger life-boat, this type is also provided with self-bailing features, but is not self-righting. The construction, in general, follows that of the larger boat except that water-tight end compartments and a house over the motor are not fitted. A small water-tight enclosure protects the motor from spray and seas. The boat is rather lightly but strongly constructed, and a semi-tunnel and shoe provide protection for the propeller when the boat is grounding. No sails are fitted, but oars and thwarts for the crew are provided. This type of boat is used generally at stations where it can be launched into the water on a carriage. It is also issued to the larger coast guard vessels for use as a life-boat.

A third type of life-boat which is generally used is the self-bailing pulling surf-boat, 25 ft. 6 in. in length, and weighing about 2,200 lb. This boat has no engine, but is manoeuvred under oars and sails only. The construction is very similar to that of the life-boat and power surf-boat already described, having water-tight compartments and deck above the load water line with freeing trunks, which give it the self-bailing feature. Although not self-righting, it can be readily righted by means of righting lines provided along the sides, which enable the crew easily to roll it right side up, when it quickly clears itself of water through the bailing trunks. It is fitted with a water-ballast tank filled by means of a hand pump, which increases the stability and sailing qualities of the boat. This type of boat is light and handy for use in launching through the surf directly from the beach, and is an exceptionally able boat when used in rescue work in broken waters. It is generally mounted on a specially built boat-wagon on which it can be quickly transported along the beach to a point abreast of a stranded vessel. Sails and centreboard are embodied in the design, and are very effective when the boat is called to a considerable distance from the station. This type of boat is also used extensively as a ship's life-boat.

Special Service Boats.—Another type of boat in general use along the New England coast is an open whaleboat commonly known as the Monomoy surf-boat. This boat is neither self-righting nor self-bailing. It is propelled by oars and sails, and is a very seaworthy craft. A number of stations are supplied with fast motorboats especially designed for law enforcement duties, as distinguished from those here described, of heavier construction and less speed, provided for rescue work under adverse conditions of weather and sea in which the paramount consideration is seaworthiness and reliability of operation. Others, situated in sheltered harbours, where the principal source of danger is from accidents to pleasure craft, are provided with light skiffs or with small motorboats designed more particularly for speed.

LIFE GUARDS: *see* GUARDS AND HOUSEHOLD TROOPS.

LIFE INSURANCE, a contract insuring the payment of money on the happening of any contingency, or one of a variety of contingencies, dependent on human life; as this definition would, however, include contracts for annuities or pure endowments, it should be limited by the condition that one of the contingencies should be death (except death by accident only). The sum insured is agreed upon at the outset and may be added to from time to time, out of profits or otherwise; life insurance therefore differs in character from other forms of insurance, the essence of which is indemnity to the insured for actual loss incurred.

The word assurance is more commonly used than insurance in connection with life contracts, the latter word being applied in general to contracts of indemnity; it is not, however, incorrect to use either word in any context.

Primitive Form of Life Insurance.—The principle that groups of persons should agree to make common cause against dangers which threaten all, but are individual in operation, is an old one. Action of this nature was moreover, in its origin, dictated by the interest of the group rather than by the interests of its members. As communications became more widely organized, the character of the group granting the benefit naturally tended to become that of a class or trade union, but until what are historically known as modern times, insuring associations were associations of persons, not of capital, and insurance of members would only have been one of their reasons for existence. Modern life insurance, mainly by companies, is concerned only with the risk to be insured against, and even institutions which were, in their origin, distinguished by some bond of class or calling among their members, are usually open to do business with all comers, and retain but a shadow of their earlier exclusiveness.

The beginnings of true life insurance, that is to say, the payment of certain benefits on death, against certain periodical subscriptions, are to be found in the Roman Collegia. The gilds of mediaeval times would, in many cases, make provision for the decent burial of a member, but the extent of such assistance would depend on the actual needs of the dead man's dependants and was not, therefore, life insurance in the full sense.

Marine insurance is generally believed to have an earlier origin than life insurance and it is therefore natural that the first definite contracts of life insurance, made with underwriters as a matter of business, should have been on the lives of mariners. The earliest contract of this type, recorded to have been made in England, was effected in 1583.

The First Companies.—An important step was the foundation in England of the first insurance companies. The Amicable Society for a Perpetual Assurance was founded in 1705, but provided merely for the dividing up of certain sums between the representatives of those members who died each year. The Royal Exchange Assurance Corporation and the London Assurance Corporation, both incorporated by royal charter in 1720, were, however, true life insurance institutions, and, with the Amicable, held the field for 40 years. During this period they effected only a moderate amount of life insurance business; also the contracts were still of the simplest nature, being as a rule for a term of one year.

The period of scientific insurance began with the foundation of the Equitable society in 1762. Until that date there had been no endeavour to graduate premium rates according to the age of the person insured, despite the obvious fact that such differentiation was called for. The material for calculating rates was, however, in existence, although it was imperfect: Dr. Edmund Halley's tables, based on the deaths in the city of Breslau in the years 1687–91, and the death rates derived from the London bills of mortality of the period, were the foundation of the society's first table of premiums. It is moreover notable that in addition to differentiating rates, the society introduced the principle of making a policy renewable from year to year throughout life. The success of the new venture was soon apparent: in 1776 it made its first actuarial valuation of assets and liabilities and returned part of the premiums paid to the insured by way of bonus; this was the beginning of the with-profit system, which might have been much longer in making its appearance, had it not been for the fact that the rates charged by the Equitable were decidedly on the safe side, although in most cases substantially less than the £5 to £6 per £100 for a year's insurance which had been the general rule until 1762.

The Gambling Act.—The Life Assurance Act of 1774, usually referred to as the Gambling Act, is a highly important landmark in the history of life insurance. Speculation in the lives of other persons, particularly public men, had become something of a scandal.

The Act forbade the issue of policies in which the names of the persons interested did not appear and also prohibited the insuring of lives in which the insured had no interest; the path was thus cleared for the development of life insurance for provident purposes only—its principal function.

The Equitable had the field to itself until towards the end of the century when the Westminster society was founded. This society instituted the principle of paying commission to agents for the introduction of business.

Many offices came into existence in the first half of the 19th century—a natural concomitant of the growth of the joint stock enterprise which marked that period: incidentally the Joint Stock Companies' Registration Act of 1844 brought in a number of recruits, but many of these were mushroom concerns and most of the leading offices had commenced business before that date.

Events Leading to Act of 1870.—There was little restraint or check on the earlier operations of the companies (the Act of 1774 was a check on the insured, not the insurer) and it is therefore not a matter of surprise that concurrently with many carefully-managed institutions, there should have grown up others whose existence was undesirable. The description given by Dickens in *Martin Chuzzlewit* of the business methods of the Anglo-Bengalee Disinterested Loan and Life Assurance Company suggests what may have been the state of affairs with certain offices; but it was not wholly a caricature. Matters were brought to a head by the disclosure of the difficulties of two companies, the Albert and the European. Both these offices had been active in absorbing lesser concerns, and, in their greed for large figures, had in many cases paid unjustifiable prices to the shareholders of the companies absorbed, without regard to the interests of the original policy-holders or those to whom they subsequently became responsible. The Albert closed its doors in 1869, and although the European did not do so for another three years, its position was a factor in hastening much needed legislation. The provisions of the Life Assurance Companies' Act of 1870 are essentially those which have governed the business in Great Britain ever since. Like most acts of parliament, it has been subject to amendment as the result of experience and it will probably be further amended in certain important respects by the bill of 1927.

The Scottish Widows Fund Life Assurance Society, established in 1815, was the first life insurance office founded in Scotland, where the business has, in proportion to the population, acquired even greater importance than it has in England.

Development Outside the United Kingdom.—Life insurance on the Continent, and in America, developed later than in Great Britain. The first successful venture in France was made in 1819, when the *Compagnie d'Assurances Générales sur la Vie* was founded. In Germany, branches of English offices were operating before the end of the 18th century, but the first German company was not founded until 1828. As for the rest of the Continent, just as the English companies had extended branches into Germany, Holland and Scandinavia, so the French companies pushed theirs into Italy, Spain, Belgium and Switzerland, and the existence of these branches gave an impetus to the formation of companies of national origin.

In addition to being served by English and Scottish offices, most of the British dominions and colonies have developed life insurance institutions of their own and the dominion offices have also carried their operations with vigour into the mother country.

The Contract and the Policy.—The first step in the taking out of a life insurance policy is the submission to the insuring company of a written statement called a proposal, setting out particulars as to the proposer's age, health, past illnesses and family history. The proposer warrants the correctness of his statements and the contract is voidable by the insurer should any of them prove untrue. In practice it is unusual for an office to make use of this power unless there has been a deliberate intention to defraud. If there is a medical examination, the truth of the statements made to the doctor is also warranted. In legal terms, an insurance contract is *uberrimae fidei,* that is to say based on the utmost good faith between the parties, and the proposer is bound to disclose all circumstances material to the risk, not excluding any in regard to which he may not be specifically questioned. The necessity for this arises from the fact that many matters essential to the contract can be only within the private knowledge of the person desiring to be insured.

Insurable Interest.—Another condition precedent to the granting of a policy is that the person effecting it should have an interest in the life to be insured, known as an insurable interest. This arises mainly from the provisions of the Act of 1774. Every adult person has, of course, an unlimited insurable interest in his or her own life. A wife has an unlimited insurable interest in the life of her husband, and it was decided in 1909 (*Griffiths* v. *Fleming*) that a husband has a similar interest in the life of his wife. Except in the cases named the interest must be pecuniary, *e.g.,* the interest which a creditor has in the life of his debtor for the amount of the debt.

The proposal, the warranted statements to the doctor, and the policy, constitute the entire contract between insurer and insured.

Modern British policies are simple in form, the essential facts and figures being incorporated in a schedule. Of the many restraints formerly in vogue, the only one in common use is the restraint on suicide during the first 12 months of the policy.

Surrender Values, etc.—Under whole life and endowment assurance contracts, where the annual premium is more than sufficient in the early years to cover the yearly risk, the office will return, after, on the average, two years' cash payments, a sum known as the surrender value. As current risk and expenses have to be allowed for, this is for policies of short duration considerably less than the total of the premiums paid. An alternative is to obtain a policy for a reduced amount, free from further premiums; this is known as a paid-up policy. Offices are as a rule prepared to lend back to the insured a proportion of the surrender value, 90% to 95%; the maximum amount which can be thus lent is the loan value. Under the laws of the State of New York, insurance companies are bound to state in their policies the surrender value for each of the first 20 years, and this is also done voluntarily by many British companies.

What are known as non-forfeiture regulations provide for the continuance in full force, for a period, without payment of premiums, of policies carrying surrender values under which a certain number of years' premiums have been paid. The period may be for a year or it may be for a number of years until the surrender value is exhausted; a provision of the former type is common in Great Britain, while the last mentioned plan is usual in America.

Proof of age, usually by the production of a birth certificate, is required, and this is best done at the outset, though it may be left until the policy becomes a claim.

Extra Risk.—In between those risks which an office can accept at its tabular rate of premium and those which are unacceptable lie a large body of risks which can be accepted on special terms. In Great Britain these are usually dealt with: (1) by an addition to the premium, (2) by the deduction, for a period of years, of a level or diminishing sum from the amount insured—described as a debt. The assessment of these risks is a matter of great difficulty, but special researches into the question of over and under weight, cancer, phthisis, circulatory disease, etc., are by degrees making the treatment of the problem less empirical. In America the question is usually decided by a system of numerical rating, positive and negative marks being given for different qualities and defects, while in certain Continental countries under-average lives are sometimes dealt with by reinsurance companies or pools, created *ad hoc.*

Extra risk due to the surroundings or occupation of the insured, as distinct from his individual peculiarities, is of a different nature. Extra premiums are charged for certain tropical countries, removable as a rule on return to a healthy climate, and in any case after a period of years; these are known as climate extras, but the portion of the world to which they apply is an ever contracting one. The additional risk for the army and navy can usually be covered by a moderate extra, 5s to 10s per £100 per annum, payable in peace time: no further extra is then demanded on the outbreak of war. The extra to be charged for the Air Force is still in process of evolution. Other occupations regarded as extra-hazardous are the liquor trade, and to a less extent, seafaring. Formerly it was usual to charge an extra to women under 40.

A person who has no definite prospect of going abroad or engaging in a hazardous occupation is given a policy which is termed world-wide and indisputable, and no climatic or occupation extra can thereafter be charged under such a policy, no matter where the insured goes or what he does.

Different Types of Insurance.—Life insurance policies may be for a definite sum throughout, or they may share in the profits of the company, such profits being allotted in the form of cash, additions to the sum insured, or reductions of the premiums. In the following brief descriptions of the principal types of policy the word assurance is employed as being that in common use.

Whole Life Assurance.—If the term is used without qualification, the sum insured is payable at death, and the premiums throughout life.

Whole Life Assurance by Limited Payments.—The sum insured is payable at death, and premiums cease at death or at the end of an agreed period.

Endowment Assurance.—The sum insured is payable at death or at the end of a fixed period, when premiums cease.

Double Endowment Assurance.—As above, except that the sum payable on survival of the agreed period is double that payable on death.

Joint Life Assurance.—The sum insured is payable when the first death arises out of a group of two or more persons. Effected by partners in a business to provide a fund on the death of either of them.

Term Assurance.—The sum insured is payable only if death arises within a period agreed upon. School fees policies are term assurances for sums payable annually until the expiry of a certain period, corresponding to that of a child's education.

Options.—A term assurance premium may be increased so as to allow the insured to continue the policy at the end of a certain period as a whole life or endowment assurance at normal rates, whatever may then be his or her state of health.

Deferred Assurance.—Children's lives may not be insured except for small sums under industrial policies. A deferred assurance policy may, however, be effected under which premiums are returnable in the event of the child's death before age 21, and which the child can continue after 21 as a whole life or endowment assurance, irrespective of health.

Group Assurance.—Insurance for a certain sum on the life of each member of a group of employees, usually term assurance renewable yearly, the sum insured often being one year's wages.

Certain special benefits are sometimes offered concurrently with life insurance. Disability benefit involves the suspension of premium payments during permanent disability, and in its most developed form, the payment in addition of a monthly sum to the insured, usually 1% of the sum insured, without prejudice to the ultimate payment of the sum insured in full. Free medical overhaul at intervals and financial assistance towards surgical treatment are further examples of special benefits offered by certain offices.

Pure endowments, payable on survival over a certain period, are not strictly life insurance, but the granting of these forms part of a life insurance company's business.

Institutions Granting Life Insurance.—*Mutual life insurance institutions* are without shareholders and all profits go to the participating policy-holders.

Proprietary life insurance institutions are nominally controlled by shareholders, who, however, only receive as a rule about 5% to 10% of the profits, the remainder going to the participating policy-holders.

Composite offices are those which transact more than one kind of insurance; they are, as a rule, proprietary.

Mortality Tables.—As this subject is dealt with under the heading DEATH-RATE, the following remarks will be confined to a brief description of the principal tables used in connection with life insurance.

Breslau Table.—Used by the Equitable society for its first premium tables.

Northampton Table.—Based on deaths in Northampton, 1735–80. Constructed on unsound basis, but erring on the safe side when issued in connection with insurance contracts. The standard table till 1815.

Carlisle Table.—Based on census and death records in two parishes of Carlisle, 1779–87. The standard table till 1872, and used after that for valuing reversions, etc.

Seventeen Offices Table.—Constructed in 1838 from the experience of insured lives, but used more in America than Great Britain.

H^m. (Healthy Males) Table.—Based on experience of insured lives till 1863. The standard British table for 30 years from 1872.

O^m. (Office Males) Table.—Based on experience of insured lives 1863–93. The standard table from 1903 onwards.

American Experience Table.—Published in 1867. Adopted as standard in several States of the U.S.A.

Thirty American Offices Table.—Based on the experience of 30 American offices and published in 1881.

American Medico-actuarial Mortality Investigation.—An investigation into the mortality of special groups, based on the experience of American and Canadian life insurance companies. Deviations due to climate, race, height and weight, and various diseases and occupations, were analysed and published in 1903 and 1912.

Among the best known Continental tables are the A.F. (France) and the Gotha (German).

Sundry tables relating to the experience of residents in the tropics, both native and European, have been compiled.

The construction of a mortality table from the crude data is a complex process, but the tabulation of particulars taken from office records is greatly facilitated by mechanical devices as the Powers and Hollerith calculating, sorting, and tabulating machines. Graduation, that is to say the removal or smoothing down of irregularities not inherent in the data, is the next step, and the tables in use by actuaries are eventually compiled by associating the graduated rates of mortality with various rates of interest to form what are technically known as commutation functions, the shaped bricks of the actuary's stock-in-trade, the combination of which in various ways enables him to compute his rates and value his risks. Select tables, as distinct from aggregate tables, are those in which the duration of the policy as well as the age of the insured is taken into account, effect being thus given to the light mortality resulting in the earlier years of insurance from the elimination of unfit lives.

New life insurance tables are in course of preparation which will unquestionably render the O^m. table obsolete.

Life Insurance Legislation.—The following are the principal British Acts relating to life insurance:—

The *Life Assurance Act, 1774,* which stopped gambling insurance.

The *Life Assurance Companies Act, 1870,* which was amended by the *Assurance Companies Act, 1909,* is to be further amended by the *Insurance Undertakings Bill, 1927* (drafted by Departmental Committee, but not yet [1928] introduced to Parliament). The essential provisions of the Act of 1909 are (1) deposit of £20,000 with the High Court, (2) annual balance sheets and revenue accounts in form prescribed, (3) valuation returns in form prescribed at least once in five years, (4) separate funds for life business, fire business, etc. The most noteworthy additions of the 1927 bill are (1) separation of assets of different classes of business as well as separation of funds, (2) more detail and greater uniformity in returns, (3) powers enabling the Board of Trade to initiate steps for winding up an apparently insolvent company.

The *Policies of Assurance Act, 1867,* regulates the notification of dealings with policies to the insurance company.

The *Married Woman's Property Act, 1882* (*Clause 11*) and the *Married Woman's Policies of Assurance* (*Scotland*) *Act, 1880* confer certain powers on married women enabling policies to be effected for their benefit on their own lives or those of their husbands.

The *Life Assurance Companies* (*Payment into Court*) *Act, 1896* enables life assurance companies to pay money, the ownership of which is doubtful or in dispute, into Court in certain cases.

The principle of British legislation is freedom combined with publicity.

The legislation of most of the British dominions and colonies is modelled on the Act of 1870 and amending acts. An additional provision met with in dominion legislation is the protection of the first £1,000 to £2,000 of life insurance, unless specifically pledged, against a deceased man's creditors. Canada follows the American model. In Australia insurance is regulated by the laws of the different States; in 1928 there was still no Commonwealth legislation, but the Government had announced its intention to remedy this defect. It may be noted that New South Wales had no specific legislation regulating life insurance up to 1927.

Legislation on the Continent of Europe is as a rule more restrictive than that of Great Britain; in general it imposes a basis of valuation and places limits on investments.

Premiums, Reserves and Bonus Distribution.—Although in practice his functions are much wider, the primary business of the actuary of a life insurance company is to calculate premiums, value risks, and deal with the distribution of profits. The basis of an office's tabular premiums is a pure or net premium, "loaded" to provide for expenses, and, in the case of with-profit premiums, for bonus additions also; the margin for contingencies is, from the nature of things, larger for non-profit than for with-profit premiums. The annual premium for a whole life or endowment assurance is, owing to the fact that the risk increases from year to year, larger at first than is required to meet the bare risk (*i.e.,* the policy's contribution to the claims expected in the year) and from this there arises the necessity to set aside and invest the balance; the amount so accumulated is called the reserve. The excess interest earned, and the saving of mortality and expenses (relatively to the assumptions on which the premiums are based), provide the main profits; to these there may be added certain extraneous profits, such as those arising from non-profit business. The different methods of allotting surplus have already been described, and there are various plans for dealing with bonus which is distributed by the reversionary bonus method, that is to say by way of additions to the sum insured. The principal of these are:—(1) The *simple bonus* plan, which provides additions at a given rate for each £100 of original insurance and each year (within the valuation period) of duration; (2) the *compound bonus* plan, providing additions at a given rate to the sum assured and previously declared bonuses; (3) various *contribution* plans, which aim in theory at a return to the insured of the surplus actually contributed. The tendency is for the valuation period to shorten; prior to the Act of 1909 the maximum was seven years, but that Act reduced it to five, and there is a growing inclination towards triennial and yearly distributions. It is obvious that while in non-profit business the rate charged is the main consideration, with-profit rates should be judged in relation to prospective bonus results, and that a high rate for a with-profit premium is not necessarily an uneconomic one.

Finance and Investments.—The investment of the funds of a life insurance office is one of the most important duties of its administration, and it is on the successful accomplishment of this function that its bonus earning power, and, in the long run, its general prosperity, depend. The primary essential is security of the capital, and, subject to this, the earning of the highest rate of interest practicable. Formerly it was held that a life insurance company should keep a small proportion of its assets in readily convertible securities, but under normal conditions this is not really necessary, as the income of a progressive company exceeds its outgo and it is moreover in a position to obtain without difficulty all the credit it is likely to require to enable it to meet an individual emergency or to take advantage of an investment opportunity. In this respect its position differs from that of a bank and also from that of a fire office, which must always be in a position to meet the loss occasioned by a big conflagration, such as the San Francisco fire of 1906. The analogy in the case of life insurance would be an epidemic comparable to the plague, a negligible risk.

Mortgages are highly suitable investments and generally absorb on the average rather more than a quarter of the funds. British government securities also account (1927) for about a quarter of the funds of all companies combined, but this is largely a result of the war and the proportion is diminishing. Home railway debenture and preference stocks are much favoured and sound industrial debentures are also bought to a certain extent. There are, moreover, certain types of security which give little or no immediate yield from interest but are certain to appreciate in value, such as low yielding redeemable stocks standing at a heavy discount, and reversionary interests: these are unsuited to the private investor, but thoroughly adapted to the needs of a life insurance office. As the funds commonly run to many millions of pounds, those responsible for their investment are of course able to effect the saving which arises from being able to underwrite new issues, and to take up large lines of stock on preferential terms. Ordinary stocks and shares are engaging a certain amount of attention but only figure to a modest extent in life office balance sheets.

Amalgamations.—The amalgamation and transfer of British life insurance business is regulated by legislation. The tendency of recent times has been for companies not to absorb other concerns but rather to secure control of them by acquisition of shares and so to avoid the amalgamation procedure necessary under the Act of 1909. A provision of the Insurance Undertakings Bill is that investments in and loans to controlled companies must be shown separately in the balance sheet; the sanction of court must be obtained for any fresh purchases of insurance stock or shares.

Expenses.—The expenses of a life insurance company are usually measured by comparing them with the annual premium income. The percentage thus arrived at is the expense ratio and it is generally in the neighbourhood of 15%. The expense ratio may be unduly lowered when the year's income includes a large proportion of single premiums, or where bonuses are used extensively to reduce premiums; on the other hand, a high expense ratio, where business is large and increasing, does not necessarily indicate extravagance. To avoid misleading comparisons, allowance should therefore be made for these factors.

Life Insurance and Income Tax.—Formerly a distinction was made between the method of taxing a purely life office and that of taxing the life insurance section of a composite office, but in 1915 this was altered, and the basis is the interest earned, less expenses. Should the profits exceed this they become the basis of assessment, but this is rarely the case.

A policy-holder is entitled to a rebate on the premiums paid by him on a life insurance policy. The scale of rebate depends on the date of the policy, *e.g.*, on insurances effected up to June 22, 1916 (inclusive), if the income does not exceed £1,000, half the standard rate; if the income exceeds £1,000 but does not exceed £2,000, three-quarters of the standard rate; if the income exceeds £2,000, the full standard rate. As regards insurance made after June 22, 1916, for all incomes subject to tax, half the standard rate. The proportion of the premium subject to rebate is limited to one-sixth of the income and 7% of the amount guaranteed by the policy to be paid at death.

Life Insurance Outside the United Kingdom.—Although life insurance owed its early development to the efforts of British companies, the extent to which it is practised in the United States and certain of the British dominions is greater than in the country of origin. In 1924, for example, it was estimated that the average amount of insurance per head of the population was £109 in the United States, £84 in Canada, and £44 in Great Britain. Moreover, the aggregate funds of the American offices are from three to four times those of Great Britain. The colossal dimensions of the leading American offices may be gauged from the fact that the Metropolitan Life Insurance Company of New York had (1927) funds of nearly £500,000,000—the largest aggregate of capital in the world.

Life insurance in the Crown colonies is extending and in India insurance on the lives of natives, both by British and Indian companies, is on an increasing scale.

On the Continent of Europe the practice of life insurance is not so widespread as it is amongst the English-speaking peoples. Sums insured per head vary from about £25 to £30 in Holland and Scandinavia to a few pounds in Germany, France, and Italy, where other forms of thrift are favoured. It is, however, probable that the average amount insured would have been considerably larger in all of the last mentioned countries had it not been for the currency depreciation caused by the World War.

Life Insurance and the World War.—A large proportion of the policies actually in force on the lives of civilians who joined His Majesty's forces were indisputable, and British insurance offices decided to make no extra charge even in cases where they were entitled to do so. Extras for new insurances ranged from £7 7s. per £100 at the outbreak of hostilities to as much as £20 per £100 per annum, and many offices declined to undertake the risk.

There were three main sources of war loss. Mortality in excess of the pre-war ratio cost the offices about £3,000,000 a year. Excess depreciation of investments—which was partly the result of increased income tax, and partly due (*e.g.*, Russian bonds) to actual default—accounted for approximately £4,000,000 a year. Increased income tax added £500,000 a year to the loss. These losses rather more than absorbed the normal profits of the period.

The change in the character of life office investments was marked. United States railway bonds, which were largely held before the war, were sold freely, and replaced by war issues, and the holdings of British government securities rose from about 1% to a maximum of 38% of the total funds. The geographical field for securities has of course been greatly narrowed, the United States and Canada being unsuitable on account of the relatively low yield of investments there, while other portions of the world have had to be avoided on account of the insecure conditions prevailing.

Post-War Developments.—Post-war currency depreciation proved disastrous in many Continental countries. In Germany and Austria it eventually became useless to collect premiums and the efforts of the companies were devoted to converting such assets as remained into forms which would not depreciate in proportion to the currency. After the achievement of stabilization, it was, however, possible to do justice to the older policy-holders under various valorization schemes and to start building up reserves again on a sound foundation.

The recovery of the British offices from the effects of the war has been remarkable. All war losses have been dealt with, and as the companies are actually able to invest, after allowing for income tax, at a higher rate than before the war, and mortality becomes steadily lighter, bonuses are on a higher scale than at any time in life insurance history. Expenses have been brought down nearly to the pre-war level. The temporary withdrawal of the American offices from the United Kingdom has resulted in an increase of business to Canadian and British offices.

The failure of the City Life Assurance Company in 1923 (and of the City Equitable Fire Insurance Company) emphasized the fact that although the Board of Trade might be fully aware that a company was in difficulties, it could take no action of itself, and that it might be difficult in practice to get the policy-holders to do so. To remedy this and other defects in the Act of 1909 a departmental committee was appointed in 1924 and its report resulted in the Insurance Undertakings Bill, already referred to.

Group insurance, disability benefit business, and insurance without medical examination, have all developed rapidly since the war. A policy without medical examination is no longer subject to any special restrictions, and the amount of insurance which companies are prepared to grant on any given life under this plan is increasing. An extension is also taking place in insurances on the lives of women.

A notable symbol of the restoration of normal working in life insurance was the holding in London, in June 1927, of the eighth International Congress of Actuaries, the first held since 1912. These congresses had previously been held at intervals of three years. The papers read on this occasion were therefore of great interest and value, embodying, as they did, the experience of all the leading countries of the world over a period of unprecedented changes.

(C. C. N.)

UNITED STATES

The first American companies were stock companies which have since given up the insurance and annuity business and have devoted their attention exclusively to banking or to execution of trusts—the Pennsylvania Company for Insurance on Lives and Granting Annuities, organized 1809, New York Life Insurance and Trust Company, 1830 (renamed Bank of New York and Trust Company, 1922) and Girard Insurance, Annuity and Trust Company, 1836. The first mutual company was the Mutual Life Insurance Company of New York which received a charter April 1842 and began business on Feb. 1, 1843; its first premium rates were based on the Carlisle and Northampton Tables and were those used previously by the New York Life Insurance and Trust Company. The New England Mutual, though chartered as early as 1835, did not begin the issuance of policies until Dec. 1843. The Nautilus Insurance Company was chartered 1841 as a joint stock company, was changed to mutual 1843, began business 1845 and was renamed New York Life Insurance Company 1849. Other early companies were the Mutual Benefit, 1845 and Connecticut Mutual, Penn Mutual and State Mutual, all 1847.

Growth and Institutions.—There are now (1928) over 300 companies with assets, as of Dec. 31, 1927, of over $15,000,000,000 and insurance in force of over $90,000,000,000; in 1927 the premium income was nearly $3,000,000,000 and the new insurance issued about $19,000,000,000. All but about 50 are stock companies but the list of mutual companies includes almost all the very large companies so that about $61,500,000,000, or over two-thirds of the total insurance, is carried by these mutual organizations. In addition to the regular stock and mutual companies are fraternal associations, primarily social or fraternal in character, with about $10,000,000,000 in force and assessment associations and stipulated premium companies with relatively small amounts.

Types of Insurance.—The life insurance now in force in the regular companies is made up of (1) ordinary, (2) industrial and (3) group. "Ordinary," issued by every company, includes policies for $1,000 or more with premiums payable annually, semi-annually or quarterly (or in rare instances, monthly). "Industrial," most of which is in three large companies, is that paid for by a weekly premium of a multiple of five cents, collected at the policy-holder's home. "Group," the greater part of which is transacted by ten companies, is that issued to an employer to cover a stated minimum number of employees on some underwriting plan precluding individual selection. The insurance in force at Dec. 31, 1927, may be roughly sub-divided into $67,000,000,000 ordinary, $15,000,000,000 industrial and $8,000,000,000 group.

State Legislation and Supervision.—An outstanding feature of the life insurance business in the United States has been the growth and character of State (as distinguished from Federal) legislation and the degree of supervision implied thereby. Each State has power to prescribe the terms and conditions upon which the insurance business may be conducted in the State and as a result insurance departments and codes of laws have evolved. The administration of the insurance department and the execution of the State law are in the hands of an insurance commissioner or superintendent of insurance whose powers and duties are defined by law. The general objectives are safety and equity to policy-holders and economy of operation.

Character of State Laws.—The New York Law is of special significance because about 90% of the insurance in force in the United States companies and 85% of their assets are in companies authorized to operate in New York. The limitations on amounts of new business and of contingency reserve are peculiar to New York. Wisconsin also has an expense limitation and some other distinctive provisions. Colorado and Oregon permit the full preliminary term method of valuation which allows a large margin for initial expenses and reduces the reserve. Illinois and several other States recognize a modified preliminary term method which produces smaller margins and larger reserves on the higher-priced policies. Texas requires companies doing business therein to invest in Texas at least 75% of the reserves on Texas business. Minnesota policies must provide that the company may defer a policy loan not more than six months from the time application is made therefor. These specimen provisions will illustrate the diversity of State laws.

Agency Methods.—The growth of life insurance in America is largely due to the development and effectiveness of the agency systems, of which there are two types, (1) general agency, under which the total field agency expense is paid to a general agent for a specified territory—city, county, State or group of States—who pays all expenses including sub-agents' compensation, the margin being his profit and (2) branch office or managerial, whereunder the compensation of sub-agents and all other organization expenses are paid by the company through a salaried manager.

Finances and Investments.—Investments, being governed by State laws, differ widely but in general are limited to (1) real estate, (2) mortgage loans, (3) collateral loans, (4) Government, State, county and municipal bonds, (5) mortgage bonds of railway and other commercial and industrial enterprises, (6) to a limited extent, preferred stocks and, to a still more limited extent, common stocks of the corporations referred to in (5) and (7) policy loans.

Taxation.—State taxes, aside from licence fees, usually consist of a tax on premiums collected in the State of from 1% to 3% (2% is used by about half the States) with varying interpretations as to what constitutes "premiums." Reciprocity usually affects the application of such laws as between States. Massachusetts is unique in levying a tax (¼%) on reserves. The Federal tax is an income tax, now (1928) 12% of the total income from interest, dividends and rents after deducting tax-exempt interest, 4% of mean reserve fund for year, dividends on stocks, investment expenses paid, taxes and other real estate expenses and minor items.

War and Post-War Experience.—War mortality was not serious even for the few companies with extensive foreign business. For the latter the depreciation of foreign currencies more than offset extra losses. The influenza mortality of 1918–19 was extremely severe, amounting to about $110,000,000 in the companies doing business in New York State. Post-War developments have included an enormous expansion in volume of business, the lowest mortality ever experienced, and a progressive decline (since about 1920) in the interest rate with corresponding appreciation of security values.

Bibliography.—*National Fraternal Congress Table,* based on experience of some of the largest and oldest fraternals and largely used in valuing liabilities of fraternal societies (1898); *Standard Industrial Table,* based on industrial experience of Metropolitan Life, 1896–1905, recognized by New York as the valuation standard for industrial policies (1907); *American-Canadian Mortality Investigation,* compiled by a joint committee of Actuarial Society of America, American Institute of Actuaries and National Convention of Insurance Commissioners in response to a request of the latter for a table exhibiting recent mortality among American insured lives and based on experience, 1900–15, of new and old standard business of about 60 American and Canadian companies (1918–19). Many tables were derived. (*See* the mortality tables listed in the article on p. 52.)

Chief repositories of both technical and general articles of current and permanent interest are: *Transactions,* Actuarial Soc. of Amer.; *Record,* Amer. Inst. of Actuaries; *Proceedings,* Ass. of Life Insurance Presidents; *Proceedings,* Association of Life Insurance Medical Directors; *Proceedings,* American Life Convention. For statistical summaries:—*Reports* of the insurance departments of New York, Massachusetts and Connecticut; *Life Insurance Year Book,* Spectator Company of New York. For information regarding policy forms and other details of company operations, including current dividend scales: *Handy Guide,* Spectator Company; *Unique Manual-Digest,* National Underwriter Company. For critical review of company operations: *Life Insurance Reports,* Alfred M. Best Company. For actuarial text-books and reports: H. Moir, *Life Insurance Primer;* J. B. Maclean, *Life Insurance; Actuarial Studies,* reports of specialized, medico-actuarial and American-Canadian mortality investigations, Actuarial Society of America. For investments: L. W. Zartman, *Investments of Life Insurance Companies.* For insurance law: A. J. Parker, *Insurance Law of New York; Corpus-Juris and Cyclopedia of Law and Procedure,* American Law Book Company. (J. S. T.)

LIFE TABLES. It has long been recognized that there are certain influences which normally affect the duration of life, and that for a large number of individuals of a homogeneous class it is practicable to frame an estimate of their mortality experience. Such estimates at first were based on conjecture rather than on the scientific analysis of observed facts. This appears to have been the case amongst the Romans who had tables for calculating the values of life interests, and no more authentic bases seem to have been discovered until towards the end of the 17th century. The first approximately accurate mortality tables were compiled by Edmund Halley, and were based on the records of baptisms and deaths in the city of Breslau in Germany. About half a century later, De Parcieux published his *Essai sur les probabilités de la Durée de la Vie Humaine* in which were incorporated several mortality tables which were for many years in general use in France. Meanwhile De Moivre had propounded his well-known theory of the law of mortality, "that the number of lives existing at any age is proportional to the number of years intercepted between the age given and the extremity of old age." As he assumed that 86 was the limiting age, according to his table the number living at any age x was $86-x$.

In 1762 the Equitable Society (London) was formed and the business of life assurance began to develop. It was not, however, until the publication in 1771 of a table, prepared by Dr. Price for the records of baptisms and deaths in the parish of All Saints, Northampton, that the science of the construction of mortality tables can be said to have been founded. A revived form of this table, published in 1783, afterwards became famous as *The Northampton Table.*

A Mortality Table.—This consists of two columns showing the numbers, out of an assumed number of births, surviving and dying at each subsequent year of age. The term *life table* in actuarial phraseology designates any collection of columns of functions involving life contingencies. The two terms are, however, commonly used indiscriminately in either sense.

There are two main sources from which material for the construction of a mortality table is obtainable, (*a*) the census returns and death registers of a community, and, (*b*) the records of assurance companies and other bodies whose operations involve the duration of life. The statistics relating to the general population are subject to misstatement of age and other inaccuracies, and it frequently happens that the information is available only in groups of ages, a circumstance which necessitates the subdivision of the group figures into numbers at individual ages The numbers both of the population and the deaths are invariably recorded according to age last birthday. On the other hand, the data obtained from assurance companies are compiled from the individual records of policy-holders who are usually required to furnish evidence of their age before the contract is completed. The numbers living at each age, known as "the exposed to risk," can therefore be scheduled according to nearest age, age last birthday, or any other arrangement that may be convenient.

The functions most usually included in a life table and their relations to one another are:—

l_x=the number of persons surviving at exact age x,

d_x=the deaths in the year of age x to $x+1$ among the l_x persons who enter on that year,

$p_x=\frac{l_{x+1}}{l_x}$, the probability of a person aged x living a year,

$q_x=\frac{d_x}{l_x}$, the probability of a person aged x dying in a year, or the rate of mortality at age x,

$\mathring{e}_x=\frac{\Sigma l_{x+1}}{l_x}+\frac{1}{2}$, the complete expectation of life, or the total future life-time which, on the average, will be passed through by a person aged exactly x.

Actuaries frequently use tables involving other decremental forces operating in conjunction with mortality, *e.g.,* marriage, widowhood, remarriage and withdrawal.

The construction of a mortality table is carried out by obtaining from the observation of a number of persons over a limited period the rates of mortality, q_x, to which they have been subject at each age. The values of q_x having been obtained, the mortality table is formed by selecting a suitable *radix,* usually taken for convenience as 100,000 at the youngest age in the table, and obtaining successive values of l_x by the formulae $l_x \times q_x = d_x$, $l_x - d_x = l_{x+1}$, or, since $q_x = 1 - p_x$, by the formula $l_x \times p_x = l_{x+1}$.

The other columns of the table can then be completed by means of the appropriate formulae.

If the recorded numbers of the population and of the deaths were free from irregularities and errors, the rates of mortality directly derived from them would, if plotted graphically, be capable of being represented by a smooth curve. These conditions are never fulfilled in actual experience and it is necessary to submit the data, or the rates derived from the data, to a process of adjustment, technically known as graduation.

Factors Affecting Mortality.—Various factors influence the rate of mortality. Age, of course, is a fundamental cause of variation, as the form of a mortality table implicitly indicates. At birth, the rate of mortality is high, but it immediately drops, and steadily decreases until about age 10 or 11, when it is at a minimum. Thereafter it increases, slowly at first, but more rapidly with advancing age.

Sex is another element to be taken into consideration. Female mortality is generally lighter than that of males. Certain special classes of lives are subject to abnormal mortality rates. Race, climate, social status, occupation, degree of urbanization or density of population, housing conditions and other aspects of environment, geographical situation, types of various diseases, are also factors which affect vitality. Of the utmost importance in connection with the experience of assured lives is the variation of mortality according to duration of assurance. Before a life assurance policy is issued, the proposer is usually required to undergo a medical examination or at least to furnish satisfactory evidence of good health. At entry into insurance the policy-holder is, therefore, a "select" life. Select rates of mortality vary according to age at entry and duration of contract, and a "select table" is arranged in a form showing the select rates converging towards and finally running into the "ultimate" rates which vary only with age. When the effects of selection are ignored and all the data irrespective of duration are combined in one mortality experience, the table is designated an "aggregate" table.

Separate tables have sometimes been constructed by excluding the first five years' experience from the data obtained for the aggregate tables, and are called "truncated aggregate" tables.

When it is desired to compare the results of different investigations of mortality experience, several criteria may be adopted, *e.g.,* (*a*), the rates of mortality at selected ages throughout the table, (*b*) the number of survivors at selected ages, (*c*) the probability of surviving a specified term of years from the attainment of selected ages, and (*d*) the expectation of life at selected ages. Of these criteria (*c*) is, perhaps, most generally satisfactory.

One feature which has been disclosed by successive investigations of the mortality experience of lives of the same class is the progressive improvement in vitality, the later investigations almost invariably revealing the lighter rates of mortality at all ages. There are no indications of any retardation in this tendency, and in several instances endeavours have been made to forecast its effects, in the one case by a definite modification of the rates of mortality directly deduced from the experience, and in the other by a suitable adjustment of the annuity values.

Standard Tables.—Brief reference may now be made to the principal mortality tables.

The *Northampton Table* was constructed by a method which gave unduly heavy rates of mortality, particularly at the higher ages. It was, however, the only authoritative measure of mortality available for many years, and the assurance companies which perforce had to adopt it as the basis of their scales of premium were enabled to accumulate large profits. The Government adopted it in 1808 for the grant of annuities, and thereby incurred a loss estimated at two million pounds before discarding it 20 years later. It was gradually superseded by the *Carlisle Table,* formed by Joshua Milne. This table was a great improvement on previous ones, and the extensive monetary tables which were based upon it are even now referred to.

The compulsory registration of births, marriages and deaths was introduced into England and Wales in 1837. The statistics which have thus become available, taken in conjunction with the successive decennial censuses, have led to the publication of a most valuable series of *English Life Tables.* The earliest tables were prepared by Dr. William Farr, whose services in the development of the science of vital statistics are pre-eminent.

Simultaneously with the publication of the national tables various sectional tables have usually been prepared, *e.g.,* the three successive *Healthy English Life Tables,* derived from the experience of the districts showing a low death rate. The most recent national table is the *English Life Table No. 9,* based on the 1921 Census and the deaths in the years 1920, 1921 and 1922.

In the United States of America the first important tables prepared by the Government were based on the 1910 Census and the deaths in 1909, 1910 and 1911 in certain States situated mainly in the north-eastern section of the country. Numerous tables have been prepared from the records of life assurance companies, the earliest being those of Griffith Davies, based on experiences of the Equitable Society of London. Tables in general use have, however, been compiled from the combined experience of a number of Life Offices. The first table of this nature was the *Seventeen Offices, or Actuaries' Table.* The date of the close of the observations was Dec. 31, 1837. It was a weakness of this table that it was based on contracts a large proportion of which were of short duration.

A more extensive investigation, that of the combined experience of 20 British Offices up to the end of 1863, was carried out by the *Institute of Actuaries.* Two very important tables were obtained from this investigation, those relating to healthy male lives, the aggregate H^m table, and the truncated aggregate $H^{m(5)}$ table. Dr. Thomas Bond Sprague later prepared a select table, the $H^{[m]}$, based on the assumption that the experience of the first five years of assurance could be linked up with the $H^{m(5)}$ experience. Assurance business in Great Britain was for many years conducted on the basis of these tables.

The most recent investigation of the experience of assured lives in Great Britain is that known as the *British Offices Experience,* compiled from the experience of 60 British Offices during the period 1863–93. This investigation was carried out on a most elaborate and comprehensive scale, and the volume describing *"The Principles and Methods"* adopted is an indispensable handbook for all students of life tables. The principal tables were the $O^{[m]}$ select and the O^m and $O^{m(5)}$ aggregate tables, and the $O^{[nm]}$ select and aggregate tables, based on the experience of participating and non-participating policies respectively. The mortality of other types of policies was also investigated, and indicated that generally the contracts with the lowest rates of premium showed the highest rates of mortality.

The mortality of annuitant lives was also examined, and the results published in the $O^{[am]}$ and $O^{[af]}$ tables, which displaced the tables derived from the earlier *Government Life Annuitant* investigations as the authoritative standard for annuity contracts. These tables are, in turn, being superseded by the *Life Office Annuitants 1900–1920 Tables* $A^{[m]}$ and $A^{[f]}$, and those based on the contemporaneous mortality experience of Government Life Annuitants. In the United States the most recent authoritative table for annuitants is the "American Annuitants" table, compiled from the experience of 20 companies carried down to the year 1918. (*See* ANNUITY.)

In the United States the table which in addition to the *Seventeen Offices or Actuaries Table* is used as a standard mortality table is the *American Experience Table, 1868,* compiled by Mr. Sheppard Homans. It was intended to represent the death rate among insured lives in America after the effects of medical selection were eliminated, and has been universally employed for valuation purposes.

The most recent American investigation produced in 1918 the *American Men Mortality Table,* derived from the experience of 59 companies during the period 1900–1915, which has already had a great influence on the operations of American insurance companies.

BIBLIOGRAPHY.—*The Institute of Actuaries, Text Book, Part II.,* by Mr. George King has for nearly half a century been recognized throughout the world as the standard work on life contingencies. *Life Contingencies,* by Mr. E. F. Spurgeon, is a more recent textbook, published by the Institute of Actuaries as the successor to Mr. King's work. There are numerous papers in the *Journal of the Institute of Actuaries,* and in the *Transactions of the Faculty of Actuaries. The Theory of the Construction of Tables of Mortality,* by the late Sir G. F. Hardy, deals particularly with graduation. *The Principles and Methods* volume gives an account of the British Offices experience, and in *Mortality of Annuitants, 1900–1920,* selection and future improvement in vitality are discussed. All these as well as numerous volumes of life tables are published by C. and E. Layton, London. A useful non-technical work, *"The Construction of Mortality and Sickness Tables—a Primer,"* by W. P. Elderton and R. C. Fippard, is published by A. and C. Black, London. The English Life Tables are contained in successive *Decennial Supplements* to the Reports of the Registrar General, published by the Stationery Office. The English Life Table No. 9, together with a *Report on Life Tables,* by Sir Alfred W. Watson, K.C.B., the Government Actuary, is contained in Part I. of the 1921 Decennial Supplement. *The Mortality of Government Life Annuitants, 1900–1920,* is also a Stationery Office publication. The Actuarial Society of America has published a number of volumes on the investigation of mortality experience, and the *Transactions* of the Society include many important papers. Other works on life tables are included in the publications of the Spectator Company of New York. (P. G. B.)

LIFT: *see* ELEVATORS.

LIGAMENT, anything which binds or connects two or more parts; in anatomy a piece of tissue connecting different parts of an organism (*see* CONNECTIVE TISSUES; JOINTS AND LIGAMENTS).

LIGAO, a municipality (with administrative centre and 14 *barrios* or districts), near the centre of the province of Albay, Luzon, Philippine Islands. It is on the railway running to Legaspi (Albay). Pop. (1939) 27,927. The Mayon volcano, with its near-perfect cone, rises to the east. Although it has erupted with destructive effects on several occasions (as in June 1928), the lava which it has spread has resulted in a fertile soil which produces abacá (Manila hemp), palay (rice) and coco-nuts. Bikol is the vernacular. Of the inhabitants aged 6 to 19 inclusive, 26·5% in 1939 attended school, while of the total population 10 years old or over, 44·9% was literate.

LIGGETT, HUNTER (1857–1935), American soldier, was born at Reading, Pa., on March 21, 1857. He graduated from the U.S. Military Academy in 1879, and saw service in the west against the Indians. In the Spanish-American war in 1898 he served on the staff of the adjutant general, and later was in the Philippines where, as major of volunteers he served for three years. In 1902 he was appointed a major in the regular army and spent several years with the department of the lakes and at Fort Leavenworth. In 1909 he attended the War college, and on being graduated in 1910 was appointed a director there, and in 1913 president, becoming brigadier general in the same year. From 1915 to 1917 he was again in the Philippines, being for one year commander of the department. In 1917 he was made major general and commander of the western department, but in September went to France as commander of the 41st Division of the American Expeditionary Force. He was at the second battle of the Marne, at St. Mihiel and in the Argonne, commanding the I. Army Corps and later the I. Army, and commanded the III. Army of Occupation on the Rhine. In 1919 he was commander of the Western Division, and in 1920 commander of the IX. Corps area, retiring on March 21, 1921, with the rank of major general.

LIGHT, subjectively, the sense impression formed in the eye. (*See* VISION.) The present article deals with it purely objectively and is concerned with the more fundamental characteristics of light and optical instruments. For the more practical applications, which are not here discussed in detail, *see* OPTICS; TELESCOPE; MICROSCOPE; INTERFEROMETER; PHOTOMETRY. The subject is conveniently still further subdivided according as to whether we are more interested in how the light originates or how it behaves after it has been emitted. The first subject is treated under RADIATION, RAYS; and SPECTROSCOPY; the present article is chiefly concerned with the behaviour of light after it has been emitted, a branch of the subject often called Physical Optics, dealing almost entirely with the Wave Theory of Light.

INTRODUCTION

It might perhaps be expected that we should begin by saying what light "really" is, and should then develop its characters from such a starting point; but this procedure is not possible, since light is essentially more primitive than any of the things in terms of which we might try to explain it. The nature of light is only describable by enumerating its properties and founding them on the simplest possible principles As these principles transcend our ordinary experiences they must be cast in a purely logical, that is to say mathematical, form. But that is never enough, for, though logic tells us what deductions must be right, it does not tell us what will be interesting, and so gives no guidance as to the *direction* the theory will take. In choosing this direction much help is derived from analogies and models, which are often loose and incomplete, but without which no proper understanding of the subject can be acquired. We shall therefore describe, largely by means of analogies, the behaviour of light, and this *is* the "real" nature of light.

Types of Radiation.—Light would be taken strictly speaking to mean only that which is seen, but it is customary to include in the term various types of invisible radiation, because, though they cannot be seen, in all other respects their behaviour is similar. These are the ultra-violet and infra-red radiations which are adjacent to the visible, and, more remotely, on the side of the ultra-violet, the X-rays or Röntgen rays, γ-rays (*see* RADIO-ACTIVITY) and the extremely penetrating *cosmic rays;* while on the side of the infra-red we have the electromagnetic vibrations of wireless telegraphy. All these radiations have one property in common, an equal speed of propagation. The most accurate measures of the velocity of light (*see* VELOCITY OF LIGHT) assign it the value $2{\cdot}99796 \pm 4 \times 10^{10}$ cm. per sec. The distinction between the various types of radiation depends on wave-length, and the following list shows roughly their wave-lengths measured in centimetres.

Electric Waves.	
Wireless telegraphy	1×10^{5}
Beam wireless	5×10^{2}
Shortest electric waves	2×10^{-2}
Infra-red Rays.	
Longest heat waves	3×10^{-2}
Longest "rest-rays"	$1{\cdot}5 \times 10^{-2}$
Average "rest-rays"	5×10^{-3}
Infra-red down to	7×10^{-5}
Visible Light.	
Limit of red	$7{\cdot}2 \times 10^{-5}$
Yellow	$5{\cdot}8 \times 10^{-5}$
Green	$5{\cdot}0 \times 10^{-5}$
Blue	$4{\cdot}5 \times 10^{-5}$
Limit of Violet	$4{\cdot}0 \times 10^{-5}$
Ultra-violet Rays.	
Limit of transparency of glass	$3{\cdot}5 \times 10^{-5}$
Limit of transparency of quartz	$1{\cdot}8 \times 10^{-5}$
Lyman region	1×10^{-5}
"Hot spark" region	1×10^{-6}
X-Rays.	
Longest X-rays	1×10^{-7}
Average X-rays	1×10^{-8}
Shortest X-rays	1×10^{-9}
γ-rays	2×10^{-10}
Cosmic rays	4×10^{-12}

It is not convenient to use the same units throughout such an enormous range. It is customary to measure wireless waves in metres. The "rest-rays" are often measured in units called μ, the thousandth of a millimetre, but for light the unit universally used is the Angström Unit (A.U.) which is 10^{-8} cm. This is also most frequently used for X-rays, though in precision work X-units of 10^{-11} cm. have been introduced. Much of what we shall say here applies to the whole range, but it is not unnatural that there should be differences, and when these occur we shall restrict ourselves to the case of light, visible, ultra-violet and infra-red.

The Appearance of Ordinary Things.—In many branches of science, though we start with familiar and crude observations, we very soon find it necessary to discuss much more recondite questions, and this leads to an elaboration of the theory, until the most important things in it are quite different from what is familiar to us. This is very emphatically true of light. For example, the most familiar thing about light is that it goes in straight lines, and hardly any of our ordinary experiences disagree with this fact. But by more refined experiments it is easy to exhibit that light is sometimes bent (diffracted) and such cases prove more important to the theory than the commonplace observations. Almost the only example of these phenomena, diffraction and interference, which is a matter of common experience, is the iridescent colours that appear on soap-bubbles and on the surface of greasy water.

So it comes about that the theory of light is not much concerned with the appearance of ordinary things, and, as we shall later have very little to say about them, we may consider them briefly here. In things we see, we may distinguish between the luminous and the non-luminous—in day-light between the sun and everything else. The non-luminous objects are only visible by light reflected from some luminous source, the sun or a lamp, and their different appearances are solely due to the different ways in which they reflect light. Thus a black object is one which does not reflect at all. A coloured object is one which reflects some colours but not others. This is easily proved by illuminating a piece of red paper by light passed through a green glass, when it will appear black because there was no red light for it to reflect. White being a mixture of all the colours, a white object is one which reflects all colours about equally, and so it looks coloured if lit by a coloured light. When two pigments are mixed together the resulting colour will be that which they are *both* capable of reflecting, and may be quite different from the colour seen when the light of two coloured lamps is projected together on to a white screen; for example if the light from red and green lamps is compounded in this way the result is a brilliant yellow, but red and green paints when mixed give a dark muddy colour because there is little light which they can both reflect (*see* COLOUR).

Many substances are really nearly transparent, but appear opaque because they are not homogeneous, so that the entering light is reflected and refracted many times until it is completely scattered. The most obvious example of this is ground glass, but the same is largely true of paper and white wood. An easy test of whether a substance is opaque in this way or by an inherent opacity to light is to see whether it is of the same colour for reflected and transmitted light. A sheet of red paper looks red whether we look at it or through it at a light, because in both cases what we see is light which has got tangled in the fibres, and at each reflexion has lost a little of the green and blue light by absorption, so that only the red emerges on both sides. On the other hand if a substance is truly opaque the colours on the two sides will be quite different. For example the yellow colour of gold is due to the fact that it reflects the yellow light more effectively than other colours and, by a paradox which we shall explain later, this means that it absorbs the yellow more strongly. If then we take a very thin sheet of gold, the yellow light will not penetrate it so easily and transmitted light will be bluish green.

HISTORY

The ancients were acquainted with mirrors and with the burning glass, but their theories of optics were rather of the metaphysical character so much more congenial than experiment to the Greek temperament. The Pythagoreans believed in an emission theory, supposing that the seen object emitted particles which bombarded the eye, but the Platonists complicated the matter by supposing that vision was produced by a triple interaction between rays emitted by the sun, the object viewed and the eye itself. Among these speculations we can only distinguish the discovery of one real scientific law, enunciated by Hero of Alexandria who saw that the equality of the angles of incidence and reflection at a mirror could be expressed by saying that the ray took the shortest possible course between object and eye. This law is the first statement of the general "principle of least action," a principle which now dominates not only geometrical optics but also dynamics.

We may omit the other speculations of the Greeks, Romans and Arabs and come to the revival of learning. The earliest developments were practical, such as the invention of spectacles and later of the telescope, with which we shall not be concerned here. The first great theoretical discovery was the law of refraction discovered by Snell in 1621, but not published until after his death by Descartes. This law asserts that when a ray of light passes from one medium to another, the plane of the two rays contains the normal to the surface, and the sines of the angles of incidence and refraction are in a constant ratio, the refractive index. Descartes was led by a metaphysical argument to maintain that light was some sort of pressure in a medium (in a very indefinite way something like the present wave theory), and thought that the velocity of light must be greater in a denser medium. This view was combated by Fermat, also on metaphysical grounds, and modern theory supports Fermat though not his reasoning. It seems to be the rule rather than the exception that correct results are first obtained from quite incorrect arguments. Fermat asserted that nature performs its operations always by the most direct path, and that therefore a ray of light between two places must take the shortest possible time. The rectilinear propagation of light and the law of reflection conform to this principle, and therefore refraction must do so too. Snell's law then implies that the velocity of light in a medium is inversely proportional to its refractive index. Fermat's "principle of least time" is the natural extension of that of Hero of Alexandria, and was later erected by Hamilton into a general method of great beauty for dealing with optical systems.

The Age of Newton and Huygens.—The first great era in the theory of light is the second half of the 17th century. Grimaldi discovered (and named) the phenomenon of *diffraction,* that light going through a fine slit cannot be prevented from spreading on the further side, and that no matter how small the source of light, the edge of a shadow cannot be perfectly sharp. Hooke independently discovered the same thing, and offered a theory approaching closely to the wave theory in that he had the idea of *wave-fronts* and of light being some sort of oscillation; but it was more than a century before it was seen that the strongest possible argument for this theory lay in the discovery of diffraction. During the same era Roemer measured the velocity of light for the first time, by a comparison of the calculated and observed times of the eclipses of Jupiter's satellites.

Of all the founders of the theory of light undoubtedly the greatest were Newton and Huygens. Newton discovered the theory of the spectrum. By passing a fine beam of sunlight through a glass prism he resolved it into its component colours:—red, orange, yellow, green, blue, indigo, violet. It had already been known that white light was resolved into colours on passing through glass or water (for example the rainbow had been explained), but it was supposed that the glass had produced a definite alteration in the light. Newton showed that, if the light passed through a second prism reversed, the coloured lights would recombine into white, but that if a single colour were selected from the spectrum, no subsequent treatment could change it in any way. He was thus led to the correct explanation of white light as a compound of all the colours, but the further details of this question would lead us into physiological optics (*see* VISION).

Newton also investigated the colours of thin plates such as soap bubbles. He placed a slightly convex lens on a flat piece of glass and observed the light reflected. At the centre the surfaces are in contact and nothing is reflected, but round this point, where they are very close, though not in contact, there appears a succession of brilliantly coloured rings, the succession of colours being black, faint blue, strong white, orange, red, dark purple, violet, blue, faint green, vivid yellow, etc. The rings become narrower and fainter as we go outwards and soon become invisible. These are not the colours of the spectrum, and their origin is better appreciated by considering the case where the illumination is by monochromatic instead of white light. There is then a dark centre surrounded by a large number of rings of the colour used. (*See* Plate, fig. 1.) The sizes of the rings depend on the colour of the light; they are closer together for blue than for red. If then we illuminate simultaneously with red and blue light there will be places where the rings fall together, so that we get alternately purple and dark, and other places where they fall apart and we get alternate rings of red and blue. Plate, fig. 2 is a photograph of this type; as the camera is unequally affected by the two colours, in some regions the rings look blurred, in others sharp. The rings in white light can be explained in the same way as due to a superposition of all the colours, and at no great distance from the centre so many of the coloured rings overlap that they become invisible.

Newton was very cautious in making theories and he did not really succeed in explaining his rings, but he attributed them to certain "fits" of reflection and transmission which later were seen to be very like the *phases* of the wave theory. As to the general theory of light he was also very non-committal, but he criticized the wave theory as being unable to explain rectilinear propagation and his followers, interpreting his views in a much narrower way than he intended, adopted a complete corpuscular theory of light which held the field for more than a century. This theory supposed that light consists of minute particles, or corpuscles, shot out from the luminous body, and attempted to explain all the phenomena by suitably modifying the properties of these corpuscles. The theory implies that the velocity of light must be proportional to the refractive index, not inversely proportional as in Fermat's principle and the wave theory, and this was later to provide a critical test which condemned it.

Huygens is the real founder of the wave theory of light. He based his belief in it primarily on the fact that, if a beam of light were like a flight of arrows, then when two beams cross these should be collisions between the arrows. He succeeded in explaining reflection and refraction, and we may consider his construction, as it lies at the foundation of modern methods. The general idea is that light is a disturbance in a medium, but it need not be specified what is the character of the disturbance; for purposes of rough visualisation we may think of the medium as a jelly which is distorted so that its particles move out of their usual places. Any disturbance then acts as a centre causing the propagation of a wave of disturbance to go out at a constant speed, so that at any subsequent time the effects of the initial disturbance will be found on a sphere surrounding it. When the initial disturbance is not confined to a single point, each point of it is to be regarded as a source, and the subsequent disturbance is the geometrical envelope of the spheres surrounding all these sources. Refraction is explained by supposing that the velocity of light is different in different media. Consider light obliquely incident on a flat surface, say of water (*see* fig. 1). The velocity of propagation outside is C the velocity of light; in the water it is v a slower velocity. The advancing disturbance is at one moment spread as a pulse over the surface AB. Each point of AB gives out a spherical pulse and, to reconstruct the wave later, we draw spheres of equal radii round all the points of AB. Obviously one such set of spheres will give the line CD as their envelope, and this shows that the light goes in the direction AC outside the water. But if we repeat the construction starting at CD we have to allow for the fact that the velocity is less in water than in free space. Thus, corresponding to the sphere of radius DF about D, we draw round C a sphere of radius $CE = v/cDF$, and it is evident that EF will be bent round more nearly parallel to the face than was CD. After this both spheres are in the water and the propagation goes straight again on to GH. This construction immediately gives Snell's law of refraction, for $\sin ACM/\sin GCN = DF/CE = c/v$, and the refractive index is simply the ratio of velocities. The construction fails in the case of very oblique incidence if v is greater than c, for then the circle round C may have radius actually greater than CF itself. Refraction is then impossible and all the light is reflected. This is the phenomenon of total internal reflection which we shall discuss later. A simpler construction than that we have given applies for reflection, and the same principle also explains diffraction, but Huygens did not find this out.

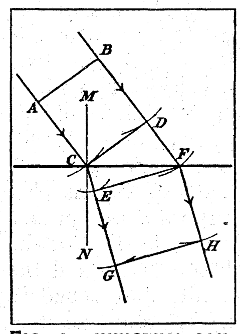

FIG. 1.—HUYGENS' CONSTRUCTION FOR REFRACTION

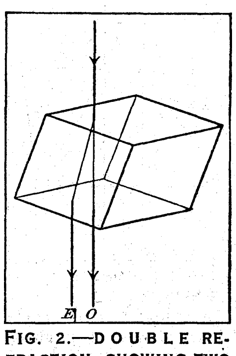

FIG. 2.—DOUBLE REFRACTION, SHOWING TWO RAYS EMERGING WHEN A LIGHT RAY STRIKES A CALCITE CRYSTAL PERPENDICULARLY

Huygens' other great investigation is connected with *double refraction.* Certain crystals of calcium carbonate, from Iceland, called calcite or Iceland spar, have the extraordinary property that objects viewed through them appear double. To reduce the matter to simpler terms it can be expressed thus: a crystal of calcite resembles a cube that has been compressed along one of its diagonals. Suppose that a narrow beam of light is incident on one face perpendicularly. If the crystal were glass the beam would emerge from the opposite face in the same line. Actually two beams emerge, one in the same way as for glass, but the other, in a new line though in a direction parallel to the first (*see* fig. 2). These are called the ordinary and extraordinary rays. Huygens successfully applied his wave construction to explain them by supposing that two surfaces must be constructed round each point, one a sphere which would give the ordinary ray, but the other a spheroid with its axis of revolution determined by the crystal axis (that is by the shortened diagonal of the cube) for the extraordinary ray. This is illustrated in fig. 3. Round the points C and D we draw, not only a sphere, but also a spheroid, which is such that the two surfaces touch at the points that lie in the direction of the crystal axis (the point K in fig. 3). The envelope of the spheres is the plane EF which shows the path of the ordinary ray, while the plane GH is the envelope of the spheroids and shows the path of the extraordinary ray. Observe that the latter ray is not perpendicular to the wave front.

Huygens also discovered, though he did not explain, the phenomenon of polarization. If we rotate our crystal about an axis in the direction of the beam and observe the projections of the two rays on a screen, the ordinary ray will stay fixed, and the extraordinary, which will be equally bright, will rotate round it. But now suppose that we isolate the ordinary ray and pass it in the same way through a second crystal. In general it will give rise to two rays, ordinary and extraordinary, but this time they will usually be of unequal brightness. If the two crystal axes are parallel, the extraordinary ray will be absent altogether, but as the second crystal is turned it will gradually grow in brightness at the expense of the ordinary, until, when the crystal has turned through a right angle, the ordinary ray will be entirely extinguished. Rotation through a further right angle will restore the ordinary ray and destroy the extraordinary. A similar rule applies for the extraordinary ray from the first crystal; it usually gives both types, but only an extraordinary ray when the crystals have their axes parallel. Newton recognised the essential features of the matter in saying that a ray of light may have *sides;* in fact that this light differs from ordinary light as a thin lath differs from a round stick. The idea of transverse vibrations had not yet been formulated, so that no further advance could be made at this stage.

We may here remark that the Huygens' wave construction explains what some may regard as a philosophic difficulty in Fermat's principle. According to this principle the rays of light between two points A and B adopt that path which takes the shortest time; and though the only way we have ordinarily of determining a minimum is to try a number of paths and see which is quickest, yet the ray appears to adopt the right course without any alternative trials. The wave construction explains why it does so, for it shows that the wave is, so to speak, all the time trying alternative routes, and is adopting the shortest because the waves in other paths cancel out.

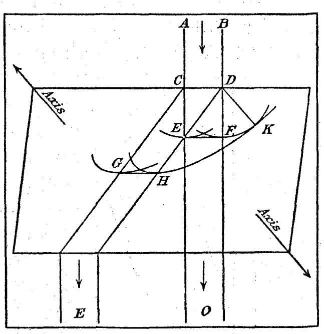

FIG. 3.—HUYGENS' CONSTRUCTION FOR DOUBLE REFRACTION
Each point of C and D sends out a sphere and spheroid wave. The spheres give the ordinary ray through EF, the spheroids the extraordinary ray through GH

In spite of these great advances the state of knowledge at the end of the 17th century was really insufficient to give a decision between the two theories, and moreover there was hardly the beginning of a mathematical wave theory as yet, so it is perhaps not surprising that the corpuscular theory of light gained the upper hand. The 18th century was singularly barren in optics and the only first-class discovery appeared strongly to support this theory. This was the discovery of stellar aberration, by Bradley (*see* ABERRATION OF LIGHT), which for corpuscles is immediately explained by the idea of relative motion; whereas with waves, though a crude explanation is not hard, the final solution was only obtained in the 20th century with the advent of relativity.

The Age of Fresnel.—The second great period of discovery coincided with the beginning of the 19th century, and the first successes fell to Young. He adopted the wave principle of Huygens, but extended its application. Thus Huygens had only considered waves of the form that we should now call pulses, but Young made use of continuous periodic waves, and so was enabled to explain Newton's rings in a manner we shall discuss later. He clearly stated the general principle of *superposition,* that "when two undulations from different origins coincide, either perfectly or very nearly in direction, their joint effect is a combination of the motions belonging to each." This principle is quite general, but Young perceived that interesting results would only follow when the two sources are *coherent,* that is to say when two beams from the *same* source are brought to superposition, for only so could the irregularities in the process of emission be the same for both. He therefore set up what has proved to be one of the classical experiments of optical theory.

Two holes are made close together in a screen, and light from a distant point passes through them and illuminates another screen. If the holes are large there will be merely two patches of light on the screen, but when the holes are made smaller diffraction occurs, so that the rays of light spread and the patches are larger instead of smaller as might be expected at first sight. When the holes are very small the patches will overlap and it is then observed that they are crossed by a number of fine bands. To understand this let us suppose the light to be monochromatic (of a single wave-length) so that the vibrations of the light-wave are in the form of a travelling sine-curve. The source of light is equidistant from the two holes A and B (fig. 4), so that at those points the waves are in the same phase (shown diagrammatically in the figure). On passing through the small hole each beam emerges as a spherical wave. At the central point O of the screen the distances to A and B are equal so the phases agree at every moment; the effect from the two holes will reinforce one another and O will be illuminated. Consider however a point P which is half a wave-length nearer to A than B. Here the waves from A and B are at every time in opposite phases (in the diagram when one wave is at the top the other is at the bottom, etc.) and so cancel, with darkness as the result. At the point Q, which is a whole wave-length nearer to A than B, the waves will reinforce each other again, because one wave is exactly a wave-length behind the other, and there will be light. Proceeding in this way the whole field is seen to be covered by alternate bright and dark bands. In the case of white light there will be a few coloured bands in the middle and the rest will look white; the colours can be worked out in just the same way as with Newton's rings. Young's interference pattern is by no means easy to observe, as it requires very careful adjustments on account of the exceedingly short wave-length of visible light. To give an idea of its magnitude, if the holes are 1 mm. apart and the screen is at a distance of 1 metre, then for red light the bright bands are a distance 0·6 mm. apart.

The investigation of polarization at this epoch received a great impetus by the discovery of Malus that, when sunlight is reflected from glass, the reflected ray may be polarized. Brewster studied the matter and found the rule that the reflected light was completely polarized when the reflected and refracted rays were perpendicular to one another. In the course of this work he discovered experimentally the formulae for the intensity of the two polarized components of light reflected from a transparent substance. If i is the angle of incidence and r that of refraction, the fraction reflected is $\sin^2(i-r)/\sin^2(i+r)$ or $\tan^2(i-r)/\tan^2(i+r)$, according to the direction of polarization. These expressions are usually called Fresnel's sine and tangent formulae, and have played a part in the history of optics. In the special case where $i+r=90°$ the tangent formula vanishes and, as the other does not, the reflected light is completely polarized. Brewster also made the important discovery that some crystals exhibit double refraction of a different type from that of Huygens. In these crystals there are two directions instead of only one for which the light does not become polarized. We may also here mention the discovery by Arago of *gyration* (formerly called "optical activity"). When a beam of polarized light is sent through a quartz crystal along the axis, or through a sugar solution, it is observed that, on emergence of the beam, the plane of polarization has rotated by an amount proportional to the length of the path it has traversed. We shall discuss all these matters in detail later.

The greatest investigator of this period was Fresnel, and in his hands optical theory attained the outline which it has kept ever since. As we shall have to deal with his work in detail we shall here only mention his discoveries without explaining them.

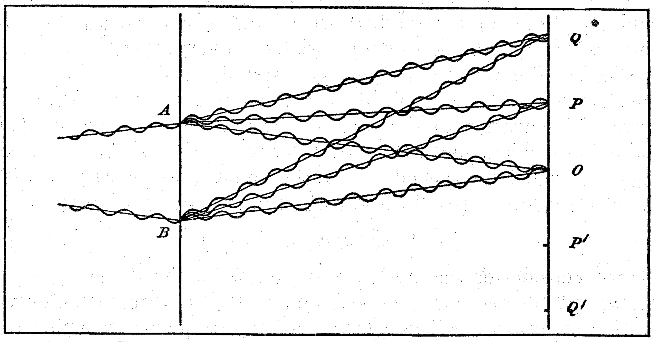

FIG. 4.—YOUNG'S INTERFERENCE EXPERIMENT
Monochromatic light falls on the two holes A, B. Point O is equidistant from them, so that the waves reinforce each other. P is ½ a wave-length nearer to A than B, so that the waves cancel out, while Q is a whole wave-length nearer, and they reinforce again. Bright bands will appear at O, Q,Q′, and darkness at P,P′

First he adapted Huygens' construction to explain diffraction, and thereby established the superiority of the wave theory over the corpuscular. In the course of this work he demonstrated the remarkable fact that there is a bright spot exactly in the centre of the shadow of a circular screen. Like Young he also made various experiments to exhibit the interference of two beams of light. He then turned his attention to the optical effects of moving bodies (including the motion of the earth) and correctly formulated all the principles; this important work had a great influence in connection with relativity theory, but is outside our scope here. Next he made the discovery (with Arago) that, when two beams of light are differently polarized, even if they arise from the same source, it is impossible to make them interfere. At this period the vibrations of light were thought to resemble those of sound, so that there seemed to be no room for polarization in the theory, but Young hit on the solution that the vibrations were transverse, so that a wave of light may have sides, as Newton had said. Fresnel next turned his attention to double refraction and completely solved the whole problem, uniting into a single system both Huygens' uniaxial and Brewster's biaxial types. Finally he deduced theoretically the laws of refraction and reflection, and obtained the sine and tangent formulae to which we have referred. Fresnel's whole work was devoted to establishing rigorous principles for light, and the enormous progress he made is the more remarkable when we remember that the mathematical theory of waves was only in its infancy, and that there hardly existed at all any dynamical theory of continuous media.

The Dynamical Theories of the 19th Century.—With the discoveries of Fresnel, the more geometrical part of the wave theory of light was practically complete; but it was still necessary to build a proper dynamical formulation, and this was the chief preoccupation of theorists during most of the 19th century. It was felt necessary to make a model of some sort of matter which should behave like the optical medium. The most obvious model suggested was that of an elastic solid, and, with the help of this, Cauchy, Neumann and others had considerable success in explaining the phenomena for a single medium, but the theories got into difficulty when it came to the passage of light from one medium to another. Only by highly artificial hypotheses was it possible to obtain the sine and tangent formulae.

The work of Green on the propagation of waves in elastic solids is the real beginning of the modern mathematical theory of waves. A piece of solid matter can be strained (altered in form or position) in three ways. It may be compressed without other change of form, or it may be sheared so that a square becomes a rhombus, or, without changing its shape, it may be rotated in position. The third type of strain can take place without the necessity of forces, but the first two require the action of forces in order that they may occur. The solid will possess two elastic constants corresponding to these forces (we are thinking of an isotropic body, not a crystal which may possess 21), and can propagate two types of wave, a longitudinal corresponding to compression, and a transverse corresponding to shear. Green showed that when a transverse elastic wave passed from one medium to another it could not help giving rise to a longitudinal wave, and for this there is no room in the theory of light. Though his result was thus mainly negative, Green's calculus firmly established what conditions a valid theory must satisfy. Under the inspiration of Green's methods Stokes gave a rigorous solution of the problem of diffraction in place of Fresnel's approximate geometrical method.

A valid formulation for the dynamical theory of light was first made by MacCullagh, who assumed that the aether was a new kind of material which opposed no resistance to compression or shear, but which resisted rotation. Such a material satisfies all the necessary conditions, but it suffers from the objection that there is no known kind of matter which has the property, and for this reason it was regarded with great suspicion and its importance was not appreciated till long afterwards. During the middle of the 19th century there were many attempts, especially by Lord Kelvin (then W. Thomson), to invent a substance which should satisfy all the necessary conditions, but they were mostly very artificial. The modern theory was finally formulated by Clerk Maxwell, about 1860, who showed that electric oscillations must involve emitted waves which would have the same transverse character and would travel with the same velocity as light. He therefore identified light with electric waves, and gave the complete system of equations (then seen to be identical with MacCullagh's) which determine the behaviour of light. This theory has firmly held the field ever since, and Maxwell's name ranks as high as any among the contributors to optical theory. The completeness of his theory, and perhaps the familiarity that grows with the lapse of time, has overcome the objection that no known matter conforms to the same rules of vibration as the aether.

The Experimental Discoveries of the 19th Century.—During the period of these great theoretical investigations the experimental side had of course not been neglected, and many important discoveries had been made and instruments invented. Fraunhofer studied diffraction in a rather different way from Fresnel, and constructed gratings by winding wire between two fine screws and by ruling lines with a diamond on glass. With these he analysed the solar spectrum, and his work is thus the origin, both in subject matter and in method, of the modern science of spectroscopy. The invention of Nicol's prism (usually called the nicol) made it easy to produce polarized light, and this has ever since been the standard instrument in the study of polarization. Stokes began the study of ultra-violet light, rendering its effect visible by means of the property of fluorescence; it is now more usually investigated by photography. Faraday discovered the theoretically very important phenomenon of magnetic gyration,—that, when a transparent substance is in a strong magnetic field, a beam of polarized light passing through it along the direction of the field has its direction of polarization rotated. This was the earliest connection discovered between light and electricity. Fizeau and Foucault developed methods of measuring the velocity of light accurately, and among other things showed that light really does go slower in water than in air, as is demanded by the wave theory (*see* FLUORESCENCE AND PHOSPHORESCENCE).

We must also mention the slow development of the theory of dispersion, *i.e.*, the dependence of the refractive index on the wave length. Fresnel and Cauchy propounded a theory which attributed it to the coarse-grainedness of the refracting medium, from which it followed that the refractive index could be expanded in powers of the inverse square of the wave-length. This is often possible, but its inadequacy was seen when Leroux discovered the phenomenon of "anomalous dispersion" (which is not really at all anomalous), that substances exist which refract the red more than the blue. A hint of the modern theory was given by Maxwell, but its real development is due to Sellmeier who showed that dispersion was an example of the general phenomenon of resonance. At the end of the 19th century Lorentz revised the whole of Maxwell's theory, introducing the idea of electrons, and in the course of his work improved Sellmeier's dispersion formula.

During the closing decades of the 19th century an aspect of the wave theory which has had results of the most far reaching importance was much studied experimentally. Fresnel had successfully treated the optical theory of moving media up to a point, but many difficulties remained with regard to the movement of the earth as a whole. Stellar aberration suggested a fixed aether through which the earth moved, but then it seemed possible that for terrestrial experiments this motion ought to be detectable. On account of the great velocity of light none of these experiments were easy, but all gave negative results; particular mention may be made of the experiment of Michelson and Morley which was of such accuracy that, though it depended on the *square* of the ratio of the earth's velocity to that of light, it definitely established the negative. The mathematical theory was developed by Larmor and Lorentz to deal with this matter, and a very profound interpretation, given to it by Lorentz, led to the promulgation of the theory of relativity by Einstein (*see* RELATIVITY).

At the close of the 19th century optical theory had attained a completeness and perfection which left hardly room for further development, and it is with this classical theory that we shall here be concerned. During the 20th century one most important branch has been added to it by the discovery of the interference of X-rays, but for the most part the centre of interest has shifted. The study of the conditions under which light is emitted has revealed fundamental difficulties in all our mechanical conceptions. This has led to the body of doctrine called the quantum theory (*q.v.*) which is antagonistic to the older classical system. Each in its own field covers a large number of phenomena, but the reconciliation is not yet complete, though it is already possible to rewrite the theory of dispersion in the new language. We shall not do this here, but shall treat it together with the rest of the subject by purely classical methods.

WAVES AND INTERFERENCE

The most familiar form of waves is of course the surface waves of water, but the term is extended to cover any vibratory effect propagated through a medium. For example if we take a long stretched string and strike it near one end, a small hump will form and will travel without change of shape down the string. Though the portion of the string humped is changing all the time, the geometrical form is unchanging and so we can endow this form with individuality and say that the wave goes at a certain speed. If x denotes the distance of any point on the string from the point of reference, or the origin, and ϕ the displacement of the string at that point, the motion is described by the differential equation

$$\frac{\partial^2\phi}{\partial x^2}=\frac{1}{c^2}\,\frac{\partial^2\phi}{\partial t^2},$$

the solution of which is $\phi=f\,(x-ct)$. This expresses the fact that, whatever the initial form, the form at time t is the same with the origin shifted a distance ct.

General Characteristics of Waves.—The vibration of a string is specially simple, because the wave undergoes no change of form, but in most cases, such as water-waves, that is not so, for as the wave travels it alters shape, and so it is no longer possible to speak of a definite velocity. It is therefore necessary to analyse the waves into definite types which can be studied separately, and the type which is incomparably the most useful is the sine-curve. That such an analysis is useful is a consequence of the principle of superposition enunciated by Young; mathematically this principle follows from the fact that the differential equations of wave motion are linear, so that if we have two solutions of a wave problem we can derive a third by taking their sum. Thus any problem can be solved by expressing the initial state as a sum, or more usually an integral, of sine-curves of various wave-lengths, then solving the motion for each of these separately and finally recombining them. This is the only method available for water-waves; and though *plane* waves of light are propagated in free space without change of form, any obstacle or refractive medium destroys this simplicity and makes the analysis necessary.

In discussing the general characteristics of waves we may conveniently think of a stretched string, but when the appropriate name is given to the dependent variable ϕ everything we shall say applies equally well to water-waves, sound, or light. Thus, ϕ in the string means the displacement of the string sideways, in water-waves the elevation of the surface above its average height, and for sound it might mean the variable part of the air pressure; for light we shall later specialize it rather more and identify it with the electric force. In all these cases the typical solution is

$$\phi=A\cos[2\pi(\nu t-x/\lambda)-\epsilon]$$

First considering the motion of a particle of the string, we keep x constant and see how ϕ depends on t. It is a pure harmonic vibration of *amplitude* A and *frequency* ν, frequency meaning the total number of vibrations described in a second. The expression $2\pi(\nu t-x/\lambda)-\epsilon$, regarded as an angle, is the *phase* at the time t at the distance x from the origin. It can be interpreted very simply by the consideration that, when a point describes a circle at uniform speed, its projection on a diameter describes a harmonic motion; then the angle between this diameter and the radius through the point is the phase-angle. The term phase, though quite precise, is often used in a looser sense, because its absolute value does not matter, whereas differences in phase are of the very greatest importance in deciding the character of a wave. We next examine the shape of the string at any instant of time and see that it is a sine curve of *wave-length* λ. The amplitude, frequency, wave-length and phase are the four quantities characteristic of any wave.

The wave is progressive because of the phase relations between the various points of the string. If at any instant we compare the phases at x and $x+a$, we see that the latter is an angle $2\pi a/\lambda$ behind, and that at a time $a/\lambda\nu$ later it will have arrived at the phase which was at x initially. We therefore take $\lambda\nu = V$ as the *wave-velocity* or *phase-velocity*; it is the rate at which the crests move. Though phase velocity plays a most important part in wave theory it is misleading to think of it as a real velocity. For example, it is a general principle that no effect of any kind can be propagated with a speed greater than c, the velocity of light in vacuo, but it is not very rare to find substances in which the phase-velocity of light is considerably higher. When we say that no effect can travel quicker than c, we are thinking of the rate at which waves advance into a region previously undisturbed, but phase-velocity only has a meaning in connection with a sine-curve, and a sine-curve extends indefinitely in both directions, so that there is no undisturbed region to which the principle can apply.

In the case of water waves, and perhaps of electric waves of very long period, we can observe the crests and so can see directly the wave-velocity and measure the amplitude, but in general it is impossible to do this. Usually we only observe some dynamical effect, such as that which occurs when the rays of light impinge on the retina of the eye. The exact form of this effect is special to each type of wave, but it is a general principle that it depends on the energy of the waves and this is proportional to the average value of the square of the amplitude of the wave-variable ϕ. This quantity is the *intensity;* it is often quite unnecessary to know the factor of proportionality associated with it. It is important to observe that the amplitude can be deduced from the intensity, but that nothing can be said about the phase; this is a consequence of the dynamical fact that only by altering the phase can the wave medium do work on the observing instrument, so that only by spoiling the phase can we observe the wave.

The case of waves in three dimensions is of course more complicated than that of one. In thinking about them the most important idea is that of the *wave-front* which is any continuous surface over which the phases are all the same. For mathematical treatment such waves are sometimes resolved into sets of plane waves going in all directions, but it is more often convenient to make use of spherical waves. It can be shown that, if a three-dimensional medium propagates plane waves according to the rule

$$\phi = A\cos[2\pi(\nu t - x/\lambda) - \epsilon],$$

then it can propagate a spherical wave of the form

$$\phi = A\cos[2\pi(\nu t - r/\lambda) - \epsilon]/r,$$

where r is the distance from the origin. The wave-fronts are spheres round the origin as centre, and the wave represents an emission from a point source at the origin. The amplitude decreases as the wave spreads out, and is always proportional to the inverse distance. The intensity is therefore proportional to the inverse square of the distance and this is the fundamental law of photometry (*see* PHOTOMETRY). This type of wave suffices for the discussion of a great many phenomena in optics, but it may be mentioned that it will require some unessential modifications when we come to discuss polarization and electromagnetic waves.

The Velocity of a Group of Waves.—Much of optical theory can be developed by the consideration of pure monochromatic waves, and indeed it may be said that experimental methods have tended to move in directions for which these suffice. The monochromatic wave, however, gives a very incomplete account of events, because it ranges over an infinite extent of time and space, whereas we usually want to know about events in some limited region. We saw, for instance, in Huygens construction for double refraction, that the extraordinary wave has its front parallel to the ordinary, but yet that the *rays* go in a different direction. Even in the simpler case of plane waves of unlimited breadth there is a similar complication when the wave-velocity depends on the wave-length, as is the case in refracting media. Let us take a *group* of approximately monochromatic waves of limited length, and find the *group-velocity* with which it travels as a whole. To construct such a group we take a sine-curve multiplied by a factor such that the waves are not of uniform height, but fall away gradually to zero on both sides of the centre. The solution then shows that, though the crests travel forward with the wave-velocity appropriate to the wave-length, yet they alter in height as they go, so that after a time the crest which was highest at first will have become quite inconspicuous, while another wave originally quite small will have grown up and taken its place as highest crest. Thus the group as a whole moves with a different velocity from its component waves. The group-velocity U is derived from the wave-velocity V by the formula $d(kV)/dk$, where k is the reciprocal of the wave-length. The phenomenon of group-velocity is easily observed from the deck of a ship, for after a very short time a large wave under observation becomes quite small while another behind it has grown at its expense. For water the wave-velocity is proportional to the square root of the wave-length, and our formula then shows that the group-velocity is half the wave-velocity. For other types of waves it may be greater than the wave-velocity, and there is nothing to prevent it even being in the opposite direction, though no case of this is known. Only in the case where the wave-velocity is independent of the wave-length is it equal to the group-velocity; in this case any wave can be propagated without change of form.

The most important application of the idea of group-velocity to optics arises in the measurement of the velocity of light. Every type of measure depends in some way on interrupting the light and thus gives the group-velocity. In free space the wave-velocity of light does not depend on the wave-length and so is the same as the group-velocity, but this is not so in other cases. The superiority of the wave theory of light over the corpuscular theory was held proved when Foucault showed directly that light goes slower through water than air; but he did not in fact prove it, for the refractive index depends on wave-velocity, and his work dealt with group-velocity. However, since either can be deduced from the other, it is easy to verify the correctness of his result indirectly. In much of optics these considerations do not arise, and so they are frequently forgotten. Nevertheless they are indispensable for a full understanding of waves, and many difficulties have been caused in the past through neglecting them.

The Pressure of Light.—In the course of his theoretical investigations Maxwell discovered the pressure of light. He derived this from the electromagnetic theory, but as a matter of fact it can be shown to follow from any wave-theory, and was foreseen in the 18th century by Euler. If plane waves fall perpendicularly on a surface it may be shown that they exert a pressure on it of a magnitude equal to the density of energy in the waves. This result is exceedingly difficult to observe, as the pressure is very small in practical cases. The first attempt led to the invention of the radiometer by Crookes. In this instrument freely moving vanes are coated with black on one side and are polished on the other. The side which is black absorbs the radiation while the reflecting side sends it back; so there is more energy in the space in front of the reflecting side and therefore a greater pressure. When the radiometer is illuminated it does go round, but the wrong way! This is due to a rather complicated effect depending on the heating of the residual gas in the vessel, and in order to observe the pressure of radiation much more delicate means are required. It was eventually measured by Lebedev by so improving the radiometer that the effect of the gas was eliminated. There are also indirect methods by which the pressure of light can be verified, chief among which is the thermodynamic law for the emission of radiation (*see* HEAT). Light pressure plays scarcely any part in our common experience, but grows to enormous values in the hot interiors of stars and plays a dominating part in controlling their state.

The Doppler Effect.—When monochromatic light passes through any fixed optical system there is one property that is always conserved, the frequency of the vibrations; but this frequency can be changed if the light is reflected by a moving mirror, or if there is a difference in the motions of source and observer. This change of frequency is called the Doppler effect, after its discoverer, and is easily explained by the wave theory. Consider a fixed source emitting light of frequency ν, and sending it to an observer who is receding at velocity v. On account of his motion the successive crests of the light-waves will reach him at longer intervals than if he were at rest and a simple calculation shows that he will receive them with a frequency $\nu\ (1-v/c)$; the light will appear to him redder than it really is. If he is approaching, it will appear bluer, and if his motion is oblique to the direction of the source, the change of frequency will depend on the component of his velocity in the line of sight. In the case where light is reflected from a receding mirror it has to traverse the increasing distance twice over, and so the effect is doubled, and the frequency of the reflected light is $\nu\ (1-2v/c)$. It should be said that these values are not quite precise when v is large. The Doppler effect plays a very important practical part in astronomy, for by its means it is possible to discover the velocity of stars in the line of sight, and thus for example to calculate the motion of the components of a double star which are so close together that they cannot be seen separate. It is also vital in the theoretical investigation of the distribution of energy in the spectrum. A further consequence arises in practical spectroscopy. In a hot gas some of the atoms will be approaching the spectroscope and so will give light bluer than the average, while others will give a redder light in consequence of their recession, and thus the light will never be purely monochromatic. In some experiments it is necessary to minimise this effect by cooling the gas with liquid air.

The Colours of Thin Plates.—There is no essential difference between the phenomena of diffraction and interference, but only a difference in emphasis. Thus the term diffraction is used for phenomena connected with the spreading of waves on passing through a slit, shadow formation, etc., while interference arises, as in Young's experiment, when two waves from separate but coherent sources are superposed. We shall now discuss some important cases of interference, including the explanation of Newton's rings.

We have already described Huygens' construction for reflection and refraction. When a beam of light falls on a surface part is directly reflected and part is refracted. Consider now a thin plate, say a soap-film, under the action of an incident beam of monochromatic light (fig. 5). The beam refracted at the first surface comes to the second, and part emerges, while the rest is reflected back. This second part comes back to the first face and part of it emerges, while part is again reflected. Thus, if we want to know the total amount reflected, we have to consider the compounded effects of all the waves arising from direct reflection and any number of internal reflections. Now, in order to explain the process, fig. 5 has been drawn as though the rays AP, CQ, ER . . . were separate from one another, but they will not in fact be so, for the film is supposed thin, whereas the incident beam is fairly broad. The reflected beams will therefore overlie one another and this is a case like Young's experiment in which we have to consider the phases of the various waves. If these phases agree we shall have a brilliant reflection, otherwise it will be feeble. We shall see that the phases only agree for one colour at a time, and so the film looks coloured though it is illuminated by white light. In order to see the detail of this we must examine the process of refraction somewhat more closely.

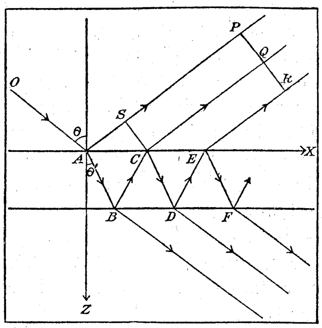

FIG. 5.—COLOURS OF THIN PLATES The total amount of light reflected will depend on the phase differences of AP, CQ, ER, and these will vary with the colour and inclination of the light

We first consider a single interface illuminated obliquely by a plane wave of light K (*see* fig. 6). This will be broken into a reflected wave L and a refracted wave M. The strengths of these can be calculated exactly in the detailed theory (they give Fresnel's sine and tangent formulae), but we do not require their values here. Let us say that, if K has unit amplitude, then L has amplitude r and M has amplitude t. We shall assume (from the more detailed theory) that there is no change of phase at the interface. We also require to consider the effect of a beam coming to the surface from the other side. Let us suppose that the reversed wave M would give a transmitted wave along K of amplitude t' and a reflected wave along N of amplitude r'. Now there is an important and very general mechanical principle, that, if all the parts of a system are simultaneously reversed in their motions, the system will retrace its course to the point from which it started. Thus, if we take a wave r along L reversed and simultaneously t along M reversed, they will give rise to unit amplitude along K reversed and no wave along N. The wave r from L gives r^2 along K and rt along N, while t from M gives tt' along K and tr' along N. We thus have the two equations $r^2+tt'=1$, $rt+tr'=0$. The last implies that r' must be equal to r, but that there is a change of phase of 180° at the interface; we can allow for it completely by simply writing $-r$ for r'.

We now return to the film of fig. 5. The reflected ray AP has amplitude r, the ray AB has t. Of this a fraction r' is reflected at B, so that tr' arrives at C and CQ has amplitude $tr't'$, while CD has tr'^2. Similarly ER will have tr'^3t' and so on. On the other side the waves emerging at B, D, F will have amplitudes tt', tr'^2t', tr'^4t', etc. We must now compare the various phases of the paths OAP, $OABCQ$, etc. Let us suppose that θ is the angle of incidence and θ' that of refraction, and that n is the refractive index. Allowing for the difference of the wave velocity in the film, the phase difference for a single pair of internal reflections will be $\frac{2\pi}{\lambda}(n.ABC-AS)$, where S is the foot of the perpendicular from C on AP. This is equal to $2\cdot\frac{2\pi}{\lambda}bn\cos\theta'$, if b is the thickness of the film; we shall denote it by 2δ. Thus if the phase at P is ϵ, that at Q is $\epsilon-2\delta$, and therefore that at R is $\epsilon-4\delta$ and so on. The whole reflected wave thus has amplitude

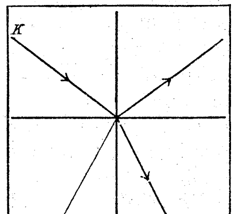

FIG. 6.—REFRACTION AT AN INTERFACE

$$r\cos\epsilon+tt'r'\cos(\epsilon-2\delta)+tt'r'^3\cos(\epsilon-4\delta)+\cdots.$$

This series is now summed and reduces, with the help of the relations between r, r', etc., to

$$\frac{2r\sin\delta}{1-2r^2\cos 2\delta+r^4}\left[-\sin(\epsilon-\delta)+r^2\sin(\epsilon+\delta)\right];$$

and the resulting intensity follows by squaring and averaging over all values of ϵ. The fraction of the incident wave reflected is

$$4r^2\sin^2\delta/[(1-r^2)^2+4r^2\sin^2\delta].$$

It can be shown similarly that the fraction transmitted is

$$(1-r^2)^2/[(1-r^2)^2+4r^2\sin^2\delta].$$

For a soap-film the coefficient r is not very large. The chief effect is when $\sin\delta$ vanishes, that is, when $bn\cos\theta'$ is any multiple of half a wave-length, for at such an angle of incidence there will be no reflection at all. Hence, when a film is lit by white light, some of the colours will be absent from the reflection, and the film will show the complementary colours. More detailed consideration than we can give here shows that these colours will not be seen well without the help of a telescope, unless the thickness of the film is very roughly of the order of twice the wave-length of ordinary light. The case of Newton's rings is very similar. The film is of air between the two glass surfaces, and the distance between these surfaces increases outwards from the point where the glasses touch, so that b passes progressively through values where there is no reflection for each colour in turn.

The Fabry and Pérot Interferometer.—The same principle of multiple reflection has been put to very important use in an instrument, the interferometer of Fabry and Pérot. Two sheets of very flat glass are set up accurately parallel, and from 1 to 5 cms. apart. The plate producing the interferences is the air between them. The characteristic of the instrument is a slight silvering of the inner surfaces of the glass, so that at each incidence nearly all the light is reflected. Now, if in our formula for reflection r is near unity, there is hardly any transmitted light at all, except when the light is very nearly incident at an angle such that $\sin\delta=0$. Divergent monochromatic light falls on one side of the plate, and only the component waves at certain definite angles can get through. A system of narrow brilliant rings will be seen with the aid of a telescope, and their radii can be used to determine the angles at which $\sin\delta=0$. An example is shown in Plate, fig. 3 and, if this is compared with Plate, figs. 1 and 2, it will be seen how much sharper the rings are in fig. 3.

The instrument has two different uses. Firstly, to measure wave-lengths absolutely, or rather to determine the length of the standard metre in terms of a more unvarying measure, the wave-length of a suitable spectral line. For this purpose the glass plates are set up several centimetres apart (it may be troublesome to get them parallel), and this distance is compared with that of the standard metre. Next it is necessary to measure the distance between the plates in terms of wave-length. The cadmium arc is the standard source of light as it gives three conveniently coloured monochromatic lines. The light from the arc traverses a prism, so that the lines are separated out, and one of them is allowed to fall on the interferometer. If the distances between the plates happens to be an exact multiple of half a wave-length, there will be a bright spot, in the middle of the telescope, surrounded by rings. More usually there will be a small ring in the middle, and, by measuring its angular radius, we can find directly the fractional part of the ratio of the plate distance to the wave-length. At first sight it would appear much more troublesome to determine the integral part as this may be as great as 100,000, but that is not so, for a relatively rough preliminary knowledge of the distance between the plates and of the wave-length can be made to yield it; and the final result is a determination of the absolute wave-length correct to 6 or 7 places of decimals.

The other use of the instrument is as a spectroscope. If a spectrum contains two lines very close together, each ring will appear doubled. The method is one of tremendous power but suffers from the disadvantage that if the two lines are not very close together one ring of the first line may fall near a different ring of the second, and it may not be easy to disentangle the meaning of what is observed. One ingenious use to which the instrument has been put is to fix the wave-length of the green "auroral" line which is given by the night sky. This is so faint that no ordinary spectroscope can be used, but its wave-length was determined with a very high degree of accuracy by means of an interferometer, the plates of which were covered with gold instead of silver, for gold specially favours the passage of green light, and so prevents the fogging of the photographic plate by the general illumination during the long exposure.

The Michelson interferometer is another instrument that can be used for the same purposes. Here a beam is divided into two by being half reflected in a slightly silvered glass plate at 45°. The two beams then go to mirrors, one of which is at an adjustable distance, and are then reflected straight back and reunited at the half-reflecting mirror. There is no multiple reflection and the fringes are therefore broad as in Newton's rings. The instrument was the first to be used in measuring the standard metre. It has another important use, for by its means it is possible to measure directly how nearly any spectral line is truly monochromatic. If the wave emitted by an atom were literally a sine-curve, this would imply that, like that curve, it started at minus infinity and continued to plus infinity (so the mere fact of switching off the light ensures that it is not one), but in fact the train of waves given out by each atom has a distinctly limited length and this can be measured by seeing how great may be the difference of paths in the two arms of the interferometer, before the interference fringes disappear. It is usually found impossible to see any fringes if this difference is more than about 70 cm., and this implies that after the atom has emitted about a million vibrations, it changes its phase arbitrarily before emitting again.

Another instrument of the same general character is the Lummer plate, in which light travels, being internally reflected, very obliquely, along the length of a glass plate silvered on both sides. All these instruments can be used for the most refined work in spectroscopy, but they all suffer from the difficulty that a single line produces a number of fringes rather close together, so that, when several spectral lines are photographed simultaneously, their fringes get mixed up in a way that is often hard to disentangle. There now exist diffraction gratings of nearly as high resolving power, which have not this complication, and the modern tendency is to use gratings for even the most accurate spectroscopic work, and to reserve the interferometer for the purposes for which it alone is suitable. (*See* INTERFEROMETER.)

DIFFRACTION

When we described Young's experiment, we regarded the two holes in the screen as themselves secondary sources of light emitting spherical waves. A similar construction was applied in Huygen's description of refraction, and may also be used in free space. We shall do this as a preliminary to describing the formation of shadows.

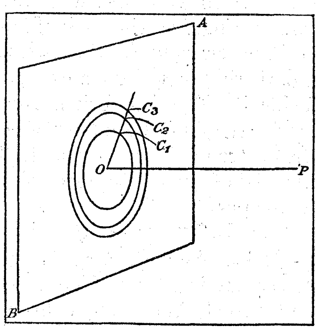

FIG. 7.—FRESNEL'S ZONES

A wave is advancing from plane AB to P. The circle round O is the first zone, and the rings outside, the succeeding ones. Zones give nearly the same effect at P, but with alternating signs

Fresnel's Construction.—In fig. 7 we have a plane wave with front at *AB* progressing towards *P*. We know of course that at *P* it will in fact be a plane wave too, with phase $\frac{2\pi}{\lambda}\cdot OP$ behind that at *O*, but we are now supposing that we can take every point in the plane *AB* as the source of secondary waves, and that the wave at *P* is due to the superposition of all these waves. In the plane *AB* describe circles round *O* of radii OC_1, OC_2 . . . etc., such that

$$PC_1-PO=\tfrac{1}{2}\lambda,\ PC_2-PO=\lambda,\ PC_3-PO=\tfrac{3}{2}\lambda,\ \text{etc.}$$

The central circle and the ring-spaces round it are called Fresnel zones, and are all of the same area. Each point is supposed to emit light, and this light will arrive at *P* with a phase depending on the distance to *P*. The phases of the waves arriving at *P* from a single Fresnel zone are all the same within half a wave-length. If we take the moment when the phase arriving from *O* is just 90°, then all the phases from points in the central zone will lie between 90° and −90°, and they will all make a positive contribution. Those from the second zone will all make a negative contribution, from the third positive and so on. We may represent the total effect as due to the sum of the effects of all the zones and write it as

$$m_1-m_2+m_3-m_4+\ .\ .\ .$$

Each of these quantities is nearly the same because the areas of the zones are equal, but they slowly diminish because the amplitude of a spherical wave varies inversely as the distance, and the outer zones are further from *P* than the central ones. To allow for this decrease we sum the zones in the form

$$\tfrac{1}{2}m_1+(\tfrac{1}{2}m_1-m_2+\tfrac{1}{2}m_3)+(\tfrac{1}{2}m_3-m_4+\tfrac{1}{2}m_5)+\ .\ .\ .\ ,$$

and then, the decrease in the *m*'s being at a constant rate, all the bracketed terms cancel, and the effect at *P* is equal to half that of the first zone. This argument is of course not a proof, but the full proof requires deeper mathematics than can be given here; for the same reason we shall not check what value must be assigned to the emission of a small area in order to give the amplitude of the reconstructed wave.

In spite of its incompleteness our argument brings out two very important facts. First, as each point of *AB* has been supposed to give out a complete spherical wave, we should expect the absurd result that there would be emission in the backwards direction towards the image point of *P* in the plane *AB*. The full solution shows that the amplitude of the secondary wave emitted at angle θ to the primary wave-front involves a factor $1+\cos\theta$, and this vanishes in the backwards direction. Secondly we should expect the phase of the wave at *P* to correspond to the average of all the phases in the first Fresnel zone, whereas we know that in fact it corresponds to that of the point *O*. To put this right (and the full theory of course proves it) we make the rule that the secondary waves are to have their phases advanced 90°, or a quarter wave-length, in front of the primary wave causing them. These rules may be regarded merely as artifices to avoid a deeper enquiry, but they have important consequences; for, when we have a thin sheet of matter in the plane *AB*, its particles will scatter the incident light in much the same way as we have been considering, but in this case neither of the two effects will come in. There will be light scattered backwards, which constitutes the reflected wave; and the light scattered forwards will be a quarter wave-length *behind* the primary wave, and this is the most primitive description of refraction.

The construction of the Fresnel zones explains the bright spot in the centre of the shadow of a circular disk. For, if the screen cuts out the first *n* zones, the wave at *P* will now be $m_{n+1}-m_{n+2}+\ .\ .\ .$, and the sum will be $\frac{1}{2}m_{n+1}$. In order to exhibit this effect the circle has to be cut with great accuracy, for if half of it is as little as a single zone wrong the amplitude at *P* will vanish. The same idea has been carried further in the construction of *zone-plates*. If we make a screen which cuts out every alternative zone, we shall get an effect proportional to $m_1+m_3+m_5+\ .\ .\ .$, which will be enormously greater than the effect without screen. Zone-plates have been made by drawing them in black on paper and then photographing down to a small scale. A brilliant spot will then be found at a point on the axis. The zone-plate illustrates wave principles admirably, but has not found any practical application.

The Formation of Shadows.—We may apply the same wave construction to explain the formation of shadows. In fig. 8, *AC* is a screen with straight edge at *C*, and we consider the light falling on different points of the screen *MN*. The wave front is supposed parallel to *ACB*, and the screen blocks out the part *AC*, so that we only have to consider the secondary waves emitted by the part *CB*. First take *P*, the geometrical edge of the shadow. If we draw the Fresnel zones for this point, they will consist of a semicircle, with C as centre, and half-rings surrounding it. Each will therefore give half the effect of the whole zone, and the resulting amplitude at P will be just half as great as if P were fully illuminated. The corresponding intensity is thus quarter as great. For a point Q we make the Fresnel construction starting at C; as Q moves away from P the sizes of the zones diminish steadily, and we therefore conclude that the intensity falls steadily from $\frac{1}{4}$ to zero. For a point R outside the shadow we make the construction in the way we did before for free space. There will then be a circle surrounded by rings, but the line through C cuts across them in such a way that some are incomplete. Suppose that R is just so far from P that the central circle is complete but is touched by the line C. Then the central zone gives its full contribution, but the second gives less than its full contribution, as do all the later ones. Consequently there is less to subtract than usual from the central zone and the light at R will be actually brighter than if there were no screen. Similarly if the circle and the first ring are complete, but the second ring is cut by the line C, the second ring will give a diminished positive contribution and the light will be fainter again. Thus outside the shadow there are a series of alternating maxima and minima of intensity gradually fading into uniform illumination at a distance from the shadow. These light and dark bands are known as diffraction fringes.

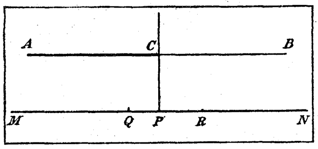

FIG. 8.—THE FORMATION OF SHADOWS
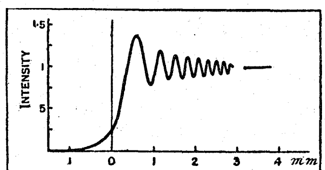
AC cuts off the light from part of the screen MN; P is the geometrical edge of the shadow, and the actual illumination in its neighbourhood is shown in fig. 9

The scale of the phenomenon depends on both the wave-length of the light λ and the distance CP. The intensity at a point R will depend on the numerical value of $PR\sqrt{\cdot CP}$. For example if CP is 1 metre and $\lambda = 5\times10^{-5}$ cm. for yellow light, the first maximum and first minimum will occur at distances 0·061 cm. and 0·094 cm. outside the geometrical edge, and will have 1·37 and 0·78 of the intensity of the incident wave. Fig. 9 shows how the intensity changes near the edge of the shadow. When the incident light is white the corresponding effect can be calculated by the superposition of all the colours; at the point of geometrical shadow the light will again be white and of quarter intensity and outside this there will first be a blue fringe. A similar process can be applied to work out the illumination due to a slit. If the slit is many wave-lengths wide it can be regarded merely as two straight edges, while if it is only a small fraction of a wave-length there wil be no shadow at all, but a uniform illumination. For intermediate cases there will be a rather complicated succession of fringes depending on the ratios of the three quantities, wave-length, breadth of slit and distance of screen. In any given case the results are easily calculable.



FROM SCHUSTER AND NICHOLSON, "THEORY OF OPTICS" (EDWARD ARNOLD & CO.)
FIG. 9.—THE EDGE OF A SHADOW
Showing how illuminative intensity rises from O inside to unity outside

The Fraunhofer Diffraction Phenomena.—There is another way, due to Fraunhofer, in which diffraction may be studied; this is in fact more important than Fresnel's in the theory of optical instruments. In this method parallel light again falls on a slit or hole, but, instead of observing the illumination on a screen, the light is now observed in a telescope focussed for infinity. The essential purpose of a telescope is that it brings all the rays going in a given *direction* into focus at a *point;* at this point a photographic plate may be placed, or alternatively the real image may be viewed with the help of a magnifying lens. The function of the telescope is thus to convert a direction into a point, and incidentally to magnify the scale. (Apart from this magnification it would be possible to see the Fraunhofer diffraction by looking at the slit with the naked eye; but the eye must be focussed for infinity and not for the slit, and this is not easy.) We must therefore find the intensities of the waves passing through a slit in various directions.

In fig. 10, AB is a slit, and we require to know what intensity goes at angle θ into the direction AM. We break up the wave at the slit into secondary waves. That arising at P has to go a distance $PR = AP\sin\theta$ further than that from A. If the phase of the wave from A is ϵ, that from P is $\epsilon - \frac{2\pi}{\lambda}x\sin\theta$, where $x = AP$. For a slit of breadth l the whole effect will be

$$\int_0^l \cos\left[\epsilon - \frac{2\pi}{\lambda}x\sin\theta\right]dx.$$

If this is integrated and then squared and averaged, we find the intensity proportional to

$$\left[\sin\left(\frac{\pi}{\lambda}l\sin\theta\right)\Big/\left(\frac{\pi}{\lambda}l\sin\theta\right)\right]^2.$$

The form of the curve $y = \sin^2 x/x^2$ is shown in fig. 11, so that to deduce what will be seen in the telescope we only require to equate x with $\pi l\sin\theta/\lambda$. Then if f is the focal length, the image corresponding to θ will be formed at a distance approximately $f\sin\theta$ from the axis of the telescope. From the curve we see there is a very strong maximum at $\theta = 0$, and that no light goes in the directions given by $\sin\theta = n\lambda/l$, that is, when BS, in fig. 10, is any multiple of the wave-length. About half way between these directions of no light there are secondary maxima, which are much weaker than the central one; even the first is less than $\frac{1}{20}$ of it. When the slit is broad the whole figure will be crowded close together. We must also consider narrow slits; *e.g.*, if the slit is exactly one wave-length broad the first zero will be at 90°; in any case nothing beyond that angle could be observed; if it is two wave-lengths broad, the first zero will fall at an angle of 30° and there will be a secondary feeble maximum at an angle of about 50°.

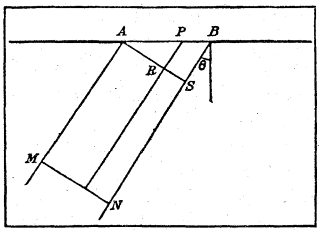


FIG. 10.—DIFFRACTION BY A SLIT

A similar construction can be applied for a hole as well as for a slit. Plate, fig. 5 shows the diffraction pattern given by a small rectangular hole. The pattern is broad in the direction in which the hole is narrow, and *vice versa.* In the case of a circular hole the pattern consists of a bright central circle surrounded by fainter rings, as shown in Plate, fig. 4. If the hole has radius R and the telescope focal length f, the bright centre is surrounded by a dark ring of radius $0{\cdot}61\times f\lambda/R$, and $\frac{5}{6}$ of the total light falls inside it. The first bright ring has radius $0{\cdot}82\times f\lambda/R$ and at its brightest point the intensity is only about one sixtieth of that at the centre of the central spot. The diffraction pattern of a circular hole is of great importance in connection with the theory of telescopes.

The Diffraction Grating.—A diffraction grating may be made by spacing a large number of slits parallel to one another at regular intervals. The general character of its action is easily understood. When monochromatic light falls on it each slit gives out a wave on the further side. For a certain direction the wave from the second slit will be exactly one wave-length behind that from the first and will reinforce it, as will all the waves from the other slits. If a is the distance between slits (measured from centre to centre), this reinforcing will occur at angle θ where $\sin\theta = \lambda/a$. This is called the spectrum of the first order. The spectrum of the second order arises when the wave from the second slit is two wave-lengths behind that from the first; its position is given by $\sin\theta = 2\lambda/a$. A similar process gives the higher orders also.

In order to discuss the grating in detail we take p slits each of breadth l. Their combined effect can be calculated in the same way as for a single slit by taking integrals from 0 to l, from a to $a+l$, $2a$ to $2a+l$, etc., and adding all together. When the expression has been summed, the intensity is formed from it and found to be as expressed in the formula on the opposite page.

$$I=\left[\frac{\sin\left(\frac{\pi l}{\lambda}\sin\theta\right)}{\frac{\pi l}{\lambda}\sin\theta}\right]^2\left[\frac{\sin\left(p\frac{\pi a}{\lambda}\sin\theta\right)}{\sin\left(\frac{\pi a}{\lambda}\sin\theta\right)}\right]^2$$

The first factor is exactly that which we found for a single slit. For a grating, l is usually small, so that this factor does not vary rapidly with the angle θ. The second factor is the important one, especially when p is a large number. The curve

$$y=\sin^2 px/\sin^2 x$$

has ordinate usually of the magnitude of about unity, but has very strong maxima of height p^2 at the values $x=0, \pm\pi, \pm 2\pi, \ldots$ etc. Thus the grating gives maxima at $\sin\theta=0, \pm\lambda/a, \pm 2\lambda/a, \ldots$ etc., the spectra of the various orders. In the neighbourhood of each of these the form of the curve is the same. Considering the case $x=0$, we can replace $\sin x$ in the denominator approximately by x and so have the curve of fig. 11. Thus each spectrum will give a pattern composed of a brilliant centre, and then feeble secondary maxima separated by darkness. The first darkness occurs when $x=\pi/p$, and this implies that in the spectrum of the nth order the first zero is at angular distance $\frac{1}{np}\tan\theta$ from the maximum. Since the second factor in I is the same for all orders the brilliancy of the different spectra will depend on the first factor. It may happen that this factor will entirely extinguish some orders; thus, if $l=\frac{1}{2}a$ there will be no even orders at all.

After the mirror and lens, the grating is the most important of optical instruments. In a transmission grating, lines are ruled on glass with a diamond. They are very fine and may be as close together as 5,000 to the centimetre. The cuts in the glass do not of course actually make it opaque, so that the grating is not really a set of slits, but they give it a periodic character which is all that is required. The second factor in I holds, but the first is invalid. Consequently the intensities in the different orders may vary greatly and in a way often unpredictable, as they depend on the shape of the cutting edge of the diamond. It has even been possible to prepare gratings in which nearly all the intensity goes into a single spectrum.

Let us suppose that we send a mixture of colours through the grating. Each colour in the light will produce its own set of spectra. In the zero order the rays are not bent, whatever the colour, and so, for $\theta=0$, the mixture will be unaltered. Turning to the side we shall first see the violet of the first order, then blue, green, yellow and red, and then darkness, for the second order of the violet (4,000 Å.U.) falls further out than the first order of the red (7,000 Å.U.). This isolation is true only of the first order (and even then only by not considering ultra-violet light); the second order red is overlapped considerably by the third order blue, and in the higher orders the spectra overlie one another completely. To eliminate this difficulty special devices have to be used, such as a rough preliminary sorting of the spectrum with a prism; or else a prism can be set with edge perpendicular to the grating lines so that it shifts the blue lines to a different level from the red. The overlapping of the spectra has been put to use in comparing wave-lengths with accuracy. Thus, if a spectrum contained a blue and a red line, such that the third order blue fell exactly on the second order of the red, we should know that the wave-lengths were exactly in the ratio 2:3. If they fall fairly close the ratio can still be fixed with accuracy, without a very precise knowledge of the grating constant. In this way a set of standard wave-lengths throughout the spectrum were first determined, but later the interferometer replaced the method.

FIG. 11.—CHART SHOWING FRAUNHOFER DIFFRACTION BY A SLIT
The curve $y=\sin^2 x/x^2$. The y ordinate measures the intensity of light at angle O where sin O is proportional to x

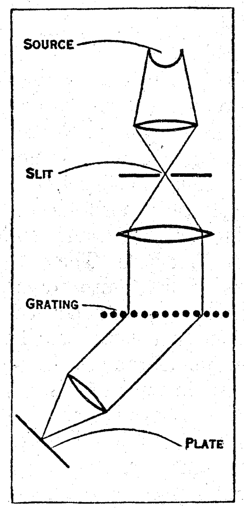

FIG. 12.—DIAGRAMMATIC VIEW OF A SIMPLE GRATING SPECTROSCOPE

For the installation of a grating spectroscope (*see* fig. 12) we require parallel light. Since most sources of light cover some area it is usual to focus the source on to a fine slit and use this slit as a secondary source. The light diverges from the slit and is passed through a collimating lens. Such a lens would turn the light from a point source into parallel light; for a slit the emergent rays will all lie in planes through the line of the slit, and, if the lines of the grating are parallel to the slit, the obliquity of the rays will not affect the diffraction. The parallel wave next comes to the grating and is diffracted. A lens is set at a suitable angle to catch the desired part of one of the spectra, and the wave is focussed on to a photographic plate. When monochromatic light is used a narrow line will appear, which will correspond in breadth to the breadth of the slit plus the breadth of the diffraction pattern that would be produced by an infinitely narrow slit.

In practical work of the highest class much complication is saved by having the grating ruled directly on a concave mirror, for this focusses the slit straight on the plate without the intervention of any lenses. It will readily be believed that the making of large gratings on this principle is a very difficult matter; it was most successfully overcome by Rowland who made a number which even now remain the most useful instruments in spectroscopy. The manufacture depends chiefly on the construction of a long screw of very regular pitch, to shift the diamond a definite distance after each line has been ruled. If the diamond should break, it is exceedingly difficult to recover the line with a new one, and all the work is wasted. A troublesome complication arises with some gratings if the screw has a systematic irregularity. Suppose for example that it rules every tenth line a little out of place. Then the true periodicity of the grating is the group of ten lines, and what we call the first order is really the tenth, though in view of the approximate regularity it will be far more brilliant than the first nine. Nevertheless in the study of a spectrum it may be that some of the strongest lines give a perceptible image corresponding to one of these lower orders and such an image might be mistaken for a real line. Images of this type are called "ghosts" and in accurate spectroscopic work it is very necessary to know what ghosts may be possessed by the grating in use.

The Nature of White Light.—It has been customary since the time of Newton to say that white light is compounded out of all the colours, but the diffraction grating suggests quite another point of view. Let us imagine that the incident light is a plane wave consisting of a single thin pulse. Each slit of the grating diffracts this pulse into all directions, and, if we observe from a given direction, we shall receive in turn the pulses which have come through each slit. They will be evenly spaced and further apart, the broader the angle from which we observe. At each position θ there will be something very like a monochromatic wave; more precisely it is a periodic wave composed of wave-lengths $a\sin\theta$ and all its submultiples; *i.e.,* out of the superposition of light of the first, second and higher orders appropriate to the angle θ. Regarding the matter in this way, we have a perfect right to say that the coloured light has been *created* by the spectroscope. This is a point of view well worth keeping in mind, for in many branches of physics we determine some property by an experiment and then attribute it to the system, even in cases where the experiment is not done, overlooking the fact that it may be the experiment itself that has evoked the property. In the present case the two points of view are reconciled by the fact that the pulse can be analysed mathematically into an integral composed of lights of all wave-lengths, and in this sense it is correct to say that white light contains all the colours, even though it is unnatural to attribute any periodic quality to a single pulse.

It may appear that the argument is special to the case of resolution by a grating, and that the spectrum of white light formed by a prism proves that the colours were there originally. Closer examination shows this to be wrong, though the argument is not so simple; by considering the property of group-velocity it can be shown that the prism will convert a single pulse into successions of pulses differently spaced for the different directions, but it would take too long to develop the idea further here. The outcome of the argument is that the analysis of light into wave-lengths is chiefly a matter of convenience, largely mathematical convenience; but this is enhanced by the fact that gases usually emit spectra consisting of very nearly pure monochromatic lines, so that it turns out to be also a practically important analysis.

The Resolving Power of Spectroscopes.—It is of great importance when working with any optical instrument to know its resolving power. If two spectral lines are sent simultaneously through a grating, the resolving power determines how close their wave-lengths may be without our confusing them. So too the resolving power of a telescope tells us what distance there must be between two stars in order that we may be sure that they are two and not one. Resolving power must be distinguished from magnification, for, as we shall see, it is possible to magnify the images indefinitely, but the only effect is to make a small indistinct image into a large indistinct image. Diffraction theory determines the resolving power of all instruments.

We will consider the resolving power of the grating, and must first distinguish it from the *dispersion*. If the lines are ruled very close together the spectra will be at wide angles, and so the spectral lines we try to resolve will be far apart; they will have a large dispersion, but, if the lines themselves are broad, it will not help the resolution. First we remember that the breadth of each line is affected by the breadth of the spectroscope slit, so that two lines may give overlapping images on this account. We need not consider this, as it may be obviated, by so narrowing the slit, that its breadth is less than the breadth of the diffraction pattern that would be given by an infinitely narrow slit. Let us suppose that we have two lines of wave length λ and $\lambda+\delta\lambda$, say the two D lines of sodium at 5,896 and 5,890 Å.U., and enquire under what conditions they can be

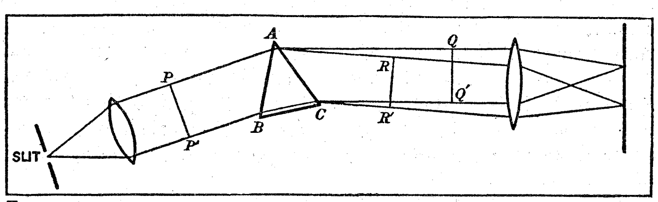

FIG. 13.—PRISM SPECTROSCOPE. THE POWER OF RESOLVING TWO SPECTRAL LINES DEPENDS ON THE LENGTH BC

separated. In the nth order spectrum they appear at positions $\sin\theta=n\lambda/a$ and $\sin(\theta+\delta\theta)=n(\lambda+\delta\lambda)/a$, so that, approximately,

$$\delta\theta=n\delta\lambda/a\cos\theta.$$

This is the dispersion of the lines, *i.e.*, the distance between the centres of the lines. Now, if the diffraction patterns of the lines are such that each main peak (of fig. 11) falls separate from the other, we can certainly distinguish that there are two lines. We could probably do so if they were a good deal closer and overlapping, but not if they were as little apart as one-tenth of the breadth of the peak. All that we require is a rough measure, and we shall take the condition that one peak falls on the first zero of the other. We saw that the first zero falls at a distance $\frac{1}{np}\tan\theta$ from the centre, and for limiting resolution this must be equal to the dispersion of the two lines, so that $\delta\lambda=\lambda/np$. The resolving power is usually defined as $\lambda/\delta\lambda$, where $\delta\lambda$ is the difference of wave-length of two lines that can just be resolved; we see that it is equal to np. The important point is that it in no way depends on the dispersion, but, for a given order of spectrum, only on the number of lines, no matter what their spacing. For example, if we want to separate the sodium lines in the first order we must have 1,000 lines, if in the second, 500. If the grating is coarse the lines may fall very close together, but a powerful telescope can still separate them; if there are fewer than 1,000 lines the telescope will merely magnify a blurred image.

We may compare this with the resolution of the Fabry-Pérot interferometer. The plate being of air, we take the refractive index as unity, and, as the incidence is nearly perpendicular, we can replace $\cos\theta'$ by $1-\frac{1}{2}\theta^2$. If $s\lambda=2b$ for one of the lines where s is a (large) integer, there will be a bright spot in the centre and the next ring will have angular radius $\sqrt{\lambda/b}$. If there is another line of wave-length $\lambda+\delta\lambda$, its innermost ring will have radius $\sqrt{s\cdot\delta\lambda/b}$. Though the fringes are fairly sharp, the opacity of the silvering of the plates sets a limit to their sharpness, and we shall not resolve the lines unless the radius of the inmost ring of the second line is a fairly large fraction, say a tenth, of that of the second ring of the first line. This shows that the resolving power should be about ten times as great as s; if the plates are 5 cm. apart it will be about 1,000,000 for visible light.

It is also interesting to consider the resolving power of a prism spectroscope (*see* fig. 13). This instrument separates lines by means of the difference in the refractive index of the glass for different colours. By an argument from geometrical optics, which we shall not give, it may be shown that the angular separation of the two lines is $dn.l/b$, where dn is the difference of their refractive indices, b is PP' the breadth of the beam, and l is BC the base of the prism. The lens will focus a beam of breadth $QQ'=b$ to a line of breadth λ/b, and the two lines will therefore be resolved if $l>\lambda/dn$. Thus, to obtain good resolution the most important factor is a great thickness of glass, and this severely limits the use of prism spectroscopes. Taking the value of dn for typical glass, we can calculate that 1 cm. will resolve the sodium lines, but if we require to resolve two lines for which $\lambda/\delta\lambda$ is half a million, as is possible with an interferometer or with a grating of half a million lines, we should require 5 metres of glass, and even if it were otherwise practicable such a thickness would be far too great to let any light through.

The Resolving Power of Telescopes.—The principal of the lens is usually discussed by geometrical methods (*see* OPTICS), but it is quite simple to work it out with the wave theory. In fig. 14 plane waves fall perpendicularly on the lens in the beam, PA,QC. The central ray through BE is retarded in the glass, but not so the extreme rays at A and C. The focus F is the point where all the secondary waves from AEC are in phase; the retardation of the central ray is balanced by the longer path of the extreme ones. The waves at AB are in phase, and the phase changes from there to F are given respectively by AF and $n{\cdot}BE+EF$, where n is the refractive index. Let BE be d, AB be r and EF be f, supposed much larger, then we have

$$d(n-1)+f=\sqrt{(f^2+r^2)},$$

whence, approximately, $f=\frac{r^2}{2d}\;\frac{1}{n-1}$, which determines the focal length of a plano-convex lens in terms of its curvature. If another set of waves at a small angle θ falls on the lens, their focus F' can be found by the consideration that the waves from A and C must be in phase, while F' is near F in a plane at right angles to the axis of the lens. We thus find that $FF'=f\sin\theta$, a familiar result in geometrical optics.

Supposing that the two waves are from stars, we enquire under what conditions they will be resolved. The image of the first star at F is of course not a point because of diffraction. We can roughly estimate its size by the consideration that there will be points near F for which the waves from A and C and all intermediate points, though not perfectly in phase, are so little out of phase, that there will be still a marked intensity. This is a question of the diffraction image of a circular hole and the radius of the central spot is $0{\cdot}61f\lambda/r$. If the centre of the image of the second star is much closer than this, we shall only have one bright spot and shall not distinguish that there were two stars. Thus the angular distance that can be resolved is $0{\cdot}61\lambda/r$. Taking visible light and measuring the radius of the telescope in millimetres this gives

$$\left(\frac{1{\cdot}17}{r}\right)'.$$

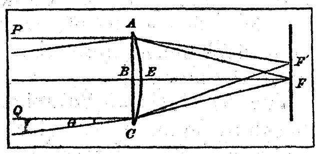

FIG. 14.—THE FOCUS OF A LENS
The power of resolving the images F and F′ depends on the size of the lens AC and not on the focal length BF

The important thing to notice is that the resolving power in no way depends on the magnification, but only on the diameter of the object glass. If the telescope has a short focal length the magnification will be small; but as long as the diameter is large the resolution will be good, and the small magnification can be overcome by the use of a stronger eye piece. This result requires one qualification, for we have assumed that the whole object glass is operative in bringing rays to the eye. When the magnification is not very great it may happen that the pupil of the eye is the effective limitation and not the object glass, and in such cases the resolving power will depend on the diameter of that part of the object glass from which light enters the pupil.

The tendency to make larger and larger telescopes is to be attributed partly to the fact that they collect more light, but much more to the increased resolving power. An extreme example is given by the measurement of the diameters of stars. Stars are all so distant that no existing telescope could hope to resolve the separate parts of their surface, and the disc seen is never perceptibly larger than that which would be produced by a geometrical point. But if we could have a telescope 50 ft. in diameter the resolving power should be sufficient to show the disc of a large star in the same way as an ordinary telescope does for a planet. It is not of course practicable to make such a telescope, but it is also not necessary; all that is required is two little pieces of such a telescope at the points A and C in fig. 14. In principle this is the way in which it has been found possible to measure the diameter of Betelgeuse and a few other stars.

The eye is an instrument similar to the telescope. Taking the pupil as 2 mm., the same calculation shows that its resolving power should be $0{\cdot}42'$. The actual limit, about $1'$, is not very different, and is no doubt affected by the structure of the retina. A similar limit would apply for any eye constructed on the same principle as man's; but insects' eyes are compound, being composed of a very large number of very small independent facets. There can be no phase relations between the separate facets, so that the resolving power can only depend on the size of each separately. It thus seems improbable that an insect can discriminate between objects less than some degrees apart.

The resolving power of the microscope presents a different problem from that of the telescope, because in the microscope we observe non-luminous objects illuminated usually by parallel or not very convergent light. The discussion of the theory will be found under MICROSCOPE, and we here only give the result. If the lens can receive light from the object over a range of 180° (and for a good microscope it very nearly does), then some rough impression of form can be detected for an object of the size of half a wave-length. By immersing the object in a refractive medium the wave-length is shortened and the resolution improved, and it may be further improved by the use of ultra-violet light.

POLARIZATION AND ELECTROMAGNETIC THEORY

In our review of the history of optics we described some of the earlier work on polarization, and we must now make its character clearer. The phenomena of interference and diffraction were all explained by regarding the light as a wave, leaving it entirely open what it is that vibrates and how it does it. In fact all that we have so far said would, with suitable changes of scale, be just as true for sound as for light. But when we come to the phenomena of double refraction, this is not so; they are only explicable if the vibrations are transverse. Though we saw that, in spite of many attempts, no material model could be found which would carry waves in the way that aether does light, still it is quite possible to visualize polarization. A string stretched horizontally may vibrate in a vertical or horizontal plane or simultaneously in both; at any instant a point of the string is displaced from its position of rest in a direction perpendicular to the line of the wire, and this position can be indicated by drawing a line in the direction and of the length of the displacement. When a light-wave is travelling through space, we can also represent it at any point and time by drawing a line in a definite direction and of a definite length. It should be explained that, unlike the case of the string, here the length is only diagrammatic and can be represented on any scale, as long as we are consistent and adopt the same scale for other points. This line is called the light-vector, and the wave is said to be transverse, because the light-vector is always found to be at right-angles to the direction of the wave, that is to say it lies somewhere in the plane of the wave-front. The reason for this will appear when we come to the electromagnetic theory; we shall first describe the main properties of polarization without justifying them.

Types of Polarized Light.—Suppose that we have a wave of plane monochromatic light advancing perpendicular to the paper. At any point in the paper we draw the light-vector, and it will go through a series of changes, returning to its original value in the period of the waves. We can represent any motion by giving the x, y co-ordinates of the end of the light-vector, and for monochromatic light these must be sine-functions of the time. If ν is the frequency we therefore take

$$X = A\cos(2\pi\nu t - \alpha), \quad Y = B\cos(2\pi\nu t - \beta)$$

as the general description of the light. We first consider a few special cases. If $B = 0$ we have a vibration in which the vector always lies in the direction of x and ranges between the values $\pm A$. This we call *plane polarized* in the direction x. Similarly if $A = 0$ we have light plane polarized in the direction y. If we have $\alpha = \beta$, we see that at any time $Y/X = B/A$, so that again we have plane polarized light, in direction arc $\tan B/A$ and with amplitude $\sqrt{(A^2+B^2)}$. Next consider the case $B = A$, $\beta = \alpha + \frac{\pi}{2}$. Then $X^2 + Y^2 = A^2$, so that the vector describes a circle; this is therefore called *circularly polarized* light. In the general case we can find the locus of the light-vector by eliminating t and get

$$\frac{X^2}{A^2} + \frac{Y^2}{B^2} - 2\frac{XY}{AB}\cos(\alpha - \beta) = \sin^2(\alpha - \beta).$$

This is an ellipse of which the axes are determined as to position and magnitude by A, B and $\alpha - \beta$. The most general type of light is therefore called *elliptically polarized*, and we recognize our previous types as degenerate ellipses.

We next consider the propagation of such waves, that is to say, the phase relations of the light-vectors for different positions of the wave-front. Our wave is now written as

$$X = A\cos[2\pi\nu(t - z/c) - \alpha], \quad Y = B\cos[2\pi\nu(t - z/c) - \beta],$$

and the character of the polarization is the same for all values of z, as it will depend on A, B and

$$(2\pi\nu z/c + \alpha) - (2\pi\nu z/c + \beta) = \alpha - \beta.$$

Next we take t as fixed and consider the way the light-vector is arranged for various values of z. We may liken it to the stretched string. If $B = 0$ it will be in the shape of a sine-curve in the plane of xz with wave-length c/ν, and similarly whenever $\alpha = \beta$, though for a different plane. If $\beta = \alpha + \frac{\pi}{2}$ and $B = A$, the locus is a screw, or helix, of radius A and pitch equal to the wave-length c/ν. If the axes are right-handed (so that a man standing with his head towards z has x to his right and y to his left), then the screw may be seen to be left-handed. This is therefore called *left-handed circularly polarized* light. If we take $\beta=\alpha-\frac{\pi}{2}$ instead, we should get a right-handed screw. The distinction between right and left-handed circularly polarized light is physically very important, as it plays a leading part in the phenomenon of gyration. In the case of elliptically polarized light the locus of light-vectors may be described as a flattened screw; it may be either right- or left-handed again, but the question is not so important physically. This suffices to describe the form of the waves, and it only remains to define the intensity. At any point this is given as the average value of the square of the light-vector; in the cases we have considered it is the average of X^2+Y^2. When the waves are travelling in an arbitrary direction instead of along z, we may have three components of the light-vector, and in such a case $X^2+Y^2+Z^2$ is to be averaged over the time.

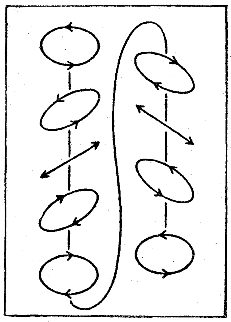

FIG. 15.—ELLIPTICALLY POLARIZED LIGHT

We must also consider the nature of ordinary unpolarized light. This has no "sides" and is symmetrical about the direction of propagation, and in this it is like circularly polarized light; but we shall see that circularly polarized light can easily be converted into plane polarized, whereas for ordinary light this is not possible, so the explanation of its symmetry must be found in another way. If the light is *rigorously* monochromatic, the phases of the components of the light-vector are maintained for ever, and such light must therefore be polarized, either plane, circularly or elliptically. In nature, however, no light is rigorously monochromatic, for the Michelson interferometer fails to show interference for path differences of more than a million wave-lengths, and this enables us to explain unpolarized light as being polarized light of which the direction is changed frequently. We suppose each atom to emit a polarized monochromatic wave which lasts for a time corresponding to a million wave-lengths, and then changes and emits one of a different polarization. The length of time of each separate type is so short that we cannot distinguish them, but merely get an average of all the different types and this average will be symmetrical about the direction of propagation.

In describing plane polarized light we have said that it is polarized in the direction x when the light-vector vibrates along x. Unhappily there is some confusion in the terminology used. When polarization was first discovered the convention was adopted that the light of the *ordinary* ray in double refraction is polarized *in the plane* through the axis of the crystal and the direction of propagation. It later appeared that the light-vector must be perpendicular to this plane, so that the old convention would have described the light as polarized in the plane of yz, which we call polarized in the direction x; and it was even sometimes loosely referred to the direction y alone. For most optical effects the behaviour is determined by the direction of the vector and not by the direction of propagation of the wave, so that it is practically inconvenient to mention two directions when one would do. The modern tendency, which we shall adopt, is to describe plane polarized light by the direction of the light-vector; thus, in double refraction we shall say that the ordinary ray is polarized at right angles to the crystal axis. Some confusion is unavoidable because the term plane polarized (instead of line polarized) is too deeply implanted to be changed, but we can avoid ambiguity by saying that light is plane polarized in some *direction,* instead of in some *plane,* and the direction is then the normal to the plane which was formerly used.

Double refraction is not the only way in which polarization is produced, and we shall discuss its other occurrences in detail later. Chief among them is reflection at a transparent surface set at a suitable angle. At other angles there is an incomplete polarization, which is sometimes very troublesome in experiments; for as light passes through any system of lenses or mirrors, it is almost impossible to prevent its becoming polarized, and this may easily obscure the study of its original polarization. We may also mention the polarization of scattered light, exemplified in the light of the sky. Again, in the diffraction of light by a slit, the two components behave rather differently, and so the light is slightly polarized; the theory we have given is sufficiently correct for small angles and we shall not consider the modification that is rigorously required. Perhaps the most interesting occurrence of all is in the Zeeman effect (*q.v.*). Here the spectral lines of an atom become displaced and split when the atom is in a strong magnetic field, and the split components are polarized in certain definite ways, from which much information can be obtained about the mechanics of the atom.

The Analysis of Polarized Light.—Polarization is chiefly, though by no means exclusively, studied by using the property of double refraction in crystals. We discuss this below, but it will here suffice to say that when a wave goes through a crystal its light-vector is resolved in two directions, mutually perpendicular and perpendicular to the direction of propagation, and the components in these directions have different wave-velocities. Suppose that we have a plate with parallel faces, and that the wave is going through it along z, while the two special directions are x and y. In such a plate the light-vector will be given by

$$X=A\cos[2\pi\nu(t-z/a)-\alpha],\quad Y=B\cos[2\pi\nu(t-z/b)-\beta],$$

where a and b are the wave-velocities for the directions x and y. If the incident light is plane polarized along x or y the wave will go through unchanged, but if it is polarized, say at angle γ on entering the plate at $z=0$, we shall have $\alpha=\beta$ and $A=C\cos\gamma$, $B=C\sin\gamma$. If the plate is of thickness l the light will emerge from the farther side as

$$X=C\cos\gamma\cos[2\pi\nu(t-l/a)-\alpha],\quad Y=C\sin\gamma\cos[2\pi\nu(t-l/b)-\alpha],$$

and so X and Y are no longer in the same phase, and the light is now elliptically polarized. Fig. 15 shows diagrammatically how this transformation comes about. If we had started with elliptically polarized light, the emergent light would in general be elliptically polarized, but in a new direction. In special cases it might become plane polarized, and this explains the principle of an important instrument used in the study of polarized light, the *quarter-wave plate.* A quarter-wave plate is made by taking l so that $2\pi\nu l/a-2\pi\nu l/b=90°$. If the incident light is elliptically polarized, with the axes of the ellipse along x and y, we may write it as

$$X=A\cos(2\pi\nu t-\alpha),\quad Y=B\sin(2\pi\nu t-\alpha).$$

After passing through the quarter-wave plate the emergent light will be

$$X=A\cos(2\pi\nu t-\alpha'),\quad Y=B\cos(2\pi\nu t-\alpha'),$$

and it is now plane polarized. As a case of special importance, if the incident light is circularly polarized, the emergent will be plane polarized at 45 degrees to the x direction, and its right- or left-handedness will be indicated according to whether the direction is between x and $+y$ or x and $-y$. Quarter-wave plates are usually made of mica, which is easily cleft into thin sheets. These sheets exhibit a rather weak double refraction, so that a quarter-wave plate is not inconveniently thin. As mica is rather soft, it is often mounted between two sheets of glass and scratches on these indicate the direction of the crystal axis.

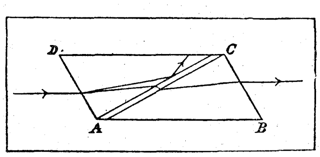

FIG. 16.—THE NICOL PRISM

We have seen how any type of polarized light can be turned into plane polarized, and it remains to consider how this can be investigated. The standard instrument is the nicol (*see* fig. 16). A rhomb of calcite, which is about 3 times as long as it is broad, is sawn across the line AC, and, after the cut has been polished, its two faces are cemented together with Canada balsam. The two ends AD and BC are also cut to a slightly different angle (68° instead of 72°). A wave, entering parallel to the prism, is doubly refracted, and, because of the slope of the face AD, the waves go in somewhat different directions, the ordinary wave being most bent. Canada balsam has refractive index intermediate between those of the ordinary and extraordinary waves, and, as the ordinary wave meets it very obliquely, it becomes totally reflected and so falls on the side *DC,* which is blackened so as to absorb it. The extraordinary wave passes freely through, and so the emergent light is plane polarized. A nicol will polarize light over a certain range of angles of incidence. The limits are set by the condition that on one side both rays are reflected at *AC* and lost, and on the other that both are transmitted; under favourable conditions the range of angles may be 25°. A typical experiment with polarized light involves the use of two nicols. The simplest example is the direct use of two "crossed" nicols. The first produces polarized light by absorbing one component; the second is placed with its axis in the same line as the first but is twisted round through 90°, so that the wave which was extraordinary wave in the first nicol is now the ordinary and so is absorbed. This device has been used for secret signalling. The signaller rotates his nicol through 90°, and though to the naked eye his lamp appears to burn steadily, if it is viewed through a fixed nicol it will go out.

When we want to study the polarization of elliptically polarized light, it must first be made into plane polarized light by some means, and then extinguished by a nicol. There will always be two adjustments to be made, because the light has two parameters, the ratio of the axes of the ellipse and their position. There are two chief methods used. A quarter-wave plate may be rotated until it lies along the principal axis, so that it renders the light plane polarized; the light can then be extinguished by a nicol. The position of the quarter-wave plate fixes the axes of the ellipse, and the angle it makes with the nicol gives the ratio of the axes. This method is specially convenient if we already know the axes of the ellipse, as is the case in some important experiments; in other cases the simultaneous making of two adjustments is troublesome. The alternative instrument is called the *compensator.* In this the analysis is in two fixed perpendicular directions, instead of along the axes of the ellipse, and we measure the relative lengths of the components of the light vector in those two directions and their phase-difference. The essential part of the compensator consists of two thin wedges of quartz, which is a rather weakly doubly refracting crystal. One wedge is cut so that the crystal axis lies in a line parallel to the edge, and the other so that it is at right angles to it and in the face; (*see* fig. 17, where the lines and dots indicate the directions of the axes). Incident light will be broken into two components in the first wedge, of which one will have a higher phase-velocity; but on entering the second this will change about, so that, if the thicknesses are exactly equal as at the centre *A,* there will be no changes of phase. Thus, incident plane polarized light will emerge as plane polarized at *A.* At any other point *B* this will not be so, because the light will have gone further through one crystal than through the other. If elliptically polarized light is incident, there will be places where it is plane polarized, and so, if we use an analyzing nicol set at the proper angle, we may observe the field crossed by dark bands. If one wedge is screwed over the other by means of the micrometer screw *M,* the bands will shift because of the changing differences in the thickness of the wedges. The reading consists in seeing how far the screw must be turned to bring one of the bands to the centre. This measures the phase-difference in the components of the light vector along and across the wedge, while the ratio of their amplitudes is given by the setting of the nicol.

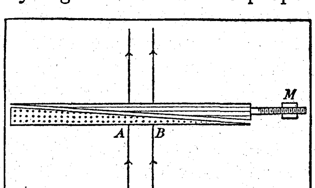

FIG. 17.—THE COMPENSATOR
The dots indicate the crystal axes of the two quartz wedges, and M is the micrometer screw

THE ELECTROMAGNETIC EQUATIONS

It was Maxwell who made the great discovery that the equations governing the behaviour of electric waves are equally applicable to light, and this provides a strict formulation for the whole theory, including of course polarization. For the derivation of the theory of electric waves *see* the article ELECTRICITY; we shall here take it as given and show how it applies for light.

Consider first the case of free space. At every point there may be an electric force $\mathbf{E}$ and a magnetic force $\mathbf{H}$. Each has both direction and magnitude and they can be most conveniently described by the components E_x, E_y, E_z and H_x, H_y, H_z along the directions x, y, z. The vector notation is well adapted to expressing their relations. In this notation

$$\frac{\partial E_x}{\partial x}+\frac{\partial E_y}{\partial y}+\frac{\partial E_z}{\partial z}$$

is written div $\mathbf{E}$ and called the divergence, while the three quantities

$$\frac{\partial E_z}{\partial y}-\frac{\partial E_y}{\partial z},\quad \frac{\partial E_x}{\partial z}-\frac{\partial E_z}{\partial x},\quad \frac{\partial E_y}{\partial x}-\frac{\partial E_x}{\partial y},$$

are the components of curl $\mathbf{E}$. A vector equation involving curl is thus three equations, when written in terms of the components.

The equations are

$$\frac{1}{c}\frac{\partial \mathbf{E}}{\partial t}=\text{curl } \mathbf{H},\ \text{div } \mathbf{E}=0;$$

$$-\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t}=\text{curl } \mathbf{E},\ \text{div } \mathbf{H}=0.$$

In these equations c is originally a rather abstruse quantity, the ratio of the electromagnetic to the electrostatic units. It is a velocity, and one of the strongest evidences for the electromagnetic theory of light is that, when purely electric methods are used to determine the ratio, it is found to be the same as the velocity of light. We shall give a few examples of solutions, but before doing so must complete the theory by giving the rule for intensity. In our previous account of intensity we left a factor of proportionality undetermined, and this was right because we had then no other physical phenomenon to link with light, so that there was no way of fixing the absolute values. Now, however, we have a much more precise formulation, because we can imagine that we might measure (very ideally of course) the electric force in the light by means of an electrometer, and we can therefore make our definition absolute. Electrical theory assigns a value to the flux of energy, *i.e.,* to the rate at which energy is carried across unit area in unit time, and this is a suitable measure for intensity. It is called the "Poynting vector," after its discoverer, and is $\frac{c}{4\pi}[\mathbf{E},\mathbf{H}]$ where $[\mathbf{E},\mathbf{H}]$ is a *vector product* with component $E_y H_z - E_z H_y$, along x, etc.

We now consider some solutions of the electromagnetic equations. One such solution may be verified to be

$$E_x=A\cos\frac{2\pi}{\lambda}(ct-z),\ E_y=0,\ E_z=0;$$

$$H_x=0,\ H_y=A\cos\frac{2\pi}{\lambda}(ct-z),\ H_z=0.$$

We see in the first place that we have a wave travelling along z with velocity c, and purely electrical experiments have shown c to be equal to the velocity of light. Secondly we see that it is a transverse wave, but it is ambiguous whether the electric or magnetic force is the light-vector. A similar solution is

$$E_x=0,\ E_y=B\cos\frac{2\pi}{\lambda}(ct-z),\ E_z=0;$$

$$H_x=-B\cos\frac{2\pi}{\lambda}(ct-z),\ H_y=0,\ H_z=0;$$

and this evidently represents the other polarized component. A third solution can be formed by superposing these two, or by superposing them with a phase difference between E_x and E_y. The intensity in such a case would be $\frac{c}{8\pi}(A^2+B^2)$.

We must now consider whether the electric or magnetic force is the light-vector. Since both always occur in the wave, a theory could be constructed in which either was so taken, and it is a matter of convenience which we choose. A number of phenomena show that the electric force is the more important, primarily because matter is constructed out of electrons and not out of magnetic particles. We may give as one example the case of *standing* waves. When a plane wave of monochromatic light falls perpendicularly on a mirror and is reflected straight back, the incident and reflected waves interfere with one another and produce a system of stationary oscillations. These may be described by

$$E_x = A\cos\frac{2\pi}{\lambda}(ct-z) - A\cos\frac{2\pi}{\lambda}(ct+z)$$

$$= 2A\sin\frac{2\pi}{\lambda}ct\sin\frac{2\pi z}{\lambda};$$

$$H_y = A\cos\frac{2\pi}{\lambda}(ct-z) + A\cos\frac{2\pi}{\lambda}(ct+z)$$

$$= 2A\cos\frac{2\pi}{\lambda}ct\cos\frac{2\pi z}{\lambda}.$$

We see that at points where z is any multiple of half a wave-length E_x vanishes all the time, whereas H_y vanishes all the time at points where z is an odd multiple of quarter of a wave-length. Suppose that our mirror is coated with a nearly transparent photographic film, of some depth, which is afterwards developed and examined in section. Then we shall find places where it is fogged by the action of the light-vector, and others where it is unaffected and the positions of these tell us that it is the electric force that is effective and not the magnetic. From this and similar cases we conclude that it is best to take the electric force as the light-vector.

REFRACTION AND DOUBLE REFRACTION

We have already made much use of the idea that the optical effect of a transparent medium can be represented by a refractive index. This is not of course an explanation of refraction; for that we shall have to consider atomic processes, but without doing this we can discuss many of its features, and can describe the experiments which have been used in its investigation. We shall be content for the most part with the description of results; to work them out in detail would involve rather elaborate mathematics.

The Electromagnetic Equations for Refracting Media.—The natural starting point for the discussion is the extension of the electromagnetic theory to cover electrical waves propagated through matter. When a static electric force acts on matter it may produce two effects: If the matter is a conductor, a current will flow according to Ohm's law; this is expressed by defining a *current density* $\mathbf{j}$ (a vector with components $\mathbf{j}_x, \mathbf{j}_y, \mathbf{j}_z$) which is given by $\mathbf{j} = \sigma E$, where σ is the specific conductivity of the medium. If the matter is an insulator, the electric force displaces the electricity in the atoms in a way that may be compared to the compression of a spring, and a new quantity has to be introduced to express this, which is called the *dielectric displacement.* In isotropic media, such as water or glass, the dielectric displacement bears a constant ratio to the electric force. We write $\mathbf{D} = \epsilon\mathbf{E}$, and call ϵ the *dielectric constant.* General electromagnetic theory then shows that the equations for free space must be altered so as to accommodate either or both of these properties of matter. We now write

$$\frac{1}{c}\frac{\partial D}{\partial t} + \frac{4\pi}{c}\sigma\mathbf{j} = \text{curl } \mathbf{H}, \quad \text{div } \mathbf{D} = 0.$$

Matter also has magnetic properties, and this suggests that the other equations should be changed as well. It is found however to be unnecessary, for the alternations of force in light are so rapid that the magnetic properties have no time to take effect. So we adhere to the equations

$$-\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t} = \text{curl } \mathbf{E}, \quad \text{div } \mathbf{H} = 0.$$

These equations together determine the behaviour of light in most types of matter, but we must remember that we always have to make observations outside, and therefore require to know how the light will pass from one medium to another. Electric theory again provides the answer; when light goes through a boundary between two media, at every point of the surface and at every instant of time, the tangential components of electric and magnetic force just on one side of the boundary must each be equal to the tangential components of the corresponding forces just on the other side. (*See* ELECTRICITY.)

Refraction in Transparent Media.—In a non-conducting isotropic medium, the equations assume the form

$$\frac{\epsilon}{c}\frac{\partial \mathbf{E}}{\partial t} = \text{curl } \mathbf{H}, \quad -\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t} = \text{curl } \mathbf{E}.$$

It is easy to verify that these are satisfied by

$$E_x = A\cos\frac{2\pi}{\lambda}\left(\frac{c}{\sqrt{\epsilon}}t - z\right), \; E_y = 0, \; E_z = 0;$$

$$H_x = 0, \; H_y = A\sqrt{\epsilon}\cos\frac{2\pi}{\lambda}\left(\frac{c}{\sqrt{\epsilon}}t - z\right), \quad H_z = 0.$$

The electric force is transverse to the waves and the wave-velocity is $c/\sqrt{\epsilon}$, so that the medium has refractive index $\sqrt{\epsilon}$. An apparent difficulty at once arises, for our result seems to imply that the refractive index should not depend on the colour of the light. This will be explained when we come to the atomic theory, where it will appear that the dielectric constant depends on the frequency of the inducing electric force.

We next consider the passage of light from one medium to another. Suppose that they have refractive indices n and n', and first suppose n to be the lesser; in the case of free space it will be unity. To find the formulae for refraction and reflection we take a given incident wave, and assume that there are reflected and refracted waves, but without making any assumptions about their wave-lengths or directions. The boundary conditions then require that the sum of the tangential components of incident and reflected forces at the boundary in the first medium, are everywhere and at every time equal to the corresponding forces in the refracted wave on the other side of the boundary. These conditions lead in the first place to the law that the frequencies of all three waves must be equal, so that the wave-length of the refracted wave is $\lambda n/n'$, and then to the law that the angle of reflection is equal to the angle of incidence θ, while the angle of refraction θ' is given by $n\sin\theta = n'\sin\theta'$. These rules can be deduced merely from the fact that there are boundary conditions and would be the same whatever the form of those conditions. Next, with the special conditions of the electrical theory, we can find the amplitudes of the reflected and refracted waves. Taking the component in which the electric force is polarized perpendicular to the plane of incidence we find as amplitude of the reflected wave $\sin(\theta-\theta')/\sin(\theta+\theta')$, while the component polarized in the plane of incidence gives $\tan(\theta-\theta')/\tan(\theta+\theta')$. These are Fresnel's sine and tangent formulae; their squares give the intensities of reflection. The intensities of the refracted wave may also be given, but are not so important.

We may now consider how the reflection varies with the angle of incidence. Take the sine formula first. For perpendicular incidence the formula becomes ambiguous, but may be replaced by $(n'-n)/(n'+n)$. For water the refractive index is about $1\frac{1}{3}$, and so, when light falls perpendicularly on water the amplitude of the reflected wave is $\frac{1}{7}$ of that of the incident, and therefore the intensity is only about 2 per cent. With increasing angle of incidence, the reflection increases somewhat (for incidence on water at 45° it becomes about 5 per cent), and, as the incidence approaches grazing, it increases rapidly up to unity, which means perfect reflection. The phase of the reflected light is always the same as that of the incident. The tangent formula behaves quite differently. For perpendicular incidence it has the same value, but it starts diminishing, and finally vanishes at the polarizing angle, when $\tan\theta = n'/n$, at which angle the reflected and refracted waves are perpendicular to one another. For water the angle of incidence is about 54°. After this it increases again and reaches unity at grazing incidence. The phase is the same as that of the incident light up to the polarizing angle, and from there onwards differs from it by 180°.

These phenomena have been much studied experimentally. The behaviour of a transparent medium depends only on its refractive index, which is most accurately determined by the refractometer (essentially, a prism of the substance); so that experiments on reflection do not provide new information, but serve as a very valuable check on the theory. Suppose, for example, that we illuminate a glass surface obliquely with light polarized in some direction neither in nor perpendicular to the plane of incidence. To find the reflection this light must be resolved into two components, one of which obeys the sine and the other the tangent formula. They will be unequally reflected, but in neither case is the phase changed at the reflection (or only through 180°, which does not matter); and so the reflected light will again be plane polarized, but in a new direction. If the light is incident at the polarizing angle the reflected light will contain only the component polarized in the direction at right-angles to the plane of incidence. If ordinary light is incident the same is true, and this process is often used for obtaining polarized light. The most refined experiments have revealed the fact that the polarization is never perfect, but the unwanted component can usually be attributed to the presence of grease on the surface. If elaborate precautions are taken to remove this grease the effect becomes very small, but it never quite vanishes. This is probably to be attributed to the fact that the surface atoms are necessarily in a different state from those inside, so that it is not possible for a medium to remain truly homogeneous up to the boundary.

We have described what happens when the incident light is in the medium of lower refractive index. In the contrary case the intensity of reflection follows similar rules for the two components, but with one very important difference. In this case the angle of refraction is larger than the angle of incidence, and the reflection becomes complete for both polarized components when the refracted ray is at 90°, at which point the inclination of the incident ray is given by $\sin\theta = n'/n$. For greater angles of incidence the phenomenon of total internal reflection supervenes, and this we must now consider.

When $\sin\theta > n'/n$ there is no angle θ' for which the equation $n\sin\theta = n'\sin\theta'$ can be satisfied, and so there can be no progressive wave in the second medium. The appropriate solution involves instead a real exponential factor. If the boundary is the z plane, and if the incident wave is at angle θ, its phase will be given by $\cos\frac{2\pi}{\lambda}\left(\frac{ct}{n} - x\sin\theta - z\cos\theta\right)$, and the appropriate solution in the second medium is $e^{-(2\pi/\lambda)z\sqrt{(\sin^2\theta - n'^2/n^2)}}\cos\frac{2\pi}{\lambda}\left(\frac{c}{n}t - x\sin\theta - \epsilon\right)$, which evidently fits the boundary condition and may be verified to satisfy the wave equations. The real exponential implies that the disturbance only penetrates a very short distance into the second medium, roughly not much more than a wave-length. When the amplitudes are worked out, the reflected wave is found to have amplitude equal to the incident, but with a changed phase, and the change is unequal for the two polarizations. Thus, if incident plane polarized light is totally reflected, the emergent light is polarized elliptically. Working on this principle Fresnel devised an instrument which turns plane into circularly polarized light.

For water and air the angle of total reflection is about 49°. Thus, when the surface of a glass of water is viewed obliquely from below, it looks like mercury. Total reflection has a curious effect on the field of view of a fish, for however close it is to the surface, everything outside the water must be crowded into a cone of angle 49°, the edge of which will represent the horizon; while, on account of the total reflection, the fish will be able to see the bottom, except for parts nearly underneath, quite as well reflected in the surface as directly. Total internal reflection is much used in optical instruments, as it provides more perfect reflection than any silvering. In many types of binocular the rays are internally reflected no less than four times between the two lenses of each telescope (*see* BINOCULAR INSTRUMENT).

Refraction in Absorbing Media.—To discuss the passage of light through metals, we take both a dielectric constant and a conduction current and, by Ohm's law, the latter will be proportional to the electric force. The first electromagnetic equation is now

$$\frac{\epsilon}{c}\frac{\partial \mathbf{E}}{\partial t} + \frac{4\pi\sigma}{c}\mathbf{E} = \operatorname{curl}\mathbf{H},$$

while the remainder are unchanged. The presence of the conduction term has an effect something like what we found in total internal reflection, for it compels us to introduce a real exponential. For a wave of frequency ν going along z a solution can be found in which

$$E_x = e^{-2\pi\nu\kappa z/c}\cos 2\pi\nu(t - nz/c),$$

provided that n and κ satisfy the equations

$$n^2 - \kappa^2 = \epsilon, \quad n\kappa = \sigma/\nu;$$

n is the refractive index, and κ is called the absorption coefficient. Considered at a given instant of time, the wave is a damped sine-curve of wave-length $c/n\nu$ and the amplitude decreases to a fraction $e^{-\kappa/n}$ of itself for each successive crest. For actual metals κ/n is quite large, so that the light can only penetrate a very short distance. The value of n could be determined experimentally from the deflection of light by a prism, if one could be made so thin as to transmit light, and κ could be determined by finding how much the light is attenuated in passing through a plate; but in view of the extreme opacity of metals such methods are very troublesome, and it is more convenient to deduce n and κ from experiments on reflection.

The principle of reflection is just the same as for transparent media, but the details are very different on account of the real exponential in the internal wave. There is a change of phase in the reflected wave, and it is different for the two polarizations. Consequently, if plane polarized light is reflected, it becomes elliptic, and the study of this ellipticity is the most powerful method of evaluating n and κ. In the case of perpendicular incidence it can be shown that the intensity reflected is $(n^2+\kappa^2+1-2n)/(n^2+\kappa^2+1+2n)$. For all metals κ is considerably larger than n, and so the reflection is not far from complete. We see how it comes about that strong absorption, or large κ, means strong reflection. The refractive indices of metals vary over a much wider range than those of transparent substances. Thus, while the latter range roughly speaking between 1 and 2·4, silver has refractive index 0·18, associated with absorption coefficient 3·67. More remarkable still is sodium, which, if it can be used untarnished, is an even better reflector than silver. Here $n = 0{\cdot}005$ and $\kappa = 2{\cdot}61$, and 99·7 per cent of the light is reflected at perpendicular incidence. In so far as wave-velocity has a meaning in such a substance, the wave-velocity is two hundred times the velocity of light.

It is hardly too much to say that there is no theory of the optics of metals. There is a general resemblance between their optical and electrical qualities in that the best conductors are the best absorbers, and therefore the best reflectors. But in all cases κ is greater than n, and this implies that the dielectric constant ϵ is negative, which has no meaning in electrical theory.

Other substances are opaque besides metals, quite apart from the opacity due to the repeated scattering of light. Indeed ordinary transparent substances are always opaque for light of some part of the spectrum, and for such light they behave much like metals. In particular, light which is strongly absorbed will be strongly reflected. Rubens took advantage of this fact in his study of "rest-rays," which consist of light in the extreme infrared. For example rock-salt absorbs light of wave-lengths round 50 μ, and so reflects it strongly, although it is transparent to other wave-lengths. If then the light from a lamp emitting all wave-lengths is reflected to and fro several times by rock-salt mirrors, the other wave-lengths will be eliminated, and the reflected light will be nearly pure. After the last reflection its wave-length is determined by means of a grating. Unlike the case of metals, here the process of absorption has been fairly completely explained with important consequences for the theory of the solid state.

Double Refraction.—In crystals the atoms are packed together in a regular manner, and this packing implies that they will fall into rows in certain directions. Consequently the physical characters of the crystal will differ for different directions, and it is said to be anisotropic. The geometrical theory of crystallography only permits of certain definite types of packing, and these are classified according to the types of symmetry they possess. For purposes of electricity and optics we need to know the way in which the anisotropy will affect the relation between electric force and dielectric displacement. It can be shown that in general the displacement need not be in the same direction as the force, but that there must always be three mutually perpendicular directions in the crystal for which they are in the same direction. We take these directions for our axes, and have

$$D_x=\epsilon_1 E_x,\quad D_y=\epsilon_2 E_y,\quad D_z=\epsilon_3 E_z.$$

But the crystal symmetry may make a further restriction. Thus in the regular system of crystals, the three mutually perpendicular axes are equivalent to one another, so that all physical properties in these three directions must be the same and therefore ϵ_1, ϵ_2, ϵ_3 must be equal. For electrical and optical purposes therefore, though not for others, the regular system is isotropic. In the hexagonal, tetragonal and trigonal systems there is an axis of 6-, 4- or 3-fold symmetry, and, if this is taken as the z-axis, it follows that $\epsilon_1=\epsilon_2$, though they need not equal ϵ_3. Calcite and quartz both belong to this type. In all other crystal classes all three ϵ's may be different. We thus have three types of crystal, the regular, the uniaxial and the biaxial. The regular behaves for light as though it were isotropic and we shall deal with the uniaxial as a special case of the biaxial (*see* CRYSTALLOGRAPHY).

For a transparent crystal the electromagnetic equations assume the form

$$\frac{1}{c}\frac{\partial \mathbf{D}}{\partial t}=\operatorname{curl}\mathbf{H},\quad \operatorname{div}\mathbf{D}=0;$$

$$-\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t}=\operatorname{curl}\mathbf{E},\quad \operatorname{div}\mathbf{H}=0;$$

together with $D_x=\epsilon_1 E_x$, $D_y=\epsilon_2 E_y$, $D_z=\epsilon_3 E_z$.
The whole question can be discussed with either E, H or D as the primitive quantity, and of course exactly the same results would emerge, but it is most convenient to take D. This is the light-vector used by Fresnel in his original theory, before it was given an electrical meaning. The process of solution consists first in eliminating E and H in terms of D, and then fitting a plane wave of arbitrary direction so as to satisfy the equations for D. If $l:m:n$ are the direction cosines of the wave front and $L:M:N$ those of the light-vector, and if the wave-velocity is V, the wave will be of the form

$$D_x=LS,\quad D_y=MS,\quad D_z=NS,$$

where $$S=A\cos\frac{2\pi}{\lambda}(Vt-lx-my-nz).$$

In giving the results of the substitution we shall write α^2, β^2, γ^2 for c^2/ϵ_1, c^2/ϵ_2, c^2/ϵ_3. Then it is found that the wave-velocity V must satisfy the equation

$$\frac{l^2}{V^2-\alpha^2}+\frac{m^2}{V^2-\beta^2}+\frac{n^2}{V^2-\gamma^2}=0.$$

This is a quadratic equation in V^2, and we conclude that for a given direction of the wave-front there are two wave-velocities. Associated with each of these values there are definite values of $L:M:N$, and these determine the polarizations of the two waves. They are at right-angles to one another and to the direction of the wave. A simple example is given by a wave going along the direction of z, where the two velocities are α and β and the directions of polarization x and y. Another example is given by a uniaxial crystal where $\alpha=\beta$. The wave-velocities are then given by

$$V=\alpha \text{ and } V^2=\alpha^2n^2+\gamma^2(l^2+m^2).$$

Thus one wave has velocity independent of the direction; this is the ordinary wave, and its light-vector lies in the plane perpendicular to the axis. The other, the extraordinary wave, is polarized in a direction contained by the axis and the wave direction, and its velocity depends on the wave direction and ranges between γ and α.

The values of the wave velocities for different directions can be best appreciated by constructing the *normal surface.* This is a two-sheeted surface constructed by laying off in every direction from an origin two radii proportional to the two wave velocities. Its general form can be seen from fig. 18 which shows a perspective drawing of a portion of it, which is repeated by reflection in the principal planes. The figure is drawn on the assumption that $\alpha>\beta>\gamma$, and it will be seen that the two sheets meet in four conical points one in each quadrant of the plane of xz, that is in the plane perpendicular to the intermediate axis. Waves going in the directions of these conical points will have the same velocity whatever their polarization, and so for these directions light will not be polarized. These are the two *optic axes* which give rise to the name biaxial. Uniaxial crystals may be regarded as a degenerate case in which the two optic axes have approached one another; the normal surface becomes a sphere and an oval surface, which touch along the direction of the axis. The normal surface does not show how the waves corresponding to the two sheets are polarized, and for this Fresnel gave a very convenient construction. The ovaloid is an oval surface obtained by laying off a radius in each direction $l:m:n$ according to the rule

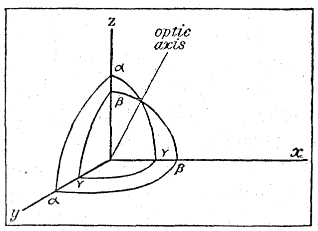

FIG. 18.—NORMAL SURFACE REPEATED BY REFLECTION IN THE OTHER QUADRANTS

$$r^2=\alpha^2l^2+\beta^2m^2+\lambda_2n^2.$$

When this surface is cut by a plane parallel to the wave front, the longest and shortest radii of the section give the two values of the wave-velocity, and their directions give the polarizations. This construction shows among other things that the wave-velocity is fixed when the polarization is given, without reference to the direction of the wave-front.

The phenomena we have so far described suffice to explain many of the features of crystal optics, in particular they are all that is required to understand the action of quarter-wave plates, nicols and other polarizing instruments, but they do not explain the fundamental fact that things seen through a crystal look double. To understand this we have to consider rays, not plane waves of indefinite breadth. In making Huygens' construction it would be wrong to draw the normal surface round each point and base the construction of fig. 3 on this, for the normal surface is only a diagram describing how plane waves can go, and does not represent the front of a wave emitted from a point. To find the form of this wave-front, we imagine that at every point of the normal surface a plane is drawn perpendicular to the radius-vector. All these planes will envelop a surface of two sheets, and this we call the ray surface. In general shape it resembles the normal surface, and has four conical points lying in the same plane, but now at different angles; these are called the ray axes. Huygens' construction is done with the ray surface, not the normal surface. For uniaxial crystals the ray surface degenerates to a sphere and a spheroid touching the sphere at the ends of the axis.

It will be readily believed that double refraction involves much complicated geometry, and the complete conquest of the subject by Fresnel is one of the greatest feats ever performed in physics. Effects can be obtained by illuminating crystals with suitably polarized light. Plate fig. 4 shows the effect obtained in the case of a uniaxial crystal, cut at right angles to the crystal axis; and fig. 5 that in the case of a biaxial crystal, cut at right angles to the bisector of the angle between the optic axes. We must omit their explanation, which requires a detailed discussion. We can only refer to the curious phenomenon of cônical refraction which was discovered theoretically by Hamilton and after-

DISPERSION OF LIGHT

1. Newton's Rings in light of one colour
2. Newton's Rings in light of two colours. The two sets of rings fall together in some places and alternately in others
3. Fabry Perot Interferometer rings in green light of mercury. The two sets of rings show that there are two lines very close together in the spectrum
4. Diffraction pattern for circular aperture
5. Fraunhofer Diffraction pattern for rectangular hole. Inset is shape of hole. It is broad in the direction where the figure is narrow
6. Uniaxial crystal illuminated between crossed nicols
7. Biaxial crystal illuminated between crossed nicols
8. Anomalous dispersion of sodium vapour. The vapour is in the form of a prism. The two breaks in the horizontal line correspond to the two D-lines, where light is absorbed. For each the light on the red side (left) is strongly refracted downwards, and on the blue side upwards. At greater distance, refraction is too small to be perceptible
9. Magnetic gyration of sodium vapour. The line on the left has one pair of components, whereas that on the right has two pairs

wards verified. When a narrow beam is sent along the axis of a biaxial crystal, the direction for the ray becomes indeterminate so that it can be anywhere on a certain cone. On emergence at the other side this cone is made into a cylinder by the surface refraction, and if this falls on a screen we get a ring of light.

Double refraction is invariably present in crystals which are not of the regular system, but is often quite small. Even in a strongly doubly refracting crystal like calcite the two principal indices are 1·66 and 1·49 so that their difference is considerably less than the refractive effect of either (which may be represented by its difference from unity). In uniaxial crystals and in biaxial of the orthorhombic system the axes are fixed by the crystal symmetry, though the principal wave-velocities may vary with the colour. In biaxial crystals of the monoclinic and triclinic systems the principal axes may vary in position as well, and the most complicated colour patterns may be produced. Some crystals, such as tourmaline, show a selective absorption, so that one of the two polarized waves cannot penetrate far into the crystal, and the light emerges from the other side plane polarized.

Double refraction also occurs when an isotropic solid is in a state of strain, and indeed the chance strains in badly annealed glass are sometimes a cause of trouble in experiments with polarized light. On the other hand advantage has been taken of the effect, for by making a transparent model, say of a girder, it is possible to find the strains set up in it by the appropriate forces in cases where the shape is too complicated for direct calculation. Another occurrence of double refraction is the Kerr effect,—an ambiguous name, as there is a second effect of magnetic type, also named after this investigator. When light is sent through the glass of a charged electric condenser, double refraction occurs, so that the component polarized in the direction of the electric force has wave-velocity slightly different from that transversely polarized; the effect is proportional to the square of the electric force across the condenser. Yet another case, predicted and discovered by Voigt is a very small double refraction when light traverses matter placed in a strong magnetic field at right angles; this is associated with magnetic gyration which we shall discuss later.

Natural Optical Gyration.—Double refraction is not the only optical effect exerted by crystals. The symmetrical properties of a crystal are of two different kinds, corresponding to rotation and reflection respectively. Most crystals have some symmetry elements of both types, but there are some which only have rotations, so that the crystal is not identical with its mirror image. The simplest geometrical form possessing this peculiarity is the screw, which cannot be superposed on its mirror image, and we therefore liken this type of crystal to a screw. Quartz is such a substance, and there exist two types of quartz crystals, which we may call right- and left-handed. Now circularly polarized light has the same quality of a screw, and we should therefore expect that a right-handed quartz crystal would react differently to right- and left-handed circularly polarized light respectively. It is in fact found that the wave-velocities are different, and this is the basis of the theory of optical gyration.

Let us suppose that n_r and n_l are the refractive indices for the two types of circularly polarized light of frequency ν. Then the right-handed wave will be

$$E_x = A\cos 2\pi\nu(t - n_r z/c), \quad E_y = -A\sin 2\pi\nu(t - n_r z/c),$$

and the left-handed

$$E_x = A\cos 2\pi\nu(t - n_l z/c), \quad E_y = +A\sin 2\pi\nu(t - n_l z/c).$$

Suppose that at the plane $z=0$ we have light polarized along the direction x. This is given by simply adding these two solutions together, and then at any value of z we shall have

$$E_x = 2A\cos 2\pi\nu\left[t - \frac{n_r+n_l}{2}\frac{z}{c}\right]\cos\pi\nu(n_l - n_r)z/c,$$

$$E_y = 2A\cos 2\pi\nu\left[t - \frac{n_r+n_l}{2}\frac{z}{c}\right]\sin\pi\nu(n_l - n_r)z/c.$$

This means that at the point z we can regard the light as plane polarized in a direction inclined to x at angle $\pi\nu(n_l - n_r)z/c$. The phenomenon is actually observed by sending plane polarized light through the medium and seeing how an analyzing nicol must be placed in order to extinguish the light. The gyrational constant is the rotation produced by a thickness of 1 cm. of the substance.

In quartz the gyration is very strong, being 217° per cm. for yellow light, but is complicated by double refraction of the uniaxial type, and it is only for light going very nearly along the crystal axis that it can be observed. There are also crystals of the regular system which exhibit the effect, for example sodium chlorate, and here it is present for all directions. It is also shown by liquids when their molecules contain a chemically asymmetric atom; such a liquid is isotropic in that all directions are equivalent, but is not, molecularly speaking, identical with its mirror image, and so it can and does refract the two types of circularly polarized light differently. Since many sugars contain an asymmetric carbon atom, measurement of the gyration is a very convenient method of estimating the strength of a sugar solution, and great practical use is made of it.

THE ATOMIC THEORY OF REFRACTION

We have so far treated refraction as an effect of matter in bulk without enquiry as to how it comes about. The gross effect must be a superposition of the effects of the separate atoms and molecules, and we shall now consider how this superposition takes place. The light arising from an atom may have a great variety of characters, but whatever these are it must have one feature, that the wave is a spherical wave with the atom in its centre. We shall therefore first investigate what types of spherical wave are possible. In discussing diffraction we described a spherical wave emerging from a point source with amplitude inversely proportional to the distance. Though that sufficed to give the outline of the theory, it took no account of polarization, and it must be further refined for our present purpose. We naturally build the complete theory by considering what types of electromagnetic waves can emerge from a point.

Types of Spherical Waves.—The transverse nature of light makes it impossible to have a wave going out uniformly in all directions. We give the mathematical form of the simplest possible wave. Let

$$S = A\cos\frac{2\pi}{\lambda}(ct - r)/r, \text{ where } r = \sqrt{(x^2+y^2+z^2)}$$

and A is a constant. Then the electric and magnetic forces are given by

$$E_x = \left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x^2}\right)S, \quad E_y = -\frac{\partial^2}{\partial x\partial y}S, \quad E_z = -\frac{\partial^2}{\partial x\partial z}S,$$

$$H_x = 0, \quad H_y = -\frac{1}{c}\frac{\partial^2}{\partial t\,\partial z}S, \quad H_z = \frac{1}{c}\frac{\partial^2}{\partial t\,\partial y}S.$$

If these are worked out they lead to expressions which are rather complicated in general, but simpler for points at a great distance from the source, and it will suffice to discuss the latter case. Consider a large globe, surrounding the source, marked with circles of latitude and longitude, the pole being the axis of x. The observer is on this sphere at angular distance θ from the pole. Then the wave that reaches him will have its electric force polarized so as to vibrate in the north and south direction, and the magnetic force will be east and west and equal in magnitude. The electric force is inversely proportional to the radius of the globe and to the square of the wave-length, but, most important of all, it varies as $\sin\theta$, vanishing at the pole and having its maximum at the equator. The actual value is

$$E = \left(\frac{2\pi}{\lambda}\right)^2 A\sin\theta\cos\frac{2\pi}{\lambda}(ct - r)/r.$$

In fig. 19 (a) the observer takes up various positions on the globe (marked by his co-latitude), and looks towards the centre; then the diagram shows the vibration of the electric force that will reach him.

In the classical electromagnetic theory this is the wave which would be emitted by an electron of charge e vibrating with frequency c/λ and small amplitude a along the x-axis at the origin, provided that $A=ea$. If the observer were to watch this motion, he would see it in perspective, and the electric force at the observer is proportional to and in the same direction as the apparent motion of the electron. It is very convenient to have a name for this type of wave, including the complete distribution in all directions round the source, and in view of the motion of the emitting electron we shall call it a *line-wave.*

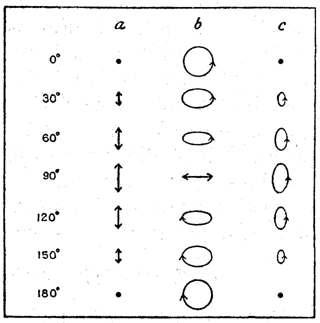

FIG. 19.—SPHERICAL WAVES
The observer, on a sphere in co-latitude on the left, looks toward the centre. The amplitude and polarization of light received are shown. (a) Line-wave, (b) circle-wave, (c) screw-wave

If the emitting electron describes a small circle instead of a line we have what we may call a *circle-wave.* This can be regarded as two superposed line-waves with their poles at right angles and phases differing by a quarter wave-length. The pole of the circle is perpendicular to the poles of both lines. Fig. 19 (b) shows the electric force as seen by the observer for various positions on the globe. Its form again resembles the perspective view he would have of the electron. At either of the poles he receives circularly polarized light, and it is important to notice that they will be of opposite types, one right-handed and the other left-handed. For other directions the light is elliptically polarized and becomes plane polarized at the equator. The intensity is twice as great at the poles as at the equator.

We must also consider a third type of wave which is not so simple. In the electromagnetic equations there is a mathematical symmetry between the electric and magnetic forces, so that we can obtain a solution by interchanging their roles. If we construct a wave by adding to the ordinary line-wave a small "magnetic" line-wave with the same pole and same frequency, we obtain a wave in which the light is everywhere of the same intensity as for a line-wave, but is elliptically polarized with axes in constant ratio and lying in the directions of the circles of latitude and longitude. Such a wave is illustrated in fig. 19 (c). It is important to notice that in this case, unlike the circle-wave, the light-vector turns in the same direction in both hemispheres. Thus the whole wave has the same screw character and we shall call it a *screw-wave.* The screw-wave cannot be emitted by any motion of an electron. It would be emitted if there were a single magnetic pole moving with the electron, but such a thing does not exist and in fact the wave can only arise from a system itself having the screw character, such as a molecule with a chemically asymmetric atom in it.

The Scattering of Light.—When light falls on an atom it sets the electrons in motion and they therefore re-emit light, and the character of this scattered light will depend on the nature of the atom as well as the incident light. But the effect of a single atom is too small to be observable, so that we always have to use a large number and the compounding of their effects produces complications. In fact the scattering of light by matter is a more primitive quality than is refraction, and it is therefore best to reduce everything into terms of scattering before we approach the theory of the behaviour of the single atom. There are several different ways in which an atom may emit light under the stimulus of light, but we can exclude some of them from consideration. Thus certain substances respond by *fluorescing,* that is to say emitting light of a different wave-length, and again there is the important phenomenon of *resonance radiation* (*q.v.*) where the wave-length of the light is unaltered, but where it appears that there is no phase relation between the incident and the scattered light. (*See* FLUORESCENCE AND PHOSPHORESCENCE.) Both these phenomena are extremely interesting, but from the present point of view they may be regarded as an absorption and simultaneous re-emission of the light, and so they belong to the theory of the emission of light and are outside our scope.

The most universal way in which atoms react to light is by the emission of waves of the same frequency and having a definite phase relation to the incident light, and this process, to which we shall limit the name of scattering, is responsible for refraction, both ordinary and double, and for gyration. In order that all these effects may be explained, we can see one property which the scattered waves must always have. The various refractive effects are all due to an interference between the original and the scattered waves, and, since the refraction is independent of the brightness of the light, it follows that the wave scattered by an atom, whatever its other characters, must be proportional in amplitude to the incident force. Another of its properties depends on the fact that for ordinary light the wave-length of the light is always far greater than the size of the atom; hence at any instant the atom is practically in a uniform field of force, and so the scattered wave will depend only on the polarization and frequency of the incident wave, but not at all on the direction of its wave-front. These conditions must hold for any atom, but apart from them there is great liberty of choice for the form of the scattered spherical wave. We shall see that for some purposes we have to assume circle-waves and screw-waves, but both ordinary and double refraction are fully accounted for by means of ordinary line-waves; moreover for transparent substances the line-wave is exactly in phase with the incident. All these results can be deduced by assuming completely general types of spherical waves and then seeing what limitations will give rise to the various refractive effects, but here we shall pursue the opposite course and shall assume the form of the scattered wave and show that our assumption is verified. For the most important case, that of the refraction of a transparent medium, we can summarize our assumptions in the form that under incident light of amplitude E_0 the wave scattered by an atom is a line-wave of the form we gave with ρE_0 written for A, and with pole along the direction of E_0. Then ρ, which depends only on the nature of the atom and on the frequency of the incident light, is the *scattering constant* of the atom.

The Light of the Sky.—The most primitive exhibition of scattering is not found in refraction, but in such phenomena as the light of the sky (*q.v.*), and it is therefore appropriate to discuss this first. Supposing that the observer looks at a point not very near the sun, the light that he sees will have been scattered through a broad angle, and the phase of the light-path, sun—atom—observer, will be different for each atom. Consequently the waves from the separate atoms do not reinforce one another. If the atoms were arranged with perfect regularity their waves would arrive at the eye with regular differences of phase and would destroy one another so that the sky would look black; however the uniform density of gases is not due to systematic regularity, but to the unsystematic regularity produced by the enormous number of atoms. The atoms of a gas have no ordered positions, as they have in a crystal, hence the brightness of sky light will depend on compounding a large number of similar waves of quite arbitrary phases and taking the average value of the result. Consider a set of n atoms each of which is giving a wave of the same magnitude, but with phases $\epsilon_1, \epsilon_2, \ldots \epsilon_n$. The resultant amplitude will be proportional to $\cos\epsilon_1+\cos\epsilon_2+\ldots+\cos\epsilon_n$, and the intensity is the square of this. Now the square will consist of terms like $\cos^2\epsilon_1$ and others like $2\cos\epsilon_1\cos\epsilon_2$. The latter of these are as likely to be negative as positive, so that they will average out, but the former has average value $\frac{1}{2}$ for each separate term. Thus the average intensity scattered by the n atoms is just n times that scattered by one. If then we want to know the brightness of the sky we only require to calculate the intensity scattered by a single atom and multiply by the number of atoms in the field of view.

We will suppose that N is the total number of atoms in a small solid angle, the illumination from which is to be found. Then, from the formula for line-waves, we shall have an intensity proportional to $NE_0^2\ \rho/\lambda^4$, and here E_0^2 is the intensity of the direct sunlight. Now in fact ρ, the scattering constant of the atom, does not depend very much on the wave-length, as long as we only consider visible light and we can therefore say that the light scattered is inversely proportional to the fourth power of the wave-length. This explains why the sky is blue even though sunlight is rather weaker in the blue part of the spectrum than the red, for the wave-length of red light is about 1·8 times that of blue, and so factor λ^{-4} is about 10 times as large for blue light as for red.

Another property of the sky-light is its polarization. Consider a point of the sky at right-angles to the sun. The unpolarized light from the sun may be broken into two polarized components, one of which has electric force pointing at the observer. The line-waves induced by this component will have the observer at their poles, and so will give no light towards him. He will therefore only receive the light of the other component, and this will be polarized in the direction perpendicular to the line joining the sun to the point observed. At other angles both polarized components are present, one in constant intensity and the other proportional to the squared cosine of the distance from the sun. If the sky is actually observed at right-angles to the sun with a nicol, it will be found that the polarization is not complete. This is partly to be attributed to rays that have been scattered several times on their way to the eye, and also to the fact that, though we have spoken only of atoms, the air is mostly composed of diatomic molecules, and for these the line-wave need not have its pole exactly coincident with the direction of the incident force. There is also usually a complication due to dust, which acts by direct reflection and makes the sky much brighter near the sun than at broad angles.

A most interesting application of the theory of sky-light was made by Lord Rayleigh (3rd baron). The barometer shows the mass of the atmosphere, and so, by a direct comparison between the brightness of the sky and that of the sun, it is possible to deduce how much light is scattered by one cubic centimetre of air at ground level. In fact, if N is the number of atoms in 1 cu.cm., we can evaluate $N\rho^2$. Now, as we shall see, we can also find $N\rho$ by a study of refraction, and hence we can estimate N. The process led to one of the earliest good determinations of the fundamental constant of Avogadro, the number of molecules in a gram molecule. Similar processes have since been applied in the laboratory, with the advantage that the incident light can be itself polarized, and similar results are obtained.

Scattering As the Cause of Refraction.—When we deduce refraction from scattering we are dealing with an incomparably greater effect than in sky-light, because here there will be phase relations between the original and the scattered waves, so that we compound the effects of the separate atoms by amplitudes instead of by intensities. We suppose that light-waves as they traverse matter have the same velocity as light in free space, but that they set up secondary waves from the atoms which, also proceeding with the velocity of light, interfere with one another and with the original wave. When the compound effect has been calculated, it is found that it can be expressed by altering the wave-velocity of the original wave and disregarding altogether the scattered waves, and in this way refraction is explained.

Take a thin sheet of atoms spread over a plane on which monochromatic light falls perpendicularly. The diagram of fig. 7 will describe the process, provided that we now regard the plane as composed of matter. Each atom will emit a line-wave, and the effect at P will consist of the superposition of these waves on the original beam, which is supposed to arrive at P undisturbed. The process is very like Fresnel's discussion of diffraction, though there we imagined that the original wave was suppressed at the plane AB. Suppose that there are N atoms per unit volume, in a thin sheet of thickness l spread over the z plane, and let the incident wave be

$$E_x = F\cos\frac{2\pi}{\lambda}(ct-z).$$

The effects that all the atoms produce at P can be summed just as in Fresnel's construction, and the result is an amplitude

$$-2\pi FNl\rho\frac{2\pi}{\lambda}\sin\frac{2\pi}{\lambda}(ct-z).$$

The important point to notice is that the phase differs by a quarter wave-length from that of the original wave; this is due to the fact that the scattered waves are in phase with the incident, and is in contrast with Fresnel's construction, in which, in order to get the right result, the phase had to be advanced by a quarter wave-length. We now add the two waves together, and, taking advantage of the smallness of the scattered wave, we find

$$F\cos\frac{2\pi}{\lambda}[ct-z+2\pi Nl\rho].$$

If we adopt the ordinary process of refraction and attribute the change of phase to the changed wave-velocity during the passage through the thickness l of the sheet of matter, we should say the emergent wave was

$$F\cos\frac{2\pi}{\lambda}[ct-z+(n-1)l],$$

and so we may identify $n-1$ with $2\pi N\rho$. This is the physical origin of refraction. We see also how the reflected wave arises, for the line-wave from each atom will be exactly the same at the point which is image of P in the plane AB as it is at P, and so the total amplitudes of the scattered waves will be the same at the two points; but for the reflected wave there is no interference with the incident light. It is easy to verify that the actual reflected intensity is that which should arise from a thin sheet of refractive index n and thickness l.

We have only treated of the small effect of a thin film, and this contains the essence of the process, but it is of course necessary to discuss matter in bulk. Here the scattered wave from every atom acts on every other atom and so complicates the wave scattered by it. Nevertheless the problem proves soluble and leads to a result not very different from the simpler case. The main difference is that we now have $\frac{n^2-1}{n^2+2}=\frac{4}{3}\pi N\rho$; in the special case when $N\rho$ is small, n is near unity, and this reduces to $n-1=2\pi N\rho$ as before. The general solution for oblique incidence verifies all the formulae that are given by the ordinary bulk theory, but the idea of scattering is helpful in seeing directly how reflection and refraction come about. When light falls on a thick slab, the atoms are set in motion and their scattered waves are all in definite phase relations to one another. If we consider a point outside the face of the slab, it will receive all these waves, but those from the interior will have phases spread uniformly round the 360° and so will cancel out. Thus the reflected wave will arise from the atoms in the face where this uniformity ceases to hold. The existence of the polarizing angle becomes immediately obvious, as it is nothing but the rule that in a line-wave there is no emission towards its pole, which is perpendicular to the direction of the refracted wave.

The formula $\frac{n^2-1}{n^2+2}=\frac{4}{3}\pi N\rho$ was discovered by Lorentz (by a rather different method) and becomes the foundation of the theory of dispersion. He deduced an important consequence from it. When a substance can exist in two states, ρ will be nearly the same for both and N will be proportional to the density, so that, if d is the density of either state, $\frac{n^2-1}{n^2+2}\frac{1}{d}$ should be the same for the two. This is verified by comparing the refractive index of a liquid and its vapour. Since their densities often differ by a factor of some hundreds, it is a very stringent test and is often fulfilled to within one or two per cent. We should hardly expect perfect agreement, because the liquid molecules are being perpetually disturbed by one another, so that there may be a small change in the value of ρ attached to each molecule.

The explanation of double refraction follows a very similar course. The sheet of matter must now be supposed to react differently under the stimulus of light according as it is polarized along x or along y. In each case there is a line wave emitted with pole along the direction of the incident force, but the amplitudes are different and so the phase changes in the two components of the transmitted wave will be different. The detailed consideration of the effect for matter in bulk is of course more complicated, but leads to Fresnel's normal surface and all its consequences. This part of the theory is complete, but there are difficulties in giving an atomic meaning to ρ, because the adjacent atoms in a crystal are not arranged isotropically and will perturb one another in a complicated manner. As a consequence, the expression $(n^2-1)/(n^2+2)$ ceases to apply; but the full discussion can only be made by a detailed study of the theory of the solid state. With the help of this theory and a knowledge of the arrangement of the atoms in calcite it has been found possible to explain its high double refraction with fair numerical accuracy.

The Scattering from Absorbing Substances.—A similar process of scattering can be used to explain the action of absorbing substances, but here it is necessary to take the scattered wave in a different phase from the incident. Supposing this phase change to be η, the scattered wave from the thin sheet of atoms will now be

$$-2\pi FNl\rho\sin\frac{2\pi}{\lambda}(ct-z-\eta).$$

If this is added on to the original wave we get

$$F(1-2\pi Nl\rho\sin\eta)\cos\frac{2\pi}{\lambda}(ct-z+2\pi Nl\rho\cos\eta).$$

The first factor means a reduction in amplitude, *i.e.*, absorption, and there is also refraction just as before. Thus by a suitable choice of ρ and η we can describe the observed behaviour of any absorbing substance. The full theory is best expressed in terms of complex quantities and leads to the equation

$$\frac{(n-i\kappa)^2-1}{(n-i\kappa)^2+2}=\frac{4\pi}{3}N\rho e^{-i\eta},\ (\text{ where } i=\sqrt{-1}),$$

so that we can deduce ρ and η from a knowledge of n and κ.

It has been mentioned that transparent substances are usually opaque for light in some parts of the spectrum, and the theory of this is fairly well understood. In these regions the phase η can take any value between 0° and 180°. This theory however does not apply to metals, and it is a very interesting fact that, if we use the observed values of n and κ to calculate ρ and η for metals, the phase change η is in all cases quite small. For the very highly reflecting sodium it is only 7′, and for silver little more than 1°, while, even for such a poor reflector as steel (58% at perpendicular incidence), the phase change is not 10°. These facts are quite unexplained; they suggest however that the phase change is not the typical characteristic of metals, but that their high reflection is rather to be attributed to a large scattering power; for, if we consider a transparent substance in which $\frac{4\pi}{3}N\rho$ is greater than unity, we find that n^2 must be negative and therefore n is imaginary, and this means that the waves in the medium are strongly damped. From this point of view metallic reflection is more like total internal reflection than like the reflection from an absorbing substance.

Natural Gyration.—We have seen how gyration arises from the difference between the wave-velocities of right- and left-handed circularly polarized light. It is a screw property and can only be exhibited by molecules containing a chemically asymmetric atom. The condition is exactly that which permits of the emission of what we have called a screw-wave, and to explain gyration it is only necessary to suppose that, under the influence of plane polarized incident light, the molecule scatters a screw-wave. We take as before a thin sheet in the xy plane illuminated by plane polarized light,

$$E_x=F\cos\frac{2\pi}{\lambda}(ct-z).$$

Each molecule emits a screw-wave which has axis along x. In any direction a screw-wave can be resolved into a main component which is like that of a line-wave and a weaker component at right-angles and a quarter period behind. Take ρ for the scattering constant of the line-wave and σ for the other component. Then, when we sum all the waves scattered by the molecules, the line-waves will compound as before into

$$-2\pi FNl\rho\frac{2\pi}{\lambda}\sin\frac{2\pi}{\lambda}(ct-z)$$

along x, but there will now be a component along y of magnitude

$$-2\pi FNl\sigma\frac{2\pi}{\lambda}\cos\frac{2\pi}{\lambda}(ct-z).$$

If we add these small quantities on to the original wave we find approximately

$$E_x=F\cos\frac{2\pi}{\lambda}(ct-z+2\pi N\rho l),$$

$$E_y=-2\pi N\sigma l\cdot\frac{2\pi}{\lambda}\cdot F\cos\frac{2\pi}{\lambda}(ct-z+2\pi N\rho l);$$

and this means that the light is now plane polarized at angle $-2\pi N\sigma l\cdot 2\pi/\lambda$ to the x direction. The rotation is proportional to l, the thickness of the sheet, and the other factors express the gyrational constant. The theory for matter in bulk gives a similar result, but presents it by showing that there are different refractive indices for right- and left-handed circularly polarized light.

Magnetic Gyration.—In our discussion of the refraction of isotropic bodies, we saw that plane polarized light might be supposed to stimulate the emission by the atom of a line-wave. Now circularly polarized light can be constructed out of two plane polarized components at right angles and differing by a quarter wave-length in phase, and what we have called a circle-wave can be constructed out of two line-waves with perpendicular poles and phases differing by a quarter period. Consequently we could have worked out the theory of refraction just as well using circularly polarized light and circle-waves, and in discussing magnetic gyration it makes a convenient starting point to do so. When an atom is in the presence of a magnetic field it behaves in a sense as though it were in rotation, about an axis along the field's direction, with velocity proportional to the field strength. We shall see how this comes about when we discuss dispersion, but can explain the gyration without reference to the detailed theory. If then the atom is illuminated by circularly polarized light, it will react differently according as its magnetic rotation is with or against the rotation of the light-vector. We may describe what happens by saying that the atom's scattering constant will no longer be ρ, but $\rho+\tau$ and $\rho-\tau$ for the two types of circularly polarized light. Here τ will be proportional to the strength of the field, and it is usually to be regarded as much smaller than ρ.

Suppose that the incident light is

$$E_x=F\cos\frac{2\pi}{\lambda}(ct-z),\quad E_y=F\sin\frac{2\pi}{\lambda}(ct-z).$$

When the scattered wave from a thin sheet is superposed on this, we have, by the same construction as before,

$$E_x=F\cos\frac{2\pi}{\lambda}[ct-z+2\pi N(\rho+\tau)l],$$

$$E_y=F\sin\frac{2\pi}{\lambda}[ct-z+2\pi N(\rho+\tau)l].$$

But if the incident light is of the opposite type it will be

$$E_x=F\cos\frac{2\pi}{\lambda}(ct-z),\quad E_y=-F\sin\frac{2\pi}{\lambda}(ct-z);$$

and the resultant wave will be

$$E_x=F\cos\frac{2\pi}{\lambda}[ct-z+2\pi N(\rho-\tau)l],$$

$$E_y=-F\sin\frac{2\pi}{\lambda}[ct-z+2\pi N(\rho-\tau)l].$$

If we add these two solutions together the incident light is

$$E_x=2F\cos\frac{2\pi}{\lambda}(ct-z),\quad E_y=0,$$

and the transmitted light is

$$E_x = 2F\cos\frac{2\pi}{\lambda}(ct-z+2\pi N\rho l)\cos\frac{2\pi}{\lambda}(2\pi N\tau l),$$

$$E_y = 2F\cos\frac{2\pi}{\lambda}(ct-z+2\pi N\rho l)\sin\frac{2\pi}{\lambda}(2\pi N\tau l);$$

so that the plane of polarization has turned through an angle $\frac{2\pi}{\lambda}(2\pi N\tau l)$. This is proportional to the thickness of the sheet and, through τ, to the strength of the magnetic field. The remaining factors are individual to the substance of which the sheet is made. The constant is often called the Verdet constant after one of the earlier investigators who measured it for a number of substances.

The magnetic gyration is usually very small for practicable magnetic fields. It occurs in all transparent isotropic substances and for light going along the axis of uniaxial doubly refracting crystals; for other directions it is masked by the double refraction. There is a very remarkable similar effect, when polarized light is reflected from the polished pole of a magnet. For perpendicular incidence the plane of polarization rotates, and for other directions there are similar more complicated changes in the rule of reflection. The Kerr effect, as it is called from its discoverer, is evidently like the magnetic gyration in transparent substances, but its theory is very incomplete.

The two types of gyration, natural and magnetic, are radically different in character, as is shown by the fact that one depends on a screw-wave, the other on a circle-wave. The consequence is that in natural gyration, if the light is reflected back so as to traverse the sheet again, its direction of polarization turns in each passage like a screw of the same type and so it comes back to its original polarization. On the other hand magnetic gyration is due to a rotation, not a screw, so that if the light is reflected back again it rotates in the same direction as before and the angle of turning is doubled.

DISPERSION

We have traced the optical effects of matter in bulk to their source in the atoms, and in doing so have only found it necessary to use the ordinary conceptions of the classical theory of dynamics, but as soon as we begin to consider the atoms themselves we get into difficulties, because in fact the atom obeys quite different dynamical rules. These rules, which are the principal subject of the quantum theory (*q.v.*), are fairly well understood, but since our whole practical experience is based on classical dynamics, they are very hard to apprehend in anything but mathematical form; regarded physically they appear to contain an unsatisfying element of irrationality, which is really to be attributed to limitations in our habits of thought. For the purposes of the present subject it is fortunately possible to some extent to avoid these difficulties. The quantum theory gives certain rules, very unlike those of ordinary dynamics, for the intensities and frequencies of the spectral lines emitted by an atom or molecule, and it also predicts how such an atom will behave under the influence of light. Though both these aspects of the theory are quite different from ordinary dynamics, they have this in common with the classical theory, that if we make up a purely classical model to imitate the emission (though in many other properties it will be quite wrong), it will react correctly for the scattering of light. For convenience of calculation we thus imagine that associated with each atom is a phantom *virtual atom,* which will suffice to work out the optical effects. An actual atom contains only a few electrons, but the virtual atom contains a *virtual electron* for each line of its spectrum, and the charges on the virtual electrons are usually much smaller than the known charge of an electron. Since the spectrum is composed of nearly monochromatic lines, we suppose that each virtual electron is free to execute approximately harmonic vibrations. The relation between the emission and the scattering of light by the atom is then akin to the relation of free to forced vibrations in a harmonic vibrator.

Free Vibrations of the Atom.—Let us suppose that we have a virtual electron of mass m vibrating along the axis of x, under a force Kx towards the origin. It will obey the equation

$$m\frac{d^2x}{dt^2}+Kx=0, \text{ or } \frac{d^2x}{dt^2}+(2\pi\nu_1)^2x=0 \text{ if } K=m(2\pi\nu_1)^2.$$

If left entirely to itself such an electron would vibrate with constant amplitude and frequency ν_1 for ever; but it cannot be regarded as left alone, because the moving electricity will be perpetually changing the electric forces everywhere in the manner that we have described as a line-wave. This wave will carry away energy, which is supplied at the expense of the electron, so that its amplitude must decrease. The electron is always linked with the aether, and it may be shown that the reaction of the aether on it can be represented by introducing a damping term so that the vibration is expressed by

$$m\frac{d^2x}{dt^2}+m(2\pi\nu_1)^2x=\frac{2}{3}\frac{e^2}{c^3}\frac{d^3x}{dt^3},$$

where e is the charge and c as usual the velocity of light. The new term is very small (except for penetrating X-ray frequencies), and the equation may be solved by approximation, and gives

$$x=Ae^{-\frac{1}{3}(e^2/mc^3)(2\pi\nu)^2t}\cos 2\pi\nu t.$$

This represents a vibration which decreases during each vibration by a fraction $\frac{1}{3}\frac{e^2}{mc^3}4\pi^2\nu$, or l/λ where l is $\frac{4\pi^2}{3}\frac{e^2}{mc^2}$; for an ordinary electron it is $3{\cdot}7\times10^{-12}$cm., and, as the charge of a virtual electron is usually smaller, the approximation is evidently justifiable for ordinary light of wave-lengths about 10^{-5} cm. The line-wave emitted by this electron will also be damped with the consequence that, in Michelson's interferometer, when the two light-paths differ by a considerable amount the interference will become imperfect. This is in fact observed, but usually for path differences somewhat shorter than might be expected. If we imagine the light to be passed through a grating we observe the same phenomenon in a slightly different way; the damping factor gives the line a finite breadth, and in fact spectral lines are nearly always somewhat broader than is indicated by the theory of pure electromagnetic damping. A variety of causes contribute to this broadening; such as the frequent collisions between the radiating atoms and air molecules, for these collisions will change the phases of the emitted waves, and the Doppler effect of the motion of the atoms, which slightly alters the frequency. These effects can both be observed directly by alterations of pressure and temperature, but it is uncertain whether they are sufficient causes of the broadening. The whole question is getting very near to the point where the classical conception of a virtual atom fails, and also to the limits of experimental technique, and all that can be said is that under the most favourable conditions it seems that the damping is not far from the value predicted by electromagnetic theory. We can avoid raising the question by introducing a fictitious damping factor which replaces the electromagnetic and may write as our equation:—

$$\frac{d^2x}{dt^2}+\sigma\frac{dx}{dt}+(2\pi\nu_1)^2x=0,$$

so that the electron's motion is resisted by a small force $m\sigma\frac{dx}{dt}$, and as long as σ is small we do not need to enquire into its origin.

It is necessary next to suppose that the atom contains a number of virtual electrons with different frequencies, and so to adjust their properties that the spectrum lines will occur in the correct relative strengths. Suppose that the first electron, with charge e_1, frequency ν_1, etc., is vibrating with amplitude a_1. Then it emits a line-wave, and, at distance r in the equator, we have seen that the intensity will be proportional to $\nu_1^4e_1^2a_1^2/r^2$. In order to compare this intensity with that given by the second electron e_2 we have to consider what their respective amplitudes will be. This requires an assumption, and the appropriate assumption to make (subject to some conditions which we shall not discuss) is the equiparation of energy, that on the average each virtual electron has the same energy. Now the energy of the first electron is $\frac{1}{2}m_1\left(\frac{dx_1}{dt}\right)^2+\frac{1}{2}m_1(2\pi\nu_1)^2x_1^2$, and this is proportional to $m_1a_1^2\nu_1^2$. We therefore conclude that the intensity of the first line will depend on $e_1^2\nu_1^2/m_1$. It happens that the quantity which is most important in spectrum theory is not the intensity itself, but the intensity divided by the fourth power of the frequency. This quantity has no name, but is always referred to as "Einstein's B" by which letter we shall therefore denote it. Then, for the line of frequency ν_s, we so choose e_s and m_s that $e_s^2/m_s\nu_s^2$ is proportional to B_s, and the intensity is proportional to $B_s\nu_s^4$.

Forced Vibrations of the Atom.—When the virtual atom is exposed to light there will be an additional force acting on it. The equation of motion of the first electron will now be

$$m_1\frac{d^2x_1}{dt^2}+m_1\sigma_1\frac{dx_1}{dt}+m_1(2\pi\nu_1)^2x_1=e_1F\cos 2\pi\nu t,$$

where F is the amplitude of the incident electric force E and ν is its frequency; the direction of the wave-front does not matter. This is the equation which gives the ordinary phenomenon of resonance, and we must consider the form that its solution takes for different frequencies of the incident light. In the first place, σ plays practically no part in the solution when it is small, unless ν is very near ν_1. Excluding that case we have

$$x_1=\frac{e_1}{m_1}\frac{F}{4\pi^2(\nu_1^2-\nu^2)}\cos 2\pi\nu t.$$

If $\nu<\nu_1$, x_1 is in phase with the electric force E and its amplitude increases strongly as ν approaches ν_1. If $\nu>\nu_1$ the phases are opposite; the amplitude is small for large values of ν, but as ν_1 is approached from above it becomes large (*see* fig. 20). There is thus a transitional stage when ν passes through ν_1, and in this stage the amplitude of x_1 has to pass from a large positive to a large negative value. In order to see how it does so we must include the damping term in our equation. There is now a phase difference between x_1 and E, and the solution is

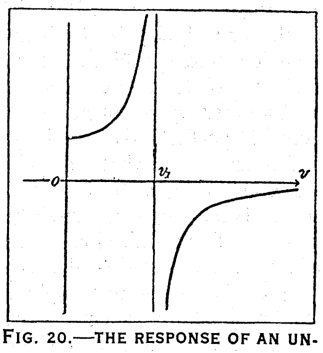

FIG. 20.—THE RESPONSE OF AN UNDAMPED RESONATOR
A periodic force throws a resonator into vibration, and for any frequency of the force the ordinate shows the amplitude of the resonator

$$x_1=\frac{e_1}{m_1}\frac{F}{2\pi\sqrt{\{4\pi^2(\nu_1^2-\nu^2)^2+\sigma^2\nu^2\}}}\cos(2\pi\nu t-\gamma),$$

where $\tan\gamma=\frac{\sigma\nu}{2\pi(\nu_1^2-\nu^2)}$. If ν is much less than ν_1 the phase angle γ is practically zero, and continues so up to values differing from ν_1 by a not very large multiple of σ. From this point on the phase grows rapidly and becomes 90° at $\nu=\nu_1$ and then increases further, so that, at an equal distance on the other side of ν_1 it is practically 180°. The amplitude follows the course of fig. 20 nearly up to ν_1, but instead of becoming infinite it attains a very large maximum at $\nu=\nu_1$ of amount $\frac{e_1}{m_1}\frac{F}{2\pi\sigma\nu}$, and then decreases. When well beyond ν_1 it has the same course as in fig. 20, but with changed sign now because the negative value is allowed for by the phase. Fig. 21 shows the general features, but it has been necessary to take a comparatively large value of σ in order to show the form clearly. In the figure σ is $2\pi\nu_1/5$, whereas for actual spectra it is of the order of $V_1\times10^{-7}$, so that in any diagram which showed the maximum the rest of the figure would be quite invisible. It thus appears that, except for frequencies very near ν_1, the damping can be disregarded, and we shall for the most part take advantage of this simplification and so make use of the curve of fig. 20 instead of fig. 21.

The Dispersion Formula.—The motion of the electron, forced in this way, will cause a line-wave to be emitted of which the magnitude is given by multiplying the amplitude of the electron's motion by its charge. Omitting the damping factor, we thus say that the electron has a scattering constant

$$e_1\cdot\frac{e_1}{m_1}\frac{1}{4\pi^2(\nu_1^2-\nu^2)}$$

which is proportional to $B_1\nu_1^2/(\nu_1^2-\nu^2)$. The other virtual electrons will give similar effects and they are all to be superposed. Thus the virtual atom will have *scattering constant* proportional to

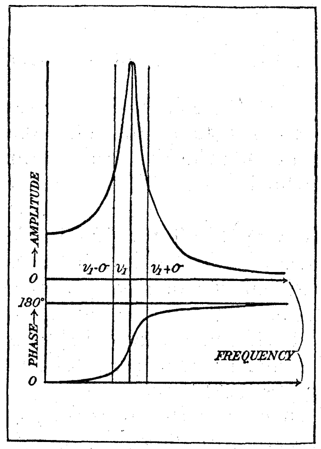

FIG. 21.—THE RESPONSE OF A DAMPED RESONATOR, THE ORDINATE OF THE UPPER CURVE SHOWING THE AMPLITUDE, THE LOWER, THE PHASE, OF THE RESONATOR

$$\rho=\frac{B_1\nu_1^2}{\nu_1^2-\nu^2}+\frac{B_2\nu_2^2}{\nu_2^2-\nu_2^2}+\cdots.$$

This is the best form for theoretical purposes, but experimental work more frequently makes use of wave-lengths. Re-writing the equation we have

$$\rho=\frac{B_1\lambda^2}{\lambda^2-\lambda_1^2}+\frac{B_2\lambda^2}{\lambda^2-\lambda_2^2}+\cdots$$

as the dispersion formula, which should apply for any wave-length not too close to λ_1, λ_2, etc. The relative magnitudes of the terms are derivable from the intensities of the associated lines in emission spectra. Their absolute values can also be given by carrying the theory somewhat deeper, and we shall touch on this below.

We may now consider the march of events when a substance is illuminated by light of increasingly shorter wave-length. We will suppose $\lambda_1>\lambda_2>\lambda_3\cdots$. We saw that the refractive index depends on the product of ρ and the number of atoms in a cubic centimetre, but, as we have omitted a factor of proportionality already, we may also omit the factor for the number of atoms, and may equate ρ above to $(n^2-1)/(n^2+2)$. For very long waves we shall have practically $(n^2-1)/(n^2+2)=B_1+B_2+\cdots$. If n^2 is deduced from this it should agree with the dielectric constant determined by purely electrical means. Though there is little doubt that this would be verified, optical observations are usually lacking for sufficiently long waves. As λ decreases the first term grows in comparison to the others, because $\lambda^2-\lambda_1^2$ gets more rapidly smaller, and just before λ_1 this term entirely dominates the refraction. At λ_1 there will be a region of absorption and on the other side the first term will be negative, the rest still positive. As λ decreases further the first term, still negative, shrinks in importance and the second grows until near λ_2 when it becomes dominant. Passing beyond λ_2 it changes sign and later shrinks in importance, its place being taken by λ_3 and so on. Finally when all the lines have been passed, $(n^2-1)/(n^2+2)$ will be negative and proportional to the square of the wave-length. For a strict test of the theoretical dispersion against experiment, we should have to work out the value of n from that of $(n^2-1)/(n^2-2)$; but for a rough comparison this is not necessary. Where $(n^2-1)/(n^2+2)$ is large so is n, when the former is negative n is less than unity, and, if n is plotted against frequency, the curve will have the same general characteristics as has $(n^2-1)/(n^2+2)$. An example of the general course of the dependence of n on frequency is given without any numerical accuracy in fig. 22. There are supposed to be three lines of which the middle one is the strongest. In the neighbourhood of each line the refraction cannot be observed on account of absorption. As each line is passed there is a strong decrease in the refractive

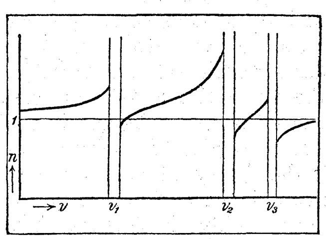

FIG. 22.—A DISPERSION CURVE SHOWING THE WAY REFRACTIVE INDEX DEPENDS ON LIGHT FREQUENCY
At ν_1, ν_2, ν_3 there will be absorption

index, associated with the change of phase of the corresponding virtual electron by 180°. Whether the refractive index actually becomes less than unity will depend on the breadth of the unobservable region and on the strength of this line compared to the others. At frequencies higher than the highest frequency of the atom the refractive index will always be less than unity, and such values have been found for X-rays, though, strictly speaking, even here the atom has higher frequencies still.

Much the most striking example of dispersion is the phenomenon called anomalous dispersion, though in fact it is not at all anomalous. There are dyes which strongly absorb certain colours in the spectrum while being transparent to the others; thus if the green is absorbed, the dye will look purple by transmitted light. In consequence of the very strong green absorption there is a reversal in the usual order of refraction. The blue light, which lies on the short wave-length side of the green, is much less refracted than the yellow which lies on the side of long wave-lengths. Fig. 23 shows with some exaggeration the way in which a prism made of such a colour would fold the spectrum back on itself. A similar effect is shown in Plate, fig. 8 for sodium vapour. Sodium has two very strong lines close together in the yellow, and both of them show anomalous dispersion. A flame containing the vapour is given the form of a prism, and white light is sent through it. This light is then sent through a spectroscope so as to spread out the colours in a direction at right angles to the dispersion of the prism. The colours on opposite sides of either of the sodium lines will be deflected in opposite directions by the prism, so that their images on the photographic plate are shifted up and down in Plate, fig. 8. The form of the dispersion curve is thus made directly evident.

On account of the brilliance and fineness of the sodium lines, sodium vapour has been used with more success than any other medium in the study of dispersion, and several important results have emerged. It has been found possible to make direct measures of the absorption of light in the immediate neighbourhood of the two lines and so to evaluate the damping factor σ; this was found to be in quite good agreement with the electromagnetic damping factor. Another important experiment consists in finding the absolute value of the scattering constants for these two lines of the sodium atom. The theory of this depends on quantum principles, and cannot be given in detail; but, loosely speaking, the two virtual electrons together correspond to a single actual electron, so that, if we can make experiments in which the two lines are indistinguishable, the scattering constant should be given by the use of the ordinary values of e and m. The straightforward way of doing this would be to observe the refraction with light of a very different colour, because then the difference between the influences of two such close lines would be insensible, but this is useless because the refraction itself becomes too small. Indirect means depending on magnetic gyration have been used, and have entirely supported the theoretical prediction that both lines are due to a single electron.

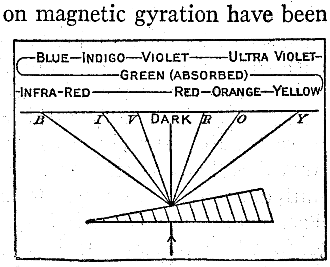

FIG. 23.—ANOMALOUS DISPERSION
The absorption in the green makes the yellow more refracted than the blue

The most accurate measures of refractive index have been made with transparent substances, substances in which the absorption only occurs far in the infra-red or ultra-violet. To analyze the dispersion the usual procedure is based on the fact that for the infra-red terms, $\lambda^2/(\lambda^2-\lambda_1^2)$, can be expanded in powers of λ^2, while for the ultra-violet terms it can be expanded in inverse powers of λ^2. A formula is therefore constructed of the type $A+C\lambda^2+\cdots+E\lambda^{-2}+F\lambda^{-4}+\cdots$, and A, C, $E\cdots$ are fitted to the observed values of $(n^2-1)/(n^2+2)$. The term in C corresponds to the infra-red lines, and A, E, F to the ultra-violet. The actual positions of the lines are then found by trial. The infra-red lines, or, more usually, bands, can often be fixed with fair accuracy, both by experiments with rest-rays and by observing the refraction near them; but the ultra-violet are more troublesome, because it is often not possible to get observations very close to the lines. Indeed it is usually found that wave-lengths and B's can be chosen with considerable latitude, and can yet give all the observed results with a high degree of accuracy. The whole process is very laborious and has only been carried out for a few substances, such as rock-salt and potassium chloride. It is found possible to represent the refraction by one term for the infra-red and perhaps two in the ultra-violet, together with a third constant term which must correspond to wave-lengths so short that $B_s\lambda^2/(\lambda^2-\lambda_s^2)$ does not change perceptibly in value in the whole region accessible to observation. The ultra-violet lines are attributed to electron vibrations of some kind, but those in the infra-red arise through the motions of whole atoms, and have been fitted satisfactorily into the general dynamical theory of the crystalline state.

The theory of the refractive indices of gases is distinctly more advanced, because their emission spectra can be studied without the radical change of state that would be necessary for solids. In the case of metallic vapours, such as sodium, the theory may be considered complete, though its practical verification is somewhat difficult. The spectrum of helium is known, and the measurement of its refraction has led to an interesting result. The lines of all atomic spectra fall into series which converge towards a finite limit λ_h, but beyond this limit there is a region in which there is emission over a continuous range of wave-lengths. Corresponding to this it is found that the refraction of helium requires an expression

$$\frac{n^2-1}{n^2+2}=\frac{B_1\lambda^2}{\lambda^2-\lambda_1^2}+\cdots+\int_0^{\lambda_h}\frac{B_x\lambda^2}{\lambda^2-x^2}\,dx.$$

In the case of the ordinary permanent diatomic gases the spectrum is not so well-known, for an electric discharge is required in order that the gas should be luminous, and this breaks the molecules into atoms. Even without this knowledge, however, one feature can be predicted for a molecule composed of two identical atoms; the atomic vibrations which are of infra-red frequency will have no optical effects at all. This is confirmed by the dispersion formulae which for the permanent gases have only ultra-violet terms.

The Dispersion of Magnetic Gyration.—The dispersion of doubly refracting and naturally gyrating substances has been studied, and fits into the same general type of formula, but the theory is very complicated. On the other hand magnetic gyration is fairly completely understood, and, as it has thrown much light on the behaviour of atoms, we may consider it in more detail. We first take the simplest case, which is not in fact exhibited by many types of atom. In a magnetic field an electron experiences a force proportional to the field and to its own velocity, in a direction perpendicular to both, and we cannot therefore now limit the electron's motion to a single line. Taking the field along z (and omitting the damping factor by the exclusion of cases where it would be important), the motion will be

$$m_1\frac{d^2x}{dt^2}+m_1(2\pi\nu_1)^2x-\frac{e_1}{c}H\frac{dx}{dt}=e_1E_x,$$

$$m_1\frac{d^2y}{dt^2}+m_1(2\pi\nu_1)^2y+\frac{e_1}{c}H\frac{dx}{dt}=e_1E_y.$$

Take the incident light to be circularly polarized, so that

$$E_x=F\cos 2\pi\nu t,\quad E_y=F\sin 2\pi\nu t.$$

Then the solution is

$$x=\frac{e_1}{m_1}\;\frac{F\cos 2\pi\nu t}{4\pi^2(\nu_1^2-\nu^2)-\dfrac{e_1H}{m_1c}\,2\pi\nu},$$

$$y=\frac{e_1}{m_1}\;\frac{F\sin 2\pi\nu t}{4\pi^2(\nu_1^2-\nu^2)-\dfrac{e_1H}{m_1c}\,2\pi\nu}.$$

But if the incident light is polarized the other way, so that

$$E_x = F\cos 2\pi\nu t,\quad E_y = -F\sin 2\pi\nu t,$$

we have

$$x = \frac{e_1}{m_1}\,\frac{F\cos 2\pi\nu t}{4\pi^2(\nu_1^2-\nu^2)+\dfrac{e_1 H}{m_1 c}2\pi\nu},$$

$$y = -\frac{e_1}{m_1}\,\frac{F\sin 2\pi\nu t}{4\pi^2(\nu_1^2-\nu^2)+\dfrac{e_1 H}{m_1 c}2\pi\nu}.$$

The change in the denominators of these shows that there is a different magnitude of response to the two types of circular polarization, and this we saw would explain the gyration.

It is of some interest to see how the gyration behaves in the immediate neighbourhood of ν_1. To simplify we will write $e_1H/4\pi m_1 c=\omega$, and it will be justifiable to write the denominator of the first solution as $4\pi^2[\nu_1^2-(\nu+\omega)^2]$, since for practicable fields ω^2 is always negligible. In the second type of motion the denominator will be $4\pi^2[\nu_1^2-(\nu-\omega)^2]$. Considering the first solution we see that for values of ν on opposite sides of $\nu_1-\omega$ there will be a phase difference of 180°. On the other hand the second solution will not show this change at the same point, but at $\nu_1+\omega$ instead. This suffices to outline the behaviour of the gyration (*see* fig. 24). As ν increases towards the value $\nu_1-\omega$ the gyration rapidly increases. At $\nu_1-\omega$ the light is absorbed, but on the other side, where it is again observable, it gyrates strongly the opposite way. As ν increases farther the gyration becomes less, though always negative, and then again increases as ν approaches $\nu_1+\omega$. After passing this it is positive and large, and rapidly decreases as ν recedes from $\nu_1+\omega$. By seeing which way the plane of polarization rotates, it is possible to find the sign of the electric charge e; this is negative as is that of the actual electron. It will be seen that our calculation indicates the presence of two regions of absorption, which implies that the original line ν_1 has been split into two by the magnetic field. The phenomenon can also be observed in emission, and is then called the Zeeman effect (*q.v.*). This effect is much more complicated than our explanation would suggest, but, with the help of the quantum theory, it has been more or less completely elucidated. Most spectral lines do not split into only two members, but into a pattern composed partly of line-waves and partly of circle-waves, and the circle-waves control the gyration. In the case of the two sodium lines, there are two pairs for one and one pair for the second.

The theory of the gyration of solids and liquids is less complete than that of metallic vapours, in just the same way as is that of refraction; but it is known to bear a very similar relationship. We can imagine that each virtual electron has an appropriate eH/mc which determines its response to the two types of circularly polarized light. If the incident light has frequency far from any of the natural frequencies of the substance, it is found that the gyration depends on terms of the form $\nu^2/(\nu_1^2-\nu^2)^2$; this means that for ordinary substances it increases much more rapidly than does the refractive index, as the colour changes from red to blue. By a comparison of the gyration of any substance with its refraction, the values of e/m for its virtual electrons can be estimated, and they are usually a fraction (mostly between ½ and 1) of the accepted value for an actual electron. The discrepancy has not been explained, but it is to be attributed to a complication rather like that of the Zeeman effect which occurs in vapours.

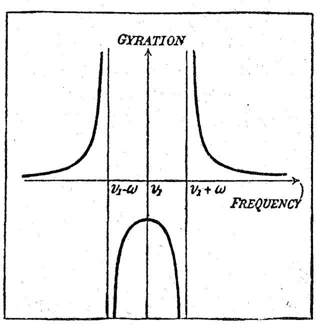

FIG. 24.—THE DISPERSION OF MAGNETIC GYRATION

ν_1 is the spectral line of frequency split by the magnetic field into $\nu_1-\omega$

In this account the principles of optics have been presented as a completed body of knowledge. Only where we leave the consideration of matter in bulk and come to atoms do we encounter more dubious questions. Since the beginning of the 20th century atomic theories have been in a state of flux, and it is necessary that we should radically revise our conception of particles, and probably of time and space as well; but, however great the changes, and however new the language, we may be sure that the older work will stand, and that the new theory will accommodate within itself the wave-theory of light.

BIBLIOGRAPHY.—There are several excellent books on the theory of light, for example: *The Theory of Optics* by P. Drude, or *The Theory of Optics* by A. Schuster (the last edition by Schuster and Nicholson includes an account of modern spectrum theory). *Physical Optics* by R. W. Wood covers the same ground from a rather more experimental point of view. An admirable account of the history of the subject is given in *History of the Theories of Aether and Electricity* by E. T. Whittaker. *The Theory of Electrons* by H. A. Lorentz is concerned especially with refraction, including the refraction of moving media. *See* also Rayleigh's *Collected Works*. (C. G. D.)

LIGHT AND RADIATION IN RELATION TO HEALTH. The phenomena of life result from the reactions of living substance to radiant energy, and depend primarily on the sun. The application of this principle in the treatment of disease by exposing the body to light is known as actinotherapy.

All radiations are conceived of as electro-magnetic waves conducted in a hypothetical medium, aether, and travelling with the velocity of light, 186,000m. a second. According to theory each of the atoms (*see* ATOM) of which a chemical element is composed consists of a central nucleus positively charged (protons and electrons densely packed, and electrons negatively charged, revolving round the nucleus in a variety of orbits with enormous speed, comparable to the planets revolving round the sun). The more complex the atom the greater the number of its electrons. When an electron is displaced from an outer to an inner orbit, radiant energy is given off. When an electron jumps from an inner to an outer orbit, energy is absorbed. Only a certain variety of orbits are possible for an electron to revolve in; a certain quantum of energy is required to effect each jump.

To have any effect on matter radiant energy must be absorbed. There then takes place a change of energy, *e.g.*, into electrical effect, heat, fluorescence, chemical action. All radiations when absorbed by a perfect black body are transformed into heat. A thermopile coated with lamp black is used for measuring in calories per sq.cm. per second, or in ergs per sq.cm. per second, intensity of radiant energy emitted by a source or received by a surface. This is the final standard of measurement. The body is composed of an infinite number of living cells. The living cell is the seat of an infinitely intricate play of energy, containing millions upon millions of molecules. We have to conceive of electrons being displaced by radiations in the atoms of these molecules, of molecular change enhanced thereby, provoking reactions which manifest themselves as signs of life, of the spirit of man evolving out of such transformations of energy.

Radiations are classified by frequency of vibration, and by wave length; they include first, the Hertzian waves used in radio with wave lengths extending to a thousand metres or more; to these waves the body is transparent; to be heard, they must be transmitted, received and transformed by suitable electrical apparatus. Then come the infra-red rays with wave lengths from 600,000 to 7,000 A.U. (Angstrom Unit = one ten-millionth of a millimetre). Absorbed largely by water and converted into heat, these rays are caught as they pass to, or come off, the earth, by the vapour-charged atmosphere. Thus is the earth kept warm to a temperate degree and life made possible. (*See* RADIATION, RAYS.)

Absorbed by the wet substance of the skin, these rays heat particularly the outer layers, whence heat is conducted to deeper parts and distributed by the blood circulating through the skin. Acting on the cool dry skin, these rays when intense provoke a dry prickling and not very agreeable sensation of heat. Next to the infra-red come the visible rays, a very narrow part of the vast radiation spectrum, with wave lengths from 8,000 to 4,000 A.U. The media of the eyes have been evolved transparent to these rays. The skin is much less transparent; while a part is reflected, a part of these rays penetrates to the cutaneous blood vessels, and absorbed therein, is changed into heat; in a cool dry skin these rays provoke transudation of water, and give thus a more agreeable sensation of heat.

The transformation of energy of visible rays taking place in the blood may have important effects as yet unknown. It is in this respect that sources of visible radiation have a superiority over infra-red rays as means of providing artificial heat; infra-red rays from hot water pipes heat rather the surface of the skin, while visible rays from sun, fire or lamp penetrate and heat the blood and tissues below the surface. Red rays are not wholly absorbed by the blood in the skin and so penetrate deeper still. By means of powerful incandescent lamps and red glass screens an agreeable and easily controlled method of applying heat to the body and provoking hyperaemia is obtained.

In the case of the eye, the parts of the visible spectrum evoke different sensations of colour, viz., red, orange, yellow, blue, violet, as the wave lengths shorten from 8,000 to 4,000 A.U. The living substance of the retina has evolved so as to react differently to the different groups of wave lengths. The living cells of the skin and the blood in the skin also react differently to infra-red, visible and ultra-violet rays, but little is yet known about this subject.

The U.V. rays are shorter than violet ones, and they, therefore, lie beyond the violet of the spectrum and are invisible, but may be made visible by fluorescent screens.

The horny layer of the skin fluoresces faintly; it can be made to fluoresce strongly by a coat of vaseline or solution of quinine. Fluorescence is produced by electrons displaced from atoms by the rays jumping back into inner orbits. A part of the energy of the rays is thus spent; fluorescence of the surface of the skin is then a means of protection against U.V. rays.

For study of the U.V. rays a quartz spectroscope is required, as glass absorbs most of these rays. They are classified by wave length as "near," 4,000 to 3,000 A.U., and "far," 3,000–2,000 A.U. The region about 3,100–2,900 A.U. is sometimes called the middle U.V., or "Dorno region," and has the most powerful sunburn action on the skin. These middle U.V. rays are so completely absorbed by living substance that they have very little power of penetration; thus, only some $\frac{1}{100}$ of rays, about 3,000 A.U., penetrates as far as the capillaries beneath the epidermis.

The main action of these rays is then, on the living cells of the epidermis. The U.V. rays shorter than 2,500 A.U. are so completely absorbed by the outer horny layer of the epidermis that they have very little action on the living cells beneath; the very far U.V. rays less than 1,800 A.U. do not penetrate air. A powerful source of U.V. has a bluish white light, and produces a pricking sensation in the conjunctiva of the eyes. To prevent conjunctivitis the eyes must be protected by glasses from such sources.

The skin is insensitive to these rays on exposure, but after sufficient exposure and a latent period of a few hours, there follow inflammatory reactions of the skin; these are pricking, flushing and slight swelling, followed later by peeling and browning. The reaction is caused primarily by the rays displacing electrons in the atoms of certain substances in the living cells, and so inducing molecular changes which after a latent period result in coagulation and death of the living substance. The dead cells desquamate and are replaced by new ones. Products of the damaged cells, by exciting the nerve endings in the epidermis, cause flushing of the blood vessels of the skin, and transudation of lymph and leucocytes. These local reactions in the irradiated skin provoke secondary reactions in the blood and body generally.

The effect of U.V. rays on living cells can be studied under the microscope, *e.g.*, on infusoria enclosed in a suitable quartz chamber. With the help of a quartz microscope and photography the effect of U.V. rays on microbes has been studied. Such a method shows up structures in living micro-organisms previously unknown. The remarkable discovery has been made that a substance, ergosterol, which is present in foods and in the skin, is activated by middle U.V. rays and becomes vitamin D required for bone formation. The want of this vitamin causes rickets and softening of the bones. Rickets can be prevented by adequate exposure of the skin to the U.V. rays of the sun or arc lamps, or by taking enough vitamin D in the food.

This one fact by itself shows the immense importance of getting rid of smoke pollution of the air, and having sun baths. Walls, glass, smoke, fogs and clothes cut off people from these beneficent rays. Irradiation of rickety children with U.V. rays increases the percentage of inorganic phosphorus and calcium in the blood, which is in them abnormally low. While provoking the formation of the brown pigment (melanin) in the skin, the U.V. rays lessen at the same time the percentage of the amino-acid tyrosin in the blood, the probable precursor of melanin. The inflammatory reaction set up by the U.V. rays provokes an increase of the power of the blood to destroy microbes as tested *in vitro,* a sign that these rays may possibly increase resistance to infection. It must be borne in mind that an over-dose has the opposite effect.

Right dosage with U.V. rays increases the sense of well-being and alertness of mind, and acts as a tonic in the winter months. Much of the stimulating effect of a visit to the Alps can be imitated by arc-light baths, combined with car rides and exercise in the open air. The fact must not be lost sight of that exposure to cool open air is as important as exposure to light. Such exposure stimulates the heat production of the body and appetite and tones up the muscles; breathing cool open air provokes blood flow through, and secretion from, the respiratory membranes; these are excellent effects. Open air is clean compared with house air which is contaminated with dust, mould and microbes.

Protection of the skin from U.V. rays is brought about mainly by swelling and thickening of the horny layer of the epidermis. The pigment which results from sunburn chiefly protects the blood from over-heating by visible rays. By absorbing of visible rays, nerve endings in the epidermis are excited, and this provokes sweating which cools the skin by evaporation. The naked pigmented races have a thin skin, and, sweating readily in the sun, lose heat easily in the shade. The pigmented skin of such races can be inflamed by U.V. rays. So long as the skin is kept cool by a flow of water, visible rays, even when concentrated by a lens (burning glass), have no sunburn effect on the skin.

The U.V. rays, on the other hand, sunburn the cold skin. Glacial burns are often very severe. It is possible to sensitize the skin to visible rays by injection of various dyes, eosin, erythrosin, and by a derivative of haemoglobin, viz., haematoporphyrin. The white skin thus sensitized, reacts to visible rays as it does to U.V. rays. Black skins are immune. Certain foods may have this sensitizing effect. Thus, only black pigs can be kept in tropical America, where the red mangold grows. There are rare cases of unfortunate people sensitive to visible rays. Exposed to light, their skin becomes inflamed and necrosed. They have to live like night animals. In some of these, haematoporphyrin is found in the urine.

Ultra-violet rays have great power to kill microbes, but as their penetrating power is very small, they only sterilize surfaces. In a skin disease such as lupus, these rays effect cure, not by directly killing the infecting tubercle bacilli, but by provoking an inflammatory reaction of the tissues which results in killing of the microbes and repair of the damage. Ultra-violet rays benefit the health of chicks and provoke egg-laying and fertility of fowls kept indoors under glass. They also, in suitable dosage, benefit growth of vegetables and fruits under ordinary glass. A particular kind of glass, called vitaglass, is transparent to the U.V. rays of the sun, and this is used for skylights with advantage. At the new monkey house at the London Zoo, the animals are given warm shelves, incandescent lamps, vitaglass skylights, louvres always open in the roof, and free access to open air playgrounds through openings closed by hinged flaps. Bathing pools are set in the playgrounds. Food rich in vitamins, with plenty of fruit and raw vegetable, is provided. These are conditions which, if provided in crêches in cities, would raise an A1 population.

Light-baths are very useful for treatment of rickets and tuberculosis, particularly tuberculosis of the skin (lupus), glands and joints; also many skin and eye diseases, and some forms of baldness. They may benefit chronic infections, *e.g.,* chronic bronchitis and asthma. Combined with visible and infra-red rays, or red rays, they may benefit forms of chronic rheumatism. Used in winter months, light-baths act as a tonic, and prevent rickets and debility of children.

The sources of U.V. rays are the sun and arc lamps. The U.V. of the sun is limited to rays longer than about 300 $\mu\mu$ owing to absorption of shorter rays by a layer of ozone placed miles high in the sky.

The artificial sources of U.V. rays are:—(1) The mercury vapour lamp; (2) the short flame arc; (3) the long flame arc. The last two may have plain carbon, or metal-cored carbon poles. Metal poles, such as tungsten or iron may be used with a short flame arc. The mercury vapour lamp is a powerful but relatively cold source of U.V. rays. A ring of incandescent lamps added to this source affords visible and infra-red rays for heating. The short flame arc, with plain carbon poles, gives much visible and infra-red and some U.V. rays as the sun does. The long flame arc, with metal-cored carbon poles gives plenty of visible and infra-red, and is at the same time a powerful source of U.V. rays. Given equal energy, the U.V. from the long flame arc may at right angles to the flame be 14 times that of the short flame arc. Much of the U.V. rays come from the flame, and to effect the best output, the positive pole must be placed below and be metal-cored (iron). The negative pole, placed above, can be plain carbon.

Half a dozen people can sit round a long flame arc, taking 2,500 Watts; at two feet distance, a dose of five minutes suffices. One half of the body can be bathed at a time, and two baths a week given. For intense local treatment, *e.g.,* required for lupus, the Kromayer, or water-cooled mercury vapour-lamp is most valuable, the dose given being five minutes, with the quartz glass of the lamp pressed on the skin—a dose sufficient to produce strong reaction and desquamation. The dose is repeated when the desquamation has passed away and the skin is again susceptible. The mercury vapour lamp or the short flamed arc with metal poles can be run off the ordinary house circuit and afford efficient sources. By means of a frosted Vitreosil screen the powerful mercury vapour lamp can be reduced to an intensity safe for domestic use.

With a screen of Chance's dark glass which transmits almost only long U.V. rays the fluorescence of substances can be studied in a dark room. This is a most useful method of identification. Thus, hair affected with ring-worm can be identified.

The far U.V. rays merge into the soft X-rays. The penetration of the skin increases again with the shortening of wave length. The X-rays produce inflammatory reaction after a long latent period, *e.g.,* two to three weeks. They are used to check the growth of cancer cells and to produce sterility. Acting on embryoes, deformities in growth and monsters may be produced by their means. Owing to the great penetration of the soft tissues by X-rays in comparison with bones, photographs of fractures and disease of bones can be obtained. The shorter the X-ray the greater is the penetration. General mild doses of X-rays have been used in treatment of asthma, and to prevent recurrence of cancer after removal of the primary growth.

X-rays are used for cure of skin diseases such as ring-worm. Great care must be used, for X-ray burns have a tendency to turn into cancer. The gamma rays of radium resemble very short ("hard") X-rays, and have the same effect as these. Tubes containing radium emanation are buried in cancers which cannot be removed with the knife, with the view of stopping growth. In certain accessible sites this treatment may be successful.

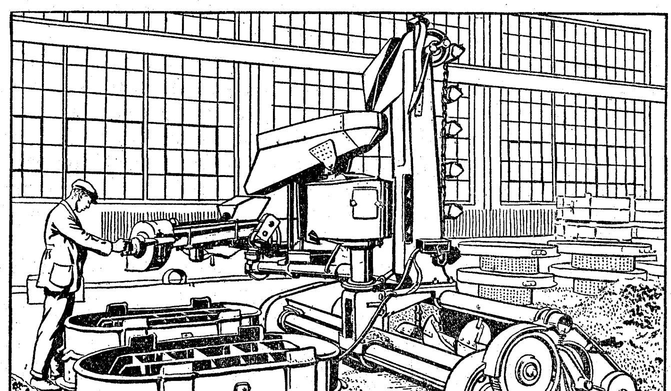
LIGHT BRIGADE. The brigade of light cavalry under the command of Lord Cardigan which carried out the famous charge at Balaklava on October 25, 1854, during the Crimean War. The charge has been immortalized by Tennyson in his poem "The Charge of the Light Brigade." The titles of the regiments which comprised the light brigade are 4th, 8th, 11th and 13th Hussars and 17th Lancers.

LIGHT (THIN) CASTINGS INDUSTRY. A highly specialized development of the ironfounding industry. Its products are designed almost exclusively for use in connection with the building trades, domestic purposes, and municipal and architectural requirements. Its development has depended on, and kept pace with, development in municipal enterprise and a rising standard in both public and private hygienic habits. Its product is cast in thin section and to this end requires an iron of high phosphorus content, giving the necessary fluidity. The actual process is quite similar in principle to that applied to any other branch of founding, but it has become so highly specialized a trade that the average ironfounder not so specializing cannot produce castings of such fine section or finish.

Classification.—For purposes of the trade light castings are classified under the following main heads:—

1. *Unfitted Goods,* including such articles as rain water and soil pipes, hot water pipes, gutters or rhones, drain pipes, gas and water pipes and the various connecting pieces required therewith, electric and gas pillars, roof lights, school desk and stable fittings, manhole covers and frames, etc.
2. *Fitted Goods,* including such articles as coal, gas, electric, and steam cooking ranges, grates, stoves, boilers, etc.
3. *Baths and Sanitary Ware,* including cisterns, sinks, etc.
4. *Hollow-ware,* including kettles, pots, pans, coppers or furnace pans, etc.
5. *Light Structural and Ornamental Castings,* including spiral stairs, fire escape stairs, verandahs, railings, gates, bandstands, shop fronts, etc.

The development of the industry as a distinct and separate branch of ironfounding may be said to date from the beginning of the 19th century, and it was with the setting up of the Board



BY COURTESY OF FOUNDRY PLANT AND MACHINERY, LTD.

TRACTOR SAND SLINGER MACHINE RAMMING MOULDS FOR LIGHT CASTINGS

This machine rams any size of box, at speeds varying from five to ten cubic feet per minute. Other models can be used in a stationary position by bolting to the floor of the moulding shop

of Health under the Act of 1848 and the powers conferred and duties devolved on local authorities thereunder that the demand for light casting sanitary products became really substantial. With the awakening of public interest in sanitation as a preventive measure against disease, individual requirements in the way of hygienic appliances also grew, and the tendency has since been for what were first deemed luxuries in the way of sanitary equipment to become necessities, with an ever advancing standard. The light castings industry set itself to cope with these demands and a real appreciation of what it has done and is doing in that direction can best be gained from a consideration of what light castings articles are included in the structure of a modern dwelling house, and of the various functions which they perform.

Gutters, etc.—The outside requirements are gutters or rhones, rain water pipes and soil pipes cast in 6ft. lengths and varying from $1\frac{1}{2}$ to 6in. diameter. The gutters, which are made to many patterns, intercept rain water from the roof and conduct it to an outlet hole to which is attached the rain water pipe which leads the water down the outside of the house to an earth drain at the foot and thence to the public sewage system. The ordinary rain water pipe and gutter are round and half round respectively, but for buildings more pretentious in design, rectangular rain water pipes and ornamental gutters are frequently required and supplied. All waste matter from the house is taken away by an outside pipe of heavier make than the rain water pipe, known as a soil pipe, which connects the lavatory, bath, and sinks with the earth drain and main sewer. It projects up to the roof of the house, the upper part acting as a ventilating pipe.

As regards the inside structure of the house, light castings requirements comprise the bath, range, interior grates for living rooms, mantel registers for bedrooms, lavatory cistern, and portable wash boiler.

Baths.—At first baths were merely painted inside. Demand for higher quality and better finish led to the introduction of what is known as the metallic enamelled bath, which was grained on the inside to give a marble effect; but this type has been almost entirely superseded by what is known as the porcelain enamelled bath, which may be either in green or white. Baths are made either parallel or taper, generally with a square end and a scoop end, although in some patterns both ends are square. The popular sizes are 5 and $5\frac{1}{2}$ft. long, of varying widths and depths. Better quality baths are made with wide rolls or rims and in some cases are cast or fitted with outside panels reaching to the floor. The normal bath type, however, stands on feet which are cast separately and bolted to snugs on the bath casting. A modern development to suit the small modern house where bathroom space is limited is the combined bath and basin, the basin being either cast in one piece with the bath or cast separately and fitted on at the square end. The whole is fitted with swivel taps for hot and cold water serving bath and basin. Better class baths are also, if required, fitted with canopies for douches, sprays, etc. These canopies are generally of plate glass.

Ranges.—Ranges are made in various types and fitted with one or more ovens which may be placed level with or to one side above the fireplace. As a general rule ranges are fitted with a hot water boiler at the back of the fire. This boiler is supplied from the cold water cistern and feeds an intermediate tank which is connected directly to the bath, basin, and sink taps. A modern labour-saving device is to substitute for the range a combination article consisting of an ordinary sitting-room fireplace with an oven attached. The oven may be either at the side or on top, and in such cases the hot water boiler is placed at the back of and heated from the interior.

Interior Grates and Mantel Registers.—An interior grate is simply a framework with a bottom grate fitted into tiles which are cemented to bricks built in between the fireplace and the wall of the house. It may be entirely open or fitted with a fixed or movable canopy of plain or ornamental design. The cheaper types are finished in ordinary black, but interior grates are supplied in oxidized copper or silver, in armour bright which gives the interior a steel appearance, and in steel itself.

The mantel register is a combined casting designed to supply both fireplace and mantelpiece. This may be supplied plain or with ornamental tiles set into the sides.

In addition to the foregoing, which may be classified as structural requirements, light castings foundries produce what may be termed furnishings in the shape of kerbs or fenders for fireplaces, kettles, pots and pans for cooking purposes, and smoothing or sad irons (ordinary, gas, and electric). The kerbs or fenders may, as in other cases, be finished in plain black or in some better quality finish.

There is also that branch of the industry which supplies the service requirements of municipalities and local authorities in connection with their gas, water, and sewage systems. The requirements in such cases are pipes which are made in 6 and 9ft. lengths, with bores of varying diameters. In the trade the water pipe is known as the underground pipe. The drain pipe is of high inside finish and tested under high pressure. Hot water pipes, which are usually made in 9ft. lengths and varying diameters, are mainly used for the heating of greenhouses, outbuildings, and public buildings such as churches, halls, etc.

Making the Patterns.—The first step in the process, which is common to all classes of castings, takes place in the drawing office where a drawing of the pattern is made. This is passed to the pattern shop where the pattern is made in wood, stucco, or an amalgam of tin and lead. It is then passed to the moulding shop, where an iron or aluminium working pattern is cast.

Unfitted Goods.—This category consists mainly of pipes and gutters and their connections. They are made in boxes of two parts, top and bottom, or in trade language, top part or "cope" and drag. The pattern is placed on a board on the floor and the bottom or drag part of the box is placed over it. The drag is rammed with damp sand, technically called "greensand," until it is absolutely firm. It is then turned over and the top part of the box is placed on it. The top part is rammed firm, and holes or gates leading down to the pattern are made in the sand. These holes or gates are for the running of the molten metal. The top part is then lifted off, the pattern drawn out, and the mould dusted and sleeked to make it absolutely smooth. A core which consists of a cylinder of the requisite length of hard sand made in a core box round a metal bar which projects at both ends is inserted in the hollow left by the pattern. The ends of the core when in place rest on two prints or bearings in the mould left by the pattern. The top part is put on and the box closed by hooking the two parts together. The mould is then ready to receive the metal. In the case of the lighter pipes, *e.g.*, rain water and soil, the gates are made on the top and the casting is run horizontally, while in the case of the heavier pipes, *e.g.*, drain and underground, the pipes are made and cast on a slope technically known as "the bank." The gates are placed at the top end of the mould and the casting is run on the slant. Still larger and heavier pipes are cast in a vertical position.

The metal is brought from the cupola in large bogies and is poured into the mould by means of hand ladles through the gates. Before the box is opened, and before even the metal has cooled, the gates are knocked off. When the iron has cooled the top part is lifted off and the pipe lifted out. The pipes are then collected and taken to the dressing shop, where any fins or raw edges are taken off them and they are brushed with steel brushes. All pipes then go before a man known as the passer for acceptance or rejection, and, if passed, are taken to be painted or coated with a tar preparation before despatch.

Fitted Goods.—The moulding process for fitted goods is in principle exactly similar to that for unfitted goods except that in the case of a perfectly flat casting a core is not required.

From the moulding shop these castings are sent, like the others, to the dressing shop, where the rough edges are taken off. Thence after inspection they pass to the grinding mill, where they are ground and buffed to give the necessary polished surfaces. They are then taken first to the fitting shop, where they are given a preliminary fitting and slight inequalities are remedied, and secondly to the finishing shop, where the individual parts are blacked, oxidized, or nickel plated, according to requirements. Thereafter they are returned to the fitting shop for final assembly. The article is then ready for the showroom or for despatch.

Baths and Sanitary Ware.—After a moulding process similar to that previously described, the bath is annealed or burned, *i.e.*, heated in a furnace known as a muffle. The purpose of annealing is to soften the metal and in particular to remove or drive out all of the various gases which may remain imprisoned in it. The bath is then dressed, sand blasted, and coated, to give a suitable ground to which the enamel can adhere. It next passes to the enamelling shop, where it is again put into the muffle and kept there until it is at the requisite heat. It is then taken out and the enamel, which is in powder form, is dusted on by means of automatic dusters or fine mesh sieves. Generally each bath receives two coats of enamel, each coat being preceded by the heating process. The bath is then laid aside for the enamel to harden, and thereafter the feet are bolted on and the outside painted. The bath is then ready for the warehouse or for despatch.

Cisterns are simply moulded, dressed, fitted, and painted, while sinks are enamelled by a process similar to that followed in the case of baths. The cast-iron porcelain enamelled sink has, however, been largely superseded by the earthenware sink.

With regard to hollow-ware and structural and ornamental castings, the process, apart from moulding, follows the lines described on p. 85, namely, dressing, tinning or enamelling, in the case of pots and pans, and in the case of spiral stairs, verandahs, shop fronts, etc., dressing and fitting.

Plate Moulding.—A development in the moulding process is the use of plate patterns. Instead of working with a loose pattern, one, two, or more articles, where the size and nature of the casting lend themselves to it, are put on what is known as a plate. At first these plates were made of cast-iron, but they have since been made, where possible, of aluminium, so as to lighten the handling of the job. There is, however, no difference in the actual moulding process, and successive processes follow, as before described, according to the nature of the article.

Machine Moulding.—For a considerable time machines have been employed to assist in the ramming of the moulds, but formerly these were chiefly used for smaller classes of work, *e.g.,* connections and certain types of flat castings. They are variously operated—by electricity, by compressed air, by hydraulic power, or by hand. In all cases the moulding box has to be filled by hand, the machine doing only the ramming. Since the World War, however, there has been put on the market a machine called the Sand Slinger which is being operated in foundries throughout the world. This machine not only fills the boxes with sand but, in the act of doing so, rams it hard. It is made to different designs for different purposes and can ram practically any size of box at speeds varying from five to ten cubic feet of sand per minute. The type most commonly in use in light castings shops is known as the Tractor machine. This takes the sand from the floor, riddles it and passes it on by means of a moving belt to the ramming head, whence it is discharged into the moulding box. The ramming head is attached to the end of a swivelling arm which has a radius of from 9 to 11ft. on either side of the machine. The machine is also made to work in a stationary position, in which case it is bolted to the floor of the moulding shop. It is also supplied in portable form so that it can be moved to any job in any part of the moulding shop. In the case of the stationary and portable types the sand has to be fed to the machine. Another type is the Motive type to which is attached a large tank with a sand carrying capacity of from eight to ten tons. This can conveniently be filled by means of an overhead conveyor.

As the ramming of the boxes in the moulding shop is one of the heaviest and most tiring jobs in the foundry, it would appear to be only a question of time before practically all classes of work are automatically rammed by the Sand Slinger or some similar type of machine. (J. K.)

LIGHTER, a barge employed in ports in loading or unloading the cargoes of ships, the name being derived from the verb "to light"; *i.e.,* to relieve of a burden. The men employed on them are termed lightermen. (*See* BARGES AND CANAL CRAFT.) Also a small mechanism, used instead of matches, in which a small wheel is twirled against a piece of ferro-cerium, throwing off sparks which ignite petrol fed through a cotton wick.

LIGHTFOOT, JOHN (1602–1675), English divine and Hebrew scholar, was born at Stoke-upon-Trent on March 29, 1602, and studied at Christ's college, Cambridge. He was a supporter of the parliament, and an original member of the Westminster Assembly (*see* his *Journal of the Proceedings,* vol. xiii. of his works). In 1643 he was made master of Catherine hall, Cambridge, and rector of Much Munden, Herts, preferments in which he was confirmed after the Restoration. In 1654 he became vice-chancellor of the university. He wrote various learned exegetical works. His later years were devoted to helping Brian Walton with the *Polyglot Bible* (1657) and to the preparation of his own best known work, *Horae Hebricae et Talmudicae* (5 vols., 1658–74). He died at Ely on Dec. 6, 1675.

See his *Whole Works,* in 13 vols., edited, with a life, by R. Pitman (1822–25) and D. M. Welton, *John Lightfoot, the Hebraist* (Leipzig, 1878).

LIGHTFOOT, JOSEPH BARBER (1828–1889), English theologian and bishop of Durham, was born at Liverpool on April 13, 1828. He was educated at King Edward's school, Birmingham, and Trinity college, Cambridge. He graduated senior classic and 30th wrangler, and was elected a fellow of his college. From 1854 to 1859 he edited the *Journal of Classical and Sacred Philology.* He became tutor of his college (1857), Hulsean professor (1861), chaplain to the prince consort and honorary chaplain to the queen, Whitehall preacher (1866) and canon of St. Paul's (1871). In 1875 he became Lady Margaret professor of divinity in succession to William Selwyn. He had previously written his commentaries on the epistles to the Galatians (1865), Philippians (1868) and Colossians (1875), which mark a new departure in New Testament exegesis in England. Lightfoot was a great grammarian and textual critic; he endeavoured to make his author interpret himself, and by considering the general drift of his argument to discover his meaning where it appeared doubtful. Thus he was able often to recover the meaning of a passage which had long been buried under a heap of contradictory glosses, and he founded a school in which sobriety and common sense were added to the industry and ingenuity of former commentators. In 1879 Lightfoot was consecrated bishop of Durham. He continued to work on his editions of the Apostolic Fathers, and in 1885 published an edition of the Epistles of Ignatius and Polycarp, collecting also much valuable material for a second edition of Clement of Rome, which was published after his death (1st ed., 1869). His defence of the authenticity of the Epistles of Ignatius is an important contribution to that very difficult controversy. He died at Bournemouth on Dec. 21, 1889, and was succeeded in the episcopate by Westcott, his schoolfellow and lifelong friend who published a sketch of his *Life* (1894).

LIGHTHOUSES. Under the general heading of Lighthouses this article includes, in addition to a description of marine lighthouse structures and apparatus, some reference to Unattended lights, Light-vessels, Lighted buoys, Aerial lighthouses and Acoustic and wireless fog signals. (*See* the following section, *Lighthouses of the United States,* for similar information concerning America.)

A lighthouse is a structure erected to carry a light for the purpose of warning or guidance, in connection with marine and aerial navigation.

Early History.—The earliest lighthouses, of which records exist, were the towers built by the Libyans and Cushites in Lower Egypt, beacon fires being maintained in some of them by the priests. Lesches, a Greek poet (*c.* 660 B.C.) mentions a lighthouse at Sigeum (now Cape Incihisari), in the Troad, which appears to have been the first light regularly maintained for the guidance of mariners. The famous Pharos of Alexandria, built by Sostratus of Cnidus in the reign of Ptolemy II. (283–247 B.C.) was regarded as one of the wonders of the world. A full account of it is given in Hermann Thiersch's *Pharos Antike, Islam und Occident* (1909). The tower, which took its name from that of the small island on which it was built, is stated to have been 600 ft. in height, but the evidence in support of this is doubtful. It was destroyed by an earthquake in the 13th century, but remains are said to have been visible as late as 1350. The name Pharos became the general term for all lighthouses, and the term "pharology" has been used for the science of lighthouse construction. The tower at Ostia was built by the emperor Claudius (A.D. 50). Other famous Roman lighthouses were those at Ravenna, Pozzuoli and Messina. The ancient Pharos at Dover and that at Boulogne, later known as *la Tour d'Ordre,* were built by the Romans and were probably the earliest lighthouses erected in western Europe. Both are now demolished.

The light of Cordouan, on a rock in the sea at the mouth of the Gironde, provides the first example now existing of a wave-swept tower. Two earlier towers on the same rock are supposed to have been built, the first by Louis le Debonnaire (*c.* A.D. 805) and the second by Edward the Black Prince. The existing structure was begun in 1584 during the reign of Henry II. of France and completed in 1611. The upper part of the beautiful Renaissance building was removed towards the end of the 18th century, and replaced by a loftier cylindrical structure rising to a height of 207 ft. above the rock (fig. 1). Until the 18th century the light was exhibited by means of an oak-log fire, and subsequently a coal fire was in use for many years. The ancient tower at Corunna, known as the Pillar of Hercules, is supposed to have been a Roman Pharos. The Torre del Capo at Genoa originally stood on the promontory of San Berrique. It was built in 1139 and first used as a lighthouse in 1326. It was rebuilt on its present site in 1643 and rises 236 ft. above the cliff. The Pharos of Meloria was constructed by the Pisans in 1154 and was several times rebuilt until it was finally destroyed in 1290. On the abandonment of Meloria by the Pisans, they erected the still existing tower at Leghorn in 1304, which has well borne the brunt of time.

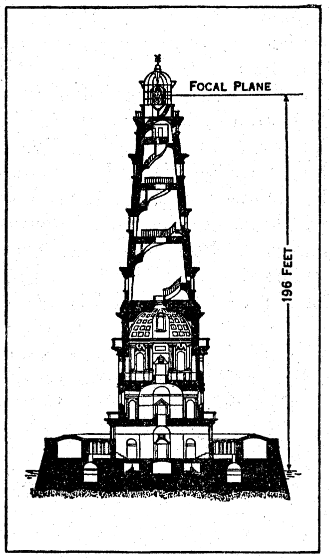


FIG. 1.—CORDOUAN LIGHTHOUSE, EARLIEST EXTANT WAVE-SWEPT TOWER

The lighthouse was begun in 1584 and stands on a rock in the Bay of Biscay near the mouth of the river Gironde

In the 17th and 18th centuries numerous towers, on which were erected braziers or grates containing wood or coal fires, were established in various positions on the coasts of Europe. Among such stations in the United Kingdom were Tynemouth (*c.* 1608), the Isle of May (1636), St. Agnes (1680), St. Bees (1718) and the Lizard (1751). The oldest lighthouse in the United States is believed to be the Boston light situated on Little Brewster island on the south side of the main entrance to Boston Harbour, Mass. It was established in 1716, the present structure dating from 1859. Other early lighthouses on the New England coast were those at Beaver Tail, near the entrance to Newport Harbour (1740), and the Brant at the entrance to Nantucket Harbour (1754). A watch-house and beacon appear to have been erected on Beacon or Lighthouse Island as well as on Point Allerton Hill near Boston, prior to 1673, but these structures would seem to have been in the nature of look-out stations in time of war rather than light-houses for the guidance of mariners.

LIGHTHOUSE STRUCTURES

The structures of lighthouses may be divided into two classes, (a) those on rocks, shoals or in other situations exposed to the force of the sea, and (b) the more numerous class of land structures.

Wave-swept Towers.—In determining the design of a lighthouse tower to be erected in a wave-swept position consideration must be given to the physical features of the site and its surroundings. Towers of this description are classified as follows: (1) Masonry and concrete structures; (2) Openwork steel and iron-framed erections on pile or other foundations; (3) Cast-iron plated towers; (4) Structures erected on caisson foundations.

(1) Masonry towers are generally preferred for erection on wave-swept rocks affording good foundation, and have also been constructed in other situations where adequate foundations have been made by sinking caissons into a soft sea bed. Smeaton's tower on the Eddystone rock is the model upon which most later designs of masonry towers have been based, although many improvements in detail have since been made. In situations of great exposure the following principles in design should be observed: (a) The centre of gravity of the tower structure should be as low as possible. (b) The mass of the structure superimposed at any horizontal section must be sufficient to prevent its displacement

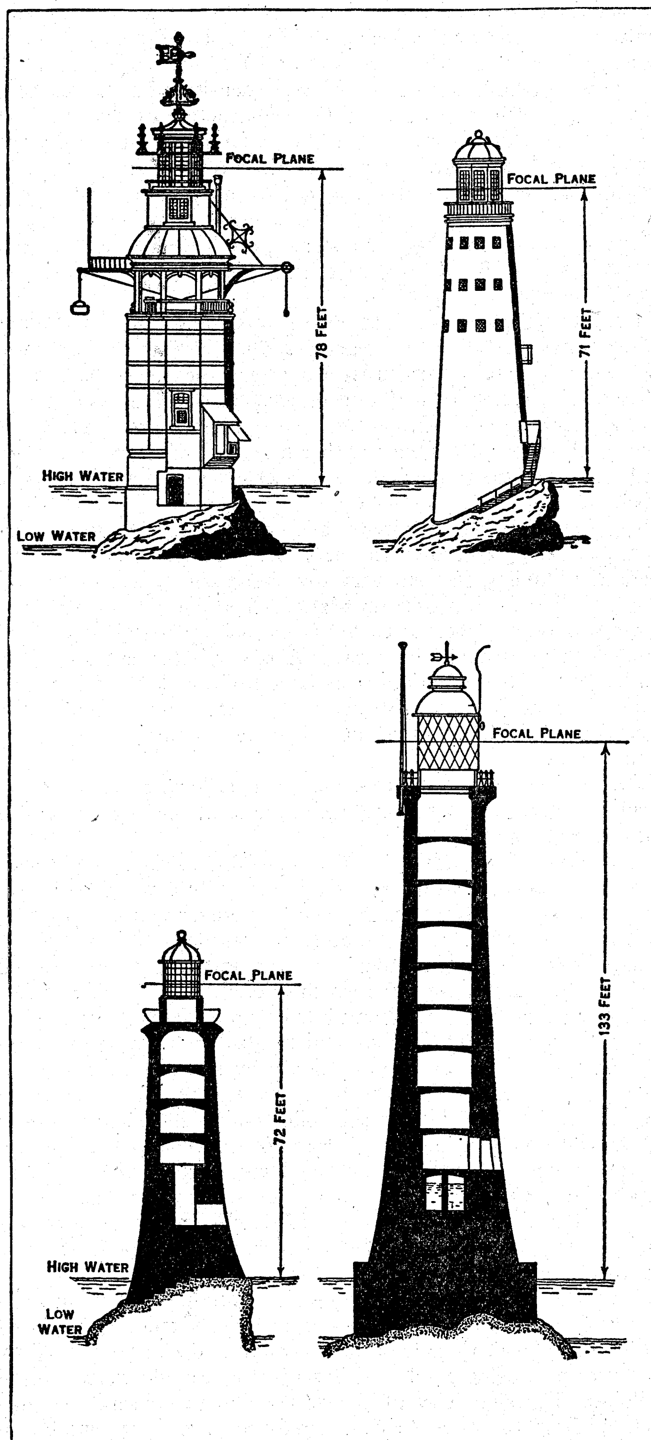

FIG. 2.—THE FOUR LIGHTHOUSES ON THE EDDYSTONE ROCKS

The towers are drawn to the same scale. The first tower was destroyed in the great storm of 1703, and the present tower was completed in 1882

by the combined forces of wind and waves without dependence on the adhesion at horizontal joint-faces or on the dove-tailing of stones introduced as an additional safeguard. (c) The structure should be circular in plan throughout, this form affording the least resistance to wave stroke and wind pressure in any direction. (d) The lower portion of the tower exposed to the direct horizontal stroke of the waves should, for preference, be constructed with a vertical face. The upper portion should be either straight with uniform batter or continuously curved in the vertical plane. External projections from the face of the tower, except in the case of a gallery under the lantern, should be avoided, the surface throughout being smooth. (e) The height from sea-level to the top of the tower should be sufficient to avoid the obscuration of the light by broken water or dense spray driving over the lantern. (f) The foundation of the tower should be carried well into the solid rock and secured to it. (g) The materials of which the tower is built should be of high density and of resistant nature. (h) The stones used in the construction of the tower, at any rate those on the outer face, should be dove-tailed or joggled one to the other in order to prevent their being dislodged by the sea during the process of construction and to afford additional stability. Of late years, cement concrete has been used to a considerable extent for maritime structures, including lighthouses, either alone or faced with masonry. Reinforced concrete has also been employed.

(2) Many examples of openwork steel and iron lighthouses exist. Some typical examples are described hereafter. This form of design is suitable for situations where the tower has to be carried on a foundation of iron or steel piles driven or screwed into an insecure or sandy bottom, *e.g.*, on shoals, coral reefs and sand banks or in places where other materials of construction are exceptionally costly and where facility of erection is a considerable advantage.

(3) Cast-iron plated towers have been erected in many situations where the cost of stone or scarcity of labour would have made the building of a masonry tower excessively expensive.

(4) Cylinder or caisson foundations have been used for lighthouse towers in numerous cases where such structures have been erected on sand banks or shoals. A remarkable instance is the Rothersand tower. Two attempts have been made to sink a caisson in the outer Diamond Shoal off Cape Hatteras on the Atlantic coast of the United States, but these endeavours have proved to be futile.

Famous Wave-swept Towers.—The following are brief descriptions of some of the more important wave-swept towers in various parts of the world.

Eddystone (*Winstanley's Tower*).—The Eddystone rocks, which lie about 14 m. off Plymouth, are fully exposed to south-western seas. Four towers have been constructed on the reef which is submerged at high-water spring tides. The first lighthouse (fig. 2a) was polygonal in plan and highly ornamented with galleries and projections which offered considerable obstruction to the sea stroke. The work was begun by Henry Winstanley, a gentleman of Essex, in 1695 and finished in 1698. In the following year, in consequence of damage by storms, the tower was increased in diameter from 16 ft. to 24 ft. by the addition of an outer ring of masonry and made solid to a height of 20 ft. above the rock, the tower being raised from 80 ft. to nearly 120 ft. This work was completed in 1700. The lower part of the structure appears to have been of stone, the upper part and lantern of timber. During the great storm of Nov. 20, 1703, the tower was swept away, those in it at the time, including the builder, being drowned.

Eddystone (*Rudyerd's Tower*).—This lighthouse was begun in 1706 and completed in 1709 (*see* fig. 2b). The structure consisted principally of oak timbers securely bolted and clamped together, the lower part being filled in solid with stone to add weight to the building. The simplicity of the design and the absence of projections from the outer face rendered the tower very suitable to withstand the onslaught of the waves, but the lighthouse was destroyed by fire in 1755.

Eddystone (*Smeaton's Tower*).—This famous work, which consisted entirely of stone, was begun in 1756, the light being first exhibited in 1759 (*see* fig. 2c). John Smeaton was the first engineer to use dove-tailed joints for the stones in a lighthouse structure. The stones, which averaged 1 ton in weight, were fastened to each other by means of dove-tailed vertical joint faces, oak key wedges, and by oak tree-nails wedged top and bottom, extending vertically from every course into the stones beneath it. During the 19th century the tower was strengthened on two occasions until in 1877, owing partly to the undermining of the rock on which the tower was built and the insufficient height of the structure, the Corporation of Trinity House determined on the erection of a new lighthouse in place of it.

Eddystone (*J. N. Douglass' Tower*).—The site selected for the new Eddystone tower (fig. 2d) is 120 ft. S.S.E. from Smeaton's lighthouse, where a suitable foundation was found, although a considerable section of the lower courses had to be laid below the level of low water. The base is vertical, 44 ft. in diameter, and all the stones are dove-tailed, both horizontally and vertically, on all joint faces, those of the foundation course being secured to the rock by Muntz metal bolts. The lantern is a cylindrical helically-framed structure with domed roof, gun-metal astragals and cast-iron pedestal. The optical apparatus in this lighthouse consists of two superimposed tiers of refracting lens panels. The burners originally fitted in Eddystone tower were of 6-wick pattern, but these were replaced in 1904 by incandescent oil-vapour burners. At the time of the completion of the lighthouse two bells, weighing 2 tons each and struck by mechanical power, were installed for fog-signalling purposes; these have since been replaced by an explosive gun-cotton fog signal. The work of preparing the foundation was begun on July 17, 1878, and the light was first exhibited on May 18, 1882.[1] The upper portion of Smeaton's tower was removed on completion of the new lighthouse and re-erected on Plymouth Hoe, where it replaced an old Trinity House sea mark. One of the principal features in the design of the new Eddystone lighthouse tower is the solid vertical base. Heavy seas are immediately broken up or reflected by it, spray alone rising to the height of the lantern gallery. The shock to which the gallery cornice of the old tower was exposed was so great that stones were sometimes lifted from their beds. Its successor presents another point of dissimilarity from Smeaton's structure, in that the stones forming the floors consist of single corbels built into the wall instead of stone arches the thrust of which, in the earlier tower, was taken by the walls strengthened by building in chains in the form of hoops. The system of constructing corbelled stone floors was first adopted by R. Stevenson in the Bell Rock lighthouse.

Bell Rock.—The Bell Rock tower (fig. 3a), which lies 12 m. off the coast of Forfarshire, stands on an exposed reef, dry at

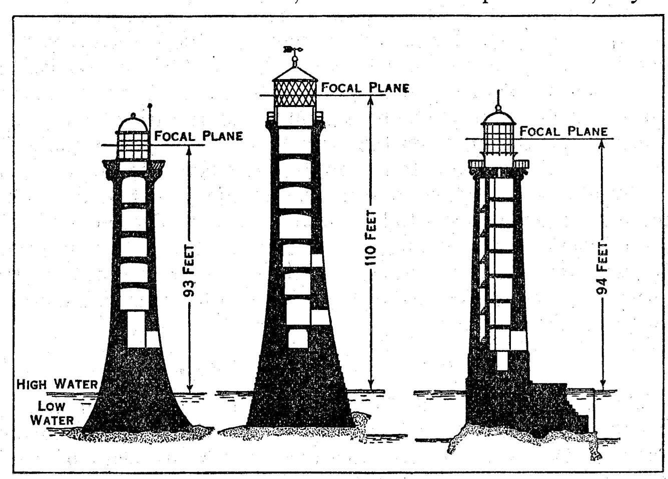

FIG. 3.—SECTIONS OF ROCK LIGHTHOUSES DRAWN TO SAME SCALE
a, Bell Rock, off the east coast of Scotland; b, Wolf Rock, off coast of Cornwall; c, Ar'men, off the coast of Finistère

low water and submerged to a depth of about 16 ft. at high water of spring tides. The rock is of hard sandstone. The lighthouse was constructed by R. Stevenson in 1807–11.

Skerryvore.—The Skerryvore Rocks, 12 m. off the island of Tyree in Argyllshire, are wholly open to the Atlantic. The tower, 150 ft. in height and designed by Alan Stevenson, was begun in 1838 and finished in 1844.

Bishop Rock.—The lighthouse on the Bishop Rock,[2] the westernmost landfall rock of the Scilly Islands, occupies perhaps

[1] *Proc.* Inst. C.E. vol. LXXV. (1883).
[2] *Proc.* Inst. C.E. vol. CVIII. (1892).

a more exposed situation than any other in the world. The first lighthouse erected there was begun in 1847 under the direction of N. Douglass. The tower consisted of a cast and wrought-iron openwork structure having the columns deeply sunk into the rock. On Feb. 5, 1850, when the tower was ready to receive the lantern, a heavy storm swept away the whole structure. In 1851 the erection of a granite tower was begun and the light was first exhibited in 1858. This structure also proved insufficient to withstand the very heavy seas to which it was exposed. Soon after its completion the 5-cwt. fog bell, fixed to the lantern gallery 100 ft. above high-water mark, was washed away and the tower vibrated considerably during storms. In 1874 it was strengthened by bolting continuous iron ties to the internal surfaces of the walls. In 1881 further signs of damage appeared and the structure was encased from its base upwards with granite blocks dove-tailed to each other and to the existing work. At the same time the elevation of the light was increased. The work was begun in 1883 and completed in 1887. Profiting by the experience gained after the construction of the new Eddystone tower, Sir J. N. Douglass decided to build the lower portion of the improved Bishop Rock tower in the form of a cylinder, but with considerably increased elevation (fig. 4).

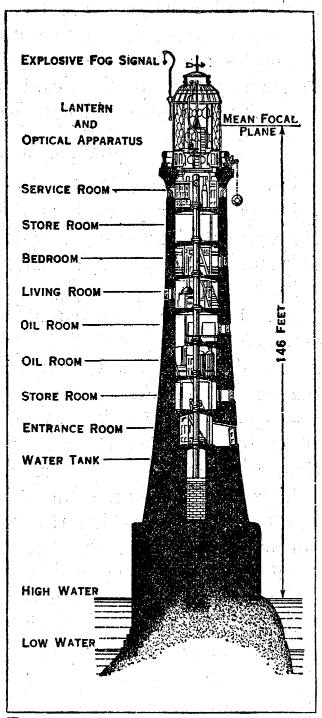

FIG. 4.—BISHOP ROCK LIGHTHOUSE, SCILLY ISLANDS
This is the second granite tower. The first granite tower was encased and raised in height in 1883–87

Minot's Ledge (Plate I.). The tower, 89 ft. in height, is built of granite upon a reef off Boston Harbour, Mass., and occupied five years in construction, being completed in 1860. The rock just bares at low water. The stones are dovetailed vertically, but not on their horizontal beds, bonding bolts being substituted for the horizontal dovetailed joints in the lower 40 ft., or solid portion of the tower.

Wolf Rock.—This much-exposed rock lies midway between the Scilly isles and the Lizard point, and is submerged to the depth of about 6 ft. at high water. The tower was erected in 1862–9 (fig. 3b). The lower part of the base has projecting steps or scarcements in order to break up the sea[1].

Dhu Heartach Rock.—The Dhu Heartach Rock, 35 ft. above high water, is 14 m. south-west of the island of Mull. The tower occupied six years in erection, and was completed in 1872. The focal plane is at a level of 145 ft. above high-water.

Ar'men.—The masonry tower, erected by the French Lighthouse Service, on the Ar'men rock off the western extremity of the Île de Sein, Finistère, occupied fifteen years in construction (1867–81). The rock is barely uncovered at low water and of small area, which made it impossible to construct a tower having a base diameter greater than 30 ft. (fig. 3c).

St. George's Reef, California.—This structure, completed in 1891, consists of a square pyramidal stone tower rising from the easterly end of an oval masonry pier, built on a rock to a height of 60 ft. above the water. The focal plane is at an elevation of 146 ft. above high water. The site is one of great exposure.

Fastnet.—The first lighthouse on the Fastnet rock, off the south-west coast of Ireland, was a circular cast-iron tower 86 ft. in height completed in 1854. It was erected on the summit of the rock which in 1895 was found to be considerably undermined. In 1899 a granite structure of increased height and founded upon a sound ledge of rock on one side of the higher, but undermined, portion of the reef, with its foundation laid near high water, was commenced and completed in 1904 (Plate II.). The focal plane is at a level of 158 ft. above high-water mark.

Maplin.—The screw-pile lighthouse erected on the Maplin Sand in the estuary of the Thames in 1838 is the earliest of its kind and served as a model for numerous similar structures in various parts of the world The piles, nine in number, are of solid wrought-iron with screws 4 ft. in diameter.

American Shoal, Florida.—This tower is typical of the openwork pile structures on the Florida reefs, and was completed in 1880. The focal plane is 109 ft. above high water.

Wolf Trap.—This lighthouse was erected during the years 1893–94 on Wolf Trap Spit in Chesapeake bay, near the site of an old openwork structure which was swept away by ice early in 1893. The tower is built upon a cast-iron caisson 30 ft. in diameter sunk 18 ft. into the sandy bottom. The depth of water on the shoal is 16 ft. at low water. The caisson was filled with concrete, and is surmounted by a brick superstructure 52 ft. in height from low water to the focal plane of the light. A somewhat similar structure was erected in 1885–87 on the Fourteen-Foot Bank in Delaware Bay. The foundation in this case was, however, shifting sand, and the caisson was carried to a greater depth.

Rothersand.—This lighthouse, off the entrance to the river Weser, in Germany, is a structure of great interest on account of the difficulties met with in its construction. The tower had to be founded on a bottom of shifting sand 20 ft. below low water and in an exposed situation. Work was begun in May 1881, when attempts were made to sink an iron caisson under pneumatic pressure. Owing to the fact that scour removed the sand from one side of the caisson it tilted to an alarming angle, but eventually it was sunk to a depth of 70 ft. below low-water. In October of the same year the whole structure collapsed. Another attempt, made in May 1883, to sink a caisson of bi-convex shape, in plan 47 ft. long, 37 ft. wide and 62 ft. in height, met with success, and after many difficulties the structure was sunk to a depth of 73 ft. below low-water, the sides being raised by the addition of iron plating as the caisson sank. The sand was removed from the interior by suction. Around the caisson foundation were placed 74,000 cu.yd. of mattress-work and stones, the interior being filled with concrete. The lighthouse (fig. 5) was completed in 1885.

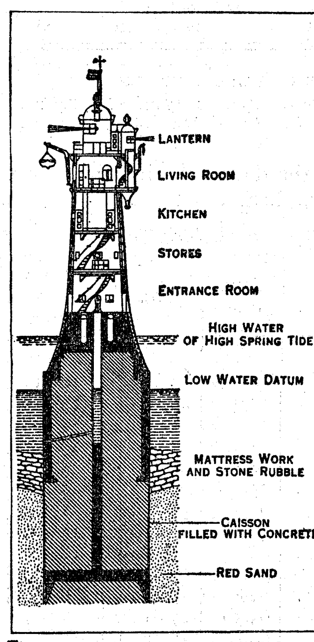

FIG. 5.—ROTHERSAND LIGHTHOUSE, NEAR THE MOUTH OF THE WESER ESTUARY, GERMANY

Other well-known wave-swept towers are those at Haulbowline Rock (Carlingford Lough, Ireland, 1823); Héaux de Brehat (Brittany, 1839); Horsburgh (Singapore, 1851); Bayes d'-Olonne (Bay of Biscay, 1861); Smalls (Pembrokeshire, 1861); Hanois (Guernsey, 1862); Daedalus reef, iron tower (Red sea, 1863); Alguada reef (Bay of Bengal, 1865); Longships (Land's End, 1872); Great Basses (Ceylon, 1873); the Prongs (Bombay, 1874); Spectacle reef (Lake Huron, 1874); Chicken rock (Isle of Man, 1874); Fowey Rocks (Florida, 1878); Rattray Head (Aberdeenshire, 1895); Beachy Head (Eastbourne, 1902); the Graves (Boston, U.S.A., 1905); and Jument d'Ouessant (Brittany, 1911).

Jointing of Stones in Rock Towers.—Various methods of jointing the stones in rock towers are employed in building. The great distinction between the towers, built by successive engineers to the Trinity House, and other rock lighthouses is that, in the former the stones of each course are dove-tailed together both laterally and vertically and are not connected by metal or

[1]*Proc.* Inst. C.E. Vol. XXX.

wooden pins and wedges and doweled as in most other cases. This dove-tail method was first adopted at the Hanois rock at the suggestion of Nicholas Douglass. The cement mortar in the joint

formed between the faces so locks the dove-tails that the stones cannot be separated without being broken.

TABLE I. *Comparative Cost of Exposed Rock Towers*

Name of structure	Total cost	Cu.ft.	Cost per cu.ft. of masonry		
	£		£	s.	d.
Eddystone (*Smeaton*) (1759) . . .	40,000	13,343	2	19	11
Bell rock, Firth of Forth (1811) . .	55,620	28,530	1	19	0
Skerryvore, Scotland (1844) . . .	72,200	58,580	1	4	8
Bishop rock, first granite tower (1858)	34,560	35,209		19	7
Smalls, Bristol Channel (1861) . .	50,124	46,386	1	1	7
Hanois, Alderney (1862)	25,296	24,542	1	0	7
Wolf rock, Land's End (1869) . .	62,726	59,070	1	1	3
Dhu Heartach, Scotland (1872) . .	72,584	42,050	1	14	6
Longships, Land's End (1872) . .	43,869	47,610		18	5
Eddystone (*Douglass*) (1882) . . .	59,255	65,198		18	2
Bishop rock, reconstruction (1887) .	64,889	45,080	1	8	9
Great Basses, Ceylon (1873) . . .	63,560	47,819	1	6	7

Fastnet, Ireland (1904)	79,000	62,600	1	5	5

Effect of Waves.—The wave stroke to which rock lighthouse towers are exposed is often considerable. During the erection of the tower at Dhu Heartach, 14 joggled stones, each of 2-tons weight, were washed away after having been set in cement at a height of 37 ft. above high water, and similar damage was done during the construction of the Bell rock tower. The effect of waves on the Bishop rock and Eddystone towers has been noted above.

Land Structures for Lighthouses.—The erection of lighthouse towers and other buildings on land presents no serious difficulties of construction; such buildings are usually of simple architectural character. Besides being built of stone, brick or reinforced concrete, land towers are frequently constructed of cast-iron plates or open steel-work with a view to economy. Fine examples of the former are to be found in many British colonies and elsewhere, that on Dassen Island (Cape of Good Hope), being typical. A cast-iron tower erected at Kijkduin, near Helder, in Holland, in 1875 is 197 ft. in height to the focal plane. Many openwork structures up to 200 ft. in height have been built. Examples are the towers erected at Cape São Thomé (Brazil) in 1882, 148 ft. to the focal plane; Mocha (Red sea) in 1903, 180 ft.; and Sanganeb Reef (Red sea) 1906, 165 ft.

OPTICAL APPARATUS

Optical apparatus in marine lighthouses is employed for concentrating the rays of light derived from a light source: (1) in the vertical plane only, to show a fixed belt of light all round the horizon, which can be made either flashing or occulting by eclipsing the light or by interposing mechanically a screen; (2) in both the vertical and horizontal planes simultaneously to produce a high-powered beam or cone of light which can be revolved, to show a flashing light, or fixed, to mark an isolated danger or narrow channel where a limited azimuth suffices; and (3) in the vertical plane and afterwards in the horizontal plane for diverting or condensing a portion of the fixed belt of light to strengthen a sector.

Three types of apparatus are used to effect these concentrations: (a) *Catoptric* in which the rays undergo reflection only at the surface of a mirror; (b) *Dioptric* in which the rays pass through a glass medium and are bent or refracted as they enter and emerge from it (fig. 8); and (c) *Catadioptric* in which the rays after entering the glass medium suffer total internal reflection be-

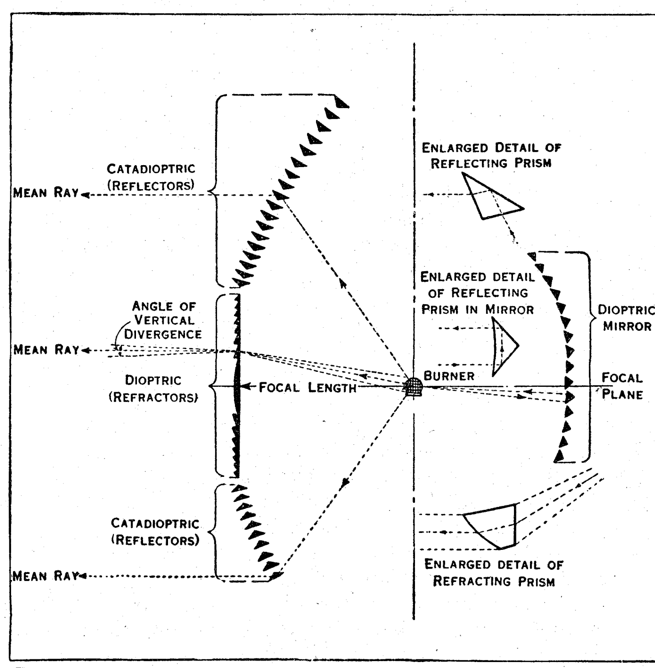

FIG. 7.—DIAGRAM SHOWING THE GLASS ELEMENTS COMMONLY USED IN LIGHTHOUSE OPTICAL APPARATUS. ELEMENTS ARE IN VERTICAL SECTION

fore emerging from it (fig. 7). The object of these several forms of optical apparatus is not only to produce characteristics or distinctions in lights to enable them to be recognized readily by mariners, but to utilize the light rays to the best advantage by their condensation. This is accomplished more effectively by the use of revolving annular lenses than by fixed belts, as greater intensities are thereby attained. Fig. 7 shows in diagrammatic form the various sections and dispositions of glass elements commonly used in lighthouse optical apparatus.

Catoptric System.—Paraboloidal reflectors, consisting of small facets of silvered glass set in plaster of Paris, were first

LIGHTSHIPS AND LIGHTHOUSES OFF THE COASTS OF ENGLAND, FRANCE AND AMERICA

1. Light vessel moored at Outer Dowsing shoal in the North sea, about 50 mi. east of the mouth of the Humber. This light vessel is equipped with dioptric apparatus balanced on a constant-level table. The illuminant is a high power electric gas-filled lamp. The vessel has a diaphone fog signal and also a submarine oscillator. **2.** Northeast End lightship, stationed north-east of Delaware bay entrance; a modern vessel with diesel engine for propulsion. Main signal light is electric, on foremast, with reserve light on mainmast. **3.** The High lighthouse, Hurst, one of two leading lights near the sea entrance to the Solent, opposite the Isle of Wight. These are now unattended lights with automatic acetylene plant (building at left). **4.** Tillamook Rock light station, off the Oregon coast; a stone structure on exposed rock. Light is 133ft. above the sea. **5.** Ile Vierge lighthouse. Finistère, Brittany, France; completed 1902. Tower is 247ft. from base to focal plane of the light. The old lighthouse tower on the left is preserved as a seamark. **6.** Minots Ledge lighthouse, about 14mi. south-east of Boston; a granite tower, built in an exposed position in the Atlantic. **7.** Aerial lighthouse, Cranbrook, Kent, off south-east coast of England. Glazing of lantern is extended over the dome, permitting the optical apparatus to direct beams of light from the horizontal up to zenith. **8.** Kilauea Point lighthouse, Hawaii, a reinforced concrete tower 52ft. high, standing on a cliff. The lens, enclosed in the lantern, has two double panels, and shows a double flashing light of 1,100,000 candlepower every 10 seconds. **9.** Martin Reef light station, on a reef in the northern part of Lake Huron. It stands in 6ft. of water, in a position exposed to heavy ice action. The light is electric, 70ft. above the water. **10.** Pacific Reef light, standing in 7ft. of water, on the outer edge of the coral reefs off the Florida coast. It is supported by iron piles driven 9 ft. into the coral reef. It is an unattended station, with an automatic acetylene light

OPTICAL APPARATUS FOR LIGHTHOUSE ILLUMINATION

1. Biform apparatus of first order, Fastnet Lighthouse, Ireland (1904), which shows a single flash every 5 secs. An incandescent oil mantle-burner is at the focus of each of the two superimposed optics
2. Burnham Leading Lights, Somerset (1928). An incandescent gas-filled electric lamp is seen at the focus of one of the fixed optical apparatus, with a reserve lamp behind it and stand-by acetylene burner (right). The automatic features include a flashing device. At left are fixed lens belt and upper prisms; right, portion of dioptric mirror. Since automatic equipment was installed in 1928 the two lighthouses are unwatched at night
3. North Saddle Lighthouse, China, a first-order apparatus of four panels, single flashing. The annular trough containing mercury, in which the float carrying the rotating apparatus is immersed, can be lowered for examination by rotating it on the central screwed column
4. Great Basses Rock Lighthouse, Ceylon. This first-order apparatus, rotated on a roller carriage, made in 1872, is an example of the slow-revolving lights employed before the introduction of mercury floats and wide lens-panels. Rotating mechanism seen in base
5. Optical apparatus in Spurn Lightvessel, with constant level table
6. Apparatus for aerial lighthouse at Cranbrook, Kent (*see* Pl. I. fig. 7)
7. Third-order biform apparatus of 6 panels and mirror, Hartland Point Lighthouse, North Devon (1927), which shows 6 flashes every 15 secs. At focus of each optic is gas-filled incandescent electric lamp of 3 K.W.

used about the year 1763 in some of the Mersey lights by William Hutchinson, who was then dock master at Liverpool. Spheroidal metallic reflectors were introduced in France in 1781, followed by paraboloidal reflectors of silvered copper in 1790 in England and France, and in Scotland in 1803. The earlier lights were of the fixed type, a number of reflectors being arranged on a frame or stand in such a manner that the emergent rays overlapped and thus illuminated the whole horizon continuously. In 1783 the first revolving light was erected at Marstrand in Sweden. Similar apparatus were installed at Cordouan (1790), Flamborough Head (1806) and at the Bell rock (1811). To produce a revolving or flashing light the reflectors were fixed on a rotating carriage having several faces. A type of paraboloidal reflector is still used for light-vessel illumination.

About the year 1900 reflecting mirrors were used in the Heligoland lighthouse in combination with electric-arc lamps. The French lighthouse service installed (1919) a quadruple-flashing light at Galite in Tunisia, which has large gilded and burnished paraboloidal reflectors and incandescent oil burners. It is, however, unlikely that such reflectors will take the place of dioptric lenses. Paraboloidal reflectors have also been used in some aerial lighthouses including that at Mount Valérien, near Paris.

Dioptric System.—The first adaptation of dioptric lenses to lighthouses is probably due to T. Rogers, who used lenses at one of the Portland lighthouses between 1786 and 1790. Count Buffon had in 1748 proposed to grind out of a solid piece of glass a lens in steps or concentric zones, in order to reduce the thickness to a minimum (fig. 8a). Condorcet in 1773 and Sir D. Brewster in 1811 designed built-up lenses consisting of stepped annular rings. Neither of these designs, however, was intended to apply to lighthouse illumination. In 1822 Augustin Fresnel constructed a built-up annular lens in which the centres of curvature of the different rings receded from the axis according to their distances from the centre, so as practically to eliminate spherical aberration; the only spherical surface being the small central part or "bull's eye" (fig. 8). These lenses were intended for revolving lights only. Fresnel next produced his cylindric refractor or lens belt, consisting of a zone of glass generated by the revolution round a vertical axis of a medial section of the annular lens (fig. 8). The lens belt condenses and parallelizes the light rays in the vertical plane only, while the annular lens does so in both planes. The first revolving light constructed from Fresnel's designs was erected at the Cordouan lighthouse in 1823. It consisted of 8 panels of annular lenses of 45° vertical aperture and having a focal distance of 920 mm. To utilize the light, which would otherwise escape above the lenses, Fresnel

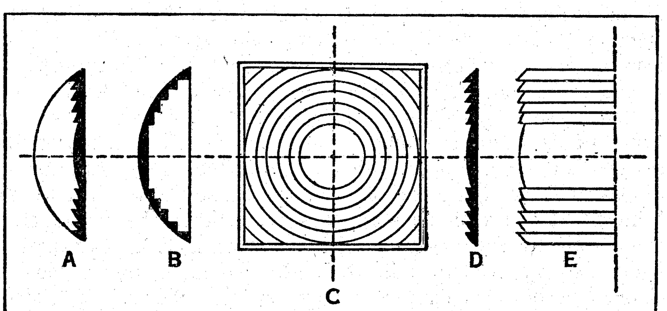

FIG. 8.—THE DEVELOPMENT OF FRESNEL'S LENSES

a, Buffon's lens; b, derivation of Fresnel's lens; c, d, elevation and section of Fresnel's annular lens; d, e, section and half elevation of Fresnel's lens belt

introduced a series of eight plain silvered mirrors, on which the light was thrown by a system of lenses. At a subsequent period mirrors were also placed in the lower part of the optic. The apparatus was mounted on rollers and revolved by clockwork. This optic embodied the first combination of dioptric and catoptric elements in one design (fig. 9). Fresnel also designed for the Chassiron lighthouse a dioptric lens with catoptric mirrors for giving a fixed light, which was the first of its kind installed (1827) in a lighthouse. This combination is geometrically perfect, but not practically so, on account of the great loss of light by metallic reflection; this is 25% greater than that resulting from the use of glass elements. Shortly before his death in 1827 Fresnel devised his totally reflecting or catadioptric prisms (fig. 7) to take the place of the silvered reflectors previously used above and below the lens elements. In these the principle of internal reflection from the face of a glass prism is made use of as well as the principle of refraction. Thus a ray of light falling on the prismoidal ring is refracted as shown in the enlarged detail of the reflecting prism and then is totally reflected emerging after a second refraction in a horizontal direction. Fresnel devised these prisms for use in fixed-light apparatus, but the principle was applied to flashing lights by T. Stevenson in 1850. Both the dioptric lens and catadioptric prism invented by Fresnel are still in general use, the mathematical calculations of the great French designer still forming the basis upon which lighthouse opticians work.

Fresnel also designed a form of fixed and flashing light in which a fixed light, varied by flashes, was produced by placing panels of straight refracting prisms in a vertical position on a revolving carriage outside the fixed light apparatus. The revolution of the upright prisms periodically increased the power of the beam by condensation of the rays, emergent from the fixed apparatus, in the horizontal plane.

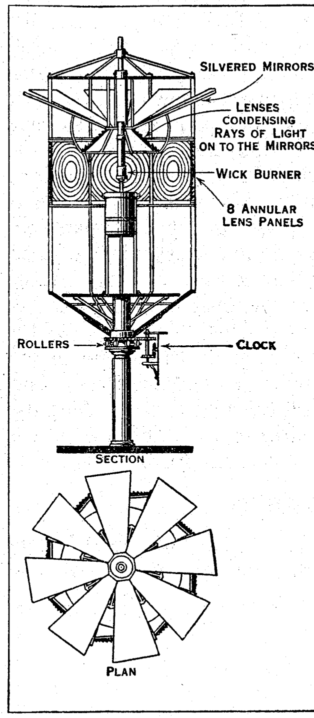

FIG. 9.—FRESNEL'S FIRST REVOLVING LIGHT, ERECTED IN 1823

This apparatus of 920 mm. focal distance, formerly at Cordouan lighthouse (river Gironde), was the first dioptric revolving light to be established

The lens segments in Fresnel's early apparatus were of polygonal form instead of cylindrical, but subsequently manufacturers succeeded in grinding glass in cylindrical rings of the form now used. The first apparatus of this description was made by the Cooksons of Newcastle in 1836 at the suggestion of Alan Stevenson, and erected at Inchkeith, Fifeshire. The first dioptric apparatus erected by the Trinity House to show a fixed light was the one formerly at Start Point in Devonshire. It was constructed in 1836.

Azimuthal Condensing Prisms.—To condense the rays from a fixed-light apparatus in certain azimuths, T. Stevenson devised in 1850 his azimuthal condensing prisms which have been variously applied in the construction of optical apparatus as, for instance, for the strengthening of coloured sectors. Applications of this system will be referred to subsequently (*see* fig. 10).

Dioptric Mirror.—An important improvement in lighthouse optical work was the invention of the dioptric mirror by (Sir) J. T. Chance in 1862. This mirror is a modification of a spherical mirror devised by T. Stevenson in 1850, in which double reflection from the internal surfaces of a catadioptric prism was employed. Chance generated the zones of prisms round the vertical axis, separated the elements and set them at increasing radii, thus producing an instrument of practical utility. By the use of the dioptric mirror rays of light which would otherwise be lost are reflected back through the focus of the source of light and are refracted or reflected with the main rays. This form of mirror is still in general use and is constructed for vertical angles up to 100°.

Spherical Lens.—Mr. C. A. Stevenson devised in 1888 annular lens panels consisting of lens elements spherical in the horizontal and vertical planes, and these, with equiangular prisms, have been used in a number of apparatus for Scottish lighthouses.

Optical Glass for Lighthouses.—In the early days of lens lights the only glass used for the prisms was made in France at the St. Gobain and Premontré works, which have long been celebrated for the high quality of optical glass they produce. The early dioptric lights erected in the United Kingdom, some 13 in all, were made by the Cooksons, who were instructed by Léonor Fresnel, the brother of Augustin. At first they tried to mould the lens and then to grind it out of one thick sheet of glass. The manufacture of lenses was abandoned by Cooksons' successors in 1845 and in 1850 Chance Bros. and Co., of Birmingham began to make optical glass, assisted by M. Tabouret, a French expert who had been a colleague of Augustin Fresnel himself. The first light made by the firm was shown at the Great Exhibition of 1851, since when numerous dioptric apparatus have been constructed by Messrs. Chance, who are, at this time, the only manufacturers of lighthouse glass in the United Kingdom. Most of the glass used for apparatus constructed in France is manufactured at St. Gobain. Some glass used by German constructors is made at Rathenau in Prussia and Goslar in the Harz.

The glass generally employed for lighthouse optics has a mean refractive index of $\mu = 1{\cdot}51$, the corresponding critical angle being $41° 30'$. Messrs. Chance have used dense flint glass for the upper and lower refracting rings of high-angle lenses (up to 97° vertical angle) and for dioptric mirrors in certain cases. This glass has a value of $\mu = 1{\cdot}62$ with critical angle $38° 5'$. The use of refracting elements for an angle greater than 60° aperture is not attended by any advantage over reflecting prisms.[1]

TYPES OF LIGHTS

Occulting Lights.—During the last quarter of the 19th century the disadvantages of fixed lights became more and more

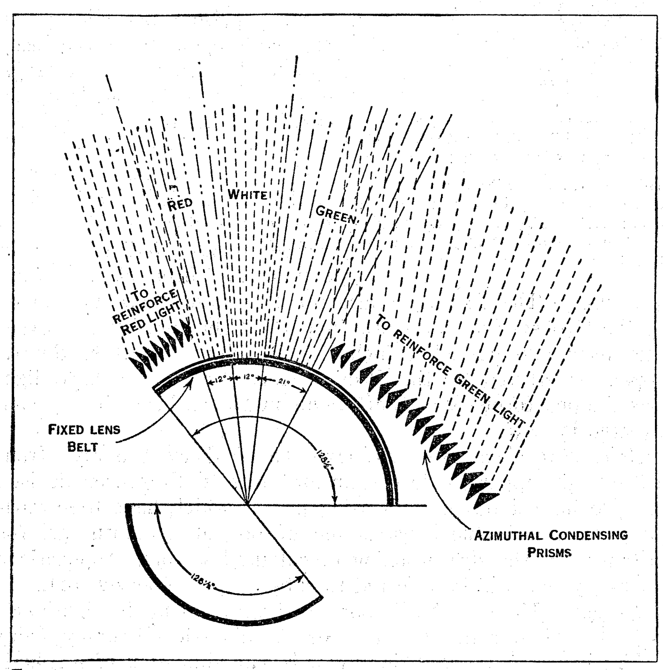

FIG. 10.—WOODMAN POINT DIRECTION-LIGHT, FREMANTLE, WEST AUSTRALIA
The diagram is a plan of the optical apparatus at the level of the focal plane. The light is condensed and directed over the channel, the dangers at the sides of which are covered by the red and green lights

apparent and they have fallen into disuse except in the case of the less important harbour and river lights. The necessity of providing a distinctive characteristic has led to the conversion of many of the fixed-light apparatus of earlier years into occulting lights, or to their supersession by more modern and powerful flashing-apparatus. The occultation of a light is produced either by a cylindrical screen lowered and raised around the burner; or by a revolving screen; or, when some form of gas burner is used, by intermittently extinguishing the light itself. Varying characteristics, comprising one or more occultations, may be procured by means of such contrivances. "Otter" screens are sometimes employed in cases where it is desired to produce different periods of occultations in two or more positions in azimuth, in order to differentiate sectors marking shoals, etc. The screens are of sheet metal blacked and arranged vertically, somewhat in the manner of the laths of a venetian blind, and operated by mechanical means.

[1] *See* W. M. Hampton, *Trans. Optical Soc.*, vol. XXIX (1928).

Leading Lights.—In the case of lights designed to act as a

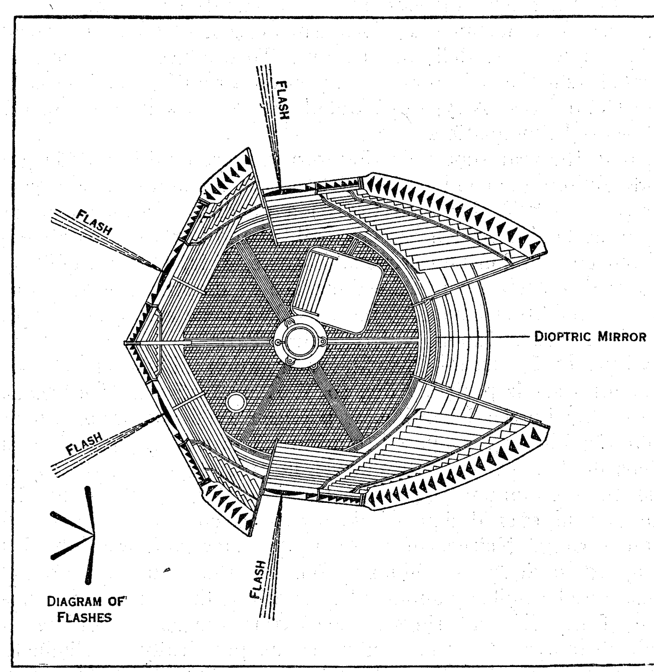

FIG. 11.—FLAMBOROUGH LIGHTHOUSE, YORKSHIRE
Sectional plan of the first-order optical apparatus at focal plane. The light shows 4 flashes every 15 seconds

lead through a narrow channel or as direction lights, it is undesirable to employ a revolving apparatus. Fixed-light optics are used in such cases, generally fitted with an eclipsing mechanism. A typical apparatus of this description is that at Woodman Point, Fremantle, West Australia (fig. 10). The occulting white-light covers the fairway, and is flanked by sectors of occulting red and green-light marking dangers and intensified by vertical condensing prisms. A good example of a holophotal direction-light is that at Suzac lighthouse (France). The apparatus consists of an annular lens 500 mm. focal distance, of 180° horizontal angle and 157° vertical, with a reinforcing mirror of 180°. The lens throws a red beam, of about $4\frac{1}{2}°$ amplitude in azimuth and 50,000 candle-power, over a narrow channel. The illuminant is an incandescent petroleum-vapour burner. Holophotal direction lenses of this type can only be applied where the sector to be marked is of comparatively small angle. Silvered metallic mirrors of parabolic section are also used for the purpose. The establishment of a direction light frequently renders the construction of separate towers for leading lights unnecessary. If two distinct lights are employed to indicate the line of navigation through a channel or between dangers they must be sufficiently far apart to afford a good lead, the front or seaward light being situated at a lower elevation than the rear or landward one.

Coloured Lights.—Colour is used as seldom as possible as a distinction, entailing as it does a considerable reduction in the power of the light. It is however necessary in some instances for differentiating sectors over dangers and for harbour lighting purposes. Alternating colours for flashing lights are not to be commended on account of the unequal absorption of the coloured and bright rays by the atmosphere. Where such a combination has been employed, as in the Wolf rock apparatus, the red and white beams have been approximately equalized in initial intensity by constructing the lens and prism panels for the red light of larger angle than those for the white beams. Owing to absorption by the red colouring of the glass screen the power of the red beam is only 40% of the intensity of the corresponding white light. The corresponding intensity of green light is 25%. When red or green sectors are employed, in conjunction with a white light from a fixed apparatus, they should if it is practicable be reinforced by mirrors, azimuthal condensing prisms, or other means, to raise the coloured beam to approximately the same intensity as the white light. With the introduction of group-flashing characteristics the necessity for using colour as a means of distinction for landfall lights disappeared. In situations such as a river fairway where a large number of buoy or beacon lights have to be provided with distinguishing characteristics, coloured lights are, however, frequently employed.

Group-flashing Lights.—One of the most useful distinctions consists in the grouping of two or more flashes separated by short intervals of darkness, the group being succeeded by a longer

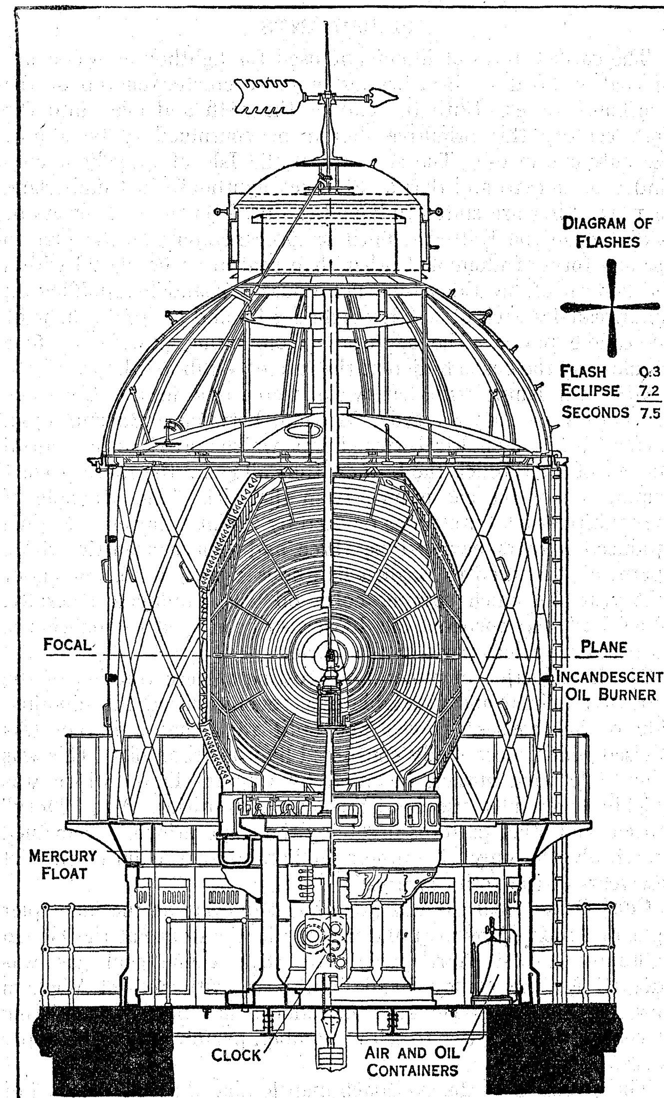

FIG. 12.—MANORA POINT (KARACHI) APPARATUS AND LANTERN
The apparatus is of 1,330 mm. focal distance; it is rotated on a mercury float and has an incandescent oil burner at its focus. The right hand half is shown in elevation and the left hand as a vertical section

eclipse. Thus two, three or more flashes of, say, half-second duration or less follow each other at intervals of about 2 seconds and are succeeded by an eclipse of, say, 10 seconds. In 1874 Dr. John Hopkinson introduced the improvement of arranging the lenses of a dioptric revolving light, together with their panels of reflecting prisms, asymetrically, setting them at an angle to produce the group-flashing characteristic. The first apparatus of this type constructed were those now in use at Tampico, Mexico (triple-flashing), and the Little Basses light-house, Ceylon (double-flashing). A modification of the system consists in grouping two or more lenses together and filling the remaining angle in azimuth by a reinforcing mirror. A sectional plan of the quadruple-flashing first-order apparatus at Flamborough, Yorkshire, is shown in fig. 11 on page 92.

Hyper-radial Apparatus.—In 1885 Messrs. Barbier of Paris constructed the first hyper-radial apparatus (1,330 mm. focal distance) to the design of D. and C. Stevenson. Apparatus of similar focal distance were subsequently established at a number of other lighthouses. That at Manora Point, Karachi, India (1908) is illustrated in fig. 12. The introduction of incandescent oil burners and electric lamps of focal compactness and high intrinsic brightness has rendered unnecessary the provision of optics of such large dimensions.

Fixed and Flashing Lights.—The use of these lights, which show a fixed beam varied at intervals by more powerful flashes, is undesirable, though a large number were constructed in the earlier years of dioptric illumination and some are still in existence. In certain conditions of the atmosphere it is possible for the fixed-light of low power to be entirely obscured while the flashes are visible, thus the true characteristic of the light is vitiated.

Screens and Cuts.—Screens of coloured glass, intended to distinguish the light in particular azimuths, and of sheet iron, when it is desired to "cut off" the light sharply on any angle, should be fixed as far from the centre of the light as possible, in order to reduce commingling, in the first case, and the escape, in the second case, of the light rays due to divergence. These screens are usually attached to the lantern framing.

Divergence.—A dioptric apparatus designed to bend all incident rays of light from the light source in a horizontal direction would, if the flame could be a point, have the effect of projecting a band or zone of light (in the case of a fixed apparatus) and a cylinder of light rays (in the case of a flashing light) towards the horizon. Under such conditions the mariner in the near distance would receive no light as the rays would pass above the level of his eye and be visible only on the horizon. In practice this does not occur, sufficient natural divergence being produced ordinarily owing to the magnitude of the flame. When the electric-arc or an incandescent electric-lamp of small focal diameter is employed it is sometimes necessary to design the prisms so as to produce artificial divergence. The measure of the natural horizontal divergence for any point of the lens is twice the angle whose tangent is the ratio of the radius of the illuminating source to the distance of the point from the geometrical centre of the lens and for calculating the vertical divergence the vertical dimensions of the light source, above and below the focal plane, must in turn be substituted for the radius, and the sum of the angles thus obtained is the total divergence. In fixed dioptric-lights there is, of course, no divergence in the horizontal plane. In revolving lights the horizontal divergence is a matter of considerable importance, determining as it does the duration of flash, *i.e.,* the length of time the flash is visible to the mariner.

Feux-Éclairs or Quick-flashing Lights.—One of the most important developments in lighthouse illuminating apparatus was in the direction of reducing the length of flash, initiated by the French lighthouse authorities about 1891, and shortly afterwards followed in other parts of the world. The early *feux-éclairs,* designed by the French engineers and others, had usually a flash of $\frac{1}{10}$ to $\frac{1}{3}$ sec. duration. As a result of experiments carried out in France in 1903–04, $\frac{3}{10}$ sec. is now generally adopted as the minimum duration for white flashing lights. If shorter flashes are used it is found that the reduction in duration is attended by a corresponding, but not proportionate, diminution in effective intensity. In the case of many electric flashing-lights the duration is of necessity reduced but the greater initial intensity of the flash permits this loss without serious detriment to efficiency. Red or green requires a considerably greater duration than do white flashes. The intervals between the flashes in single-flashing lights of this character are also small, usually $2\frac{1}{2}$ to 5 seconds. In group-flashing lights the intervals between the flashes are about 2 sec. or even less, with periods of 7 to 15 sec. between the groups, which may be arranged to show any number up to six flashes, as in the older forms of apparatus. The *feu-éclair* type of apparatus enables a higher intensity of beam to be obtained by reason of the greater ratio of condensation of light, the employment of panels of greater angular breadth than those formerly used being possible with a higher rotatory velocity. It has been urged that short flashes are insufficient for taking bearings, but the utility of a light in this respect does not seem to depend so much upon the actual length of the flash as upon its frequent recurrence at short intervals.

It was soon found impracticable to revolve an optical apparatus with its mountings, sometimes weighing as much as 7 tons, at the higher rate of speed required for *feux-éclairs* by means of the old system of roller carriages, though for a certain number of small quick-revolving lights ball bearings have been successfully adopted. It has therefore become almost the universal practice to carry the rotating portions of the apparatus upon a mercury float. This application of mercury rotation was the invention of O. Bourdelles. The arrangement consists of an annular cast-iron trough containing mercury with a similar but slightly smaller annular float immersed in it and displacing a volume of the liquid metal whose weight is equal to that of the apparatus supported. In all cases provision is made for lowering the mercury bath or raising the float and apparatus for examination. An example of a mercury float is shown in Plate II., fig. 3.

Multiform and Twin Apparatus.—In order to double the power to be obtained from a single apparatus at stations where lights of exceptionally high intensity are desired, the expedient of superimposing one complete lens apparatus on another has sometimes been adopted, as at the Bishop rock (fig. 4), Hartland point (Plate II.) and at the Fastnet lighthouse in Ireland (Plate II.). Triform and quadriform apparatus have also been erected in Ireland. The adoption of the multiform system involves the use of lanterns of increased height. Another method of doubling the power of a light is by mounting two complete and distinct optics side by side on the same revolving table. This expedient has been frequently adopted by French designers.

"Orders" of Apparatus.—Augustin Fresnel divided his dioptric lenses into "orders" or sizes depending on their focal distance. This division is still used, although two additional "orders" known as "small third order" and "hyper-radial" respectively are in ordinary use. The following table gives the focal distance of the several sizes:—

TABLE II.

Order	Focal distance, mm.
Hyper-radial	1,330
1st order	920
2nd "	700
3rd "	500
Small 3rd order	375
4th order	250
5th "	187·5
6th "	150

Lenses of smaller focal distance are also made for buoy and beacon lights.

Light Intensities.—The powers of lighthouse lights given in the Admiralty *Lists of Lights* are expressed in terms of "lighthouse units" (one lighthouse unit = 1,000 pentane candles). In France the "*bougie decimale*" and in America the "American candle" are identical with the standard pentane candle. The Hefner unit used in Germany, Holland, etc., is 0·9 of the pentane candle. The intensity of a beam of light emitted from a dioptric apparatus depends upon the brilliancy or intrinsic brightness of the source of light and the projected area of the optical panel, in the case of a revolving light, or of the pillar of light in the case of an optic of fixed section. The theoretical value of the intensity can be computed from the formula $I = iA$. Where I is the total intensity of the emergent beam; i is the mean intrinsic brightness obtained by dividing the total light intensity of the source by the area of its projected image in various planes and A the projected area of the optical panel (for revolving apparatus) or the height of glass multiplied by the breadth of the illuminating source (for optics of fixed section).

In practice, owing to the inequalities of the illuminating source and the losses due to refraction, reflection and absorption experienced by the rays in their passage through the optical elements and the lantern glazing, the actual value is found to be about 50% of the theoretical value. By the addition of a mirror the intensity of that part of the panel reinforced by it is increased by about 30%. Deductions must be made in the case of coloured lights (*see* paragraph on "coloured lights," p. 92).

The mathematical theory of optical apparatus for lighthouses and formulae for the calculations of profiles will be found in the works of the Stevensons, Chance, Allard, Reynaud, Hopkinson, Ribière and others.

ILLUMINANTS

The earliest form of illuminant used for lighthouses was a fire of coal or wood set in a brazier or grate erected on top of the lighthouse tower. Until the end of the 18th and even into the 19th century this primitive illuminant continued to be almost the only one in use. The coal fire at the Isle of May light continued until 1810 and that at St. Bees lighthouse in Cumberland to 1823. Fires are stated to have been used on the two towers of Nidingen, in the Kattegat, until 1846. Smeaton was the first to use any form of illuminant other than coal fires; he placed within the lantern of his Eddystone lighthouse a chandelier holding 24 tallow candles each of which weighed ⅖ lb. and emitted a light of 2·8 candle power. The aggregate illuminating power was 67·2 candles and the consumption at the rate of 3·4 lb. per hour.

Oil.—Oil lamps with flat wicks were used in the Liverpool lighthouses as early as 1763. Argand, between 1780 and 1783, perfected his cylindrical-wick lamp which provides a central current of air through the burner, thus allowing the more perfect combustion of the gas issuing from the wick. The principle of the multiple-wick burner was devised by Count Rumford. Fresnel produced burners having two, three and four concentric wicks. Sperm oil was used in English lighthouses until 1846, but about that year the much cheaper colza oil was employed generally. Olive, lard, and cocoanut oils have also been used for lighthouse purposes in various parts of the world.

The introduction of mineral oil, costing a mere fraction of the expensive animal and vegetable oils, revolutionised the illumination of lighthouses. It was not until 1868 that a burner was devised which successfully consumed hydro-carbon oils. This was a multiple wick burner, invented by Captain Doty, which was quickly taken into use by lighthouse authorities. The "Doty" burner, and other patterns involving the same principle, remained practically the only oil burners in lighthouse use until the last few years of the 19th century.

Coal Gas.—Coal gas was introduced in 1837 at the inner pier light of Troon (Ayrshire) and in 1847 it was in use at the Heugh lighthouse (West Hartlepool). In 1878 cannel-coal gas was adopted for the Galley Head lighthouse, with 108-jet Wigham burners. Sir James Douglass introduced gas burners consisting of concentric rings, two to ten in number, perforated on the upper edges.

The invention of the Welsbach mantle placed at the disposal of the lighthouse authorities the means of producing a light of high intensity combined with focal compactness. For lighthouse purposes gaseous illuminants other than coal-gas are as a rule more convenient and economical, and give better results with incandescent mantles. Mantles have, however, been used with ordinary coal-gas in instances where a local supply of suitable types is available.

Incandescent Mineral-oil Burners.—Incandescent lighting with high-flash mineral oil was first introduced by the French lighthouse service in 1898 at L'Ile Penfret lighthouse. The incandescent burners now in use in lighthouse services all the world over are all made on the same principle, but differ in details. The principle consists in injecting the liquid petroleum under pressure into a vapourizer where it is heated by subsidiary jets and converted into vapour. This vapour issues from a nozzle and, drawing in air, passes into a chamber in the head of the burner where it mixes to form a combustible gas for the incandescence of the mantle; at the same time a small proportion of the gas is diverted to the subsidiary jets. A small reservoir of compressed air—charged by means of a hand-pump—is used for providing the

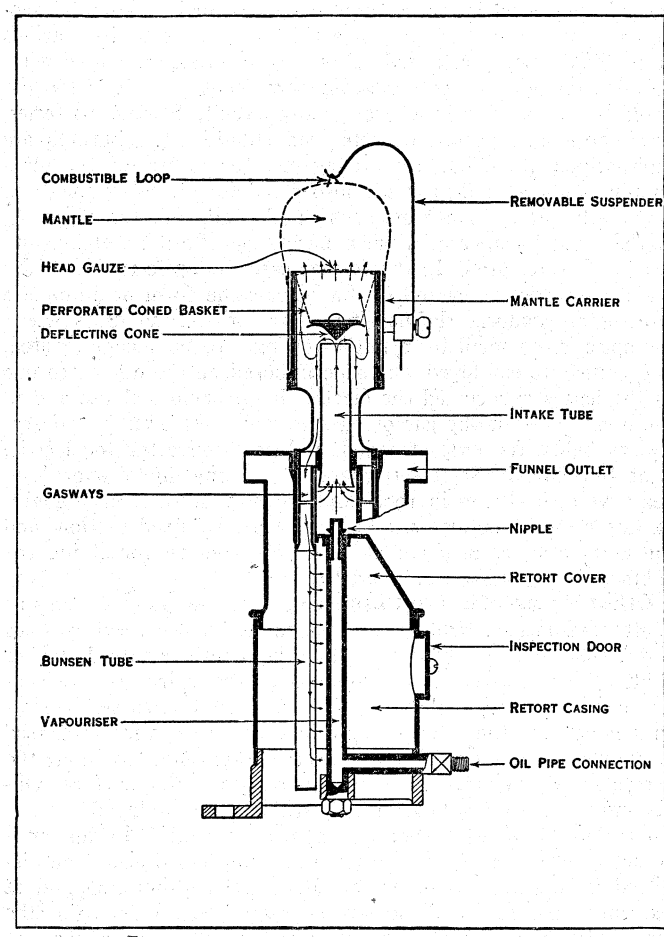

FIG. 13.—"HOOD" PETROLEUM-VAPOUR BURNER

necessary pressure for injection. On first ignition the vapourizer is heated by a spirit flame to the required temperature.

The candle-power of apparatus in which ordinary multiple-wick burners were formerly employed is increased more than six times by the substitution of suitable incandescent-oil burners. In 1902 incandescent-oil burners were adopted by the general lighthouse authorities in the United Kingdom. The "Hood" burner used in the Trinity House service is illustrated in fig. 13 and the "Chance" type in Plate II. The mantles are of the soft autoform (or self-forming) type which has taken the place of the collodin mantles employed in the older forms of burner. Particulars of the burners in ordinary use are as follows:—

Mantle diameter, mm.	Service intensity—standard candles	Intrinsic brightness per sq.cm. of projected area in standard candles	Consumption of oil—pints per hour
35	660	53	0·75
50	1,150	52	1·25
75	2,200	50	2·25
100	3,300	48	3·25

Oil Gas.—Pintsch's oil-gas system introduced in the '70s of the last century is the prototype of the several methods of gas lighting now employed for the majority of buoy and other unattended lights and, before the end of the 19th century was in general use in many countries. Incandescent oil-gas burners were introduced both for buoy and beacon lighting as well as for a few attended lights early in the 20th century. The use of ordinary oil-gas necessitates its periodical supply by means of large transport containers in which it is stored at a pressure of from 9 to 10 atmospheres, a disadvantage which has led to its gradual supersession by acetylene or other forms of oil-gas (*see* below).

An oil-gas, known by the name of its inventor, Blau, of Augsburg, has been employed to some extent, particularly in Germany and Holland, since about 1906 as a substitute for ordinary oil-gas. It is produced in retorts in much the same manner as the older variety but at a lower temperature (550°–600° C) and can be compressed to 100 atmospheres, at which pressure the hydrocarbons are liquefied. This liquid gas is stored and transported in cylinders weighing about 130 lb. and is expanded from them at about 9 atmospheres pressure into the body of the buoy or the receivers at the beacon or lighthouse. When it is used with an incandescent mantle of large size an intrinsic brightness of about 25 candle-power per sq.cm., or about 40% more than ordinary oil-gas, is obtainable.

Another variety of compressed oil-gas known as B.B.T., introduced in France about 1924, has also been used for buoy and beacon lighting. It does not liquefy at 140 atmospheres, at which pressure it is transported in containers each weighing about 2 cwt. It is burnt only in conjunction with an incandescent mantle and the intrinsic brightness obtained is slightly higher than that realized with Blau gas.

Acetylene.—Acetylene (*q.v.*) was first experimented with for buoy and beacon lighting about 1896, open-flame burners being used. An incandescent-mantle burner consuming acetylene was used at the Chassiron lighthouse (France) in 1902. Oil-gas, enriched by the addition of 20% of acetylene, was for a time used in Germany and Holland for buoy and beacon lighting. It was not, however, until about 1906, when the difficulties associated with its employment had been overcome by the introduction of dissolved acetylene, that the gas came into general use for coast lighting. Acetylene in this form is stored at a pressure of 10 to 15 atmospheres in cylinders, usually weighing about 2 cwt., filled with a porous material and charged with acetone in the presence of which the gas is dissolved. Owing to the higher intrinsic brightness of the flame and the convenient transport of the gas it is now in common use throughout the world not only for buoy and beacon lighting but also for many coast lights of secondary importance and unattended revolving lights, mantle burners being sometimes employed.

Acetylene generated on the spot on the carbide-to-water principle is nevertheless still used by some lighthouse authorities, for unattended lights. Comparatively frequent attention in renewing the charge is, however, required in these cases. The intrinsic brightness obtained in some incandescent-acetylene burners is about equal to that of autoform-mantle petroleum-vapour burners.

Electricity.—Electricity for lighthouse illumination was first experimented with in England in 1858 at South Foreland by Trinity House. This was followed by its adoption at Dungeness in 1862, and at Souter point on the coast of Durham in 1871. Both these installations were later abandoned, the former in 1874 and the latter in 1923 when a first-order biform flashing-light with incandescent oil-burner replaced it. Electricity was installed at St. Catherines in the Isle of Wight in 1888 and was also in use at the Isle of May lighthouse at the mouth of the Firth of Forth from 1886 to 1924. Arc lamps formerly provided the illuminant in all large apparatus, but the development of high power, gas-filled, electric-filament lamps has caused their supersession for lighthouse use. A special type of lamp with highly concentrated filament was evolved by the Dutch lighthouse service in 1918 and has been made in sizes up to 4 kw. (Some experimental 4 kw. lamps under trial in Holland [1928] have an intrinsic brightness of about 1,800 candles/cm^2. Lamps of 20 kw. have been used experimentally for aerodrome lighting.)

Economies have been effected by the introduction of these lamps combined with automatic electric equipment, and where in addition a local supply of current is available the reduction of maintenance charges at electric stations is considerable. For instance at the South Foreland, which has been a permanent electric station since 1872, an engineer and four keepers were formerly required to maintain the establishment, which included a steam electric-generating plant. With the introduction of the filament lamp and automatic equipment in 1926 the establishment was reduced to one keeper. High-tension cables were brought from Dover to the lighthouse; the clock machine revolving the lens is wound electrically; and a lamp-changer automatically replaces a lamp when the filament of the one in service burns out or brings a stand-by acetylene burner into focus if the electric supply fails. A tell-tale device in the keeper's quarters warns him if any derangement takes place. The filament lamp is 8,000 c.p., 80 v. and 50 amp., and has a mean intrinsic brightness of 1,000 candles/cm^2. A somewhat similar installation has been substituted for the arc lamp at the Lizard (1926), but in this case the current is generated at the lighthouse, the personnel being reduced from five to three. At other important coast lighthouses including Pendeen, Skerries and Hartland point (Plate II.), in order to obviate a watch being kept during fog both in the engine room and the lantern, electric light has been introduced in place of the petroleum-vapour lamps and the apparatus in the lantern made automatic. The electric current is generated by semi-diesel engines direct-coupled to the dynamos. Similar installations have been put into four new Trinity House light-vessels (1926–27).

Electricity was used at the old south lighthouse at La Hève (France) in 1863, and in 1910 there were 13 important electric lights on the French coast. Arc lamps were employed and generating plant, usually steam driven, was provided at each station. The high cost of maintaining such stations prevented any extension of their use on a large scale in France as in other countries; but since 1920 the conversion of some of the then existing electric stations to incandescent-filament lighting has been effected. At other stations too, where current from public supplies is available, electricity has been introduced. Blau gas is commonly employed for the stand-by burners in French electric lighthouses. In Holland several electric-arc and petroleum-vapour lights have been superseded by electric filament lamps since 1919. At Ameland, a generating set is provided and at Kijkduin, current is taken from the public supply.

MISCELLANEOUS LIGHTHOUSE EQUIPMENT

Modern lighthouse lanterns usually consist of a cast-iron or steel pedestal, cylindrical in plan, on which is erected the lantern glazing, surmounted by a domed roof and ventilator (fig. 12). Adequate ventilation is of great importance, and is provided by means of ventilators in the pedestal and a large ventilating dome or cowl in the roof. The astragals carrying the glazing are of wrought steel or gun-metal. They are frequently arranged helically or diagonally, thus causing a minimum of obstruction to the light rays in any vertical section and affording greater rigidity to the structure. The glazing is usually $\frac{1}{4}$ in. thick plate-glass curved to the radius of the lantern. In situations of great exposure the thickness is increased. Lantern roofs are of sheet steel or copper secured to steel, gunmetal or cast-iron rafter frames. At certain lighthouses it is found necessary to erect a grille or network outside the lantern to prevent the numerous sea birds, attracted by the light, from breaking the glazing by impact. Lanterns vary in diameter from 5 to 16 ft. or more, according to the size of the optical apparatus. For first-order apparatus a diameter of 14 ft. is usual and 12 ft. for second-order.

The lantern, gallery handrails and principal metallic structures in a lighthouse should be connected to a copper lightning conductor (*q.v.*) carried to a point below low water or terminating in an earth plate embedded in wet ground.

Revolving-light apparatus are rotated by clockwork mechanism actuated by weights or spring driven. The clocks are fitted with speed governors and also warning apparatus to indicate when re-winding is required. Where current is available small electric motors are often employed either for automatic re-winding of the clockwork or for driving the rotating mechanism direct. In modern gas-lit apparatus the pressure of the gas is sometimes made use of to revolve the lens table.

At rock and other isolated stations, accommodation for the keepers is usually contained in the towers. In the case of land lighthouses, dwellings are provided in close proximity to the tower. The watch room should be situated immediately under the lantern floor. Oil is generally stored in galvanized steel tanks.

UNWATCHED AND UNATTENDED LIGHTS

Electric.—Since 1884, when an iron beacon lighted by an incandescent-electric lamp supplied with current from a secondary battery was erected on a tidal rock near Cadiz, various forms of electric unattended lights have been experimented with. In 1928 many such lights were in permanent use where current could be obtained from a local supply circuit. Storage batteries, small automatic generating sets, and stand-by gas burners are alternatively provided to guard against the failure of the main supply. Automatic devices are also fitted for changing one lamp for another if the lamp in focus should fail, and for switching in the stand-by apparatus when necessary. Both revolving and fixed optics are used. In the former case the optic is rotated by a small electric motor and in the latter some form of automatic interrupter produces the flashing characteristic. In cases where the optic is too small for a burner changer to be accommodated, two lenses are employed, one superimposed on the other. In one of the lenses is focussed the electric lamp in normal use and in the other the stand-by gas or electric lamp. An example of secondary lights, formerly attended, and now converted to electric, is at Burnham in Somerset where two leading lights over $\frac{1}{4}$ m. apart were so altered in 1928, and are now unwatched at night. In this case the optics (*see* Plate II.) are of fixed section, and the automatic features include a flashing device for giving the lights their respective characteristics.

Other Forms of Beacon Lighting.—Among other systems of unattended beacon lighting adopted in lighthouse services since about 1880, but now little used, may be mentioned the Lindberg light, a Swedish invention employing a volatile spirit; the Benson-Lee lamp having a carbon-tipped wick; the French permanent-wick lamp; and the Wigham lamp in which a flat wick immersed in petroleum travelled over a horizontal roller so that the petroleum was volatilised from a constantly renewed surface. Oil-gas, mostly in its modified forms is still largely employed.

Acetylene Lights.—The gas is provided either by an automatic generator or else in the form of compressed acetylene dissolved in acetone. In order to reduce the consumption and at the same time give a distinctive characteristic to the light, the gas is usually passed through an automatic flashing mechanism which works continuously until the supply is exhausted. Waste of gas during daylight is sometimes obviated by using a sun-valve, which is a device to turn off the gas at daybreak and turn it on at dusk. Sun-valves depend for their automatic action on the differential expansion of two distinct metals under the influence of light rays or on the difference in the absorption of light rays by black and bright bodies respectively. The movement of a lever arm, brought about by a small movement of the light-sensitive element, actuates a valve which opens and closes the gas supply. Acetylene in unattended lights is burnt either as an open flame or in conjunction with a mantle.

The "Aga" system of acetylene lighting, developed in Sweden about 1904, has been extensively used both in that and other countries for all classes of unattended lights, including buoys. It was first adopted in England in 1913. Other systems embodying similar principles are also in use. The "Dalen" incandescent mantle burner embodies a mix-flasher which automatically controls the character of the light and regulates the mixing of air and gas for consumption in an inverted soft-mantle burner.

In some unattended lights with acetylene illumination the lenses are rotated by a gas pump as the gas passes to the mixer and burner, the lens table moving on ball bearings or a mercury float; the sun-valve automatically controls the duration of lighting; a pilot jet serves to re-ignite the main burner at sunset; and an automatic changer provides for the replacement of a broken mantle. Incandescent mantle burners and acetylene equipment have also been installed in a number of lighthouses of secondary importance, formerly attended by keepers, and now converted to unwatched or semi-watched lights. Among such in

THE LIGHT IS ELECTRIC, OF ABOUT 270,000 C.P. THE SHIP HAS THREE FOG-SIGNALS; VIZ., A COMPRESSED-AIR SIREN, A SUBMARINE OSCILLATOR AND A WIRELESS FOG-SIGNAL, THE TWO LAST BEING SYNCHRONISED

England are the lights at the Rock (Liverpool); Great Orme Head and St. Tudwall (Carnarvonshire); Berry Head (S. Devon); Peninnis Head (Scilly Isles); East Usk (Mon.); and Great Castle Head (Pembrokeshire). The Menai lighthouse has been fitted with an open-flame acetylene equipment. In some cases, where the consumption of gas is large, acetylene generators on the carbide-to-water system have been installed, as at the Inner Fern and Bamburgh lights on the coast of Northumberland, and the two first-order leading lights at Hurst (Plate I., fig. 3), on the mainland opposite the Isle of Wight.

Acetylene in the dissolved form is at present the best and most economical illuminant for entirely unwatched lights when electric current is not available. Its use has enabled many unattended lights to be established and maintained at a comparatively small cost in positions where a light attended by keepers would be impracticable as, for example, on some parts of the Australian coast.

LIGHT-VESSELS

The earliest light-vessel established in English waters was that placed at the Nore in 1732. The early lightships were of small size and carried lanterns of primitive construction suspended from the yard-arms. Modern light-vessels are usually of steel construction and are of various dimensions. The following may be taken as the limits in the Trinity House service:

Length	80 to 114 ft.
Beam	20 „ 26 „
Depth moulded	13 „ 15½ „
Displacement	200 „ 500 tons

The larger vessels are employed at outside and exposed stations, the smaller ships being stationed in sheltered positions and in estuaries. The moorings usually consist of 3-ton mushroom anchors and 1¾″ or 1⅝″ open-link cables. The lanterns used in some of the older vessels are 8 ft. in diameter surrounding the mast upon which they are hoisted at night and lowered to the deck level during the day. Fixed lanterns mounted on hollow steel masts are now gradually displacing the older type. The first English light-vessel so equipped was constructed in 1904.

Self-propelled light-vessels, some of which are of much larger dimensions than any British light-vessel, are employed at the majority of stations in the United States, and there are a few in exposed situations in other countries including France, Sweden, Holland (fig. 14) and Germany.

Until about 1895 the illuminating apparatus used in light-vessels was almost exclusively of catoptric form, consisting for the most part of 21 in. silvered paraboloidal reflectors, having mineral-oil burners in focus, hung in gimbals to preserve the horizontal direction of the beam. In a few cases incandescent-mantle burners or electric-filament lamps have been substituted for the old wick-burners in catoptric apparatus. Dioptric apparatus is now usually provided in new lightships, not only in Britain but in other countries also. The French lighthouse service in 1896 devised the first dioptric revolving light for a light-vessel. This ship, the Talais,[1] was lit by an incandescent oil-gas burner. A much larger vessel, the Sandettié, of 342 tons displacement, was completed in 1902. The new type of floating light was afterwards adopted by other lighthouse authorities, and many vessels constructed on the lines of the Sandettié were built during the first decade of the 20th century. In England the

[1]The Talais and another similar vessel constructed in 1899 were later converted into unattended light-vessels.

first of the class was stationed at the Swin Middle in 1905 (now—1929—at the Mid-Barrow Station). Most of these vessels were fitted with revolving dioptric lenses suspended in gimbals below the lens table and counterbalanced by a heavy pendulum weight. The apparatus was mounted on ball bearings in some cases and on a mercury float in others, the lenses being revolved by clockwork or gas. Another method of suspending the dioptric apparatus has recently been developed, the design being a Swedish invention. This device, known as the constant-level table, has been fitted in several vessels, including that at the Barrow Deep in the approaches to the Thames. In this vessel the illuminant is acetylene employed with a mantle. The lens is mounted on a table made to revolve on ball bearings by the gas on its way to the burner. The lens table is balanced, near the centre of gravity, on a pivot in the lantern, and connected by three vertical pull-wires to a pivoted counter-balance weight, placed in the hull of the ship at the rolling centre of the vessel, which controls the movement of the upper table (Plate II., fig. 5). As the motion imparted to the lower balance weight is small, the swinging of the lens table is less than with the former arrangement of pendulum and gimbal suspension. In the older vessels oil-gas illumination was employed but this has been replaced in the later ships by incandescent-acetylene or incandescent-oil burners, and high-powered gas-filled electric lamps. Four light-vessels fitted with such electric lights and dioptric apparatus were in service on English stations in 1928.

An experimental electric-light installation on board a Mersey light-vessel in 1886 proved unsuccessful.

Fog signals, where provided on modern light-vessels, are generally in the form of sirens or diaphones worked by compressed air. The compressors are driven by steam or oil engines in the older installations and by semi-diesel engines in the more modern vessels.

Unattended Light-vessels.—In 1881 an unattended light-vessel illuminated by Pintsch's oil-gas was constructed for the Clyde. The light was occulting and the vessel carried a gas-holder containing a supply of gas under a pressure of six atmospheres sufficient to maintain the light for three months. Bells are often fitted on this class of light-vessel, the clappers being swung by the roll of the ship or worked by a gas-operated machine.

The improvements made in recent years in the design and construction of unwatched lights and their proved reliability have made it possible for many attended light-ships in positions of secondary importance to be replaced by unwatched vessels. Large economies, both in the cost of construction and of maintenance, have thereby been effected. These unattended vessels range in size from small boats to large vessels, and are fitted with dioptric apparatus and acetylene or Blau-gas lighting.

Communication Between Light-vessels and the Shore.—As far back as 1886 experiments were instituted at the Sunk light-vessel, off the coast of Essex, with the object of providing telephonic communication with the shore by means of a submarine cable. In spite of great difficulties experienced in maintaining the cables several light-vessels were ultimately equipped with this means of communication, and cables were also laid to many pile lighthouses and isolated rock and island stations. Wireless telephone installations have now (1929) superseded all the cable communications with light-vessels.

DISTINCTION AND DISTRIBUTION OF LIGHTS, ETC.

The following are the various light characteristics which may be exhibited to the mariner:—

Fixed.—Showing a continuous or steady light. Seldom used in modern lighthouses and generally restricted to small port or harbour lights. A fixed light is liable to be confused with lights of shipping or neighbouring shore lights.

Flashing.[1]—Showing a single flash, the duration of darkness always being greater than that of light. This characteristic or that immediately following is generally adopted for important lights. The French authorities have given the name *Feux-Éclair* to flashing lights of short duration.

Group-flashing.—Showing groups of two or more flashes in quick succession separated by short eclipses with a larger interval of darkness between the groups.

Fixed and Flashing.—Fixed light varied by a single flash, which may be preceded and followed by a short eclipse. This type of light, in consequence of the unequal intensities of the beams, is unreliable.

Fixed and Group-flashing.—Similar to the preceding and open to the same objections.

Occulting.—A continuous light eclipsed at regular intervals, the duration of light being equal to or greater than that of darkness.

Group Occulting.—A continuous light with groups of two or more occultations.

Alternating.—Lights having any of the foregoing characteristics and which alter in colour are indicated by the addition of the word "alternating" to the appropriate description. When used alone in describing a light the word indicates two distinct colours alternating without any intervening eclipse. Alternating lights are not to be recommended for reasons which have already been referred to.

Colour.—The colours usually adopted for lights are red and green. A white light is to be preferred whenever possible, owing to the great absorption of light by the use of red or green glass screens.

Sectors.—Where coloured lights are employed to distinguish cuts or sectors, they should be shown from apparatus of fixed section and not from revolving apparatus. In marking the passage through a channel, or between sandbanks or other dangers, coloured-light sectors are arranged to cover the dangers, white light being shown over the fairway with sufficient margin of safety between the edges of the coloured sectors next the fairway and the dangers.

Choice of Characteristic and Description of Apparatus.—In determining the choice of characteristic for a light, due regard must be paid to existing lights in the vicinity. No light should be placed on a coast line having a characteristic the same as, or similar to, another in its neighbourhood unless one or more lights of dissimilar characteristic, and at least as high power and range, intervene. In the case of landfall lights the characteristic should differ from any other within a range of 100 m. In narrow seas the distance between lights of similar characteristic may be less. Landfall lights are the most important of all and the most powerful apparatus available should be installed at such stations. The distinctive characteristic of a light should be such that it may readily be recognized by a mariner without the necessity of accurately timing the period or duration of flashes. For landfall and other important coast stations flashing dioptric-apparatus of the first-order (920 mm. focal distance), or its equivalent in power, with powerful burners are required. In countries where the atmosphere is generally clear and fogs are less prevalent than on the coasts of Britain, second- or third-order lights suffice for landfalls, having regard to the high intensities available by the use of improved illuminants. Secondary coast lights may be of second-, third- or fourth-order of flashing character, and important harbour lights of third- or fourth-order. Less important harbours and places where considerable range is not required, as in estuaries and narrow seas, may be lighted by flashing lights of fourth-order or smaller size. Where sectors are requisite, occulting apparatus should be adopted for the main light: or subsidiary lights, fixed or occulting, may be exhibited from the same tower as the main light but at a lower level. In such cases the vertical distance between the high and the low light must be sufficient to avoid commingling of the two beams at any range at which both lights are visible. Such commingling or blending is due to atmospheric aberration.

Range of Lights.—The range of a light depends first on its elevation above sea-level and secondly on its intensity. Most

[1]For the purposes of the mariner a light is classed as flashing or occulting solely according to the duration of light and darkness and without any reference to the apparatus employed. Thus the light shown by a fixed apparatus, in which the light source is mechanically eclipsed but yet the period of darkness is greater than that of light, is classed in the Admiralty *List of Lights* as a "flashing" light.

important lights are of sufficient power to render them visible at their full geographical range in clear weather. On the other hand there are many harbour and other lights which do not meet this condition.

The distances from which lights are visible, given in lists of lights—except in the cases of lights of low power for the reason given above—are usually calculated in nautical miles as seen from a height of 15 ft. above sea-level, the elevation of the lights being taken as above high water. Under certain atmospheric conditions, and especially with the more powerful lights, the glare of the light (by reflection from the clouds) may be visible considerably beyond the calculated range.

TABLE III.

DISTANCES AT WHICH OBJECTS CAN BE SEEN AT SEA, ACCORDING TO THEIR RESPECTIVE ELEVATIONS AND THE ELEVATION OF THE EYE OF THE OBSERVER.* (A. STEVENSON)

Heights in feet	Distances in nautical miles	Heights in feet	Distances in nautical miles
5	2·565	120	12·56
10	3·628	150	14·02
15	4·443	200	16·22
20	5·130	250	18·14
30	6·283	300	19·87
40	7·255	400	22·94
50	8·112	500	25·65
60	8·886	600	28·10
70	9·598	700	30·28
80	10·26	800	32·45
100	11·47	900	34·54
		1000	36·28

**Example:* A light 200 ft. high will be visible 22.50 nautical miles to an observer, whose eye is elevated 30 ft. above the water; thus, from the table:

30 ft. elevation, distance visible 6·28 nautical miles
200 ,, ,, ,, ,, 16·22 ,, ,,
22·50 ,, ,,

Elevation of Lights.—The elevation of the light above sea-level need not, in the case of landfall lights, exceed 200 ft., which is sufficient to give a range of over 20 nautical miles. One hundred and fifty feet is usually sufficient for coast lights. Lights placed on high headlands are liable to be enveloped in banks of fog at times when at a lower level the atmosphere is comparatively clear (*e.g.*, the old Beachy Head light). No definite rule can, however, be laid down, and local circumstances, such as configuration of the coast line, must be taken into consideration in every case.

Choice of Site.—Landfall stations should receive first consideration and the choice of location for such a light ought never to be made subservient to the lighting of the approaches to a port. Subsidiary lights are available for the latter purpose. Lights installed to guard shoals, reefs, or other dangers should, when practicable, be placed seaward of the danger itself, as it is desirable that seamen should be able to "make" the light with confidence. Sectors marking dangers seaward of the light should not be employed except when the danger is in the near vicinity of the light. Outlying dangers require marking by a light placed on the danger or by a floating light in its vicinity.

LIGHTED BUOYS

Pintsch's oil-gas was first used for a light carried on a buoy in 1878. An automatic occulter, worked by the gas passing from the reservoir to the burner, was introduced in 1883. The majority of buoy lights lit by oil-gas are fitted with multiple-jet or Argand burners, but incandescent mantles are also employed. Ordinary oil-gas has been largely superseded by other forms of gas illumination (*see* p. 96). Gas buoy-lights are usually provided with sufficient storage capacity to run the light unattended for three months or longer. The lanterns used for all forms of buoy lighting are self-contained with cylindrical dioptric lenses of fixed-light section usually 150 to 375 mm. diameter. Some of the largest types of gas buoy in use have an elevation from water level to the focal plane of over 26 ft., and a beam intensity of more than 1,000 candle-power. One buoy placed at the entrance to the Gironde in 1907, has an elevation to the focal plane of 34 feet. Spar buoys may be adopted for situation where strong tides or currents prevail.

Acetylene Gas Buoys.—Although some experimental work was done as early as 1896, acetylene gas was first regularly used for buoy lighting early in the 20th century when automatic water-to-carbide generators were employed in Canada for producing the gas, the generators being placed in the body of the buoy. This system never gave entirely satisfactory results and its use is attended by danger of explosion. It has almost everywhere been superseded by the dissolved acetylene system first applied to buoy lighting in Sweden. The normal acetylene buoy equipment maintains the light without recharging up to 12 months (fig. 15).

Electric Buoys.—Buoys have been fitted with electric light both fixed and occulting. Six spar buoys were laid down in the Gedney channel, New York Lower Bay, in 1888. The wear and tear of the cables, by which current was supplied from a shore station, caused considerable trouble and expense, and the lights were replaced by gas-lighted apparatus in 1904. Electric buoys were also used extensively in Germany early in the present century; but in 1929, very few, if any, examples of this method of buoy lighting remain in service.

Bell and Whistling Buoys.—Bells or whistles are frequently fitted to gas buoys as well as to unlighted marking buoys. An acetylene lighted whistle-buoy is illustrated in fig. 15. Submarine bells have also been fitted to buoys but their functioning in such positions is unreliable.

AERIAL LIGHTS

Light signals are needed by air craft in night flying, just as they are required by the mariner. Air craft travel in three dimensions and also at higher velocities than a ship. Light signals for the guidance of an airman must therefore be at short intervals and must be visible from the horizon up to the zenith. One form of optical apparatus for an aerial lighthouse comprises a lower section similar to the portion below the focal plane of a marine revolving light; above this is a section of a fixed-light optic with its axis horizontal instead of vertical as in a marine fixed-light. The lower revolving lens emits a high-power beam of light of small angle with its axis just above the horizontal while the upper segment throws a narrow band of light of lower power from the horizontal to the vertical. Although an airman would pick up the main beam emitted by such an apparatus at, say, 30 m., he would be above it (if flying at a height of about 6,000 ft.), when at a distance of about 20 m. and not near enough to pick up the weaker beam. To compensate for this the lower lens and the illuminant are made of such dimensions and power that the main beam is stronger than is actually required in the direction of its axis and a portion of the rays from this beam is bent upwards by means of refracting prisms placed in front of the panel, thus reinforcing the light in the direction where additional power is required (fig. 16). The effect of this adjustment is shown by the range curve. The optical apparatus is rotated on a mercury float or on ball bearings as in a marine lighthouse.

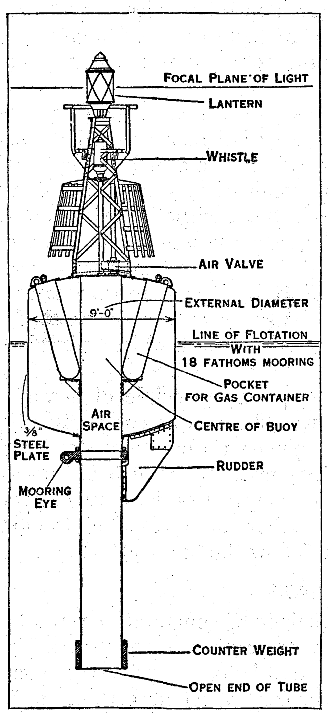

FIG. 15.—ACETYLENE-LIGHTED WHISTLING BUOY (TRINITY HOUSE) The body is welded steel; the whistle is sounded by the motion of the buoy compressing air in the central tube

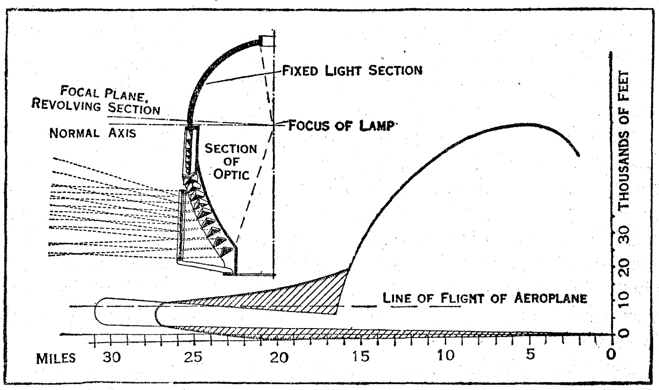
In some aerial apparatus, as at Cranbrook (Kent), reflecting mirrors are used as well as refractors in front of the lower part of the lens, and refracting prisms are employed instead of the fixed-light lens in the upper part of the apparatus.

Both catoptric and dioptric apparatus have been employed in France in the construction of aerial lighthouses, and in some of them powerful electric-arc lights have been used. The aerial light at Dijon (1925) is of great power and is made up of four sets of double dioptric lenses (8 in all) of 500 mm. focal distance, having an arc lamp at the focus of each lens, projecting parallel beams



BY COURTESY OF MESSRS. CHANCE BROTHERS

FIG. 16.—VERTICAL SECTION OF A PANEL OF AN OPTIC FOR AN AERIAL LIGHTHOUSE AND THE RELATIVE RANGE-CURVE

of light in groups of four. The lighthouse at Mont Valérien, near Paris (1926) is provided with catoptric projectors of gilded metal, a portion of the series of mirrors being arranged to direct the light rays in directions between the margins of the main beams and the zenith. The electric arc is also employed in this case. At Le Bourget a fourth-order dioptric apparatus is installed with a gas-filled electric lamp of 8,000 c.p. in focus. Lanterns containing the apparatus of aerial light have glazed roofs as well as the side glazing usual in marine lighthouses.

Neon tubes emitting a red light have been used at the Croydon aerodrome since 1924 for the guidance of airmen in fog because of the large percentage of red rays which have a higher power of penetration in fog. The Croydon beacon is of 13,500 c.p. and consists of clusters of Neon tubes, 16 ft. long, without lenses or reflectors of any description. A flashing characteristic is given to the signal by interrupting the current. Many of these lamps are in use in the United States, Germany and France. It is doubtful whether the Neon tube under fog conditions is superior to other methods of aerial lighting by means of which beams—both white and red—of much higher total intensity can be projected.

In Great Britain and France the guiding principle of airways lighting is (in 1929) to provide powerful lights at comparatively long distances apart, which can be picked up by airmen at long range flying either low down or at comparatively high altitudes. In the United States and in Germany the practice is to lay a series of comparatively low-power lamps at short intervals along the air route, the airmen being expected to follow the line marked out.

FOG-SIGNALS

The introduction of coast fog-signals is of comparatively recent date. They were, until the middle of the 19th century, practically unknown except so far as a few isolated bells and guns were concerned. In times of fog the mariner can expect no certain assistance from even the most efficient system of coast lighting, since beams of light of high power are frequently entirely dispersed and absorbed by the particles of moisture, forming a sea fog of even moderate density at relatively short distances from the shore. The careful experiments and scientific research which have been devoted to the subject of aerial-acoustic fog-signalling have produced much that is useful and valuable to the mariner, but unfortunately the practical results thus far obtained have not been so satisfactory as might be desired owing to (1) the very short range of the most powerful signals yet produced under certain unfavourable acoustic conditions of the atmosphere, (2) the difficulty experienced by the mariner in judging at any time how far the atmospheric conditions are against him in listening for the expected signal, and (3) the difficulty in locating the position of a sound signal by phonic observations. The future of marine fog signalling may lie in the direction of wireless signals, but it is unlikely that acoustic signals will be dispensed with even if reduced in number.

Bells and Gongs are the oldest and, generally speaking, the least efficient forms of fog signals. Under very favourable acoustic conditions the sounds are audible at considerable ranges. On the other hand, 2-ton bells have been inaudible at distances of a few hundred yards. Bells are frequently used for beacon and buoy signals. When employed in conjunction with a lighted beacon they are sometimes rung mechanically either by clockwork or by compressed CO_2 gas. Electric striking mechanism has also been employed where current is available.

Explosive Signals.—Guns were long used at many lighthouse and light-vessel stations in Great Britain, and are still found at some foreign stations. In 1878 sound rockets charged with gun-cotton were first employed at Flamborough Head and were afterwards supplied to many other stations.[1] The nitrated gun-cotton or tonite signals now in general use at rock and other lighthouses where accommodation is limited are hung at the end of an iron jib or pole attached to the lantern or other structure, and fired by means of a detonator and electric battery. An example will be noticed in the illustration of the Bishop rock lighthouse, the jib being attached to the lantern (fig. 4). Sometimes the explosive is combined with aluminium in the charge to give a brilliant flash in addition to the detonation.

The acetylene fog-gun is an automatic or semi-automatic signal in which a mixture of air and acetylene is exploded at short intervals in a gun chamber. It is economical in working cost and occupies little space; but its power cannot be compared with that of a compressed-air siren. The admission of air and acetylene is controlled by an automatic gas-valve and the charge is fired by a spark. Signals can be sounded as frequently as every ten seconds.

An acetylene gun was established at the Dhu Heartach rock lighthouse (west coast of Scotland) in 1912. The gun continues in action without attention from the time when it is started until it is stopped by the keeper. The gas is generated automatically on the carbide-to-water principle.

On the Clyde there are two isolated beacon structures which are equipped with automatic guns started and stopped by wireless control from Gourock pier. Several other stations in Scotland and elsewhere are provided with these guns.

Whistles and Reed Horns.—Whistles, whether sounded by air or steam, are not used in Great Britain although they are still employed as fog signals in the United States, Canada and Sweden. It has been objected that their sound bears too great a resemblance to steamers' whistles; and they are wasteful of power.

Reed horns, in their original form, were the invention of C. L. Daboll, an experimental one, of his manufacture, being tried in 1851 by the United States Lighthouse Board. The reed horn was adopted by Trinity House in 1862 after being improved by W. Holmes and many examples from his designs are now in use at secondary stations in Britain and America. Normally they are sounded at a pressure of 15 lb. per in. with air furnished by power-driven compressors, semi-diesel engines being commonly used in modern installations. When operated by hand the working pressure is 5 lb. per square inch.

Sirens and Diaphones.—These are considered to be the most efficient aerial sound-signals which can be obtained for lighthouse purposes. One or other of them is usually employed when first-class signals are required and space is available for the accommodation of the necessary plant. Both are compressed-air instruments, but differ somewhat in operation. The diaphone, in its modern form the more powerful instrument, was invented in Canada by J. P. Northey, about 1903, and consists of a piston reciprocating in a cylinder, around both of which are cut circumferential slots or ports. The piston is fitted with an operating head to which air is admitted, first on one side and then on the other, for giving to it the reciprocating motion. As the slots in the two units pass and repass one another, air is being admitted through them to produce the impulses or sound waves, and upon the number of times these ports open and close each second de-

[1]The Flamborough Head rocket was superseded by a siren fog signal in 1908.

pends the note. In the case of the siren the piston revolves in the cylinder instead of having a reciprocating motion, but otherwise the principle of air admission is the same in both instruments. Each is fitted with a trumpet-horn or resonator and the working air-pressure is 30 lb. per sq.in. for the diaphone and 25 lb. per sq.in. for the siren. The diaphone note is usually about 180 vibrations per sec. or F sharp in the tenor clef; it terminates with a quick descending note termed the "grunt" at the end of each blast. This grunt is a valuable distinctive feature as it can sometimes be heard when the remainder of the signal is inaudible.

To provide the air for these instruments compressing machinery and large capacity air storage receivers are required. In recent Trinity House installations two instruments with their axes approximately 120° apart horizontally are fitted for distributing the sound over a wide arc. In the diaphone installations at Flamborough, Hartland and Skerries (1927) the mouths of the two trumpets are placed on a common vertical axis with their centres half a wave-length apart, to give effect to the theory propounded by the third Lord Rayleigh that vertical dispersion of sound was by this means avoided. A similar arrangement has also been introduced at some French stations.

The siren in a primitive form was invented by John Robison (1739–1805). Cagniard de la Tour evolved the disc form and gave it the name of siren. The first steam siren was patented by Brown of New York. The cylindrical form and the centrifugal governor now commonly used are due to G. H. Slight.

Nautophones.—A form of aerial-acoustic instrument called the Nautophone has recently been devised which consists of an electrically vibrated diaphragm sounding a high note. In its present state of development (1929) it compares, as regards intensity, with a reed horn.

Submarine Bell and Oscillator Signals.—As early as 1841 J. D. Colladon conducted experiments on the lake of Geneva to test the suitability of water as a medium for transmission of sound-signals and was able to convey distinctly audible sounds through water for a distance of over 21 m.; but it was not until 1904 that any successful practical application of this means of signalling was made. Submerged bells are used principally in connection with light-vessels and are struck by clappers actuated by pneumatic or electrical mechanism. They have also been fitted to buoys and beacon structures, and placed on the sea bed. In the first case the bell is actuated by the motion of the buoy and in the others by electric current, transmitted by cable from the shore.

The oscillator or electro-magnetic submarine fog-signal is actuated electrically from the lightship to which it is attached or from the light station with which it is connected. The instrument, which came into use during the World War, comprises a vibrating diaphragm of large dimensions, and its principle of operation is similar to the working of a telephone. It sends out a high note to which can be given a characteristic code notation. The instrument has been fitted in several light-vessels in European and American waters. The underwater range of the oscillator has been known to exceed 50 m. as compared with 10 m. for the bell.

To take full advantage of the signals thus provided it is necessary for ships approaching them to be fitted with special receiving microphones installed below the water line and in contact with the hull plating. The signals are audible by the aid of ear-pieces similar to ordinary telephone receivers. Not only can they be heard at considerable distances and in all conditions of weather, but their direction in reference to the moving ship can be determined approximately. When they are established in conjunction with a wireless-beacon fog-signal and when the acoustic and radio-signals are made to synchronize, as at the Nantucket Shoals light-vessel (U.S.A.), they provide in combination a valuable means of determining distance by observing the interval of time between the reception of the two signals (*see* below).

Wireless Fog Signals.—Wireless fog signals,[1] designed for continuous transmission from light stations, provide a means by which a navigator may obtain a direct bearing on the transmitting station. They are of three types: (1) a stationary wireless-beacon transmitter from which a characteristic signal is sent out in all directions, so that it can be picked up by a ship fitted with a direction-finder or wireless-compass[1]; (2) a rotating short-wave directional wireless-beam transmitter, which sends out a different characteristic signal on all points of the compass as it revolves; these signals are received on a special aerial, and as the wireless beam is directional and as each signal represents a definite bearing, the particular signal heard gives the bearing of the ship from the station; (3) a rotating wireless-loop transmitter, which is revolved at a pre-arranged constant speed and sends out on north and east zero points a characteristic signal, followed during the remainder of its revolution by a continuous dash. The bearing in this case is taken by means of a stop-watch, in conjunction with an ordinary wireless receiver, and is obtained by noting the time which elapses between the hearing of one or other of the zero-point signals and the total extinction of the continuous dash. As the loop makes so many revolutions in a definite period, the determination of the bearing is merely a matter of computation between the speed of rotation and the time recorded by the stop-watch.

(1) *Wireless-beacon.*—Each system has its particular merits, but the first, that is, the beacon station, is probably the most effective of the three. It is comparatively cheap to install and easy to maintain, while the system is applicable either on shore or on board a light-vessel. Moreover, this form of wireless fog-signal necessitates a ship being fitted with a direction-finder which enables a bearing to be obtained not only of the beacon-station but also of other ships at sea during fog; or, as has frequently been proved with advantage, of a ship in distress. When the wireless-signal is combined with a submarine-signal and made to synchronize with it, distance from, as well as direction of, the station can be obtained.

A beacon-station of this type was established at Round island in the Scilly islands in 1927. In the beacon, a simple valve transmitter of ½ kw. power generating interrupted continuous waves is employed working on an open twin L aerial. The wave-length is 1,000 metres. Good bearings are obtainable from it at a distance of over 100 m. The whole equipment is automatically controlled, even to the replacement of transmitting valves in case of failure, by a master-clock which sends out signals every half hour by Greenwich mean time. During foggy weather the time interval is reduced. Little attention is required and it has been found practicable to run the station without addition to the lighthouse staff. Similar signals were established in 1928 at 12 other British stations, including two light-vessels and others were in course of erection. Wireless fog-signals of the same general type have been installed by other lighthouse services, notably those of the United States (where 57 stations were in operation in 1928), Holland, France, Sweden and Canada. An experimental station was established in France in 1912 but the first permanent wireless fog-signals were put into service in the United States in 1921 on light-vessels in the approaches to New York harbour.

(2) *Rotating-beam.*—A wireless fog-signal in the class of the second type has been established at Inchkeith in the Firth of Forth (1922). It works on a 6·2-metre wave-length and though the receiving apparatus is simple and inexpensive, the transmitter in its present state of development has disadvantages in that the range is small, and a large rotating structure is required for producing the beam. In addition, as the bearings must be given relative to a fixed zero, the system is inapplicable for use on a light-vessel.

(3) *Rotating-loop.*—The third system, which was developed by the Royal Air Force, possesses an advantage in that an ordinary receiving apparatus and stop-watch only are required for taking bearings, but the power employed is over ten times that of the beacon-transmitter for less range, while the cost is considerably greater. The cost of maintenance too is high, as

[1]Other designations are:—*Radio beacons, Radio fog-signals, Wireless beacons* and, in France, *Radiophares.*

[1]Synonyms are:—*Radio-compass* and *Goniometer.*

a careful watch must be kept on the timing of the rotation of the loop and the large power-plant requires constant attention. The transmitter is delicate and must be free from local interference if accuracy of bearing is to be assured; so that sites for this type of station have to be carefully selected. Like the second system, it cannot be applied on a lightship because of the necessity of having fixed zero-points. Loop stations have been established experimentally at Gosport and Farnborough and further trials of the system are being carried out at Orfordness.

Wireless fog-signalling and position-finding are (1929) still in the state of active experiment and development.[1] They are undoubtedly destined to be one of the most important navigational aids in the future. The desideratum appears to be a system, applicable to stations both ashore and afloat, which employs a wireless signal whose bearing is quickly and directly ascertainable by the navigator himself and which, when combined with submarine acoustic-signals, can be used for ascertaining distance.

LIGHTHOUSE ADMINISTRATION

The principal countries of the world possess organized and central authorities responsible for the installation and maintenance of coast lights and fog-signals, buoys and beacons.

British Isles.—In England Trinity House is the general lighthouse authority. The Corporation of Trinity House, or according to its original charter, "The Master Wardens and Assistants of the Guild Fraternity or Brotherhood of the most glorious and undivided Trinity and of St. Clement, in the Parish of Deptford Strond, in the county of Kent," existed in the reign of Henry VII. as a religious house with certain duties connected with pilotage, and was incorporated during the reign of Henry VIII. In 1565 it was given certain rights to maintain beacons, etc., but not until 1680 did it own any lighthouses. Since that date it has gradually purchased most of the ancient privately-owned lighthouses and has erected many new ones. The act of 1836 gave the corporation control of English coast-lights with certain supervisory powers over the numerous local lighting authorities, including the Irish and Scottish boards. The corporation now consists of a Master, Deputy-master, and 22 Elder Brethren (ten of whom are honorary), together with an unlimited number of Younger Brethren, who, however, perform no executive duties. In Scotland and the Isle of Man the lights are under the control of the commissioners of northern lighthouses, constituted in 1786 and incorporated in 1798. The lighting of the Irish coast is in the hands of the commissioners of Irish lights formed in 1867 in succession to the old Dublin Ballast board. The principal local light authorities in the United Kingdom are the Mersey Docks and Harbour board and the Clyde Lighthouse trustees. The three general lighthouse boards of the United Kingdom, by the provisions of the Mercantile Marine Act of 1854, are subordinate to the Board of Trade, which controls all finances.

On Jan. 1, 1928, the lights and fog-signals in service under the control of the several authorities in the British Isles were as follows:—

TABLE IV.

Authority	Light-houses	Minor lights	Light-vessels		Aerial-acoustic fog signals			Submarine fog signals	Wireless fog signals
			Manned	Unat-tended	Explosive	Sirens, diaphones, reed horns, etc.	Bells, etc.		
Trinity House	87	8	45	2	13	75	11	19	8
Commissioners of Northern Lighthouses	151	7	1	4	11	40	3	..	2
Irish Lights Commissioners	82	4	10	..	14	23	4	5	1
Mersey Docks and Harbour Board	14	17	3	..	..	5	7	1	1
Admiralty	3	31	..	..	..	4	1	..	..
Clyde Lighthouse Trust	5	12	..	..	2	3	2	..	..

Other local lighting authorities	192	940	2	2	4	43	69	1	..
Totals	540	1023*	63	9	44	196	98	27	13†

*Lighted buoys and some harbour and river lights of minor character are not included in the above list.
†Including some signals established during 1928.

In the Trinity House service at shore lighthouse stations where there is no fog-signal there are usually two keepers, and at rock stations four, one being ashore on leave. At a shore fog-signal station there is an additional keeper. The crews of light-vessels as a rule consist of 11 men, three of them and the master or mate going on shore in rotation. The average annual cost of maintenance (excluding repairs) of an English shore lighthouse, with two keepers, is £477. For shore lighthouses with three keepers and a siren fog-signal the average cost is £811. The maintenance of a rock lighthouse with four keepers and an explosive fog-signal is about £1,310, and an electric-light station with a diaphone fog-signal costs about £1,200 annually to maintain. A light-vessel of the average type with a power-driven fog-signal entails in England an annual expenditure on maintenance of approximately £2,500, excluding the cost of periodical overhaul.

Other Countries.—The lighthouse board of France is known as the Commission des Phares, dating from 1792 and remodelled in 1811, and is under the direction of the minister of public works. The chief executive officers are an *Inspecteur Général des Ponts et Chaussées*, who is the director of the service, and another engineer of the same corps, who is engineer-in-chief and secretary. The board has control of about 770 lights, including those of Corsica, Algeria, etc. In Denmark, Austria, Holland, Italy, Sweden, Norway and many other countries the minister of marine has charge of the lighting and buoying of coasts; in Belgium the public works department controls the service, and in Spain the lighthouse service is established on lines similar to that of France.

In Canada the coast lighting is in the hands of the minister of marine, and in most of the other British dominions and colonies the public works departments have control of lighthouse matters. For the lighthouse service of the U.S.A. *see* following article.

THE UNITED STATES

The first lighthouse in America, a tall masonry tower, was built in 1716 by Massachusetts at the entrance to Boston harbour. The original Colonies on the Atlantic, largely dependent on water traffic, gave early attention to lighthouses. Congress, in 1789, immediately after the national government's organization, provided for lighthouses and buoys, 12 having been built by the colonial governments. In 1852 Congress established the Lighthouse Board, substituting for it in 1910 the Lighthouse Service. On July 1, 1939 the Lighthouse Service was consolidated with the U.S. Coast Guard, in the Treasury Department.

The problems of lighthouse construction are similar everywhere in the world, but the Great Lakes and north Atlantic ice action, southern coast hurricanes, and some earthquake areas need particular attention. This country has about 30 important lighthouses on submarine or unusually exposed sites, some involving difficult engineering; only a few of these are wave-swept lighthouses of primary significance. The following are important or typical wave-swept U.S. lighthouses:

Minots Ledge (1860), south of Boston harbour, the most notable, built on a reef, bare only at low water, exposed to the Atlantic's sweep; its construction lasted over 5 years. Steps were cut to receive the foundation. The conical-shaped tower is of granite, the first 40 ft. solid, base 30 ft. diameter, the light elevated 85 ft. The stones are dove-tailed in each course, connected vertically by bonding bolts, and eight long iron posts pass through the lower courses into holes in the ledge.

White Shoal (1910), marking a shoal in northern Lake Michigan. A timber crib 72 ft. square towed to the site, filled with stone, was sunk in 22 feet of water; this supports concrete pier, tower and light 125 feet above water. *Martin Reef* (1927), northern Lake Huron, has a similar substructure.

On the Great Lakes important structures on submarine foundations mark shoals, usually replacing the original lightships. Timber crib foundations, economical, satisfactory in fresh water, are favoured. Other types are: Concrete caissons towed to site, sunk on bottoms previously levelled, and filled with stone, i.e., *Lansing Shoal* (1928), Lake Michigan. *Spectacle Reef* (1874), Lake Huron and *Stannard Rock* (1882), Lake Superior have coffer-dams in protecting piers, the former for a stone tower on rock, the latter for a wrought iron cylinder foundation pier fitted to rock and concrete-filled.

Sabine Bank (1906), marking a sand bank about 14 m. off the Gulf coast, is a cast iron tower and substructure, standing in 18 feet of water. The iron caisson was towed to the site and sunk 20 ft. in sand by pneumatic process, the only U.S. lighthouse foundation so placed in the open sea. There are others in protected waters.

Pacific Reef (1921), marking the outer edge of coral reefs off the Florida southern coast. It is supported by nine iron piles, each driven 9 ft. into the coral reef, the piles pass through, and are partially supported by, iron discs 4 ft. in diameter resting on the coral surface. In 7 ft. of water, it supports an iron open work structure. Although only an automatic acetylene light, 45 ft. high, it illustrates recent practice, at moderate cost. Six other lights, along the Florida reefs, on similar foundations, are notable structures, the tallest being *Sombrero Key* (1858), 160 feet.

Tillamook Rock (1881), a stone structure on a small rock islet 1 m. off the Pacific coast, south of the Columbia river's mouth, the most notable lighthouse on the United States western coast due to its position on extremely exposed rock, in deep water and open to the Pacific sweep. Landing is impossible directly on the rock, and can be made only by hoisting from a boat. Seas break sometimes over the lantern 145 ft. elevation. *St. George Reef* (1891) off the California coast is in a similarly difficult position.

Many lighthouses in water were built on screw-pile foundations, but none recently; one, *Sand Key Light* (1853), Florida, is 120 ft. high. Of many handsome masonry lighthouses along the coast, especially the low-lying Atlantic seaboard, *Cape Hatteras* is the highest, 193 feet though not now used for lighthouse purposes. Reinforced concrete has been extensively used recently to construct light towers, wharves and buildings.

The most notable is *Navassa Island Light* (1917), on a desert West Indian island, tower 162 ft., cylindrical shaft 15 ft. diameter. Another primary light of reinforced concrete is *Kilauea Point* (1913), Hawaiian islands; tower 52 ft. high, on a cliff.

Apparatus, Illuminants and Characteristics of American lights are similar to standard world practice, but have some diverging developments. Concentrating light by using rapidly revolving lenses with few panels, and superior illuminants, gives beams of sufficient power with smaller lenses; no lenses larger than third order (500 mm., 20 in. radius) have been installed since 1913; numerous large lenses, have been replaced by more efficient optical apparatus.

The primary light standard, the electric incandescent lamp, using commercial current or current generated at the station, has replaced the older kerosene oil vapour apparatus. Incandescent electricity is most satisfactory because of its power, convenience and adaptability. It is efficient to electrify certain stations for illuminant, operating sound fog signal and radio-beacon, and lighting buildings.

Electricity is very convenient for signals controlled remotely, as those near jetty ends. Small plants or primary cells generate electric energy for minor lights. The principal difficulty in putting incandescent electric lamps in old lenses is the too concentrated light source, and insufficient divergence of beam; this is being overcome by various methods.

Acetylene gas compressed in cylinders is increasingly used for unwatched or semi-watched lights of medium importance. Acetylene under incandescent mantles, or more elaborate acetylene apparatus is not used. Electric and dissolved acetylene equipment has advanced automatic apparatus installation and conversion to unattended stations. About 60% of lights, including buoys and excluding rivers, are now automatic.

Automatic apparatus extends lighthouse facilities to remote regions like Alaska.

Distinguishing principal coast lights by flashing or occulting characteristics, and eliminating fixed lights, progresses steadily. Characteristics are simple, quickly and easily recognized without timing. Preferred limitations are: that a single important light flash be not less than 0·3 sec. in duration, a minor light not less than 0·1 sec., that the characteristic be repeated preferably twice a minute, and one light of a range, or two lights in line, be fixed. Colour is valuable in distinguishing but illumination is reduced to about 30%—a serious drawback. Red and green are used for secondary lights.

Uniformity of Buoyage.—The United States of America has long had a fairly standardized system to show the relation of buoys to channels, by colours, shapes and numbers, this system having in part been prescribed by law in 1850. International uniformity in buoyage and lights would add safety and convenience to navigation. Limited but important action on this at the International Marine Conference, Washington, 1889, resulted in considerable uniformity.

The United States system, based largely on the 1889 conference, is, for vessels coming from sea: red buoys, conical-shaped ("nun"), even numbers, on right side of channel; cylindrical black buoys, flat tops ("can"), odd numbers on left side; horizontal red and black-banded buoys mean shoals or dangers; vertical black and white stripes show clear channels; with coloured lights, red on right and green on left of entrances or channels, but white may be on either side.

Colour and shape to mark the relations of buoys to channels are in nearly world-wide use; shape alone is not enough, because not readily applicable to important classes of buoys, such as gas, whistle, bell and spar. Moreover, experience shows that both colour and shape do not differentiate too much the respective channel sides. Colour is the most obvious, readily applied characteristic, and there is far greater world colour uniformity than in other buoy characteristics. The Washington Conference recommendations now embrace about 80% of world buoyage, including France, Germany, Scotland, Ireland, Argentina, United States, Canada, Japan, India, China, Philippines, Australia, New Zealand. The American buoyage system, light characteristics and apparatus are as simple as may be, so as to avoid confusion, and to be more definite and reliable.

Lightships are placed, on foggy coasts, to mark outstanding dangers, or port approaches. The first was placed in Chesapeake bay (1820).

Fixed structures on shoals, or gas buoys, have replaced many originally placed in inland waters; Great Lakes lightships are thus being gradually retired. There are 31 lightships stations, with 10 relief ships. Of the stations 25 are outside on the Atlantic and Pacific coasts, where it is impracticable to build lighthouses, yet where they are vital to traffic, *i.e.,* Nantucket lightship moored in 30 fathoms, 41 m. from land, guards shoals to the north and most trans-ocean vessels approaching the United States Atlantic coast steer for this vessel, one of the world's most important seamarks.

A full-powered vessel, 132 ft. long, crew of 16, it has a flashing incandescent electric light of 22,000 candle-power, compressed air fog whistle, radio-beacon and synchronized submarine oscillator. It is an oil-burning steam vessel, No. 112 (1936). Several lightships have Diesel engines, and 3 ships have Diesel-electric propulsion.

Lightships moored in the sea off the Atlantic coast, exposed to tropical hurricanes and other severe storms, receive special attention as to vessel design and moorings to ensure station permanency. For years attempts to keep lightships off New York and Cape Hatteras failed.

Severe storms have sometimes torn lightships from their moorings. Cast steel chain is being used for moorings, so as to better retain lightships on station. Mushroom anchors up to 4 tons are being used.

Buoys.—The American coast's great length and intricacies require 15,000 buoys. The increase in lighted buoys is a notable advance. In 1939, 1,881 lighted buoys were on station. Nearly all lighted buoys use acetylene gas compressed in tanks, set in buoy pockets, but electric lighted buoys are increasing in number. Steel buoys of various sizes are extensively used to mark channels and shoals. Wooden spars are being replaced advantageously by small inexpensive steel buoys. Though not very effective fog signals, there are 226 whistle buoys and 811 bell buoys, some of the latter provided with chimes having 4 different notes, to distinguish from the bells.

All buoys and moorings are relieved at least once a year, old buoys brought to depots, cleaned and repainted. Their great number makes this an important and time-consuming task. (*See* article on Buoy.)

Sound Fog Signals.—Radio-beacons, described later, are the most effective fog signal. Various types of sound signals, using compressed air or electricity, are employed, but their value is limited, due to short and undependable range, and the impracticability of taking accurate bearing on them. But, so far as may be foreseen, sound fog signals will remain indispensable. Steam whistles formerly used extensively, are being replaced by more efficient apparatus. Variously actuated electric sirens, reed horns and bells serve for minor sound signals.

The United States uses no explosive fog signals and but few signals (bells) operated by hand.

Though automatic sound fog signals would be of great value, there are, besides the bell and whistle buoys, only 29 bells actuated by carbon dioxide gas; these are useful where a moderate signal suffices that can readily be reached, but are not dependable otherwise.

Nearly all fog signal machinery and apparatus is installed in duplicate for greater reliability.

Radio-beacons.—These stations emit radio signals on distinctive codes. Allied with the radio direction finder on shipboard, they are considered the most important addition to navigational apparatus since the mariner's compass. They furnish the first generally available means ever provided of taking accurate bearings on invisible objects at considerable distances.

The first successful radio-beacons were placed at three stations near New York in 1921; the system has now grown in the United States and outlying territories to 141 stations, about one-third the number in the world. The transmitting apparatus is generally timed to sound one out of each three minutes, during fog or low visibility; also at certain half or quarter hours in clear weather. Each station sends a characteristic code signal differing from any other within range. Signals are of interrupted continuous wave type, sent with tube transmitters; tests are being made with continuous wave signals; standard wave length is 1,000 metres (300 kilocycles per second), but to lessen interference between adjacent stations in congested localities, wave lengths have been staggered somewhat, between 952 and 1,052 metres (315 and 285 kilocycles).

A few important stations, *i.e.,* Nantucket lightship, are operated with 500 watts; the standard power for other coast stations, and on the Great Lakes, is 200 watts; for inland waterways as low as $7\frac{1}{2}$ watts are being tried. This system is extending rapidly. If conditions favour, bearings correct to 1° or 2° up to 200 m. away are obtained. Rotating radio-beacons have not been introduced here, as they can not be placed on lightships, the most important radio-beacon stations.

The above system with the radio direction finder on board ship is the only possible general navigational system through radio bearings. The systematic operation of radio-beacons during clear weather is being extended; correct bearings may be taken far beyond the range of any other aids. (R. R. W.)

Airways Lighting in the United States.—The installation, operation and maintenance of the Federal Airways System, including the lighting of the various airways comprising the whole network, are under the jurisdiction of the Administrator of the Civil Aeronautics Authority. Prior to the creation of the Authority in 1938, these tasks had since 1926 been the responsibility of the Department of Commerce, administered successively by the Lighthouse Service and the Bureau of Air Commerce. With the completion of a $7,000,000 two-year airways modernization program in 1939, there were in operation 24,249 miles of lighted airways equipped with 2,016 beacon lights, 238 radio range stations providing directional guidance, 68 radio position markers, 95 scheduled weather broadcasting stations, 23,658 miles of weather reporting teletypewriter circuits and an additional 10,676 miles of traffic control circuits, both with a total of 332 teletypewriter stations, and 273 intermediate fields for emergency use.

Standard light equipment consists of 36-in. and 24-in. revolving beacons with parabolic mirror and 1,000 or 500 watt electric lamps developing approximately 2,000,000 beam candle-power and course light projectors flashing code numbers identifying the beacon along the airway and showing the course. Commercial electric power operates the apparatus mounted on steel skeleton towers. Engine-driven (gasoline or Diesel) generators in a small power house at the tower's foot furnish electricity if commercial power is unavailable. Astronomic clocks turn lights on and off. Boundary lights and cone markers 300ft. apart outline intermediate fields, green range lights mark best runways and red lights mark air navigation obstructions. Internally lighted fabric wind cone on beacon towers at landing fields indicates wind direction and force (*see* also Aerodrome; Aviation, Civil). (X.)

Administration.—The maintenance of aids to marine navigation is a function of the United States Coast Guard, having been placed under that organization on July 1, 1939, and consists of the maintenance of lighthouses, lightships, radio-beacons, fog signals, buoys, and beacons upon all navigable waters of the United States and its possessions; including Atlantic and Pacific coasts of continental United States, the Great Lakes, the Mississippi river and its tributaries, Puerto Rico, the approaches to the Panama canal, the Hawaiian islands, and Alaska.

The chief administrative officer is the Commandant of the

Coast Guard, with headquarters at Washington, D.C. Under his direction the functions of establishment, construction, maintenance, and operation of aids to navigation are carried on through administrative and engineering divisions in Washington, and by the various district offices. Because of the wide geographic distribution of aids to navigation on the sea coasts, the Great Lakes, and navigable rivers of the United States, with an aggregate coast line of over 40,000 miles, the field work of the service is carried on by district organizations. There are 13 Coast Guard districts, carrying on lighthouse work, as well as other functions of the Coast Guard. Each district is under the supervision of a commander, assisted by a suitable engineering and administrative force, and equipped with the necessary supply and buoy depots, and with suitable vessels for the maintenance of the navigational aids.

The total cost of maintaining the aids to marine navigation for 1938 was $13,340,659, of which $2,847,809 was for new works, repairs and improvements. Average costs for that year are: primary seacoast light station, $5,592; river post light, $122; sea-going tender (Atlantic), $70,332; exposed lightship, $28,300. Total aids in 1939, 29,606, of which 9,862 are lighted. The Philippines have 440 local aids, the Panama Canal 715, making a grand total for U.S. Territories of 30,761.

LIGHTING AND ARTIFICIAL ILLUMINATION.

Man, in his social and economic development, has been engaged in continuous effort to utilize the hours of darkness through the application of artificial illumination to human needs. The respect in which light has been held throughout the ages suggests that proficiency in its use could be regarded as a criterion of the degree of civilization which a people has attained. New methods of providing artificial illumination, although invariably opposed by proponents of the method in current use, aided other contemporary developments in raising the standard of living.

Methods of producing light remained primitive and crude in design over long periods of time, and when new and improved methods were introduced, the use of the earlier forms continued so that at no time has one method completely replaced another. In the middle of the 20th century there were parts of the world in which the resinous wood torch, the oil lamp, the candle and various forms of the kerosene lamp were used.

Artificial illumination is obtained as a result of combustion, incandescence or electric discharge with or without fluorescence, and its development has been the efficient production of light without heat. Sources of light may be divided into three classes: (1) vegetable and animal fatty substances; (2) carbonaceous matters, gases and oils; and (3) electrical (*see* fig. 1).

HISTORICAL DEVELOPMENT

The earliest form of artificial illumination was the fire used by primitive man for warmth and for protection against wild beasts, and burning pieces of resinous wood plucked from the campfire were the first torches. From this beginning, which antedates written history by thousands of centuries, the torch as a source of illumination has continued in use throughout the world. It has assumed various forms, bundles of thin splinters bound together by rushes and dipped in pitch or wax being used by the ancient Greeks and Egyptians, by natives of the East Indies, and at different periods by the Indians of North and South America.

The flambeau of the middle ages, carried by pedestrians at night, was a torch consisting of twisted fibre coated with some inflammable substance. These torches provided the earliest form of street lighting, being fastened in metal holders to the outside walls of houses. Pieces of resinous wood, stuck between the stones of the fireplace, gave forth bright but smoky flames for lighting homes of early New England. This type of illumination was being used in rural homes of the poorer type as late as 1928.

Unusual sources of artificial illumination are the "animal lights" used in tropical countries. Glow-worms, beetles and fireflies are described as being confined in lanterns in the West Indies, and in Java they are stuck in wax in shallow saucers, the light given off by them being sufficient for performing night tasks within a small area. Early accounts from tropical America describe a great beetle which furnished enough light for a traveller to find his way at night.

Oily carcasses of various animals with a wick drawn through them have been used; records of use of the penguin in this manner being most common.

Oil Lamps.—The earliest prehistoric lamp dates to the Mousterian age. This was a hollowed piece of stone, very crude, found at Le Moustier, France, in 1928. On the Mesopotamian plains terra-cotta lamps of 7000–8000 B.C. have been found and copper and bronze lamps of Egypt and Persia of the year 2700 B.C. have been found by archaeologists at various times.

By 1000 B.C. an advancement in lighting efficiency was provided by a wick of vegetable fibre burning in a saucer type vessel holding olive or nut oil. About 950 B.C. Homer spoke of the "Festival of Lamps," these lamps being flat saucers filled with castor oil and salt, with a wick floating on the surface. By 500–400 B.C. lamps burning oil had come into general domestic use. The Romans made lamps of unglazed and glazed terra-cotta, having two or more spouts. Later bronze and iron lamps were introduced and designs became more elaborate although the principle of producing light remained the same. About 100 B.C. the Romans also developed the first true lantern of horn, cylindrical in form, with a perforated top. Lamps were in general use among the early Jews, Greeks and Romans; the "seven-branched candlestick" of Biblical times and the lamps of the vestal virgins were of the vegetable oil type.

Pliny, in about A.D. 50, mentioned oil found on the shores of the Adriatic as being used for lamps, this being the first record of the use of mineral oil in illumination. Japanese history of the year A.D. 615 mentions "burning water" and Marco Polo, in his 13th century writings, speaks of the oil springs of Baku as furnishing oil satisfactory for lighting purposes.

Improving the efficiency of oil-burning lamps became a matter of interest to scientists at a very early period. Hero of Alexandria, who lived during the latter half of the first century, A.D., devised a lamp in which the raising of the oil to the wick was effected by pressure of a liquid of greater specific gravity (brine) acting through a column of air.

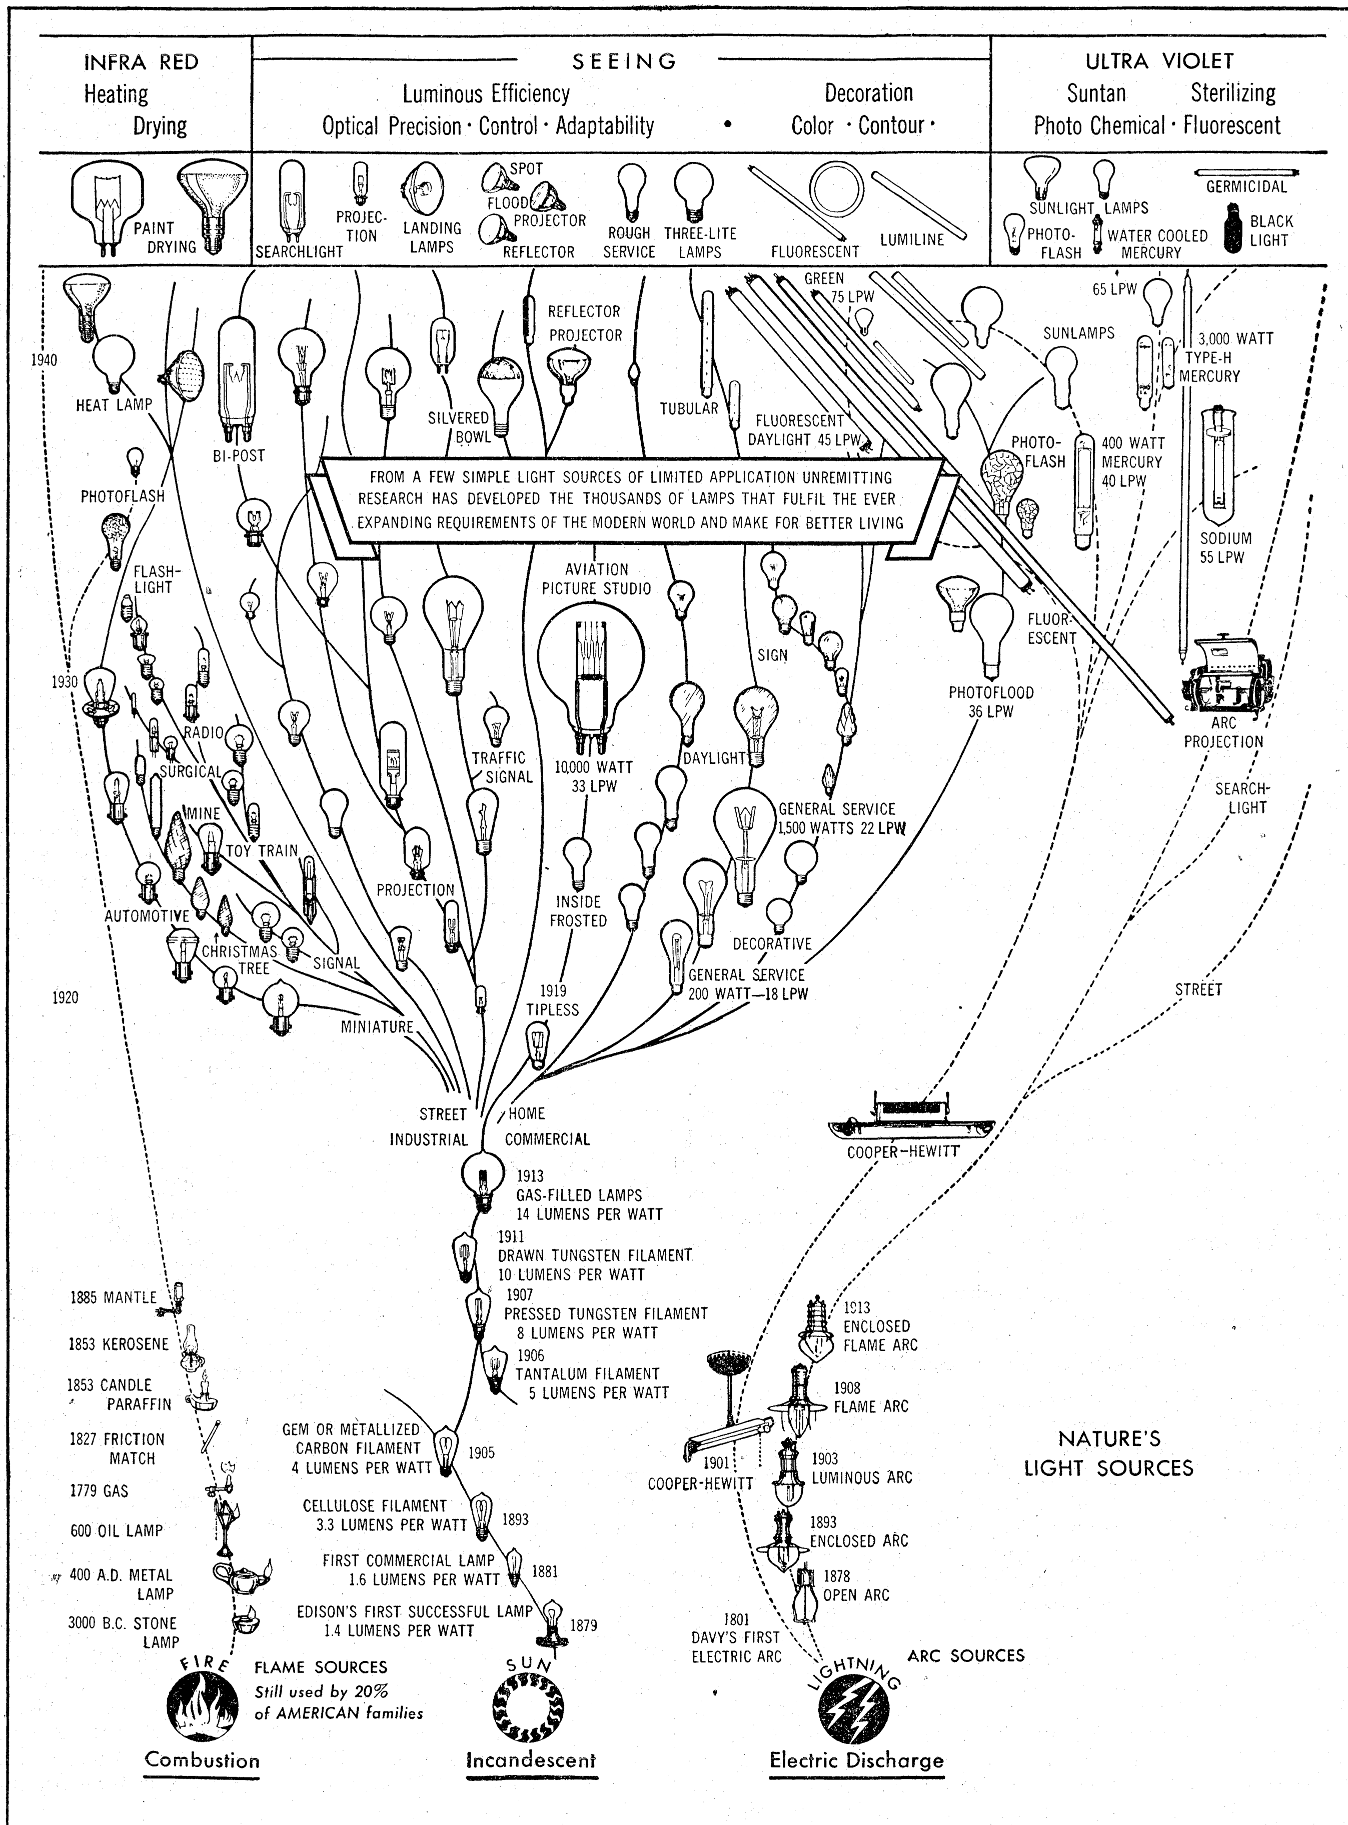
Leonardo da Vinci, in 1490, dissatisfied with the meagre quantity of light afforded by the oil lamp and flickering of the flame, added a chimney in the form of a glass cylinder fitted into a glass globe filled with water. The light burned steadily and through lens action the work surface was brightly lighted for night study. Da Vinci recognized the components of "seeing" as shown by the fact that he also devised water lenses for correcting near vision; the first recorded analysis that "seeing" is a combination of light and vision.

Various types of oil lamps were used through the 14th to 17th centuries, but there was little improvement in their efficiency during that period. The "Betty lamp" of the Pilgrims (1620), the name of which was derived from the German *besser* meaning "better," was a metal receptacle with a wick lying in a slot and protruding from one side. This lamp was equipped for hanging from mantlepieces or shelves, fish oil being the chief illuminant.

Toward the end of the 18th century Ami Argand, physicist of Geneva, introduced a lamp, patented in 1784, furnished with a round burner and tubular wick, and a chimney for directing and regulating the flow of air to the flame. An accident led to the discovery that a round glass chimney reduced flickering, thereby improving the quality of the light, and the Argand lamp marked the greatest advancement in artificial illumination to that date.

In 1800, B. G. Carcel added a clockwork pump to the Argand lamp for raising and feeding oil to the wick, and because of the steadiness of the light produced, the lamp in this form became a photometric standard.

In 1847, James Young produced distilled oils from coal, which was an improvement over previous illuminants, but the discovery



COURTESY LAMP DEPARTMENT OF GENERAL ELECTRIC COMPANY

FIG. 1.—PICTORIAL SUMMARY OF LIGHT

of petroleum by E. L. Drake in 1859 provided an inexpensive illuminant with such a high degree of lighting efficiency that the crude oil lamp was practically superseded.

From 1859 to 1879 an average of 80 patents a year were granted for various types of improved lamps for burning oil, one of the most important being the duplex burner lamp introduced in 1865 by Joseph Hinks. In 1868, the "Wells light" introduced a process of combining an oil spray with vaporized oil through the use of pressure. This process gave a highly luminous flame and the principle is used in modern flare lamps. The Kitson lamp of 1885 was a pressure type lamp using platinum mantles, replaced later by Welsbach mantles.

During the latter half of the 19th century oil lamps underwent many changes and improvements in an effort to make them more attractive for domestic use and more efficient for industrial purposes. They were mounted on elaborate bases, the oil reservoirs were decorated, some were designed for suspension from ceilings and others were portable. These latter designs carried over into the 20th century and the kerosene lamp with a flat wick in a perforated metallic holder, and a plain glass chimney is used extensively in outlying districts and poorer homes.

Candles.—The invention of the candle may be regarded as contemporaneous with the need for a portable means of artificial illumination, and candlemaking is probably one of the oldest industries of mankind. The candle is defined as a porous, combustible core surrounded or saturated with an inflammable solid. Therefore, the primitive man who first selected a highly resinous bit of wood to use as a torch was the original chandler. Among aboriginal races in Africa, oily nuts were burned in saucers of clay, and some more ingenious individuals strung these nuts on twigs, thereby obtaining continuous illumination.

The true candle dates from the days of the Romans. In A.D. 100 Greek and Roman candles were made of flax threads coated with pitch or wax, although the Phoenicians are credited with the first use of wax candles about A.D. 400. The candle was not in as common use as the oil lamp for several centuries, but returned during the middle ages, and the 16th to 18th centuries marked its greatest use. Throughout this period and until the discovery of petroleum, candles provided the only method of artificial illumination available to people of average means. The use of candles has been closely related to religion throughout history, and the supplying of candles appears as a large item in expense accounts of the early church. Various materials have been used in the manufacture of candles, the earliest being rush piths dipped in tallow. Later, splinters of wood, also dipped in tallow or beeswax and called "kindle lights" were used. Home-made candles of Pilgrim days were of tallow. With the opening of the whaling industry in the 18th century, spermaceti, a crystalline substance from the head of the sperm whale, came into use and spermaceti candlemaking was an important industry of the time. The spermaceti candle, because of its clear, steady flame, was used as a standard of measure for artificial light, the term "one candle-power" being based on the light given by a pure spermaceti candle weighing one-sixth pound and burning at the rate of 120 grains an hour. The development of stearine in 1823 and of paraffin in 1850 furnished improved materials for candles.

Candleholders have assumed various forms, much attention being given to more elaborate designs for those holding single candles for portable use, and multiple holders for mounting on walls or suspension from ceilings. In Italy in 1492, the Prickett chandelier was introduced, being a multiple-spiked holder mounted in groups around a decorative figure on the wall. Mutton-fat candles were forced on the spikes. In the 15th century crystal chandeliers equipped with small cups for holding candles of refined wax were used for lighting homes, ballrooms and public gathering places. One hundred twenty of these candles would have been required to equal one 100-watt lamp, and the number required to illuminate a large room produced considerable heat.

As late as 1834 candles in elaborate chandeliers were used for illumination of the house of commons in England, and their replacement by gas was strongly opposed by members. With the advent of gas as an illuminant, use of candles was gradually confined to church ceremonies, decorative domestic purposes and festive occasions.

Gas.—The development of gas as an illuminant provides a striking example of the length of time that elapses before a scientific idea is developed into useful application. Ancient records of Egypt and Persia prove numerous instances of spontaneous discharge of combustible gases from fissures in the earth. That natural gas was employed as an illuminant by the Chinese centuries before the Christian era is shown by records of great antiquity telling of gas brought to the surface from beds of rock salt 1,500 to 1,600 ft. deep, conveyed through bamboo pipes and used for lighting salt mines and homes in Szechwan province.

In 1664, near Wigan, Lancashire, England, Dr. John Clayton discovered a pool of natural gas while draining water from a ditch, and suspected a nearby coal mine as its source. Probably the earliest record of the possibility of extracting inflammable material from coal by distillation was in 1739 when Dr. Clayton published an extract from a letter written to the Hon. Robert Boyle, who died in 1691, describing experiments along this line as satisfactory. In 1726, Dr. Stephen Hales stated in a paper before the Royal Society of London that 158 grams of Newcastle coal would yield 180 cu.in. of "inflammable air," and in 1733 Sir James Lowther sent specimens of distilled coal gas to the Royal society for experimentation.

No attempt was made to use gas for illuminating purposes, however, until 1784 when Jean Pierre Minckelers used it for lighting his lecture room at the University of Louvain. Contemporaneously, in Paris, France, Philippe Lebon experimented with distillation of gas from various materials for domestic use, and in 1799 Lebon patented a "thermo-lampe," using gas distilled from wood.

First use of gas as an illuminating agent on a large scale is ascribed to William Murdoch, a Scotchman, living at Redruth, Cornwall, England. In 1792, Murdoch lighted his home with gas produced in large iron retorts and conveyed a distance of 70 ft. through metal pipes. In 1798 he installed a gaslighting system in the engineering works of Boulton and Watts, Soho, near Birmingham, England, this installation being exhibited to the public in 1802. Shortly thereafter Murdoch was providing gas commercially for several shops in the vicinity, the cotton mill of Phillips and Lee in Manchester and Stonyhurst college.

Public prejudice against the new illuminant, denounced as dangerous and impractical, caused its adoption to be slow. Credit for dispelling this prejudice is given to F. A. Winsor, a German, who worked with great zeal and patience on the improvement of illuminating gas for a number of years. Through his efforts the first public installation of gaslights was made in London in 1807, and the Chartered Gas Light and Coke Co. was founded by him in 1810. For this reason, Winsor is referred to as the "father of gaslighting."

In 1813 Westminster bridge, London, was illuminated by gas, and Paris adopted gas for street lighting in 1818, but by 1829 there were only 40 public gas lamps in that city, while 3,000 oil lamps were still in use. However, within a few years most of the cities in England and Europe had installed gaslighting systems.

The first domestic use of gas in the United States was in 1806, when David Melville, of Newport, R.I., lighted his home and the street directly in front of it with gas generated on the premises. First interior commercial use was in 1816 when gaslights were installed in the New theatre in Philadelphia, Pa.

Between 1820–80, interest centred about purification of gas for obtaining higher illuminating power, and in the improvement of burners. Burners of many types were developed, those of the "batwing" or "fishtail" type, so-called because of their shape, being most commonly used. In 1879 William Sugg developed the Sugg-Argand burner, consisting of perforated concentric metal rings. This burner, designed to compete with the electric lamp in illuminating power, created a light of high intensity with great economy through use of an increased air draught produced by pressure.

Because of increasing interest in electricity as an illuminant during the latter part of the 19th century, much effort was directed toward improvement of gaslighting. Dr. Carl Auer von Welsbach experimented for ten years on production of the Welsbach mantle, considered the most important development in the history of incandescent gaslighting. First public exhibition of the Welsbach system of lighting was in London in Feb. 1887, and by 1900 incandescent gaslighting was permanently established.

The Welsbach mantle consisted of a cylinder woven of Sea Island and Egyptian cotton soaked in a solution of 99% thoria and 1% ceria, this ratio giving maximum illuminating efficiency. The top of the mantle was then soaked in solutions of various other rare earths for shrinking, and after being dried the mantle was ignited, burning out the organic matter and leaving a skeleton of the cotton form composed of metallic oxides. Stiffening for shipping purposes was obtained by dipping in a solution of collodion and camphor. In use the mantle was suspended in a special holder, over a Bunsen burner in which gas and air combined before reaching the point of ignition, so that in place of the ordinary gas flame, the metallic oxides composing the mantle were heated to incandescence, emitting a brilliant light. Experiments made to improve the colour of the light, which had a decided greenish cast, determined that by using varying combinations of rare earths in solution for impregnating the mantles, different colours of light could be obtained.

Bunsen burners of all types, inverted and upright, were used and the mantles were adapted for use with high pressure gas systems, high pressure oil lamps, kerosene lamps and acetylene lamps. Welsbach mantles have continued in use with various types of lamps.

Acetylene Gas.—Edmund Davy, nephew of Sir Humphry Davy, knew of the existence of this gas in 1835, and in 1866 M. P. E. Berthelot, a French chemist, performed experiments in its production, but not until 1892 was its manufacture and use as an illuminant described by Henri Moissan. Simultaneously, in the U.S., Thomas L. Willson discovered the electrochemical production of calcium carbide and demonstrated that acetylene gas obtained by immersion of calcium carbide in water produced an intense white light. A report issued in 1909 indicated that 290 towns in the U.S. were lighted by acetylene gas. Later its use was confined to emergency lighting in remote areas, for military purposes and for lighting buoys and beacons; its advantage for the latter purpose being that an acetylene light can be charged, lighted and then left unattended for six months or more.

Pintsch Gas.—Originally developed for lighting of railroad cars, and named after its inventor Julius Pintsch of Germany, this gas was produced by destructive distillation of petroleum and compressed to facilitate storage and transportation. Used in Europe for many years, it was brought to the U.S. in 1866, and in 1910 there were 93 Pintsch gas works in the U.S., Canada and Mexico supplying compressed gas to nearly 400 railroad stations. It was used extensively on steamships and for lighthouses.

Similar to Pintsch gas were the numerous "bottled gases" developed in subsequent years, and in use under various trade names (1945). These provide illumination in areas where electricity is not available, being used with lamps equipped with the Welsbach type mantles.

By 1911 conversion of gas fixtures for use with electricity had begun. While 50% of the gas manufactured in the U.S. in 1916 was used for lighting, and the Welsbach mantle had so cheapened gaslighting that in cost per unit of illumination it had no competitor, electricity was rapidly replacing gas for general illuminating purposes. However, in England and Europe gas enjoyed wide use for a number of years longer, since in 1926 when Buffalo, N.Y., was making plans to replace all existing gas lamps with electric arc and incandescent lamps for street lighting, the earlier electric street lighting of almost all boulevards and parks in Paris had been replaced by high-pressure gas lamps, automatically lighted and controlled.

Electric Lamps.—In 1650 Otto von Guericke of Magdeburg, Germany, discovered that light was produced by electricity, or by electrical excitation. He demonstrated that when a globe of sulphur was rotated rapidly and friction was produced by pressure of the hand during rotation, a luminous glow could be observed. About 1700 Francis Hawksbee used this discovery, together with a glass globe exhausted by means of a vacuum pump, also invented by Von Guericke, to produce the first "electric light." When the globe was rotated at high speed, then rubbed with the hand, it emitted a faint glow of light.

Following this demonstration, which created much excitement among scientists of England, numerous physicists experimented with production of light by electrical excitation, but without marked success until 1802. In that year Sir Humphry Davy demonstrated that strips of platinum or other metals could be heated to incandescence electrically and would give off light for some time. In 1809, Davy, using a battery of 2,000 cells to pass a current through charcoal terminals, produced the arc light, so called because of the shape of the luminous flame created when an electrical current passed across the gap between the carbon points.

Throughout the 19th century, development of the arc lamp and the incandescent lamp were parallel. In 1840 Sir William Robert Grove demonstrated the Grove system of lighting before the Royal Institution of England, lighting the auditorium in which he lectured with lamps using platinum coils heated to incandescence by means of the Grove battery. The lamps gave only feeble light and the system proved impractical, being complicated and expensive. It has been estimated that cost of the current produced by the Grove battery was several hundred dollars a kilowatt hour.

In 1841 Frederick de Moleyns of Cheltenham, England, obtained the first patent granted for an incandescent lamp. His lamp was unique, consisting of a glass sphere from which the air had been exhausted, and containing powdered charcoal bridging the gap between two platinum wires or filaments. Light was produced by passage of current through the platinum filaments, heating the charcoal to incandescence. However, the globe blackened quickly and the lamp was short-lived.

In 1845 Thomas Wright of London obtained the first patent for an arc lamp, and in the same year an American, J. W. Starr of Cincinnati, Ohio, obtained a British patent for two electric lamps of the incandescent type. Starr invented the first true metallic filament lamp and a magnetoelectric generator with which to produce current for lighting purposes. He died at the age of 25, before he could put his original ideas to practical use.

During the latter part of the 19th century many scientists endeavoured to find a practical method of producing artificial illumination by electricity on a commercial basis, and there are records of occasional use of electric lamps throughout the period. In 1849 a scene in Giacomo Meyerbeer's opera, *Le Prophet,* at the Paris opera house was illuminated by electric light; an old print shows Mons. Ch. de Chagny demonstrating incandescent lighting for collieries, and in 1857 the first commercial installation of an electric arc light was made in the lighthouse at Dungeness, England.

In 1872 Alexandre de Lodyguine, Russian physicist, made a lamp having a V-shaped piece of graphite for a filament, operating in a glass globe filled with nitrogen gas. Two hundred of these lamps were installed about the Admiralty dock, in St. Petersburg (Leningrad), and a company was formed to exploit the lamp but unreliability of operation and cost made it impractical for general use and the company failed. During the following ten years Russian scientists developed various lamps using the same principle, but none was of practical value.

In 1876 Paul Jablochkov, a Russian electrical engineer, announced that within a few months he would introduce an illuminating agent which would entirely supersede gas, the popular illuminant of that period; and in 1876 the "Jablochkov candle" marked an epoch in artificial illumination toward which the previous 30 years of laboratory experiment had led. The Jablochkov candle was an arc lamp having parallel carbon rods separated by a thin wall of clay, or a mixture of sand and glass, which vaporized during burning of the arc. Alternating current was used to ensure equal rates of consumption of the two points of the rods. This lamp was widely used commercially, first public demonstration being given at the Paris exposition in 1878, and it was used for lighting the boulevards of Paris for a number of years.

First installation of arc lamps for public lighting in the U.S.

was in 1879 when the public square in Cleveland, Ohio, was lighted by 12 Brush carbon arc lamps, the system developed by Charles F. Brush.

Before the Edison incandescent carbon filament lamp was patented in 1880, numerous scientists directed their efforts toward production of a satisfactory incandescent lighting system, outstanding among them being Sir Joseph Wilson Swan, English physicist. In 1850 Swan had devised carbon filaments of paper; later he used cotton thread treated with sulphuric acid and mounted in glass vacuum bulbs. Utilizing this lamp, called the "electric glow lamp" he gave the first public exhibition of electric lighting on a large scale at Newcastle, England, in 1880.

A demand for a smaller electric lamp for domestic purposes, and operating with greater efficiency than any produced to that time, led to consideration of the problem of "subdividing the electric light." Outstanding work was done in the U.S. by Moses G. Farmer, Hiram S. Maxim and William E. Sawyer.

Final development of the incandescent lamp was the result of concurrent work by Joseph Swan and Thomas A. Edison. Edison had recognized early in his experiments along this line that improved methods of distribution of electricity were necessary before the incandescent lamp could be generally adopted for commercial use, and much of his effort was directed to that end. However, in 1878 he established a well-equipped laboratory at Menlo Park, N.J., and after much experimentation produced the first satisfactory incandescent lamp. This lamp consisted of a high-resistance carbon filament operating in a vacuum, having platinum wires imbedded in the glass for carrying the current through the glass to the filament. He obtained a patent on this lamp in Jan. 1880, after having given a public demonstration of his first complete incandescent lighting system at Menlo Park on Dec. 21, 1879.

First commercial installation of Edison's lamp was made in May 1880, on a steamship operated by the Oregon Railway and Navigation company. This installation, consisting of 115 lamps, was operated successfully for 15 years.

The arrival of the incandescent electric light, from an industrial standpoint, may be said to date from the year 1881. In 1882 the Pearl St. station in New York city was put into service, and is considered the forerunner of the great central stations subsequently developed. In England, in 1882 an exhibition of electric lighting was held at the Crystal palace and by this time incandescent lamps had been installed in numerous public buildings.

When the incandescent lamp was introduced as a public illuminant, fear was expressed that it might be injurious to the eyesight, particularly when used for long periods by indoor workers. In 1898 the oculists of London petitioned parliament to pass laws against the use of unshaded lights, claiming danger to the eyes from exposure to high intensity lights in shops, offices and on the street. As a result research was instituted on various types of shades and reflectors. One of the earliest reflectors used commercially was the one-piece silvered glass reflector developed by E. L. Haines, and installed in show windows in Chicago, Ill., and other cities in the U.S.

Closely related to the incandescent gas mantle and suggested by it, was the Nernst glower, unique among illuminants of its time as the first practical attempt to substitute some other incandescent substance for carbon filaments. Patented in 1901 by H. W. Nernst of Germany, it utilized a filament composed of oxides of rare earths heated to incandescence by passage of electrical current. Mixtures of two or more oxides were found to be most satisfactory, and in 1905 the commercial Nernst glower consisted of 85% zirconia and 15% vitria. The Nernst lamp did not achieve wide use, but investigations carried out to improve this lamp had considerable effect on the development of the incandescent lamp.

Werner von Bolton discovered the possibility of using tantalum for lamp filaments about 1902, and in 1906 the tantalum lamp was put on the market in the U.S., but disappeared from use about 1913.

In 1904 Willis R. Whitney of Schenectady, N.Y., produced the heat-treated or metallized carbon filament lamp, with a higher degree of efficiency than any previous incandescent lamp. This was the last new development to make use of the carbon filament, for work had begun on the application of tungsten for lighting purposes.

From the beginning of the development of the incandescent lamp, scientists were concerned with the problem of the conversion of electrical energy into light in the most efficient manner possible, and with the discovery of tungsten as a material for filaments this seemed to have been achieved. The tungsten filament lamp represented the greatest advancement ever made in the quality and efficiency of incandescent lighting, and quickly replaced carbon, tantalum and metallized carbon filaments for commercial use.

First tungsten filament lamps, introduced in the U.S. in 1907, made use of "pressed" tungsten, manufactured by a process perfected by Alexander Just and Franz Hanaman of Vienna. William D. Coolidge of Schenectady, N.Y., discovered a process for producing drawn tungsten filaments, greatly improving the strength of tungsten lamps. This process was patented in 1913 and lamps of this type were immediately adopted for general use.

Tungsten filament lamps were developed in a variety of sizes and shapes, for domestic and commercial use and for some highly specialized purposes. In 1935 they were available in shapes varying from the common pear-shaped or round bulb type to tubular forms several feet long. A very small lamp, known as the "grain o' wheat" lamp, having a bulb only 2 mm. in diameter and 8.7 mm. long, became valuable to the medical profession, providing a light source for internal investigation and surgical work. Other lamps as large as 10,000 watts were being used in 1937 for airport lighting and in the motion picture industry. The largest incandescent lamp built up to 1945 was a 50,000 watt lamp for display purposes which found some use in a special application.

In 1913 Irving Langmuir discovered that use of inert gases inside the incandescent lamp bulb would permit higher filament temperature without rapid disintegration, with increased efficiency. Nitrogen alone was first used, but research determined that other gases were more satisfactory, and in 1937 gas-filled lamps contained an atmosphere of 80% argon and 20% nitrogen. Low first cost, ease of maintenance and adaptability gave this lamp such importance in the lighting field that other incandescent lamps practically disappeared. A further improvement introduced in 1937 was the coiled-coil type of filament for general service lamps, adopted by most manufacturers and by 1945 the gas-filled coiled-coil filament lamp was the most efficient incandescent lamp in use.

The history of the incandescent lamp between 1920 and 1935 was also concerned with improving the quality of lighting, including introduction of inside frosted bulbs and bulbs of various colours for domestic purposes. Development of lighting from concealed sources, or "indirect lighting" made rapid strides, increasing the level and quality of illumination in homes, schools and offices.

Electric Discharge Lamps.—At the beginning of the 20th century interest became centred in artificial illumination by means of gaseous conductor lamps, later called "electric discharge" lamps. Early research in the field was done by Heinrich Geissler, German physicist, about 1850, who invented the Geissler tube by means of which was demonstrated the phenomenon of luminosity accompanying the discharge of electricity through rarified gases. In 1887, Geissler tubes were used largely for laboratory demonstrations, but in 1897 tubes of various colours were used successfully for a display commemorating the Diamond Jubilee of Queen Victoria of England. This use of Geissler tubes was made possible through the discovery, by John W. S. Rayleigh and Sir William Ramsay, of the rare gases argon, neon, xenon and krypton, in 1895. Argon had been discovered originally by Henry Cavendish in 1785, but was not recognized as having any practical value until the experiments by Rayleigh and Ramsay.

The Moore tube, developed by D. McFarlan Moore, between 1891 and 1904, along the principle of the Geissler tube, made use of nitrogen and carbon dioxide. Nitrogen was found to produce a yellow light, while carbon dioxide gas furnished light of a pinkish-white colour, closely approximating daylight, making this light invaluable for colour matching. It was for this purpose that Moore tube lights were most widely used. First commercial installation was made in a store in Newark, N.J., in 1904. Principal objections to the Moore tube for general lighting purposes were difficulty of installation and repair, and the complicated valve mechanism required to maintain the gas in the tube at the correct pressure.

The mercury vapour lamp, originated by L. Arons of Germany, in 1892, was not manufactured on a commercial basis until taken over by the Cooper-Hewitt Co. Peter Cooper-Hewitt introduced the mercury arc lamp in 1901, its efficiency proving to be two or three times that of the contemporary incandescent lamp. Chief limitation to its use was the peculiar spectral quality, caused by concentration of the light rays produced in three restricted regions of the spectrum, and the complete absence of red. Research designed to improve this by introduction of other gases into the tube failed to produce satisfactory results until Cooper-Hewitt devised a fluorescent screen which converted some of the excess of blue and green light and a little of the yellow into red, thereby materially improving the colour. First practical installation of the Cooper-Hewitt lamp was in the composing room of the New York *Evening Post* in 1903. Creating a shadow-free light, without glare, the lamp was immediately given wide use for industrial lighting in the U.S. In Europe in 1937 use of the mercury arc lamp was about equally divided between interior and street lighting.

Cooper-Hewitt also developed the quartz tube mercury lamp, used extensively in biological research. A later form of the quartz tube lamp, based on research carried on in the laboratories of the Phillips company in Eindhoven, Neth., led to exploitation in Europe of a small water-cooled or capillary type of mercury arc lamp, developed in 1935. Subsequently the U.S. type of this lamp was used primarily for photographic work and for searchlights.

Research had been continuous in the use of rare gases for illumination purposes. In 1910 Georges Claude experimented with electric discharge tubes containing neon, argon, helium, krypton and xenon and within a decade the neon sign industry had developed. The novel effects obtainable with neon tubes gave them wide use for advertising purposes, their extreme adaptability, high luminosity and brilliant colours making them particularly suitable in this field. Efficiency of light production by use of neon tubes was too low for general illumination, and none of the colours was satisfactory for interior lighting.

During 1933 the most promising source of illumination among electric discharge lamps was the high intensity sodium vapour lamp. Not satisfactory for commercial or domestic use because of characteristic yellow colour, reports from an experimental installation of sodium vapour lamps along a highway in the Netherlands were very favourable. Subsequent major applications were for highway lighting and general outdoor lighting where colour discrimination was not required; and by 1945 sodium vapour lamps were being used for highway lighting and illumination of bridges and vehicular tunnels all over the world.

In 1936 the fluorescent lamp was in process of development. Offering a highly efficient low power source in various colours, the fluorescent lamp afforded the nearest approach to "cold light" ever devised in practical form. Fluorescent lighting differed from incandescent lighting in that the light was produced not by heating a tungsten filament to incandescence, but by fluorescence of certain chemicals under radiation of ultra-violet light. The fluorescent lamp in 1936 consisted of a low pressure mercury arc of about 15 watts, enclosed in a glass tube, the inside of which was coated with mineral salts (phosphors) having fluorescent qualities. The efficiency and colour of the light were determined by the particular salt used. Practical application of the fluorescent lamp on a large scale in 1938 marked a major development in the field of artificial illumination. Until that time fluorescent lighting had been the object of laboratory experiment, but in 1939 numerous permanent installations of fluorescent lighting were made and general lighting by these lamps was completed in two large factories in the U.S. In that year also, fluorescent lighting was an integral part of the decorative scheme of the New York world's fair.

During the ensuing six years research designed to improve fluorescent sources was carried on extensively, and low and high voltage fluorescent lighting found many new applications in interior lighting and luminous decorative design. Fluorescent light was gradually adopted for industrial lighting, for store lighting and for show windows, but not until 1942 was it used to any extent for home lighting, although many specialized applications had been made. In 1944, experimental installations of fluorescent lamps for street lighting were made, but they were not in general use for that purpose. The period of World War II found fluorescent lighting being adopted for many specialized uses, for naval and military purposes, aviation lighting, railway lighting and for increasing use in the industrial field.

World-wide interest in artificial illumination gathered momentum with the beginning of the 20th century. Great expositions held in many parts of the world featured spectacular lighting using the latest developments. "Festivals of Light" were held in many cities, and in 1937 Sweden celebrated the tenth anniversary of its "Association for the Culture of Light" with an electric week.

Wide-spread interest was shown in the psychological and physiological aspects of higher levels of illumination as related to human welfare, one evidence of this being the adoption in 1937 of a factories bill in England containing provisions for compulsory adoption of standards of lighting in all factories and workshops.

Artificial illumination has been accepted as an architectural medium, and lighting is no longer a thing of utility alone, but an intrinsic part of the architectural design of buildings. Specialized types of lighting for various industrial, agricultural and domestic fields have been investigated and adopted.

Street Lighting.—Street lighting during the ancient Egyptian civilization was more advanced than during any subsequent period until A.D. 1500. In A.D. 400 Antioch in Syria was lighted at night by lamps suspended on ropes, this being the first recorded attempt at organized street lighting. However, it is not probable that streets of that period were generally lighted since the Romans considered the use of flambeaux and lanterns necessary for travelling through the cities at night, as shown in numerous early writings.

Compulsory street lighting came into effect as early as 1367, when Charles V ordered the placing of lamps at stated intervals in the streets of Paris for crime prevention. In 1415 Sir Henry Burton, lord mayor of London, ordered all householders to hang out lanterns on winter evenings between All Hallows and Candlemas, this practice being followed for 300 years in London.

Street lights of this early period were oil-burning lamps, torches fastened in holders to outside walls of houses, or open wire or iron baskets containing pieces of burning wood. This latter form was used in Paris as late as 1729, when there were nearly 6,000 lanterns of this type in use. In the United States during this period street lighting was accomplished by placing candles in house windows, but in 1769 a law was passed in New York compelling householders to display a lantern outside every seventh house, thereby illuminating the street.

In 1662 the first commercial street lighting enterprise was enfranchised in Paris, consisting of a corps of public lantern bearers, who for a small fee would accompany wayfarers to their homes. In 1694 Edward Heming, in London, obtained the exclusive rights for placing lights outside every tenth door, for a modest remuneration from houseowners, who were required by law to provide lighting for the streets. However, in 1735, contracting for street lighting was taken out of private hands and passed into the jurisdiction of the common council, and a small tax was levied to cover the cost.

Oil lamps for street lighting came into use in London in 1736, and about the same time in Paris. In 1745 a marked improvement was introduced by the addition of polished metal reflectors, called *reverbere.* Oil lamps equipped with these reflectors created a brilliant light found objectionable by many citizens, and in 1736 further improvement was made by a modified form of reflector considered highly satisfactory, and adopted for general use throughout Paris. General highway lighting was introduced for the first time with the use of these lamps along the road from Paris to Versailles in 1777. Lamps of this type remained in use in France until replaced by public gaslighting.

In 1762, wooden lamp posts supporting oil lamps provided the first municipal street lighting system installed in New York city, and street lighting as a public service was not installed in Boston, Mass., until 1792. By the end of the 18th century, although most cities of England and Europe had adopted general street lighting systems, very few U.S. cities were lighted by more than candles or oil lamps placed in house windows, and in small towns the streets remained unlighted until the advent of kerosene lighting.

First public street lighting by gas was in 1807, when one side of Pall Mall in London was illuminated by clusters of gas lamps, and in 1813 Westminster bridge was also lighted by gas. Paris adopted gas for street lighting in 1818, Berlin in 1827 and other European cities followed in quick succession.

Baltimore, Md., in 1821, was the first city in the U.S. to adopt gas for street lighting. In 1827 gas conveyed through mains made of wooden logs supplied the first public system of gaslighting for New York city, and by 1836 gas was in general use for public lighting in the larger cities throughout the U.S. With the development of high pressure gas in 1897, improved systems of gaslighting came into general use.

Development of the electric arc lamp in 1878 gave impetus to street lighting, about two-thirds of a mile of the Avenue de L'Opéra being lighted by Jablochkov candles, an early form of the arc lamp, during the universal exhibition in Paris in that year. First public street lighting by arc lamps was introduced in Cleveland, Ohio, in 1879, and the arc lamp in its various forms held first place for public street lighting until well into the 20th century. Incandescent lamps were given limited use for street lighting throughout their development, the first incandescent lamp to achieve use in this field being the gas-filled lamp with coiled tungsten filament, in 1915.

Increased use of the automobile, about 1920, with attendant higher traffic speeds on highways and congested traffic conditions in cities, brought a demand for higher levels of illumination for streets and highways. More improvements in street lighting were reported during 1922 than during any previous year of electric lighting. While gas lamps were still in use in many U.S. cities, and some installations of gas street lighting were made during that year, electric lighting for streets and highways was receiving much attention in an effort to reduce traffic accidents. Lighting from electric signs and store windows contributed largely to general illumination in the business district, but outlying districts were felt to be inadequately lighted.

Development of electric discharge lamps provided highly satisfactory sources of light for street and highway illumination. Sodium vapour lamps were widely adopted for this use, although in 1928 Great Britain reported that combinations of mercury vapour and incandescent lamps were being used for lighting from 600 to 700 miles of highways and streets in that country. By that year New Jersey had taken the lead in the U.S. with 220 miles of lighting on state highways, a 56-mile installation of highway lighting in that state being at that time the longest lighted highway in the world.

MODERN LIGHT SOURCES

Nonelectrical

Candles.—The modern candle is usually produced by moulding, and may be composed of stearine, wax, spermaceti or paraffin. The wick is a cotton yarn either plaited or braided and treated with mineral salt. Candles are used for festive occasions, decoration and in places where other portable lights are not available. The modern candle is completely consumed without objectionable odour or smoking, and burns uniformly.

Kerosene.—The kerosene lamp with reservoir, a perforated metal chimney holder which admits a supply of air and a chimney of glass has not deviated markedly from the improved types suggested by Argand. Kerosene is available in most parts of the world and the kerosene lamp is widely used in regions lacking modern gas or electrical facilities.

Gas.—Gas used for illumination may be of three types: natural; manufactured and distributed from a central plant; or "bottled gas" delivered to the premises in containers. Although acetylene gas may be delivered in drums it is more frequently generated at the lamp by chemical action. The burner used with the acetylene gas lamp is usually of the "fishtail" flat flame type, and the acetylene lamp is used by miners and as navigation markers.

To reach a maximum of efficiency with any gaslighting equipment and to give a light comparable with incandescent and fluorescent lighting, some form of Welsbach burner must be used. This burner is used in both the portable and stationary forms of gaslight source.

Electrical

Arc Lamps.—The atmospheric arc lamp, which at one time ranked as the most important electric light source, lost its importance with the movement to "subdivide the electric light." Its present value (1945) lies in the concentration of the light and the intensity of the light source. It is used in large-wattage units for searchlights and for projection, and where a special need exists for the blue and ultra-violet portion of the spectrum. When desired the colour of the arc light may be controlled by use of various materials in the electrodes.

Arc lamps may be classified as: (1) carbon arcs, using pure carbon electrodes and producing light by the incandescence of the electrode; (2) flame arcs, using mineralized carbon electrodes and producing the light from a luminous arc with some incandescence at the electrode ends; (3) magnetite and luminous arcs, using metallic electrodes and producing light from a luminous arc into which are conducted light-giving elements from the cathode. With the exception of the last group, arc lamps have been developed for both D.C. and A.C. operation.

Arc lamps operating at atmospheric pressure are essentially constant current lamps and when operated in parallel it is necessary to control the flow of current by a ballast. Arcs will not start with the applied voltage at which they will operate, because they have a negative volt ampere characteristic. Arc lamps must be equipped with automatic mechanisms for starting the arc and adjusting the electrodes. The maximum brightness obtained in an arc lamp depends upon the size of the carbons and operation of the arc more than upon the nature of the carbon. The carbon arc lamp operates at an efficiency of from 40 to 65 lumens per w., and the brightness varies from 160 candles per sq.mm. to 1,200 candles per sq.mm. The objectionable noise and unsteady operation of the earlier types have been overcome in the modern arc lamp. Special arc electrodes and construction are used for wavelength standard measurements, and the line at the red end (6432.5696 angstroms) of the cadmium arc has been so accurately measured that the standard of length could be reproduced by using this wave length as a base.

The flame arc is little used in the U.S. and the metallic arc has been largely replaced by the incandescent lamp for street lighting. Street lighting practice in the U.S. employs the series arc, while in European practice the multiple system is preferred.

For military use the carbon arc has proved more satisfactory than other types of light sources. Since the arc approaches a point source of light, it works well with precision optical systems. In the searchlight and projection field, ranges of from 20 amp. at 55 volts (1,100 w.) for 10-mm. carbons to 200 amp. at 90 volts (18,000 w.) for 16-mm. carbons are used. These D.C. arcs give most of their light from a very hot positive crater.

Incandescent Lamps.—Edison's contribution to the art of incandescent lamp making was a carbon filament of such a length and diameter as to produce a lamp of 100 w. with a life of 600 hrs. and efficient enough in light production to compete with the existing flame sources, when placed across a 110-v. circuit. This lamp produced 1.8 lumens per w.; the comparable incandescent lamp with improvements to 1945 had an equivalent of 16.5 lumens per w.

Losses.—Losses in the incandescent lamp are caused by: (1) inadequate filament efficiency control: (2) heat conduction by leads and supports; (3) voltage loss in the leads; (4) light absorption by the glass and the base; and (5) bulb blackening. The lamp engineer recognizes that higher temperature filaments will produce a more satisfactory light quality and a more efficient lamp; therefore, progress has been marked by increased filament temperatures. Drawn tungsten wire, because of its favourable radiating characteristics, lower vapour pressure, high melting point, high tensile strength and ductility has become the preferred material for lamp filaments. This metal seems to be available in sufficient quantity for all lighting needs since filaments for 75,000 40-w. or 1,000 500-w., 115-v. lamps can be made from one pound. No known substance exists with the efficiency of tungsten for converting electrical energy into light with no reservations as to cost, manufacturing difficulties or other considerations. The introduction of machines into the manufacture of incandescent lamps aided in the production of a superior, uniform lamp at a nominal cost, and high quality of the lamp is maintained by rigid specifications and tests.

Gas-filled and Vacuum Incandescent Lamps.—Air is exhausted from the lamps to eliminate oxygen, thereby preventing filament vapourization. Air seepage into an incandescent lamp causes rapid deterioration of the filament and whitening of the bulb.

Attempts to introduce inert gases into the carbon lamp for increasing filament temperatures failed because the resultant losses by conduction neutralized filament temperature gains.

The first major improvement of the tungsten lamp was the introduction of an inert gas into the bulb. Nitrogen was first used because the rarer gases were too expensive to obtain; however, by improved processes enough argon is now available so that the atmosphere surrounding the filament is composed of 80% argon and 20% nitrogen. Krypton has better characteristics than argon, but its cost offsets any gains from its use. Because the gas used must be very pure and free from moisture, "getters" are used for removing harmful gases and water vapour.

Higher lamp efficiency can be obtained by increasing the size of the filament, because the protective sheath of gas which reduces loss depends upon filament size. Coiling the filament increased the efficiency of the 500-w., gas-filled lamp by 40% as compared with the same size straight filament vacuum lamp.

The next step in reducing filament loss was an apparent increase in filament size produced by winding the coiled filament around a mandrel, forming the coiled-coil filament with an additional 10% to 15% increase in efficiency.

End Losses.—Materials used for lead-ins and supports have been improved and the number of supports has been reduced until end losses from these sources have been reduced to about 2%. Elimination of a support increases the efficiency approximately 0.5%. In the 40-w. lamp, supports have been reduced from 11 in the vacuum tungsten lamp to 3 in the gas-filled lamp.

Lamp Blackening.—A certain amount of blackening inside the bulb is inevitable and is removed in some of the high-intensity short-life lamps by sealing coarse tungsten powder inside the bulb, for scouring the inside surface at intervals, increasing both the light output and useful life of the lamp. In the bipost lamp the vapourized tungsten is removed by passing the hot gases carrying the vapour from the filament through a screen above the filament.

Mechanical Features.—The incandescent lamp is an assemblage of a mount, a base and a glass bulb. Lamps of 40-w. or larger contain gas, which permits higher temperature of the filaments. The usual mixture of gas is argon and nitrogen, but in special types krypton or hydrogen are used. The complete mount consists of: (1) the stem which carries the molybdenum support wires held in a glass button at the end of the stem; (2) the exhaust tube; (3) lead-in wires with a nickel-iron core and a copper sleeve used in the press because they have the same coefficient of expansion as glass, and of copper to the base and nickel to the filament; and (4) the tungsten filament. In some of the larger sizes a mica disk on the stem protects the socket from the filament heat when the lamp is burned base up. The base is used for the connection to the electrical circuit. To protect the line fuse or to open when the filament arcs there is a small fuse just outside the stem press on the mount.

The filaments are supported in many ways for various types of duty. The filament form determines the position in which the lamp may be burned and its resistance to vibration. The filament form also controls the incandescent plane important in projector service. The base of the lamps adapts it to the holder of the equipment, and is cemented except where current requirements would produce an excessive heat, when the fastening is by mechanical means. When the screw lacks carrying capacity in large lamps, it is replaced by the bipost base which forms a pin-type positive connection. Where accurate location is essential prefocus bases are used so that in an optical system lamps may be interchanged with the filament remaining in the same plane. Bayonet, disk and pin bases are used on smaller types and tubular lamps.

Eight shapes of lamps were offered in 1945 to the trade in the U.S. because of production controls, many more being available on the European market. In the U.S. 20 principal types of lamps consume 95% of the electrical energy used in lighting. The remaining 5% embodied the same principles but were manufactured for special services.

Spectral Quality of the Incandescent Lamp.—The light emitted from the incandescent lamp is deficient in blue radiation and very strong in the red, the exact distribution depending on filament temperature which in turn is influenced by lamp size. If additional radiation is desired in the blue region, lamps are overvoltaged resulting in shorter lamp life. The enclosing bulb influences the spectral distribution, the "daylight" lamp using a blue bulb for correcting this region, which lowers lamp efficiency because of the light absorbed by the filter.

Other Factors Affecting Light Output.—The frequency of the system supplying the incandescent lamp will influence its output. A lamp filament varies as the current decreases from maximum to zero. This is noticeable in the lower frequencies, and is present to some extent in the 60-cycle system, although invisible to the unaided eye. The larger the lamp, the more "carry-over" there will be. A 40-w. lamp has 14% variation at 60-cycles, while a 500-w. lamp has only 4% and the same sizes range from 23% to 12% with 25 cycles. Flicker in lighting will be noticed if a 3% change of voltage is applied for a two-cycle duration.

Lamps should be operated at rated voltage, for instance, a 10% increase of voltage causes a consumption of 117% watts, gives 136% lumen output, 350% lamp cost per 1,000 hr. and a lumen-hour cost of light equivalent to 100.5%, while a 10% decrease of voltage causes an 85% wattage consumption, gives 70% lumens, 24% lamp cost per 1,000 hr. and a 113.9% lumen-hour cost of light. The selection of 1,000 hr. for a lamp life is determined by a balance between lamp cost, power cost, cost of maintenance and overhead.

As the temperature of the filament was increased, lamp brightness also increased so that besides using special equipment for light control, the bulb of the lamp was given special treatment. Enamelling processes first used for this were inefficient, and increased the collection of dirt. The most successful treatment is an inside frosting. The outside treatment absorbed 5% to 20% of the light, while inside frosting absorbs approximately 1%. There is a secondary gain in that the lamp bulb is strengthened by the process.

Gaseous Vapour Lamps

Low-pressure Mercury Vapour Lamps.—The Cooper-Hewitt source was the first of the commercial low-pressure lamps. These have been built in 200 to 1,600-w. sizes using mercury gas, at 1 to 2 mm. pressure, and a mercury cathode, giving a relatively cool light (200° to 250° C.). The tubes have a rated life of 4,000 hr., which advantage is offset by the poor colour characteristics. The tube will operate on either A.C. or D.C. current but in each instance special means must be used for starting, this being part of the auxiliary equipment. The volt-ampere characteristics of the mercury arc are such that within certain limits the voltage is approximately constant throughout a range of current variation.

The modern lamp is 50 in. long, consumes 250 watts, which has been pushed from 18 lumens per w. to 24 lumens per w., has a brightness of 0.031 candles per mm. and a pressure of 0.0003 atmospheres.

Cooper-Hewitt 85-w. Fluorescent Lamp.—The advent of the use of fluorescent materials suggested the possibility of applying phosphors to the principles developed in the low-pressure tube. On a competitive basis the new lamp offered had a life of 3,000 hr., was rated at 85-w., delivered 4,000 lumens, which is 47 lumens per w., and operated on a full-wave rectifier with a power factor of 85% for the complete auxiliary. As it operates on D.C. there is no stroboscopic effect.

Low-pressure Mercury Vapour, Incandescent Lamps Combination.—Much experimental work has been done in an effort to correct the poor colour quality of the mercury arc. The combination of Cooper-Hewitt tubes with incandescent lamps was an additive method of colour correction. Although this correction did not produce a colour matching light, it did produce a soft white light which for a time found favour in commercial and industrial fields. For adaption to desired luminaire design, tubes were produced in straight, round and square form with a possibility of obtaining "U" and "M" tubes. Most pleasing results were obtained by combinations of 2-w. of incandescence with 1-w. of mercury, giving a lumen ratio of 2.5 lumens to 1 lumen respectively. The development of the fluorescent lamp with its excellent colour of light-control possibilities superseded this more complex and expensive means of producing a pleasing colour quality in lighting.

High-Pressure Mercury Vapour Lamps.—The radiation from a mercury arc changes with pressure, and ranges of pressure from 30 atmospheres to about 280 atmospheres have been investigated. At high pressures the spectral lines of mercury radiation are no longer sharp but are broadened, giving a background radiation. This broadening is greater toward the red end of the spectrum, which improves the light quality with respect to colour, although it still does not give a balanced spectrum.

One disadvantage of this source is that it requires a starting time ranging from minutes in the ordinary type to seconds in one special 1,000-w. unit, and any interruption requires a repetition of the starting cycle. Although efficient in itself, the unit is usually used in combination with incandescent lighting to (1) ensure continuity of light, and (2) to correct the colour of the light source by additive means. The combination should be made on a lumen-to-lumen basis between the high-pressure mercury lamp and the incandescent lamp.

Table I gives the characteristics of the general high-pressure mercury lamps, which besides being used for general lighting have many special applications.

The 1,000-w. lamp with its quartz lamp enclosed in a water jacket is one of the brightest compact lighting units offered. It is a relatively cool light because the heat is conveyed away by the circulating water. The initial lumens are 65,000 or 65 lumens per w., the rated life, 75 hr. It requires 4 sec. for starting and 2 sec. for a restart, and operates at 110 atmospheres with a brightness of 300 candles per sq.mm.

Other Gaseous Vapour Discharge Lamps.—The sodium vapour lamp, built in 300- to 500-w. sizes, gives efficiencies of 50 to 70 lumens per watt. The discharge gives a warm yellow light with almost monochromatic radiation. Because of this colour characteristic the lamps are not suitable for home or commercial use, but may be adapted for some industrial installations. When used for highway lighting they are both successful and economical.

High-Voltage Neon Lamps.—The neon lamp bulb is associated with the cold cathode group, with the luminescence produced by an electrical discharge through gases. They are efficient when of considerable length and have a rated life of 3,000 hr. Neon tubes contain a high percentage of neon gas, giving the characteristic orange-red colour; to obtain other colours mercury, argon, carbon dioxide and xenon are used, and coloured glass tubes are used in conjunction with the gases. The voltages range from 8,000 to 12,000 volts. The operation of the high-voltage cold-cathode and the high-voltage hot-cathode fluorescent lamp is the same except at the cathodes, where the cold-cathode lamp has the higher voltage loss. Actually, the hot-cathode lamp is cooler even though the filament is present.

Prior to the introduction of the fluorescent coating, sign tubing had little application for illumination purposes, its low lumen output being used to create luminous patterns. With fluorescent coating, and depending on diameter, current rating and length, 20 to 30 lumens per w. are obtainable. The units are from 4 to 10 ft. long and are connected in series to operate from 1,000 to 15,000-v. transformers. By 1945 there was a definite competition from sign manufacturers for some of the interior lighting business, and claims of 10,000 hours of operation have been made. (*See* Table II.)

TABLE I.—*General Lighting High-pressure Mercury Vapour Lamps Characteristics*

Watts	Lumens at 100 hr.	Lumens per watt*	Rated life (hr.)	Starting time (min.)	Restart time (min.)	Pressure atmospheres	Brightness c./sq.mm.
100	3,000	30	1,000	3	3	8	9
250	10,000	40	2,000	4	4	4	4
400	16,000	40	3,000	7	7	1.2	1.4
3,000	120,000	40	2,000	7	8	0.7	0.29

*Efficiency of the lamp only. To compare with incandescent lamp it is necessary to reduce the lumens per watt because of transformer loss, approximately 20%.

Fluorescent Lamps

Low-voltage, Low-pressure, Hot-cathode, Mercury Vapour Fluorescent Lamps.—These lamps are designated as "fluorescent lamps." The fluorescent lamp is a glass tube coated on the inside with a phosphor (fluorescent powder) and filled with mercury vapour, with a trace of argon to facilitate starting. After starting, the current is carried essentially by the mercury vapour. The design adjustment is such that the desired resonant radiation of mercury at 2,537 angstroms is produced. Small coils of tungsten wire (electrodes) are sealed into each end and these filaments are

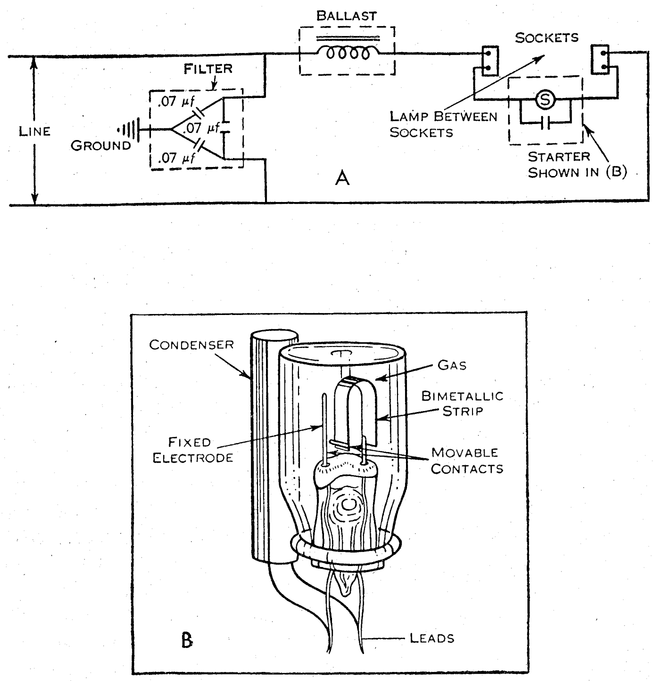

FIG. 2.—(A) FLUORESCENT LAMP CIRCUIT WITH FEEDBACK FILTER

The socket holds the lamp, the ballast (a coil of wire wound on an iron core) furnishes the *inductive kick* to start the arc and limits the flow of current through the arc; the filter reduces feedback into the electric supply circuit which may cause radio interference. (B) Internal Elements of the Glow-switch Starter.—The bulb is filled with neon, helium or argon gas and has a fixed electrode and a movable contact. At starting, the voltage is high across the glow switch and the glow heats the switch elements causing the switch to close. The lamp cathodes are now placed in the circuit and are heating. When the glow switch opens, the mercury vapour will be ready for the arc. The glow switch opens when it has cooled, which follows the shorting of the glow at closing, which removes the heating source. On opening there is an *inductive kick* from the energy stored in the ballast striking an arc. During the operation of the lamp the voltage across the glow switch is too low to cause a glow, therefore, the switch stays open until the lamp is turned off. In the "no-blink" type of auxiliary a thermal switch keeps the glow starter from operating when a faulty lamp develops

coated with an active electron emissive material. The lamp is essentially a discharge lamp with a negative volt-ampere characteristic, and requires ballast equipment.

The ultra-violet radiated from the conducting mercury gas energizes the phosphor which radiates light in the visible region. Different mixtures of the powders forming the phosphors control the colour of the emitted light. Some modifications with coloured glass must be made to obtain the ranges of colour desired. In the 40-w. fluorescent lamp approximately 1% of the radiation in the visible region is delivered by the mercury vapour, the total 22.5% converted into visible radiation being more than three times the radiation from the 40-w. incandescent lamp, which delivers only 7% of its wattage in the visible region.

Operation.—The operation of the fluorescent lamp requires two switches, one for normal switching as in the incandescent lamp and the other for closing the circuit on the cathodes for an instant, allowing the cathodes to preheat, then opening, producing an inductive voltage which causes the arc to strike (fig. 2b). The choke or ballast (fig. 2a) limits the current flow when the lamp is operating. Circuits have been designed for the elimination of this switch, always a source of operating trouble. For the higher voltage hot-cathode lamps and for cold-cathode types, no switch is needed.

The fluorescent lamp has a high efficiency but introduces several operating characteristics which produce a lighting installation less simple in theory and functioning than the incandescent lamp. Complications caused by necessary auxiliary equipment are reflected in the reliability of the lighting system.

Characteristics.—Diameter and length of the fluorescent lamp depend upon several factors. Design has been centred about 1-in. and $1\frac{1}{2}$-in. tubes for the lower voltages, and the $\frac{3}{4}$-in. tube for the higher voltages. The fluorescent lamp is more critical to both voltage and surrounding temperature than the incandescent lamp. The operating voltage divides between the electrode drop (12 to 18 volts) and the voltage gradient, which is the voltage per in. of tube required to neutralize the ions at the walls, plus the conversion of the energy into radiation. The starting voltage is about four times the operating voltage.

When a single lamp is being used, the stroboscopic effect caused by the lamp being extinguished twice during each cycle is annoying in some operations. This may be eliminated by using two lamps in the same luminaire, with the circuit so arranged that the lamps do not extinguish at the same time. This effect is different from "swirling," a type of lamp flicker which is also annoying. The swirl may appear in a new lamp or at any time in its life and may disappear as suddenly as it occurred.

The fluorescent lamp can be the cause of radio interference either from direct radiation, radiation from the electric supply or from feedback from the line. Proper filtering will eliminate the last two causes, while removal of the radio from the field or proper screening will eliminate the first (fig. 2a).

Failure of the lamp to function properly may lie within the lamp itself, in the auxiliary or the switch. The safest rule to follow in correcting the fault is to eliminate by replacement with spare parts which should be available, in the order of switch, lamp, then ballast; but under no circumstances should the lamp be left in operation if trouble develops.

Economic Consideration.—Economic consideration of the fluorescent lamp requires a very close study of cost of both equipment and power. The first cost of the fluorescent lamp is relatively high as compared with the incandescent lamp, while its operation cost is relatively low. Replacement of small wattage incandescent lamps by fluorescent lamps of the same wattage will give 3.5 times more light, and replacement of an incandescent lighting system by a fluorescent system of equal quality will give about twice as many lumens per watt. However, the simplicity of operation and maintenance of the incandescent system must be considered.

Since fluorescent lighting systems create less heat, they are valuable in conjunction with modern air-conditioning systems and they are also of great usefulness where colour-matching, or coloured lighting is required.

Because of the various ways in which efficiencies may be stated, many claims have been made concerning fluorescent lamps, but it is necessary to include all the losses in the auxiliary with the lamp wattage to arrive at a correct evaluation. Brightness of the fluorescent lamp is much less than that of the incandescent lamp, but it is still so bright that neither the eye nor the work should be directly exposed to it. Any comparison of lighting systems must be on the basis of equal quality of lighting (*see* Table III).

TABLE III.—*Fluorescent Lamps "White" Characteristics**

Watts or size (in.)	Tube size (in.)	Current lumens †	Lumens per watt ‡	Brightness ft.L.

LIGHTING FOR VARIOUS KINDS OF INTERIORS

1. Continuous rows on 10-ft. centres light a factory room. Each reflector contains two 40-watt fluorescent lamps mounted approximately 9½ ft. above the floor. Rows at right angles form a grid pattern, produce 80 foot-candles maintained in service on the work plane
2. Fluorescent lighting units in a schoolroom which are open at the top to light the ceiling
3. Lighting for the inspection of paintings in an art gallery, filtered through prismatic glass plates in the ceiling
4. Continuous rows of lamps in a luminous soffit produce pleasing wall and ceiling brightness in this section of a department store
5. Individually located diffuse aluminum troffers in an office, spaced on 3-ft. centres in the crosswise direction
6. Continuous-row troffers for an office

MODERN LIGHTING ARRANGEMENTS

1. Show windows are lighted with 150-watt filament lamps in reflectors on 14-in. centres. Luminous panel of tempered enamelled glass with attached letters lighted from the rear by ten 4-ft. white fluorescent lamps in two rows in a white finished cavity
2. Sales area in the Marshall Field & Company store. Coves contain about 110 40-watt fluorescent lamps; the centre fixture eight 40-watt fluorescent and 20 60-watt filament lamps. Eight louvred downlights and two lens plate units each use 300-watt filament lamps
3. A library. John Simpson, Jr., High School, Mansfield, Ohio, lighted with luminous indirect incandescent fixtures. An area 22½ ft. by 44 ft. is lit by eight fixtures with an average intensity of 23 foot-candles
4. Crystal Pool in Glen Echo Park, Washington, D.C. Underwater units and overhead floodlights make this pool safe as well as attractive at night
5. National Gypsum company offices, Buffalo, New York. The foyer is lighted by five rows of the troffers on 5-ft. centres
6. Major league baseball at night. Philadelphia (Pennsylvania) Athletics Shibe park, where 780 1,500-watt floodlights on 8 towers 150 ft. in height provide intensity of 185 foot-candles on the infield, 120 on the outfield

VARIOUS TYPES OF STANDARD LIGHTING UNITS

1. A porcelain enamel steel reflector known as the RLM Dome. Made to uniform minimum specifications by many manufacturers, it is of high quality construction, has an efficiency of at least 70%, uses inside frosted or white bowl lamps preferably, and is most often mounted 9–12 ft. from the floor
2. The Glassteel Diffuser—similar to Fig. 1 but producing a more diffused light as a result of the lamp-enclosing glass globe. Used at medium low mounting, for general industrial areas
3. An elliptical angle reflector used for lighting vertical and inclined surfaces, usually constructed of porcelain enamel steel. In general the above three industrial units are available for 100- to 1,000-watt lamps
4. A prismatic enclosing globe, for stores and offices. Other types are available in which, by scientific arrangement of the prisms, wide differences in light distribution are procurable for specific needs
5. An open top luminous bowl unit for indirect lighting. The prevailing trend in office, school and similar commercial applications is toward semi-indirect and indirect units which can produce high intensities with minimum glare discomfort
6. One of many varieties of show window reflectors. Individual design is based on the general proportions of show windows, with due consideration for both horizontal and vertical illumination
7. An ornamental street lighting unit for parkway or residential thoroughfare illumination. Pendant types are also frequently used
8. A special type of outdoor unit—an airport landing field floodlight whose output must be spread over large horizontal areas, usually employing 3,000- and 5,000-watt lamps
9. A typical commercial fluorescent lighting unit
10. A 3-lamp, 40-watt closed-end industrial fluorescent unit

MODERN HOME LIGHTING ARRANGEMENTS

1. Studio bedroom. General illumination comes from the fluorescent ceiling fixture, from fluorescent lamps concealed behind the window valance, and above and in the bookcase
2. The recessed box in the overhang (three 25-watt filament bulbs) is especially effective with this simple architectural treatment
3. A kitchen entirely lighted by fluorescent lamps. Sink, range and work counters are locally lighted. In the section over the sink two 30-watt fluorescent lamps are recessed and covered by glass. Under the front edge of the cabinets are single 15-watt fluorescent lamps
4. Across the top of the recess are two rows of three 30-watt fluorescent tubes covered by frosted glass and a valance of fabric. The niches are lighted by long, slender fluorescent tubes mounted vertically in the front and at the sides of each niche. These tubes are 42″ long (approximately 25 watts each)
5. General lighting is produced from a continuous cove that conceals an unbroken line of fluorescent lamps (10 watts per running foot). The sectional davenport is backed by a fluorescent-lighted ledge
6. Dining room chandelier designed to provide general lighting throughout the room and glareless light downward on the table. This is accomplished by a diffusing glass reflector under the metal shade. Fixtures of this style are made to accommodate a three-light lamp with a choice of 100, 200 or 300 watts, plus a 32-watt circular fluorescent lamp

APPLIED LIGHTING

In applying lighting to any task, consideration must be given to both the human and the mechanical elements involved. In the design of a lighting installation the opinions and requirements of the eye specialist, the architect and the interior decorator must be considered, as well as the control and the amount of lighting. A successful lighting system must be a part of the building or activity for which it has been designed.

Measurement of Light.—Light is measured by its capacity to produce a sensation. The eye interprets this sensation in that region of the electro-magnetic spectrum which extends from 7,600 A. (angstroms) to 3,800 A. The eye does not respond equally to the radiant energy in this octave, responding more efficiently to the green and yellow than to the reds, blues and violets.

There are three units of special importance in the application of lighting in practice; the lumen (unit of luminous flux), the foot-candle (ft.c.) (1 lumen incident per sq.ft.) and brightness. Brightness is measured by foot-lamberts (ft.L.) for surfaces of low intensity and by candles per sq.in. for sources of high intensity. In the metric system the corresponding units are the lux (1 lumen incident per sq.m.), and the lambert (1 lumen per sq.cm.) for brightness. The lumen is used in lighting calculations, while field measurements are made of illumination (foot-candles) and brightness (ft.L. or candles per sq.in.).

Illumination is measured by means of a light meter (foot-candle meter) usually of the photoelectric type. When using the photoelectric light meter care should be exercised because its positive indication often leads to a false sense of security in the results. Unless the cell is corrected by a proper filter to correspond to the response curve of the eye, readings under coloured lights will be incorrect. There may be electrical contact errors caused by incomplete contact of the conductor and the cell surface. Light coming from the radiating surface may be blocked by either the observer or the edge of the cell frame.

Measurements of brightness are made with some form of brightness meter which the observer is required to adjust for photometric balance. This is to some degree subjective, in particular where the source measured does not match the standard lamp in colour temperature. In the past, average illumination has been relied upon to a great extent, but present tendency is to give serious consideration to brightness, and future design will continue in this direction.

Lighting Environment.—The act of seeing depends upon vision, the size of the object and its brightness, the contrast between object and background and the length of time the object is exposed for viewing. The first essential to proper seeing conditions is that the eyes be corrected; the second essential is the proper amount and quality of lighting from artificial sources.

Period of Exposure.—If the object is large and long periods of time are allowed for exposure, the task can be adequately lighted with little illumination, but for small objects and short exposure periods, the illumination must be correspondingly increased. The retina will retain an image with no consciousness on the part of the observer that the lighting is continuous if the flicker is rapid. Motion picture projection bears witness to this fact. However, sudden changes of light at long intervals will cause blurring of moving objects, which becomes more pronounced at low foot-candle levels of illumination. The stroboscopic effect from fluorescent lamps and the 25-cycle flicker are examples of a lack of continuity of light.

Size of Object.—The size of an object establishes the lighting requirements. By size is meant visual size, which is a combination of dimensions of the smallest detail which must be observed and the distance of the object from the eye. More foot-candles are needed for smaller objects, all other factors being equal. The normal eye can distinguish any object which subtends an angle of one minute. This is an important factor in the design of signs which are to be seen from some distance.

Contrast.—An object is seen more clearly if background and object are of different colours. A white object against a black background can be more readily seen than a black object against a black background. This fact is utilized in industry to obtain contrast between the machine and its moving parts, the material being worked and the surround (visual field).

Brightness.—Brightness leads directly to the visibility of the object. A very dark object requires more foot-candles for illumination than one with a high reflection factor. For many years foot-candles of illumination were the index to lighting design and specifications, and failure to recognize the importance of reflection factor led to faulty lighting. More attention is being paid to the brightness of the task and its surroundings in design.

Glare.—When brightness becomes irritating it is recognized as "glare." Glare contributes more to the poor quality of a lighting system than any other factor. Glare may depend upon several conditions present in the lighting system: (1) high brightness of the source; (2) high brightness contrast between the source and the background; (3) location of the source in the field of view; (4) the total volume of the light entering the eye; and (5) the time of exposure to the brightness source. The correction of any one of these contributing factors becomes simple when it is considered individually. Because of the injurious effect of glare, either direct as from a source, or reflected from some object which reflects a specular image, bare lamps exposed in any plane should never be used. It is of prime importance that all forms of glare be controlled properly.

Investigation and experience have established principles for studying the installation in order to control glare. These are not recommended as precise, but are suggestive of order of evaluation: (1) the light output of a source cannot be increased as fast as its area, but it is safe to increase the output as fast as the diameter; (2) increasing the foot-candles ten times in a room permits only doubling the brightness of the light source; (3) doubling the mounting height of a unit allows a lumen output of approximately three times that used previously; (4) brightness ratio of adjacent areas should be within limits of ten to one; (5) there should be more light on the work than at the eye; (6) each light in a row makes the same contribution to glare. All these specifications are based on equal comfort from the lighting system.

Proper Amount of Lighting.—The severity of the task is the first index to the amount of light required. Lighting may be specified as: (1) For severe and prolonged tasks with details small, contrast low, and speed of operation high, 100 ft.c. or more should be used, best obtained by supplementary lighting. (2) For installations in which speed is not a factor and the object is small, 50 to 100 ft.c should be used, and again should be obtained by supplementary lighting. (3) For normal industrial and commercial tasks, 20 to 50 ft.c. will suffice and may be supplied by a well-designed general lighting system. Where economy is a factor supplementary lighting should be used. (4) For most recreational needs and ordinary tasks which are not prolonged throughout the working day, 10 to 20 ft.c. from a general lighting system is satisfactory. (5) Where seeing is important but not prolonged, the contrast good, the object fairly large and the speed of movement slow, 5 to 10 ft.c. from a general lighting system is specified. (6) Levels of less than 5 ft.c. should be specified only for casual and nonhazardous passageways. This is obtainable with a relatively cheap general lighting installation since for this use the quality of the lighting is of minor importance.

Considering the high foot-candle level to which the eye is accustomed out-of-doors, it is logical to believe that the eye will function best under high foot-candle levels of properly controlled light; that is, light in which quality of distribution approaches that of the out-of-doors. Control of the surround requires a reduction in the foot-candles. The spectral quality of the light source has no influence on seeing and the modern light source does not contain enough of the harmful wave lengths so that repeated applications are injurious.

Colour and Shadow.—Colour and shadow are not necessarily factors in seeing but are of importance in recognition of objects. Colour must be treated carefully when used in conjunction with light. If coloured light is used, white or neutral gray makes the best surround. With the incandescent lamp, usually considered as white light, the spectral distribution of the output must be considered when colours are to be extenuated or are to appear in their natural intensity.

Moods are suggested and depth control is effected by colours. Although the lighting specialist is not to assume the functions of the artist or the decorator, it is necessary in the application of lighting to recognize the effect light has upon colour and atmosphere and to proceed accordingly.

Shadows may be either detrimental or helpful, depending upon the task to be performed. For decoration the shadow removes the monotony of a uniform lighting system and adds atmosphere to areas of relaxation, as in the home. In industry the shadow facilitates inspection tasks, emphasizes reliefed surfaces and thereby improves visual conditions. Where there is moving machinery or the work lies within a single plane, shadow is detrimental both to safety and visibility. Small concentrated sources will produce harsh, severe shadows, while large area sources of low brightness will produce, for practical purposes, a shadowless surface. Between these two extremes are gradations adaptable to specific types of tasks. Shadow control on stair treads, at corners and on moving machine parts are important applications of light to safety.

The Surround.—The surface which the eye encounters as relaxation areas from a severe task should be properly prepared and illuminated both for light reflection and psychological effect. Brightness of the surround should be at least 10% of the brightness of the task, although research has shown that, if it were feasible, the task and the surround should be equally bright.

Ceilings should have a reflection factor of 75% or more, and side walls of from 50% to 70%. Any trim above 30 in. from the floor may be as dark as desired up to a small percentage of the wall surface. The use of warm and cool colours in shades or tints makes little difference if the reflection factors are correct.

Factors Controlling the Effectiveness of a Lighting System.—These factors should be considered carefully when analyzing a lighting system: (1) The quantity of light should be such as to produce a desired brightness for the severity of the task. (2) There should be no direct glare from the light source and the reflected glare should be reduced to a minimum. This can be aided by selection of equipment and work surfaces producing no specular images. (3) Uniformity of the lighting should be controlled. For tasks in one plane such as writing, drawing and reading, a shadow-free light is desirable. For tasks in three dimensions such as relief work and inspection, a nonuniform light may be better. (4) Illumination of the surround is essential for the relief of eye strain by providing the proper atmosphere for eye relaxation.

The amount of illumination has been so strongly stressed that frequently quality of lighting is sacrificed by lack of consideration of the elements outside the brightness of the light falling on the task. A lower foot-candle level with proper control is better than a high foot-candle level improperly controlled. The recommendations of the Illuminating Engineering society for the amount of illumination are conservative specifications.

Light Control.—Primitive light sources required no shielding and there was no attempt to control artificial lighting until the 13th century when mirrors were placed behind the Venetian standlamp, the *lucerna.* In 1490 Leonardo da Vinci introduced control by refraction, and in 1745 polished metal reflectors were used in the *reverbere.* For the most part control of light belongs to the 20th century.

Classes of Substances.—Transparent materials are not effective with modern light sources because the bare source has a brightness which must be controlled. Transparent material can be used with lighting equipment having very low candlepower; however, this class of equipment is more for period reproduction than for lighting, and when used for lighting as well as decoration the quality of light is very poor.

Translucent materials are more widely used than any other light-control substance, and the introduction of plastics into this field in 1933 marked a new stage of light-control development. Translucent glasses of the more dense types (opal and alabaster) are used for light backgrounds, while the configurated, decorated, structural and architectural glasses are used for decoration where atmosphere rather than illumination of a task is important. The flashed opal, cased, enamelled and light opal glasses have a relatively high transmission and good diffusing qualities. These latter two classes of glass have been widely used in the better grade of lighting glassware and luminous elements.

The opaque materials are used primarily as reflectors and shields. Reflectors for beam control should have a high reflection factor and usually some form of protected metal film or treated metal is used, silver and aluminum ranking high for this application. For industrial equipment, white enamel and paints on opaque surfaces give high reflection with reasonable maintenance and replacement.

Light-Beam Control.—There are three ways in which the light beam may be controlled: (1) reflection; (2) transmission; and (3) refraction. The opaque materials are of the reflection type, and the translucent of the transmission type. Refraction is redirection of light caused by surface shape of the transmitting material. One of the most efficient means of control is by use of prisms, but control in one direction may cause bright spots in others, if not properly designed.

Nature of the Surface.—Light may be diffused by transmission or reflection from a surface, and diffused light is very acceptable for lighting purposes. Redirected light, or even scattered light has its merits in the instance of the special reflector, but may cause specular images or highlights producing objectionable reflected glare. It is recommended that all lighted surfaces within the line of vision (walls and equipment) be of the diffusing type.

Optical Control.—Where accurate control of the light is desired, as in projectors or searchlights, optical reflectors or lenses may be used and for fine control these devices must be accurate. For automobile headlights and floodlights the control lenses and the reflectors may be made by moulding the glass and drawing or spinning the metal.

Luminaire and Installation.—The design of the lighting equipment and the character of the room and cleanliness are controlling factors in lighting efficiency and light distribution.

Lighting equipment is classified into five groups:

Classification	Approximate Light Distribution	
	% Upward	% Downward
Direct	0–10	90–100
Semidirect	10–40	60–90
General diffusing	40–60	40–60
Semi-indirect	60–90	10–40
Indirect	90–100	0–10

The dimensions of the room, colour of the ceiling and side walls, as well as the efficiency, depreciation and candlepower distribution of the equipment control the output. In design the equipment is classified by a coefficient of performance ("utilization factor") designating the control in the room of the light from the luminaire, and the "coefficient of utilization" which includes the luminaire efficiency and, therefore, designates control from the lamp to the work surface. These coefficients may be determined accurately for a specific equipment or may be grouped into classes for practical use.

Classification of Outdoor Equipment.—Lighting units for outdoor service are classified as "floodlights" when the area is not restricted in pattern, and may have broad, medium or narrow beams. The broad beam equipment is used where the surface to be illuminated is in the immediate area; narrow beam equipment is used for more distant areas. For a controlled beam the "projector" or "searchlight" is used, the first lacking the optical accuracy of the latter. Rotating or fixed equipments used for signal systems are classified as "beacons." Floodlighting is used for safety, protection, advertising and recreational lighting, while railroads, navigation and aviation use the various forms of signal lighting.

Design of the Lighting Installation.—There are two methods of lighting design, the "point-by-point" and the "lumen." Each has its specific use and the accuracy attained with each is satisfactory for practical purposes. The point-by-point method is used to determine the illumination at a point from a specific lighting equipment for which the distribution curve is known. Where there is no inter-reflection the point-by-point method gives the total illumination on the surface at the point, but in an enclosure inter-reflections will increase the illumination. The point-by-point method is accurate for outdoor lighting, for calculation and design of supplementary lighting and for down lights in interiors. The lumen method is satisfactory for determining the illumination within enclosures and is the procedure accepted in the designing of interior illumination. This is a method of determining average illumination and not specific illumination at a point. Although the method is relatively simple, it considers room proportions, colouration of the room, efficiency of the equipment, type of equipment to be installed and conditions contributing to the depreciation of the lighting system, such as operation and the presence of dirt. The method is based upon empirical data obtained by careful research into the actual performance of lighting systems in controlled installations.

The Point-by-Point Method.—This method assumes that for actual conditions the source of light may be considered a point source when the illumination is to be determined on a surface that is at least five diameters from the light source.

The illumination at a point *d* distance from a source (fig. 3) is directly proportional to the intensity of the source and inversely as the square of the distance. This is the illumination on a surface normal to the incident beam of light. When the horizontal or the vertical illumination is desired, the illumination on the normal is corrected by the cosine of the vertical angle for the horizontal and by the sine of the vertical angle for the vertical illumination. Determination of the normal illumination (fig. 3):

$$E_N = \frac{I\theta}{d^2} \qquad \text{(a)}$$

horizontal illumination,

$$E_H = E_N \cos\theta \qquad \text{(b)}$$

vertical illumination,

$$E_V = E_N \sin\theta \qquad \text{(c)}$$

Lumen Method.—The general expression for the determination of the necessary lamp size is:

Lumens per outlet =

$$\frac{\text{Area per outlet x foot-candles}}{\text{Efficiency x utilization factor x maintenance factor}} \qquad \text{(d)}$$

The following steps are necessary in the logical solution of a specific determination:

(1) Have a simple but complete sketch of the room to be lighted, with information as to its use, location, dimensions, and any special information as to the placing of work surfaces and machines with the bay dimensions of the ceiling pattern and the nature of any beam structures at the ceiling.

(2) Determine the number of units and the spacing of the units. It is good practice to arrange the units symmetrically and space the units at the corners of squares dividing the room into a symmetrical pattern. Where beams or other obstructions are present the pattern of outlet arrangement should conform to the general ceiling pattern. Outlet spacing should not exceed 1.5 times the mounting height above the work surface for units of the direct, semidirect and general diffusing type, and not more than twice the height of the ceiling above the work surface for the semi-indirect and indirect units. The spacing to the side wall should be approximately one-half the spacing between units. From the layout with the location of the lamps marked it is possible to determine the area per outlet.

(3) The amount of illumination must be determined for the specific task to be performed. The general requirements previously given will determine in general the foot-candles. To determine the best recommended practice for an installation reference should be made to the *Recommended Practices of the Illuminating Engineering Society.*

(4) Equipment must be chosen for the particular task to be performed. In industrial installations the equipment must usually be relatively inexpensive and easy to clean, and will be of the direct or semidirect type, as the ceiling and walls cannot be expected to reflect much of the light. For commercial installations diffusing types are preferable. In either instance the more successful lighting is obtained where the light source is large and of low brightness. In the indirect system of lighting the ceiling acts as a reflector. Use of luminous elements and cove lighting attains lighting conditions similar to that of indirect lighting. The introduction of the fluorescent lamp requiring many tubes to obtain the desired foot-candles gives a light distribution comparable with an indirect lighting installation. The practice of using bare fluorescent lamps without proper light control will produce lighting with distressing glare while indirect lighting will not.

(5) The *efficiency* and the *utilization factor,* or their product, the *coefficient of utilization,* must be determined for the type of equipment chosen. The room proportion, room colouration and type of equipment enter into this coefficient. The manufacturer of the equipment can supply this information for the specific equipment chosen or values may be chosen for the general type, given in widely published tables. Considering the very light ceiling, and a fairly light side wall colouring, the utilization factors average approximately 0.5 for direct equipment, 0.3 for semi-indirect equipment and 0.25 for indirect equipment. High coefficients are associated with large and light rooms, and the lower coefficients with small and dark rooms. The over-all efficiency utilization factor of a lighting system is relatively poor.

(6) The *maintenance factor* (one minus depreciation factor) is an estimate of the cleanliness of the location and the maintenance of the lighting system. This factor ranges from 60% in relatively poor conditions to as high as 75% under favourable conditions. Direct equipment will maintain better lighting under the adverse conditions of normal industrial usage than will the semi-indirect or indirect lighting systems, which are generally used for commercial purposes.

Having determined the quantities to substitute, the result given is the number of lumens required per outlet (equation d). From manufacturer or laboratory data a lamp or a number of lamps may be selected which will most nearly approximate the required lumens. These lamps are rated in watts and should be so specified. Since the lumen output is constantly being changed in the manufacture of lamps it is desirable to refer to the latest tables of lumen output.

The incandescent lamp in medium sizes emits approximately 18 to 20 lumens per w. while the fluorescent lamp emits approximately 45 lumens per w., including ballast loss. The larger the incandescent lamp, the more efficient the output, and the 40-w., hot-cathode, fluorescent lamp reaches the optimum developed for general service to 1945. Fluorescent lamps are being developed in circular form and for operation at higher voltages exceeding the lumen values given above.

Cove Lighting.—Where the lighting equipment is concealed by

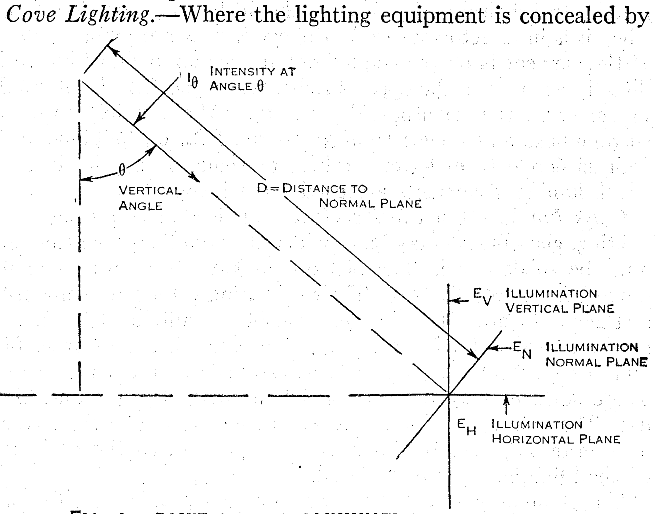

FIG. 3.—POINT SOURCE ILLUMINATION CALCULATIONS

The illumination on the normal, vertical and horizontal planes are given by the equations a, c, b respectively coves, with the ceiling and upper wall used as a luminous surface, the system may be designed by the lumen method. Good reflecting equipment will have an efficiency of approximately 70% while the cove itself may show efficiencies ranging from 25% to 40%. Recessed coves and coves close to the ceiling will have utilization factors of 0.35.

Coves placed too close to the ceiling will give an uneven illumination, a ratio of 1 ft. from the ceiling to every 5 ft. of lighted surface being the minimum that should be used. Plaster coves, finished with the wall and ceiling surface, are very inefficient and will give spotty lighting. The use of reflectors increases cove efficiency and with the correct design the coves can be moved closer to the ceiling. Where the control is obtained by use of some form of prismatic lens it is possible to mount the light source against the ceiling. Relief decorations must be cross-lighted to eliminate undesirable shadows, and produce uniform lighting.

The designer has a choice of having uniform light along the cove or producing a scalloped effect by using clear lamps which create a brushed pattern on the wall. For uniform light properly spaced, inside-frosted lamps, recessed lamps utilizing the concealing surface for reflection, or tubular lamps are required. The fluorescent lamp is applicable to cove lighting.

Luminous Architectural Elements.—Luminous elements became a part of general lighting design following the Century of Progress exposition at Chicago, in 1933. They are applicable both to the exterior or interior of buildings. The term is applied to large, low-brightness lighting sources under which it is correct to consider all forms of indirect lighting as well as architectural elements. The correct application of this type of lighting demands close study, with consideration of the design of the structure as a whole. Luminous elements may take the form of panels, recesses, cavities, niches, pylons, columns, pilasters, parapets, spandrels, soffits, beams, coves, coffers, or mouldings, or may be incorporated into any architectural design. The light may be controlled by diffusing glass, reflectors, louvers, grillwork or by design of the element shape.

The louver, although a very satisfactory control, is not efficient. The concentrating type is the most efficient, but the diffusing reflector causes appreciable loss, reaching a maximum when the distributing system is combined with a cover glass. There are two types of louvers, "source-concealing," which conceal the light source 10° from vertical only, and "general-concealing," which conceal both the source and the reflector 30° from vertical. From 15% to 50% more lumens must be allotted for the losses in louvers. The louver itself may take the form of a decorative element.

The lumen method is used in the design of the luminous element. Projecting elements have utilization factors of 0.5 and maintenance factors of 0.75, while the flush types have utilization factors of 0.7. Efficiency varies from 10% to 90% depending on the reflection material, the shape and the transmission media. In brightness the element should be so proportioned that when it is in direct exposure to the eye it does not exceed 75 ft.L. If the element is on the ceiling and at such an angle as not to be directly exposed to the eye, a brightness of 500 ft.L. is allowable. For exteriors the brightness depends upon the illumination of the surroundings and ranges from 30 to 400 ft.L. on buildings to as high as 600 ft.L. in letter strokes for signs, on applications for which luminous elements are used extensively.

Glass Blocks.—Used in structures for decorative purposes and lighting, glass blocks may be considered as luminous elements and must be so designed. The blocks will have transmission values ranging from 10% to 85%. Their obscuring value varies inversely as their efficiency. The transmission of an individual block cannot be considered, as the transmission value of a wall or surface built of glass blocks is largely controlled by the construction. These surfaces may be constructed for both daytime and night use. The lighting equipment must not interfere with light transmission during the day and must be so placed that the rudiments of good lighting are not violated.

It is commonly accepted by the lighting specialist that the providing of illumination is the least successful function performed by windows. Glass blocks allow light to enter but eliminate the normal view from the window. Sunlight falling upon glass blocks will produce a brightness surface which must be controlled and the removal of a window which can be opened makes it necessary to remove the building heat by some other means. Consideration of glass walls or surfaces exposed to the outside requires careful co-ordination of functional design by the architect and the illuminating engineer.

Floodlighting.—Floodlighting should be designed to produce an effective harmony with the object to be lighted. Daylight effect cannot be reproduced by floodlights, and the effect produced must be studied carefully. The simple straight lines of modern structures are excellent subjects for floodlighting. Statues and monuments should be lighted in collaboration with the artist, while recreational areas and sports fields should be lighted to satisfy the requirements of those proficient in the particular sport.

Locating Equipment.—In locating equipment the surrounding buildings, topography, area to be lighted and economical aspects of the installation must be considered. If not located directly on the building to be illuminated, the equipment may be located on adjacent buildings, electric service poles, street lighting standards (for buildings not in excess of three floors), in shrubbery or trees, or on poles installed for the purpose. On the building itself, ledges, cornices and parapets will provide concealment. When sports, construction and air strips are lighted it is usually necessary to supply towers, poles or special mounting elements.

Equipment Characteristics.—For illumination at a distance, narrow beam equipment is used, ranging from searchlights with optical control to standard narrow beam (15° or less) equipment. For near areas broad beam (30° and over) equipment is used. Intermediate ranges and surface areas may use medium beam (16° to 29°) equipment. The lumen method of design is used for determination of the average illumination with a standard maintenance factor of 0.7 and the output is determined from the beam lumens of the equipment. Since little if any light can be obtained by inter-reflection, such light as does not strike the specific area to be illuminated, is lost. There must be provision for control of the "spill light" which may become objectionable, and there must be about 10% overlapping of beam pattern so as to attain some degree of uniformity. Tables of recommended ft.c. should be used and buildings with reflection factors of 20% or less will prove uneconomical to illuminate. Loading areas and railway yards have been successfully lighted by floodlighting, as well as areas where construction schedules require 24-hr. operation.

Operation and Maintenance.—The success of a lighting system depends upon selection of the proper installation and lighting source and the maintenance. The lighting source should be the most economical, determined from first cost of the equipment, its installation and the power and labour costs in the community where the installation is to be made. Frequently there may be a choice of several schemes and systems which will be adequate and satisfactory as to lighting quality and no general rule can be applied which definitely determines any combination as superior.

For "seeing," even the monochromatic lights seem to prove equally efficient and comfortable to users. Research has not been able to determine any one source quality which is superior to another for the usual seeing tasks. When colour-matching is involved in production, daylight sources of artificial light have proved more satisfactory than natural daylight. No artificial source for lighting, either incandescent or fluorescent, radiates wave lengths which under continued usage are harmful to the eyes; neither has it been found that any one of these, including daylight sources, has superior qualities for seeing.

Lamp Selection.—The general service lamp, in the voltage rating of the electric system, satisfies the usual conditions. For severe tasks under conditions of vibration, heat, weathering and unusual position, the type of lamp designed for the particular service should be selected. Special usage lamps vary in their base construction, cementing and filament suspension. In lamps of the projection type the filaments may be arranged into a single plane.

Fluorescent lamps of the hot-cathode type may be selected from several sizes in length and wattage, with some lengths being available in the cold-cathode type. The fluorescent lamp has various voltage requirements which must be met by the selection of the correct auxiliary equipment. Development of the circular-type fluorescent lamp permits a selection of form as well.

Proper Voltage.—Since the electric lamp is critical to the applied voltage, to be efficient, lamps should be operated at their rated voltage. To maintain the voltage at the lamp it is necessary to install adequate wiring systems. The voltage at the lamp, when the system is fully loaded, should not deviate more than 2%. Wiring systems that are inadequate are expensive for reasons of output loss and extra losses in the wiring system. A 120-v. incandescent lamp burned at 115 v. gives only 86.4% of the normal lumen output and will be operating at 92.3% efficiency. The fluorescent lamp is even more critical to voltage change than the incandescent lamp, to the extent of becoming inoperative at incorrect voltages.

Maintenance.—From the first hour that a lighting system begins to operate it deteriorates through darkening of the lamp, dirt accumulation on the lighting equipment and general depreciation of the reflecting surfaces. When this depreciation of the system reduces the initial illumination about 30% it is necessary to consider some form of maintenance. The loss can be partially restored by renewing the darkened lamps, cleaning the equipment and, if these fail, by either washing or painting the reflecting surfaces. A schedule of washing equipment monthly and walls every two years (this requires painting every six years) is satisfactory in the average commercial installation. The installation must be designed so that maintenance is possible at low unit costs.

The "smashing point" of lamps, at which it is economical to replace the lamp even though it is still operative, is reached when the lumen output of the lamp has been reduced to the point at which the cost of energy consumed per million lumen-hours exceeds the average cost of light produced up to that time, including initial cost of lamp and energy.

Study has shown that the renovated lighting system could gain 12% by repainting of reflecting surfaces, 20% by cleaning and 19% by using new lamps with proper voltage ratings, a total of 51%.

SPECIFIC APPLICATION

Home Lighting.—Entrance lighting should serve as a welcome to the home and as a protection at night. Brackets on each side of the door should have 40-w. lamps and where a general lighting is used on an entrance porch, a 60-w. lamp should be used. The position of the light should be such as to illuminate the person outside the door. The front entrance may have a bracket or soffit light which not only illuminates the entrance but contains an illuminated house number. The numerals should be at least 3 in. high and have ½-in. strokes. Back entrances and grade entrances should be lighted along the same principles. The lighting should be such that all steps or offsets in the approaches are illuminated for safety.

Hard glass projectors and flood lamps may be used to illuminate the grounds, the drive and the area surrounding the garage. Lights placed under the eaves may be used both for making the property attractive at night and for protection. There should be outlets available for garden lighting and seasonal decorative lighting.

Hall lights should be simple in construction and properly selected to become a part of the passage area. Selection and location of equipment should be such that it is not unsightly from above if located on the ceiling of a hall from which other floor levels are reached. The average hall can be adequately lighted with 40- to 80-w. equipment.

Living Room Lighting.—There should be a central fixture with 150-w. or more, and bracket lighting may be used for both decoration and useful lighting. The bracket lights should be well shielded and use 60-w. lamps. Portable lamps usually make up a major portion of the working light, and floor types should have from 150-w. to 500-w. with table types using from 100-w. to 150-w. Built-in lighting may be used for lighting recesses or dark areas and if properly planned may reduce the need for portable lights. The correct number of outlets and a wide distribution of these will permit of flexibility in rearranging the rooms. One duplex outlet per 20 running ft. of baseboard would be a minimum allowance. If there is more than one entrance to the room, lighting should be controlled from each entrance. Living room outlets should be distributed over several circuits and wall receptacles controlled by means of a switch.

Dining Room Lighting.—The dining table being the centre of interest in this room, illumination of the table surface is the principal function of dining room lighting. When used for dining purposes only, little attention need be given to any requirements other than desires of the occupants, but it is often necessary that the dining room table serve as a study centre or work surface. When this is the case, illumination from either the centre fixtures or portable lamps must be increased and controlled for this purpose. As a rule the dining room table is the largest free surface in a home and is frequently used for any work requiring a large surface. To meet this requirement it should be illuminated uniformly over its entire surface.

Choice of equipment for the dining room is similar to that for living rooms and all outlet and switching requirements are the same. Suspended centre fixtures should be from 30 to 36 in. above the table top. Some form of "down lighting" should be used to illuminate the table when set, to produce the desired glint and sparkle from table service. Central fixtures designed to produce the above effect should not be used if the dining room is required to serve as a work area also. A minimum of 150-w. should be used in a central fixture. Brackets are usually decorative and lighting behind valances and cornices, or built-in, may supply the general lighting, using either 40-w. fluorescent lamps or 10-w. per running ft. of incandescent lighting.

Kitchen, Laundry, Workshop and Garage Lighting.—The utility areas need the illumination level specified for the difficulty of work to be performed in them. The equipment is less decorative and less expensive, but it must have equal if not better lighting characteristics than for other areas of the home.

The kitchen should have a central light of 150-w. or more in incandescent lighting or equivalent light output from fluorescent lamps. Each of the work surfaces (stove, sink and counter surfaces) should be independently illuminated. A minimum of 40-w. each for these supplementary lights will usually prove satisfactory. Shadows caused by using a central fixture alone are annoying and may be dangerous. The availability of a concentrating light permitting close inspection of food is desirable.

In the laundry, direct lighting equipment of the R.L.M. reflector type is inexpensive and efficient. If used with a 150-w. silver-bowl lamp, specular images are eliminated with little loss of light. In the home workshop, this same type of lighting, either incandescent or fluorescent, can be used over the work bench or where some constructive hobby is in progress.

The garage, coal storage area and furnace room each require adequate light, not so much for work purposes as for safety. The R.L.M. reflector equipped with inside-frosted lamps of 75- to 100-w. will illuminate these areas satisfactorily. Two fixtures, one mounted at the front and one at the rear of the garage, give satisfactory lighting even when cars are in the garage. There should be an outlet available for a portable lamp for necessary adjustments and work. Portable lamps should meet the requirements for cords and sockets in damp places with an approved guard for protection.

Bathrooms.—The important light centre in the bathroom is the mirror, which may be illuminated by an encircling light or by side brackets providing shadow-free light on the person reflected, and not upon the mirror. Fluorescent lamps in the brackets distribute the light more evenly. The light in the bathroom should be controlled by a switch located away from any grounded plumbing or other grounded metallic conductor. For economy in the small bathroom, the bracket light may be the only one, but a ceiling light is desirable and in the large room it is essential. Ceiling lights of 100 w. and bracket lights of 20 to 40 w. are satisfactory. If fluorescent lamps are used, the larger diameter tubes are of a lower brightness and, therefore, better. Switches should be located at each door. An additional convenience is a night light which may be incorporated in the switch assembly, or as an additional baseboard light.

Bedrooms.—Since the modern bedroom is frequently used for sewing, reading, writing and study purposes, as well as for sleeping, the lighting must be adapted to these various needs. A ceiling fixture with a relatively low brightness should be installed to reduce glare. This is particularly important for rooms to be occupied by children. For small rooms the ceiling fixture should use a 40-w. lamp, and for large rooms, 100-w. should be used. If all or part of the furniture is of the built-in type lighting equipment may be incorporated in the design at a relatively low cost. Bracket lights for mirrors and dressing tables and trough lights for full-length mirrors are desirable. Supplementary lighting may be obtained by portable lamp stands or pin-up lamps installed over the bed, either of which should provide sufficient illumination for reading. Closets should have a simple but adequate lighting system, usually a bracket light with a pull-chain socket and a 60-w. lamp. Drop cords should not be used because of the danger of fire if clothes come in accidental contact with the lighted lamp. In an elaborate installation door switches can be used for turning the light on and off.

Detailed specifications for home lighting can be found in *Recommended Practice of Home Lighting,* of the Illuminating Engineering society.

School and Public Building Lighting.—Although children attend school during daylight hours, it is during the season of the year in which days are short and frequently cloudy, requiring additional artificial light to illuminate the desks farthest from the window to a minimum level, though not equal to that at the window. In sight-saving rooms, artificial illumination is necessary even on the brightest day to illuminate writing boards and desks more than 10 ft. from the window. In elementary grades the eyes are subjected to tasks incompatible with the natural accommodation of the eye. Poor lighting will influence the posture of the student, who seeks positions of least discomfort for the eyes and at the same time attempts to balance out strains upon body muscles. Every effort should be made to furnish the amount of illumination that is needed, the light being given off from the source and secondary surfaces in such a way as to eliminate all elements of discomfort. High levels of illumination without proper control are more detrimental than properly controlled low levels.

The amount of lighting should range from 50 ft.c. for the sight-saving room (and in some instances for drafting rooms which are to be used for long periods) to 5 ft.c. for passageways and locker rooms. The average classroom should have a minimum illumination of 25 ft.c. For high over-all efficiencies ceilings should reflect 75% of the light, and side walls 50% to 60%. Matte finishes should be used on all surfaces, and any glass doors, glass in picture frames or any other specular material should be eliminated to avoid reflection of images to any other position in the room. Desk tops and floors should have light finishes.

Writing boards should have dull finishes and be placed so as to eliminate reflected glare. Marked colour contrast between the writing boards and surrounding finish is a source of discomfort and not very pleasing in room composition.

Natural lighting seems essential in the school, not so much because of the light itself as for the psychological atmosphere which is created by windows. Orientation of the building controls the benefits to be obtained from the lighting. Orientation depends upon climactic and seasonal conditions and no standard rules can be applied. Rooms with unilateral lighting are least difficult to control. Lighting should come from the left, never from the right and front of the room. Window structures should be reduced to a minimum so as to avoid casting shadows. Even in corner rooms there is little value to windows in the rear of the room. The top of the window should be as near the ceiling as possible, not less than a distance above the floor equal to one-half the room width. To increase the glass area in a room it is better to add height than width. The glass area should be as large as possible, not less than 18% of the floor area when starting three feet from the floor, or 16% when starting four feet from the floor. These percentages are for rooms in which all glass area is exposed to the sky; if trees or buildings obscure the light, the glass area is increased proportionately. Windows at the front of the room should stop at the front row of seats; at the rear they should be carried close to the back wall. The skylight frequently used over auditoriums should be eliminated, for it is difficult to clean, frequently subject to leaks and makes light control difficult.

Window light control must intercept the direct sunlight and diffuse it throughout the room, eliminate the glare from any exterior surfaces and control the relative illumination at different points in the room. The venetian blind, which may be classified as a louver control, may be used to deflect the light to the ceiling, thereby diffusing the light over the room, at the same time intercepting the direct or annoying reflected light from the outside. A double shade, drawing up and down from the centre of the window, has second place as a light-control device. To use projection equipment the room may be darkened by a second set of dark shades running in light-sealing guides. When selecting the light equipment, efficiency and light control should be the most important points to consider with emphasis on appearance, construction, maintenance and flexibility for the service.

The standard school room, measuring 20 by 30 ft. with a 12-ft. ceiling requires six outlets for incandescent lamps and an equivalent for fluorescent lighting. Usually the row of desks farthest from the window must have artificial light even on the brightest days. Photoelectric equipment should be used to control the light.

Industrial Lighting.—Good lighting in industry should correlate with plant safety, improved quality of product, increased production with decreased costs, better use of floor space, better seeing conditions for the employees, more cleanliness and neatness, better supervision of the work, less eyestrain and with a decrease of labour turnover because of improved morale.

Because it is necessary to see easily and accurately and often quickly, the glare, diffusion, direction and distribution of the light must be given special consideration and definitely controlled. Where severe tasks are performed or where economics does not justify a high level of illumination, extensive use must be made of the supplementary light. Attention must be directed toward specular images and veiling glare. This must be controlled by using large low-brightness lighting equipment or systems.

Correct reflecting factors for ceilings, walls and floors should be used in industry. Light colours will give high utilization factors and the painting of the recessed work areas of the machines will, by inter-reflection, illuminate details of the work. Use of paint contrast is an aid to speed and safety in production. For ceilings and side walls light colours should be used; for machines, a corresponding reflection factor in a contrasting colour so that masses, either moving or stationary, can be recognized. White-reflecting surfaces should be used on all enclosures tending to cast a shadow on the task.

Machine tools and inspection lighting require separate study. Machine tool operations controlled by dial settings or measurements with calipers, micrometers and dial gauges should have source brightnesses of low value, located to give satisfactory illumination without veiling glare or specular images. Inspection lighting sometimes requires specular images. Mirroring of the light source in the work makes it possible to detect flaws and irregularities; however, the inspector must be protected by positioning and control of the brightness contrast.

Natural lighting should be utilized to the greatest extent. Lighting from a window decreases very rapidly, the horizontal illumination falling from 200 ft.c. near the window to 5 ft.c. at 20 feet from the window. Although windows present a surface of low brightness or are reduced to one of low brightness by controlling means, the extent of the surface in itself produces deleterious glare effects. A worker should never face directly into a window, because even a large low-brightness surface becomes annoying with time. Saw-tooth, monitor or skylight illumination in modern factory construction offers better light control than large glass side walls. Natural lighting should be considered in proportioning the room in factory design. If one wall contains

4. Brilliant complicated ramifications of flashes of lightning striking to the plain beyond the hill
5. A dangerous area for lightning discharges; in the foreground an oil derrick together with the switching station and lines of a gas and electric company, Drumright, Oklahoma

windows, the room should have a depth perpendicular to this wall of less than twice the window height above the floor. When two parallel sides have windows, the room depth should not exceed six times the window height. Monitor window width should be one-half the monitor width. The height of the saw-tooth window should be one-third the span. As a general rule, window area should be approximately one-third the floor space.

Windows need periodic cleaning, both inside and outside to maintain efficiency. When using natural lighting, glare from windows, as well as that produced by any object on the outside must be controlled. Because daylight is so variable this lighting must be used in conjunction with proper arrangement and switching of artificial light. Photoelectric control of lighting circuits is desirable to maintain a minimum level of illumination at machines. When portions of the shop must be lighted by artificial lighting, and the remainder uses natural lighting, it is necessary to have the illumination in the artificially lighted area much brighter than normal night lighting because of excessive brightness contrast between the areas under the two arrangements. Industrial plants are being built without windows and operated entirely under artificial lighting with satisfactory results. Windows are not considered good lighting sources by illuminating engineers; however, windows have a psychological value.

The U.S. *Recommended Practice of Industrial Lighting* discusses factory and industrial lighting in detail.

Street Lighting.—Street lighting design should lead to recognition of the presence of an object and not necessarily to distinguishing fine details. Objects on the street or highway are discerned by silhouette when the illumination on the object is lower than the background, as when the object lies between two approaching cars; the reverse silhouette occurs when the object is more brightly lighted than the background, which requires relatively high illumination, usually in the vicinity of the lighting equipment. If details and colour of the object are discernible very high illumination is responsible. When the object emits specular light the visibility is caused by glint. Shadow and shadow pattern are important in recognition of the presence of an object. This effect depends upon the amount of relief and the angularity of the light.

The utilization and recognition of the above factors are more important in adequate street lighting than the production of the equivalent of daylight. The problem requires the best visibility consistent with a relative low cost per unit of light. Some traffic centres require more than usual visibility lighting, because of the presence or congregation of pedestrians. In these localities both the pedestrian and the driver must quickly discern objects with enough distance of visibility to react safely.

Equipment should direct the greater portion of the light toward the street, not skyward or into adjoining properties. Sufficient spill light should illuminate the sidewalk for protection and travel. There should be a proper adjustment between mounting height, spacing and lamp size. Mounting height may vary from 15 to 30 ft. and will depend upon glare, foliage interference and appearance. High mountings are associated with wider spacing and larger lamps, thereby reducing the first cost and operating cost. In residential districts, lower mounting heights, though not desirable, are used because of foliage. The spacing-mounting height ratio should not exceed eight to one. Lighting standards may be placed opposite one another or staggered on the two sides of the street; in alleys and outlying side streets, standards along one side of the street may be used. The equipment should either eliminate glare, or the time exposure to glare should be reduced to a minimum. Avoidance of pavements or surfacing which does not reflect light will aid street lighting; even black surfaces can be improved by correct top dressing.

Streets are classified according to the volume of maximum night traffic per hour (going both ways). Class divisions recommended are (1) very light traffic, (2) light traffic, (3) medium traffic, (4) heavy traffic, (5) very heavy traffic, (6) heaviest traffic, ranging from 150 vehicles per hr. and under to 4,000 per hr. and over. The street illumination, for average values, ranges from 0.1 ft.c. to 1.5 ft.c. Business districts, street intersections, boulevards and park drives, alleys, bridges, traffic circles, tunnels and other unusual problems must be subjected to a detailed analysis and lighting specified to meet the needs. (*See* also LIGHT; VISION.)

Further data may be obtained from the manufacturers; information concerning past practice and recent developments from the *Transactions* of the American and English Illuminating Engineering Societies. Information on illuminating engineering, from *Scientific Basis of Illuminating Engineering* by Parry Moon (1936); on illumination practice, from *Electrical Illumination* by John O. Kraehenbuehl (1942); and for fluorescent lighting, from *Fluorescent Lighting Manual* by Chas. L. Amick (1942). (J. O. K.)

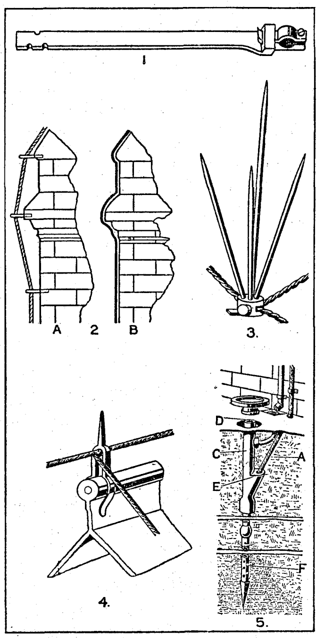
LIGHTNING, the visible flash accompanying an electric discharge between two clouds or between a cloud and the earth. In certain electrical conditions a cloud becomes highly charged by the coalescence of droplets, for a large drop has a less superficial area than the total area of its constituent droplets; hence its electric potential and that of the whole cloud, rises. When the cloud passes near another cloud stratum or a projection on the earth, a discharge of lightning occurs. In the case of "forked" lightning the actual path of the discharge is visible but "sheet" lightning is merely the visible illumination of a cloud by a discharge of which the actual path is not seen. Rain and certain "lightning conductors" discharge the electricity quietly to earth, hence lightning frequently ceases on the fall of rain (*see* ELECTRICITY, ATMOSPHERIC).

LIGHTNING BUG, the name often given in the United States to the firefly (*q.v.*).

LIGHTNING CONDUCTOR, or, according to Benjamin Franklin, "lightning rod," the name usually given to apparatus designed to protect buildings or ships from the destructive effects of lightning (Fr. *paratonnerre*, Ger. *Blitzableiter*). The upper regions of the atmosphere being at a different electrical potential from the earth, the thick dense clouds which are the usual prelude to a thunder storm serve to conduct the electricity of the upper air down towards the earth, and an electrical discharge takes place across the air space when the pressure is sufficient. Lightning discharges were distinguished by Sir Oliver Lodge into two distinct types, the *A* and *B* flashes. The *A* flash is of the simple type which arises when an electrically charged cloud approaches the earth without an intermediate cloud intervening. In the second type *B*, where another cloud intervenes between the cloud carrying the primary charge and the earth, the two clouds practically form a condenser and when a discharge from the first takes place into the second the free charge on the earth side of the lower cloud is suddenly relieved, and the disruptive discharge from the latter to earth takes such an erratic course that according to the Lightning Research Committee "no series of lightning conductors of the hitherto recognized type suffice to protect the building." In Germany two kinds of lightning stroke have been recognized, one as *zündenden* (causing fire), analogous to the *B* flash, the other as *kalten* (not causing fire), the ordinary *A* discharge. The destructive effect of the former was noticed in 1884 by A. Parnell, who quoted instances of damage due to mechanical force, which he stated in many cases took place in a more or less upward direction.

The object of erecting a number of pointed rods to form a lightning conductor is to produce a glow or brush discharge and thus neutralize or relieve the tension of the thunder-cloud. This, if the latter is of the *A* type, can be successfully accomplished, but sometimes the lightning flash takes place so suddenly that it cannot be prevented, however great the number of points provided, there being such a store of energy in the descending cloud that they are unable to ward off the shock. A *B* flash may ignore the points and strike some metal work in the vicinity; to avoid damage to the structure this must also be connected to the conductors. A single air terminal is insufficient. Besides multiplying the number of points, numerous paths, as well as interconnections between the conductors, must be arranged to lead the discharge to the earth. According to Lodge "there is no space near a rod which can be definitely styled an area of protection, for it is possible to receive violent sparks and shocks from the conductor itself, not to speak of the innumerable secondary discharges that are liable to occur in the wake of the main flash." The report of the Lightning Research Committee contains many examples of buildings struck in the so-called "protected area."

Franklin's original rods (1752) were made of iron, and this metal is still employed throughout the continent of Europe and in the United States. British architects, who objected to the unsightliness of the rods, eventually specified copper tape, which is generally run round the sharp angles of a building in such a manner as to increase the chances of the lightning being diverted from the conductor. The popular idea is that to secure the greatest protection a rod of the largest area should be erected, whereas a single large conductor is far inferior to a number of smaller ones and copper as a material is not so suitable for the purpose as iron, which offers more impedance, and allows the flash to leak away by damping the oscillations. Iron is not suitable in cities, or factories where coal is used.



TYPES OF LIGHTNING CONDUCTORS
1, Holdfast; fixed, to allow sufficient space for the conductor to clear projections. 2A, sharp bends prevented by holdfasts. 2B, method condemned by L.R.C. rules. 3, aigrette, fixed to a horizontal conductor. 4, holdfast on tiles; horizontal conductor, jointed by U-shaped lead. 5, tubular earth

In 1876 J. Clerk Maxwell read a paper before the British Association in which he brought forward the idea (based on Faraday's experiments) of protecting a building from the effects of lightning by surrounding it with a sort of cage of rods or stout wire. It was not, however, until the Bath meeting of the British Association in 1888 that the subject was fully discussed by the physical and engineering sections. Sir Oliver Lodge showed the futility of single conductors, and advised the interconnection of all the metal work on a building to a number of conductors buried in the earth. The action of lightning flashes was also demonstrated by him in lectures delivered before the Society of Arts (1888). The Clerk Maxwell system was adopted to a large extent in Germany, and in July 1901 a sub-committee of the Berlin Electrotechnical Association was formed, which published rules. In 1900 a paper entitled "The Protection of Public Buildings from Lightning," by Killingworth Hedges, led to the formation, by the Royal Institute of British Architects and the Surveyors' Institution, of the Lightning Research Committee, on which the Royal Society and the Meteorological Society were represented. The *Report,* edited by Sir Oliver Lodge, Sir John Gavey and Killingworth Hedges, was published in April 1905. An illustrated supplement, compiled by K. Hedges and entitled *Modern Lightning Conductors,* contains particulars of the independent reports of the German committee, the Dutch Academy of Science, and the Royal Joseph university, Budapest. A description is also given of the author's modified Clerk Maxwell system, in which the metal work of the roofs of a building forms the upper part, the rain-water pipes taking the place of the usual lightning-rods.

A number of failures of conductors were noticed in the 1905 report of the Lightning Research Committee. One cause was the insufficient number of conductors and earth connections; another was the absence of any system for connecting the metallic portion of the buildings to the conductors. In some cases the main stroke was received, but damage occurred by side-flash to isolated parts of the roof. There were several examples of large metallic surfaces being charged with electricity, the greater part of which was safely discharged, but enough followed unauthorized paths, such as a speaking-tube or electric bell wires, to cause damage. In one instance a flash struck the building at two points simultaneously; one portion followed the conductor, but the other went to earth jumping from a small finial to a greenhouse 30 ft. below. (Photographs and specimens showing such damage are exhibited in gallery 44, Geophysics, of the Science Museum, London.)

Construction of Conductors.—The general conclusions of the Lightning Research Committee agree with the independent reports of similar investigators in Germany, Hungary and Holland. The following is a summary of the suggestions made: "The conductors may be of copper, or of soft iron protected by galvanizing or coated with lead. A number of paths to earth must be provided; well-jointed rain-water pipes may be utilized." Every chimney stack or other prominence should have an air terminal. Conductors should run in the most direct manner from air to earth, and be kept away from the walls by holdfasts (fig. 1), in the manner shown by *A* (fig. 2); the usual method is seen in *B* (fig. 2), where the tape follows the contour of the building and causes side flash. A building with a long roof should also be fitted with a horizontal conductor along the ridge, and to this aigrettes (fig. 3) should be attached; a simpler method is to support the cable by holdfasts armed with a spike (fig. 4). Joints must be held together mechanically as well as electrically, and should be protected from the action of the air. At Westminster Abbey the cables are spliced and inserted in a box which is filled with lead run in when molten.

Earth Connection.—A copper plate not less than 3 sq.ft. in area and $\frac{1}{8}$ in. thick may be used if buried in permanently damp ground and surrounded with charcoal or carbon. (If coke is used it must be thoroughly washed.) Instead of a plate there are advantages in the tubular earth shown in fig. 5. The conductor *A* packed in carbon *C,* descends, jointed at *E,* to the bottom of the perforated tube *F,* which is driven into the ground, a connection being made to the nearest rain-water pipe to secure the necessary moisture; in dry seasons it is watered at *D.* Plate earths should be tested every year. The number of earths depends on the area of the building, but at least two should be provided. Insulators on the conductor are of no advantage, and it is useless to gild or otherwise protect the points of the air-terminals. Heated air offers a good path for lightning (which is the reason why the kitchen-chimney is often selected by the discharge). A copper-band, with a number of points, should be fixed near the top of factory chimney stacks; there should be at least two interconnected conductors to earth. All roof metals, such as finials, flashings, rain-water gutters, ventilating pipes, cowls and stove pipes, should be connected to the system of conductors. The efficiency of the installation depends on the interconnection of all metallic parts, also on the quality of the earth connections, each of which should not exceed a resistance of 5 ohms. A disconnecting joint for testing should be inserted near the ground. In the case of magazines used for explosives, it is questionable whether the usual plan of erecting rods at the sides of the buildings is efficient.

The only way to ensure safety is to enclose the magazine in iron; the next best is to arrange the conductors so that they surround it like a bird cage. The numerous elevated fire-lookout stations in the United States are safeguarded by means of a skeleton cage of wire cable, connected to earths, sometimes made by blasting the solid wall. A new system for petroleum storage tanks, invented by J. M. Cage of Los Angeles, Calif., U.S.A., aims at the prevention of lightning discharges by dissipation; three parallel wires armed with points are suspended from steel towers and completely enclose the area to be protected.

LIGHTNING INSURANCE: *see* FIRE INSURANCE.

LIGHT ORGAN: *see* COLOUR-MUSIC.

LIGHT RAILWAYS, MILITARY. Railways of less than standard gauge have often been used for military purposes. A great development of such "light railways" came during the

World War of 1914–18. Two general types of track were used, both of 60cm. gauge: (1) "foreways" consisting of sections of steel ties and rails bolted in units about 16ft. long; (2) 30ft. rails weighing 25lb. per yard, on small wood ties and preferably ballasted, of the general type of standard gauge railways.

Rolling-stock.—The rolling-stock consisted of three types of wagon: (1) Low-sided four-wheel trucks with capacity of four tons. (2) Flat bogie wagons with carrying capacity of eight tons. (3) Bogie well-wagons with carrying capacity of 10 tons. The last mentioned were used almost entirely for transporting heavy ammunition.

Motive Power.—The motive power consisted of: (1) Six-wheel coupled locomotives weighing up to 14 tons, capacity 60h.p., and capable of hauling 65 tons up a gradient of 1 in 40. (2) Four-wheel coupled locomotives weighing up to eight tons, capacity 35h.p., and capable of hauling 40 tons up a gradient of 1 in 40. (3) Petrol tractors weighing up to four tons and capable of hauling a load of 14 tons up a gradient of 1 in 40; these petrol tractors had two gears, the speed on the low gear being about four miles and on the high gear 10 miles per hour.

During the latter part of the World War, 1917–18, light railways were very extensively used on the Western front for transporting supplies to the smaller supply depôts away from the standard-gauge railways, and ammunition to the heavy gun and howitzer positions. During 1917–18, 1,780m. of light railway were laid, but only about half of this was ever used. While the war was stationary light railways were of very great service to the armies, but as soon as a retreat or a continued advance took place they became out of action. They are not economical, the maintenance alone during 1917 requiring an average of 15 men per mile, which, as the lines became consolidated, was reduced to five men per mile. The average effective haul of a locomotive was 23 train miles per day, and that of a tractor was 20 train miles per day. The average coal consumption per locomotive was 62 lb. of coal per effective train mile and the average petrol consumption per tractor was ·56gal. of petrol per effective train mile. The average loaded wagon mile per day per effective was 4·25.

With the advance in Sept. 1918, light railways were of great assistance in getting forward ammunition and evacuating the wounded. They were joined on to the German 60cm. railways which had not been destroyed, but they were soon left behind and the armies relied entirely on the standard gauge railways and road transport. Light railways, when worked to their maximum capacity, carry, on an average, about 140 tons of supplies per mile of track per day, according to the grading of the line, and the cost in man-power for operating purposes only, as compared with a standard-gauge railway, is as 3·45 to 1 per mile and cost in man-power for construction as 2·2 to 4·7. The extension to light railways, known as "foreways," and used for carrying supplies from the end of the light railways up to the trenches, consisted of 60cm. gauge track laid on an unballasted formation; the rails weighing about 9 lb. per linear yard of rail on sleepers weighing 8 lb. and spaced 3ft. apart, centre to centre; on these lines flat-topped, four-wheel trolleys were pushed by two men during the night right up to the communication trenches. (D. L.; X.)

American Practice in the World War.—The American light railways were 60-cm. gauge like those of the French, British, Italians and Germans. The service of the narrow gauge lines began at the standard gauge railheads, up to which point the transportation of munitions and supplies was carried out by standard gauge railways and canals. At the railheads or corresponding canal heads transfer was made either directly or after storage to the equipment of the 60-cm. lines. The light railways were extended very nearly to the front line trenches, and they were constructed, maintained, and operated by special regiments assigned to the light railway service. Regimental headquarters combined the functions of military control over light railway personnel and the management of railway lines in a given sector. Motive power consisted of steam locomotives, 4-cylinder geared gasoline locomotives of 50 and 35 h.p. and small gasoline locomotives.

A central assembly and repair shop for light railway equipment was established at Abainville (Meuse), and comprised 70,000 sq.ft. of buildings, including an erecting shop, smith shop, machine shop, foundry, gasoline engine repair shop, car shop, oil house, power plant, storehouse, and carpenter shop. The largest number of American light railway troops engaged at any one time was between Sept. 15, and Nov. 9, 1918, when the number rose to 13,650. The daily net tonnage handled by narrow gauge lines operated by the American Expeditionary Force was 8,100 tons in Oct. 1918. It was found that the average progress in the construction of new line was at the rate of 3 ft. of completed track per man per day. An average of 2·2 men per km. was required for maintenance of way. Contrary to the British and French practices, the Americans lengthened the usual haul of freight in certain cases far beyond anything previously considered practicable for 60-cm. army lines. The average for the entire American light railway operation was 15·2 km., which is about 30% above British or French practice. On Nov. 10, 1918, the American light railways were operating 623 km. of main line, with a personnel on operation alone of 57 officers and 3,557 men. The total of tonnage handled by light railways from the commencement of operation to Feb. 1, 1919, was 860,652.

Lessons from World War.—First, light railway traffic was more easily interrupted than paved road traffic; 2nd, it was claimed that standard gauge tracks with light rails and light rolling stock were better than narrow gauges, in that they could be made suitable for heavy traffic, if desired. (G. B. T.; X.)

LIGHTSHIP or **LIGHTVESSEL,** a vessel bearing a light, and frequently a fog-signal in addition, for the guidance and warning of mariners. Lightships vary in size from small decked boats, carrying an unattended light which functions automatically for several months, up to self-propelled ships of over 700 tons displacement, provided with powerful lighting and fog-signalling apparatus and manned by crews of 15 men or more. They are usually moored in positions marking shifting shoals or other submerged dangers, or in wide sandy estuaries where a fixed lighthouse or lighted beacon cannot conveniently be placed. Many unattended floating-lights of considerable size and power are now in use. The first lightship to be established in English waters was that placed at the Nore in 1732. (*See* LIGHTHOUSES.)

LIGHT-YEAR, an astronomical unit of length, the distance travelled by light in the course of one year, being equivalent to about six million million (6×10^{12}) miles. The distance of stars may be measured in terms of this unit or in terms of the parsec (*q.v.*).

LIGNE, CHARLES JOSEPH, PRINCE DE (1735–1814), soldier and writer, came of a princely family of Hainaut, and was born at Brussels in 1735. He distinguished himself at Breslau, Leuthen, Hochkirch and Maxen, and after the Seven Years' War rose to the rank of lieutenant field marshal. An intimate friend and counsellor of Emperor Joseph II., he lived luxuriously on his estates, returning to his military duties during the War of the Bavarian Succession, and again in 1784. During his travels in Europe he was a prominent figure both in society and in scholastic circles. In 1787 he was with Catherine II. in Russia, accompanied her in her journey to the Crimea, and was made a Russian field marshal by the empress. In 1788 he was present at the siege of Belgrade. Shortly after this he was invited to place himself at the head of the Belgian revolutionary movement, in which many of his relatives took part, but he declined. He was given the rank of field marshal (1809) and an honorary command at court, where he lived in comparative luxury devoting himself to literary work. He lived long enough to characterize the proceedings of the congress of Vienna with the famous *mot: "Le Congrès danse mais ne marche pas."* He died at Vienna on Dec. 13, 1814. His grandson, Eugene Lamoral de Ligne (1804–1880), was a distinguished Belgian statesman.

His collected works appeared in thirty-four volumes at Vienna during the last years of his life (*Mélanges militaires, littéraires, sentimentaires*), and selections were published in French and German, and in English (1927).

LIGNITE. Unfortunately the terms "brown coal" and "lignite" have come to be used interchangeably. Commonly speaking, all the immature coals of, chiefly, tertiary origin, whether black or brown, woody, amorphous, or having a conchoidal or cubical fracture, are called lignites.

Lignite is a French word, probably derived from *Lithanthrax Lignius* which, according to Hausmann was used by Wallerius (*Systema Mineralogicum*, Vol. 2 p. 98, 1775) for the woody type of coal. Thus the great mass of German brown coal is not lignite in the sense of being a woody coal which splits up into slabs on drying, but an amorphous brown earthy substance or brown coal containing bands of lignite. Many countries contain immature black coal, differing little in appearance from true bituminous coal, which is usually known by the name of "black lignite," an inappropriate designation seeing they have no woody structure. To these coals, the Geological Survey of the United States of America has applied the term "sub-bituminous" coal, restricting the word lignite to those coals of lower grade which are either lignitic in character or are brown coals, which would appear to afford a satisfactory distinction and definition (*see* the section *Lignite* under Coal and Coal Mining). (R. R.)

LIGONIER, JOHN (Jean Louis) **LIGONIER,** Earl, cr. 1766 (1680–1770), British field marshal, came of a Huguenot family settled in England. He served throughout Marlborough's campaigns in Flanders (1702–10). In 1720 he became colonel of the "Black Horse" (now 7th Dragoon guards), a command which he retained for a period of 29 years. At Fontenoy Ligonier commanded the British foot, and acted throughout the battle as adviser to the duke of Cumberland. During the "Forty-Five" he was called home to command the British army in the Midlands, but in Jan. 1746 was placed at the head of the British and British-paid contingents of the Allied army in the Low Countries. He was present at Roucoux (Oct. 11, 1746) and, as general of horse, at Val (July 1, 1747), where he led the charge of the British cavalry, his horse being killed and he himself taken prisoner, though exchanged in a few days. With the close of the campaign ended Ligonier's active career, but (with a brief interval in 1756–57) he occupied various high civil and military posts to the close of his life. In 1766 he became field marshal.

See Combes, *J. L. Ligonier, une étude* (Castres, 1866), and the histories of the 7th Dragoon guards and Grenadier guards.

LIGUORI, ALFONSO MARIA DEI (1696–1787), saint, was born at Marianella, near Naples, on Sept. 27, 1696, the son of Giuseppe dei Liguori, a Neapolitan nobleman. He studied law, passed his examination for the doctor's degree at the age of 16 and practised law for eight years. Giving up the bar, he was ordained priest in 1726. In 1732 he founded the Congregation of the Most Holy Redeemer, commonly called the Redemptorists, In 1762 he became bishop of Sant' Agata del Goti, a small town about 30 mi. east of Naples. He resigned this bishopric in 1775 and died on Aug. 1, 1787. He was canonized in 1839, and declared a doctor of the church in 1871. His feast is celebrated Aug. 2.

After his death his Congregation of the Most Holy Redeemer spread rapidly throughout the world. In 1945 it numbered more than 6,000 members.

Besides his congregation, Liguori is known especially for his spiritual writings. They have had an almost unparalleled circulation; up to 1939 his various works had gone through some 17,500 editions, and had been translated into 60 languages. His works fall into three classes. The first, in the field of moral theology, is headed by his *Theologia Moralis,* which first appeared in 1748, and went through nine editions in his lifetime, and more than 60 after his death; this he later summarized in a short work, *Praxis Confessarii.* The second is that of his ascetical or devotional writings, written for all classes of Catholics, priests, nuns, lay people, and including especially his *Visits to the Blessed Sacrament, The Glories of Mary, The True Spouse of Christ* (for nuns) and *The Selva* (for priests). The third class is that of his dogmatic writings, especially *History of Heresies* and his works on the infallibility of the pope; also his various works on the power of prayer. The latter theme he stressed so constantly throughout all his writings that he is known popularly as "The Doctor of Prayer."

Liguori was also a musician and poet. Many of the hymns he composed and put to music are still the favourites of the people of southern Italy. His Christmas hymn, *Tu Scendi dalle Stelle,* in particular, is as closely associated with Christmas in Italy as are *Adeste Fideles* and *Silent Night* in other countries.

Among Catholic theologians, Liguori is known as the founder of *equiprobabilism.* This is a system of principles designed to guide the conscience when in doubt as to whether free from, or bound by, a given law. The system is based on the legal axiom, "in doubt, the presumption favours the possessor." Applying it to doubts of conscience, Liguori laid down these three principles. (1) In a doubt with equally probable reasons pro and con, a person is free from the obligation of the law if he has been free from it hitherto,—for freedom is in possession, and the presumption favours the possessor. (2) In a doubt with equally probable reasons pro and con, a person is bound to keep the law if he has been bound by it hitherto,—for then the law is in possession. (3) In a doubt, when the reasons are not equally probable pro and con, but considerably more probable on the side of the obligation of the law, then the law must be kept.

Bibliography.—See *Lives* by A. M. Tannoia, a pupil of Liguori's, (3 vols., Naples 1798–1802) English translation by F. W. Faber (4 vols., London, 1848–49); also Villecourt (4 vols., Tournai, 1863); K. Dilgskron (2 vols., Regensburg, 1887); A. Capecelatro (2 vols., Rome, 1893); A. C. LIGURES BAEBIANI, a settlement of Ligurians in Samnium, Italy. The towns of Taurasia and Cisauna in Samnium had been captured in 298 B.C. by the consul L. Cornelius Scipio Barbatus, and the territory of the former remained Roman state domain. In 180 B.C. 47,000 Ligurians from Luna (Ligures Apuani), were transferred to this district, and two settlements were named after the consuls of 181 B.C., the Ligures Baebiani and the Ligures Corneliani.

The site of the former town lies 15 mi. N. of Beneventum, on the road to Saepinum and Aesernia. The site of the other settlement—that of the Ligures Corneliani—is unknown.

LIGURIA, a modern territorial division of Italy containing the provinces of Genoa, Imperia, Savona and Spezia, and once forming the republic of Genoa. It lies between the Ligurian Alps and the Apennines on the north, and the Mediterranean on the south, and extending from the frontier of France on the west to the Gulf of Spezia on the east. Its northern limits touch Piedmont and Lombardy, while Emilia and Tuscany fringe its eastern borders, the dividing line following as a rule the summits of the mountains.

The area of Liguria is 2,098 sq.mi. Pop. (1936) 1,466,915, as compared with 1,075,760 in 1901. The railway from Pisa skirts the entire coast of the territory, throwing off lines to Parma from Sarzana and Spezia, to Milan and Turin from Genoa and to Turin from Savona; there is also a line from Ventimiglia north to Cuneo and Turin by the Col di Tenda. Its sparsely-peopled mountains slope gently northward towards the Po, descending, however, abruptly into the sea at several points; the narrow coast district is famous under the name of the Riviera (*q.v.*).

The principal products of Liguria are maize, wine, oranges, lemons, fruits, olives and potatoes, though the olive groves are being rapidly supplanted by flower gardens. In the mountains the forests are important and considerable hydraulic power is also derived from the streams and used for railway traction, etc.

Copper, manganese and iron pyrites are mined: and Sardinian lead is smelted at Pertusola on the Gulf of Spezia. The principal industries are ironworks, foundries, iron shipbuilding, engineering and boilerworks (Genoa, Spezia, Sampierdarena, Sestri Ponente, etc.), railway signals (Savona) and the manufacture of cottons and woollens.

The inhabitants have always been adventurous seamen—Columbus and Amerigo Vespucci were Genoese—and the coast has several good harbours, Genoa, Spezia and Savona being the best. In educational and general development, Liguria stands high among the regions of Italy.

Archaeology and Philology.—In earlier times the Ligurians occupied a much more extensive area than the ninth Augustan region of Italy; for instance, Strabo gives earlier authorities for their possession of the land on which the Greek colony of Massalia (Marseille) was founded; and Thucydides speaks of a settlement of Ligurians in Spain who expelled the Sicani thence. Southward their domain extended as far as Pisa on the coast of Etruria and Arretium inland in the time of Polybius (ii. 6). Seneca (*Cons. ad Helv.* vii. 9), states that the population of Corsica was partly Ligurian. For the archaeological side of the question *see* GOLASECCA and COMACINES, THE. Archaeological evidence shows them to have been a part of the "Mediterranean race," and confirms the tradition as to the area they occupied. The Bronze age rock engravings near Ventimiglia (*q.v.*) are interesting. Their culture was much modified in the Iron age by a Celtic invasion, after which the two peoples were inextricably mixed.

On the linguistic side some fairly certain conclusions have been reached. We may note the frequency of the suffix *-asco-* (and *-usco-*) both in ancient and in modern Ligurian districts, and as far north as *Caranusca* near Metz, and also in the eastern Alps and in Spain. Most of the Ligurian proper names (*e.g.*, the streams, *Vinelasca, Porcobera, Comberamea; mons Tuledo; Venascum*) have a definite Indo-European character, as have those preserved in Latin inscriptions of the Ligurian districts, such as the *Tabula Genuatium* (C.I.L. I. 584) of 117 B.C. A complete collection of Ligurian place and personal names combined with the inscriptions of the district is printed in *The Pre-Italic Dialects*, edited by R. S. Conway and J. Whatmough. There is strong evidence in these names that the language spoken before the Roman conquest was Indo-European, and belonged to those languages which preserved the original *q* as Latin did, and did not convert it into *p* as did the Umbro-Safine tribes. The same is probably true of Venetia (*see* VENETI), and of an Indo-European language preserved on inscriptions found at Coligny and commonly referred to the Sequani. The "Lepontic" inscriptions found in a small area (50 m. by 35 m.) round the lakes of Como, Lugano, Maggiore and Orta, are also Ligurian, with Celtic affinities. The Ligurian ethnica show the prevailing use of the two suffixes *-co-* and *-ati-*, which there is reason to refer to the pre-Roman stratum of population in Italy. (*See* VOLSCI.)

The Ligurians were eventually restricted more and more to the county adjoining the Gulf of Genoa, and at last they occupied only an area bounded by the upper reaches of the Po and Ticino on the north, the Arno on the east, and the Alps and the Var on the west. They are described as thin and wiry, short of stature and dark complexioned, hardy and warlike people winning a difficult livelihood from the soil, but also interested in commerce, and some of them daring seafarers.

The Ligurian coast became gradually subject to the Romans, and the road along it must have been correspondingly prolonged: up to the end of the Hannibalic war the regular starting-point for Spain by sea was Pisae; in 195 B.C. it was the harbour of Luna (Gulf of Spezia), though Genua must have become Roman a little before this time, while, in 137 B.C. C. Hostilius Mancinus marched as far as Portus Herculis (Villafranca), and in 121 B.C. the province of Gallia Narbonensis was formed and the coast-road prolonged to the Pyrenees. In 14 B.C. Augustus restored the whole road from Placentia to Dertona (Via Postumia), and thence to Vada Sabatia (Via Aemilia [2]) and the River Varus (Var), so that it thenceforth took the name of Via Julia Augusta. (*See* AEMILIA, VIA [2].) The other chief roads of Liguria were the portion of the Via Postumia from Dertona to Genua, a road from above Vada through Augusta Bagiennorum and Pollentia to Augusta Taurinorum, and another from Augusta Taurinorum to Hasta and Valentia. The names of the villages—Quarto, Quinto, etc.—on the south-east and Pontedecimo on the north of Genoa allude to their distance along the Roman roads. Even the Roman Liguria, forming the ninth region of Augustus, was thus far more extensive than the modern, including the country on the north slopes of the Apennines and Maritime Alps between the Trebia and the Po, and extending a little beyond Albintimilium. On the west Augustus formed the provinces of the Alpes Maritimae and the Alpes Cottiae. Towns of importance were few, owing to the nature of the country. Dertona was the only colony, and Alba Pompeia, Augusta Bagiennorum, Pollentia, Hasta, Aquae Statiellae, and Genua may also be mentioned; but the Ligurians dwelt entirely in villages, and were organized as tribes. The mountainous character of Liguria made the spread of culture difficult; it remained a forest district, producing timber, cattle, ponies, mules, sheep, etc. Oil and wine had to be imported, and when the cultivation of the olive began is not known.

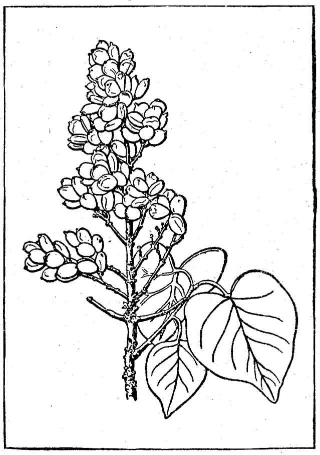
The arrangement made by Augustus lasted until the time of Diocletian, when the two Alpine provinces were abolished, and the watershed became the boundary between Italy and Gaul. At this time we find the name of Liguria extended as far as Milan, while in the 6th century the old Liguria was separated from it, and under the Lombards formed the fifth Italian province under the name of Alpes Cottiae. In the middle ages the ancient Liguria north of the Apennines fell to Piedmont and Lombardy, while that to the south, with the coast strip, belonged to the republic of Genoa.

LI HUNG CHANG (lē-hoong-chahng) (1823–1901), Chinese statesman, was born on Feb. 16, 1823 at Hofei, in Ngan-hui. In 1847 he became a Chin-shih, or graduate of the highest order, two years later entering Hanlin university. He raised a regiment of militia against the Taiping rebels, thus earning the good will of the commander-in-chief, Tseng Kuo-fan. In 1859 he was transferred to the province of Fu-kien, where he was given the rank of taotai, or intendant of circuit. But at Tseng's request Li was recalled to take part against the rebels. He found his cause supported by the "Ever Victorious Army," which, after having been raised by an American named Ward, was finally placed under the command of Charles George Gordon. With this support Li gained victories which led to the surrender of Suchow and the capture of Nanking. For these exploits he was made governor of Kiangsu, was decorated with the yellow jacket, and was created an earl. An incident connected with the surrender of Suchow left a lasting stain upon his character. By an arrangement with Gordon the rebel wangs, or princes, yielded Nanking on condition that their lives should be spared. In spite of the assurance given them by Gordon, Li ordered their instant execution. This breach of faith so enraged Gordon's indignation that he seized a rifle and would have shot Li if he had not saved himself by flight. On the suppression of the rebellion (1864) Li took up his duties as governor, but on the outbreak of the rebellion of the Nienfei, a remnant of the Taipings, in Ho-nan and Shan-tung (1866) he was ordered again to take the field, and suppressed the movement. A year later he was appointed viceroy of Hukwang, where he remained until 1870, when the Tientsin massacre led to his transfer to the scene. He was appointed to the viceroyalty of the metropolitan province of Chihli, where he actively repressed anti-foreign sentiment. For his services he was made imperial tutor and member of the grand council of the empire, and was decorated with many-eyed peacocks' feathers.

To his duties as viceroy were added those of the superintendent of trade, and from that time until his death, with a few intervals of retirement, he practically conducted the foreign policy of China. He concluded the Chifu convention with Sir Thomas Wade (1876), and thus ended the difficulty caused by the murder of Mr. Margary in Yunnan; he arranged treaties with Peru and Japan, and he actively directed the Chinese policy in Korea. On the death of the emperor T'ungchi in 1875 he effected the *coup d'état* by which the emperor Kwang Sü was put on the throne under the tutelage of the two dowager empresses; and in 1886, on the conclusion of the Franco-Chinese war, he arranged a treaty with France. When viceroy of Chihli he had raised a large, well-drilled and well-armed force, and spent vast sums both in fortifying Port Arthur and the Taku forts and in increasing the navy. For years he had watched the successful reforms effected in Japan, and he feared and hated a conflict. But in 1894 events forced his hand, and war broke out. Both on land and at sea the Chinese forces were ignominiously routed, and in 1895, on the fall of Wei-hai-wei, the emperor sued for peace. Li represented the emperor at the Shimonoseki conference.

With great diplomatic skill Li pleaded the cause of his country, but finally had to agree to the cession of Formosa, the Pescadores, and the Liaotung peninsula to the conquerors, and to the payment of an indemnity of 200,000,000 taels. By a subsequent arrangement the Liaotung peninsula was restored to China, in exchange for an increased indemnity. During the peace discussions at Shimonoseki an attempt was made on his life. He was wounded, but soon recovered. In 1896 Li represented the emperor at the coronation of the tsar, and visited Germany, Belgium, France, England and the United States of America. For some time after his return to China he was virtually constituted minister for foreign affairs; but in 1900 he was transferred to Canton as viceroy of the two Kwangs. The Boxer movement induced the emperor to recall him to the capital, and the peace of Sept. 1901 was largely secured by his efforts. He died on Nov. 7, 1901. He left three sons and one daughter.

LILAC or **PIPE TREE** (*Syringa vulgaris*), a shrub of the family Oleaceae. The genus contains over 25 species of ornamental hardy deciduous shrubs and trees, native in eastern Europe and temperate Asia. They have opposite, generally entire leaves and large panicles of small regular flowers, with a bell-shaped calyx and a 4-lobed cylindrical corolla, with the two stamens characteristic of the family attached at the mouth of the tube. The common lilac is said to have come from Persia in the 16th century, but is doubtfully indigenous in Hungary, the borders of Moldavia, etc.



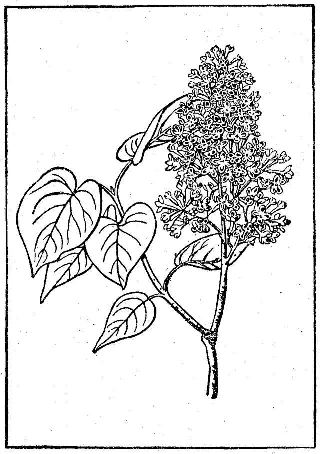
FROM COOPER AND WESTELL, "TREES AND SHRUBS OF THE BRITISH ISLES" (DENT & SONS, LTD.)
BRANCH OF THE LILAC (SYRINGA VULGARIS) SHOWING FRUIT

Two kinds of *Syringa,* viz. *alba* and *caerulea,* are figured and described by Gerard (*Herball,* 1597), which he calls the white and the blue pipe privets. The white is the common privet, *Ligustrum vulgare,* which, with the ash tree, *Fraxinus excelsior,* are the only members of the family found wild in Great Britain.

The "blue pipe privet" is the lilac, as both figure and description agree accurately with it. It was carried by the European colonists to northeast America, and is still grown in gardens of the northern and middle states.

There are many fine varieties of lilac, both with single and double flowers; they are among the commonest and most beautiful of spring-flowering shrubs.

The Persian lilac of gardens (*S. persica*), also known as the Chinese or Rouen lilac, a small shrub 4 to 6 ft. high with intense violet flowers appearing in May and June, is much cultivated for ornament.



FROM COOPER AND WESTELL, "TREES AND SHRUBS OF THE BRITISH ISLES" (DENT & SONS, LTD.)
BRANCH OF THE LILAC (SYRINGA VULGARIS) SHOWING INFLORESCENCE

Of other species, *S. josikaea* from Transylvania, has scentless bluish-purple flowers; *S. emodi,* a native of the Himalayas, is a handsome shrub with large ovate leaves and dense panicles of purple or white strongly scented flowers. Lilacs grow freely and flower profusely in almost any soil and situation, but when neglected are apt to become choked with suckers which shoot up in great numbers from the base.

They are readily propagated by means of these suckers. By far the most handsome lilacs, of which there are hundreds of varieties, are of hybrid, mostly French origin. Notable collections of these are found at Rochester, N.Y., and at the Arnold Arboretum, Jamaica Plain, Mass.

Syringa is also a common name for the mock orange, which are unrelated shrubs of the genus *Philadelphus.* (N. Tr.)

LILBURNE, JOHN (*c.* 1614–1657), English political agitator, born in the county of Durham, was apprenticed at 12 years old to a clothier in London, but he appears to have early addicted himself to the "contention, novelties, opposition of Government, and violent and bitter expressions" for which he afterwards became so conspicuous as to provoke the saying of Harry Marten (the regicide) that, "if the world was emptied of all but John Lilburn, Lilburn would quarrel with John, and John with Lilburn." He appears at one time to have been law-clerk to William Prynne. In Feb. 1638, for his share in importing and circulating *The Litany* and other publications of John Bastwick and Prynne, offensive to the bishops, he was sentenced by the Star Chamber to be publicly whipped from the Fleet prison to Palace Yard, Westminster, there to stand for two hours in the pillory, and afterwards to be kept in gaol until a fine of £500 had been paid. He did not regain his liberty until Nov. 1640, one of the earliest recorded speeches of Oliver Cromwell being made in support of his petition to the House of Commons (Nov. 9, 1640). In 1641 he received an indemnity of £3,000. He now entered the army, and in 1642 was taken prisoner at Brentford and tried for his life; sentence would no doubt have been executed had not the parliament by threatening reprisals forced his exchange. He soon rose to the rank of lieutenant-colonel, but in April 1645, having become dissatisfied with the predominance of Presbyterianism, and refusing to take the covenant, he resigned his commission, presenting at the same time to the Commons a petition for arrears of pay. His violent language in Westminster Hall led in July to his arrest and committal to Newgate. He was discharged in October. In Jan. 1647 he was committed to the Tower for a short time for accusations against Cromwell. In Feb. 1649 he along with other petitioners presented to the House of Commons a paper entitled *The Serious Apprehensions of a part of the People on behalf of the Commonwealth,* which he followed up with a series of pamphlets attacking the council. On April 11 he was again imprisoned, but was acquitted of sedition at his trial in the following October. In 1650 he was advocating the release of trade from the restrictions of chartered companies and monopolists.

In Jan. 1652 Lilburne was banished, but he returned from the Low Countries in 1653. He was immediately arrested; the trial (July 13–Aug. 20) issued in his acquittal, to the great joy of London, but it was nevertheless thought proper to keep him in captivity for "the peace of the nation." He was detained successively in the Tower, in Jersey, in Guernsey and in Dover castle. At Dover he came under Quaker influence, and in 1655, on giving security for his good behaviour, he was set free. He now settled at Eltham in Kent, where he died on Aug. 29, 1657.

His brother, Colonel Robert Lilburne, was among those who signed the death-warrant of Charles I. In 1656 he was M.P. for the East Riding of Yorkshire, and at the restoration was sentenced to lifelong imprisonment.

See Clement Walker, *The Compleat History of Independency,* vol. ii. (4 pts., 1661); W. Godwin, *History of the Commonwealth,* vol. iii. (4 vols., 1824–28); D. Masson, *Life of Milton,* vol. iv. (7 vols., 1859–94); Andrew Bisset, *Omitted Chapters of the History of England,* vol. i. (1864) of *History of the Commonwealth* (2 vols., 1867).

LILIACEAE, in botany, a family of Monocotyledons belonging to the series Liliiflorae, and generally regarded as representing the typical order of Monocotyledons. The plants are generally perennial herbs growing from a bulb or rhizome, sometimes shrubby as in butcher's broom (*Ruscus*) or tree-like as in species of *Dracaena, Yucca* or *Aloe.* The flowers are with few exceptions hermaphrodite, and regular with parts in threes, the perianth which is generally petaloid occupying the two outer whorls followed by two whorls of stamens, with a superior ovary of three carpels in the centre of the flower; the ovary is generally three-chambered with a number of anatropous ovules on axile placentas. The fruit is a capsule splitting along the septa (septicidal), or between them (loculicidal), or a berry; the seeds contain a small embryo in a copious fleshy or cartilaginous endosperm. Liliaceae is one of the larger families of flowering plants containing about 2,700 species in 233 genera being approximately one-eighth of the Monocotyledons; it is of world-wide distribution. It contains many useful plants (onion, leek, garlic) and garden plants (lily, tulip, hyacinth). The plants show great diversity in vegetative structure, which together with the character and mode of dehiscence of the fruit affords a basis for the subdivision of the family into tribes, eleven of which are recognized. The following are the most important tribes.

Melanthioideae.—The plants have a rhizome or corm, and the fruit is a capsule. Many are north temperate and three are represented in Britain, viz. *Tofieldia,* an arctic and alpine genus of small herbs with a slender scape springing from a tuft of narrow ensiform leaves and bearing a raceme of small green flowers; *Narthecium* (bog asphodel), herbs with a habit similar to *Tofieldia,* but with larger golden-yellow flowers; and *Colchicum,* a genus with about 30 species including the meadow saffron or autumn crocus (*C. autumnale*). *Colchicum* illustrates the corm-development which is rare in Liliaceae, though common in the allied family Iridaceae. *Gloriosa,* well known in cultivation, climbs by means of its tendril-like leaf-tips; it has handsome flowers with recurved orange-red or yellow petals; it is a native of tropical Asia and Africa. *Veratrum* is an alpine genus of the north temperate zone.

Asphodeloideae.—The plants generally have a rhizome bearing radical leaves, as in asphodel, rarely a stem with a tuft of leaves as in *Aloe,* very rarely a tuber (*Eriospermum*) or bulb (*Bowiea*). The flowers are borne in a terminal raceme, the anthers open introrsely and the fruit is a capsule, very rarely, as in *Dianella,* a berry. *Asphodelus* (asphodel) is a Mediterranean genus; *Simethis,* a slender herb with grassy radical leaves, is a native of west and southern Europe extending into south Ireland. *Anthericum* and *Chlorophytum,* herbs with radical often grass-like leaves and scapes bearing a more or less branched inflorescence of small generally white flowers, are widely spread in the tropics. Other genera are *Hosta,* native of China and Japan, cultivated in the open air in Britain; *Hemerocallis,* a small genus of central Europe and temperate Asia—*H. flava* is known in gardens as the day lily; *Phormium,* a New Zealand genus to which belongs New Zealand flax, *P. tenax,* a useful fibre-plant; *Kniphofia* (red-hot poker), South and East Africa, several species of which are cultivated; and *Aloe*. A small group of Australian genera closely approach the family Juncaceae in having small crowded flowers with a scarious or membranous perianth; they include *Xanthorrhoea* (grass-tree or black-boy) and *Kingia.*

FROM H. J. ELWES, "MONOGRAPH OF THE GENUS LILIUM"

LONG-FLOWERED WHITE LILY (LILIUM LONGIFLORUM). A, SCALY BULB, WITH TWO SMALL BULBS

Allioideae.—The plants grow from a bulb or short rhizome; the inflorescence is an apparent umbel formed of several shortened monochasial cymes and subtended by a pair of large bracts. The largest genus *Allium* has about 325 species—7 are British; *Agapanthus* or African lily is a well-known garden plant; in *Gagea,* a genus of small bulbous herbs found in most parts of Europe, the inflorescence is reduced to a few flowers or a single flower; *G. lutea* is a local and rare British plant.

Lilioideae.—Bulbous plants with a terminal racemose inflorescence; the anthers open introrsely and the capsule is loculicidal. It contains about 30 genera, several being represented in Britain. The typical genus *Lilium* and *Fritillaria* are widely distributed in the temperate regions of the northern hemisphere; *F. meleagris,* snake's head, is found in moist meadows in some of the southern and central English counties; *Tulipa* contains about 50 species in Europe and temperate Asia, and is specially abundant in the dry districts of central Asia; *Lloydia,* a small, slender alpine plant, widely distributed in the northern hemisphere, occurs on Snowdon in Wales; *Scilla* (squill) is a large genus, chiefly in Europe and Asia—*S. nutans* is the blue-bell or wild hyacinth; *Ornithogalum* (Europe, Africa and west Asia) is closely allied to *Scilla*—*O. umbellatum,* star of Bethlehem, is naturalized in Britain; *Hyacinthus* and *Muscari* are chiefly Mediterranean; *M. racemosum,* grape hyacinth, occurs in sandy pastures in the eastern counties of England. To this group belong a number of tropical and especially South African genera, such as *Albuca, Urginea, Drimia, Lachenalia* and others.

Dracaenoideae.—The plants generally have an erect stem with a crown of leaves which are often leathery; the anthers open introrsely and the fruit is a berry or capsule. It contains a small number of genera, several of which, such as *Yucca, Dracaena* and *Cordyline* include arborescent species in which the stem increases in thickness continually by a centrifugal formation of new tissue; an extreme case is afforded by *Dracaena Draco,* the dragon-tree of Teneriffe. *Yucca* and several allied genera are natives of the dry country of the southern and western United States and of Central America. *Dracaena* and the allied genus *Cordyline* occur in the warmer regions of the Old World.

Asparagoideae.—Plants growing from a rhizome; fruit a berry. *Asparagus* contains about 120 species in the dryer, warmer parts of the Old World; it has a short creeping rhizome, from which springs a slender, herbaceous or woody, often very much branched, erect or climbing stem, the ultimate branches of which are flattened or needle-like, leaf-like structures (cladodes), the true leaves being reduced to scales or, in the climbers, forming short, hard, more or less recurved spines. *Ruscus aculeatus* is butcher's broom, an evergreen shrub with flattened leaf-like cladodes, native of the southerly portion of England and Wales; the small flowers are unisexual and borne on the face of the cladode; the male contains three stamens, the filaments of which are united to form a short stout column on which are seated the diverging cells of the anthers; in the female the ovary is enveloped by a fleshy staminal tube on which are borne three barren anthers. *Polygonatum* and *Maianthemum* are allied genera with a herbaceous leafy stem and, in the former axillary flowers, in the latter flowers in a terminal raceme; both occur rarely in woods in Britain; *P. multiflorum* is the well-known Solomon's seal of gardens, so called from the seal-like scars on the rhizome of stems of previous seasons, the hanging flowers of which contain no honey, but are visited by bees for the pollen. *Convallaria* is lily of the valley; *Aspidistra,* native of the Himalayas, China and Japan, is a well-known pot plant; its flowers depart from the normal arrangement of the family in having the parts in fours (tetramerous). *Paris,* including the British Herb Paris (*P. quadrifolia*), has solitary tetra- to poly-merous flowers terminating the short annual shoot which bears a whorl of four or more leaves below the flower; in this and in some species of the nearly allied genus *Trillium* (chiefly temperate North America) the flowers have a fetid smell, which together with the dark purple of the ovary and stigmas and frequently also of the stamens and petals, attracts carrion-loving flies, which alight on the stigma and then climb the anthers and become dusted with pollen; the pollen is then carried to the stigmas of another flower.

Luzuriagoideae are shrubs or undershrubs with erect or climbing branches and fruit a berry. *Lapageria,* a native of Chile, is a favourite greenhouse climber with fine bell-shaped flowers.

Smilacoideae are climbing shrubs with broad net-veined leaves and small dioecious flowers in umbels springing from the leaf-axils; the fruit is a berry. They climb by means of tendrils, which are stipular structures arising from the leaf-sheath. *Smilax* is a characteristic tropical genus containing about 210 species; the dried roots of some species are the drug sarsaparilla.

The two tribes *Ophiopogonoideae* and *Aletroideae* are sometimes removed from the Liliaceae and placed in the family, Haemodoraceae. The plants have a short rhizome and narrow or lanceolate basal leaves; and they are characterized by the ovary being often half-inferior. They contain a few genera chiefly old world tropical and subtropical. The leaves of species of *Sansevieria* yield a valuable fibre and the tubers of *Ophiopogon japonicus* are edible. *See* K. Krause in Engler and Prantl, *Die Natürlichen Pflanzenfamilien,* ed. 2, 15a:227–386, fig. 81–161 (1930).

LILIENCRON, DETLEV VON (1844–1909), German poet and novelist, was born at Kiel on June 3, 1844. He entered the army and took part in the campaigns of 1866 and 1870–71, in both of which he was wounded. He retired with the rank of captain, and spent some time in America. On his return (1882) he entered the civil administration at Kellinghusen in Holstein, where he remained till 1887. After some time at Munich, he settled in Altona and then at Altrahistedt, near Hamburg, where he died on July 22, 1909. He first attracted attention by the volume of poems *Adjutantenritte und andere Gedichte* (1883), which was followed by several dramas, a volume of short stories, *Eine Sommerschlacht* (1886), and a novel, *Breide Hummelsbüttel* (1887). In the collections of short stories which appeared under the titles *Unter flatternden Fahnen* (1888), *Der Mäcen* (1889) and *Krieg und Frieden* (1891), he gave powerful, realistic studies of war. Liliencron is one of the greatest of modern German lyric poets; his *Adjutantenritte,* with its fresh original note, broke with the well-worn literary conventions which had been handed down from the middle of the century. His other volumes of lyrics were *Der Heidegänger* (1893), *Neue Gedichte* (1893), *Bunte Beute* (1903), and the posthumous *Gute Nacht* (1909). To this poetical work should be added the humorous epic in *Ottava rima, Poggfred* (1896; re-written and extended 1904). Liliencron's genius was essentially lyric. He has many exquisite lines, and many perfect stanzas, but few perfect long pieces. In much of his work the influence of the quiet landscape of Holstein is evident.

Liliencron's *Sämtliche Werke* were published in 14 vols. (1904–05), and edit. by R. Dehmel (8 vols., 1911–13). *See* studies by H. Spiero (Berlin and Leipzig, 1913, bibl.); H. Maynz (1920); I. Wichmann (1922). His published correspondence includes *Ausgewählte Briefe* (ed. Dehmel, 2 vols., 1910); *Liliencrons Briefe an seinen Verleger* (ed. W. Friedrich, 1910); *Unbegreiflich Herz,* letters to his first wife (ed. H. Spiero, 1925).

LILIENTHAL, OTTO (1848–1896), German inventor and aeronaut, was born at Auklam on May 23, 1848. With a view to studying the problem of equilibrium, Lilienthal made careful observations of the flight of birds, and succeeded in constructing an aeroplane in which a gliding flight could be maintained. Although his work was improved upon by Pilcher, to Lilienthal belongs the credit of demonstrating the superiority of arched over flat surfaces and of reducing gliding flight to regular practice. He made over 2,000 glides in safety, but on Aug. 9, 1896, his machine was upset by a sudden gust of wind, and he was killed near Rhinow. He was the author of a valuable book, *Der Vogelflug als Grundlage der Fliegekunst* (1889).

LILITH, a female demon of Jewish folk-lore, equivalent to the English vampire. The personality and name ("night-monster") are derived from a Babylonian-Assyrian demon Lilit or Lilu. Lilith was believed to have a special power for evil over children. The superstition was extended to a cult surviving among some Jews even as late as the 7th century A.D. In the Rabbinical literature Lilith becomes the first wife of Adam, but flies away from him and becomes a demon.

LILLE (L'Ile), a city of northern France, capital of the department of the Nord, 154 mi. N. by E. of Paris on the Northern railway. Pop. (1936) 200,757. Lille lies in a rich agricultural and industrial plain on the right bank of the Deûle. In 1030, Count Baldwin IV of Flanders surrounded with walls a little town which had arisen around the castle of Buc. In the first half of the 13th century, the town obtained communal privileges. Destroyed by Philip Augustus in 1213, it was rebuilt by Joanna of Constantinople, countess of Flanders, but besieged and retaken by Philip the Fair in 1297. After having taken part with the Flemings against the king of France, it was ceded to the latter in 1312. In 1369 Charles V, king of France, gave it to Louis de Male, who transmitted his rights to his daughter Margaret, wife of Philip the Bold, duke of Burgundy. Under Burgundian rule Lille prospered and its merchants were at the head of the London Hansa. Philip the Good made it his residence. With Flanders it passed from the dukes of Burgundy to Austria and then to Spain. After the death of Philip IV of Spain, Louis XIV reclaimed the territory and besieged Lille in 1667. He forced it to capitulate, but preserved its liberties. In 1708, after an heroic resistance, it surrendered to Prince Eugène and the duke of Marlborough. The treaty of Utrecht restored it to France.

In World War I Lille was first reached by advance German patrols in Aug., 1914. It was afterwards re-occupied by the French, but they retired again early in Oct., the serious defense of the city not being part of the general plan of campaign. After several days' bombardment the Germans entered on Oct. 12, 1914, and remained till Oct., 1918, when they were outflanked by the Allied capture of neighbouring towns. The deportation of a large number of citizens in 1916 was the culminating point of tyranny suffered by the people of Lille under war conditions.

The city was a favourite resort for German officers on leave, as it was not shelled by the Allies, although it was within range of the guns.

Lille is the headquarters of the I army corps, and has an enceinte and a pentagonal citadel, one of Vauban's finest works, west of the town, across the Deûle. Before 1858 the town, fortified by Vauban about 1668, occupied an elliptical area of about 2,500 yd. by 1,300, with the church of Notre Dame de la Treille in the centre, but the southern ramparts and ditches were replaced by the Boulevard de la Liberté, a straight line from the goods railway station to the citadel. The new enceinte encloses the old communes of Esquermes, Wazemmes and Moulins-Lille, the area of the town being thus more than doubled and boulevards and squares added. The district of St. André to the north is the only elegant part of the old town. Outside the enceinte populous suburbs surround the city and on the north and east demolition of fortifications and rapid building are making Lille expand towards Roubaix and Tourcoing. At the demolition of the southern fortifications, the Paris gate, erected in 1682 in honour of Louis XIV, after the conquest of Flanders, was preserved. On the east are the Ghent (1617) and Roubaix (1622) gates, in Renaissance style, in bricks of different colours. On the same side the Noble-Tour is a relic of the mediaeval ramparts. There are water gates for the canal of the Deûle and for the Arbonnoise, which extends into a marsh in the southwest. The citadel, with barracks and arsenal, is surrounded by public gardens. The churches possess valuable pictures and the modern cathedral of Notre Dame de la Treille has an ancient statue of the virgin, an object of pilgrimage. Lille was made a bishopric in 1913. The Bourse (17th century) is built round a courtyard; the Hôtel d'Aigremont, the Hôtel Gentil and other houses are in the Flemish style; the Hôtel de Ville was destroyed in the explosion of a munition dump in 1916 but a part of an old palace of Philip the Good (15th cent.) near to it still remains. The Palais des Beaux-Arts contains a museum and picture galleries including a unique collection of original designs of the great masters and a celebrated wax model of a girl's head usually attributed to some Italian artist of the 16th century. Many pictures were removed before the French evacuated Lille in 1914 and the galleries were largely restored after the end of the war in 1918. The large military hospital was once a Jesuit college.

Lille is the seat of a prefect and has tribunals of first instance and of commerce, a board of trade arbitrators, a chamber of commerce and a branch of the Bank of France. It is the centre of an académie (educational division) and has a university with faculties of laws, letters, science and medicine and pharmacy, together with a Catholic institute comprising faculties of theology, law, medicine and pharmacy, letters, science, a technical school, and a department of social and political science. There are also a higher school of commerce, a national technical school, schools of music and fine arts, and the industrial and Pasteur institutes.

The chief industries are the spinning of flax and the weaving of cloth, table-linen, damask, ticking and flax velvet. The spinning of flax thread for sewing and lace-making is specially connected with Lille. The manufacture of woollen fabrics and cotton-spinning and the making of cotton-twist of fine quality are also carried on. There are important printing establishments, state factories for the manufacture of tobacco and the refining of saltpetre and very numerous breweries, chemical, oil, white lead and sugar-works, distilleries, bleaching-grounds, dye-works, machinery and boiler works. Plant for sugar-works and distilleries, military stores, steam-engines, locomotives, and bridges of all kinds are produced by the company of Fives-Lille. Lille is one of the most important junctions of the Northern railway, and the Deûle canal affords communication with neighbouring ports and with Belgium. Trade is chiefly in the raw material and machinery for its industries, in the products thereof, and in the wheat and other agricultural products of the surrounding district.

LILLEBONNE, a town of France in the department of Seine-Inférieure, $3\frac{1}{2}$ mi. N. of the Seine and 24 mi. E. of Le Havre by the Western railway. Pop. (1936) 5,033. It lies in the valley of the Bolbec at the foot of wooded hills. Lillebonne—under the Romans, *Iuliobona*—was the capital of the Caletes in the time of Caesar, by whom it was destroyed. Rebuilt by Augustus, it became an important focus of Roman roads, but was later ruined by barbarian invasion. The remains of ancient baths and of a great theatre have been brought to light, and many Roman and Gallic relics found. The mediaeval fortifications were built of materials from the theatre.

The church of Notre-Dame has a 16th century tower and portal; the donjon of a 13th century castle stands in the park. The principal industries are cotton-spinning and the manufacture of calico and candles.

LILLIBULLERO or **LILLIBURLERO,** the name of a song popular at the end of the 17th century, especially among the army and supporters of William III. in the war in Ireland during the revolution of 1688. The tune appears to have been much older, and was sung to an Irish nursery song at the beginning of the 17th century. The attribution to Henry Purcell is based on the very slight ground that it was published in *Music's Handmaid,* 1689, as "A new Irish Tune" by Henry Purcell.

The doggerel verses have generally been assigned to Thomas Wharton, and deal with the administration of Talbot, earl of Tyrconnel, appointed by James as his lieutenant in Ireland in 1687. The refrain of the song *Lilliburlero bullen a la* gave the title of the song. Wharton claimed he had "sung a king out of three kingdoms" and Burnet says "perhaps never had so slight a thing so great an effect." The air was introduced with success by Gay (*q.v.*) into *The Beggar's Opera.*

LILLO, GEORGE (1693–1739), English dramatist, son of a Dutch jeweller, was born in London on Feb. 4, 1693. He was brought up to his father's trade and was for many years a partner in the business. His first piece, *Silvia, or the Country Burial,* was a ballad opera produced at Lincoln's Inn Fields in Nov. 1730. On June 22, 1731, his domestic tragedy, *The Merchant,* renamed later *The London Merchant, or the History of George Barnwell,* was produced by Theophilus Cibber and his company at Drury Lane. The piece is founded on "An excellent ballad of George Barnwell, an apprentice of London who . . . thrice robbed his master, and murdered his uncle in Ludlow." Lillo went back to the Elizabethan domestic drama of passion of which the *Yorkshire Tragedy* is a type. Scoffing critics called it, with reason, a "Newgate tragedy," but it was regularly acted for many years at holiday seasons for the moral benefit of the apprentices. The last act contained a scene, generally omitted on the London stage, in which the gallows actually figured. In 1734 Lillo celebrated the marriage of the Princess Anne with William IV. of Orange in *Britannia and Batavia,* a masque. His other dramas were: *The Christian Hero* (1735), *Fatal Curiosity* (1736), an adaptation of *Pericles, Prince of Tyre,* with the title *Marina* (1738) and *Elmerick, or Justice Triumphant* (1740). Lillo died on Sept. 3, 1739. He left an unfinished version of *Arden of Feversham,* which was completed by Dr. John Hoadly and produced in 1759. Lillo has a certain cosmopolitan importance, for the influence of *George Barnwell* can be traced in the sentimental drama of both France and Germany.

See *Lillo's Dramatic Works with Memoirs of the Author by Thomas Davies* (reprint by Lowndes, 1810); Leopold Hoffmann, *George Lillo* (Marburg, 1888); Paul von Hofmann-Wellenhof, *Shakspere's Pericles und George Lillo's Marina* (1885).

LILLY, WILLIAM (1602–1681), English astrologer, was born in 1602 at Diseworth in Leicestershire. He received a tolerably good classical education at the school of Ashby-de-la-Zouche. In his eighteenth year, his father having fallen into great poverty, he went to London and was employed in attendance on an old citizen and his wife. His master, at his death in 1627, left him an annuity of £20; and, Lilly having soon afterwards married the widow, she, dying in 1633, left him property to the value of about £1,000. He now began to dabble in astrology, reading all the books on the subject he could find, and particularly studying Valentine Naibod's *Commentary on Alchabitius.* He then began to issue his prophetical almanacs and other works, which met with serious attention from some of the most prominent members of the Long Parliament. The chief difference between Lilly and the mass of the community at the time was that, while others believed in the general truth of astrology, he ventured to specify the future events to which its calculations pointed. Even from his own account of himself, however, it is evident that he did not trust implicitly to the indications given by the aspects of the heavens, but kept his eyes and ears open for any information which might make his predictions safe.

After the Restoration Lilly very quickly fell into disrepute. His sympathy with the parliament, which his predictions had generally shown, was not calculated to bring him into royal favour. He came under the lash of Butler, who, making allowance for some satiric exaggeration, has given in the character of Sidrophel a probably not very incorrect picture of the man; and, having by this time amassed a tolerable fortune, he bought a small estate at Hersham in Surrey, to which he retired, and where he diverted his talents to the practice of medicine. He died in 1681.

Lilly's life of himself, published after his death, is still worth looking into as a remarkable record of credulity. In 1852 a prominent London publisher put forth a new edition of Lilly's *Introduction to Astrology,* "with numerous emendations adapted to the improved state of the science."

LILOAN, a municipality of the province and island of Cebu, Philippine Islands, 10 mi. N.E. of Cebu, the provincial capital. Pop. (1939) 13,662. One of the principal coal deposits on the island is at Liloan, but the main industry is fishing. The agricultural products include palay (rice), maize (corn), sugar, coffee, coco-nuts and tropical fruits. Cebuano, a dialect of Bisayan, is the vernacular. Of the inhabitants aged 6 to 19 inclusive, 25·1% in 1939 attended school. Of the total population 10 years old and over, 36·1% was literate.

LILY, *Lilium,* the typical genus of the family Liliaceae, embracing nearly 60 species, all confined to the northern hemisphere, and widely distributed throughout the north temperate zone. The earliest in cultivation were described in 1597 by Gerard (*Herball,* p. 146), who figures eight kinds of true lilies, which include *L. candidum* and a variety, *bizantinum,* two umbellate forms of the type *L. bulbiferum,* named *L. aureum* and *L. cruentum latifolium,* and three with pendulous flowers, apparently forms of the martagon lily. Parkinson, in his *Paradisus* (1629), described five varieties of martagon, six of umbellate kinds—two white ones, and *L. pomponium, L. chalcedonicum, L. carniolicum* and *L. pyrenaicum*—together with one American, *L. canadense,* introduced in 1629. For the ancient and mediaeval history of the lily, *see* M. de Cannart d'Hamale's *Monographie historique et littéraire des lis* (Malines, 1870). Later authorities for description and classification of the genus are J. G. Baker ("Revision of the Genera and Species of Tulipeae," *Journ. of Linn. Soc.* xiv, p. 211, 1874), and J. H. Elwes (*Monograph of the Genus Lilium,* 1880). Information on the cultivation of lilies and their diseases will be found in the report of the Conference on Lilies, in the *Journal of the Royal Horticultural Society,* 1901, in L. H. Bailey, *The Standard Cyclopaedia of Horticulture,* 1933, and in Helen M. Fox, *Garden Cinderellas,* 1932.

The structure of the flower represents the simple type of monocotyledons, consisting of two whorls of petals, of three free parts each, six free stamens, and a consolidated pistil of three carpels, ripening into a three-valved capsule containing many winged seeds. In form, the flower assumes three types: trumpet-shaped, with a more or less elongated tube, e.g., *L. longiflorum* and *L. candidum;* an open form with spreading perianth leaves, e.g., *L. auratum;* or assuming a pendulous habit, with the tips strongly reflexed, *e.g.,* the martagon type. All have scaly bulbs, which in three west American species, as *L. humboldti,* are remarkable for being somewhat intermediate between a bulb and a creeping rhizome. *L. bulbiferum* and its allies produce aerial reproductive bulbils in the axils of the leaves. The bulbs of several species are eaten, such as of *L. avenaceum* in Kamchatka, of *L. martagon* by the Cossacks, and of *L. tigrinum,* the tiger lily, in China and Japan. Medicinal uses were ascribed to the species, but none appear to have any marked properties in this respect.

The white lily, *L. candidum,* was one of the commonest garden flowers of antiquity, appearing in the poets from Homer downwards side by side with the rose and the violet. According to Hehn, roses and lilies entered Greece from the east by way of Phrygia, Thrace and Macedonia (*Kulturpflanzen und Hausthiere,* 3rd ed., p. 217). Mythologically the white lily, *Rosa junonis,* was fabled to have sprung from the milk of Hera. As the plant of purity it was contrasted with the rose of Aphrodite. The word *κρίνον*, on the other hand, included red and purple lilies, Plin. *H.N.* xxi, 5 (11, 12), the red lily being best known in Syria and Judaea (Phaselis). This perhaps is the "red lily of Constantinople" of Gerard, *L. chalcedonicum.* The lily of the Old Testament (shôshan) may be conjectured to be a red lily from the simile in Cant. v, 13, unless the allusion is to the fragrance rather than the colour of the lips, in which case the white lily must be thought of. The "lilies of the field," Matt. vi, 28, are *κρίνα,* and the comparison of their beauty with royal robes suggests their identification with the red Syrian lily of Pliny. Lilies are not a conspicuous feature in the flora of Palestine, and the red anemone (*Anemone coronaria*), which dots all of the hillsides of Galilee in the spring, is more likely to have suggested the figure.

The noble *L. auratum,* with its large white flowers, having a yellow band and numerous red or purple spots, is a magnificent plant when grown to perfection; and, so are the varieties called *rubro-vittatum* and *cruentum,* which have the central band crimson instead of yellow; and the broad-petalled *platyphyllum,* and its almost pure white sub-variety called *virginale.* Of *L. speciosum* (well known to most gardeners as *lancifolium*), the true typical form and the red-spotted and white varieties are grand plants for late summer blooming.

The tiger lily, *L. tigrinum,* and its varieties *fortunei, splendidum* and *florepleno,* are among the best species for the flower garden.

The pretty *L. leichtlinii* and *L. monadelphum* with drooping yellow flowers and the scarlet drooping-flowered *L. tenuifolium* make up, with those already mentioned, a series of the finest hardy flowers of the summer garden. The Indian *L. giganteum* is perfectly distinct in character, having broad heart-shaped leaves, and a noble stem 10 to 14 ft. high, bearing a dozen or more large deflexed, funnel-shaped, white, purple-stained flowers; *L. cordifolium* (China and Japan) is similar in character, but dwarfier in habit.

The word "lily" is loosely used in connection with many plants which are not really members of the genus *Lilium,* but belong to genera which are quite distinct botanically.

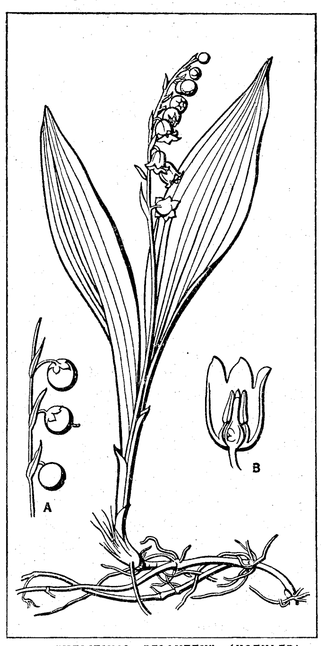
Thus, the Lent lily is a *Narcissus;* the African lily is *Agapanthus africanus;* the Belladonna lily is *Amaryllis belladonna* (*see* AMARYLLIS); the Jacobaea lily is *Sprekelia formosissima;* the Mariposa lily is *Calochortus;* the Peruvian lily is *Alstroemeria;* St. Bernard's lily is *Anthericum liliago;* St. Bruno's lily is *Paradisea liliastrum;* the water lily is *Nymphaea;* the giant water lily of the Amazon is *Victoria regia* (*q.v.*); the arum lily is *Zantedeschia aethiopica;* and there are many others, among them the day lilies (*Hemerocallis*).

No true lily is found native in Great Britain. In North America about 20 native species occur. In the eastern half of the continent the best-known are the wood lily (*L. philadelphicum*), the meadow lily (*L. canadense*), the American Turk's-cap lily (*L. superbum*) and Gray's lily (*L. grayi*). Noteworthy among the ten native lilies found in the Pacific states are the Washington lily (*L. washingtonianum*), the Columbia lily (*L. columbianum*) and the Humboldt lily (*L. humboldti*).

LILYE or LILY, **WILLIAM** (*c.* 1468–1522), English scholar, was born at Odiham in Hampshire. He entered the University of Oxford in 1486, and after graduating in arts went on a pilgrimage to Jerusalem. On his return he put in at Rhodes, which was still occupied by the knights of St. John, under whose protection many Greeks had taken refuge after the capture of Constantinople by the Turks. He then went on to Italy, where he attended the lectures of Sulpitius Verulanus and Pomponius Laetus at Rome, and of Egnatius at Venice. After his return he settled in London (where he became intimate with Thomas More) as a private teacher of grammar, and is believed to have been the first who taught Greek in that city. In 1510 Colet, dean of St. Paul's, who was then founding the school which afterwards became famous, appointed Lilye the first high master. He died of the plague on Feb. 25, 1522.

Lilye is famous not only as one of the pioneers of Greek learning, but as one of the joint authors of a book, familiar to many generations of students during the 19th century, the old Eton Latin grammar. The *Brevissima Institutio,* a sketch by Colet, corrected by Erasmus and worked upon by Lilye, contains two portions, the author of which is indisputably Lilye. His verse *Antibossicon ad Gulielmum Hormannum* (1521) is directed against a rival schoolmaster and grammarian, Robert Whittington, who had "under the feigned name of Bossus, much provoked Lilye with scoffs and biting verses."

See the sketch of Lilye's life by his son George, canon of St. Paul's, written for Paulus Jovius who was collecting for his history the lives of the learned men of Great Britain; and the article by J. H. Lupton, formerly sur-master of St. Paul's School, in the *Dict. Nat. Biog.*



FROM "MEDIZINAL PFLANZEN" (KOEHLER)
LILY OF THE VALLEY, SHOWING UNDERGROUND STEM
A, a spray with fruit
B, vertical section through flower

LILY OF THE VALLEY (*Convallaria majalis*), a beautiful plant of the lily family (Liliaceae), native to woods in some parts of England, Europe, northern Asia and in the higher Allegheny mountains of North America. It is widely cultivated for its dainty, white, nodding, fragrant flowers, borne in spring on slender stalks, which, like the two oblong basal leaves, rise from an underground creeping stem.

LIMA, a coast department of central Peru; area, 15,048 sq.mi.; population (1940), 849,171. The coastal plain is for the most part narrow and covered in many places by vast alluvial fans, built by streams which originate in the western watershed of the Cordillera; spurs from the Andes interrupt the lowland at irregular intervals. The department lies within the belt of arid climates which extends southward along the west coast of South America from the Gulf of Guayaquil to central Chile. Nowhere along the coast of Lima does the average annual rainfall exceed two inches, and many years may pass during which there is no measurable rainfall. From June to October fog and stratus clouds are frequent phenomena along the coast and lower slopes of the Cordillera. In a zone of variable width along the western slopes of the mountains (roughly between 2,500 and 4,500 ft. above sea level, but varying with latitude) the clouds come in direct contact with the ground, producing a drenching mist (*garua*) which supports a lush growth of herbaceous annuals (*loma*). Above the zone of the *lomas* there is a regular rainy season from October to April. Thus the two zones complement each other in providing pasturage for the considerable livestock industry of the *sierra*. Agriculture in the arid coastal zone antedates the rule of the Incas, but the irrigation works and terraced gardens of the Indians were ruined by neglect during the first centuries of Spanish occupation. The period of commercial agriculture dates from about 1885, at which time the white and mestizo landowners began to grow sugar cane, cotton, fruits, vegetables and forage crops in the coastal oases. With the development of irrigation works, many of which have been subsidized by the government, tens of thousands of acres of desert land have been brought under cultivation, with cotton ranking first in acreage and value of crops produced. (R. W. RD.)

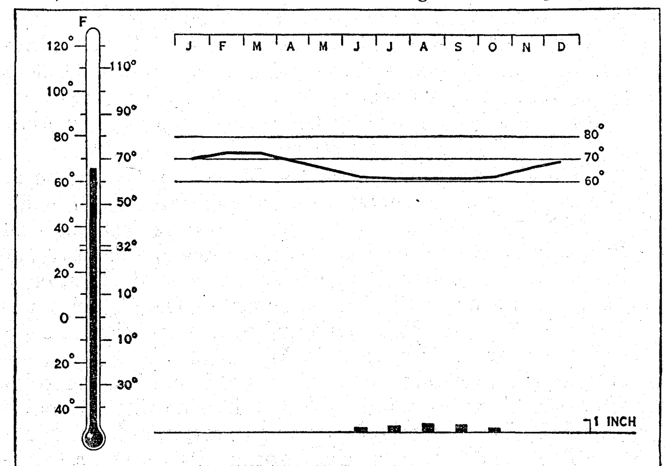
LIMA (a corruption of Rimac), capital of Peru and of the department of Lima (12° 2′ 34″ S., 77° 7′ 36″ W.), on the Rimac, a river in summer, a rivulet in winter, is 8½ mi. from its seaport, Callao (*q.v.*). In the desert coast zone, nearly 500 ft. above sea level, the city is surrounded by an irrigated plain, out of which rise, here and there, rugged hills, among them San Cristóbal (1,411 ft.) just north of the city. Population (1940) 533,645. The climate is moderate, the mean annual temperature being 66° F; it seldom drops below 54° or rises above 80°. Though there is almost no precipitation, the sky is overcast during the winter, when fogs and high relative humidity make it seem colder than it is.

History.—Lima was founded as the City of the Kings by Francisco Pizarro on Jan. 18, 1535, on the left bank of the Rimac. He traced the outlines of the chief plaza (*Plaza de Armas*) and the checkerboard of streets enclosing square areas (*manzanas*) with open plazas at intervals, a pattern which still survives. On the same day he laid the cornerstone of the cathedral, consecrated in 1625, where his remains may still be seen. Lima became the luxurious capital of the viceroys, the first of whom arrived in 1544. The obligatory centre of Spanish trade on the entire continent, it was the focus of Spanish colonization in South America. By a grant from Charles V, the Universidad Mayor de San Marcos was founded in 1551 under Dominican direction and secularized in 1571. The first archbishop was appointed in 1545. In 1570 the Inquisition was established. As vast wealth from the mines accumulated, the city was embellished with elaborate balconies and carved stone portals, while churches and monasteries glittered with gold and silver. Stone bridges were built across the Rimac; that of 1610 is still standing. Meanwhile, for protection against attacks of foreign pirates, the Duque de la Palata (viceroy 1681–89), built the city walls which stood until 1870, when they were razed and replaced by the present boulevards. This metropolis of a colonial empire was destroyed by earthquake on Oct. 28, 1746, and little in the present city antedates that catastrophe.

During Peru's struggle for independence Lima was the centre of Spanish resistance, and even after independence was declared (1821), it remained rigidly conservative. The era of reconstruction was followed by a vast influx of money from guano deposits, which resulted in some public improvements, such as the railway to Callao (1851), lighting and water systems. The city has suffered from all the revolutions which have convulsed Peru under the republic, but the greatest calamity was its occupation by a Chilean army from Jan. 17, 1881, to Oct. 22, 1883. During that time public buildings and scientific, literary and artistic collections were systematically pillaged. The spirit, as well as much of the history of Lima, is embodied in the six volumes of *Tradiciones Peruanas* by Ricardo Palma.

Streets, Buildings and Public Utilities.—The present city is a curious blend of old and new. The streets, about 30 ft. wide, are paved with stone or asphalt. Most of them have a different name on every block. The houses are usually one story in height, of adobe covered with plaster, built about a patio with plants and flowers, and barred outer windows. The better ones are two storys high, with balconies overlooking the street. The Torre-Tagle mansion, now the foreign office, is the best remaining example of secular colonial architecture. The *Plaza de Armas* is still the centre of Lima, from which tram and omnibus lines radiate. It is surrounded by the cathedral on the east, the archbishop's palace, municipal building, government palace (Palace of the Viceroys), recently rebuilt and enlarged; shops and arcades. On the *Plaza de la Inquisición* is the ancient Inquisition building, now the senate house, and the chamber of deputies is near by.

All the plazas of Lima have fountains, shrubs and flowers, and some, statues of national heroes including Manco Capac, Bolívar,



WEATHER GRAPH OF LIMA. THE THERMOMETER INDICATES THE ANNUAL MEAN TEMPERATURE. THE CURVE SHOWS THE NORMAL MONTHLY TEMPERATURE, AND THE COLUMNS, THE NORMAL MONTHLY PRECIPITATION. MONTHS NOT ACCOUNTED FOR IN COLUMN HAVE A "TRACE" OF PRECIPITATION, LESS THAN 0.1 INCH

San Martín and Bolognesi. Many wide avenues, paved with concrete, are favourite promenades. The *Paseo Colón,* 1 mi. long, 150 ft. wide, with a statue of Columbus, is bordered by trees, flowers and beautiful residences. At one end is the Exposition park, 30 ac. of gardens, walks, artificial lakes, the national museum, mining and metallurgy exposition building and a zoological garden. A favourite promenade for the poorer classes is the *Alameda de los Descalzos,* north of the river, a shady avenue with statues and marble benches, leading to the monastery of the barefoot friars. Several concrete or asphalt highways have been built to neighbouring towns and suburbs, such as the *Avenida del Progreso* to Callao and *Avenida Leguía* to Miraflores, five miles to the south. Electric tramways and buses run to Miraflores, Barranco and Chorrillos, to Magdalena and through Callao to La Punta, all of which are bathing and yachting resorts. In and about Lima there are more than 90 mi. of street railways.

During winter, the favourite resort is Chosica, 30 mi. east of Lima on the Central railway, with a sunny climate above the fogs. Chosica may also be reached by the Central highway. Peruvians are fond of sports, especially association football. There is a modern country club with tennis courts, golf links and polo field. The Jockey club has a racecourse with large grandstand, but the best races are now held at the *Hipódromo San Felipe,* recently built by the government. The bull ring, *Plaza de Toros* in Alameda de Acho, built in 1768, holds 8,000 people. There are several theatres of the better class, and a score of cinemas. The ancient City of the Kings is beginning to take on a modern appearance, with tall office buildings, banks, schools, dwellings, excellent hotels, tobacco monopoly headquarters, post and telegraph office, and a large central market housed in a two-story building which covers an entire block.

An enlarged water supply involved building two reservoirs of reinforced concrete, of 26,000,000 and 13,000,000 litres capacity, additional collecting galleries, a new aqueduct, and renewing 62 mi. of pipe. A 16 in. main has also been built to Miraflores.

Churches and Other Institutions.—In spite of these modern improvements, the past still presides over Lima. More than 50 Spanish colonial churches are scattered throughout the city, among which are Santo Domingo, San Francisco, La Merced, San Agustín and the Sanctuary of Santa Rosa de Lima, built on the site of the house where she was born in 1586, besides monasteries and convents of which that of San Francisco is the largest. Freedom of worship was granted to Protestants in 1915, and there are now seven Protestant churches. Among the clubs, some of which are located on the *Plaza de Armas,* should be mentioned the National, founded 1855, Union, 1868, and many foreign clubs such as the Phoenix (British) club. Learned societies include the Athenaeum, founded (1877) as a literary organization, the Historical institute (1905) and the Geographical society (1888), with a library of 10,000 volumes, 2,000 maps and a small museum as well as a seismological observatory. Its bulletins are a treasure house of information. The Corps of Mining and Hydraulic Engineers (1902) also issues bulletins indispensable to a student of the field. There is a national academy of medicine (1885), an outgrowth of that established by Dr. Unánue in 1787, engineers' and lawyers' clubs, a geological society and many more.

Education.—The University of San Marcos (1551) has faculties of theology, jurisprudence, medicine, political and economic science, philosophy, history and letters, mathematical, physical and natural sciences, and institutes of pharmacy and dentistry. It has a library, two museums, a department of physical education, a gymnasium and a meteorological observatory. The Catholic university has faculties of letters, jurisprudence and political science. A school of engineering was established in 1876 with departments of mines, civil engineering and architecture. There is a school of scientific agriculture, a military school in Chorrillos, a naval academy in La Punta, a school of arts and crafts, a popular university, established in 1921, a school of fine arts (1918), a teachers' college (1905), normal schools, a reform school for boys, the Jorge Chávez school of aviation, a national academy of music and conservatory, business and language schools, numerous secondary schools for boys, the largest of which is Guadalupe (1841) and some for girls, though the majority of schools for girls are convents or private schools. There are in all ten museums, which include collections of Peruvian antiquities, arts, costumes and paintings of scenes and characters in national history. The Lima charity organization maintains public hospitals, including the Arzobispo Loayza, modern in design and equipment. There are many private hospitals, eight volunteer fire companies, five large markets and a modern prison. The National library, founded in 1821 and destroyed by the Chileans in 1881, was razed by fire on May 10, 1943, destroying the library's valuable collection of some 120,000 volumes. A new library is being built on the same site. There is postal and telegraphic service with cable connection at Callao, and wireless communication from a high-power station near Lima. Lima's airport, 3 mi. from the city at Limatambo, is the west coast terminus of the new Panagra-Panair transcontinental air service. There are many newspapers, chief among them *El Comercio* (1839), and periodicals devoted to various interests, some illustrated, some published in foreign languages.

Trade, Industry and Finance.—Hydroelectric power for city lighting and tramways, as well as for industrial purposes, is furnished by the Lima Light, Power and Tramways company, transferred by high-tension wires from Chosica and Yanacoto. Business is chiefly in the hands of wholesale houses, both native and foreign, which export raw products and import manufactured goods. They have chains of branch houses throughout the republic. Many of these have fine buildings in Lima, as do also insurance companies, construction firms and large corporations, both national and foreign, whose activities are elsewhere in the republic.

The most important manufacturing industry is textiles; eight cotton and two woollen mills have a total production of more than 30,000,000 yd. a year. Other industries are tanneries, factories for making shoes and leather articles, hats, furniture, chocolate and biscuits, tile, candles, soap and powder; also oil refineries, coke ovens and railway shops, flour mills, distilleries and breweries.

The *Estanco del Tabaco,* subsidiary of the National Tax Collecting company, has a factory in Lima which produces cigarettes and cigars. Some recently established industries include factories for making glass, Portland cement, aluminum articles for household use, rubber goods, hosiery and chemicals (caustic soda and chloride of lime). There are shops of all sizes and a merchants' association, as well as many workmen's protective associations.

The principal banks, with branches in other cities, are the Bank of London and South America; Italian bank (1889), now the Credit Bank of Peru; Popular bank (1899); Royal Bank of Canada (1916); National City bank (1920). The *Caja de Ahorros* (Savings bank) was established in 1868, the *Caja de Depósitos y Consignaciones* (a depository for government trust funds such as customs receipts, internal taxes, tobacco and salt revenues) in 1905 and the Reserve bank in 1922 (*see* also PERU).

(M. T. BI.; X.)

LIMA, a city of northwestern Ohio, U.S.A., 79 mi. S.S.W. of Toledo; the county seat of Allen county. It is on federal highways 25 and 30S (the Harding), and is served by the Baltimore and Ohio, the Detroit, Toledo and Ironton, the Erie, the Nickel Plate and the Pennsylvania railways, and by motor truck and bus lines. Pop. (1940) 44,711 by federal census. The principal crops of the vicinity are corn, oats, wheat, soybeans, onions, sugar beets and potatoes. Lima supports over 100 diversified industries, including the manufacturing of steam locomotives, diesel engines, cigars, electric and neon signs, steam shovels, steel castings, school and highway buses, electric motors, rubber and petroleum products. At one time it was the centre of the northwest Ohio oil fields, which at peak production (1890–1900) had an annual output of over 20,000,000 bbl. As production diminished in later years, the network of pipe lines was extended until today Lima is the centre of a huge pipe-line distribution system operated by six major oil companies through Lima from the oil fields of Wyoming, Texas and Oklahoma, to the Great Lakes and the east coast. Lima was settled in 1831 and chartered in 1842. Near by are three state parks: Indian lake, Lake St. Mary's and Ft. Amanda. Ohio Northern university at Ada, O., and Bluffton college at Bluffton are near by.

LIMAÇON: *see* CURVES, SPECIAL.

LIMAN VON SANDERS, OTTO (1855–1929), German soldier, was born in Stolp, Prussia, Feb. 18, 1855. Entering the German army in 1874 he held various posts in the cavalry, and in 1913 was sent to Turkey as leader of a German military mission. His appointment as commander of the 1st Turkish army was annulled on account of Russian protests, but he remained inspector of the Turkish army. Made a Prussian general in Jan. 1914, in Nov. of the same year he was given the chief command of the Turkish troops in the Caucasus. In March 1915, as commander of the 5th Turkish army, he successfully opposed the British and French attacks on the Dardanelles and Gallipoli. In 1918 von Sanders succeeded von der Goltz as leader of the Turkish forces in the middle east, and was in command in Syria and Palestine when General Allenby was victorious there. Von Sanders escaped capture, but after the armistice gave himself up to the Allies and was interned until Aug. 1919. He gave an account of his experiences in Turkey in *Fünf Jahre Türkei* (1920; Eng. trans. 1928), a book which throws much light on the Dardanelles campaign and on Turkish politics. He died at Munich on Aug. 23, 1929.

LIMASOL (anc. LEMESSUS), a seaport on the south coast of Cyprus, in Akrotiri Bay with a considerable trade in wine and carobs. Pop. (1944) 17,825. Only a fort attributed to the 13th century has survived many earthquakes and much warfare. In the neighbourhood are the ancient sites of Amathus and Curium. Limasol was the scene of the marriage of Richard I, king of England, with Berengaria of Navarre, in 1191.

LIMB. (1) A word of Teutonic origin, meaning any member of the body, but now restricted to the legs and arms. The word is also used of the main branches of a tree, of the projecting spurs of a range of mountains, of the arms of a cross, etc. "Limb" was used by ecclesiastical writers of the 16th and 17th centuries of a person as being a component part of the church or other corporate body; *cf.* such expressions as "limb of the law," etc. It is also a term for an estate dependent on another, or for the subordinate members of the Cinque Ports, attached to one of the principal towns; Pevensey was thus a "limb" of Hastings. (2) An edge or border, frequently used in scientific language for the boundary of a surface; *e.g.,* the edge of the disk of the sun or moon, or of the expanded part of a petal or sepal in botany. This word is a shortened form of *limbo* or *limbus,* Lat. for "edge," for the theological use of which *see* LIMBUS.

LIMBA, a small group of intelligent, dark-skinned people of medium stature, living in the valleys of the upper Little Skarcies and Kakuna rivers in Sierra Leone, skilled traders, speaking an ancient language related to Landuman and Timne. They are grouped in confederated villages under a paramount chief. The paternal nephew marries the widow of his paternal uncle. The Limba are organized in clans and have secret societies and age classes. They are engaged in cultivation, arboriculture and cattle-raising. Their religion is animist in type, and there are traces of totemism.

See N. W. Thomas, *Anthropological Report on Sierra Leone* (1916).

LIMBACH, a town in the *Land* of Saxony, Germany, in a manufacturing district 6 mi. W.N.W. of Chemnitz. Pop. (1939) 19,663. Its industries include the making of hosiery, gloves, cloth, silk and sewing-machines, and dyeing and bleaching.

LIMBORCH, HENDRICK VAN (1680–1758), Dutch painter, was born at The Hague, Holland. He studied painting under Adriaan van der Werff, whose style he imitated rather successfully, although he never acquired the skill of his master. Limborch is known for landscapes, portraits and historical paintings. His extant works include "The Repose in Egypt" and "The Golden Age," both of which hang in the Louvre, "Venus and Cupid" and "Cupid and Psyche."

LIMBORCH, PHILIPP VAN (1633–1712), Dutch Remonstrant theologian, was born on June 19, 1633, at Amsterdam, where his father was a lawyer. He received his education at Utrecht, at Leyden, in his native city and finally at Utrecht university, which he entered in 1652. In 1657 he became a Remonstrant pastor at Gouda, and in 1667 he was transferred to Amsterdam, where, in the following year, the office of professor of theology in the Remonstrant seminary was added to his pastoral charge. He was a friend of John Locke. He died at Amsterdam, April 30, 1712.

His most important work, *Institutiones theologiae christianae, ad praxin pietatis et promotionem pacis christianae unice directae* (Amsterdam, 1686, 5th ed., 1735, Eng. trans. 1702), is a full and clear exposition of the system of Simon Episcopius and Stephan Curcellaeus. The fourth edition (1715) included a posthumous "Relatio historica de origine et progressu controversiarum in foederato Belgio de praedestinatione." Limborch also wrote *De veritate religionis Christianae amica collatio cum erudito Judaeo* (Gouda, 1687); *Historia Inquisitionis* (1692), in four books prefixed to the "Liber Sententiarum Inquisitionis Tolosanae" (1307–23) and *Commentarius in Acta Apostolorum et in Epistolas ad Romanos et ad Hebraeos* (Rotterdam, 1711). His editorial labours included the publication of various works of his predecessors and of *Epistolae ecclesiasticae praestantium ac eruditorum virorum* (Amsterdam, 1684), chiefly by Jakobus Arminius, Joannes Uytenbogardus, Konrad Vorstius (1569–1622), Gerhard Vossius (1577–1649), Hugo Grotius, Simon Episcopius (his granduncle) and Gaspar Barlaeus; they are of great value for the history of Arminianism. An English translation of the *Theologia* was published in 1702 by William Jones (*A Complete System or Body of Divinity, Both Speculative and Practical, Founded on Scripture and Reason,* London, 1702); and a translation of the *Historia Inquisitionis,* by Samuel Chandler, with "a large introduction concerning the rise and progress of persecution and the real and pretended causes of it" prefixed, appeared in 1731.

LIMBOURG, POL DE (*fl. c.* 1400), Flemish miniature painter, the most famous of three brothers whose family name was Malouel, all of whom followed the same profession. At one time Pol travelled to Italy to study at first hand the works of contemporary Italian artists, whose influence is clearly evident in his later work, but little else is known of the details of his early life. Any records there may have been have disappeared, probably destroyed by the wars which ravaged the Netherlands during his lifetime.

For a time he and his two brothers, Hermann and Janneken, worked for Philip the Bold, duke of Burgundy, beginning for him the illustration of the *Bible historiée.* This manuscript was later finished by other hands after Philip's death in 1404 had terminated the brothers' efforts on it. Not long after, probably about 1411, they entered the service of Philip's brother, John, duke of Berry, and it was under his patronage that Pol did his best work, the illuminating of the two prayer books, *Les Très Riches Heures du duc de Berry* and *Les Heures d'Ailly.* Although Pol did not finish the first manuscript in his lifetime, he and his brothers are thought to be responsible for nearly half of it, and it may have been partially completed after his death by Hubert and John van Eyck, whose style Pol was one of the first of the Flemish painters to foreshadow.

LIMBURG, one of the many small feudal states into which the duchy of Lower Lorraine was split up in the second half of the 11th century. The first count was Walram of Arlon, who married Judith, the daughter of Frederick of Luxembourg, duke of Lower Lorraine (d. 1065), who bestowed upon him a portion of his possessions lying upon both sides of the river Meuse. It received its name from the strong castle built by Count Walram on the river Vesdre, where the town of Limburg now stands. Henry, Walram's son (d. 1119), was turbulent and ambitious. On the death of Godfrey of Bouillon (1089) he forced the emperor Henry IV to recognize him as duke of Lower Lorraine. He was afterwards deposed and imprisoned by Count Godfrey of Louvain, on whom the ducal title had been bestowed by the emperor Henry V (1106). For three generations the possession of the ducal title was disputed between the rival houses of Limburg and Louvain. At length a reconciliation took place (1155). The name of duke of Lower Lorraine thenceforth disappeared, the rulers of the territory on the Meuse becoming dukes of Limburg, those of the larger territory to the west, dukes of Brabant. With the death of Duke Walram IV (1280) the succession passed to his daughter, Irmingardis, who was married to Reinald I, count of Guelders. Irmingardis died without issue (1282); and her cousin, Count Adolph of Berg, laid claim to the duchy. His rights were disputed by Reinald, who was in possession and was recognized by the emperor. Too weak to assert his claim by force of arms Adolph sold his rights to John I, duke of Brabant (*q.v.*) in 1283. This led to a long and desolating war which lasted until 1288. At the end of that time, finding the power of Brabant superior to his own, Reinald in his turn sold his rights to Count Henry III of Luxembourg.

Henry and Reinald, supported by the archbishop of Cologne and other allies, now raised a great army. The rival forces met at Woeringen and John of Brabant gained a complete victory, after which the duchies of Limburg and Brabant passed under the rule of a common sovereign. The duchy comprised during this period the bailiwicks of Hervé, Montzen, Baelen, Sprimont and Wallhorn and the counties of Rolduc, Daelhem and Falkenberg, to which was added in 1530 the town of Maastricht. The provisions and privileges of the famous Charter of Brabant, the *Joyeuse Entrée* (*q.v.*), were from the 15th century extended to Limburg and remained in force until the French Revolution.

By the Treaty of Westphalia (1648) the duchy was divided into two portions, the counties of Daelhem and Falkenberg with the town of Maastricht being ceded by Spain to the United Provinces, where they formed what was known as a "Generality-Land." At the peace of Rastatt (1714) the southern portion passed under the dominion of the Austrian Habsburgs and formed part of the Austrian Netherlands until the French conquest in 1794. During the period of French rule (1794–1814) Limburg was included in the two French departments of Ourthe and Meuse Inférieure. In 1814 the old name of Limburg was restored to one of the provinces of the newly created kingdom of the Netherlands, but the new Limburg comprised, besides the ancient duchy, a piece of Gelderland and the county of Looz. At the revolution of 1830 Limburg, with the exception of Maastricht, threw in its lot with the Belgians, and during the nine years that King William refused to recognize the existence of the kingdom of Belgium, the Limburgers sent representatives to the legislature at Brussels and were treated as Belgians. When in 1839 the Dutch king suddenly announced his intention of accepting the terms of the settlement proposed by the treaty of London, as drawn up by representatives of the great powers in 1831, Belgium found herself compelled to relinquish portions of Limburg and Luxembourg. The part of Limburg that lay on the right bank of the Meuse, together with the town of Maastricht and a number of communes on the left bank of the river, became a sovereign duchy under the rule of the king of Holland. In exchange for the cession of the rights of the Germanic confederation over the portion of Luxembourg which was annexed by the treaty to Belgium, the duchy of Limburg (excepting the communes of Maastricht and Venloo) was declared to belong to the Germanic confederation. This somewhat unsatisfactory condition of affairs continued until 1866, when at a conference of the great Powers, held in London to consider the Luxembourg question (*see* LUXEMBOURG), it was agreed that Limburg should be freed from every political tie with Germany. Limburg became henceforth an integral part of Dutch territory.

In Dec. 1918 indignation was expressed by Belgium at the authorization by the Dutch government of the passage of the retreating German army through Limburg, which enabled the Germans to save 70,000 to 120,000 men and to carry away the proceeds of their exactions in Belgium, and a large quantity of war material. Feeling in Belgium was the more inflamed because the Dutch government had refused to liberate the Belgians interned in Holland until the consent of Germany had been obtained; an attitude which should have had its logical counterpart in the internment of the retreating Germans. It was felt that Holland had created a precedent affecting the security of Belgium. In 1918–19 a proposal was brought before the Peace conference in Paris for the revision of the treaty of 1839, in order to place Dutch Limburg under Belgian rule. This was not favourably received in Paris and was strenuously opposed in Holland. It was finally vetoed. Limburg was occupied by Germany in 1940.

See P. S. Ernst, *Histoire du Limbourg* (Liége, 1837–52); M. J. de Poully, *Histoire de Maastricht et de ses environs* (1850); *Diplomaticke bescheiden betreffends de Limburg-Luxemburgsche aangelegenheden 1866–67* (The Hague, 1868); C. J. Luzac, *De Landen van Overmuze in Zonderheid 1662* (Leyden, 1888); R. Fruin, *Geschied. der Staats-Instellingen in Nederland* (The Hague, 1901).

LIMBURG, the N.E. province of Belgium, part of the ancient duchy of Limburg. The part of the duchy east of the Meuse was transferred to Holland by the London conference and a part including the old capital, now called Dolhain, was put into the province of Liége.

The Kempen, a wild heath district, has coal under it, workings on which began in 1906 and production in 1917. Towns include Hasselt (the capital), St. Trond, Tongres, Maeseyck and Looz, from the last of which an ancient ducal family takes its title. There are 3 administrative *arrondissements,* 13 cantons and 206 communes. Area 929 sq.mi. Pop. (est. 1939) 420,817, or 452.9 per sq.mi.

LIMBURG, a town in the Prussian province of Hesse-Nassau, on the Lahn, here crossed by a bridge dating from 1315, and on the main railway line from Coblenz to Lollar and Cassel. Pop. (1933) 12,002. It is the seat of a Roman Catholic bishop and the small seven-towered cathedral, dedicated to St. George the Martyr, was founded early in the 10th century and consecrated in 1235. It was restored in 1872–78. Limburg, which has a castle, was a flourishing place during the middle ages and had its own line of counts until 1414, when it was purchased by the elector of Trier. It passed to Nassau in 1803. Its industries include the manufacture of tobacco, soap, machinery of various kinds, paints and leather.

LIMBURG, the southeasternmost and smallest province of the Netherlands, bounded north by Gelderland, northwest by North Brabant, southwest by the Belgian province of Limburg and south by that of Liége and east by Germany. Its area is 846 sq.mi. and its population (est. 1938) was 602,983, the density per sq.mi. being 713. In the extreme southeast there are Cretaceous hills rising to over 300 ft. (the highest land in the Netherlands), while the rest of the province is formed of more recent deposits. It is watered by the Meuse (Maas), which forms part of its southwestern boundary (with Belgium) and then flows through its northern portion, and by such tributaries as the Roer. Its capital is Maastricht, at the ancient river-crossing, giving its name to one of the two administrative districts into which it is divided, the other being Roermond. Venlo is a station on the railway from Crefeld to Breda which crosses the province, while subsidiary lines link it with Maastricht to the south and Nijmwegen to the north.

The richest part of the province is the southeast: on the loess deposits here there is a rich cultivation of wheat, rye, sugar beet and fruit. There is a coalfield near Heerlen and Kerkrade, and among the industries of Maastricht are glass, porcelain and leather. The province was speedily overrun by German troops during the invasion of May 1940.

LIMBURG CHRONICLE or **FESTI LIMPURGENSES,** a German chronicle written probably by Tileman Elhen von Wolfhagen after 1402. It is a source for the history of the Rhineland between 1336 and 1398 but is more valuable philologically and for the folk-lore and pictures of manners which it contains.

First published by Faust in 1617, it was edited by Wyss for *Monumenta Germaniae historica. Deutsche Chroniken,* Band iv (Hanover, 1883). *See* A. Wyss, *Die Limburger Chronik untersucht* (Marburg 1875).

LIMBURGITE, in petrology, a dark-coloured volcanic rock resembling basalt in appearance, but containing normally no felspar. The name is taken from Limburg (Germany), where it occurs in the well-known rock of the Kaiserstuhl. It consists essentially of olivine and augite with a brownish glassy ground mass, in which a second generation of small augites frequently occurs; more rarely olivine is present also as an ingredient of the matrix.

The principal accessory minerals are titaniferous iron oxides and apatite, and in some limburgites large phenocrysts of hornblende and biotite are found; in others large crystals of soda-orthoclase or anorthoclase. Haüyne is an ingredient of some of the limburgites of the Cape Verde Islands. Rocks of this group occur in considerable numbers in Germany (Rhine district) and in Bohemia, also in Scotland (Whitelaw hill, Haddington), Auvergne, Spain, Kilimanjaro, Brazil, etc. They are associated principally with basalts, nepheline- and leucite-basalts and monchiquites. From the last-named rocks the limburgites are not easily separated as the two classes bear a very close resemblance in structure and in mineral composition.

The ground mass of the monchiquites is not a glass, however, but crystalline analcite. Limburgites may occur as flows, as sills or dikes, and are sometimes highly vesicular. Closely allied to them are the *augitites,* which are distinguished only by the absence of olivine; examples are known from Bohemia, Auvergne, the Canary Islands, Ireland, etc.

LIMBUS, a theological term denoting the border of hell, where dwell those who, while not condemned to torture, yet are deprived of the joy of heaven. The more common form in English is "limbo," which is used both in the technical theological sense and derivatively in the sense of "prison," or for the condition of being lost, deserted, obsolete. In mediaeval theology there are (1) the *Limbus Infantum* and (2) the *Limbus Patrum.*

1. The *Limbus Infantum* or *Puerorum* is the abode to which human beings dying without actual sin, but with their original sin unwashed away by baptism, were held to be consigned; the category included, not unbaptized infants merely, but also idiots, cretins and the like. The word "limbus," in the theological application, occurs first in the *Summa* of Thomas Aquinas; for its extensive currency it is perhaps most indebted to the *Commedia* of Dante (*Inf.* c. 4). The question as to the destiny of infants dying unbaptized presented itself to theologians at a comparatively early period. Generally speaking it may be said that the Greek fathers inclined to a cheerful and the Latin fathers to a gloomy view. Thus Gregory of Nazianzus (*Orat.* 40) says "that such children as die unbaptized without their own fault shall neither be glorified nor punished by the righteous Judge, as having done no wickedness, though they die unbaptized, and

as rather suffering loss than being the authors of it." Similar opinions were expressed by Gregory of Nyassa, Severus of Antioch and others—opinions which it is almost impossible to distinguish from the Pelagian view that children dying unbaptized might be admitted to eternal life, though not to the kingdom of God. In his recoil from Pelagian heresy, Augustine was compelled to sharpen the antithesis between the state of the saved and that of the lost and taught that there are only two alternatives—to be with Christ or with the devil, to be with Him or against Him. Following up, as he thought, his master's teaching, Fulgentius declared that it is to be believed as an indubitable truth that "not only men who have come to the use of reason, but infants dying, whether in their mother's womb or after birth, without baptism in the name of the Father, Son and Holy Ghost, are punished with everlasting punishment in eternal fire." Later theologians and schoolmen followed Augustine in rejecting the notion of any final position intermediate between heaven and hell but otherwise inclined to take the mildest possible view of the destiny of the irresponsible and unbaptized. Thus the proposition of Innocent III that "the punishment of original sin is deprivation of the vision of God" is practically repeated by Aquinas, Scotus and all the other great theologians of the scholastic period, the only outstanding exception being that of Gregory of Rimini, who on this account was afterward called "tortor infantum."

The first authoritative declaration of the Latin Church upon this subject was that made by the second council of Lyons (1274) and confirmed by the council of Florence (1439), with the concurrence of the representatives of the Greek Church, to the effect that "the souls of those who die in mortal sin or in original sin only forthwith descend into hell, but to be punished with unequal punishments." Perrone remarks (*Prael. Theol.* pt. iii, chap. 6, art. 4) that the damnation of infants and also the comparative lightness of the punishment involved in this are thus *de fide;* but nothing is determined as to the place which they occupy in hell, as to what constitutes the disparity of their punishment or as to their condition after the day of judgment. In the council of Trent there was considerable difference of opinion as to what was implied in deprivation of the vision of God, and no definition was attempted, the Dominicans maintaining the severer view that the *Limbus Infantum* was a dark subterranean fireless chamber, while the Franciscans placed it in a region of light above the earth. Some theologians continue to maintain with Bellarmine that the infants "in limbo" are affected with some degree of sadness on account of a felt privation; others, following the *Nodus praedestinationis* of Celestine Sfrondati (1649–96), hold that they enjoy every kind of natural felicity, as regards their souls now and as regards their bodies after the resurrection, just as if Adam had not sinned. In the condemnation (1794) of the synod of Pistoia (1786) the 26th article declares it to be false, rash and injurious to treat as Pelagian the doctrine that those dying in original sin are not punished with fire, as if that meant that there is an intermediate place, free from fault and punishment, between the kingdom of God and everlasting damnation.

2. The *Limbus Patrum* or *Sinus Abrahae* ("Abraham's Bosom") is defined in mediaeval theology as the place in the underworld where the saints of the Old Testament were confined until liberated by Christ on his "descent into hell." Regarding the locality and its pleasantness or painfulness nothing has been taught as *de fide*. It is sometimes regarded as having been closed and empty since Christ's descent, but other authors do not think of it as separate in place from the *Limbus Infantum*. The whole idea, in the Latin Church, has been described as the mere *caput mortuum* of the old doctrine of Hades, which was gradually superseded in the west by that of purgatory.

LIME, the fruit of *Citrus aurantifolia,* which is regarded by W. T. Swingle (1943) as distinct and not closely related to any other *Citrus* species. It is thought to be native to the East Indies and to have been brought from there, by man, to the Asiatic mainland and, finally, to the subtropical countries of Europe and north Africa. Spanish and Portuguese explorers introduced the lime to the West Indies and the American continents in the early part of the 16th century. It escaped from cultivated areas in southern Florida and elsewhere and has been found in various places growing wild, as individual trees or sometimes as thickets (H. J. Webber, 1943).

The lime tree seldom grows more than 8 to 15 ft. high, and, if not pruned, becomes shrublike in character of growth; branches spreading, irregular, with short stiff twigs, small leaves and an abundance of small, very sharp thorns; leaves pale green; small white flowers, usually borne in clusters; fruit $1\frac{1}{4}$–$1\frac{3}{4}$ in. in diameter, oval to nearly globular, often with small apical nipple; peel very thin, greenish yellow when fruit is ripe; pulp tender, very juicy, yellowish green in colour, and decidedly acid. As a group, limes somewhat exceed lemons in both acid and sugar content. There are, however, some varieties so lacking in citric acid that they are known as sweet limes; they are not commonly grown in comparison with the acid type.

The lime hybridizes readily with other *Citrus* species, and numerous hybrid varieties are grown as novelties; a few are grown for commercial purposes. Perhaps the most important of the hybrids is the Perrine lemon, an intrageneric hybrid of Mexican lime (*C. aurantifolia*) and Genoa lemon (*C. limon*), which resembles more nearly the lemon than the lime, both in fruit and foliage characteristics and in resistance to frost. This fruit was originated in Florida in 1909 by investigators in the United States department of agriculture and is recommended for local production and use for parts of Florida, Louisiana and Texas.

The two general groups of acid limes grown in the United States are the Mexican and the Tahiti. The former group is characteristic of the species *C. aurantifolia,* described above. Numerous thornless strains of Mexican limes have arisen from seedlings and from bud sports, the first one being recorded in the West Indies in 1892. The trees of the Tahiti group resemble the lemon and are larger and more vigorous than those of the Mexican group; leaves larger and darker coloured. The fruit is larger and more elongated than the Mexican lime; peel thicker; fruit nearly seedless. The flavour of the fruit of the two groups is similar, but the Tahiti lime lacks some of the bouquet which is typical of the Mexican. The Tahiti lime so closely resembles a lemon that the fruit could easily be confused except for the colour of the pulp and the distinctive taste. From the appearance of the Tahiti group, there seems to be a possibility that this fruit may be a hybrid between the lemon and the typical Mexican lime (Webber, 1943).

Methods of culture, propagation and pest control for limes are comparable to those used in other citrus orchards (*see* LEMON and ORANGE). Limes are less resistant to cold than are lemons, and are therefore planted only in relatively frostless locations. It is for this reason that they are grown in the warmer subtropical countries, such as the West Indies and Mexico; in the United States, they are grown only in the extreme south of Florida and in certain favourable sites in California. This fruit is especially popular in Egypt, and production in that country in 1936 exceeded the combined production of the rest of the world. The supply of limes consumed in United States comes from the aforementioned sources in the western hemisphere, with Mexico the most important source.

Concentrated lime juice may be prepared in a manner similar to that used in preparing lemon juice. The yield of fresh juice depends upon the variety and the condition of the fruit and varies from 60 to 90 gal. per 2,000 lb. of fruit. The small Mexican lime is less readily handled by machinery in the reaming process than are the larger varieties.

Lime juice has been supplanted to a great degree by lemon juice. For limeade and some carbonated and alcoholic beverages, lime juice is preferred; but fresh limes are usually available during the summer months, when such drinks are most in demand. The lime is also used for various culinary purposes. It contains no vitamin A and less vitamin C than the lemon; its use as a preventive of scurvy has therefore become secondary to that of lemons and oranges.

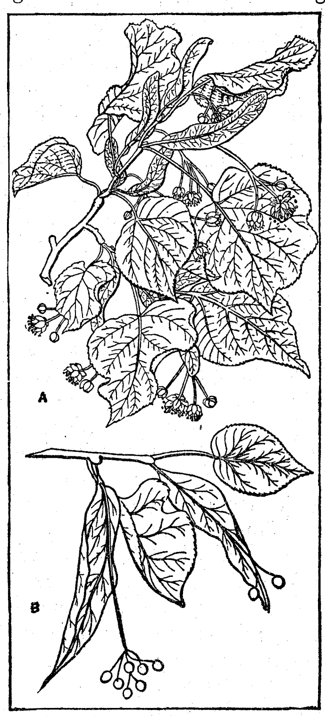
Lime oil is a by-product of this fruit, the chief centre for its production being the West Indies. Citrate of lime and citric acid are also prepared from limes.

Bibliography.—W. T. Swingle, "The Botany of Citrus and Its Wild Relatives of the Orange Subfamily (Family Rutaceae, Subfamily Aurantioideae)," vol. 1, chap. iv, in *The Citrus Industry* (1943); H. J. Webber, "Cultivated Varieties of Citrus," vol. 1, chap. v, in *The Citrus Industry* (1943). (L. D. B.)

LIME, the name given to a viscous exudation of the holly-tree, used for snaring birds and known as "bird-lime" (O. Eng. *lim,* Lat. *limus,* mud, from *limere,* to smear); the popular name of calcium oxide or "quick-lime," a substance employed since very early times as a component of mortars and cementing materials. It is prepared by the burning of limestone (a process described by Dioscorides and Pliny) in kilns similar to those described under Cement. The value and subsequent treatment of the product depend on the purity of the limestone; a pure stone yields a "fat" lime which readily slakes; an impure stone, especially if magnesia be present, yields an almost unslakable "poor" lime. (*See* Cement; Concrete; and Mortar in Building for details.) Pure calcium oxide, CaO, obtained by heating the pure carbonate, is a white amorphous substance, which can be readily melted and boiled in the electric furnace, cubic and acicular crystals being deposited on cooling the vapour. It combines with water, evolving much heat and crumbling to pieces; this operation is termed "slaking" and the resulting product "slaked lime"; it is chemically equivalent to converting the oxide into hydroxide. An aqueous solution of the hydroxide, known as lime-water, has a weakly alkaline reaction; it is employed in the detection of carbonic acid. "Milk of lime" consists of a cream of the hydroxide and water. Dry lime has no action upon chlorine, carbon dioxide and sulphur dioxide although, in the presence of water, combination ensues. In medicine lime-water, applied externally, is an astringent and desiccative, and it enters into the preparation of *linamentum calcis* and carron oil which are employed to heal burns, eczema, etc. Applied internally, lime-water is an antacid; it prevents the curdling of milk in large lumps (hence its prescription for infants); it also acts as a gastric sedative. It is an antidote for mineral and oxalic acid poisoning (*see* also Calcium).

LIME CEMENT: *see* Cement.

LIME or **LINDEN.** The lime trees, species of *Tilia,* are familiar timber trees with sweet-scented flowers which are borne on a common peduncle proceeding from the middle of a long strap-like bract. The genus, which gives the name of the family Tiliaceae, contains about 30 species of trees, natives of the north temperate zone. The general name *Tilia europaea,* European lime, includes several well-marked sub-species, often regarded as distinct species by many authorities. These are: (1) the small-leaved lime, *T. ulmifolia* (or *T. parvifolia*), probably wild in woods in England and also wild throughout Europe, except in the extreme southeast, and Russian Asia; (2) *T. europaea* (or *T. intermedia*), the common lime, which is widely planted in Britain but not wild there, has a less northerly distribution than *T. ulmifolia,* from which it differs in its somewhat larger leaves and downy fruit; (3) the large-leaved lime, *T. platyphyllos* (or *T. grandifolia*), occurs only as an introduction in Britain and is wild in Europe south of Denmark. It differs from the other two limes in its larger leaves, often 4 in. across and downy beneath, its downy twigs and its prominently ribbed fruit. The lime sometimes acquires a great size; one is recorded in Norfolk as being 16 yd. in circumference, and Ray mentions one of the same girth. The famous linden tree which gave the town of Neuenstadt in Württemberg the name of *Neuenstadt an der grossen Linden* was 9 ft. in diameter.



THE LIME (TILIA EUROPAEA)
A. Flowers in small cymes arising from axils of leaf of current year. B. Fruits

The lime is an object of beauty in the spring, when the delicately transparent green leaves are bursting from the protection of the pink and white stipules which have formed the bud-scales, and retains its fresh green during early summer. Later, the fragrance of its flowers, rich in nectar, attracts innumerable bees; in the autumn the foliage becomes a clear yellow but soon falls. Among the many famous avenues of limes are the Unter den Linden of Berlin and the avenue at Trinity college, Cambridge.

The economic value of the tree chiefly lies in the inner bark, sometimes called bast, and the wood. The former was used for paper and mats and for tying garlands by the ancients. Bast mats are now made chiefly in the U.S.S.R., the bark being cut in long strips when the inner layer is easily separable from the corky superficial layer. The wood is used by carvers, being soft and light, and by architects in framing the models of buildings. Turners use it for light bowls, etc.

T. americana (basswood) is one of the most common trees in the forests of Canada and extends into the eastern and southern United States. It is sawed into lumber and under the name of whitewood is used in the manufacture of woodenware, cheap furniture, etc., and also for paper pulp. It was cultivated by Philip Miller at Chelsea in 1752. There are at least 10 other species of basswood native to the southeastern United States, but their separation is fraught with difficulty. (E. S. Hr.)

LIMEHOUSE, a parish of east London, England, in the eastern part of the metropolitan borough of Stepney, on the north bank of the Thames river. It is bordered by the West India and the East India docks and is therefore largely inhabited by labourers from the docks and by sailors, both natives of London and foreigners off merchant ships temporarily in port. A common form of philanthropy has been the establishment of homes and hostels for seamen in Limehouse. The parish also contains London's Chinese quarter. The Limehouse Cut, a channel which connects the Lea with the Thames, was constructed in 1769. St. Anne's, the parish church, was designed by Nicholas Hawksmoor, a pupil of Sir Christopher Wren, and was begun in 1724. It was restored after 1850, when it was partially destroyed by fire on Good Friday. The name Limehouse is probably a corruption of the original Lime Hurst or Lime Host, which referred to the limekilns in the district.

LIMERICK, THOMAS DONGAN, Second Earl of (1634–1715), governor of New York, was born in Castletown, Ireland. He began his career in the army, serving first in England and later under Louis XIV in France in an Irish regiment. He abandoned the army, however, to accept the position of lieutenant-governor of Tangiers, an office he resigned in 1680. Two years later the Duke of York named him governor of New York, which included, at that time, a portion of New England.

Dongan was responsible for a number of important developments in the history not only of New York but of the entire group of American colonies. The so-called "Charter of Liberties," drawn up by the New York assembly, which he convened shortly after he arrived in the colony, served as the basis of New York's later constitution and of the constitution of the entire United States in many of its provisions. It was, however, never put into effect in New York, since the Duke of York, although he signed it, failed to return the charter to the colony, probably because of its extreme liberalism. Dongan helped to fix the boundaries of New York by treaty with the Indians and by agreement with the surrounding colonies and Canada. His charters for the cities of New York and Albany both remained in effect for many years after they were drawn up, New York's for more than 100 years and Albany's for nearly 200. He was responsible for convincing the king of England that French power in America should not be allowed to increase if the English were to maintain their supremacy, especially with regard to the Indians of the Five Nations, and his Indian policy set the example for English colonial governors thereafter.

In 1688 Dongan was relieved of his governorship but remained in New York until 1689, when he was forced to take refuge in New England because of the persecution of Roman Catholics which followed the fall from power of James II. He returned to England in 1691 and seven years later succeeded his brother as earl of Limerick. His family's lands had been seized even before he received the title, and he never recovered them. He died in London, a poor man, on Dec. 14, 1715.

LIMERICK, a western county of Eire, province of Munster, bounded north by the Shannon estuary and the counties of Clare and Tipperary, east by Tipperary, south by Cork and west by Kerry. The area is 663,971 ac., or about 1,037 sq.mi. Pop. (1936) 141,153.

This is mainly a Carboniferous Limestone county, with fairly level land, broken by ridges of Old Red Sandstone. On the north-east, the latter rock rises on Slievefelim, round a Silurian core, to 1,523 ft. In the south, Old Red Sandstone rises above an enclosed area of Silurian shales at Ballylanders, the opposite scarp of Old Red Sandstone forming the Ballyhoura hills on the Cork border. The Galtee mountains, which extend into Tipperary, attain in Galtymore a height of 3,015 ft. Volcanic ashes, andesites, basalts and intrusive sheets of basic rocks are well seen under Carrigogunnell castle and in a ring of hills round Ballybrood. The coals in the west are not of commercial value. Lead-ore has been worked in places in the limestone.

The Shannon is navigable for large vessels to Limerick, above which are the rapids of Doonas and Castleroy and a canal. Castleconnell is a fishing centre. The Maigue, which rises in the Galtees and flows into the Shannon, is navigable as far as the town of Adare.

Limerick was included in the kingdom of Thomond. Afterwards it had a separate existence under the name of Aine-Cliach. From the 8th to the 11th century it was partly occupied by the Danes. (*See* LIMERICK, City.) Limerick is one of the 12 counties generally considered to owe their formation to King John. About 100,000 ac. of the estates of the earl of Desmond, which were forfeited in 1586, were situated in the county, and other extensive confiscations took place after the Cromwellian wars. In 1709 a German colony from the Palatinate was settled by Lord Southwell near Bruff, Rathkeale and Adare.

There are remains of round towers at Ardpatrick and at Dysert; another at Kilmallock is largely a reconstruction. There are remains of stone circles, pillar stones and altars at Loch Gur. In several places there are remains of old moats and tumuli. Besides the monasteries in the city of Limerick, the most important monastic ruins are those of Adare abbey, Askeaton abbey, Galbally friary, Kilflin monastery, Kilmallock and Monaster-Nenagh abbey.

Limerick includes the greater part of the Golden Vale, the most fertile district of Ireland, which stretches from Cashel in Tipperary nearly to the town of Limerick. Along the banks of the Shannon there are fertile tracts of meadowland formed of deposits of calcareous and peaty matter. The soil in the mountainous districts is mostly thin and poor and incapable of improvement. The large farms are almost wholly devoted to grazing. All the crops (of which oats and potatoes are the principal) show a decrease, but there is a growing acreage of meadowland. Cattle, sheep, pigs, goats and poultry are all extensively reared. Coarse woollens are manufactured and also paper, and there are many meal and flour mills. The flax-spinning and weaving industry is now practically extinct.

Limerick is the headquarters of an important salmon-fishery on the Shannon. The Great Southern main line crosses the south-eastern corner of the county, with two branches to the city of Limerick from Limerick Junction and from Charleville and lines from Limerick southwestward to Tralee in County Kerry and to Foynes on the Shannon estuary. The administrative county of Limerick and the county borough of Limerick together return 7 members to Dáil Eireann.

LIMERICK, a county borough, port and the chief town of Co. Limerick, Eire, occupying both banks and an island (King's island) of the river Shannon, at the head of its estuary, 129 mi. W.S.W. of Dublin by rail. Pop. (1936) 41,061.

Limerick is said to have been the *Regia* of Ptolemy and the *Rosse-de-Nailleagh* of the Annals of Multifernan. There is a tradition that it was visited by St. Patrick in the 5th century, but it is first authentically known as a settlement of the Danes, who sacked it in 812 and afterward made it the principal town of their kingdom of Limerick but were expelled from it toward the close of the 10th century by Brian Boroimhe. From 1106 till its conquest by the English in 1174 it was the seat of the kings of Thomond or North Munster, and, although in 1179 the kingdom of Limerick was given by Henry II to Herbert Fitzherbert, the city was frequently in the possession of the Irish chieftains till 1195. Richard I granted it a charter in 1197.

By King John it was committed to the care of William de Burgo, who founded English Town, and for its defense erected a strong castle. The city was frequently besieged in the 13th and 14th centuries. In the 15th century its fortifications were extended to include Irish Town, and until their demolition in 1760 it was one of the strongest fortresses of the kingdom. In 1651 it was taken by General Ireton, and after an unsuccessful siege by William III its resistance was terminated in 1691 by the treaty of Limerick. The dismantling of its fortifications began in 1760, but fragments of the old walls remain. The original municipal rights of the city had been confirmed and extended by a succession of sovereigns, and in 1609 it received a charter constituting it a county of a city and also incorporating a society of merchants of the staple, with the same privileges as the merchants of the staple of Dublin and Waterford. The powers of the corporation were remodelled by the Limerick Regulation Act of 1823.

The prosperity of the city dates chiefly from the foundation of Newtown Pery in 1769 by Edmund Sexton Pery (d. 1806), speaker of the Irish house of commons. Under the Local Government Act of 1898 Limerick became one of the six county boroughs having a separate county council. The city is divided into English Town (on King's Island), Irish Town and Newtown Pery, the first including the ancient nucleus of the city, and the last the principal modern streets. The main stream of the Shannon is crossed by Thomond bridge and Sarsfield or Wellesley bridge. The first is commanded by King John's castle, on King's Island, a Norman fortress fronting the river. At the west end of the bridge is preserved the Treaty stone, on which the Treaty of Limerick was signed in 1691. The cathedral of St. Mary, also on King's Island, was originally built in 1142–80 and exhibits some Early English work. The modern Roman Catholic cathedral of St. John is in early pointed style. The churches of St. Munchin (to whom is attributed the foundation of the see in the 6th century) and St. John, Whitamore's castle and a Dominican priory, are of interest.

Communication with the Atlantic ocean is open, while inland navigation is facilitated by a canal which avoids the rapids above the city. Quays extend for about 1,600 yd. on each side of the river, and vessels of 600 tons can moor alongside at spring tides. There is a graving dock with a length of 428 ft., a breadth of 46 ft. and a depth of 17 ft. The wet dock has a length of 830 ft., a breadth of 465 ft. and a depth of 20 ft. The principal imports are grain, timber and coal. The exports consist mainly of fish and agricultural produce. The principal industrial establishments include flour mills (Limerick supplying most of the west of Ireland with flour), factories for bacon-curing and for condensed milk and creameries. Some brewing, distilling and tanning are carried on, and the manufacture of lace is maintained at the Convent of the Good Shepherd; but a formerly important textile industry has lapsed. The salmon fisheries of the Shannon, for which Limerick is the headquarters of a district, are the most valuable in Ireland.

LIMERICKS. The origin of this very popular type of nonsense-verse is lost in obscurity, and recent research work has done little to pierce the gloom. Nor is it known for what reason the name "Limerick" is attached to it. The theory that the title derives from the chorus "Will you come up to Limerick?" sung after impromptu verses composed at convivial parties, helps us not at all, since there is no record of this kind of verse being used at such parties. Rather is the limerick a kind of ribald epigram, passed on by word of mouth, and more often whispered than sung.

Langford Reed, the only collector of limericks who has toiled valiantly with their history, suggests that "this peculiar form of verse was brought direct to Limerick by the returned veterans of the Irish Brigade, who were attached to the French army for a period of nearly 100 years from 1691." The brigade was organized in Limerick, and when disbanded was no doubt responsible for giving currency to many rude barrack-room songs; but the evidence of a French origin for the five-lined metrical scheme of the limerick rests upon very feeble foundations. Langford Reed quotes from Boswell's *Life of Johnson:*

On s'étonne ici que Caliste
Ait pris l'habit de Moliniste;
Puisque cette jeune beauté
Ôte à chacun sa liberté
N'est-ce pas une Janseniste?

—an epigram in *The Menagiana* (1716) on a young lady who appeared at a masquerade dressed as a Jesuit during the fierce contentions of the followers of Molinos and Jansenius. But Reed also quotes:

Digerie, Digerie, Doge,
La souris ascend l'horloge;
L'horloge frappe
La souris s'échappe,
Digerie, Digerie, Doge,

and appears to consider this a true limerick form, thus permitting the verse-form almost as wide a license in metre as it has latterly attained in morals.

It may be sufficient to suppose that the limerick satisfies some natural instinct of the ear in rhymed verse, the prefatory couplet demanding a third line as complement, and staving this off, for the sake of surer effect, by the interposed short lines. But this would not account for the famous limericks of Edward Lear, in his *Book of Nonsense* (1846), where the last line is merely a choric repetition, employing one of the previous rhymes, and adding little or nothing to the sense. In spite of this defect, Lear certainly gave to what is now known as the limerick its modern popularity—some even assert that "learick" is the proper form of the word—and established at once its insistence on topography and its attention to varieties of personal behaviour.

There was a young girl of Majorca
Whose aunt was a very fast walker;
She walked sixty miles
And leaped fifteen stiles,
Which astonished that girl of Majorca.

Or again,

There was an old person of Anerly
Whose conduct was strange and unmannerly:
He rushed down the Strand
With a pig in each hand,
But returned in the evening to Anerly.

Lear, however, did previsage the now usually accepted formula:

There was an old man at the Cape
Who made himself garments of crape;
When asked "Will they tear?"
He replied "Here and there,
But they keep such a beautiful shape!"

Limericks have been composed upon every conceivable topic, not excluding philosophy and religion—

There was a young man who said "Damn!
It is borne upon me that I am
An engine which moves
In predestinate grooves,
I'm not even a bus; I'm a tram!"

but their usual themes became similar to those of the epigrams of Martial, and would doubtless so have remained, milder variants being substituted when blushes were to be spared, had it not been for their sudden vogue at the beginning of the present century as a subject for prize competitions in the newspapers, which gave large sums of money to readers for supplying the cleverest last line. The judges in these competitions must have had poor ears for scarcely any of the winning lines contained the correct number of feet. A good limerick should have the consecutive fluency of conversational prose, the metre remaining faultlessly dactylic throughout. No better example can be given than

There was an old man of Khartoum
Who kept two tame sheep in his room:
"For," he said, "they remind me
Of one left behind me,
But I cannot remember of whom."

Fantastic rhyme schemes to the limerick are innumerable. As for instance,

The lifeboat that's kept at Torquay
Is intended to float in the suay:
The crew and the coxswain
Are sturdy as oxswain,
And as smart and as brave as can buay.

Limericks have been translated into all languages, and the globe has been ransacked for rhymable towns. The best verses contain the largest amount of improbable incident or of subtle innuendo that can be crowded into the available space, and they may be regarded as the fixed English form for light or indelicate epigrammatic satire, as opposed to the ordinary rhyming quatrains which are used on more dignified occasions. (E. V. K.)

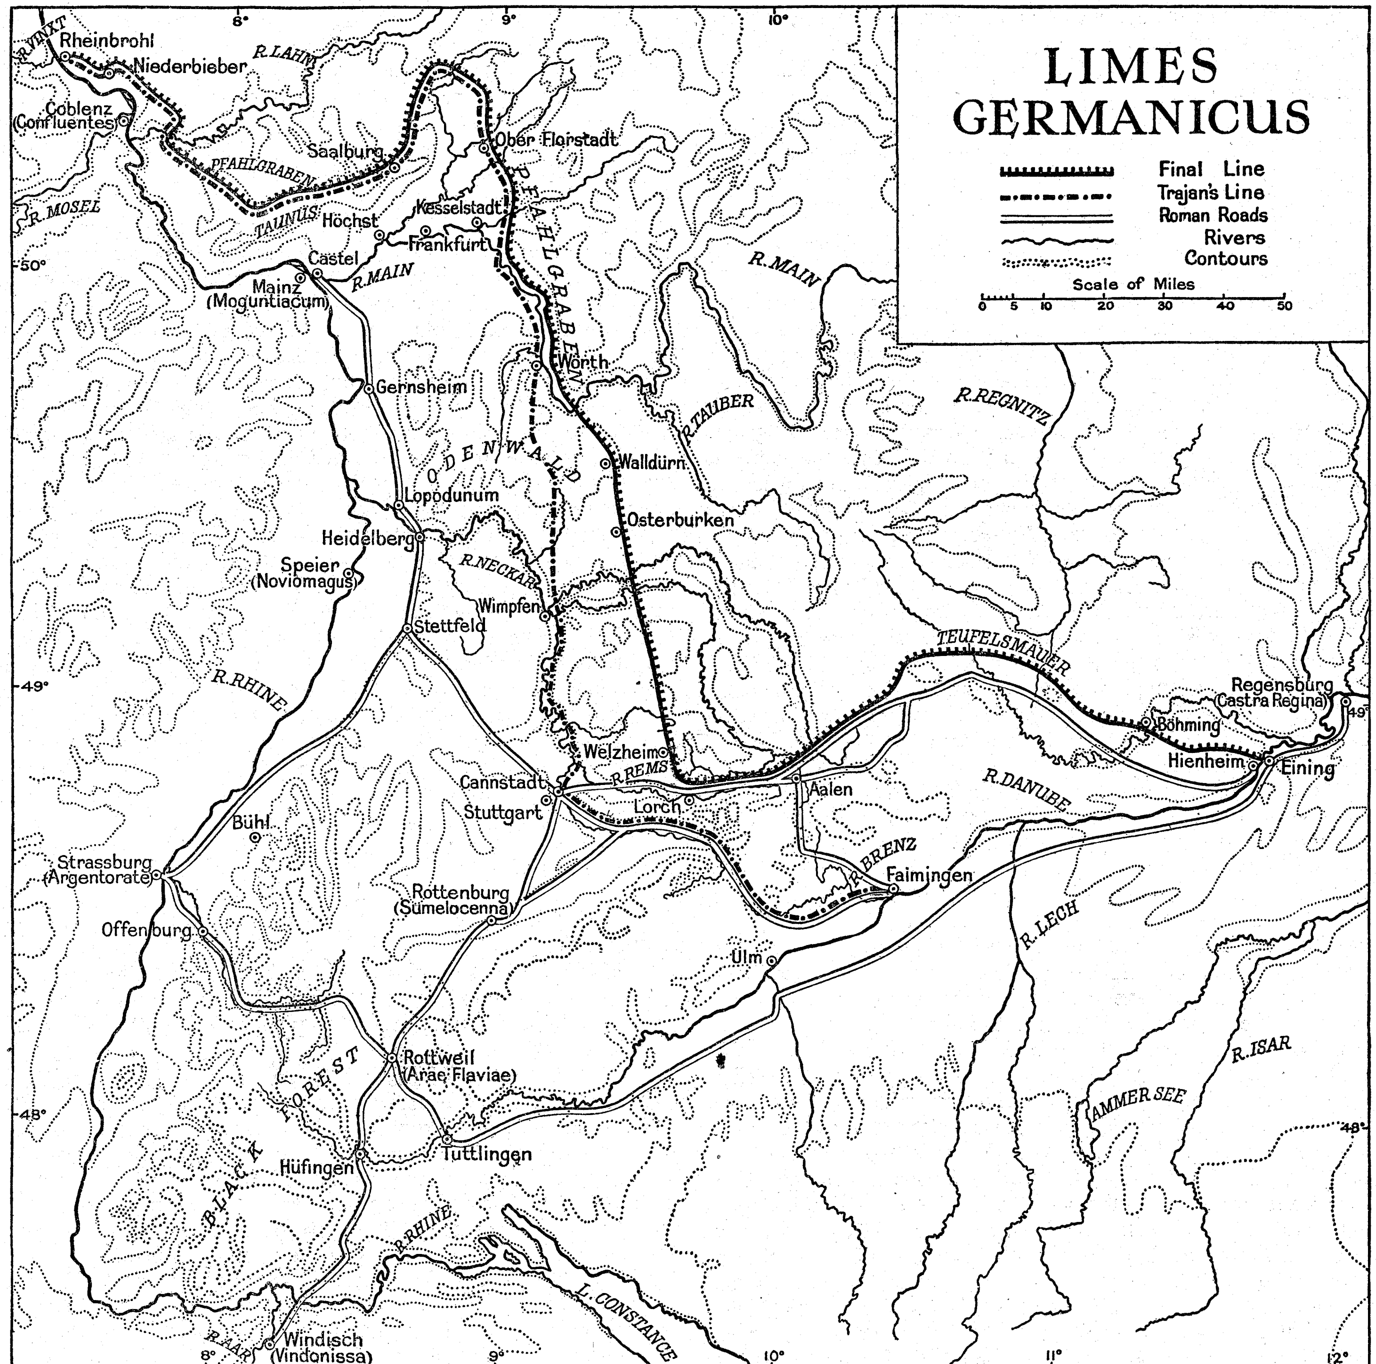
LIMES GERMANICUS. The Latin *limes* denoted a path, a boundary path, or boundary; hence it was utilized to denote frontiers marked in some distinct fashion. In the sense of frontiers, the term has been extended by modern historians. Thus the Wall of Hadrian in North England (*see* BRITAIN: *Roman*) is now sometimes styled the *Limes Britannicus,* and so forth. In particular the frontier lines which bounded the Roman provinces of upper (southern) Germany and Rhaetia, stretching from near Bonn on the Rhine to near Regensburg on the Danube, are called the *Limes Germanicus.* The history of these lines is the subject of the following paragraphs. They have become much better known through systematic excavations and other researches, and though many details are still doubtful, their general development can be traced.

From the death of Augustus (A.D. 14) till after A.D. 70, Rome accepted as her German frontier the water-boundary of the Rhine and upper Danube. Beyond these rivers she held only the fertile plain of Frankfürt, opposite the Roman border fortress of Moguntiacum (Mainz), the southernmost slopes of the Black Forest and a few scattered têtes-du-pont. The northern section of this frontier, where the Rhine is deep and broad, remained the Roman boundary until the empire fell. The southern part was different. The upper Rhine and upper Danube are easily crossed. The frontier which they form is inconveniently long, enclosing an acute-angled wedge of foreign territory—the modern Baden and Württemberg. Geographical convenience and movements of Roman subjects across the Rhine combined to urge a forward policy at Rome, and Vespasian began a series of advances which gradually closed up the acute angle, or at least rendered it obtuse.

The first advance came about A.D. 74, when what is now Baden was invaded and roads carried from the Roman bases on the upper Rhine, Strassburg (Argentoratum) and Windisch (Vindonissa) to Rottweil (Arae Fluviae). This road was subsequently extended to Cannstadt, meeting a road from Mainz, and was then probably extended to reach the Danube at Faimingen below Ulm. The point of the angle was broken off. The second advance was made by Domitian about A.D. 83. He pushed out from Moguntiacum, extended the Roman territory east of it, and enclosed the whole within a systematically defended frontier with numerous blockhouses along it and larger forts in the rear.

Among the blockhouses was one which by various enlargements grew into Saalburg fort, near Homburg. This advance necessitated a third movement, the construction of a frontier, connecting the annexations of A.D. 74 and 83. The line of this frontier ran from the Main to the upper waters of the Neckar, and was defended by a chain of forts. The whole was reorganized, probably by Hadrian, with a continuous wooden palisade reaching from the Rhine to the Danube. Either Hadrian or Pius marked out a new frontier roughly parallel to, but in advance of, these two lines.

This is the frontier which is now visible and visited by the curious. It consists of two distinct frontier works; one, known as



FROM H. F. PELHAM, "ESSAYS ON ROMAN HISTORY," BY PERMISSION OF THE CLARENDON PRESS

the Pfahlgraben (or "Pale"), is an earthen mound and ditch, best seen in the neighbourhood of the Saalburg, but which once extended from the Rhine southwards into southern Germany. The other, which begins where the earthwork stops, is a stone wall, though not very formidable, the Teufelsmauer ("Devil's Wall"); it runs roughly east and west parallel to the Danube, which it finally joins at Hienheim near Regensburg. The Pfahlgraben is extraordinarily direct in its southern part, which for more than 50 m. runs mathematically straight and points almost absolutely true to the Polar star. It is an ancient frontier laid out in American fashion. This frontier remained for about 100 years, and no doubt in that long period much was done to it. The exact date even of the Pfahlgraben and Teufelsmauer is uncertain. But the pressure of the barbarians began to be felt seriously in the latter part of the 2nd century A.D., and the whole or almost the whole district E. of the Rhine and N. of the Danube was lost about A.D. 250.

Bibliography.—The best English account is in H. F. Pelham's essay in *Trans. of the Royal Hist. Soc.*, vol. xx., reprinted in his *Essays on Roman History*, p. 179–211 (1911), where the German authorities are fully cited. *Cf.* J. E. Sandys, *Companion to Latin Studies* (1921).

LIMESTONE, in petrography, a rock consisting essentially of calcium carbonate ("carbonate of lime"). Many varieties are included within the group, some of which are very distinct, but all have certain properties in common, arising from the similar chemical composition, and mineralogical characters. All limestones, exclusive of dolomite (*q.v.*) dissolve readily in cold dilute acids, giving off bubbles of carbon dioxide. Even "weak" acids like citric or acetic acid will effect this change, though the mineral acids are more commonly employed. Limestones are readily scratched with a knife-blade or the edge of a coin, their hardness being 3; but unless they are earthy or incoherent, like chalk or calcareous sinter, they do not disintegrate by pressure with the fingers and cannot be scratched with the finger-nail. When free from impurities limestones are white, but they generally contain small quantities of minerals other than crystalline calcium carbonate which affect their colour. The presence of iron oxide or clay results in creamy, yellowish or brownish coloration; iron sulphide and carbonate, or carbonaceous and bituminous impurities, render limestones bluish, grey or black. Crystalline limestones or marbles, which in the process of metamorphism (*see* METAMORPHISM) have been mineralogically reconstituted under the action of heat or pressure, frequently contain minerals like epidote, chlorite, olivine, serpentine, garnet, spinel and augite of varying colours. The specific gravity of limestones ranges from 2·6 to 2·8 in typical examples.

In the field, limestones are usually recognizable by their characteristic method of weathering. Where reasonably pure, they may display solution-phenomena such as smooth, rounded surfaces, or may be covered with narrow runnels cut by rain. In such cases there is little soil, and plants and trees grow only in fissures where insoluble impurities from the limestone have collected. Thus in mountainous districts limestones tend to yield bare rocky ground (*e.g.,* the Karst) or country covered by scanty soil and short grass. The rain which falls on them sinks into the earth and passes underground. All waters in such regions tend to be hard on account of the abundant carbonate of lime dissolved during percolation. Thus caves, swallow-holes, sinks, pot-holes and underground rivers are formed. By redeposition of the carbonate of lime in underground caves stalactites, stalagmites and deposits of travertine, often beautifully tinted by impurities, are produced. The chalk downs are celebrated for their close green swards; surface-waters are often notably scarce, although the chalk in depth holds large supplies of water. Impure limestones such as those of the Cornbrash, Oolites and Lias contain enough impurities in the form of clay, sand and other mineral matter to yield thick soils of considerable agricultural value.

Most limestones are of organic origin, and are formed from the debris of the skeletons of animals. Off the coast of Florida a fine chalky deposit (drewite) is being laid down on the sea-bed, apparently as a result of the precipitating power of bacteria. Foraminifera, crinoids (sea-lilies), shells and corals build up considerable masses of limestone. Some bands of the chalk are largely composed of foraminifera such as *Globigerina.* Another notable foraminiferal limestone, that made by the disc-shaped *Nummulites,* is well developed in Mediterranean countries. From this rock the pyramids of Egypt were built.

Crinoidal limestones, although frequently found in the older rocks, such as the Carboniferous, are not now being formed on any scale, for these organisms are not abundant at the present day. The small cylindrical joints (or ossicles) of these organisms are easily recognized ("St. Cuthbert's beads") on the Northumbrian coast, washed out of the Carboniferous Limestone. Coral limestones are being formed over a large extent of the tropical seas. Ancient coral-reefs have been recognized in the older rocks of the earth's crust. They are usually composed of pure limestone (free from silt and sand), but may subsequently be altered to dolomite, as in the well-known region of the Tirol. Shelly limestones may consist of Mollusca or of Brachiopoda, the former occurring plentifully in Secondary and Tertiary rocks, but the latter in limestones of rather earlier age. The remains are often fragmentary, and the limestones may, like shore-sands to-day, consist of a mixture of comminuted shell-fragments and muddy, silty or even sandy material. Other organisms such as corallines (bryozoa), sea-urchins, starfishes, crustaceans and sponges contribute material to the formation of these rocks. Fresh-water limestones are composed usually of the shells of Mollusca (*e.g., Paludina* limestone) which inhabit lakes; they are often marly from an admixture of clay.

Consolidation and cementation are effected by finer calcareous material or subsequent crystallization of the carbonate of lime. Limestones are very susceptible to chemical changes and may be replaced by iron oxide or carbonate, yielding ores of great commercial value. They may be silicified and become cherts, often with the retention of their organic structures. On certain islands in the Pacific (Ocean I. etc.), they become phosphatized from the replacement of carbonate by the phosphates removed by percolating waters from guano. Such rock-phosphate is utilized for artificial fertilizers.

Limestones are used for a large variety of economic purposes. They are "burnt" for lime, or when argillaceous, hydraulic lime; when intimately mixed with sandy clay and burnt, they yield portland cement; in their purer forms they are widely used in the chemical, glass, soap-making and silicate industries; they serve as fluxes in the preparation of basic steel; and oolitic, dolomitic and ornamental limestones are utilized for building-stones, and less pure varieties for road-stones.

Dolomite-rock, also known as dolomitic or magnesian limestone, consists principally of the mineral dolomite, which is a carbonate of magnesium and calcium, but often contains admixture of other substances such as calcite, quartz, carbonates and oxides of iron, argillaceous material and chert or chalcedony. Dolomites when pure and well crystallized may be snowy white (*e.g.,* some examples from the eastern Alps) but are commonly yellow, creamy, brownish or grey from the presence of impurities. Dolomite dissolves only very slowly in dilute hydrochloric acid in the cold, but readily when the acid is warmed. Dolomites of compact structure have a higher specific gravity than limestones, but they often have a cavernous or drusy character, the walls of the hollows being lined with small crystals of dolomite having a pearly lustre and rounded faces. They are also slightly harder, and for this reason and on account of their greater resistance to weathering, they last better as building-, paving- and road-stones. Dolomites are rarely fossiliferous, as the process of dolomitization (which may be either pene-contemporaneous with, or subsequent to, the formation of the limestone) tends to destroy any organic remains originally present. Many dolomites, particularly those of Permian age in the north of England (Sunderland) show remarkable concretionary structures. The beds look as if made up of rounded balls of all sizes. These are composed of radiating calcite crystals. Dolomites furnish excellent building-stones, such, for example, as those of the north-east of England (Mansfield stone, etc.). Parts of the houses of parliament at Westminster are built of dolomite. Granular dolomite is also used, on account of its refractoriness to heat, for lining the hearths of furnaces in which basic steel is prepared. (P. G. H. B.)

LIMICOLAE, shore birds, known as suborder Charadrii, including jaçanas, snipe, oyster catchers, lapwings, plovers, woodcock, sandpipers, stilts, avocets, phalaropes, pratincoles and sheathbills (*qq.v.*). (G. F. Ss.)

LIMINA APOSTOLORUM, an ecclesiastical term used to denote Rome and especially the church of St. Peter and St. Paul. A *Visitatio Liminum* might be undertaken *ex voto* (in accordance with a vow) or *ex lege* (in accordance with a law). In 743 a Roman synod decreed that all bishops subject to the metropolitan see of Rome should meet personally every year in that city to give an account of the state of their dioceses. Gregory VII and Sixtus V greatly enlarged the number of bishops subject to this law; the latter, in a bull of 1584, ordering all bishops in the world to pay visits to Rome at stated intervals. Benedict XIV in 1740 extended the summons to all abbots, provosts and others who held territorial jurisdiction.

LIMING. Very early in the development of agriculture it was noted that the use of calcic materials, such as slaked lime [$Ca(OH)_2$], ground limestone ($CaCO_3$) and marl, not only increased crop yields in many instances, but also improved the physical condition of the soil. Liming has become a general agricultural practice, and the list of materials utilized includes, in addition to those named above, ground dolomite (a double carbonate of calcium and magnesium), ground oyster shells, furnace slags (mostly calcium silicates) and several other materials. In general, limestone and dolomite bring equal responses, but dolomite proves more effective in those regions where commercial fertilizers have been used extensively for decades. The role of calcium compounds in the soil is by no means a simple one, and, in spite of much research, all of its actions are not yet fully understood. It is known that certain plants will not grow in highly acidic soils. The addition of lime naturally decreases the acidity of such a soil, but inasmuch as the highly acidic condition of the soil is itself an indication of a calcium deficiency, the effect of liming is to supply needed calcium as well as to decrease the acidity.

When rocks and minerals weather to form a soil, such of the resultant products as are soluble in water containing dissolved carbon dioxide and bacteria-generated acids are either used by plants or lost by leaching. Where rainfall is sufficient, this process sooner or later develops a soil of relatively low calcium and magnesium content. The remaining bases are held chiefly in chemical combination with the clay. When the clay yields bases to plants or loses them through leaching, the soil becomes progressively acidic. The acidity is a symptom of calcium deficiency, and some of the micro-organisms favourable to plant growth, such as the nitrogen-fixing bacteria, do not function in a highly acidic soil environment.

In regions of moderate to high rainfall most soils are acidic, a fact expressed in technical parlance by saying that the *p*H of the soil is less than 7. The root sap of most agricultural plants is faintly acidic, the *p*H varying from 4 to 6. Legumes such as alfalfa and clover grow well in a soil of *p*H about 6.5 when calcium and the other necessary mineral elements are present, whereas some agricultural crops grow satisfactorily in somewhat more acidic soil. In general, a soil *p*H from 6 to 8, *i.e.*, from slightly acidic to slightly alkaline, is favourable for nearly all agricultural plants. All crops remove calcium from the soil, however, and liming is necessary to maintain the supply and thereby prevent the normal acidity of the soil from increasing beyond a desirable limit.

A soil should not be overlimed, for this will depress the availability of added phosphate and other plant nutrients, particularly potassium and magnesium and some of the minor nutrients such as boron, iron, zinc and manganese.

There is a decided calcium deficiency in nearly all agricultural areas of the United States where rainfall exceeds 30 in. annually. The use of liming materials, ground limestone in particular, is increasing rapidly in these areas. In the decade 1933–43, the use of liming materials increased in the United States about tenfold, from 1,670,000 tons to 17,885,000, largely because of grants-in-aid made to farmers by the Federal Agricultural Adjustment administration. The requirement is far greater than the amount applied even under the stimulus of federal aid. (H. A. Cs.)

LIMIT, a mathematical concept of great importance which has emerged slowly through long historical stages; it is best presented through an account of its origin and development. Among the ancients the method of exhaustion played the rôle which in more recent times has been taken by the method of limits; the former is ascribed to Eudoxus (*q.v.*) of Cnidus. It was frequently employed by Euclid (*q.v.*), and was further developed by Archimedes (*q.v.*). In one form it may be stated as follows: If from a magnitude more than half of it is taken away, and from the remainder more than half is taken, and from what then remains more than half is again taken, and if this process is continued, the magnitude remaining will ultimately become less than any magnitude which may have been pre-assigned. This principle is frequently employed in the *Elements* of Euclid for finding areas and volumes. To find the area of a circle, for instance, we may inscribe a regular polygon and find its area; then we may inscribe a larger regular polygon including the former and differing in area from the area of the circle by less than half the difference of area between the preceding polygon and the circle; we may then repeat the process indefinitely. According to the principle of exhaustion a polygon will thus be obtained whose area differs from that of the circle by less than any pre-assigned magnitude. Nowadays we say that the areas of these inscribed polygons approach the area of the circle as a limit in accordance with the following abstract definition of limit:

A variable x is said to approach a given constant a as a limit if the law of variation of x is such that the numerical value of the difference between x and a becomes and remains smaller than any (whatever) pre-assigned positive number.

In finding the area of a circle by the method just indicated the variable x has for its values the areas of the inscribed polygons while the constant a is the area of the circle. Here the variable x remains always less than its limit. If we should similarly find the area a of a circle by means of circumscribed polygons, then the corresponding variable x would always remain greater than its limit a. According to the definition in its general form x may vary in such a way as to be sometimes less than a and sometimes greater than a and indeed sometimes equal to a. What is essential is that it shall vary so that the numerical value of the difference between a and x shall become and shall remain less than any (whatever) positive number assigned in advance.

The method employed by Archimedes was more general than the simple method of exhaustion already described. It consisted in enclosing the magnitude to be evaluated between two others which can be brought by a definite process to differ by less than any pre-assigned magnitude. Thus in finding the area of a circle he employed regular inscribed and regular circumscribed polygons and showed that the number of sides could be taken large enough to render the difference in area between such an inscribed and such a circumscribed polygon less than any pre-assigned magnitude.

Arithmetical Theory of Limits.—The reduction of the idea of limit to the arithmetic form given in the foregoing formal definition is due to John Wallis (*q.v.*). His method, described in modern language, rests on the simultaneous consideration of a sequence, $a_1, a_2, a_3, \ldots$ of numbers arranged in order according to some law, and a number a such that the varying differences $a-a_n$ as n increases, become and remain smaller than any pre-assigned number whatever. The arithmetic character of the notion of limit was put in clearer light by Augustin Cauchy (*q.v.*) in his demonstration of the existence of definite integrals of continuous functions. Wallis always supposes essentially that the limit is known or that its existence is evident. In the work of Cauchy we have the clear conception of the existence of the limit as dependent upon certain properties of the numbers constituting the infinite set of values of the variable. In this connection the fundamental theorem for limits of sequences is the following:

In order that the sequence $a_1, a_2, a_3, \ldots$ shall have a limit it is necessary and sufficient that for each positive number ϵ there shall exist a positive integer n such that the difference a_m-a_n shall be numerically less than ϵ for every integer m greater than n.

The method of limits, in its arithmetical formulation, underlies the entire development of the infinitesimal calculus and has important applications in geometry and mechanics. The general principle of convergence to a limit, summed up in the general theorem just stated, provides a criterion for the existence of the limit of a sequence of numbers; and a considerable part of modern mathematical analysis is devoted to the problem of obtaining special forms of the general principle suited to particular classes of cases. The logical development of the theory depends essentially on the introduction of irrational numbers and cannot be carried through without a previous development of the theory of these numbers. (*See* NUMBER and NUMBER SEQUENCES.)

Typical Limiting Processes.—If u and v are variables approaching the limits a and b respectively and if c is a constant, then the variables cu, $u+v$, $u-v$, uv, u/v approach respectively the limits ca, $a+b$, $a-b$, ab, a/b, the last holding only when b is different from zero. These facts afford the rules for the elementary operations with limits. (*See* also SERIES.)

The proposition that x approaches the limit a is written in the symbolic form $\lim x=a$. If x approaches the limit a then a function $f(x)$ of x may approach a limit A; that is, as x varies according to its law of variation, the variation of $f(x)$ according to the induced law of variation may be such that the difference between $f(x)$ and A becomes and remains smaller than any assigned number. In that case we write

$$\lim_{x=a} f(x)=A$$

If x varies so as to become numerically larger than any pre-assigned number whatever, then x is said to become infinite. We write this statement symbolically in the form $\lim x=\infty$. It is not to be understood that there is a number infinity (∞) which x approaches; the symbol merely says that x becomes infinite in the sense of the definition as given. As x becomes infinite a function $f(x)$ of x may approach a limit A or it may become infinite; in these respective cases we write

$$\lim_{x=\infty} f(x)=A, \lim_{x=\infty} f(x)=\infty$$

Of course, as x approaches a limit or becomes infinite a given function may neither become infinite nor approach a limit. Thus if x approaches zero as a limit over all numbers near zero the function $\sin (1/x)$ does not approach a limit but oscillates between the bounds -1 and 1.

If $a_1, a_2, a_3, \ldots$ is a sequence of real numbers and if a number a exists such that for every positive number ϵ each of an infinite number of the elements $a_1, a_2, a_3, \ldots$ lies between $a-\epsilon$ and $a+\epsilon$ then a is said to be a value approached by the sequence. In this case a subsequence of the given sequence exists of such sort as to admit the limit a If there is a subsequence of positive numbers in the given sequence such that the elements of the subsequence become infinite then the given sequence is said to admit ∞ as a value approached; if a subsequence of negative numbers has this property then the given sequence is said to admit $-\infty$ as a value approached. The greatest value approached is called by Cauchy the greatest limit of the sequence; the least value approached is called the lowest limit of the sequence. If the greatest limit and the lowest limit are equal, then the variable has a limit in the sense of the earlier definition. In fact it may be shown that a necessary and sufficient condition that a sequence shall have a limit in the sense of the earlier definition is that it shall admit but one value approached.

See Hobson's *Theory of Functions of a Real Variable*, Cambridge University Press, vol. I. (3rd ed. 1927) and vol. II. (2nd ed. 1926). *See* also *Encyclopédie des Sciences Mathématiques*, tome I., vol. I., pp. 133–208. (R. D. CA.)

LIMITATION, STATUTES OF, the name given to Acts of parliament by which rights of action are limited in England, Wales and the north of Ireland to a fixed period after the occurrence of the events which give rise to the cause of action. This is one of the devices by which lapse of time is employed to settle disputed claims. The principle was first adopted in English law in connection with actions for the recovery of real property. At first a fixed date was taken, and no action could be brought of which the cause had arisen before that date. By the Statute of Westminster the First (3 Edward I. c. 39), the beginning of the reign of Richard I. was fixed as the date of limitation for such actions. Possession of rights in *alieno solo* from time immemorial was held to be an indefeasible title, and the courts held time immemorial to begin with the first year of Richard I.

A large number of statutes since that time have established periods of limitation for different kinds of actions. Of those now in force the most important are the Limitation Act 1623 for personal actions in general, and the Real Property Limitation Act 1833 relating to actions for the recovery of land. The latter statute has been much amended by the Real Property Limitations Act 1874.

By s. 14 of the Act of 1833, when any acknowledgment of the title of the person entitled has been given to him, the statute begins to run from that fact. By s. 15, persons under the disability of infancy, lunacy or coverture, or beyond seas, and their representatives, are to be allowed ten years from the termination of this disability, or death (which shall have first happened), notwithstanding that the ordinary period of limitation shall have expired.

By the Act of 1623 actions of trespass, detinue, trover, replevin or account, actions on the case (except for slander), actions of debt arising out of a simple contract and actions for arrears of rent not due upon specialty shall be limited to six years from the date of the cause of action. Actions for assault, menace, battery, wounds and imprisonment are limited to four years, and actions for slander to two years. Persons labouring under the disabilities of infancy, lunacy or unsoundness of mind are allowed the same time after the removal of the disability. When the defendant was "beyond seas" (*i.e.*, outside the United Kingdom and the adjacent islands) an extension of time was allowed, but by the Real Property Limitation Act of 1874 such an allowance is excluded as to real property, and as to other matters by the Mercantile Law Amendment Act 1856.

An acknowledgment, whether by payment on account or by mere spoken words, was formerly sufficient to take the case out of the statute. The Act 9 Geo. IV. c. 14 (Lord Tenterden's Act) requires any promise or admission of liability to be in writing and signed by the party to be charged, otherwise it will not bar the statute.

Contracts under seal are governed as to limitation by the Act of 1883, which provides that actions for rent upon any indenture of demise, or of covenant, or debt or any bond or other specialty, and on recognizances, must be brought within 20 years after cause of action. Actions of debt on an award (the submission being not under seal), or for a copyhold fine, or for money levied on a writ of *fieri facias*, must be brought within six years. With regard to the rights of the Crown, the principle obtains that *nullum tempus occurrit regi*, so that no statute of limitation affects the Crown without express mention. But by the Crown Suits Act 1769, as amended by the Crown Suits Act 1861, in suits relating to land, the claims of the Crown to recover are barred after the lapse of 60 years. For the prosecution of criminal offences generally there is no period of limitation, except where they are punishable on summary conviction. In such case the period is six months by the Summary Jurisdiction Act 1848. Suits and indictments under penal statutes are limited to two years if the forfeiture is to the Crown, to one year if the forfeiture is to the common informer. Penal actions by persons aggrieved are limited to two years by the Act of 1833. Prosecutions under the Riot Act can only be sued upon within 12 months after the offence, and offences against the Customs Acts within three years. By the Public Authorities Protection Act, 1893, a prosecution against any person acting in execution of statutory or other public duty must be commenced within six months.

Trustees are expressly empowered to plead statutes of limitation by the Trustees Act 1888. For further information *see* the Crown Suits Acts 1769 and 1861, Summary Jurisdiction Acts 1848 and 1925, the Riot Act, the Customs Acts, the Public Authorities Protection Act 1893, the Criminal Law Amendment Acts 1885 and 1922, and the Trustees Act 1888. (*See* PRESCRIPTION, LACHES.)

As regards the application and adoption of the English statutes in the colonies, *see* W. Burge, *Commentaries on Colonial and Foreign Laws* (new ed., 1907–27), vol. iv., pt. ii.

United States.—The various States possess their own statutes of limitation which are modelled in the main upon the English statutes but differ widely in their minor details. Real actions are usually not barred for twenty years, whereas personal actions survive only for six years. Numerous distinctions exist with reference to personal actions, a distinction generally being drawn between actions sounding in contract and those sounding in tort, the latter having a shorter *period* ranging from two to six years. About half the States have copied the provisions of the English statute of 1833 known as Lord Tenterden's Act requiring any promise or acknowledgment of liability to be in writing in order to revive a debt barred by the period of limitation. Separate statutes prescribe varying periods of limitation for the prosecution of criminal offenses. A difference of opinion exists in the State courts as to whether the statute of limitations must be specially pleaded in order to be available as a defense. A few States take judicial notice of the running of the period but most States insist that the defendant must expressly claim the benefit of the statute.

LIMOGES, a town of west-central France, capital of the department of Haute-Vienne, formerly capital of the old province of Limousin, 176 m. S. by W. of Orléans on the railway to Toulouse and a junction for Poitiers, Angoulême, Périgueux and Clermont Ferrand. Pop. (1936) 91,375.

Limoges sent a large force to the defense of Alesia. In 11 B.C. it took the name of Augustus (*Augustoritum*); but in the 4th century it was called anew by the name of the *Lemovices*, whose capital it was. It then contained palaces and baths, had its own senate and the right of coinage. Christianity was introduced by St. Martial. From the 5th century onwards Limoges suffered greatly through wars. Under the Merovingians Limoges was celebrated for its mints and its goldsmiths' work. In the middle ages and until 1792 the town was divided into two distinct parts, each surrounded by walls. The Château, which grew up around the tomb of St. Martial in the 9th century, and was surrounded with walls in the 10th and again in the 12th, was under the jurisdiction of the viscounts of Limoges, and contained their castle and the monastery of St. Martial; the *Cité,* under the jurisdiction of the bishop, had but a sparse population, the habitable ground being practically covered by the cathedral, the episcopal palace and other churches and religious buildings. In the Hundred Years' War the bishops sided with the French, while the viscounts were unwilling vassals of the English. In 1370 the *Cité,* which had opened its gates to the French, was taken by the Black Prince and given over to fire and sword. The religious wars, pestilence and famine desolated Limoges in turn but Henri d'Aguesseau and Turgot helped it to recover. Limoges celebrates every seven years the Fête d'Ostension during which the relics of St. Martial are exposed for seven weeks, attracting large numbers of visitors. It dates from the 10th century, and commemorates a pestilence believed to have been stayed by the saint.

The town, on a hill on the right bank of the Vienne, comprises two parts originally distinct, the *Cité* with narrow streets and old houses occupying the lower slope, and the town proper the summit. In the latter a street known as the Rue de la Boucherie is occupied by a powerful and ancient corporation of butchers. Boulevards have replaced the ramparts, outside which are suburbs with wide streets and spacious squares. The cathedral was begun in 1273, in 1327 the choir was completed, and before the middle of the 16th century the transept, with its fine north portal and the first two bays of the nave; from 1875 to 1890 the construction of the nave was continued, and it was united with the west tower (203 ft. high) the base of which belongs to a previous Romanesque church. In the interior there is a magnificent rood loft of the Renaissance. St. Michel des Lions (14th and 15th centuries) and St. Pierre des Queyroix (12th and 13th centuries) contain interesting stained glass. An old basilica of St. Martial was pulled down after 1794. The Vienne is crossed by a railway viaduct and four bridges, two of which, the Pont St. Étienne and the Pont St. Martial, date from the 13th century. The museum includes a rich ceramic collection.

Limoges is the headquarters of the XXII army corps and the seat of a bishop, a prefect, a court of appeal and a court of assizes, and has tribunals of first instance and of commerce, a board of trade, arbitrators and a chamber of commerce. The educational institutions include a national school of decorative art. The chief industry is that of making and decorating porcelain, others are enamelling, a mediaeval industry revived at the end of the 19th century, the making of shoes and clogs and skin gloves, cloth weaving, straw paper making and printing. The Vienne is navigable for rafts above Limoges, and the logs brought down by the current are stopped at the entrance of the town by the inhabitants of the Naveix quarter, who form a special gild for this purpose.

LIMÓN or **PUERTO LIMÓN,** principal Caribbean port of Costa Rica, capital of the Province of Limón and shipping point of the leading banana plantations of the country. Pop. (1941) est. at 9,320. Limón is the eastern terminus of the Costa Rica railway, one of the first railways built on the Caribbean, and was the shipping point by mule and ox-cart of rails, a locomotive and cars, to San José, for the concession provided that the railway be built out from San José, in the mountains, and not merely up from the sea. This railway (103 mi. long) is now the chief route of travel to and from San José and carries millions of bunches of bananas yearly from the surrounding plantations to Port Limón. The town has a deep-water pier, with cranes and mechanical loading devices, and the banana ships are loaded at the dock. Limón is a port of call for liners from Europe and the United States, and is on the route of travel from the Panama Canal Zone to San José, which, as it is the nearest highland city to the canal, is a popular vacation resort. The United Fruit Company has large storehouses and administrative offices in Limón, and the chief business of the town is importing and exporting, the chief items of export being bananas and coffee.

LIMONITE or BROWN IRON-ORE, a natural ferric hydrate named from the Gr. λειμών (meadow), in allusion to its occurrence as *bog-ore* in meadows and marshes. It is never crystallized, occurring in earthy or compact masses which are sometimes mammillated, botryoidal, reniform or stalactitic and may have a fibrous internal structure. Its hardness is about 5, and its specific gravity varies from 3·5 to 4. The colour is yellow to brown. Limonite gives a brown streak, which distinguishes it from haematite with a red, and from magnetite with a black, streak. In many cases it has been formed by the alteration of other iron minerals; *e.g.,* by hydration from haematite or magnetite, or by oxidation and hydration from siderite or pyrites. It has been commonly assumed that a series of hydrates of ferric oxide exist in nature, some of which have received specific names —*turgite, limonite, xanthosiderite, limnite;* but recent researches by Posnjak and Merwin (*Amer. Jour. of Sc.,* 1919, p. 311), have shown that there is no foundation for this assumption, there being only one true hydrate, namely, ferric oxide monohydrate, $Fe_2O_3{\cdot}H_2O$. It occurs in two polymorphs as the minerals, goethite (*q.v.*) and lepidocrocite and in an amorphous condition as limonite. The latter mineral contains a variable quantity of absorbed and capillary water. The so-called turgite, which has less water than the monohydrate, appears to represent a solid solution of goethite with haematite, together with enclosed and absorbed water. (*See* also IRON: *Compounds of Iron.*) Limonite abounds at Salisbury and Kent, Conn., in Berkshire county, Mass., and in Vermont, Pennsylvania, Alabama, Ohio, etc., and is a common ore in many European countries. (F. H. HA.)

LIMOUSIN (or LIMOSIN), **LÉONARD** (*c.* 1505–*c.* 1577), French painter, the most famous of a family of seven Limoges enamel painters, was the son of a Limoges innkeeper. He was at the beginning of his career influenced by the German school—indeed, his earliest authenticated work, signed L. L. and dated 1532, is a series of eighteen plaques of the "Passion of the Lord," after Albrecht Dürer, but this influence was counterbalanced by that of the Italian masters of the school of Fontainebleau, Primaticcio, Rosso, Giulio Romano and Solario, from whom he acquired his taste for arabesque ornament and for mythological subjects. Nevertheless the French tradition was sufficiently ingrained in him to save him from becoming an imitator and from losing his personal style. In 1530 he entered the service of Francis I. as painter and *varlet de chambre,* a position which he retained under Henry II. For both these monarchs he executed many portraits in enamel—among them plaques depicting Diane de Poitiers in various characters,—plates, vases, ewers, and cups, besides decorative works for the royal palaces, for, though he is best known as an enameller distinguished for rich colour, and for graceful designs in grisaille on black or bright blue backgrounds, he also enjoyed a great reputation as an oil-painter. His last signed works bear the date 1574, but the date of his death is uncertain, though it could not have been later than the beginning of 1577. It is on record that he executed close upon two thousand enamels. He is best represented at the Louvre, which owns his two famous votive tablets for the Sainte Chapelle, each consisting of twenty-three plaques, signed L. L. and dated 1553; and many portraits. Other representative examples are at the Cluny and Limoges museums, and in the London collections.

See *Léonard Limousin: peintre de portraits* (*L'Oeuvre des peintres émailleurs*), by L. Boudery and E. Lachenaud (Paris, 1897)—with a catalogue of the known existing examples of the artist's work. *See* also Alleame and Duplessis, *Les Douze Apôtres—émaux de Léonard Limousin,* etc. (Paris, 1865); L. Boudery, *Exposition retrospective de Limoges en 1886* (Limoges, 1886), *Léonard Limousin et son oeuvre* (Limoges, 1895), *Limoges et le Limousin* (Limoges, 1865); A. Meyer, *L'Art de l'émail de Limoges, ancien et modern* (Paris, 1896); Émile Molinier, *L'Émaillerie* (Paris, 1891).

LIMOUSIN, a former province of France. In the time of Julius Caesar the *pagus Lemovicinus* covered the county now comprised in the departments of Haute-Vienne, Corrèze and Creuse, with the *arrondissements* of Confolens in Charente and Nontron in Dordogne. These limits it retained until the 10th century, and they survived in those of the diocese of Limoges (except a small part cut off in 1317 to form that of Tulle) until 1790. The break-up into great fiefs in the 10th century, however, tended rapidly to disintegrate the province, until at the close of the 12th century Limousin embraced only the viscounties of Limoges, Turenne and Comborn, with a few ecclesiastical lordships, corresponding roughly to the present *arrondissements* of Limoges and Saint Yrien in Haute-Vienne and part of the *arrondissements* of Brive, Tulle and Ussel in Corrèze. In the 17th century Limousin, thus constituted, had become no more than a small *gouvernement*.

Limousin takes its name from the *Lemovices*, a Gallic tribe whose country was included by Augustus in the province of *Aquitania Magna*. Politically it shared in general the vicissitudes of Aquitaine, whose dukes were its over-lords from 918 until 1264, after which it was sometimes under them, sometimes under the counts of Poitiers, until the French kings succeeded in asserting their direct over-lordship. It was, however, until the 14th century, the centre of a civilization of which the enamelling industry (*see* ENAMEL) was only one expression. The Limousin dialect, now a mere *patois*, was regarded by the troubadours as the purest form of Provencal.

LIMPKIN, a single species of big, brown, rail-like bird of the Americas, constituting the family Aramidae, closely related to the crane (*q.v.*). This bird (*Aramus scolopaceus*), 28 in., called courlan or crying bird from its loud, prolonged, wailing cry, and limpkin from its peculiar halting gait as it hunts along the ground, ranges lowlands from eastern Argentina north to southern Mexico, Puerto Rico and Hispaniola, one race (*A. s. pictus*) resident in interior of the Florida peninsula and southern Georgia (Okefinokee swamp). It is found along borders of wooded streams, bayous, sloughs or in open marshes, sometimes uplands, where it runs rail-like through tangle with long strides, flies with short concave wings slowly flapping, neck extended, legs dangling or perches heronlike on a small tree. It feeds on mollusks, crustaceans, aquatic insects, frogs, worms, in the Everglades largely on large greenish fresh-water snails (*Ampullaria*) carried to nest or favourite feeding perch, held firmly in one foot, and struck several powerful blows with the 4-in. bill, which is then forced into the spiral opening of the shell to pull out the animal. The bulky nest is of leaves, twigs and Spanish moss, in tall sawgrass or among vines in bush or low tree over or near water; the eggs, four to six, rarely eight, are buff splashed with browns and drabs.

(G. F. Ss.)

LIMPOPO or Crocodile, a river of S.E. Africa more than 1,000 mi. in length, next to the Zambezi the largest river of Africa entering the Indian ocean. Its head streams rise on the northern slopes of the Witwatersrand less than 300 mi. due W. of the sea, but the river makes a great semicircular sweep across the high plateau. For a great part of its course the Limpopo forms the north-west and north frontiers of the Transvaal. Its banks are well wooded and present many picturesque views. In descending the escarpment of the plateau the river passes through rocky ravines, piercing the Zoutpansberg near the northeast corner of the Transvaal at the Toli Azimé falls. In the low country it receives on the right bank its chief affluent, the Olifants river (450 mi. long), which shares with the main river the distinction of having cut back across the eastern escarpment, and of draining parts of the interior plateau. The Limpopo enters the ocean in 25° 15′ S. The mouth, about 1,000 ft. wide, is obstructed by sand banks. In the rainy season the Limpopo loses a good deal of its water in the swampy region along its lower course. High-water level is 24 ft. above low-water level, when the depth in the shallowest part does not exceed 3 ft. The river is navigable all the year round by shallow-draught vessels from its mouth for about 100 mi. to a spot known as Gungunyana's Ford. In flood time there is water communication south with the river Komati (*q.v.*). At this season stretches of the Limpopo above Gungunyana's Ford are navigable. The river valley is generally unhealthy.

The basin of the Limpopo includes the northern part of the Transvaal, the eastern portion of Bechuanaland, southern Matabeleland and a large area of Portuguese territory north of Delagoa bay. Its chief tributary, the Olifants, has been mentioned. Of its many other affluents, the Macloutsie, the Shashi and the Tuli are the most distant northwest feeders. Among the streams which, flowing north through the Transvaal, join the Limpopo is the Nylstroom, so named by Boers trekking from the south in the belief that they had reached the river Nile. In the coast region the river has one considerable affluent from the north, the Chengane, which is navigable for some distance.

The Limpopo is a river of many names. In its upper course called the Crocodile, that name is also applied to the whole river. Though claiming the territory through which it ran the Portuguese made no attempt to trace the river. This was first done by Captain J. F. Elton, who in 1870 travelling from the Tati goldfields sought to open a road to the sea via the Limpopo. He voyaged down the river from the Shashi confluence to the Toli Azimé falls, which he discovered, following the stream thence on foot to the low country. The lower course of the river had been explored 1868–69 by another British traveller—St. Vincent Whitshed Erskine.

LINACEAE, the flax family, comprising 22 genera and 320 species, mostly herbs and shrubs. The only important genus of this family of dicotyledons is *Linum*. (*See* FLAX; LINSEED.) For a consideration of the genera *see* H. Winkler, "Linaceae," Engler and Prantl, *Die Natürlichen Pflanzenfamilien* 19a:82–130, fig. 43–59 (1931).

LINACRE (or LYNAKER), **THOMAS** (*c.* 1460–1524), English humanist and physician, was probably born at Canterbury. He attended the cathedral school of Canterbury, then under the direction of William Celling (William Tilly of Selling), one of the earliest Greek scholars in England. Linacre entered Oxford about the year 1480, and in 1484 was elected a fellow of All Souls' college. Shortly afterward he visited Italy in the train of Celling, who was sent by Henry VII as an envoy to the papal court, and he accompanied his patron as far as Bologna. There he became the pupil of Angelo Poliziano, and afterward shared the instruction which that great scholar imparted at Florence to the sons of Lorenzo de' Medici. The younger of these princes became Pope Leo X, and was in after years mindful of his old companionship with Linacre. Among his other teachers and friends in Italy were Demetrius Chalcondyles, Hermolaus Barbarus, Aldus Romanus the printer, of Venice, and Nicolaus Leonicenus of Vicenza. Linacre took the degree of doctor of medicine with great distinction at Padua. On his return to Oxford he formed one of the brilliant circle of Oxford scholars.

Linacre does not appear to have practised or taught medicine in Oxford. About the year 1501 he was called to court as tutor of the young prince Arthur. On the accession of Henry VIII he was appointed the king's physician, and practised medicine in London, having among his patients most of the great statesmen and prelates of the time, as Cardinal Wolsey, Archbishop Warham and Bishop Fox. In 1520 he received priest's orders, though he had for some years previously held several clerical benefices. There is no doubt that his ordination was connected with his retirement from active life. Literary labours, and the cares of the foundation which owed its existence chiefly to him—the Royal College of Physicians—occupied Linacre's remaining years until his death on Oct. 20, 1524.

Linacre was more of a scholar than a man of letters, and rather a man of learning than a scientific investigator. He was one of the first Englishmen who studied Greek in Italy, whence he brought back to his native country and his own university the lessons of the "New Learning." Among his pupils was one—Erasmus—and others of note in letters and politics, such as Sir Thomas More, Prince Arthur and Queen Mary. Colet, Grocyn, William Lilye and other eminent scholars were his intimate friends.

Linacre wrote a Latin grammar (*Progymnasmata Grammatices vulgaria*), composed in English, a revised version of which was made for the use of the Princess Mary, and afterward translated into Latin by Robert Buchanan; and a work on Latin composition *De emendata structura Latini sermonis* (1524). His only medical works were his translations. None of his translations of Aristotle has survived. The following are the works of Galen translated by Linacre: (1) *De sanitate tuenda,* printed at Paris in 1517; (2) *Methodus medendi* (Paris, 1519); (3) *De temperamentis et de Inaequali Intemperie* (Cambridge, 1521); (4) *De naturalibus* *facultatibus* (London, 1523); (5) *De symptomatum differentiis et causis* (London, 1524); (6) *De pulsuum Usu* (London, without date). Linacre also translated, for Prince Arthur, an astronomical treatise of Proclus, *De sphaera,* which was printed at Venice by Aldus in 1499. The accuracy of these translations and their elegance of style were universally admitted. They have been generally accepted as the standard versions of those parts of Galen's writings, and frequently reprinted, either as a part of the collected works or separately.

The foundation by royal charter of the College of Physicians in London was mainly due to Linacre, and he was the first president of the new college, which he further aided by conveying to it his own house, and by the gift of his library. Shortly before his death Linacre obtained from the king letters patent for the establishment of readerships in medicine at Oxford and Cambridge, and placed valuable estates in the hands of trustees for their endowment. Two readerships were founded in Merton College, Oxford, and one in St. John's College, Cambridge. The Oxford foundation was revived by the university commissioners in 1856 in the form of the Linacre professorship of anatomy.

The materials for Linacre's biography are to a large extent contained in the older biographical collections of George Lilly (in Paulus Jovius, *Descriptio Britanniae*), Bale, Leland and Pits, in Wood's *Athenae Oxonienses* and in the *Biographia Britannica;* but all are completely collected in the *Life of Thomas Linacre,* by Dr. Noble Johnson (1835). Reference may also be made to Dr. Munk's *Roll of the Royal College of Physicians* (2nd ed., 1878); and the Introduction, by Dr. J. F. Payne, to a facsimile reproduction of Linacre's version of *Galen de temperamentis* (Cambridge, 1881).

LINARES, an inland province of central Chile, bounded north by Talca, east by Argentina, south by Ñuble and west by Maule. Pop. (1940) 134,968; area 3,791 sq.mi. The river Maule forms its northern boundary and drains its northern and northeastern regions. The province belongs partly to the great central valley of Chile and partly to the western slopes of the Andes, the S. Pedro volcano rising to a height of 11,800 ft. not far from the sources of the Maule. The northern part is fertile, as are the valleys of the Andean foothills, but arid conditions prevail throughout the central districts, and irrigation is necessary for the production of crops. The vine is cultivated to some extent, and good pasturage is found on the Andean slopes. The province is traversed from north to south by the Chilean Central railway, and the river Maule gives access to the small port of Constitución, at its mouth. From Parral, near the southern boundary, a branch railway extends westward to Cauquenes.

LINARES, a town of southern Spain, in the province of Jaén, among the southern foothills of the Sierra Morena, 1,375 ft. above sea-level and 3 mi. N.W. of Guadalimar river. Pop. (1940) 31,720 (mun., 47,562). It is connected by four branch railways with the argentiferous lead mines on the north-west, and with the main railways from Madrid to Seville, Granada and the principal ports on the south coast. Its population is chiefly engaged in the lead mines, and in the manufacture of powder, dynamite, match for blasting purposes, rope and the like. The mining plant is entirely imported, and smelting, desilverizing and the manufacture of lead sheets, pipes, etc., are carried on. Linares lead is unsurpassed in quality. About 2 mi. S. is the village of Cazlona, with remains of the ancient *Castulo.* Linares remained in government hands until shortly before the close of the civil war of 1936–39.

LINCOLN, EARLS OF. The first earl of Lincoln was probably William de Roumare (*c.* 1095–*c.* 1155), who was created earl about 1140. King Stephen granted the earldom to one of his supporters, Gilbert de Gand (d. 1156), who was related to the former earl. After Gilbert's death the earldom was dormant for about 60 years; then in 1216 it was given to another Gilbert de Gand, and later it was claimed by the great earl of Chester, Ranulf or Randulph, de Blundevill (d. 1232). From Ranulf the title to the earldom passed through his sister Hawise to the family of Lacy, John de Lacy (d. 1240) being made earl of Lincoln in 1232. He was son of Roger de Lacy (d. 1212), justiciar of England and constable of Chester. It was held by the Lacys until the death of Henry, the 3rd earl.

Henry served Edward I. in Wales, France and Scotland, both as a soldier and a diplomatist. He succeeded (1296) Edmund, earl of Lancaster, as commander of the English forces in Gascony. He fought at Falkirk in July 1298. He was then employed by Edward to negotiate successively with popes Boniface VIII. and Clement V., and also with Philip IV. of France; and was present at the death of the English king in July 1307. Under Edward II. he joined Earl Thomas of Lancaster and the baronial party, was one of the "ordainers" appointed in 1310 and was regent of the kingdom during the king's absence in Scotland in the same year. He died in London on Feb. 5, 1311, and was buried in St. Paul's cathedral. He married Margaret (d. 1309), granddaughter and heiress of William Longsword, 2nd earl of Salisbury, and his only surviving child, Alice (1283–1348), became the wife of Thomas, earl of Lancaster, who thus inherited his father-in-law's earldoms of Lincoln and Salisbury. Lincoln's Inn in London gets its name from the earl, whose London residence occupied this site. He founded Whalley abbey in Lancashire, and built Denbigh castle.

In 1349 Henry Plantagenet, earl (afterwards duke) of Lancaster, a nephew of Earl Thomas, was created earl of Lincoln; and when his grandson Henry became king of England as Henry IV. in 1399 the title merged in the crown. In 1467 John de la Pole (*c.* 1464–87), a nephew of Edward IV., was made earl of Lincoln, and the same dignity was conferred in 1525 upon Henry Brandon (1516–45), son of Charles Brandon, duke of Suffolk. Both died without sons, and the next family to hold the earldom was that of Clinton. Edward Fiennes Clinton, 9th Lord Clinton (1512–85), lord high admiral and the husband of Henry VIII.'s mistress, Elizabeth Blount, was created earl of Lincoln in 1572. The title is still held by Clinton's descendants. In 1768 Henry Clinton, the 9th earl (1720–94), succeeded his uncle Thomas Pelham as 2nd duke of Newcastle-under-Lyne, and since this date the title of earl of Lincoln has been the courtesy title of the eldest son of the duke of Newcastle.

See G. E. C(okayne), *Complete Peerage,* vol. v. (1893).

LINCOLN, ABRAHAM (1809–1865), sixteenth president of the United States, was born on Feb. 12, 1809, on a farm in Kentucky. In early childhood he was moved to another farm "in the valley (of Knob creek) surrounded," in his own words, "by high hills and deep gorges"; a rocky unfruitful soil where the furious washing of a "big rain in the hills" would sometimes sweep new planting "clear off the field." Here, in virtually peasant conditions, his childhood was spent.

The paternal descent, though unknown to him beyond the third generation back, has been traced by enthusiastic genealogists to a lost or strayed member of a distinguished New England family of the same name. On his mother's side he was descended from an east Virginia family of the name of Hanks who were of humble station. His grandmother, Lucy Hanks, migrated with her parents in 1782 to the Virginia mountains. There soon afterward she had a natural child, Nancy Hanks, who eventually removed to Kentucky and married in 1806 Thomas Lincoln. Their second child but first son was Abraham Lincoln. Nothing is known of the father of Nancy Hanks, though there is a persistent tradition that he was a Virginia aristocrat. Nancy's famous son appears to have believed this story and to have felt that whatever distinction he possessed had come to him from this unacknowledged heritage of aristocracy. Lincoln's parents have become the subject of sentimental controversy to such a degree that it is hard to remove the clouds of myth surrounding them and uncover the actual humanity which their son inherited. It seems tolerably certain that the father, Thomas, was a shiftless person who tried this and that, both carpentering and farming, who had something of the vagabond in his blood, also something of the dreamer, and was always at heart a rolling stone. Besides shifting from farm to farm in Kentucky he subsequently took his family far afield, settling in Indiana when Abraham was eight years old, and moving on to Illinois when his son was 21. Nancy Hanks is even more shadowy. Though enthusiasts talk of her as "a forest madonna," it is impossible to say what they mean. It may be believed that she was good-looking, sensitive, pious, with an air about her that seemed to bespeak a different social world from the one in which she moved. She also seems to have been something of a dreamer. Many, if not all, frontier women of the old days were that. Their lives were hard, their emotions in the main were sealed up, but all around them was the mystery of the primitive forest; they treasured it in silence and gave vent to it only now and then in the ecstasies of religious revival. It is not fanciful to perceive in Abraham Lincoln all the characteristics of these two nor to believe that during much of his life they were appearing and disappearing in a way that is sometimes bewildering and that not until late in life were they blended coherently.

In 1816 Thomas Lincoln insisted on taking to the road. Tradition has it that Nancy was loath to go, that she was oppressed by a sense of unhappiness. The winter of 1816–17 was spent by the Lincolns in a "half-faced camp"—that is, a cabin with but three walls, the fourth side being entirely open—on land for which Thomas had contracted in the valley of Pigeon Creek in southern Indiana. His son remembered long afterward that their settlement was "in an unbroken forest" and that, young as he was, "an ax was put into his hands" at once, and that all of them accepted as their chief task the clearing of the wood. A cheerless life ensued—"pretty pinching times," he says. After two years of dreary struggle, Nancy Lincoln broke down and was carried off by an epidemic which swept the country-side in the autumn of 1818. The pathetic note that somehow is present always in her story closes with a glimpse of her husband returning to his former trade as a carpenter and fashioning her coffin out of green lumber.

Lincoln's home was in Indiana from his eighth year until shortly after his twenty-first birthday. During this period his father married secondly a Kentucky widow, Sarah Bush Johnson. In his stepmother, Lincoln found a kind, practical, understanding friend. To her, doubtless, may be traced an increase of general comfort in the family's way of living. Nevertheless, they continued to be poor people in a poor community. Thomas Lincoln never rose above the estate of a peasant farmer. Abraham had less than a year's schooling. Such as he had was mainly in Indiana, though a very little elementary schooling had been given him in Kentucky. None of it went beyond "readin', writin' and cipherin'." Although, in his own words, "there was absolutely nothing to excite ambition for education" he had an innate hunger for it and would lie before the fire at night doing sums with a piece of wood for a slate. A few books which early came his way were eagerly devoured. *Pilgrim's Progress, Aesop, Robinson Crusoe,* Weem's *Life of Washington* and Franklin's *Autobiography* were the earliest foundations of that sense of style which later was one of his characteristics.

He was a good-humoured, rather idle, imaginative boy who appears to have been a general favourite. Unlike the typical frontiersman he never became a hunter, never pulled a trigger on anything larger than a wild turkey. "I was raised to farm work," he writes. Even as a boy he exhibited a faculty for story-telling, could make jingling rhymes on occasion and was a droll mimic. His easy-going camaraderie informs an oft-repeated anecdote. In spelling class a little girl hesitated between "i" and "y"; Lincoln slyly put his finger on his own eye. About the same time occurred his first experiment with imagination. A party of travellers stopped briefly at his father's house while their wagon was being mended. Among them was a little girl who took the boy's fancy. After she had gone he wove out of the memory an elaborate romance in which he was the hero of an elopement and she the heroine. Talking long after of this boyish dreaming he said, "I think it was the beginning of love for me." Of his real experiences the first that opened up the world beyond Pigeon Creek occurred when he was 19. This raw farm-hand was engaged as "hired man merely" to go down to New Orleans on a flat-boat. The strange old semi-Spanish city even as late as 1828 was a striking, exotic place unlike anything else in the United States. The strength of the imaginative faculty in Lincoln is attested by much evidence both direct and indirect. Who can doubt that New Orleans was as wonderful to him as the *Arabian Nights?* And yet with singular reticence he has left no record of his impressions. Reticence, degenerating at times into secretiveness, is one of his fixed characteristics. A second journey to New Orleans three years later is also without the slightest explanatory comment either in his letters or his table talk.

Between these two journeys, the Lincoln family with several of their "in-laws" formed a small migration to Illinois (March 1830). The women went in a wagon drawn by oxen. The men walked. Abraham was the ox-driver during much of the journey. By this time he was a very tall young man, six feet three or four, raw-boned, lanky, but possessed of immense physical strength. He was noted for the skill and power with which he could wield an axe. During his first autumn in Illinois he made use of his skill as an axe-man splitting fence rails. A contract to split three thousand rails was not filled until late in the following winter. At this time he was casting about for other employment. His father was comfortably settled on a new farm, but the son had had enough of farming. Presently, he fell in with a trader, Denton Offcutt, who engaged him for that second trip to New Orleans already mentioned. A good deal of legend has grown up about this journey. Most of it may be discarded. It seems likely, however, that he saw more of slavery than on the previous journey and that what he saw shocked him. But the evidence is irregular.

First Essay in Politics.—One result of this journey was the employment of Lincoln as clerk in a general store which Offcutt decided to open in the village of New Salem, Ill. During six years (1831–37) Lincoln counted himself a resident of New Salem. It was a forlorn village, one of those accidental congestions of population that often appeared on the frontier with no true reason for their existence and that eventually melted off the map. There was a mill, a tavern, a few stores and a handful of people. The Offcutt store proved a failure. Offcutt left town and Lincoln was without employment. He turned to politics. This move had been made possible by events that reveal two more of his fundamental characteristics. New Salem contained a group of young roughs known as the Clary Grove Boys, who were eager to try the mettle of any new-comer in the town. A wrestling match was arranged between their best man and Lincoln in which the unexpected happened, the local hero was overthrown. The astonishing part of the episode was the promptness with which Lincoln, while not displacing their leader in their estimation, won over both him and them, with the result that they formed the nucleus of a devoted personal following. A peculiar power to attract men, joined with complete ability to remain himself, becomes hereafter characteristic of all he does. The secret appears to lie in the blending in his own mind of humour and toleration combined with a singular non-censorious purity of life, and all reinforced by his immense physical strength. How far his peculiar character was enhanced, in the eyes of ordinary humanity, by his capacity for what Stevenson would have called "a large and genial idleness" is worth considering.

His first candidacy for the legislature (1832) was unsuccessful. Two years later New Salem changed its mind and elected him. He continued to represent the town during the remainder of his stay there. All the while he was extremely poor. For a time he tried to keep a store in partnership with a man named Berry. They failed, leaving debts which Lincoln assumed and which he slowly, painfully paid off during the next 15 years. He obtained the beggarly office of postmaster at New Salem but this did not suffice for a livelihood. In desperation he borrowed a book on surveying and with extraordinary mental quickness made himself at home in it. He subsisted by working as a surveyor during several years. Meanwhile, he formed a friendship with John T. Stuart who advised him to study law. To gain admittance to the bar in a frontier community was, in those days, a simple matter. Lincoln read hard by himself, obtained a licence to practise, removed to Springfield and on April 12, 1837, entered into partnership with Stuart. An episode of his life at New Salem was his enlistment as a volunteer in the Black Hawk War (1832). His Clary Grove friends also enlisted and made their earliest display of devotion by electing him captain of their company. This was in the midst of his first candidacy for the legislature. He saw no fighting. Apparently he was so easy-going as an officer that the real soldiers at the front regarded him as inefficient. The one

LINCOLN'S GETTYSBURG ADDRESS

THE Battle of Gettysburg was fought on the first, second and third days of July, 1863. On November 19 of the same year a portion of the battlefield was dedicated as a final resting place for those who died there. The main address on that occasion was one of two hours in length, delivered by Edward Everett, the best known orator of the time. After his address, Lincoln delivered the short speech now so famous. Lincoln had begun the preparation of this address the day before the dedication while still in Washington. After reaching Gettysburg he spent a portion of the evening and of the next morning in finishing the address, writing it out, partly in ink and partly in pencil. He delivered the address, however, without even a passing reference to his written draft. At the time almost no attention was paid to this address, it being relegated to the inner pages of the newspapers, while Edward Everett's elaborate oration received unqualified praise. It was not until many years later that the address became recognized as one of the classic utterances of all time.

It is interesting, however, to know that Edward Everett wrote to Mr. Lincoln on the day following the address, saying: "I wish that I could flatter myself that I had come as near to the central idea of the occasion in two hours as you did in two minutes."

The following is the text of the Gettysburg Address:

"FOURSCORE and seven years ago our fathers brought forth on this continent a new nation conceived in liberty and dedicated to the proposition that all men are created equal. Now we are engaged in a great civil war testing whether that nation, or any nation so conceived and so dedicated, can long endure. We are met on a great battlefield of that war. We have come to dedicate a portion of that field as a final resting-place for those who here gave their lives that that nation might live. It is altogether fitting and proper that we should do this. But, in a larger sense, we cannot dedicate, we cannot consecrate, we cannot hallow this ground. The brave men, living and dead, who struggled here have consecrated it far above our poor power to add or detract. The world will little note nor long remember what we say here, but it can never forget what they did here. It is for us the living rather to be dedicated here to the unfinished work which they who fought here have thus far so nobly advanced. It is rather for us to be here dedicated to the great task remaining before us—that from these honoured dead we take increased devotion to that cause for which they gave the last full measure of devotion—that we here highly resolve that these dead shall not have died in vain, that this nation under God shall have a new birth of freedom, and that government of the people, by the people, for the people, shall not perish from the earth."

valuable result of the episode is a fragment of writing in which he describes the scene of a skirmish where he arrived with his company in time to bury the dead. The few sentences, in which we glimpse the dead men "painted all over" by the red sunset, have a strange undertone that is perhaps the first appearance in his preserved memorabilia of the mystical vein which was part of his distinctiveness. Mysticism of some sort was universal in the frontier people. Usually it took a supernatural bent. One cannot doubt that Lincoln's mother was an instinctive mystic in the familiar sense. But her sort of mysticism did not descend to her son. In its place, the same fundamental impulse toward wonder and awe established a frame of mind that might be called naturalistic mysticism. Years afterward, on his first visit to Niagara, Lincoln was for the moment lost in reverie; but the subject of his reverie was neither supernatural nor, as so readily it might have been, literary; he was lost in wondering where all the water came from. This ability to be so impressed by the stark realities of life and death and nature that they took on all the significance of the supernatural reappeared frequently throughout his later life. Along with it were evidences of the familiar forms of supernaturalism. He confessed himself to be "superstitious." He believed in dreams as omens. On the day before his death he narrated a dream which he had the night before. He told the cabinet he had had that same dream preceding all the great events of the war. He was sure its recurrence presaged a great and fortunate happening.

In the New Salem period occurred his first actual love affair, of which anything is known. Doubtless there is some significance in the fact that he recognized, even if playfully, that the beginning of love for him was the idle dreaming over the girl in the wagon. All his life long there was a certain remoteness in him, a something that made him not quite a realist, but which was so veiled by apparent realism that careless people did not perceive it. He did not care whether they perceived it or not, was willing to drift along, permitting circumstances to play the main part in determining his course and not stopping to split hairs as to whether his earthly attachments sprang from genuine realistic perceptions of affinity or from approximation more or less to the dreams of his spirit. Of a girl named Ann Rutledge who lived at New Salem and died there in 1835, aged 19, very little is certainly known. She was a daughter of the tavern keeper. Lincoln boarded for a time in her father's house. Young as she was, Ann had had a desperate love affair which turned out badly (the man disappeared) before Lincoln fell in love with her. The affair was cut short by her sudden death from malarial fever. The episode has been magnified out of all proportion to the known facts by sentimental biographers. It may be safely dismissed as not deeply significant in itself. Traditions of its aftermath have more importance. They reveal the profound sensibility, also the vein of melancholy and the unrestrained emotional reaction which came and went, in alternation with boisterous mirth, to the end of his days. Following Ann's death he fell into a state of morbid depression which appears to have given rise to the report that he had a streak of insanity. Apparently he himself felt a terror of this side of his make-up, a terror that is revealed in the most mysterious of his experiences, several years later. He recovered rapidly from the abnormal condition following Ann's death. Perhaps it was on the rebound from the melancholy affair of Ann that he became entangled the next year in an affair that caused him almost at once to wish he was out of it. Mary Owens was a bouncing, sensible lass with whom he drifted into an engagement but who was not long in deciding that he was "deficient in those little links that make up the chain of a woman's happiness." This affair overlapped his removal to Springfield. Mary Owens broke the engagement, greatly to his relief, in the spring of 1838. Two years passed and Lincoln found himself engaged to Mary Todd, a beautiful young woman, high-spirited, well-educated and much higher in social origin than he. The fact of their engagement is evidence that now at 29 he had either "arrived" or was on the sure road to arrival. The Springfield of 1840 contained a wide variety of stocks and characters but all were united in a democracy of endeavour where ability and promise were the prime qualifications for admission to society. Though Lincoln, very probably, was accurately described by Mary Owens, although he was undeniably awkward, even crude, the powers that had enthralled Clary Grove had continued to develop. Both men and women appear to have trusted him so completely as to pay no heed to his peculiarities and to give no thought to his origin. His melancholy and a curious vein of indecision did not ordinarily manifest themselves. He was still a member of the legislature, and both as politician and lawyer he had captured general confidence. Springfield took his engagement to Mary Todd as altogether appropriate.

There followed that mysterious experience which has never been explained. On Jan. 1, 1841—"the fatal first of January," as he called it—the engagement was broken off. After his death his biographer, Herndon, gave to his other biographer, Lamon, a story he had pieced together, to the effect that a date had been set for the wedding of Lincoln and Mary Todd, that everything was in readiness, the bride dressed for the ceremony, but that no bridegroom appeared, that he was discovered by friends in a state of temporary insanity. Infinite controversy has grown out of this story. One of Mary Todd's sisters told a third biographer, Jesse W. Weik, that it was true; another sister told a fourth biographer that it was false. There can be no doubt that the facts in the story are all in confusion. No marriage licence for Abraham Lincoln and Mary Todd was issued either in 1840 or 1841. But what lay behind the story, and why the two sisters of the bride should have disagreed about it as they did, is an unsolved puzzle. That Lincoln was in a desperate frame of mind in Jan. 1841 is attested in his own letters, especially in one recently made public by Dr. Barton. He wrote to his partner Stuart, on Jan. 20, 1841, "I have within the last few days been making a most discreditable exhibition of myself in the way of hypochondriasm"; therefore, he was much concerned that a certain Dr. Henry should be induced to remain in Springfield through the gift of the office of postmaster. At the same time he proved not incapable of discharging his duties in the legislature, though speaking of himself as "the most miserable man living." A safe conclusion is that while he had sufficient control of himself to keep at routine work with an appearance of steadiness he was suffering from intense nervous excitement—similar, doubtless, to that which he had experienced in 1835—that it alarmed him deeply, that somehow it upset his engagement and led those who knew about it at all to form the rash conclusion of virtual though concealed insanity. Within nine months he was himself again. His recovery is recorded in a group of letters which form the most remarkable personal monument of him that has survived. A close friend, Joshua F. Speed, had removed from Springfield to his former home in Kentucky. Lincoln visited him in the summer of 1841. He returned to Springfield in a wholesome frame of mind. The letters of Speed in the next 12 months show that the latter also had fallen into a painful state of introspection, doubting whether he truly loved the woman to whom he was engaged. Lincoln, now in a serenely cheerful mood, analyses his case, roundly lectures him and indirectly draws an outline of his own psychology. He exclaims, "I know what the painful point with you is at all times when you are unhappy; it is an apprehension that you do not love her as you should. What nonsense!" Again he writes, "I have no doubt that it is the peculiar misfortune of both you and me to dream dreams of Elysium far exceeding all that anything earthly can realize." Nevertheless, "I was always superstitious," he concludes later. "I believe God made me one of the instruments for bringing your Fanny and you together, which union I have no doubt He foreordained." While this correspondence was proceeding his recovered cheerfulness found expression in another love affair, a slight, playful episode, with a chit of a girl, Sarah Rickard, 17 or 18 years old when he was 32 and 33—a flirtation more properly than an affair. Which one cried it off it is not known; but it is quite plain that neither suffered as a consequence. In the latter part of 1842 Lincoln was in high good spirits. One of his characteristics in these earlier years was a love of sarcasm. His political speeches were at times biting. Only an idolizer can escape the conclusion that he indulged this propensity through sheer love of it. He gave it free rein in derisive open letters to the Sangamon

Journal making fun of an enemy politician, James Shields. Lincoln pretended to be an illiterate person—a sort of countrified parallel to Yellowplush—and signed himself "Aunt Rebecca." Ironical fate inspired Mary Todd and a girl friend of hers, who presumably thought Aunt Rebecca the essence of funniness, to try their hand at the same sort of thing. Their open letter to Shields also got into print. Shields, in a rage, demanded the authorship of the letters. Lincoln assumed responsibility both for what he had written and for the work of the young women. Shields challenged him. Lincoln reluctantly accepted. The duel was prevented through the intercession of friends at the very last moment. Senator Beveridge was the first to point out that the incident probably made a lasting impression on Lincoln because thereafter his sarcastic vein disappeared. An immediate result was a meeting with Mary Todd, followed by reconciliation and their marriage on Nov. 4, 1842.

Lincoln was still poor. The debts contracted in New Salem were not yet cleared away. But his political position as a local leader in the Whig Party was now well established. A change in law partners had created the firm of Logan and Lincoln (1841), the senior member of which was one of the most distinguished lawyers of the State. In 1843 the junior member felt he had a chance for Congress. The failure of his effort to secure the nomination was explained in a letter which he wrote soon after: "There was, too, the strangest combination of church influence against me. . . . It was everywhere contended that no Christian ought to go for me because I belonged to no church, was suspected of being a deist, and had talked about fighting a duel."

Attitude to Religion.—The report that he was a deist may be taken as evidence that he had talked rashly upon the subject of religion or, more exactly, upon sceptism. His rashness of speech politically in these early years appears to have been paralleled in other connections. On Washington's birthday, 1842, he had made an address before the Washingtonian Temperance Society which, while it expressed the most unconditional disapproval of intemperance, held a brief for sympathy with the drunkard as an individual, for putting aside all condescension with regard to him. Views of this sort were not likely to be popular in a frontier community where one was expected to be heartily one thing or another. But doubtless the real cause of his momentary unpopularity lay in sceptical books that had fallen into his hands, particularly Volney's *Ruins of Time,* about which he appears to have talked too freely for his own good. That these books really affected him may be doubted. Far more plausible is the assumption that the year 1843 marks a general change in his attitude to the rest of the world, and that just as he put a stop to his political sarcasm so also he pulled himself together and put aside a corresponding early impulse for religious banter.

It is hard to believe that Lincoln was at any time a genuine sceptic. His temper was essentially religious. The letters to Speed give clear evidence of a mood of faith which reappeared long afterward in his Fast Day Proclamations and in certain fragments that are among his most extraordinary writings. His peculiar mysticism would not let him escape from that community of wonder which made all the frontier people, if they thought at all about unseen things, one spiritual kindred. His belief in dreams is again in point. When he called himself superstitious he probably meant to acknowledge belief in the supernatural but at the same time to evade all attempt to define his belief. Here is one of his main characteristics. He both is and is not of the world that produced him. So far as wonder, awe, the sense of mystery go, he is one with his mother, with strange and vehement revivalists who roamed the frontier country and gave ghostly ministration to souls athirst for ecstasy. But on all points of dogma he has nothing in common with them. While still a boy he is reported to have made mock of revivals. Certain it is that the fury, the vindicative theology, the hell-fire creed of those religious primitives deeply offended him. With such theology and such ethics he stood in strong contrast through his amazing power to be, at the same time, passionless in temper while unfaltering in conviction. His religious attitude was put into words in the latter part of his life when he said, "I have never united myself to any church because I have found difficulty in giving my assent, without mental reservations, to the long complicated statements of Christian doctrine which characterize their Articles of Belief and Confessions of Faith. When any church will inscribe over its altar, as its sole qualification for membership, the Master's condensed statement of the substance of both Law and Gospel 'Thou shalt love the Lord thy God, with all thy heart and with all thy soul and with all thy mind, and thy neighbour as thyself' that church will I join with all my heart and with all my soul."

It must not be supposed that the change about 1843 was obvious and unconditional. It was merely a facing in a new direction. Thereafter sarcasm and rash banter—the impulse to play with other men's ideas—steadily ebb, though once in a while they suddenly flood back, as in some of the savage passages of the debates with Douglas in 1858. As a party speaker and debater Lincoln had formed bad mental habits, of which he may not have been aware, which did not wholly disappear until many years had passed. For one thing the humour in his political speeches was crude to a degree. It was the conventional humour of his time. Almost the only deliberate instance that has survived is a speech which was made when at last he had succeeded in getting into Congress. His aim was to ridicule Lewis Cass; the way he did it, like so much American humour of that day, suggests Dickens at his worst.

In Congress, where he served a single term, 1847–49, Lincoln was a staunch party man doing the routine business of the Whig organization with conventional faithfulness. Like all the rest of the Whigs, he tried to carry water on both shoulders with regard to the Mexican War, voting army supplies, posing as the soldiers' friend, but denouncing the president for having forced them into a position where they could not patriotically do anything else. Certain resolutions introduced by Lincoln and dubbed "the spot resolutions" obtained notoriety. They called upon the president to indicate the precise spot where previous to his declaration of war American blood had been shed on Mexican soil. Lincoln's one congressional action that revealed an individual point of view was a bill for emancipating slaves in the District of Columbia. Long since he had become a hater of slavery. But he had had no toleration for the Abolitionists. As far back as 1837, at the end of a session of the legislature when all its serious business was out of the way, he had introduced resolutions asserting "that the institution of slavery is founded on both injustice and bad policy; but that the promulgation of abolition doctrines tends rather to increase than to abate its evils"; asserting also that Congress had power to abolish slavery in the District of Columbia but "that the power ought not to be exercised unless at the request of the people of the District." During 12 years he had held to this serene and unemotional attitude while the storm of Abolition swept over the country, and in 1849 he restated his views of 1837. His bill provided for emancipation in the District with consent of the voters and with compensation to the owners. The bill was not considered. Lincoln had not satisfied anyone as a Congressman. The local political machine did not admit that he deserved any special consideration and felt that others were entitled to their day in the sun at Washington. The younger Whigs wanted a more aggressive type of leader. Apparently he was out of it politically in Illinois. Lincoln's life is a succession of waves of energy rising and falling. There is good reason to believe that his spirit was in an ebb tide, a tide of disappointment and depression, when he returned from Congress in 1849. Such a mood was likely to make manifest in Lincoln the vein of indecision that was in the background of his nature, that he did not conquer until after the tremendous experiences of 1862. At this critical moment he was offered the governorship of the new territory of Oregon. He seems to have thought, for a space, of following his father's example and escaping from trouble by seeking a new horizon. His wife saved him. A long controversy has raged about her character and whether she and her husband were truly congenial. That Mrs. Lincoln was a matter-of-fact, perhaps a self-willed, even tyrannical woman is not unlikely. That in some respects her narrow vision and her dogmatic firmness may have been the saving of her husband is equally probable. She was emphatic on the refusal of the Oregon offer. Her husband acquiesced. They remained in Springfield and Lincoln escaped his last serious temptation to follow in the footsteps of wandering Thomas.

The next five years were devoted to the law. The firm of Logan and Lincoln had disappeared (1845) and the more famous firm of Lincoln and Herndon had taken its place. During this period Lincoln at last became prosperous. Though not a legal scholar he was a great jury lawyer. He had a genius for perceiving the essentials of a case. It was a saying of his, "If I can strip this case of technicalities and swing it to the jury I'll win it." He was fanatically honest. Having been deceived by a client when on the circuit, he threw up the case in the midst of the trial, withdrew to his hotel and sent word to the presiding judge, "My hands are dirty and I came over to clean them."

The Peoria Speech.—He was recalled to politics by the Kansas-Nebraska Act of 1854 opening the north-western territories to slavery. The five years of hard work at the law had developed in him exceptional powers of lucid argument. When Stephen A. Douglas became the champion of the Kansas-Nebraska Act Lincoln was urged to reply to him. He did so at Peoria on Oct. 16, 1854. The great speech delivered that day gave him his place in history. The change from the inadequate politician who had failed in Congress five years before is so great as to seem all but incredible. For directness of vision, for scope of argument, for breadth of sympathy the speech is unrivalled by anything in the previous literature of the slavery controversy. Unlike the Abolitionists he admitted no abstractions into his thought on this subject and no vindictiveness; he was wholly the democrat and the humanitarian; he wanted to check the extension of slavery because he thought it inhuman but even more because, as he put it, "new free states are places for poor people to go to and better their condition." This was the key-note of his thought ever after, both in regard to the territories and in regard to the preservation of the Union. He admitted frankly that his overmastering concern was the welfare of the free poor people of the white races.

The Peoria speech made him famous. His political ambition immediately sprang to life again. He stood for the senatorship. But though the Whigs accepted him as their candidate they were not strong enough to elect him. At the last moment Lincoln scored a partial triumph by throwing his votes to Lyman Trumbull, a seceding Democrat opposed to the policies of Douglas. There followed a political duel between Lincoln and Douglas culminating in the famous debates of 1858 when both were candidates for the senate. Douglas obtained the prize. But Lincoln was now one of the conspicuous leaders of the day. After much hesitation he had joined the New Republican Party two years previous to his defeat by Douglas. At the State Republican Convention in 1856 he made his "Lost Speech" which was not reported at the time but which is supposed to have been a masterpiece of compelling oratory. His speech accepting the Republican nomination for the senate (1858) contained the most noted single passage in any of his speeches. It began, "A house divided against itself cannot stand. I believe this Government cannot endure permanently half slave and half free."

This was the idea upon which he rang the changes in the debates with Douglas. In one of them, by skilful questioning he forced Douglas into a dilemma from which he could extricate himself only by formulating what at once became known as "the Freeport Doctrine." Douglas was defending the idea of complete local autonomy on the subject of slavery—"squatter sovereignty," as it was called—and yet trying to avoid challenging the validity of the recent decision of the supreme court in the Dred Scott case which denied that it was possible to close a territory to slavery. Lincoln's purpose was to trap Douglas into taking a position which, while it might save him with the Illinois Democrats who were for squatter sovereignty and indifferent to the supreme court, would split the party as a whole by alienating the Southerners who were strong for the Dred Scott decision. Driven to the wall, Douglas chose to make sure of Illinois and announced the doctrine that no matter what the court might do, slavery could exist only through friendly local legislation and therefore that squatter sovereignty was omnipotent. He was returned to the senate but the national Democratic Party was split in two. The man who had out-generalled Douglas and split the Democrats was inevitably a possible candidate for the presidency two years later. During 1859 he hesitated whether he was strong enough to risk letting his name go before the Republican Convention. Long before he made up his mind his friends were hard at work. At length he consented.

It was while this determination was still young that he went to New York and delivered what is probably the best known though far from the greatest of his speeches, the address at Cooper Union on Feb. 27, 1860. A large part of his purpose was to dissociate the Republican cause from the recent attempt of John Brown to provoke a slave insurrection. He succeeded brilliantly in giving to the Republican position a sober and conservative cast. Cooper Union established him as at least second choice for president in the minds of many of the Eastern Republicans. When, in the Republican National Convention at Chicago, it became plain that none of these Easterners could nominate his first choice, many of them combined with the Western supporters of Lincoln to nominate him uproariously on the third ballot. In the election, out of some 4,500,000 votes cast, he got less than 2,000,000 and all but about 24,000 of these were in the Free States. But this minority of the popular vote was so distributed that it gave him the electoral college and elected him president.

In 1860 Lincoln was in one of those rising tides of energy that had come and gone throughout his life. Its culmination was reached on Dec. 20, the very day on which South Carolina seceded. *See* UNITED STATES (OF AMERICA), THE: *History*. Congress had met; it was believed that a compromise could be made with the Slave States on the basis of a division of the territories between slavery and freedom. Thurlow Weed had come to Springfield on behalf of the Republican leaders to find whether Lincoln would participate in compromise. On Dec. 20 he closed the door by issuing an ultimatum: he insisted on complete exclusion of slavery from the territories but he would promise to let slavery alone in the States and to advocate a strenuous enforcement of the laws for recovering fugitive slaves and returning them to their owners. This decision put an end to compromise and led straight to war. The next 18 months form the most singular period in Lincoln's life. They are his last period of the ebb tide. During this period he is often at the mercy of his indecision. And yet, from this welter of uncertainty he issues suddenly, in July, 1862, the final Lincoln, sure of himself and master of his world.

Interval of Indecision.—The startling change in his mood following his ultimatum was revealed in fatuous speeches which he made on the way to Washington. The Southern Confederacy had been formed and yet he assured the country that there was no crisis but an "artificial" one. His Inaugural, though it struck a new note of literary power, merely exhorted the seceding States to return into the Union and discoursed at length upon slavery. Until April 14, when Sumter was fired upon, he was all indecision, taking advice from every member of his cabinet (*see* SEWARD, WILLIAM H.; CHASE, SALMON P.; WELLES, GIDEON), and though he promptly accepted the gage of battle, issuing a call for volunteers (*see* AMERICAN CIVIL WAR), he allowed a cabal of rash and headstrong senators to force his hand and that of his commanding general (*see* MCDOWELL, IRVIN), with results that ended in the defeat of the Union forces at Bull Run. He shook off momentarily the influence of the senatorial cabal and appointed a Democrat, George B. McClellan as commander of the army of the Potomac. But he soon lost faith in McClellan and blunderingly interfered with his plans. He permitted the creation of various bodies such as an army board with ill-defined and conflicting functions. Having required McClellan to submit his plans to a council of general officers, Lincoln attended the council and promised to be governed by the opinion of the majority. The strange story of the latter part of the period of uncertainty is summed up in the contrast between his attitude at this council and his attitude about four months later, after McClellan's defeat in the Seven Days, when Lincoln visited the front and summoned the generals before him to make reports but asked of them no advice. Meanwhile he had suffered a profound personal affliction in the death of his favourite son and had been tormented almost beyond endurance by officious senators now organized in the Committee on the Conduct of the War. What caused his sudden emergence into self-confidence is a mystery. The transitional moment appears to be a sudden visit to West Point and a long confidential talk with Gen. Scott. A few days later, in his conferences at the front, he took things into his own hands and never thereafter relinquished supreme control.

His story thenceforward is the story of his country. It is needless here to do more than catalogue in order the main events; his struggle with the Committee on the Conduct of the War for control of the army; his removal of Gen. Frémont because of the latter's rash course of freeing slaves in Missouri; the narrow avoidance of war with England by promptly acknowledging the error of Commander Wilkes when he boarded a neutral ship and took off Confederate envoys; the establishment of a new understanding with regard to contraband (*see* further article on NEUTRALITY); his gradual solution of the problem of army control in a democracy; his slow acceptance of the idea that the policy of emancipation must be accepted as a war measure partly to solidify his own support at home, partly to secure international support; his issue of the Emancipation Proclamation, tentatively on Sept. 22, 1862, permanently on Jan. 1, 1863; his temporary loss of popularity due largely to the terrible sufferings of the Federal armies in 1864 and the combination against him of the Abolitionists of the senate who felt he was lacking in sternness; the salvation of his leadership by Sheridan's victories in the Shenandoah valley and Sherman's capture of Atlanta; his second election as president; his opposition to Congress with the purpose of setting up a generous plan of reconstruction in the conquered South. The latter purpose inspired one of his most notable actions. Shortly before his death, he proposed to his cabinet to urge upon Congress the appropriation of $400,000,000 to assist the South in its economic recovery. The opposition of the cabinet led him to set the scheme aside, temporarily, as he thought. His last public address contained an assurance to the nation that he was pondering this difficult problem. "I am considering and will not fail to act when satisfied that action will be proper." At that same moment, a fanatic of secession, John Wilkes Booth, was planning his assassination. While Lincoln was sitting in Ford's theatre, on the night of April 14, 1865, Booth stole into his box and shot him through the head. He lingered unconscious until 7:25 the next morning when he died.

During the years that had followed his election as president the qualities that had enabled him to attain success were all in process either of transformation or of reorganization. The former is the dominant note until midsummer 1862; the latter in the remaining years. But there is no definite division in time. In some respects the period of uncertainty contradicts itself. Timid and indecisive in action as, in the main, he was in that period, he was never more clear and self-sufficient in thought. Two sides of his nature were in conflict. While as man of action he waited upon the opinions of others, as man of thought he consulted no one and formulated his position out of his own meditations. This is strikingly apparent in the contrast as State papers of the First Inaugural and the First Annual Message. In March 1861 Lincoln still believed that the divisions of the sections was a mere quarrel over the extension of slavery. He had not then taken the measure of the secession movement and did not understand that independence, not simply the preservation of slavery, was what the South had in view. He was still blinded by the provincial bias of Springfield, by his own lack of contact with Washington. In the next eight months he made the great discovery of his life—that there was no one cause of secession, that the South had become a nation within the Union, that both the Southerners who loved slavery and the Southerners who hated slavery were tired of living with the North and wanted a legal separation. In these months while he fumbled weakly with the reins of power his mind called up all its reserves and set to work to form a philosophical-historical defense of the cause of the Union. The result was his most remarkable State paper, the First Message. Its origins lie undoubtedly in a long train of thoughts that had been moving through his mind, more or less subconsciously, during 20 years. All that while he had been growing in the belief that the basic issue of the time was not the freedom of the slaves but the preservation of the ideal of democracy. Jefferson came very near being his patron saint. Two propositions were in solution in his mind when he was elected president: that slavery must be checked because it was an aristocratic institution inimical to the interests of the "plain people"; that the Union was sacred because it made possible a great experiment in government "of the people, for the people and by the people." Neither of those ideas played an important part at the Inaugural; they are the bedrock of the Message. Incidentally, the Message contained an historical argument which was based on inadequate knowledge and has not stood the test of scientific criticism. The immeasurable importance of the Message is as the statement of a creed. "This is essentially a people's contest. On the side of the Union it is a struggle for maintaining in the world that form and substance of government whose leading object is to elevate the condition of men; to lift artificial weights from all shoulders; to clear the paths of laudable pursuit for all; to afford all an unfettered start and a fair chance in the race of life."

Evolution As a Writer.—Even more striking than the precipitation of political thinking is the sudden leap forward of his power as a writer. Previous to 1860 he had displayed a wonderful gift of lucidity; his style differed from the prevailing styles of the time in his love of temperance, in a general repudiation of rhetoric, in candour, in serenity. He had also the gift of noble rhythm. But in those early days his language lacked beauty in any rich sense; it was not shot through with imagination; it had nothing of what was vaguely termed "the poetical." This quality appeared suddenly in the First Inaugural. Thereafter his writing steadily grew in richness without letting go its soundness of method, without becoming decorated, without lapsing into rhetoric. Here is another mystery of his later development. How he had gathered into himself a subterranean sense of beauty in words, whether it had grown out of long reading of the Bible, Shakespeare and Burns—the favourite books of his maturity—whether it linked back with his mother's world, with its forests and empty spaces, its loneliness and its lampless nights of stars, who can say? Something perhaps may be allowed to the influence of the brilliant Seward whose hand is known to be present in the First Inaugural, and who was certainly his close friend as well as secretary of State during the later years. But such literary sense as Seward possessed is slight compared with that which appears in Lincoln's Fast Day Proclamations, in his description of the map of the United States in the Second Inaugural Message, in the oration at Gettysburg on Nov. 19, 1863, in the Second Inaugural, in some fragments and letters such as the famous letter to Mrs. Bixby upon the death of her sons in battle, or the letter to Gen. Hooker on Jan. 26, 1863, informing him of his appointment as commanding general and quietly discussing in the most objective vein his recent talk that "both the army and the Government needed a dictator. . . ." The speech at Gettysburg condensing into one page of eloquent prose the purport of the First Message is probably his most famous utterance.

There is a new sense of balance in him and of self confidence. He has grasped the full nature of his task as military executive of a democracy and has thought out his own conception of the division and articulation of powers among the president, the legislature and the generals. He puts this conception firmly into effect despite furious clamour from Congress. In the latter stage of his government he follows his own judgment alone in making or unmaking generals, but once they are in command he permits no civilian interference with their plans. His own meddling in army matters in 1861 has no parallel after 1862. The terrible Committee on the Conduct of the War, which had the temper and aimed to get the power of the great Committee of the French Revolution, was slowly but steadily forced into insignificance. The aim of the committee and its associates was to conduct the war on a purely partisan basis while Lincoln was determined to conduct it on a national basis transcending party. Broadly speaking, he was successful. It was as the "Union" not merely as the

"Republican" candidate that he was re-elected in 1864. In all his later thinking two ideas which have been frequently overlooked were harped upon. He steadily insisted that the United States formed a strictly federal community, that the States were as essential to its welfare as was the central Government and that he was fighting neither to enable the North to dominate the South nor to centralize the Union through the overthrow of the States. His party enemies were for Northern domination and for centralization. The second idea, too often overlooked or explained away, is his steady insistence on the executive as the proper centre of gravity in exceptional conditions and his virtual assumption of the rôle of dictator. No small part of the significance of this final stage is the struggle between himself and Congress for possession of the extraordinary powers which inevitably are generated in time of war. Nowhere was he denounced more bitterly than in the House of Representatives by fanatical Republicans. His views upon both these crucial matters were summed up in the Emancipation Proclamation which is even more important as a statement of administrative policy than as a step in the history of Abolition. Quite frankly, he defended the theory that the "war powers" of the president formed a virtual dictatorship in two open letters justifying the punishment by military process of persons charged with sedition. He was able to maintain this bold attitude involving a questionable interpretation of the Constitution because of the dominance he acquired in the hearts and imaginations of the mass of the people. Defending the most high-handed case of military arrest (*see* VALLANDIGHAM, CLEMENT LAIRD) he said of this great power which he claimed for the president, "if he uses the power justly, the . . . people will probably justify him; if he abuses it, he is in their hands to be dealt with by all the modes they have reserved to themselves under the Constitution."

His success in his second election when the mere politicians of his party very generally intrigued against him was a justification of himself as the tribune of the people. His hold upon them was accomplished partly by his utterances, partly through the communication to others of the vivid and compelling impression he made on individuals close to him, partly through the open receptions which he held every few days which any one was permitted to attend. He called them his "baths of public opinion." Through them he found out the heart of the nation and communicated himself to the nation.

In the character revealed in these later days are found all the qualities of the earlier unfused Lincoln, excepting only those which began to disappear about 1843, and taken separately they do not appear different from what they once had been. He was still susceptible to fits of melancholy so profound that he felt them to be all but unendurable. On the other hand he was still recklessly humorous, telling funny stories on all occasions, sometimes giving offence by so doing. To a Congressman who showed dislike for his stories he said, "You cannot be more anxious than I have been constantly since the beginning of the war; and I say to you now, that were it not for this occasional vent I should die." The difference between the earlier Lincoln and the later is not in the details but in the whole. The same elements have been recombined in a changed pattern. There are salty, coarse elements in 1864 no less than in 1834, but instead of forming discords they now blend. He has achieved an individual tone all his own, comparable to that amazing unity of discordant elements that pervades and makes inimitable the great masterpieces of literature. His secretaries adored him. One of them, John Hay, has left admirable contemporary sketches of his personality. "The Tycoon (as his secretaries called him) is in fine whack. I have rarely seen him more serene and busy. He is managing this war, the draft, foreign relations and planning a reconstruction of the Union all at once. I never knew with what a tyrannous authority he rules the cabinet until now. The most important things he decides and there is no cavil. . . . There is no man in the country so wise, so gentle and so firm."

The measure of his difference from most of the men who surrounded him is best gauged by his attitude toward the fundamentals of religion. For all his devotion to his cause he did not allow himself to believe that he knew the mind of God with regard to it. He was never so much the mystic as in his later days and never so far removed from the dogmatist. Here was the final flowering of that mood which appears to have lain at the back of his mind from the beginning—his complete conviction of the reality of a supernatural world joined with a belief that it was too deep for man to fathom. His refusal to accept the "complicated" statements of doctrine which he rejected carried with it a refusal to predicate the purposes of the Almighty. Again, that singular characteristic, his power to devote himself wholly to a cause and yet to do so in such a detached unviolent way that one is tempted to call it passionless. He retained nothing of the tribal forms of religion and was silent while they raged about him with a thousand tongues. Upon this innermost subject the best expression of him is an amazing fragment which he wrote down but which was not intended for any eye but his own. "The will of God prevails. In great contests each party claims to act in accordance with the will of God. Both may be, and one must be, wrong. God cannot be for and against the same thing at the same time. In the present civil war it is quite possible that God's purpose is something different from the purpose of either party; and yet the human instrumentalities, working just as they do, are the best adaptations to effect His purpose. I am almost ready to say that this is probably true; that God wills this contest and wills that it shall not end yet. By His mere great power on the minds of the now contestants, He could have either saved or destroyed the Union without a human contest. Yet the contest began. And, having begun, He could give the final victory to either side any day. Yet the contest proceeds."

BIBLIOGRAPHY.—The most famous life of Lincoln is by his law partner, William H. Herndon, in collaboration with J. W. Weik, *The True Story of a Great Life* (1890). It has been the subject of furious controversy. Ward H. Lamon, with *The Life of Abraham Lincoln* (1872), antedated Herndon in publication but drew freely from Herndon's materials. J. W. Weik, who had collaborated with Herndon, brought out long afterward *The Real Lincoln* (1922). The literature that has grown up about Lincoln numbers literally thousands of volumes. Conspicuous is *Abraham Lincoln: A History* (1890), by his secretaries, John G. Nicolay and John Hay, published with the approval of his son, Robert Todd Lincoln. There are two general collections of his writings: *Complete Works of Abraham Lincoln,* Nicolay and Hay ed. (1905); *The Complete Works of Abraham Lincoln,* George Haven Putnam and Arthur Brookes Lapsley ed. (1888–1906). Neither of these collections is complete. At intervals new letters are discovered and published; for example, *Uncollected Letters of Abraham Lincoln,* first brought together by Gilbert Tracy (1917). Many important details of his origin and early life have been determined by William E. Barton, notably in *The Paternity of Abraham Lincoln* (1920); in *The Life of Abraham Lincoln* (1925); and *The Women Lincoln Loved* (1927). Recent biographies that deserve attention are Ida M. Tarbell, *The Life of Abraham Lincoln* (1917); Lord Charnwood, *Abraham Lincoln* (1917); Nathaniel Wright Stephenson, *Lincoln* (1922). The Lincoln Memorial Association is publishing gradually a record of his daily life. What promised to be the definitive life of Lincoln was undertaken by Albert J. Beveridge and was to be on the same scale as his monumental life of Marshall. Unfortunately, but two volumes had been completed at the time of his sudden death in 1927. They were published under the title *Abraham Lincoln* (1928), and supersede everything that has been written on the portion of Lincoln's life previous to 1858. (N. W. S.)

LINCOLN, a city and county of a city, municipal, county and parliamentary borough, and the county town of Lincolnshire, England. Pop. (1938) 63,050. Area 7.08 sq.mi. It is on the summit and south slope of the limestone ridge of the Cliff range of hills, which rises from the north bank of the river Witham, at its confluence with the Foss Dyke, to an altitude of 200 ft. above the river. The cathedral stands on the hill, and is a landmark for miles. Lincoln is 130 mi. N. by W. from London by the L.N.E.R.; it is also served by branches of the L.M.S. ry.

History.—The British Lindun, which, according to the early geographer, Ptolemy, was the chief town of the Coritani, was probably the nucleus of the Roman town of Lindum. This was at first a Roman legionary fortress, and on the removal of the troops northward was converted into a municipality with the title of *colonia.* Important structural remains attest the rank and importance of the place, which, however, did not attain a very great size. Its bishop attended the council of Arles in 314, and Lincoln (*Lindocolina, Lincolle, Nicole*) is mentioned in the

Itinerary of Antoninus written about 320. Although said to have been captured by Hengest in 475 and recovered by Ambrosius in the following year, the next authentic mention of the city is Bede's record that Paulinus preached in Lindsey in 628 and built a stone church at Lincoln in which he consecrated Honorius archbishop of Canterbury.

The Danes in 877 established themselves at Lincoln, which was one of the five boroughs recovered by King Edmund in 941. A mint existed here in the reign of Alfred and was maintained until the reign of Edward I. At the time of Domesday, Lincoln was governed by twelve Lawmen, relics of Danish rule, each with hereditable franchises of sac and soc. The strength of the position of the castle built by William I in 1068, brought much fighting on Lincoln.

In 1141 King Stephen regained both castle and city from the empress Maud, but was attacked and captured in the same year at the "Joust of Lincoln." In 1144 he besieged the castle, held by the earl of Chester, and recovered it as a pledge in 1146. In 1191 it was held by Gerard de Camville for Prince John; in 1210 it stood a siege by the partisans of the French prince Louis, who were defeated at the battle called Lincoln Fair on May 19, 1217. Granted by Henry III to William Longespée, earl of Salisbury, in 1224, the castle descended by the marriage of his descendant Alice to Thomas Plantagenet, and became part of the duchy of Lancaster.

In 1157 Henry II gave the citizens their first charter, granting them the city at a fee-farm rent and all the liberties which they had had under William II. In 1200 the citizens obtained release from all but pleas of the crown without the walls, and pleas of external tenure, and were given the pleas of the crown within the city according to the customs of the city of London, on which those of Lincoln were modelled. The charter also gave them quittance of toll and lastage throughout the kingdom, and of certain other dues. The mayor's office was abolished by Henry III and by Edward I in 1290, though restored by the charter of 1300. In 1275 the citizens claimed the return of writs, assize of bread and ale and other royal rights, and in 1301 Edward I, when confirming the previous charters, gave them quittance of murage, pannage, pontage and other dues. The mayor and citizens were given criminal jurisdiction in 1327, when the burghmanmot held weekly in the guildhall since 1272 by the mayor and bailiffs was ordered to hear all local pleas which led to friction with the judges of assize. The city became a separate county by charter of 1409, when it was decreed that the bailiffs should henceforth be sheriffs and the mayor the king's escheator, and the mayor and sheriffs with four others, justices of the peace, with defined jurisdiction. As the result of numerous complaints of inability to pay the fee-farm rent of £180 Edward IV enlarged the bounds of the city in 1466, while Henry VIII in 1546 gave the citizens four advowsons, and possibly also in consequence of declining trade the city markets were made free of tolls in 1554. Incorporated by Charles I in 1628 under a common council with 13 aldermen, 4 coroners and other officers, Lincoln surrendered its charters in 1684, but the first charter was restored after the Revolution, and was in force till 1834.

Parliaments were held at Lincoln in 1301, 1316 and 1328, and the city returned two burgesses from 1295 to 1885, when it lost one member. After the 13th century the chief interests of Lincoln were ecclesiastical and commercial. As early as 1103 Odericus declared that a rich citizen of Lincoln kept the treasure of King Magnus of Norway, supplying him with all he required, and there is other evidence of intercourse with Scandinavia. There was an important Jewish colony, Aaron of Lincoln being one of the most influential financiers in the kingdom between 1166 and 1186. Made a staple of wool, leather and skins in 1291, famous for its scarlet cloth in the 13th century, Lincoln had a few years of great prosperity, but with the transference of the staple to Boston early in the reign of Edward III, its trade began to decrease. The craft guilds remained important until after the Reformation, a pageant still being held in 1566. The fair now held during the last whole week of April seems to be identical with that granted by Charles II in 1684. Edward III authorized a fair from St. Botolph's day to the feast of SS. Peter and Paul in 1327, Henry IV granted one in 1409 for fifteen days before the feast of the Deposition of St. Hugh, and William III gave one for the first Wednesday in September in 1696.

Architecture.—The ancient British town occupied the crown of the hill beyond the Newport or North Gate. The Roman town consisted of two parallelograms of unequal length, the first extending west from the Newport gates to a point a little west of the castle keep. The second parallelogram, added as the town increased in size and importance, extended due south from this point down the hill towards the Witham as far as Newland, and thence in a direction due east as far as Broad street. Returning thence due north, it joined the southeast corner of the first and oldest parallelogram in what was afterwards known as the Minster yard, and terminated its east side upon its junction with the north wall in a line with the Newport gate. This is the oldest part of the town, and is named "above hill." After the departure of the Romans, the city walls were extended still farther in a south direction across the Witham to the great bar gate, the south entrance to the High street of the city; the junction of these walls with the later Roman one was effected immediately behind Broad street. The south portion, named "below hill," contains the principal business premises and the railway stations.

Lincoln cathedral contains the earliest purely Gothic work extant, as well as every style from the simple massive Norman of the central west front and the later Norman of the west doorways and towers onward through all the Gothic styles, of each of which both early and late examples appear. The building material is the oolite and calcareous stone of Lincoln Heath and Haydor, which has the peculiarity of becoming hardened on the surface when tooled. Formerly the cathedral had three spires, all of wood or leaded timber. The spire on the central tower, which would appear to have been the highest in the world, was blown down in 1547. Those on the two western towers were removed in 1808. In 1921 the north and southwest and centre towers were found to be in imminent danger of collapse. To save them they, with the west transept, Galilee porch and nave were treated by grouting, the work being completed in 1932. The peal of 12 bells in the southwest tower, of which four were a World War I memorial to ringers, were lowered 30 ft. and the upper part of the tower was reconstructed with a lantern roof and the lower louvers were closed.

The ground plan of the first church, adapted from that of Rouen, was laid by Bishop Remigius in 1086, and the church was consecrated three days after his death, on May 6, 1092. The west front consists of an Early English screen (*c.* 1225) thrown over the Norman front, the west towers rising behind it. The earliest Norman work is part of that of Remigius; the great portals and the west towers up to the third story are Norman *c.* 1148. The upper parts of them date from 1365. Perpendicular windows (*c.* 1450) are inserted. The nave and aisles were completed *c.* 1220. The transepts mainly built between 1186 and 1235 have two rose windows; that in the north Early English, that in the south Decorated. The first has contemporary stained glass. These are called respectively the Dean's Eye and Bishop's Eye. A Galilee of Early English work forms the entrance of the south transept. Of the choir the western portion known as St. Hugh's (1186–1204) is the famous first example of pointed work; the eastern, called the Angel choir, is ornate work completed in 1280. Perpendicular canopied stalls fill the western part. The great east window, 57 ft. high, is an example of transition from Early English to Decorated *c.* 1288. Other features of the interior are the Easter sepulchre (*c.* 1300), and the organ screen of a somewhat earlier date. The great central tower is Early English as far as the first story, the continuation dates from 1307. The total height is 271 ft.; and the tower contains the bell, Great Tom of Lincoln, weighing over 5 tons. The dimensions of the cathedral internally are—nave, 252×79.6×80 ft.; choir, 158×82×72 ft.; angel choir, which includes presbytery and lady chapel, 166×44×72 ft.; main transept, 220×63×74 ft.; choir transept, 166×44×72 ft. The west towers are 206 ft. high.

The buildings of the close that call for notice are the chapter-house of ten sides, 60 ft. diameter, 42 ft. high, with a vestibule of the same height, built *c.* 1225, and therefore the earliest of English polygonal chapter-houses, and the library, a building of 1675, which contains a small museum. The episcopal palace contains work of the date of St. Hugh, and the great hall is mainly Early English. There is some Decorated work, and much Perpendicular, including the gateway. It fell into disuse after the Reformation, but by extensive restoration was brought back to its proper use at the end of the 19th century. The see covers almost the whole of the county, with very small portions of Nottinghamshire; it included all Nottinghamshire until the formation of the bishopric of Southwell in 1884. At its earliest formation, when Remigius, almoner of the abbey of Fécamp, removed the seat of the bishopric here from Dorchester in Oxfordshire shortly after the Conquest, it extended from the Humber to the Thames, eastward beyond Cambridge, and westward beyond Leicester. It was reduced, however, by the formation of the sees of Ely, Peterborough and Oxford, and by rearrangement of diocesan boundaries in 1837. Lincoln cathedral possesses the finest copy extant of Magna Carta (1215). It was exhibited at the New York World's Fair, 1939–40, and was afterwards sent to the Library of Congress, Washington, where it remained during World War II.

The Newport Arch or northern gate of *Lindum* is one of the most perfect specimens of Roman architecture in England. It consists of a great arch flanked by two smaller arches, of which one remains. The Roman Ermine street runs through it, leading northward almost in a straight line to the Humber. Fragments of the town wall remain at various points; a large quantity of coins and other relics has been discovered; and remains of a burial-place and buildings unearthed. Of these last the most important is the series of column-bases, probably belonging to a Basilica, beneath a house in the street called Bail Gate, adjacent to the Newport Arch. A villa in Greetwell; a tesselated pavement, a mile-stone and other relics in the cloister; an altar unearthed at the church of St. Swithin, are among many other discoveries. Among churches, apart from the minster, two of outstanding interest are those of St. Mary-le-Wigford and St. Peter-at-Gowts (*i.e.,* sluice-gates), both in the lower part of High street. Their towers are examples of very early Norman work, though they possess characteristics of pre-Conquest workmanship. Bracebridge church shows similar early work; but as a whole the churches of Lincoln show plainly the results of the siege of 1644.

There were formerly three small priories, five friaries and four hospitals in or near Lincoln. The preponderance of friaries over priories of monks is explained by the fact that the cathedral was served by secular canons. Bishop Grosseteste was the devoted patron of the friars, particularly the Franciscans, who were always in their day the town missionaries. The Grey friary, near St. Swithin's church, is a picturesque two-storied building of the 13th century, now housing a museum. The building known as John of Gaunt's stables, actually St. Mary's Guildhall, is of two stories, with Norman doorway and moulding. The Jew's House is another 12th-century building; and Norman remains appear in several other houses, such as Deloraine Court and the House of Aaron the Jew. Lincoln Castle, lying west of the cathedral, was newly founded by William the Conqueror when Remigius decided to found his minster under its protection. The site, with its artificial mounds, is of much earlier, probably British, date. There are Norman remains in the Gateway Tower; parts of the walls are of this period, and the keep dates from the middle of the 12th century. Among mediaeval gateways, the Exchequer Gate, serving as the finance-office of the chapter, is a fine specimen of 13th-century work. Pottergate is of the 14th century, and Stonebow in High Street of the 15th, with the Guildhall above it. St. Dunstan's Lock is the name, corrupted from Dunestall, now applied to the entrance to the street where a Jewish quarter was situated; here lived the Christian boy afterwards known as "little St. Hugh," who was asserted to have been crucified by the Jews in 1255. His shrine remains in the S. choir aisle of the minster. Other antiquities are the Perpendicular conduit of St. Mary in High street and the High bridge, carrying High street over the Witham and retaining some old houses upon it. The principal industry is the manufacture of agricultural machinery and implements; there are also iron and steel foundries and maltings, and a large trade in corn and agricultural produce. The race course, famous for the Lincolnshire handicap, is owned by the corporation. The county borough of Lincoln with the urban district of Bracebridge returns one member to parliament.

LINCOLN, a city of central Illinois, U.S.A., on Federal highway 66, and served by the Chicago and Alton, the Illinois Central and the Illinois Traction (electric) railways; the county seat of Logan county. The population was 11,882 in 1920 (87.6% native white), and was 12,752 in 1940 by the federal census. Lincoln is the seat of the state institution for feeble-minded children (established in Jacksonville in 1865 and moved there in 1878); Lincoln college (Presbyterian; founded 1865); and the Illinois Odd Fellows' Orphans' home. It is the shipping point for large quantities of grain and other farm products. Principal manufactured products are chinaware, caskets and garments. There are coal mines in the vicinity. Lincoln was founded in 1835 and chartered in 1857. It was named after Abraham Lincoln before he became famous, while he was practising law in Springfield. He helped plan the city, and did the legal work connected with its incorporation. The old courthouse in which he practised is still standing.

LINCOLN, the capital city of Nebraska, U.S.A., and the county seat of Lancaster county, 55 mi. S.W. of Omaha, on Salt creek. It is on federal highways 6, 34 and 77; and is served by the Burlington, the Chicago and North Western, the Missouri Pacific, the Rock Island and the Union Pacific railways. The population was 54,948 in 1920, of whom 7,198 were foreign-born white and 896 were Negroes; and was 81,984 in 1940 by federal census.

The city has a land area of 24.3 sq.mi. on a gentle swell of the prairie, rising from the valley at its western border, and an altitude of 1,167 ft. at the state capitol. It is regularly laid out, with wide streets, beautifully shaded by trees which have all been planted since the founding of the city. Boulevards add to the attractiveness of the residential section, and a zoning plan is in operation. There are 21 city parks with a total of 1,321.25 ac. The assessed valuation of property in 1940 was $98,398,490.

The state capitol, which was completed in 1932, is one of the most impressive architectural achievements of America. From a massive base (of two stories) rises a central tower 400 ft. high, surmounted by the figure of a sower. The architect was Bertram Grosvenor Goodhue; the sculptor, Lee Lawrie; the interior mural decorations are by Augustus Vincent Tack and Miss Hildreth Miere; the inscriptions and symbols were chosen by Hartley B. Alexander. At the western approach to the capitol grounds is a statue of Abraham Lincoln by Daniel Chester French.

The University of Nebraska (*q.v.*) covers 75 ac. on the north edge of the business section and includes Nebraska Memorial stadium, seating 40,000. The state agricultural college covers 320 ac. 2 mi. northeast of the downtown campus. Nebraska Wesleyan university (chartered 1887), Union college (Seventh Day Adventist; 1891), Lincoln Airplane and Flying school and three business colleges are located there. Lincoln is the home of the widely famed Great Cathedral choir, headquarters of the Nebraska Art association and has a fine symphony orchestra.

State institutions include the penitentiary, an insane hospital, a men's reformatory, a home for dependent children and an orthopaedic hospital. The state fair grounds are there, and salt-water bathing is available at Capital beach, in a lake formed from one of the old salt basins.

Lincoln ships large quantities of grain and has one of the country's largest flour mills. Its extensive wholesale and jobbing trade amounted to $33,314,000 in 1939. The retail section is among the midwest's finest; retail trade is estimated at $40,000,000 annually. Factory output in 1939 was valued at $14,496,016.

Leading manufactures are flour, railroad freight cars, meat products, brick and tile and printing materials. One of the world's largest creameries is located there. Bank clearings for 1940 totalled $148,365,267.

In 1838 the salt basins of Lancaster county (smooth floors of hard clay, covered with a glistening layer of crystallized salt) were described by a commissioner sent by the U.S. Government to settle some Indian disputes; and in 1856 they were brought prominently to public notice by Government surveyors, and attracted the first permanent settlers to this region. Several small salt works did a thriving business in the early '60s, but the industry died out when the railroads brought into competition salt produced by the cheaper methods of the eastern manufacturers. In 1886 the State sank a deep test-well, with disappointing results, and no serious efforts have been made since to use the deposits for the production of salt; but one of the largest basins has been converted into a salt lake and developed as a pleasure resort. A small village called Lancaster, which served as the county seat, remained from the early experiments.

In 1867 the first legislature of the State of Nebraska, in the Capital Removal Act, designated a commission to select a site for a new capital city, to be named Lincoln. The commission, on July 29, 1867, decided on this hamlet of Lancaster, a cluster of ten stone and log-houses on the bare prairie, 100 m. from the nearest railroad. From the sale of building lots in September they raised $53,000 (later increased to $78,000) for the construction of the capitol; and in spite of tremendous obstacles (architect, contractors and labour were difficult to find, and all materials had to be hauled by team 40 to 60 m.) they had the building ready for the opening of the next legislature on Jan. 1, 1869. The city was incorporated, and formally declared to be the county seat, in 1869. In 1870 the population was 2,300. The first railroad (the Burlington and Missouri River) reached Lincoln in July 1870, and was soon followed by several others. In 1880 the population was 13,003; in 1890, 55,154; in 1900 it dropped to 40,169; by 1920 it had again reached the high point of 1890. Recent annexations to the city include University Place and Bethany, 1926; College View, 1929; Havelock, home of the Burlington railroad shops, 1930. The most discouraging part of Lincoln's history was 1872–76, when for four successive seasons a scourge of locusts and grasshoppers devastated the region.

Lincoln was the home of William Jennings Bryan from 1887–1921, and there he published *The Commoner.*

LINCOLN HIGHWAY, an American highway 3,384 m. in length, connecting New York with San Francisco, Calif. It was organized in 1913 as a memorial to Abraham Lincoln. Its development has helped advance the State and Federal highway systems of the United States. It is improved, hard or paved throughout and traverses impressive mountain, desert and prairie territories. The highway serves Philadelphia and Pittsburgh, Pa., Akron, O., South Bend, Ind., Chicago, Ill., Cedar Rapids and Council Bluffs, Ia., North Platte, Neb., Cheyenne and Rock Springs, Wyo., Salt Lake City, Utah, Ely, Reno and Carson City, Nev., and Sacramento, Calif.

LINCOLN JUDGMENT, THE. In this celebrated English ecclesiastical contest, the bishop of Lincoln (Edward King) was cited before his metropolitan, the archbishop of Canterbury (Dr. Benson), to answer charges of various ritual offences committed at the administration of Holy Communion in the diocese of Lincoln in Dec. 1887. The question at issue related to certain details in the celebration of Holy Communion: especially whether it was lawful for the celebrant (as the bishop had done) to mix water with the wine in the chalice during the service; to take the eastward position (facing the altar); and to make the sign of the cross in the air. The validity of the archbishop's jurisdiction was upheld by the judicial committee of the privy council, and Dr. Benson heard the case, and in the end pronounced no admonition or condemnation on the bishop. His action was confirmed by the judicial committee. The case is now mainly of historical interest, questions of a more fundamental character having arisen in the interval. (See *The Church and the Law Courts,* under article ENGLAND, CHURCH OF.)

LINCOLNSHIRE, an eastern county of England, bounded north, by the Humber, east by the North sea and the Wash, south-east for 3 m. by Norfolk, south by Cambridge and Northamptonshire, south-west by Rutland, west by Leicestershire and Nottinghamshire, and north-west by Yorkshire. The area is 2,662.9 sq.mi. It is the second largest county in England. The main structural features lie across the county from north to south, the two chief being the limestone escarpment of Oolitic rocks in the west (with the Inferior Oolite, extending from the boundary of Rutland, due north past Lincoln to the Humber, and forming the sharp westward-facing scarp of the Lincoln Edge) and the chalk escarpment of the Wolds in the east. Between these two, in order from west to east, run the parallel belts of Middle and Upper Oolite, consisting of Oxford clay, Corallian and Kimmeridge clay, and a narrow fringe of lower greensand. Beyond the limestone to the west, stretches of plain consisting of (1) Triassic Keuper with gypsum in the Isle of Axholme and the valley of the Trent, with red clay, often worked for bricks and with Rhaetic beds at the junction of the Trias and Lias; (2) a broad stretch of Lias rocks, with valuable ironstone deposits in the Lower Lias. The Middle Lias, which enters the county at Woolsthorpe, has iron ores at Dinton and Caythorpe, and the Upper Lias entering at Stainby, passes by Grantham and Lincoln, where it is worked for bricks. Building stone also is quarried at Lincoln and freestone at Ancaster. The remaining belt is a coastal marshland extending from the Humber and passing into the Fens (formed of silt and peat) in the Isle of Axholme on the north-west, the vale of Ancholme on the north, and most of the country south-east of Lincoln. Whiting is made from the chalk near the Humber and lime is made on the Wolds. Sandy shores on the North sea have given rise to the health resorts of Cleethorpes, Skegness, Mablethorpe and Sutton-on-Sea. Boulder clay is plentiful on the chalk, especially in the north of the county, where there is also much glacial sand. The drainage pattern of the county is simple on the whole, being mostly longitudinal (the Trent—only partly in Lincolnshire—the Ancholme, the Witham— except in its middle section—and the Langworth—a tributary of the Witham). Some streams draining from the chalk are consequent in their lower courses. A striking feature is the gap at Lincoln, through which the Trent waters formerly flowed out, until captured at Newark (Notts.) by a subsequent stream working back from the Humber.

History.—Lincolnshire is not rich in pre-historic finds. There are very few traces of Palaeolithic man in the county, though flint implements of Palaeolithic type have been found at Lincoln. At the dawn of the Metal age, Beaker folk, using the Humber entry penetrated south along the Jurassic belt and built round barrows. In the pre-Roman or Romano-British Iron age, Lincoln was evidently a military site, since bronze clasps often associated with such settlements have been found there. Of the details of the English conquest of the district little is known, but at some time in the 6th century Engle and Frisian invaders appear to have settled in the country north of the Witham, where they became known as the Lindiswaras. In the 7th century the supremacy over Lindsey alternated between Mercia and Northumbria, but few historical references to the district are extant until the time of Alfred. At this period the Danish inroads upon the coast of Lindsey had already begun, and in 873 Healfdene wintered at Torksey, while in 878 Lincoln and Stamford were included among the five Danish boroughs.

The origin of the three main divisions of Lincolnshire is anterior to that of the county itself, and the outcome of purely natural conditions, Lindsey being in Roman times practically an island bounded by the swamps of the Trent and the Witham on the west and south, and on the east by the North sea, while Kesteven and Holland were respectively the regions of forest and of fen.

The shire court for Lincolnshire was held at Lincoln every 40 days, the lords of the manor attending with their stewards, or in their absence the reeve and four men of the vill. The ridings were each presided over by a riding-reeve, and wapentake courts were held in the reign of Henry I. 12 times a year, and in the reign of Henry III. every three weeks, while twice a year all the freemen of the wapentake were summoned to the view of frankpledge or tourn held by the sheriff. The boundaries between Kesteven and Holland were a matter of dispute as early as 1389 and were not finally settled until 1816.

Lincolnshire was originally included in the Mercian diocese of Lichfield, but, on the subdivision of the latter by Theodore in 680, the fen-district was included in the diocese of Lichfield, while the see for the northern parts of the county was placed at "Sidnacester," generally identified with Stow. Subsequently both dioceses were merged in the vast West-Saxon bishopric of Dorchester, the see of which was afterwards transferred to Winchester, and by Bishop Remigius in 1072 to Lincoln. Benedictine foundations existed at Ikanho, Barrow, Bardney and Partney as early as the 7th century, but all were destroyed in the Danish wars, and only Bardney was ever rebuilt. The revival of monasticism after the Conquest resulted in the erection of ten Benedictine monasteries, and a Benedictine nunnery at Stainfield.

The Cistercian abbeys at Kirkstead, Louth Park, Revesby, Vaudey and Swineshead, and the Cistercian nunnery at Stixwould were founded in the reign of Stephen, and at the time of the Dissolution there were upwards of a hundred religious houses in the county.

In the struggles of the reign of Stephen, castles at Newark and Sleaford were raised by Alexander, bishop of Lincoln, against the king. The seizure of Lincoln by Stephen in 1141 was accompanied with fearful butchery and devastation. In the baronial outbreak of 1173 Roger Mowbray, who had inherited the Isle of Axholme from Nigel d'Albini, garrisoned Ferry East, or Kinnard's Ferry, and Axholme against the king, and, after the destruction of their more northern fortresses in this campaign, Epworth in Axholme became the principal seat of the Mowbrays. In the struggles between John and his barons Lincoln in 1216 made peace with the king by surrendering hostages for the payment of a fine of 1,000 marks, but after the landing of Louis the city was captured by Gilbert de Gant, then earl of Lincoln. After his disastrous march to Swineshead Abbey, John journeyed through Sleaford to Newark, where he died, and in the battle of Lincoln in 1217 Gilbert de Gant was captured and the city sacked. At the time of the Wars of the Roses the county, owing to territorial influence, was mainly Lancastrian, and in 1461 the Yorkist strongholds of Grantham and Stamford were sacked to such effect that the latter never recovered. In the Civil War of the 17th century, Lindsey for the most part declared for the king. Lord Willoughby of Parham was a prominent Parliamentary leader, and the Isle of Axholme and the Puritan yeomanry of Holland declared for the parliament. In 1643 Cromwell won a small victory near Grantham, and the Royalist garrisons at Lynn and Lincoln surrendered to Manchester. In 1644, however, Newark, Gainsborough, Lincoln, Sleaford and Crowland were all in Royalist hands, and Newark only surrendered in 1646.

At the time of the Domesday survey there were between 400 and 500 mills in Lincolnshire; 2,111 fisheries producing large quantities of eels; 361 salt-works; and iron forges at Stow, St. Mary and at Bytham. Lincoln and Stamford were flourishing centres of industry, and markets existed at Kirton-in-Lindsey, Louth, Old Bolingbroke, Spalding, Barton and Partney. The early manufactures of the county are all connected with the woollen trade, Lincoln being noted for its scarlet cloth in the 13th century, while an important export trade in the raw material sprang up at Boston. The deforestation of Kesteven in 1230 brought large areas under cultivation, and the same period is marked by the growth of the maritime and fishing towns, especially Boston (which had a famous fish-market), Grimsby, Barton, Saltfleet, Wainfleet and Wrangle. The Lincolnshire towns suffered from the general decay of trade in the eastern counties which marked the 15th century, but agriculture was steadily improving, and with the gradual drainage of the fen-districts culminating in the vast operations of the 17th century, over 330,000 acres in the county were brought under cultivation, including more than two-thirds of Holland. The fen-drainage resulted in the extinction of many local industries, such as the trade in goose-feathers and the export of wild fowl to the London markets. Other historic industries of Lincolnshire are the breeding of horses and dogs and rabbit-snaring.

As early as 1295 two knights were returned to parliament for the shire of Lincoln, and two burgesses each for Lincoln, Grimsby and Stamford. In the 14th century Lincoln and Stamford were several times the meeting-places of parliament or important councils, the most notable being the Lincoln parliament of 1301, while at Stamford in 1309 a truce was concluded between the barons, Piers Gaveston and the king. Stamford discontinued representation for some 150 years after the reign of Edward II.; Grantham was enfranchised in 1463 and Boston in 1552. Under the act of 1832 the county was divided into a northern and southern division, returning each two members, and Great Grimsby lost one member. Under the act of 1868 the county returned six members in three divisions and Stamford lost one member. Under the act of 1885 the county returned seven members in seven divisions; Lincoln, Boston and Grantham lost one member each and Stamford was disfranchised.

Architecture.—At the time of the suppression of the monasteries in the reign of Henry VIII. there were upwards of 100 religious houses; and among the Fens rose some of the finest abbeys held by the Benedictines. The Gilbertines were a purely English order which took its rise in Lincolnshire, the canons following the Austin rule, the nuns and lay brothers that of the Cistercians. These houses were at Alvingham, Catley, Holland Brigg, Lincoln, before the gate of which the first Eleanor Cross was erected by Edward I. to his wife, Newstead in Lindsey, Sempringham, the chief house of the order, founded by St. Gilbert of Gaunt in 1139, of which the Norman nave of the church is in use, Stamford (a college for students) and Wellow. There were nunneries of the order at Haverholme, Nun Ormsby and Tunstall.

The following are a few of the most famous abbeys. Barlings (Premonstratensian), northeast of Lincoln, was founded 1154, for 14 canons. The tower, Decorated, with arcading pierced with windows, and the east wall of the south wing remain. The Benedictine Mitred abbey of Crowland (*q.v.*) existed in 1051. Part of the church is still in use. Thornton abbey (Black Canons) in the north near the Humber was founded in 1139. There remain a fragment of the south wing of the transept, two sides of the decagonal chapter house (1282) and the beautiful west gate-house, Early Perpendicular (1332–1388), with an oriel window on the east. Kirkstead abbey (Cistercian) was founded in 1139. Little remains beyond an Early English chapel of singular beauty.

In the Parts of Lindsey several churches present curious early features, particularly the well-known towers of St. Peter, Barton-on-Humber, St. Mary-le-Wigford and St. Peter at Gowts, Lincoln, which exhibit work of a pre-Conquest type. Stow church for Norman of various dates, Bottesford and St. James, Grimsby, for Early English, Tattershall and Theddlethorpe for Perpendicular are fine examples of various styles.

In the Parts of Kesteven the churches are built of excellent stone which abounds at Ancaster and near Sleaford. The church of St. Andrew, Heckington, is the best example of Decorated architecture in the county; it is famed for its Easter sepulchre and fine sedilia. The noble church of St. Wulfram, Grantham, with one of the finest spires in England, is also principally Decorated; this style in fact is particularly well displayed in Kesteven, as in the churches of Caythorpe, Claypole, Navenby and Ewerby.

The finest churches are principally in the Parts of Holland although the district is composed wholly of marsh land and is without stone of any kind: the churches of the south part of this district probably owe their origin to the munificence of the abbeys of Crowland and Spalding. The church of Long Sutton, besides its fine Norman nave, possesses an Early English tower and spire which is comparable with the very early specimen at Oxford cathedral. Whaplode church also has fine Norman work; the churches of Kirton-in-Holland, Pinchbeck and Weston have good Early English work; for Decorated those at Donington and Spalding should be noted, and for Perpendicular, Gedney, together with parts of Kirton church. Of the two later styles, however, by far the most splendid example is the famous church of St. Botolph, Boston (*q.v.*), with its magnificent lantern-crowned tower or "stump."

There are few remains of mediaeval castles. Those of Lincoln and Tattershall are the most noteworthy, and there are also fragments at Boston and Sleaford. The city of Lincoln is remarkably rich in remains of domestic architecture from the Norman period onward.

Agriculture and Industries.—Lincolnshire is one of the principal grain-producing counties, about 86% of total area of 1,699,791 ac., being under cultivation in 1939. Wheat at 237,579 ac. was the largest grain crop, being greater than that of oats and barley combined; both cattle and sheep are raised in large numbers (244,361 and 472,736 respectively in 1939), and horses have long been famous. Apart from mining, the industries are largely agricultural, and agricultural machinery is made at Lincoln, Boston, Gainsborough and Louth. Iron-smelting at Scunthorpe, and the increase of shipping and of commerce—based on timber from the Baltic and dairy-produce from Denmark—at Grimsby and Immingham, are recent developments. In mediaeval times the coast was important for salt, and the small harbours were much used for fishing. Boston became important in connection with the Hanseatic trade. At the present day, fishing is chiefly carried on by companies owning deep-sea trawlers. In the marshlands stock-raising and dairying are important. There is market gardening on the loamy soils. Bone-crushing, tanning, the manufacture of oil-cake, and rope-making are carried on in various places. Gainsborough has considerable traffic on the Trent, and Sutton Bridge is a lesser port on the Wash. The National Trust owned only 7 ac. in Lincolnshire in 1942.

Communications.—Lincoln was an important meeting place of Roman roads, and today it is a great railway centre. Except for a branch line on the L.M.S. railway from Newark to Lincoln and a joint line of the L.M.S. railway and L.N.E. railway from Sutton Bridge through Spalding to Melton Mowbray (Notts.), the country is served entirely by the L.N.E. railway. The main line from Peterborough to Doncaster passes through the south-west of the county, while a branch line links up Spalding, Boston, Louth, Grimsby, Barton and other places near the coast. From Lincoln lines radiate in all directions to Gainsborough, Barton, Louth and the coast, Boston, Spalding, Stamford, etc. Canals connect Louth with the Humber, Sleaford with the Witham, and Grantham with the Trent near Nottingham; the great rivers and many of the drainage cuts are navigable.

Population and Administration.—The geographical county is divided into three trithings or ridings—the Parts of Holland, Kesteven and Lindsey. Each is a separate administrative county and their areas in square miles are 418.5, 724.2 and 1,520 respectively, with populations estimated in 1938 at 95,560, 114,400 and 427,570. Lincolnshire, though an east coast county, lost only 1% of its population through wartime population movements, caused mainly by evacuation, between Sept. 1939 and Feb. 1941. The Parts of Lindsey contain two county boroughs, Grimsby and Lincoln, 13 wapentakes, 2 sokes and 2 hundreds, besides the liberty of Lincoln. Kesteven, exclusive of the soke and borough of Grantham and the borough of Stamford, has 9 wapentakes; and Holland, 3 wapentakes. The county is in the Midland circuit and is divided into 20 petty sessional divisions, of which 2 are in Holland and 4 in Kesteven. In Lindsey the boroughs of Grimsby and Lincoln have each a distinct commission of the peace and a separate court of quarter sessions, and the municipal borough of Louth has a separate commission of the peace. In Kesteven the municipal boroughs of Grantham and Stamford have each a separate commission of the peace and separate courts of quarter sessions. In Holland, Boston has a distinct commission of the peace. For parliamentary purposes the county is divided into seven divisions, namely, in the Parts of Kesteven, Grantham, Rutland and Stamford, and the parliamentary county of Holland with Boston; in the Parts of Lindsey, Brigg, Gainsborough, Horncastle and Louth, and the parliamentary boroughs of Grimsby and Lincoln, each returning one member.

LINCOLN TUNNEL: *see* HOLLAND AND LINCOLN VEHICULAR TUNNELS.

LIND, JAMES (1716–1794), Scottish physician, who has been called the "founder of naval hygiene in England," took his M.D. at Edinburgh in 1748. He was physician to the Royal Naval Hospital at Haslar (1758–83), and then physician to the royal household at Windsor. When Lind went to Haslar scurvy was rife in the navy, and he had as many as 350 cases in a ten-weeks' voyage. As early as 1593 Sir Richard Hawkins had discovered the utility of orange and lemon juice in the sailors' diet. Lind revived it; an admiralty order prescribed the use of lemon juice (1795), and scurvy disappeared from the navy. He also studied typhus (then known as jail fever), recommending disinfection by the smoke of wood; suggested the use of hospital ships for sick sailors in tropical ports; arranged (1761–62) for the distillation of sea-water for drinking purposes; and secured many important and beneficial changes in life on board ship. Lind died on July 13, 1794. His three classical works are: *A Treatise on the Scurvy* (1754); *On the most effectual means of preserving the Health of Seamen* (1757); and *Essay on Diseases of Europeans in Hot Climates* (1768).

LIND, JENNY (1820–1887), the famous Swedish singer, was born at Stockholm on Oct. 6, 1820, the daughter of a lace manufacturer. Mlle. Lundberg, an opera-dancer, first discovered her musical gift, and induced the child's mother to have her educated for the stage; during the six or seven years in which she was what was called an "actress pupil," she occasionally appeared on the stage, but in plays, not operas, until 1836, when she made a first attempt in an opera by A. F. Lindblad. She was regularly engaged at the opera-house in 1837. Her first great success was as Agathe, in Weber's *Der Freischütz,* in 1838, and by 1841, when she started for Paris, she had already become identified with nearly all the parts in which she afterwards became famous. But her celebrity in Sweden was due in great part to her histrionic ability, and her wonderful vocal art was only attained after a year's hard study under Manoel Garcia.

Her first appearance in England was as Alice in Meyerbeer's *Robert le Diable* at His Majesty's Theatre (May 4, 1847). The furore she created was prodigious. She sang in several of her favourite characters, and in that of Susanna in Mozart's *Figaro,* besides creating the part of Amalia in Verdi's *I Masnadieri,,* written for England and performed on July 22. In the autumn she appeared in operas, in Manchester and Liverpool, and in concerts at many provincial centres. At Norwich began her acquaintance with the bishop, Edward Stanley (1779–1849), which was said to have led to her final determination to give up the stage as a career.

After four more appearances in Berlin, and a short visit to Stockholm, she appeared in London in the season of 1848, when she sang in Donizetti's *L'Elisire d'amore* and Bellini's *I Puritani,* in addition to her older parts. At the beginning of the season of 1849 she intended to give up operatic singing, but a compromise was effected by which she was to sing the music of six operas, performed without action, at Her Majesty's Theatre; but the first, a concert performance of Mozart's *Il Flauto magico,* was so coldly received that she felt bound, for the sake of the manager and the public, to give five more regular representations, and her last performance on the stage was on May 10, 1849, in *Robert le Diable.* In 1850, just before leaving for America, she sang the soprano music in *The Messiah* at Liverpool with superb art. She remained in America for nearly two years, being for a great part of the time engaged by P. T. Barnum. In Boston, she married (1852) Otto Goldschmidt (1829–1907), whom she had met at Lübeck in 1850.

For some years after her return to England, her home for the rest of her life, she appeared in oratorios and concerts, and her dramatic instincts were as strongly and perhaps as advantageously displayed in these surroundings as they had been on the stage, for the grandeur of her conceptions in such things as the scene of the widow in *Elijah* and the religious fervour of "I know that my Redeemer liveth," could not have found a place in opera. In her later years she took an active interest in the Bach Choir, conducted by her husband, and not only sang herself in the chorus, but gave the benefit of her training to the ladies of the society. For some years she was professor of singing at the Royal College of Music. Her last public appearance was at Düsseldorf on Jan. 20, 1870, when she sang in *Ruth,* an oratorio composed by her husband.

She died at Malvern on Nov. 2, 1887. The supreme position which she held so long in the operatic world was due not only to the glory of her voice, and the complete musicianship which distinguished her above all her contemporaries, but also the naïve simplicity of her acting in her favourite parts, such as Amina, Alice or Agathe. In these and others she had the precious quality of conviction, and identified herself with the characters she represented with a thoroughness rare in her day. Unharmed by the perils of a stage career, she was a model of rectitude, generosity and straightforwardness, carrying the last quality into a certain blunt directness of manner that was sometimes rather startling.

See S. Dorph, *Jenny Lindiana till hundraårsminnet* (Uppsala, 1919) and *Jenny Linds triumftäg genom nya världen och övriga leonadsöden* (Uppsala, 1918); J. T. H. Norlind, *Jenny Lind;* Scott Holland & W. S. Rockstro, *Jenny Lind the Artist* (London, 1891; abridged, 1893).

LIND-AF-HAGEBY, EMELIE AUGUSTA LOUISE (1878–), British writer, born in Sweden on Sept. 20, 1878, was educated in Stockholm and at Cheltenham college, England. From 1896 onwards she lived in England, and in 1912 became a naturalized British subject. She worked actively for the movement towards the emancipation of women. She was a strong opponent of vivisection, and founded several societies, including the international federation of anti-vivisection and animal protection societies (1909). At the outbreak of World War I her three hospitals for wounded horses were authorized by the French government (the Purple Cross), and two years later she opened a sanatorium for French and Serbian soldiers, and children who had suffered through the war, at Carqueiranne. She became a well-known public speaker, and wrote numerous books and pamphlets on humanitarian subjects.

Her works include *August Strindberg* (1913); *Mountain Meditations* (1917); *Marriage and the New Woman* (1920); *Women's Right to Work* (1920); *Be Peacemakers* (1924); *The Great Fox-Trot* (1938).

LINDAU, PAUL (1839–1919), German dramatist and novelist, the son of a Protestant pastor, was born at Magdeburg on June 3, 1839. He was educated at the gymnasium in Halle, and then studied in Leipzig, Berlin and Paris. Lindau was one of the most brilliant journalists of his day. He began as correspondent to the German press while he was a student in Paris. He founded *Das Neue Blatt* (Leipzig, 1870), and the famous monthly *Nord und Süd* (1878), which he edited until 1904. Many of his contributions to the press were collected in a series of entertaining volumes. He was appointed intendant of the court theatre at Meiningen in 1895, but removed to Berlin in 1899, where he became manager of the Berliner Theater, and subsequently, until 1905, of the Deutsches Theater. *Marion* (1868) was the first of a long series of plays in which he showed a mastery of the stage and a command of witty and lively dialogue. Among the more famous were *Maria und Magdalena* (1872), *Tante Therese* (1876), *Gräfin Lea* (1879), *Die Erste* (1895), *Der Abend* (1896), *Der Herr im Hause* (1899), *So ich dir* (1903), and he adapted many plays by Dumas, Augier and Sardou for the German stage. Five volumes of his plays have been published (1873–88). His work also includes some volumes of short stories, a novel-sequence with the general title, *Berlin,* and many other novels, all of them popular. He died in Berlin on Jan. 31, 1919. *See* his admirable and entertaining *Nur Erinnerungen* (1917).

LINDAU, a town and pleasure resort in the *Land* of Bavaria, Germany, central point of the transit trade between Bavaria and Switzerland, situated on two islands off the northeastern shore of Lake Constance. Pop. (1939) 17,475. On the site now occupied by the town there was a Roman camp, the *castrum Tiberii,* and the authentic records of Lindau date back to the end of the 9th century. In 1274, or earlier, it became a free imperial town. In 1804 it lost its imperial privileges and passed to Austria, being transferred to Bavaria in 1805.

LINDBERGH, CHARLES A. (1902–), American aviator, and the first flyer to make a New York to Paris non-stop flight, was born on Feb. 4, 1902, at Detroit, Mich. When about two months old Lindbergh's parents took him to Little Falls, Minn., where he later graduated from high school. His interests led him to study engineering at the University of Wisconsin for three semesters and to enroll in a flying school in Lincoln, Neb.

On March 19, 1924, he enlisted as a flying cadet in the air service of the War Department at Kelly field, Texas, and in the spring of 1925 was commissioned second lieutenant. In Nov. 1925 he enlisted in the 110th squadron of the 35th Division Missouri National Guards as first lieutenant and in the following November was made a captain in the Officers Reserve Corps. On April 15, 1925, he entered upon his duties as an air-mail pilot on the route from St. Louis to Chicago, and it was while flying this route that he decided to compete for the $25,000 prize offered by Raymond B. Orteig for a New York to Paris non-stop flight.

In St. Louis he found men to finance the building of the plane "Spirit of St. Louis." He left San Diego for New York city, via St. Louis, at 3.55 P.M. Pacific time, on May 10; arrived at Curtiss field, L.I., at 5.33 P.M. on May 12, making a record for an overland flight. At 7.52 A.M. of May 20 he left Roosevelt field, L.I., for Paris, and arrived there, at Le Bourget, at 10 P.M. Paris time, on the evening of the 21st. He was awarded the French cross of the Légion d'honneur, the British royal air force cross and, in the United States, the distinguished flying cross and the Congressional medal. He was promoted to colonel. Following his enthusiastic reception in Washington and New York city, he made an air tour of 78 cities and every state in the union. Upon invitation from President Calles of Mexico he made a non-stop flight from Washington, D.C., to Mexico City Dec. 13–14, 1927. The "good-will" mission continued to Central America, northern South America and the West Indies—in all, 16 countries. For this flight of 7,860 mi. he was awarded the Woodrow Wilson medal and $25,000. He returned to St. Louis on Feb. 13, 1928, and subsequently became chairman of the technical committee of the Transcontinental Air Transport. In 1933 he flew from America to Copenhagen by way of Greenland, Iceland and the Shetland Isles. In 1929 he married Anne Morrow, daughter of Dwight W. Morrow. The kidnapping of their first child, Charles Augustus, Jr., attracted world-wide attention. In 1935 the Lindberghs left the U.S. for England and returned in 1939. Lindbergh resumed his work in the U.S. air corps, but resigned in April 1941 when Pres. Roosevelt criticized his opposition to U.S. intervention in World War II prior to the country's entry into the war. He joined the America First committee in April 1941 and on Dec. 10 of the same year volunteered his services to the U.S. air corps. Later he was associated with the Ford Motor company as a research engineer in war production.

Anne Lindbergh revealed considerable ability in her books *North to the Orient* (1935); *Listen! The Wind* (1938); and *Wave of the Future* (1941). The latter was assailed for its alleged sympathetic views on totalitarianism. Lindbergh wrote *We,* an autobiography (1927).

LINDENTHAL, GUSTAV (1850–1935), American engineer, was born at Brünn, Austria, May 21, 1850, and was educated there, and at Vienna. After some experience in railway and bridge work in Austria and Switzerland, he went to the United States in 1871. He was engineer at the Centennial Exposition, Philadelphia, 1874–77, and then practised in Pittsburgh as consulting engineer in railway and bridge construction till 1890, when he moved to New York City. In 1902–03 he was commissioner of bridges for the City of New York. He designed and acted as consulting engineer for the steel arch bridge spanning the East river at Hell Gate, which was opened for traffic March 1917. With its approaches, it is about 3½ mi. in length, and at the date of completion contained the longest steel arch in the world (1,017 feet). Its cost was approximately $18,500,000.

LINDESAY, ROBERT, of Pitscottie (*c.* 1530–*c.* 1590), Scottish historian, of the family of the Lindesays of the Byres, was born at Pitscottie, in the parish of Ceres, Fifeshire, which he held in lease at a later period. His *Historie and Cronicles of Scotland,* covering the period from 1437 to 1456, the only work by which he is remembered, is described as a continuation of that of Hector Boece, translated by John Bellenden. Sir Walter Scott made use of it in *Marmion.*

The *Historie and Cronicles* was first published in 1728. A complete edition of the text (2 vols.), based on the Laing ms. No. 218 in the University of Edinburgh, was published by the Scottish Text Society in 1899 under the editorship of Aeneas J. G. Mackay. The ms. formerly in the possession of John Scott of Halkshill, is fuller, and, though in a later hand, is, on the whole, a better representative of Lindesay's text.

LINDET, JEAN BAPTISTE ROBERT (1749–1825), French revolutionary, was born at Bernay (Eure), and was an *avocat* at Bernay. Appointed deputy to the Legislative Assembly and then to the Convention, he furnished a *Rapport sur les crimes imputés à Louis Capet* (Dec. 10, 1792), and voted for the death of Louis without appeal or respite. As member of the Committee of Public Safety he successfully organized the food supply of the army in the face of great difficulties. Without being formally opposed to Robespierre, he did not support him, and he was the only member of the Committee of Public Safety who did not sign the order for the execution of Danton and his friends. He opposed the Thermidorian reaction, and defended Barère, Billaud-Varenne the Collot d'Herbois on March 22, 1795. Himself denounced on May 20, 1795, he was defended by his brother Thomas (Constitutional bishop and member of the Convention) but escaped condemnation by the vote of amnesty of the 4th Brumaire, year IV. (Oct. 26, 1795). He was minister of finance from June 18 to Nov. 9, 1799, but refused office under the consulate and the empire. In 1816 he was proscribed by the Restoration government as a regicide, and left France until just before his death on Feb. 17, 1825.

See Amand Montier, *Robert Lindet* (1899).

LINDLEY, JOHN (1799–1865), English botanist and horticulturist, was born Feb. 5, 1799, at Catton, near Norwich, where he was educated. In 1820 he published an original *Rosarum Monographia* with descriptions of new species, and drawings executed by himself, and in 1821 *Monographia Digitalium,* and "Observations on Pomaceae," contributed to the Linnean society. Shortly afterwards he went to London, where, while writing the descriptive portion of the *Encyclopaedia of Plants,* he became convinced of the superiority of the "natural" system of A. L. de Jussieu, as distinguished from the "artificial" system of Linnaeus followed in the *Encyclopaedia.* The conviction found expression in *A Synopsis of the British Flora, arranged according to the Natural Orders* (1829) and in *An Introduction to the Natural System of Botany* (1830). In 1829 Lindley accepted the chair of botany in University college, London, which he retained till 1860. He died at Turnham Green on Nov. 1, 1865.

His works also include *An Outline of the Structure and Physiology of Plants* (1832), *A Natural System of Botany* (1836), *The Fossil Flora of Great Britain* (with W. Hutton, 1831–37), *Flora Medica* (1838), *Theory of Horticulture* (1840), *The Vegetable Kingdom* (1846), *Folia Orchidacea* (1852–59), *Descriptive Botany* (1858). He was editor of the *Botanical Register* and *Gardeners' Chronicle.*

LINDLEY, NATHANIEL LINDLEY, Baron (1828–1921), English judge, son of John Lindley (*q.v.*), was born at Acton Green, Middlesex, on Nov. 29, 1828, and educated at University college school and University college, London. Called to the bar at the Middle Temple in 1850 he began practice in the court of chancery, and became a Q.C. in 1872. In 1875 he was appointed a justice of common pleas, and in pursuance of the changes made by the Judicature Acts, became a justice of the common pleas division of the High Court of Justice, and in 1880 of the queen's bench division. In 1881 he was raised to the Court of Appeal and made a privy councillor; in 1897 he succeeded Lord Esher as master of the rolls, and in 1900 was made a lord of appeal in ordinary, with a life peerage and the title of Baron Lindley. He resigned the judicial post in 1905, and died at East Carlton, near Norwich, on Dec. 9, 1921. Lord Lindley was the last serjeant-at-law appointed. His reputation is mostly a professional one. He was at home throughout the law; a brilliant example of his judgments will be found in *Colls* v. *Home and Colonial Stores* (1904, A.C. 179). He published *An Introduction to the Study of Jurisprudence* (1855), a translation of Thibaut's *System des Pandekten-Rechts: Treatise on the Law of Partnership* (2 vols., 1860), with a supplement in 1862. This work has since been developed into two text-books, *Lindley on Companies* and *Lindley on Partnership.*

See *The Times* (Dec. 12, 1921); *Law Journal* (Dec. 17, 1921); *Dict. Nat. Biog.* (Supp: 1912–21).

LINDLEY, WILLIAM (1808–1900), English engineer, was born in London on Sept. 7, 1808. He was engaged for a time in railway work in various parts of Europe, and then settled in Hamburg, as engineer-in-chief to the Hamburg-Bergedorf railway. His first achievement was to drain the Hammerbrook marshes, and so add some 1,400 ac. to the available area of the city. His real opportunity, however, came with the great fire which broke out on May 5, 1842, and burned for three days. The strong measures he adopted to prevent the spread of the fire, including the blowing-up of the town hall, brought his life into danger with the mob, who professed to see in him an English agent charged with the destruction of the port of Hamburg. Lindley was then appointed consulting engineer to the senate and town council, to the Water Board and to the Board of Works. He constructed a complete sewerage system, and designed, between 1844 and 1848 the water-works of the city, the intake from the Elbe being at Rothenburgsort. In 1846 he erected the Hamburg gas-works; public baths; wash-houses were built, and large extensions to the port executed according to his plans in 1854; and he supervised the construction of the Altona gas and water-works in 1855. Among other services he rendered to the city were the trigonometrical survey executed between 1848 and 1860, and the conduct of the negotiations which in 1852 resulted in the sale of the "Steelyard" on the banks of the Thames belonging to Hamburg jointly with the two other Hanseatic towns, Bremen and Lübeck.

In 1860 he left Hamburg, and during the remaining 19 years of his professional practice he was responsible for many engineering works in various European cities, among them Frankfort-on-the-Main, Warsaw, Pesth, Düsseldorf, Galatz and Basel. In Frankfort he constructed sewerage works on the same principles as those he followed in Hamburg, and the system was widely imitated in Europe and America. He advised the New River Company of London on the adoption of the constant supply system in 1851; and he was commissioned by the British Government to carry out various works in Heligoland, including the big retaining wall "Am Falm." He died at Blackheath, London, on May 22, 1900.

LINDO, MARK PRAGER (1819–1879), Dutch prose writer, of English-Jewish descent, was born in London on Sept. 18, 1819. He settled in Holland, taught English, studied at Utrecht, and made translations from the works of the classic English novelists. He also wrote humorous original sketches and novelettes in Dutch, which he published under the pseudonym of De Oude Herr Smits ("Old Mr. Smits"). Lindo's serious original Dutch writings he published under his own name, the principal one being *De Opkomst en Ontwikkeling van het Engelsche Volk* ("The Rise and Development of the British People," 2 vols, 1868–1874)—a valuable history. Lindo was appointed an inspector of primary schools in the province of South Holland in 1865, a post he held until his death at The Hague on March 9, 1879.

LINDSAY, the family name of the earls of Crawford. The family is one of great antiquity in Scotland, the earliest to settle in that country being Sir Walter de Lindesia, who attended David, earl of Huntingdon, afterwards King David I., in his colonization of the Lowlands early in the 12th century. His descendants divided into three branches, whose heads sat as barons in the Scottish parliament for more than 200 years before the elevation of the chief of the house to an earldom in 1398. The Lindsays held the great mountain district of Crawford in Clydesdale, from which the title of the earldom is derived, from the 12th century till the close of the 15th, when it passed to the Douglas earls of Angus. *See* Crawford, Earls of.

See A. W. C. Lindsay, afterwards earl of Crawford, *Lives of the Lindsays, or a Memoir of the Houses of Crawford and Belcarres* (3 vols., 1843 and 1858).

LINDSAY, SIR COUTTS, 2nd Bart. (1824–1913), English artist, was born on Feb. 2, 1824 and died at Kingston on May 7, 1913. He entered the army, where he commanded the 1st Regt. of the Italian Legion during the Crimean War. Between 1862 and 1874 he exhibited many pictures, and in 1877 founded the Grosvenor Gallery, London, which exhibited the works of the pre-Raphaelite group and other artists outside the academic circle.

LINDSAY, NICHOLAS VACHEL (1879–1931), American writer, was born at Springfield (Ill.), Nov. 10, 1879. In 1897 he entered Hiram college, Ohio, but left after three years to study art in Chicago and New York. For several winters he was a Y.M. C.A. lecturer, and during 1909–10 lectured for the Anti-Saloon League in his native State. Meanwhile he had begun during the summers a series of wanderings on foot which carried him through many States, reciting or singing his own verses like an ancient minstrel, and delivering an occasional lecture in return for food and lodging. He has published *General William Booth Enters Into Heaven, and Other Poems* (1913); *The Congo, and Other Poems* (1914); *Adventures While Preaching the Gospel of Beauty* (1914, prose); *The Chinese Nightingale, and Other Poems* (1917); *The Golden Book of Springfield* (1920, prose); *The Golden Whales of California, and Other Rhymes in the American Language* (1920); *Going-to-the-Sun* (1923); *Going-to-the-Stars* (1926); *Every Soul is a Circus* (1929). He died Dec. 5, 1931.

His *Collected Poems* (rev. ed. 1925) contains autobiographical material. *See* also "Salvation with Jazz" in Carl Van Doren's *Many Minds* (1924) and Stephen Graham's *Tramping with a Poet in the Rockies* (1922).

LINDSAY, NORMAN (1879–), Australian artist, was born at Creswick, Victoria, on Feb. 23, 1879. He began to draw for a Melbourne newspaper at 16, and in 1901 moved to New South Wales. He became the chief cartoonist of the Sydney *Bulletin,* a post which he retained for many years. His chief characteristics are imaginative power, grim strength, marked individuality of style and a certain coarseness. All of these qualities are apparent in his illustrations to Theocritus, Boccaccio, Casanova and Petronius, the best of which have been collected in *The Pen Drawings of Norman Lindsay* (1918). Among his other published works are *Redheap* (1931), *Saturdee* (1933), *Pan in the Parlour* (1934) and *Age of Consent* (1938). He illustrated many books and was the joint founder of the Endeavour Press.

LINDSAY, a town and port of entry of Ontario, Canada, and capital of Victoria county, on the Scugog river, 69 mi. N.E. of Toronto by rail, on the Canadian Pacific and Canadian National railways. Pop. (1941) 8,403. It has steamboat communication, by way of the Trent canal, with Lake Scugog and the ports on the Trent system. It contains saw and grist mills, agricultural implement and other factories.

LINDSEY, BENJAMIN BARR (1869–1943), American judge, was born at Jackson, Tenn., on Nov. 25, 1869. He was educated in the public schools and attended Notre Dame (Indiana) university and the Southwestern Baptist university, Jackson, Tennessee. At the age of 16 he began to earn his livelihood in Denver, continuing his studies in a law office. He was admitted to the Colorado bar in 1894. In Jan. 1899 he was appointed public guardian and administrator of Denver. He was instrumental in securing the passage of the Colorado juvenile court law of April 12, 1899, which led to the reform of juvenile court procedures in treating delinquent children. He was judge of that court from 1900 to 1927, and then moved to California, where he was elected judge of the superior court in 1934. He was an internationally known jurist and lecturer, and was an advocate of "companionate marriage," for which he was widely publicized. He was also the author of the first parental laws in the United States making the juvenile court a parental and family court as well, and also of the "chancery court procedure" in dealing with adult offenders. He wrote *Problems of the Children* (1903); *The Beast* (with Harvey O'Higgins) (1910); *Children in Bondage* (with George Creel) (1914); *Pan-Germanism in America* (1919); *The Doughboy's Religion* (with Harvey O'Higgins) (1920); *The Revolt of Modern Youth* (with Wainwright Evans) (1925); *Childhood, Crime, and the Movies* (1926); *The Companionate Marriage* (with Wainwright Evans) (1927); *The Dangerous Life* (1931), an autobiography; and many brochures on juvenile delinquency, domestic relations and crime. He died in Los Angeles, Calif., March 26, 1943. (*See* CHILDREN'S COURTS.)

LINDSTROM, GUSTAF (1829–1901), Swedish palaeontologist, was born at Wisby in Gotland on Aug. 27, 1829. In 1848 he entered the university at Uppsala, and in 1854 he became interested in the zoology of the Baltic, and published several papers on the invertebrate fauna, and on the fishes. He described the fossils of the Silurian rocks in Gotland; also remains of the fish *Cyathaspis* from Wenlock beds, and (with T. Thorell) a scorpion *Palaeophonus* from Ludlow beds at Wisby. He determined the true nature of the operculated coral *Calceola;* and while he described organic remains from other parts of northern Europe, he worked especially at the Palaeozoic fossils of Sweden. In 1876 he was appointed keeper of the fossil Invertebrata in the State museum at Stockholm, where he died on May 16, 1901.

See obituary (with portrait), by F. A. Bather, *Geol. Mag.* (1901).

LINDUS, one of the three cities of Rhodes, before their synoecism, situated at Vroulia on the east coast with a finely placed acropolis and good natural harbour. Danish excavators have discovered the early temple of Athena Lindia on the Acropolis, and splendid Propylaea, resembling those at Athens; other early temples, rock-inscriptions, a theatre and rock-tombs. The sculptors of the Laocoon are among the priests of Athena Lindia. On the Acropolis is a castle, built like many houses in the town by the Knights of St. John in the 14th century.

BIBLIOGRAPHY.—Chr. Blinkenberg and K. F. Kinch, *Exploration archéologique de Rhodes* (Copenhagen 1904–07); *Fouilles de Vroulia Lindiaca* (several memoirs).

LINE, primarily of thread or cord, a succession of objects in a row, a mark or stroke, a course in any particular direction.

In mathematics several definitions of the line may be framed. The synthetical genesis of a line from the notion of a point is the basis of Euclid's definition, (γραμμὴ δὲ μῆκος ἀπλατές "a line is widthless length"), and in a subsequent definition he affirms that the boundaries of a line are points. The line appears in definition 6 of the *Elements* as the boundary of a surface. Another synthetical definition, also treated by the ancient Greeks, but not by Euclid, regards the line as generated by the motion of a point, and, in a similar manner, the surface was regarded as the flux of a line, and a solid as the flux of a surface. Analytical definitions, although not finding a place in the Euclidean treatment, have advantages over the synthetical derivation. Thus the boundaries of a solid may define a plane, the edges a line, and the corners a point; or a section of a solid may define the surface, a section of a surface the line, and the section of a line the point. The line has only extension and is unidimensional; and the point, having only position has no dimensions.

The definition of a straight line is a matter of much complexity. Euclid defines it as the line which lies evenly with respect to the points on itself. Archimedes defines it as the shortest distance between two points. The definition, "a straight line is one which when rotated about its two extremities does not change its position," is essentially due to Heron of Alexandria (*q.v.*).

In analytical geometry the right line is always representable by an equation, or equations, of the first degree; thus in cartesian co-ordinates of two dimensions the equation is of the form $Ax+By+C=0$, in triangular co-ordinates, $Ax+By+Cz=0$. In three-dimensional co-ordinates, the line is represented by two linear equations. (*See* ANALYTIC GEOMETRY; LINE GEOMETRY; CURVE; CURVES, SPECIAL.)

LINEAL, in law the relationship of persons directly descended from a common ancestor, as distinguished from collateral relationship or consanguinity. *See* COLLATERAL.

LINEAR ALGEBRAS, number systems whose elements combine under addition and multiplication and which are also n-dimensional linear spaces of geometry. The co-ordinates of the points of the space are assumed to be quantities of any field F. (*See* FIELDS for the definition of an arbitrary field and the definition of many other terms used in this article.)

The general n-dimensional linear space over an arbitrary field F may be defined by postulates but may be thought of most simply as any mathematical equivalent of the space consisting of sequences $u=(a_1, \ldots, a_n)$ with elements $a_1, \ldots, a_n$ in F. The elements a_i are called the co-ordinates of u and we call u a *vector* in n-dimensional linear space.

If $v=(b_1, \ldots, b_n)$ we define the sum of the vectors u and v to be $u+v=(a_1+b_1, \ldots, a_n+b_n)$. The elements of F are frequently called *scalars* and we define the *scalar product* $cu=uc$ of a vector u by a scalar c to be $cu=(ca_1, \ldots, ca_n)$.

A set of vectors $u_1, \ldots, u_m$ of a linear space L over F is said to form a *basis* of L if every vector of L can be expressed in one and only one way as a linear combination $a_1u_1+ \ldots +a_m u_m$ with coefficients a_i in F. Then m is the same for all bases of L and is called the *dimension* or *order* of L. It is actually the integer n above.

A subset M of L is said to form a linear *subspace* of L if $au+bv$ is in M for every a and b of F, u and v of M. Then M is a linear space of order $m \leqq n$ over F and M=L if and only if $m=n$.

We are finally ready to define linear algebras. A *linear algebra* A of order n over F is a linear space of order n over F such that the product uv of any two elements of A is in A and the distributive law holds. If $u_1, \ldots, u_n$ form a basis of A over F the products u_iu_j must be in A for $i, j=1, \ldots, n$. Then we may make any linear space into an algebra by prescribing a set of n^3 elements g_{ijk} in F such that $u_iu_j=g_{ij1}\, u_1+ \ldots +g_{ijn}\, u_n$. The remaining products $(a_1u_1+ \ldots +a_nu_n)\ (b_1u_1+ \ldots +b_nu_n)$ may then be obtained by use of the distributive law.

The multiplication constants g_{ijk} which define an algebra are quite arbitrary. When they are all zero the algebra is called a *zero algebra* and every product $uv=0$. An algebra of order one is either a zero algebra or is mathematically equivalent to F itself.

When conditions are imposed on an algebra the multiplication constants are, of course, restricted. We note that all algebras satisfy the commutative and associative laws for addition, the subtraction law, and the distributive law. If the commutative law for multiplication is satisfied we call the algebra a *commutative algebra;* if the associative law for multiplication is satisfied, we call the algebra an *associative algebra,* and if the division law is satisfied we call the algebra a *division algebra.*

Algebras with an infinite basis have been studied but are not of as great interest as the algebras defined above. The major interest in linear algebras to 1934 was in associative algebras, particularly division algebras. However there has been a strong interest in various types of nonassociative algebras after that time.

The simplest example of an algebra is the commutative associative division algebra A of order n over F. These are the algebraic extensions of degree n over F. (*See* FIELDS.) These algebras are generalizations of the special case of the field of all complex numbers considered as an algebra of order two over the field of all real numbers. This algebra is a cyclic field defined by the equation $x^2+1=0$ whose roots are i and $-i$. Its numbers may be represented as vectors (directed line segments from the origin) on the two dimensional Euclidean plane, and the chief geometric advantage of this representation is that the usual pair of formulas for the rotation of axes through an angle θ may be replaced by the complex number product formula $x+yi=(x'+y'i)(\cos\theta+i\sin\theta)$.

Quaternions.—Soon after complex numbers were applied to the study of directed lines in a plane, attempts were made to find numbers for directed lines in Euclidean space of three dimensions. What was desired was a commutative associative division algebra of order three over the field of all real numbers. However, no such algebra exists. Indeed no commutative associative division algebra over the real field exists except the field of complex numbers.

In 1843 Sir William Rowan Hamilton announced his discovery of "quaternions." This is the algebra of order four over the field of real numbers. It has a basis of elements $1, i, j, k$ where 1 behaves as a unity element, that is, $1a=a1=a$ for every element a of the algebra. Also $k=ij=-ji$, $i^2=j^2=-1$ and these relations together with the associative law complete the definition of multiplication.

The reader will have noticed that the algebra is a noncommutative algebra since ij and ji are not equal. It is the only associative division algebra over the field of all real numbers other than that field (an algebra of order one) and the field of all complex numbers.

A linear subspace B of an algebra A is a subalgebra of A if uv is in B for every u and v of B. The algebra of real quaternions defined above (the term "real" indicates that the coefficient field is the field of all real numbers) contains three subalgebras with respective basis $1, i$ and $1, j$ and $1, k$. Each of these algebras is equivalent to the field C of all complex numbers. Indeed if q is any quaternion not a scalar multiple of the quaternion 1 the subalgebra F $[q]$ with basis $1, q$ is equivalent to C.

If F is any field of characteristic not two we may define an algebra with a basis $1, i, j, ij$ such that $ji=-ij$ and $i^2=a$, $j^2=b$, $(ij)^2=-ab$, where a and b are in F. Such an algebra is called a *generalized quaternion algebra.* A *rational* generalized quaternion algebra is a generalized quaternion algebra over the field of all rational numbers. Such algebras have important connections with certain theorems of the elementary theory of numbers. They are division algebras if and only if b is not expressible in the form c^2-ad^2 for c and d in F.

Cyclic Algebras.—In 1905 Leonard Eugene Dickson defined a class of algebras called *cyclic* or *Dickson* algebras. He generalized the quadratic field F $[i]$ of quaternions to be an arbitrary cyclic field $Z=F(x)$ of degree n over F defined by a root x of an equation $f(x)=0$ whose roots are the iteratives $P^i(x)$ of a polynomial $P(x)$. He then imbedded Z in an algebra A of order n^2 over F with a basis consisting of the power products x^iy^j $(i, j=0, 1, \ldots, n-1)$ of two generating elements x and y. Then every element of such an algebra can be expressed uniquely as the formal sum $h_0(x)+h_1(x)y+ \ldots +h_{n-1}(x)y^{n-1}$ where the polynomials $h_i(x)$ are in Z. Two such sums may be multiplied by the use of the distributive law and the formulas

$$y^jh(x)=h[P^j(x)]y^j,\ y^n=g\neq 0\ (j=1, \ldots, n),$$

where g is in F.

Every cyclic algebra is associative and conditions that a cyclic algebra be a division algebra are known.

Crossed Products.—*Crossed products* are further generalizations of quaternions. Instead of a cyclic field Z a normal field defined by a root of an equation $f(x)=0$ is employed. The roots of this equation are then polynomials $P_1(x)=x$, $P_2(x)$, $\ldots$, $P_n(x)$ and $P_i[P_j(x)]=P_k(x)$ for some k. The crossed product is now an algebra whose elements are uniquely expressible in the form $h_1(x)y_1+h_2(x)y_2+ \ldots +h_n(x)y_n$ such that

$$y_jh(x)=h[P_j(x)]y_j,\ y_iy_j=g_{ij}(x)y_k,$$

where the $g_{ij}(x)$ are all not zero and are in Z. The quantities g_{ij} are not arbitrary in the sense that the algebra will not even be associative unles certain restrictions are imposed on them. Crossed products of order 16 have been constructed which are associative division algebras and which are not cyclic algebras.

Direct Sums and Products.—If M and N are linear subspaces of a linear space L and every element of L is uniquely expressible as a sum $u+v$ where u is in M and v is in N we call L the sum of M and N and write L=M+N. The order of L is the order of M plus the order of N. If an algebra A=B+C where B and C are subalgebras of A such that $uv=vu=0$ for every u in B and v in C we call A the direct sum of B and C and write $A=B\oplus C$. We call B and C the components of A. The result may be generalized to direct sums $B_1\oplus B_2\oplus \ldots \oplus B_t$.

An algebra A is called the direct product of two of its subalgebras B and C and we write $A=B\times C$ if every element of A can be expressed as the sum $b_1c_1+ \ldots +b_rc_r$ of a finite number of terms b_ic_i with b_i in B and c_i in C, the products $bc=cb$ for every b of B and c of C, and the order of A is the product of the order of B by the order of C. The concept of a direct product has turned out to be a very important tool in the theory of algebras. A notable result is that the direct product of two cyclic algebras of relatively prime orders is a cyclic-algebra.

Matric Algebras.—The set of all n-rowed square arrays (matrices) with elements in F forms an algebra M of order n^2 over F. It can be shown that the matrices e_{ij} with one in the i-th row and j-th column and zeros elsewhere form a basis of M and that multiplication of matrices is defined by

$$e_{ij}e_{jk}=e_{ik},\ e_{ij}e_{tk}=0\ (j\neq t,\ i,\ j,\ k,\ t=1,\ldots,n).$$

This associative algebra is called the *total matric* algebra of degree n over F.

A cyclic algebra with $g=1$ is a total matric algebra. A crossed product with all the quantities $g_{ij}=1$ is a total matric algebra. If the coefficient field of the real quaternion algebra is extended to be the complex field the algebra becomes a total matric algebra of degree two. The direct product of a total matric algebra of degree n and a total matric algebra of degree m is a total matric algebra of degree nm.

Every algebra A can be represented by an equivalent subalgebra of the total matric algebra whose degree n is either the order of A or one more than that order. Thus the theory of linear associative algebra may be regarded as a part of the theory of matrices.

The Wedderburn Theory.—A linear subspace M of an algebra A is called an ideal of A if ma and am are in M whenever a is in A and m is in M. Hence an ideal consists either of zero alone and is the zero ideal, or is a subalgebra of A with the property that when we multiply any element of the subalgebra by an element in the main algebra the product falls back into the subalgebra.

An algebra N is called a nilpotent algebra if there is an integer k called the index of N such that every product of k elements of N is zero and at least one product of $k-1$ elements of N is not zero. We call an ideal a nilpotent ideal if it is a nilpotent algebra and an ideal of A.

The radical of an algebra A is the nilpotent ideal of A having largest order. It can be shown to contain all nilpotent ideals of A.

An algebra is called a semisimple algebra if its radical is the zero ideal. It is called a simple algebra if it is not a zero algebra of order one and if its only ideals are itself and the zero ideal.

In the years before 1907, the field of reference for nearly all work on linear algebras was either the field of all real numbers or the field of all complex numbers. The subject seemed to be nearly devoid of interest when the 1907 paper of Joseph Henry MacLagen Wedderburn on the structure of algebras over an arbitrary nonmodular field appeared. He proved the following results:

Every linear associative algebra A over a nonmodular field F is either semisimple or nilpotent or is expressible as the sum K+N of its radical N and a semisimple algebra K. Any two determinations of K are equivalent.

Every semisimple algebra K is expressible as the direct sum of uniquely determined simple components.

Every simple algebra S is expressible as a direct product M×D of a total matric algebra M and a division algebra D. Any two determinations of M, D are equivalent.

The latter two theorems hold also for a modular field, and the first theorem holds under an additional hypothesis. The results of Wedderburn gave new life and interest to the subject of linear algebras. It essentially reduced all questions on the structure of algebras to those on the multiplicative relations of the algebras K and N, the structure of nilpotent algebras, and the structure of division algebras. Major emphasis has always been placed on the last topic since such algebras are much closer to the number systems of elementary algebra.

Central Simple Algebras and Division Algebras.—The centre of a simple algebra S is the set C of all elements c in S such that $cs=sc$ for every element s of S. Then C is a field and S may be expressed as an algebra over C. If C=F we call S a central simple algebra. There is no need to consider anything but central simple algebras since we may always select the centre as our reference field F.

Total matric algebras are central simple. The direct product of two central simple algebras is central simple. The order of a central simple algebra S is the square of an integer n called the degree of S. Write S=M×D where M is a total matric algebra and D is a division algebra. Then the centre of S is the centre of D and S is central simple if and only if D is a central division algebra.

If S=M×D and T=M_0×D where M and M_0 are total matric algebras and D is a division algebra the algebras S and T are said to be similar. Every central simple algebra is similar to a crossed product. This vital theorem implies that we may theoretically construct all division algebras by constructing all crossed products and then removing total matric algebras as direct factors.

All central division algebras of degree two are generalized quaternion algebras and hence cyclic; all of degree three are also cyclic. All central division algebras of degree four are crossed products and need not be cyclic algebras. It is not yet known whether or not there exist central division algebras of degree five over an arbitrary field F which are not cyclic algebras.

The most remarkable theorem in the theory of division algebras is the stating that all central division algebras over an algebraic number field are cyclic algebras. This was proved in 1932 by Abraham Adrian Albert, Richard Brauer, Emmy Noether and Helmut Hasse as a consequence of algebraic theorems of Albert, Brauer and Noether and algebraic number theorems of Hasse and his students (notably W. Grunwald).

Riemann Matrices.—If $f(u_1,\ldots,u_p)$ is a meromorphic function of p independent complex variables $u_1,\ldots,u_p$ with $2p$ independent period systems these systems form a period or Riemann matrix

$$W=(w_{jk})\ (j=1,\ldots,p;\ k=1,\ldots,2p).$$

Let W′ be the result of interchanging the rows and columns of W and $\overline{W}'$ be the result of then replacing each element of W′ by its complex conjugate. Then W is characterized by the existence of a rational skewsymmetric matric C such that $WC\overline{W}'=O$, and $\sqrt{-1}\,WC\overline{W}'=(g_{hk})$ for numbers g_{hk} such that

$$x_1g_{11}\bar{x}_1+\cdots+x_h\,g_{hk}\bar{x}_k+\cdots+x_{2p}g_{2p,\,2p}\bar{x}_{2p}$$

is positive for all complex numbers $x_1,\ldots,x_{2p}$.

An important problem in the theory of period matrices with applications to algebraic geometry is that of determining all $2p$-rowed square matrices D with rational elements such that EW=WD where E has p rows of complex number elements. The set of all such matrices D then forms a linear associative algebra over the field of all rational numbers called the multiplication algebra of W.

The properties of a Riemann matrix W are such that it may be replaced at any time by an isomorphic matrix gWG where g and G are nonsingular matrices, g has complex elements, G has rational elements. The multiplication algebra of W is always semisimple and is a division algebra if and only if W is pure, that is, not isomorphic to a Riemann matrix

$$\begin{pmatrix} W_1 & O \\ O & W_2 \end{pmatrix},$$

where W_1 and W_2 are Riemann matrices, the zeros are matrices with elements all zero. This result due to Henri Poincaré reduces the study of multiplication algebras to the multiplication algebras of pure Riemann matrices.

The centre of the (division) multiplication algebra of a pure Riemann matrix is a field K. Then K may be equal to F where F=R(y), R is the field of all rational numbers, $f(y)=O$, the complex roots of $f(y)=O$ are all real numbers $y_1,\ldots,y_t$. This F is what is called a totally real field. If X=F the only possible multiplication algebra of a pure Riemann matric of this kind is either F or a generalized quaternion algebra over F. If K≠F then K=F(x) where $x^2=q$ in F, $q(y_1),\ldots,q(y_t)$ are all negative. In this case the multiplication algebra is a cyclic algebra of arbitrary degree n over K defined by a cyclic field which is the direct product of K and a totally real cyclic field of degree n over F.

Nonassociative Algebras.—The theory of nonassociative algebras is a subject containing many theories each as elaborate as the theory of associative algebras. Among these perhaps the most important is the theory of Lie Algebras. These are algebras connected with the theory of continuous groups. Nonassociative algebras all have some properties in common with associative algebras and the Wedderburn theory can be applied to yield some results on nonassociative algebras.

Nonassociative division algebras are of great interest and the theory of real nonassociative division algebras has some importance for topology (*q.v.*). It is known that the order of every division algebra over the field of all real numbers is a power of two and a division algebra of order eight (necessarily nonassociative) was constructed by Arthur Cayley in 1843. This algebra consists of elements $a+bw$ where a and b are quaternions. If $a=a_1+a_2i+a_3j+a_4k$ define $\bar{a}=a_1-a_2i-a_3j-ak$. Then the Cayley algebra is defined by the multiplication law $(a+bw)\ (c+dw)=(ac-\bar{d}b)+(da+b\bar{c})w$. The algebra is not associative since $i(jw)=(\bar{i}\bar{j})w=-(ij)w$. It is not yet known whether or not there exist division algebras of order 16 or n>16 over the real field.

LINE ENGRAVING, the process of incising lines in a metal plate from which it is intended to take an impression or print. It differs from other reproductive process in that: (1) the engraved line is that part which is printed, *i.e.,* it is intaglio as opposed to surface printing (employed in woodcut, *q.v.*); (2) the line is incised without the use of chemical action (employed in

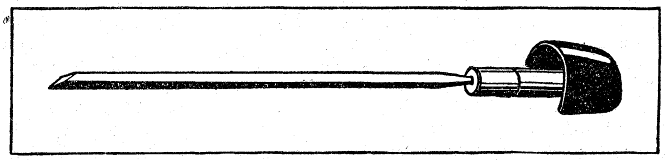

FIG. 1.—THE BURIN OR GRAVER USED FOR INCISING LINES INTO THE METAL PLATE

etching, *q.v.*); (3) the line is incised with a burin or graver (fig. 1), a sharp chisel-like tool of quadrangular section, which is pushed *forward* and removes a small shaving, leaving the edges at the furrow comparatively clean (as opposed to drypoint [*q.v.*], where the line is scratched by a needle drawn towards the operator, which in its passage leaves minute ridges on either side of the line, called burr). In line engraving the infinitesimal burr which is left by the graver (shown enlarged in fig. 2) is removed (as in fig. 3) by a sharp instrument called a scraper (fig. 4), whereas the effect produced by the burr is of the essence of drypoint.

The method of printing from an engraved plate is the same as from an etched plate. (*See* ETCHING.)

HISTORY AND TECHNIQUE

There is very little doubt that engraving was first practised north of the Alps, but at what place or at what exact time must remain a matter of uncertain conjecture. That it was evolved in the workshops of the goldsmiths, subsequently to the more obvious process of woodcut, is generally admitted; a date somewhere between 1410 and 1430, and a place somewhere between the Alps and the North sea, in the basin of the Rhine, may be regarded as probable. The earliest engravings have generally been considered to be those of an artist named, from the subject of his most striking work, the Master of the Playing Cards. The place where this engraver, who was almost certainly a goldsmith, worked was probably South Germany or Switzerland. Engraving, in his hands, was already an elaborate medium, presupposing a previous development of some years. The Master of the Flagel-

FIG. 4.—THE SCRAPER

lation of 1446, the first engraving to bear a date, worked in a very similar style and may be assumed to be the pupil of the Master of the Playing Cards. Contemporary with the latter, or possibly even earlier, is an engraver who worked in the Netherlands or Burgundy, known as the Master of the Death of Mary. His ideas of distance and perspective were less advanced than those of his German contemporary, but this may have been an individual weakness not necessarily implying an earlier date. There were other engravers working about the same time or a little later whose work can be distinguished and localized in Burgundy or Flanders.

With the Master who signed with the initials E.S., and some of whose works are dated 1466 and 1467, engraving in Germany had reached a further stage of development. The dates on his engravings mark the end of what was probably a long career, and his earlier works show his derivation from the Master of the Playing Cards. The number of his surviving engravings, something over 300, implies that he was, at any rate, primarily an engraver by profession, and the influence of his style and technique on all subsequent engraving north of the Alps and even in Italy, can hardly be exaggerated. Martin Schongauer of Colmar (d. 1491) clearly derives from the Master E.S., and may even have been his pupil. He has developed from E.S.'s still rather tentative technique a regular system of cross hatching admirably suited to his purposes, and the precision and delicacy of his technical equipment, combined with the distinction and real power of his design, go to make his engravings among the most beautiful achievements of the 15th century. Contemporary with Schongauer, and the only engraver of the period at all comparable to him in importance, is the anonymous artist known as the Master of the Hausbuch (or of the Amsterdam cabinet), who probably worked somewhere in the neighbourhood of Mainz and is known as a painter and draughtsman; he was presumably, unlike Schongauer, only secondarily an engraver. His work has almost the freedom and some of the character of drypoint and is very different in style from Schongauer's.

The last quarter of the 15th century in Germany is a period prolific in engravers. Schongauer's immediate scholars and imitators, whose names or initials it is not necessary to enumerate here, are numerous. The course of engraving in the Netherlands after the middle of the 15th century runs more or less parallel with that in Germany, though there are no artists of equal importance with E.S. and Schongauer.

Albrecht Dürer of Nuremberg (1471–1528) who, though not actually Schongauer's pupil as an engraver, is his virtual successor, carries on the Gothic tradition and later develops it, in contact with the Italian renaissance and by the power of his own fantastic and thoughtful temperament, into that grand and most significant expression of the Teutonic genius which we recognize in such engravings as the "Knight, Death and the Devil," the "Melancolia" and the "St. Jerome." Dürer was more than an engraver, but it was in this medium, perhaps, that his genius found the most perfect expression; he must be considered in view of this absolute fitness of means to expression as one of the greatest, if not the greatest, of the world's engravers.

Lucas van Leyden (1494–1533) in Holland, was in his own time placed on a level with Dürer, but posterity will hardly endorse this contemporary view, though his earlier engravings, beginning with the "Mahomet and the Monk Sergius" dated 1508 in his 15th year, have a naïve directness and lucidity of expression which are admirable. His engraving further marks an increase in the delicacy of tone values, which even Dürer had not attained. His later work shows a surrender, first to the influence of his great German contemporary, then to that of Raphael's works as interpreted by Marcantonio Raimondi.

Italy.—Vasari's statement that the art of engraving was invented by Maso Finiguerra about the year 1460 has long been disproved. Not only, as we have seen, was engraving known and practised north of the Alps some decades earlier, but even in Italy itself examples dating from at least ten years before Finiguerra's alleged discovery, can be found. These earliest Italian engravings, which emanate most probably from the workshops of Florentine goldsmiths, are in marked contrast to contemporary German productions, showing a much lower level of technical skill both in the actual engraving and in the printing. A first small group of Florentine engravings dating from about 1450 was succeeded by another group which may with very great probability be associated with the name of Maso Finiguerra (1426–1464). There is every reason to credit the tradition that he was an engraver, and the style of this second group is closely related to that of works in intarsia authenticated as his, and to that of a large group of works in niello (*q.v.*), an art of which he was reputed to be the greatest master. Closely connected with, and probably executed in Finiguerra's workshop after the master's death, are a number of

EARLY ENGRAVINGS FROM ITALY AND THE COUNTRIES NORTH OF THE ALPS

1. "Raphael's Dream" by Marcantonio Raimondi (*c.* 1480–*c.* 1530), an Italian artist who did much of his best work in association with Raphael between 1510 and 1520
2. "Battle of the Nudes," the only engraving by the Florentine painter and sculptor, Antonio Pollaiuolo (1429–98)
3. Study by the artist known as "The Master of the Playing Cards," generally considered to be the first engraver. He probably worked in South Germany or Switzerland between 1410 and 1430
4. Landscape after Rubens by *Schelte a Bolswert* (*c.* 1586–1659), one of the best of the engravers in the Rubens school
5. "St. Jerome in his Study," engraved in 1514 by Albrecht Dürer of Nuremberg (1471–1528)
6. "Joseph in Prison" by Lucas van Leyden (1494–1533), a Netherlander whose work is marked by naïve directness and delicacy of tone value
7. The right portion of the frieze, "The Battle of the Sea Gods," by Andrea Mantegna (1431–1506), Italian engraver and painter

LINE ENGRAVINGS OF THE 15TH TO THE 20TH CENTURY

1. Illustration by William Blake (1757–1827) for the book of Job. 2. "Les Adieux" engraved (1777) by N. de Launay, the younger, after a design by J. M. Moreau, the younger (1741–1814). 3. One of the 300 engravings by the Master E. S., 15th century, German. 4. "A Woman of Scanno" by Robert Austin (1895–   ), English. 5. "Mercury and Argus" engraved by J. T. Willmore (1800–63) after J. M. W. Turner (1775–1851). 6. "The Nativity" by Martin Schongauer (*c.* 1446–1488), German. 7. "Frockas, Count de Feria" one of the series known as Van Dyck's "Iconography." Engraved by Paul Pontius (1603–58). 8. "The Cumaean Sybil" by Andrea Mantegna (1431–1506), Italian. 9. "Louis II., Prince de Conde" Aug. 1662, engraved by Robert Nanteuil (1623–28), French

other engravings, such as the series of the "Prophets and Sibyls." These, with the engravings actually attributed to Finiguerra, are usually grouped together as Florentine engravings in the Fine Manner as opposed to a more important group distinguished as in the Broad Manner. These, which are mostly later in date than the fine manner prints, some being copies from the latter, aim at reproducing the effect of pen drawings and derive their inspiration in part from Botticelli. Baccio Baldini who, Vasari states, engraved Botticelli's designs, may be the engraver of some of them.

The first great Florentine painter actually to use the graver himself was Antonio Pollaiuolo; his only engraving, the "Battle of the Nudes," is stylistically to be included in the group of prints in the broad manner. In Andrea Mantegna (1431–1506), Italy produces her first really great engraver, great rather as an artist than as a craftsman. The "Virgin and Child," probably one of his earlier works, the great Entombment and the frieze of the "Battle of the Sea Gods" are as noble expressions of the great painter's genius as any of his pictures. A whole group of engravers was inspired by Mantegna and worked after his designs. Their work owes most of its worth to Mantegna, though they are competent workmen in the same manner. No greater contrast could be found with Mantegna's style than that of Jacopo de' Barbari (d. after 1512), a Venetian, who assimilated the northern technique of engraving and used it to express a rather charming vein of his own.

By the beginning of the 16th century we find quite a number of known engravers working in the north of Italy, such as Benedetto Montagna of Vicenza (about 1470 to after 1540), who continues the style of his more important father, the painter Bartolommeo, the gifted Giulio Campagnola in Venice (about 1482 to after 1514), whose work, executed in a curious dot manner akin to the later stipple, shows the nearest approach in engraving to the effects Giorgione was aiming at in painting, and others.

But it is to Rome by way of Bologna that we must now turn. Marcantonio Raimondi (*c.* 1480–*c.* 1530), trained in the workshop of the goldsmith-painter, Francia, in the latter city, at first engraved solely after drawings by or in the style of his master. Marcantonio's powers and his technique gradually improved with study and by copying Dürer and Lucas van Leyden, and after a stay in Florence and Venice he betook himself about 1510 to Rome. Here he came into contact with Raphael, who supplied the engraver with sketches from which to work. It is this contact which has given to Marcantonio his enormous, perhaps exaggerated reputation. We possess Raphael's drawings for "The Massacre of the Innocents," Marcantonio's most famous engraving, and can consequently judge of it not only on its merits, but in relation to Raphael's conception, and it stands the test triumphantly. With Raphael's death, in 1520, the life went out of Marcantonio's work; he continued to engrave after his paintings, but there is an obvious deterioration.

Sixteenth Century Engraving.—The influence exercised by Raphael, especially through the engravings made by Marcantonio and his followers, over European art south and north of the Alps, can hardly be exaggerated, though, in Germany, the victory of the Raphaelesque was not so overwhelming or so sudden. The so-called Little Masters, the two Behams, Bartel (1502–1540) and Hans Sebald (1500–1550) and George Pencz (*c.* 1500–1550) of Nuremberg, together with Jacob Binck (d. about 1569) and Heinrich Aldegrever (1502–after 1555) continued the tradition of original engraving, along the lines which Dürer had inaugurated, and added something to the sum of the engraver's achievement, and in Ratisbon Albrecht Altdorfer (*c.* 1480–1538), of a previous generation, was the chief exponent of a quite individual style. But with about the year 1550, engraving, as well as the other arts in Germany, has passed its prime and the second half of the century is a decline, redeemed by fewer and fewer works of originality.

With the middle of the century engraving in the Netherlands has become commercialized. Engravers are employed by publishing firms, like that of Jerome Cock at Antwerp, to reproduce works, Netherlandish and Italian alike, for which there appears to be a demand. Even works engraved by Italians are published in the Netherlands, while Netherlandish engravers at the same time work in Italy, so that the sharp lines formerly delimiting the national styles are blurred. The tendency is for the technique of Italian engraving, which from the first owed something to northern models, to assume an even more northern character, while the influence of Italy is a general one on all northern art and only incidentally on engraving. The output of engraving in what is now Belgium, especially in Antwerp, during the two middle quarters of the century is enormous, but its character uninteresting; after about 1570 the centre shifts to Holland and it is the school of Hendrik Goltzius, Jacob Matham and Jan Saenredam, who continue and exaggerate the mannerisms of Lucas van Leyden's later style, which is most characteristic of the period and has the most influence on the subsequent development of engraving.

In Italy the school which Marcantonio had founded comprised a number of skilful engravers who continued the work of popularizing the paintings of Raphael and his pupils. But it was the Marcantonio in his latest and least satisfactory phase, who was their model, and the pupils rather than Raphael himself their inspiration. By about 1560 the art is mainly represented in the persons of foreign engravers like Cornelius Cort, and it is in this school that Lodovico Carracci and other Italian artists were trained.

In France, the 16th century produced one outstanding artist of small accomplishment as an engraver, but a remarkable genius, Jean Duvet (1485–*c.* 1561), and a group of engravers working at Lyons in the first half of the 16th century produced work of some decorative charm, while the portrait engravers foreshadow the great school of portrait engraving that followed in the 17th century.

The Seventeenth Century.—By the beginning of the 17th century engraving has come definitely to be regarded as a reproductive medium. Original engraving is now an exceptional phenomenon. Generally speaking, however, during this and the succeeding centuries the engravers are either independent or employed by publishing firms to engrave after miscellaneous artists, some living and some deceased. A feature of the 17th century is the increasing popularity of portrait engraving, which now became practically the most important branch of the art. (*See* SCULPTURE: *Portrait.*)

The engravers formed in the school of Rubens derive technically from Goltzius and his successors. Their brilliant but formal and inelastic technique, though sponsored by the master himself, was, it must be admitted, unsuited for the rendering of the spontaneity and exuberance of Rubens. The engravings are, in fact, dull, certainly the one fault of which Rubens himself could not be accused. But the best of these engravers, Pieter Soutman (1580–1657), Lucas Vorsterman the elder (1595–*c.* 1675), and his pupil, Paul Pontius (1603–1658), and the brothers Boëtius (*c.* 1580–1634) and Schelte (*c.* 1586–1659), a Bolswert, are admirable engravers in their way. Some of these also contributed to the famous series of engravings known as Van Dyck's *Iconography*. Eighteen of these plates were in the first place etched by Van Dyck himself, to be finished in some examples but not improved by the regular engravers. These elaborated plates suffer in contrast to Van Dyck's masterly etchings, but they are, in fact, sound examples of engraving, and exercised a considerable influence on subsequent engravers of portrait. In Holland, at the same time, an interesting and important school of portrait engraving came into existence, which was not without influence on the French school of engravers.

It was in France, and mainly in the special branch of portrait, that engraving in the 17th century attained its greatest perfection. The 16th century Netherlandish style of portrait engraving practised by T. de Leu, Leonard Gaultier and others, survived into the beginning of the 17th century. It was the influence of painting as practised by Rubens, Van Dyck and Philippe de Champaigne, which altered the conception of portrait painting, and consequently of portrait engraving. The earliest engravers to show the new influences at their fullest extent were Jean Morin (d. 1650) and Claude Mellan (1598–1688), though the former's work is mainly etched. Mellan, in particular, founding his technique on that of the engravers of the Italian school, evolved a very distinctive and effective style from which cross-hatching was entirely eliminated, and which depended on the variation in the breadth of the individual parallel lines. Robert Nanteuil (1623?–1678), unlike Morin and Mellan, not only engraved, but himself drew the vast majority of his portraits, which adds greatly to their liveliness and lifelikeness. His style, deriving from that of Mellan and the engravers of the school of Rubens in the first place, was later improved by the addition of elements borrowed from engravers like Morin. He models his faces in a series of small wedge shaped strokes, cunningly contrived to reproduce the desired texture. Gerard Edelinck (1640–1707), though lacking Nanteuil's extraordinary sincerity, is an engraver of great ability, and his interpretation of pictures by Lebrun and portraits by Rigaud and Largillière are typical examples of the art of the *grand siècle* at its *apogée,* while Antoine Masson (1636–1700) may be regarded as the third great portrait engraver of the century.

The 17th century in England produced one engraver of a merit, not comparable to that of Nanteuil, but still considerable, William Faithorne the elder (about 1616–1691), whose models are Claude Mellan, and later Nanteuil. But line-engraving in England was superseded in popularity towards the end of the century by the newly-invented process of mezzotint (*q.v.*), and Faithorne formed no school and had few successors of lasting influence.

The Eighteenth Century.—The pre-eminence of French engraving in the 17th is still more marked in the succeeding century. France has now become the artistic centre of Europe. The technique developed by Gerard Edelinck and Gerard Audran is continued and, if possible, further refined by the Drevet family, their scholars and successors, until engraving has been reduced to an almost mechanical formula, perfect in its way, but without life or individuality.

Portrait painting is not considered, however, as the most important product of the 18th century. It is in the engraving of society *genre* that we have to seek what is newest and most typical of the century. Watteau's elegant world of society, its most characteristic creation, is faithfully reflected in contemporary engraving. A number of skilful engravers were employed by Watteau's friend, Julienne, to engrave the master's complete works after his death. These engravers succeed in rendering in line the shimmer and the grace of Watteau's painting, as far as this was translatable.

The style of engraving which was formed in the interpretation of Watteau's works was obviously well adapted for illustration, which now begins to have an importance which it had not enjoyed since the 16th century. There arose at the same time, in cultivated and fashionable society, a new desire to possess beautifully illustrated volumes, and new editions of standard works illustrated by the leading engravers of the day found a ready sale. It was the professional engravers in the Watteau tradition who were employed not only to engrave but also to design these illustrations. In many, if not in most cases, indeed, pressure of work made it impossible for them actually to engrave what they had designed, and they were necessarily forced to employ others to do this. But even in the latter case so close is the connection between the designer, who is an engraver himself, and the executant engraver, that engraving has ceased to be merely reproductive and has again become a medium of direct and original expression. A characteristic of reproductive line-engraving from the beginning of the 18th century onward (it is especially important in the case of the French illustrators and of the engravers of the Turner school) is the use of etching for the preliminary laying in of the design subsequently gone over and completed with the graver. The number of able illustrators who worked in France during the latter part of the century is very large and their excellence extremely uniform. Two artists may be singled out for especial mention, J. M. Moreau the younger (1741–1814), and Augustin de St. Aubin (1736–1807).

Italy, in the 18th century, has nothing to show in engraving at all comparable. The most original work was that produced in Venice by Giovan Marco Pitteri (1703–1786), in a style resembling that of Mellan. The work of Giovanni Volpato (1733–1803), and his famous pupil, Raphael Morghen (1758–1833), with all its prodigious skill, is decidedly devoid of life and character.

In England excellent work was done in engraving by Sir Robert Strange (1721–1792), who learnt his art in Paris, by William Woollett (1735–1785), whose landscapes after Richard Wilson especially form a real contribution to engraving, and by William Sharp (1749–1824), whose works after English portrait painters are of particular excellence.

Nineteenth Century.—Illustration in England, though it had never attained the distinction which had marked it in France, was not brought to a sudden end, as it was on the other side of the Channel, by the Revolution. A great deal of work, much of it, however, wholly or in part in stipple, was produced in this line in England at the end of the 18th and beginning of the 19th century.

The name which stands out at the period is that of William Blake (1757–1827), who, trained as a regular engraver, still executed his most characteristic and distinguished work in other mediums. The illustrations to the *Book of Job* and Young's *Night Thoughts,* wonderful as their conception is and worthy of Blake's genius, are carried out with much of the monotonous accomplishment of contemporary work, and lose, rather than gain, by the skill which Blake had acquired as a professional engraver. The popularity of Turner is reflected in the very numerous landscape engravings which were made by such engravers as W. B. and G. Cooke, John Pye, R. Brandard, E. Goodall and others, after his water colour drawings. They are usually in the form of illustrations and on a small scale, but engraving seems hardly suited to the rendering of the peculiar qualities of the great landscape painter, and, amazing as is the skill with which Turner's obviously untranslatable creations are interpreted, the dullness of entire efficiency engrosses them. This blight, and the beginning of the use of mechanical means such as machine ruling, lies over all the work produced in England, and indeed, in Europe and America, in the middle of the century. Merely reproductive as its purpose was, engraving obviously had no future in competition with the rapidly perfected photographic processes, and by the end of the century had died out almost completely.

Engraving of a less elaborate form, its technique deriving from that of the age of Dürer, had pursued its humble course almost uninterrupted through the 17th, 18th and 19th centuries in the hands of engravers of heraldic bookplates. Craftsmen like C. D. Sherborn (1831–1912) in England, did sound work in this field, and form a link which connects the recent revival of engraving since the World War within the great tradition. It is too early yet to speak of the permanence or importance of this movement, which, if partly archaistic in tendency, still derives its chief strength from the realization that the engraved line has a particular incisive beauty and character of its own, a character more circumscribed and more exacting than that which the etched line possesses. Engravers like Pieter Dupont (1870–1911) in Holland, who was perhaps the earliest rather isolated resuscitator of the medium, E. Laboureur in France, whose work in line, however, differs singularly little from his etched work, and in England younger men like Stephen Gooden, R. S. Austin and Job Nixon are doing work of originality and character. (*See* ENGRAVING.)

LINE GEOMETRY. In geometry, curves and other loci are frequently regarded as generated by a point, the position of which is defined by certain conditions. A straight line however may be thought of as the generating element, such as a tangent to a curve, or as a generator of a cone. That branch of geometry in which the line is regarded as the generating element is called line geometry.

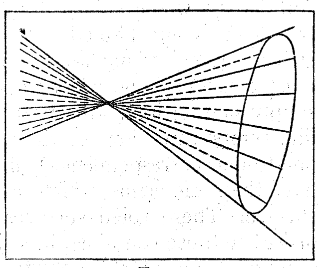

FIG. 1

A point in space is determined by its distances from three planes which intersect in one point (*i.e.*, by its *co-ordinates*), and a plane is defined by the totality of the points the co-ordinates of which satisfy a linear equation. The coefficients of the co-ordinates in the equation are called *plane co-ordinates*. A point and a plane are in united position when their co-ordinates satisfy a certain bi-linear equation (*i.e.*, linear in the co-ordinates of the point, and also linear in the co-ordinates of the plane). The principle of duality (*q.v.*) asserts that for every theorem involving points, obtained from properties of point co-ordinates, there is another involving planes, and conversely. These properties remain true if each point co-ordinate is replaced by any linear fractional homogeneous expression in four numbers x_1, x_2, x_3, x_4 with common denominator and non-vanishing determinant. The numbers x_i are called *projective point co-ordinates*. Similarly, u_1, u_2, u_3, u_4 may be taken as *projective plane co-ordinates*, and the condition for united position may be expressed by the equation $\Sigma\ u_i x_i = 0$.

In the plane, the projective co-ordinates, x_1, x_2, x_3, may be defined either as point co-ordinates or as line co-ordinates, thus giving rise to point-line duality in the plane. In space a straight line is self dual; it is uniquely determined by any two distinct points on it, or by any two distinct planes through it. The line itself may be regarded as an element; for many purposes in kinematics, in dynamics, and in optics this is more advantageous than to have it defined indirectly in terms of points or planes.

Line Co-ordinates.—Given two points $(x_1, x_2, x_3, x_4) = (x)$, $(y_1, y_2, y_3, y_4) = (y)$ on a line, the six expressions of the form $x_i y_k - x_k y_i$ are called its *homogeneous line co-ordinates* p_{ik}. Apart from a constant factor common to all, they are independent of what two distinct points are chosen. Among them there is a quadratic relation which is identically satisfied $P \equiv 0$. All the relations between two lines, such as distance, angle or condition for intersection, or any other relation, can be expressed in terms of their co-ordinates. A line meets two distinct planes each in one point, finite or infinite, and a point in each is determined when its two co-ordinates are fixed. Thus it follows that a line is determined by four independent co-ordinates, or there exist ∞^4 lines in space.

When the co-ordinates p_{ik} satisfy one equation, there are ∞^3 lines singled out, which constitute a *complex;* if they satisfy two such equations, the ∞^2 lines constitute a *congruence;* if they satisfy three, the ∞^3 lines belong to a *ruled surface;* if they satisfy four, there will be only a finite number of lines. The linear complex $\Sigma a_{ik} p_{ik} = 0$ can, by a proper choice of a system of co-ordinates, be reduced to the form $xy' - x'y + k(z - z') = 0$, in which x, y, z and x', y', z' are the cartesian co-ordinates of any two points on a line. If $k = 0$, the complex is special; it now consists of all the lines which meet the fixed line $x = 0$, $y = 0$, the *axis*. If k is not zero, the line $x = 0$, $y = 0$ is still called the axis but not all the lines of the complex meet it. The complex can be visualized in various ways. It is identical with the null system of mechanics, *i.e.*, the totality of those axes of rotation with regard to which a system of forces in space have a moment of rotation zero. In a linear complex there is, associated with every point P (pole) (*see* POLE AND POLAR) a plane π (polar) passing through it which contains a pencil of lines with vertex at P. Dually, the lines of a linear complex lying in a plane pass through a point called the pole of the plane. As P describes a line l, its polar plane as to a linear complex $A = 0$ describes a pencil with axis a line l'. Dually, every plane π' through l has a pole P' on l'. Two such lines l, l' are called *conjugate polars* as to $A = 0$. When l is a line of $A = 0$, $1 = l'$. Any line of $A = 0$ which meets l will also meet l' and every line which meets both l and l' is a line of $A = 0$. By this transformation a linear complex $B = 0$ is changed into a linear complex $B' = 0$. If A and B are in involution, $B = B'$. The six co-ordinate complexes $x_i = 0$ in the Klein system are mutually in involution.

A geometric picture can be obtained as follows: let a be the axis, and π any plane perpendicular to a. If the plane be moved parallel to itself, and rotated into itself about a, the translation and the tangent of the angle of rotation being in proportion, then every point P of π will describe a right circular helix. The lines of the complex are the normals to these ∞^2 helices.

The lines which belong to two linear complexes $A = 0$, $B = 0$ belong to every complex of the system $\lambda\ A + \mu B = 0$ for every value of λ and μ. Within this system are two special complexes $A' = 0$, $B' = 0$, and the linear congruence may be defined as the ∞^2 lines which meet two given lines, called the directrices of the congruence. They may be distinct, coincident or imaginary. When they are coincident, the congruence consists of ∞^1 pencils of lines with vertices P on the directrix d, and lying in planes π through d, such that P, π are projectively related.

Two complexes $A = 0$, $B = 0$ are in involution when on every line p of the complex, the poles of an arbitrary plane through p in $A = 0$, $B = 0$ are harmonic (*i.e.*, with cross ratio $= -1$; *see* PROJECTIVE GEOMETRY: *Cross-Ratio*) as to the intersections of p with the axes of the two special complexes $A' = 0$, $B' = 0$ in the system.

The lines which belong to three linear complexes $A = 0$, $B = 0$, $C = 0$ constitute the ∞^1 lines of a regulus, *i.e.*, one system of generators of a quadratic surface; if they are real, they form a hyperboloid of one sheet, or a hyperbolic paraboloid. These lines also belong to every linear complex of the form $\lambda A + \mu B + \nu C = 0$. The other system of generators belongs to three independent linear complexes, each of which is in involution with $A = 0$, $B = 0$, $C = 0$.

The lines belonging to four linear complexes are the two transversals of the axes of the four independent special linear complexes contained in the system. They may be distinct, co-incident or imaginary. These ideas had been recognized in part by various writers, but they were first put into systematic form in terms of co-ordinates by Arthur Cayley in 1860. The results attracted the attention of several mathematicians, in particular of Julius Plücker, who soon contributed a number of notes leading to their further development. Eight years later appeared the first part of Plücker's book on line geometry.

By means of a simple transformation of the line co-ordinates p_{ik}, the quadratic identity $P \equiv 0$ can be reduced to the sum of six squares, $\Sigma x_i^2 = 0$. These x_i are called *Klein co-ordinates;* they furnish one of the most striking examples in mathematics of the power and the ease of obtaining results in consequence of a proper notation.

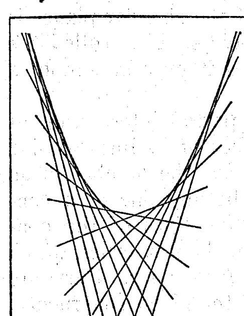

FIG. 2

The Line-sphere Transformation.—The p_{ik} or the x_i can also be interpreted as the co-ordinates of a sphere, since the co-ordinates of the centre and the length of the radius furnish four independent quantities which determine a sphere. By making the co-ordinates homogeneous, and by expressing the length of the radius in terms of the coefficients in the equation of the sphere, the quadratic identity appears. Two lines which intersect are thus transformed into two spheres which touch each other. The points of space (spheres of zero radius) are the images of the lines of a certain complex; the planes of space (spheres whose radii become infinite) are the images of the lines of a certain special linear complex. A linear equation in sphere co-ordinates (linear complex of spheres) defines the ∞^3 spheres which cut a fixed sphere at a constant angle.

The line-sphere transformation together with its projective generalizations, is a powerful weapon in the study of certain curves and ruled surfaces. Thus, all the sextic ruled surfaces (120 types) and those of order seven having a straight line directrix (about 300 types) have been determined by this method.

Mapping on Hyperspace.—If the p_{ik} (or the x_i) are thought of as homogeneous point co-ordinates in space of five dimensions, the quadratic identity $P=0$ becomes the equation of a quadric variety, hence line geometry may be interpreted as the geometry on a quadric variety in five-way space. A linear complex is then the section of the quadric by a linear four-way space, and hence it defines a three-dimensional quadratic variety in space of four dimensions. By stereographic projection this can be mapped on the points of three-way space, hence there is a one-to-one correspondence between the points of ordinary space and the lines of any linear complex.

The Cylindroid.—The axes of the complexes of a pencil describe a ruled cubic surface, the cylindroid, which is of value in the application of line geometry to dynamics, as is shown in the treatise of Ball. It may be generated as follows: Given a line d, and on it two points P, P'. Through P draw any line p perpendicular to d, and through P' draw a line p' perpendicular to d and to p. Now as a variable point G moves along d from P to P', associate with it a line g always passing through G, perpendicular to d, and such that the distance from P is proportional to the cosine of double the angle that g makes with the plane d, p. At P, g coincides with p, at P', g coincides with p' and when G is in the middle of the segment PP', g makes an angle of 45° with the plane d, p. Then think of a second line g' doing the same thing, but winding in the other direction. The line d is a double line on the resulting surface. The planes containing the pairs of intersecting lines g, g' are all parallel to a fixed plane; they intersect in an ideal line d' which also lies on the surface.

By taking d for the z axis, $x-y=0$, $z=h$ for p, $x+y=0$, $z=-h$ for p', the equation has the form

$$z(x^2+y^2)=2hxy.$$

Every ruled cubic with two distinct directrix lines can be projected into this form.

The General Complex.—An algebraic equation homogeneous and of order n in p_{ik}, together with the identity $P=0$ defines a complex of order n. By holding one point (y) fixed, the points (x) which satisfy the equation all lie on a cone of order n, having (y) as vertex. Similarly, the lines of the complex which lie in a fixed plane all touch a curve of class n. For an arbitrary point, the complex cone has no multiple or cuspidal generators, and in an arbitrary plane the complex curve has no double or inflexional tangents. A point (y) which is the vertex of a cone having a double generator is called a *singular point*. The locus of the singular points is a surface. Similarly, the plane (u) which contains a complex curve with a double or inflexional tangent is called a *singular plane*. The envelope of the singular planes is identical with the locus of the singular points. It is called the *surface of singularities;* in particular cases it may be simply a curve.

A congruence may be the complete or partial intersection of two complexes. If it is algebraic the number of its lines passing through an arbitrary point is called its *order*, the number in an arbitrary plane is called its *class*. Let p be any line of a congruence, the distance from p to consecutive lines of the congruence is a certain differential expression of the first order, which vanishes to the third order for two points P, P' on p. These are called *foci*, and their locus, as p describes the given congruence, is the *focal surface*, to which p is a bitangent. P and P' may describe the same surface, or different surfaces, or either or both may describe a curve. In the last case the congruence consists of the lines which intersect both curves. Congruences of lines are of particular importance in differential geometry (*q.v.*), both metric and projective, *e.g.*, that formed as lines of curvature, asymptotic lines, etc., and that formed by the tangents to one parameter systems of curves on a surface, as by the normals to a surface. They are also of importance in optics.

The complete or partial intersection of three complexes is a *ruled surface*. The number of its lines which meet a given line is its *order*, which is also its *class*. For every order greater than two, a con-conical ruled surface must have one or more double curves. Every plane section is either proper or, if composite, must consist of one proper curve and of straight lines, counted simply or multiply. All the plane sections, apart from straight-line components, are birationally equivalent (their points are in one-to-one correspondence), hence if the surface is algebraic all have the same genus, which may be called the genus of the ruled surface. These ruled surfaces of maximum gênus for a given order are those contained in a linear congruence. If all the generators of a ruled surface are tangents to a curve C, the surface is called a *developable surface*. Then C appears on the surface as a cuspidal curve. The surface also contains double curves, if the order of the curve C is greater than 3.

Every generator of a non-developable ruled surface of order n meets $n-2$ other generators.

The Quadratic Complex.—If $\phi=0$ is the equation of the complex of order 2, then the lines belonging to it satisfy the equation $\phi+\lambda P=0$ for every value of λ. When the discriminant of this form has six distinct roots λ_i, the equation can be reduced to $\phi=\Sigma\lambda_i x_i^2=0$ when $P=\Sigma x_i^2=0$. The surface of singularities is in this case the most general Kummer surface of order and class 4, with 16 double points and 16 singular planes, *i.e.*, planes which touch the surface at every point of a conic. Each conic passes through six double points, and each double point lies on six such conics. The same surface is also a complete focal surface for six congruences of order and class 2, namely those defined by $\phi=0$, $x_i=0$ $(i=1, 2, \ldots, 6)$.

The surface is invariant under the operation of interchanging the points of contact of the lines of each congruence; these generate a finite group of order 32, of which 16 are harmonic homologies, and 16 are involutorial correlations. For particular forms of ϕ, corresponding particularities exist in the Kummer surface. Thus, if $\phi=\Sigma a_{ik}p^2_{ik}=0$, the complex consists of lines which intersect two given quadrics harmonically. The surface of singularities is now the tetrahedroid. The six nodes on each conic are in involution. It is a projective generalization of the wave surface of Fresnel. This complex is known as Battaglini's complex. Another particularization is that in which the λ-discriminant is a square and each λ_i makes every first minor vanish. The complex consists of the lines which meet the faces of a fixed tetrahedron in projective tetrads. The surface of singularities consists of the faces of the tetrahedron. This complex is called the *tetrahedral complex*. The first systematic study of the quadratic complex was made by Battaglini, who assumed, erroneously, that the most general one could be expressed as a linear function of the squares of the p_{ik}.

The correction of this error led to the complete classification according to the form of the λ-discriminant, thus affording one of the early applications to the theory of elementary divisors. The Kummer surface also furnished one of the first illustrations of a surface which remains invariant under an infinite number of distinct birational transformations, but this property is shared by the focal surface of many other congruences. Line geometry shows close connection among various branches of mathematics.

This important report of about 250 pages cites over 1,500 titles, practically all the bibliography, and brings the development of the subject down to the time at which it was written. (V. Sn.)

LINEN AND LINEN MANUFACTURES. Under the name of linen are included all the yarns spun and fabrics woven from flax fibre. (*See* Flax.)

From the earliest periods of human history till almost the close of the 18th century linen manufacture was one of the most extensive and widely disseminated of the domestic industries of European countries. The industry was most largely developed in Russia, Austria, Germany, Holland, Belgium, the northern provinces of France, and certain parts of England, in the north of Ireland, and throughout Scotland; and in these countries its importance was generally recognized by the enactment of special laws, having for their object the protection and extension of the trade. The inventions of Arkwright, Hargreaves and Crompton in the later part of the 18th century, benefiting almost exclusively the art of cotton-spinning, and the unparalleled development of that branch of textile manufactures, largely due to the ingenuity of these inventors, gave the linen trade as it then existed a fatal blow. Domestic spinning, and with it hand-loom weaving, immediately began to shrink; the trade which had supported whole villages and provinces entirely disappeared, and the linen manufacture, in attenuated dimensions and changed conditions, took refuge in special localities, where it resisted, not unsuccessfully, the further assaults of cotton, and, with varying fortunes, rearranged its relations in the community of textile industries. The linen industries of the United Kingdom were the first to suffer from the aggression of cotton; more slowly the influence of the rival textile reached other countries.

In 1810 Napoleon I. offered a reward of 1,000,000 francs to any inventor who should devise the best machinery for the spinning of flax yarn. Within a few weeks thereafter Philippe de Girard patented in France important inventions for flax spinning by both dry and wet methods. His inventions, however, did not receive the promised reward and were neglected in his native country. In 1815 he was invited by the Austrian Government to establish a spinning mill at Hirtenberg, near Vienna, which was run with his machinery for a number of years, but it failed to prove a commercial success. In the meantime English inventors had applied themselves to the task of adapting machines to the preparation and spinning of flax. The foundation of machine spinning of flax was laid by John Kendrew and Thomas Porthouse, of Darlington, who, in 1787, secured a patent for "a mill or machine upon new principles for spinning yarn from hemp, tow, flax or wool." By innumerable successive improvements and modifications, the invention of Kendrew and Porthouse developed into the perfect system of machinery with which, at the present day, spinning-mills are furnished; but progress in adapting flax fibres for mechanical spinning, and linen yarn for weaving cloth by power-loom was much slower than in the corresponding case of cotton.

Modern Methods of Manufacture.—The modern manufacture of linen divides itself into two branches, spinning and weaving, to which may be added the bleaching and various finishing processes, which, in the case of many linen textures, are laborious undertakings and important branches of industry. The flax fibre is received in bundles from the scutch mill, and, after having been classed into various grades according to the quality of the material, is labelled and placed in the store ready for the flax mill. The whole operations in yarn manufacture comprise (1) hackling, (2) preparing, and (3) spinning. For commoner types of yarn, a process known as carding replaces that of hackling.

Hackling.—This first preparatory process consists not only in combing out, disentangling and laying smooth and parallel the separate fibres, but also serves to split up and separate the strands of fibre which, up to this point, have been agglutinated together. The hackling process was originally performed by hand, and it was one of fundamental importance, requiring the exercise of much dexterity and judgment. The broken, ravelled and short fibres, which separate out in the hackling process, form tow, an article of inferior value to the spinner. A good deal of hand-hackling is still practised, especially in Irish and continental mills; and it has not been found practicable, in any case, to dispense entirely with a rough preparation of the fibre by hand labour. In hackling by hand, the hackler takes a handful or "strick" of rough flax, winds the top end around his hands, and then, spreading out the root end as broad and flat as possible, by a swinging motion dashes the fibre into the hackle teeth or needles of the rougher or "ruffer." The rougher is a board plated with tin and studded with spikes or teeth of steel about 7in. in length, which taper to a fine sharp point. The hackler draws his strick several times through this tool, working gradually up from the roots to near his hand, till in his judgment the fibres at the root end are sufficiently combed out and smoothed. He then seizes the root end and similarly treats the top end of the strick. The same process is again repeated on a similar tool, the teeth of which are 5in. long and much more closely studded together, and for the finer counts of yarn a third and a fourth tool may be used, of still increasing fineness and closeness of teeth. In dealing with certain varieties of the fibre, for fine spinning especially, the flax is, after roughing, broken or cut into three lengths—the top, middle and root ends. Of these the middle cut is most valuable, being uniform in length, strength and quality. The root end is more woody and harsh, while the top, though fine in quality, is uneven and variable in strength. From some flax of extra length it is possible to take two short middle cuts; and, again, the fibre is occasionally only broken into two cuts. Flax so prepared is known as "cut line," in contradistinction to "long line" flax which is the fibre unbroken. The subsequent treatment of line, whether long or cut, does not present sufficient variation to require further reference to these distinctions.

In the case of hackling by machinery, the flax is first roughed and arranged in stricks, as above described under hand hackling. In the construction of hackling machines, the general principles of those now most commonly adopted are identical. The machines are known as vertical sheet hackling machines, their essential features being a set of endless leather bands or sheets revolving over a pair of rollers in a vertical direction. These sheets are crossed by iron bars, to which hackle stocks, furnished with teeth, are screwed. The hackle stocks on each separate sheet are of one size and gauge, but each successive sheet in the length of the machine is furnished with stocks of increasing fineness, so that the hackling tool at the end where the flax is entered is the coarsest, say about four pins per inch, whereas that to which the fibre is last submitted has the smallest and most closely set teeth. The finest tools may contain from 45 to 60 pins per inch. Thus the whole of the endless vertical revolving sheet presents continuous series of hackle teeth, and the machines are furnished with a double set of such sheets revolving face to face, so close together that the pins of one set of sheets intersect those on the opposite stocks. Overhead, and exactly centred between these revolving sheets, is the head or holder channel, from which the flax hangs down while it is undergoing the hackling process on both sides. The flax is fastened in a holder consisting of two heavy flat plates of iron, between which it is spread and tightly screwed up. The holder is 11in. in length, and the holder channel is fitted to contain a line of six, eight or 12 such holders, according to the number of separate bands of hackling stocks in the machine. The head or holder channel has a falling and rising motion, by which it first presents the ends and gradually more and more of the length of the fibre to the hackle teeth, and, after dipping down the full length of the fibre exposed, it slowly rises and lifts the flax clear of the hackle stocks. By a reciprocal motion all the holders are then moved forward one length; that at the last and finest set of stocks is thrown out, and place is made for filling in an additional holder at the beginning of the series. Thus with a six-tool hackle, or set of stocks, each holder full of flax from beginning to end descends into, and rises from, the hackle teeth six times in travelling from end to end of the machine. The root ends being thus first hackled, the holders are shot back along an inclined plane, the iron plates unclamped, the flax reversed, and the top ends are then submitted to the same hackling operation. The tow made during the hackling process is carried down by the pins of the sheet, and is stripped from them by means of a circular brush placed immediately under the bottom roller. The brush revolves in the same direction as, but quicker than the sheet, consequently the tow is withdrawn from the pins. The tow is then removed from the brush by a doffer roller, from which it is finally removed by a doffing knife. This material is then carded by a machine similar to, but finer than, the one described under JUTE (*q.v.*). The hackled flax, however, is taken direct to the preparing department. In the machine just described the work is usually performed by four operatives, who feed in the holders, remove them at the opposite end, and change the stricks of flax—end for end—in the holders. The automatic hackling machine does all this work except that of the first feed. The holders are removed, the nuts unscrewed, the flax turned, the nuts screwed tight and the furnished folder replaced in the machine by ingenious mechanism. Further, in some machines, the hackled stricks are mechanically fed into the spread-board—a type of drawing frame.

Preparing.—The various operations in this stage have for their object the proper assortment of dressed line into qualities fit for spinning, and the drawing out of the fibres to a perfectly level and uniform continuous ribbon or sliver, containing throughout an equal quantity of fibre in any given length. From the hackling the now smooth, glossy and clean stricks are taken to the sorting room, where they are assorted into different qualities by the "line sorter," who judges by both eye and touch the quality and capabilities of the fibre. So sorted, the material is passed to the spreading and drawing frames, a series or system of machines all similar in construction and effect. The essential features of the spreading frame are: (1) the feeding cloth or creeping sheet, which delivers the flax to (2) a pair of "feed and jockey" rollers, which pass it on to (3) the gill frame or fallers. The gill frame consists of a series of narrow hackle bars, with short closely studded teeth, which travel between the feed or retaining rollers and the drawing or "boss and pressing" rollers to be immediately attended to. The fallers are moved forward, at a slightly greater speed than that of the retaining rollers, by means of spiral screws, and the flax fibres are drawn out or attenuated by the drawing rollers; meanwhile the fibres are straightened between the gill pins of the fallers. When the fallers successively approach within a short distance of the drawing rollers, they are pushed downwards into a lower plane to be carried backwards by a similar but coarser spiral screw to a point near the retaining roller, when they are pushed upwards to repeat the cycle. They thus form a field of pins or an endless moving level toothed platform for carrying away the flax from the feed rollers. This is the machine in which the fibres are, for the first time, formed into a continuous length termed a sliver. In order to form this continuous sliver, it is necessary that the short lengths of flax should overlap each other on the spread sheet or creeping sheet. This sheet contains four or six divisions, so that four or six lots of overlapped flax are moving at the same time towards the first pair of rollers—the boss rollers or retaining rollers. The fibre passes between these rollers and is immediately caught by the rising gill pins which carry the fibre towards the drawing rollers. The pins of the gills should pass through the fibre so that they may have complete control over it. The fibre is thus carried forward to the drawing rollers, which have a surface speed of from ten to 30 times that of the retaining rollers. The great difference between the speeds of the retaining and drawing rollers results in each sliver being drawn out to a corresponding degree. Finally all the slivers are run into one and in this state are passed between the delivery rollers into the sliver cans. Each can should contain the same length of sliver, a common length being 1,000yd. A bell is automatically rung by the machine to warn the attendant that the desired length has been deposited into the can. From the spreading frame the cans of sliver pass to the drawing frames, where from four to 12 slivers combined are passed through feed rollers over gills, and drawn out by drawing rollers to the thickness of one. A third and fourth similar doubling and drawing may be embraced in a preparing system, so that the number of doublings the flax undergoes, before it arrives at the roving frame, may amount to from 1,000 to 100,000, according to the quality of yarn in progress. Thus, for example, the doublings on one preparing system may be $6 \times 12 \times 12 \times 12 \times 8 = 82{,}944$. The slivers delivered by the last drawing frame are taken to the roving frame, where they are passed singly through feed rollers and over gills, and, after drafting to sufficient tenuity, they are slightly twisted by flyers and wound on bobbins, in which condition the material—termed "rove" or "rovings"—is ready for the spinning frame.

The preparation of tow for spinning differs in essential features from the processes above described. Tow from different sources, such as scutching tow, hackle tow, etc., differs considerably in quality and value, some being very impure, filled with woody shives, etc., whereas other kinds are comparatively open and clean. A preliminary opening and cleaning is necessary for the dirty, much-matted tows, and in general thereafter they are passed through two carding engines called respectively the breaker and the finisher cards till the slivers from their processes are ready for the drawing and roving frames. In the case of fine clean tows, on the other hand, passing through a single carding engine may be sufficient. The processes which follow the carding do not differ materially from those followed in the preparation of rove from line flax.

Spinning.—The spinning operation, which follows the roving, is done in two principal ways, called respectively dry spinning and wet spinning; the first being used for the lower counts or heavier yarns, while the second is exclusively adopted in the preparation of fine yarns. There is also a demi-sec method of spinning employed in some mills. The spinning frame does not differ in principle from the throstle spinning machine used in cotton manufacture. The bobbins of flax rove are arranged in rows on each side of the frame (the spinning frames being all double) on pins in an inclined plane. The rove passes downwards through an eyelet or guide to a pair of nipping or retaining rollers between which and the final drawing rollers, placed in the case of dry spinning from 18in. to 22in. lower down, the fibre receives its final draft while passing over and under cylinders and guide-plate, and attains that degree of tenuity which the finished yarn must possess. From the last rollers the now attenuated material, in passing to the flyers, receives the degree of twist which compacts the fibres into the round hard cord which constitutes spun yarn; and from the flyers it is wound on the more slowly rotating spool within the flyer arms, centred on the top of the spindle. The amount of twist given to the thread at the spinning frame varies from 1·5 to 2 times the square root of the count. In wet spinning the general sequence of operations is the same, but the rove, as unwound from its bobbin, first passes through a trough of water heated to about 150° F.; and the interval between the two pairs of rollers in which the drawing out of the rove is accomplished is very much shorter. The influence of the hot water on the flax fibre appears to be that it softens the gummy substance which binds the ultimate fibres together, and thereby allows these fibres to a certain extent to be drawn out without breaking the continuity of the fibre; and further it makes a finer, smoother and more uniform strand than can be obtained by dry spinning. The extent to which the original strick of flax as laid on the feeding roller for (say) the production of a 50 lea yarn is by doublings and drawings extended, when it reaches the spinning spindle, may be stated thus: 35 times on spreading frame, 15 times on first drawing frame, 15 times on second drawing frame, 14 times on third drawing frame, 15 times on roving frame and 10 times on spinning frame, in all 16,537,500 times its original length, with $8 \times 12 \times 16 = 1{,}536$ doublings on the three drawing frames. That is to say, 1yd. of hackled line fed into the spreading frame is spread out, mixed with other fibres, to a length of about 9,400m. of yarn, when the above drafts obtain. The drafts are much shorter for the majority of yarns.

The next operation is reeling from the bobbins into hanks. By act of parliament, throughout the United Kingdom the standard measure of flax yard is the "lea," called also in Scotland the "cut" of 300 yards. The flax is wound or reeled on a reel having a circumference of 90in. ($2\frac{1}{2}$yd.) making "a thread," and 120 such threads form a lea. The grist or count of all fine yarns is estimated by the number of leas in 1lb.; thus "50 lea" indicates that there are 50 leas or cuts of 300yd. each in 1 lb. of the yarn so denominated. With the heavier yarns in Scotland the quality is indicated by their weight per "spyndle" of 48 cuts or leas; thus "3 lb. tow yarn" is such as weighs 3 lb. per spyndle, equivalent to "16 lea," because jute count $\times$ lea count $= 48 \therefore \frac{48}{16}$ lea $= 3$ lb. per spyndle.

The hanks of yarn from wet spinning are either dried in a loft with artificial heat in one of the many modern hank-drying machines or exposed over ropes in the open air. When dry they are twisted back and forward to take the wiry feeling out of the yarn, and made up in bundles for the market as "grey yarn." English spinners make up their yarns into "bundles" of 20 hanks, each hank containing 10 leas; Irish spinners make hanks of 12 leas, $16\frac{2}{3}$ of which form a bundle; Scottish manufacturers adhere to the spyndle containing 4 hanks of 12 cuts or leas.

Commercial qualities of yarn range from about 6 lb. tow yarns (8 lea) up to 160 lea line yarn. Very much finer yarn up even to 400 lea may be spun from the system of machines found in many mills; but these higher counts are only used for fine thread for sewing and for the making of lace. The highest counts of cut line flax are spun in Irish mills for the manufacture of fine cambrics and lawns which are characteristic features of the Ulster trade. Exceedingly high counts have sometimes been spun by hand, and for the preparation of the finest lace threads it is said the Belgian hand spinners must work in damp cellars, where the spinner is guided by the sense of touch alone, the filament being too fine to be seen by the eye. Such lace yarn is said to have been sold for as much as £240 per pound. In the Great Exhibition of 1851, yarn of 760 lea, equal to about 130m. per lb. was shown which had been spun by an Irish woman 84 years of age. In the same exhibition there was shown by a Cambray manufacturing firm hand-spun yarn equal to 1,200 warp and 1,600 weft or to more than 204 and 272m. per lb. respectively.

Bleaching.—A large proportion of the linen yarn of commerce undergoes a more or less thorough bleaching before it is handed over to the weaver. Linen yarns in the green condition contain such a large proportion of gummy and resinous matter, removable by bleaching, or by benzine previous to bleaching, that cloths which might present a firm close texture in their natural unbleached state would become thin and impoverished in a perfectly bleached condition. Nevertheless, in many cases it is much more satisfactory to weave the yarns in the green or natural colour, and to perform all bleaching operations in the piece. Many manufacturers allow about 20 to 25% of loss in weight of yarn in bleaching from the green to the fully bleached stage, but some bleachers can obtain the desired degree of whiteness with a much lower percentage of loss; and the intermediate stages of boiled, improved, duck, cream, half bleach and three-quarters bleach, all indicating a certain degree of bleaching, have corresponding degrees of loss in weight. The differences in colour resulting from different degrees of bleaching are taken advantage of for producing patterns in certain classes of linen fabrics.

Linen thread is prepared from the various counts of fine bleached line yarn by winding the hanks on large spools, and twisting the various strands, two, three, four or six cord, as the case may be, on a doubling spindle similar in principle to the yarn spinning frame, excepting, of course, the drawing rollers. A large trade in linen thread has been created by its use in the machine manufacture of boots and shoes, saddlery and other leather goods, and in heavy sewing-machine work generally. The thread industry is largely developed at Lisburn, near Belfast, at Johnstone, near Glasgow, Bridport, Dorsetshire, and at Paterson, N.J., United States. Fine cords, net twine and ropes are also twisted from flax.

Weaving.—The difficulties in the way of power-loom linen weaving, combined with the obstinate competition of hand-loom weavers, delayed the introduction of factory weaving of linen fabrics for many years after the system was fully applied to other textiles. The principal difficulty arose through the hardness and inelasticity of the linen yarns, owing to which the yarn frequently broke under the tension to which it was subjected. Competition with the hand-loom against the power-loom in certain classes of work is conceivable, although it is absolutely impossible for the work of the spinning wheel to stand against the rivalry of drawing, roving and spinning frames. To the present day, in Ireland especially, a great deal of fine weaving is done by hand-loom. Warden states that power was applied on a small scale to the weaving of canvas in London about 1812; that in 1821 power-looms were started for weaving linen at Kirkcaldy, Scotland; and that in 1824 Maberly and Company, of Aberdeen, had two hundred power-looms erected for linen manufacture. The power-loom has been in uninterrupted use in the Broadford factory, Aberdeen, which then belonged to Maberly and Company, down to the present day, and that firm may be credited with being the effective introducers of power-loom weaving in the linen trade.

The various operations connected with linen weaving, such as winding, warping, dressing, beaming and drawing-in, do not differ in essential features from the like processes in the case of cotton weaving, etc., neither is there any significant modification in the looms employed. (*See* WEAVING.) Dressing is a matter of importance in the preparation of linen warps for beaming. It consists in treating the spread yarn with flour or farina paste, applied to it by flannel-covered rollers, the lowermost of which revolves in a trough of paste. The paste is equalized on the yarn by brushes, and dried by passing the web over steam-heated cylinders before it is finally wound on the beam for weaving.

Fabrics.—Linen fabrics are numerous in variety and widely different in their qualities, appearance and applications, ranging from heavy sail-cloth and rough sacking to the most delicate cambrics, lawns and scrims. The heavier manufactures include as a principal item sail-cloth, with canvas, tarpaulin, sacking and carpeting. The principal seats of the manufacture of these linens are Dundee, Arbroath, Forfar, Kirkcaldy, Aberdeen and Barnsley. The medium weight linens, which are used for a great variety of purposes, such as tent-making, towelling, covers, outer garments for men, linings, upholstery work, etc., include duck, huckaback, crash, tick, dowlas, osnaburg, low sheetings and low brown linens. Plain bleached linens form a class by themselves, and include principally the materials for shirts and collars and for bed sheets. Under the head of twilled linens are included drills, diapers and dimity for household use; and damasks for table linen, of which two kinds are distinguished—so-called single or five-leaf damask, and double or eight-leaf damask, the pattern being formed by the intersection of warp and weft yarns at intervals of five and eight threads of yarn respectively. The fine linens are cambrics, lawns and handkerchiefs; and lastly, printed and dyed linen fabrics may be assigned to a special though not important class. In a general way it may be said regarding the British industry that the heavy linen trade centres in Dundee and the adjoining counties; medium goods are made in most linen manufacturing districts; damasks are chiefly produced in Belfast, Dunfermline and Perth; and the fine linen manufactures have their seat in Belfast and the north of Ireland. Leeds and Barnsley are the centres of the linen trade in England.

Linen fabrics have several advantages over cotton, resulting principally from the microscopic structure and length of the flax fibre. The cloth is much smoother and more lustrous than cotton cloth; and, presenting a less "woolly" surface, it does not soil so readily, nor absorb and retain moisture so freely, as the more spongy cotton; and it is at once a cool, clean and healthful material for bed-sheeting and clothing. Bleached linen, starched and dressed, possesses that unequalled purity, gloss and smoothness which make it alone the material suitable for shirt-fronts, collars and wristbands; and the gossamer delicacy, yet strength, of the thread it may be spun into fits it for the fine lace-making to which it is devoted. Flax is a slightly heavier material than cotton, while its strength is about double.

LINENFOLD, a panel decoration of the late Gothic period common in north Europe and England, especially used in woodwork, for wainscots, screens, chests, etc., and consisting of a representation of folded or pleated cloth or parchment, with the folds vertical. Certain 14th century French woodwork already shows panels thickened at the centre, with concave surfaces at each side; this thickness is terminated at top and bottom by curved lines. An additional scrolling or pleating of the surface developed this simple type into the elaborate linenfold decoration of the following century. Linenfold panels are especially common in the flamboyant work of France and in late Gothic in Flanders; it is probably through Flemish influence that they were introduced into England.

LINEN-PRESS, a contrivance, usually of oak, for pressing sheets, table-napkins and other linen articles, resembling a modern office copying-press. Linen-presses were made chiefly in the 17th and 18th centuries, and are now chiefly interesting as curiosities of antique furniture.

LINER, a colloquial term used to describe large ocean-going passenger ships. (*See* SHIP.)

LING, PER HENRIK (1776–1839), Swedish medical-gymnastic practitioner, was born at Ljuna. After taking his degree in divinity in 1797 he travelled abroad, earning a precarious living by teaching. In 1804 he returned to Sweden and became teacher of fencing at the University of Lund. He then took the medical course and elaborated a system of gymnastics, divided into four branches: (1) pedagogical, (2) medical, (3) military, (4) aesthetic. In 1813 Ling became principal of the Royal Gymnastic Central Institute opened in Stockholm for the training of gymnastic instructors. In recognition of his introduction of gymnastics for therapeutic purposes, popularly known as the "movement cure" or Swedish massage, the Swedish General Medical Association elected him a member in 1831. Ling's collected works (*Samlade Arbeten*) were published in 3 vols. (1859–65).

LING (*Molva molva*), a food fish of the cod family, elongate in form, with terminal mouth, strong canines in the lower jaw, a short first dorsal fin, a long second dorsal and anal, and a rounded caudal.

It is a deep-water fish, ranging from Iceland and northern Europe to the Bay of Biscay; it is piscivorous, and reaches a length of 7 feet.

LING: *see* ERICACEAE; HEATH.

LINGARD, JOHN (1771–1851), English historian, was born on Feb. 5, 1771 at Winchester. Educated at the English college at Douai, where he spent some time as tutor in the family of Lord Stourton, in Oct. 1794 he settled along with seven other former members of the old Douai college at Crook hall near Durham, where on the completion of his theological course he became vice-president of the reorganized seminary. In 1795 he was ordained priest, and soon afterwards undertook the charge of the chairs of natural and moral philosophy. In 1808 he accompanied the community of Crook hall to the new college at Ushaw, Durham, but in 1811, after declining the presidency of the college at Maynooth, he withdrew to the secluded mission at Hornby in Lancashire, where for the rest of his life he devoted himself to literary pursuits. In 1817 he visited Rome, where he made researches in the Vatican Library. In 1821 Pope Pius VII. created him doctor of divinity and of canon and civil law; and in 1825 Leo XII. is said to have made him cardinal *in petto*. He died at Hornby on July 17, 1851.

Lingard wrote *The Antiquities of the Anglo-Saxon Church* (1806), of which a third and greatly enlarged edition appeared in 1845 under the title *The History and Antiquities of the Anglo-Saxon Church; containing an account of its origin, government, doctrines, worship, revenues, and clerical and monastic institutions;* but the work with which his name is chiefly associated is *A History of England, from the first invasion by the Romans to the Commencement of the reign of William III.* (8 vols., 1819–30).

See the notice by Tierney prefixed to vol. x. of the 6th ed. of the *History* (1854–55); and M. Haile and E. Binney, *Life and Letters of John Lingard* (1911).

LINGAYATS. An independent Saiva sect, or, indeed, the only strictly Saiva sect, are the *Vīra Saivas,* more commonly called *Lingayats* (popularly Lingaits) or *Lingavats,* from their practice of wearing on their person a phallic emblem of Siva, made of copper or silver, and usually enclosed in a case suspended from the neck by a string. Apparently from the movable nature of their badge, their *Gurus* are called *Jangamas* ("movable"). This sect counts numerous adherents in southern India. The reputed founder, or rather reformer, of the sect was Basava (or Basaba), a Brahmin of the Belgaum district who seems to have lived in the 11th or 12th century. According to the Basava-purana he early in life renounced his caste and went to reside at Kalyana, then the capital of the Chalukya kingdom, and later on at Sangamesvara near Ratnagiri, where he was initiated into the Vīra Saiva faith which he subsequently made it his life's work to propagate. His doctrine, a kind of reaction against the severe sacerdotalism of Sankara, has spread over all classes of the southern community, most of the priests of Saiva temples there being adherents of it; whilst in northern India its votaries are only occasionally met with, and then mostly as mendicants, leading about a neatly caparisoned bull as representing Siva's sacred bull *Nandi.*

LINGAYEN, a municipality (with administrative centre and 23 *barrios* or districts) and capital of the province of Pangasinan, Luzon, Philippine islands, about 110 mi. N. by W. of Manila, on the south shore of the Gulf of Lingayen, and on a low and fertile island in the delta of the Agno river. Pop. (1939) 30,655. Palay (rice) is the principal crop. Fishing is also a leading industry, and wine is made from the nipa palm. The Pangasinan language is the vernacular. Of the inhabitants between the ages of 6 to 19 inclusive, 44·5% in 1939 attended school. Of the population 10 years old and over, 56·4% was reported as literate. Lingayen was a principal landing point for Japanese troops in their drive southward to Manila in Dec. 1941.

LINGEH, a port of Persia on the shores of the Persian gulf in 26° 33′ N., 54° 53′ E., about 300 m. S.E. of Bushire; with the tract immediately around it, it forms part of the administrative district of the "Gulf Ports." The old port was at Kung, seven m. E. where the Portuguese had a "factory" and exercised political and commercial influence long after the loss of Hormuz (*q.v.*) until 1711. During the reign of the Zand dynasty, Lingeh was seized by Arabs from Ras-al-Khaimah who retained possession till 1887 when the Persian Government reestablished their authority. The population is estimated at 8,000 during the summer rising to 12,000 after the return of the pearling fleet in winter. The town, comparatively well built and of pleasing appearance from the sea, extends for about a mile along the shore but, with the exception of an extensive belt of date palms, the surroundings are extraordinarily arid and the hills at the back of the town, which rise to 1,200 metres, render communications with Lar and the hinterland difficult. There is no harbour for larger vessels and the anchorage is about three-quarters of a mile off-shore in 5 fathoms. Lingeh has a good reputation for boat-building and repairing. At one time it rivalled Bahrein as a centre for the collection and export of pearls; but the headquarters of the trade is now on the Arabian coast. The tonnage of trade in 1925–26 was 14,906, then showing an upward tendency, and the number of steam-vessels calling was 96, of which 90 were British. Exports were fresh and dried fruits, carpets, skins, flax, tobacco, gum and assafoetida, chiefly to India. Steamers of the British India Steam Navigation Company call fortnightly in each direction. There is a wireless station which communicates with the rest of the world through Henjam.

(2 vols., 1892); *The Persian Gulf Pilot* (published by the Admiralty, Hydrographic Dept., 7th ed. 1924). (P. Z. C.)

LINGEN, town in the Prussian province of Hanover, Germany on the Ems canal, 43 mi. N.N.W. of Münster. Pop. (1939) 13,987. It has manufactures of paper, sausages and a trade in cattle. Among its other industries are weaving and ore mining. Lingen was the seat of a university from 1685 to 1819. The county of Lingen in 1508 was divided into an upper and a lower county, but the two were united in 1541. A little later Lingen was sold to the emperor Charles V., and passed in 1597 to Maurice, prince of Orange. After the death of the English king, William III., in 1702, it passed to the king of Prussia, and in 1815 the lower county was transferred to Hanover, only to be united again with

Prussia in 1866.

LINGUA FRANCA, a term used in different parts of the world of languages used over wide areas as secondary to the indigenous form of speech, thus enabling intercourse to be developed. English is frequently called the lingua franca of the whole world as, at one time, French was the lingua franca of diplomacy. English, in various degrees of distortion, is spoken all over the world, but in special areas are found examples of a lingua franca such as (1) the so-called Mandarin Chinese, (2) Malay, (3) Hindustani, and (4) Swahili.

Mandarin Chinese.—This language, properly *kuan hua* (literally "speech of officials"), is the lingua franca of the old Chinese empire and the modern republic, with the multiplicity of dialects of Chinese, some almost forming distinct languages. Mongols, Tibetans, Manchus, Koreans, Tungus peoples and others of different language stocks who were or are under Chinese governance learned *kuan hua,* which is the simplified speech of North China, in order that they might transact business and conduct official enquiries in any part of China. (*See* CHINESE LANGUAGE.)

Malay.—This simple tongue from early times became "the commercial language of the East Indies." The simplest of the many tongues in Indonesia (*q.v.*), it spread until peoples of nearly 40 different nationalities speak it to the exclusion of their mother-tongue. (*See* MALAY LANGUAGE.)

Hindustani.—A common name for the "popular" speech of North India. It is used by Bengalis, Gujaratis, Panjabis and many other peoples as a lingua franca. (*See* HINDOSTANI LANGUAGE.)

Swahili (*q.v.*).—This important Bantu language has spread widely and is the lingua franca of Bantu Africa. (*See* BANTU LANGUAGES.)

See O. Jespersen, *Language* (1922); A. Meillet, *Linguistique Historique et Linguistique Générale* (1926).

LINGUET, SIMON NICOLAS HENRI (1736–1794), French journalist and advocate, was born on July 14, 1736, at Rheims. He was admitted to the bar in 1764, where he became one of the most famous pleaders of his century, but was dismissed in 1775 on account of his bitter attacks against his fellow advocates, especially against Gerbier (1725–88). He then founded the *Journal de politique et de littérature,* but was compelled to resign and leave the country after the publication of a sarcastic article on the French Academy. After some years as a free-lance abroad, publishing the *Annales politiques, civiles et littéraires* in London and Brussels, he attempted to return to France in 1780, and was imprisoned for two years for an attack on the duc de Duras (1715–89). After a further period abroad he returned to France in 1786 as an Austrian councillor of state, and obtained 24,000 livres from the duc d'Aiguillon for legal services rendered some 15 years earlier. His fame at the time surpassed that of his rival Beaumarchais. He then visited the emperor at Vienna to plead the case of Van der Noot and the rebels of Brabant. On his return to Paris in 1791 he defended the rights of San Domingo before the National Assembly; his last work was written in defence of Louis XVI. He retired to Marnes, near Ville d'Avray to escape the Terror, but was captured and guillotined at Paris on June 27, 1794, on the charge of "having flattered the despots of Vienna and London."

Linguet's writings include *Histoire du siècle d'Alexandre le Grand* (Amsterdam, 1762); *Histoire impartiale des Jésuites* (Madrid, 1768, condemned to be burned); *Fanatisme des philosophes* (Geneva and Paris, 1764); *Histoire des révolutions de l'empire romain* (1766–68); *Théorie des lois civiles* (an attack on the politics of Montesquieu, London, 1767); *Mémoires sur la Bastille* (London, 1789, Eng. trans. Dublin, 1783 and Edinburgh, 1884–87). His best legal treatise is *Mémoire pour le comte de Morangies* (1772). *See* J. Cruppi, *Un avocat journaliste au 18e siècle, Linguet* (1895); A. Philipp, *Linguet, ein Nationalökonom des XVIII. Jahrhunderts* (Zurich, 1896); A. Lichtenberger, *Le Socialisme utopique* (1898), pp. 77–131.

LINKAGES, in mechanics, are an assemblage of rods hinged together so that the parts may move among themselves, being generally intended to perform some particular kind of useful motion. Nearly all machinery consists of linkages either obvious or disguised. The piston rod, crank and connecting rod of a steam engine is a linkage. A pantograph is another. Linkage is used also in biology, to denote the coupling of two hereditary characters (*see* HEREDITY).

A linkage may consist of any number of rods, and their motion may take place in a space of three dimensions or in one of two dimensions (a plane). A crank shaft out of alinement would still work, provided the joints permitted it, and would be working in three dimensions. It is, however, only plane linkages which have received much notice, and of them the most attention has been paid to the one which consists of four rods jointed together to form a deformable quadrilateral. Considering one bar as fixed, it can be removed and replaced by fixed pivots about which the bars that were jointed to it can rotate. This has caused the mechanism to receive the name "three bar linkage."

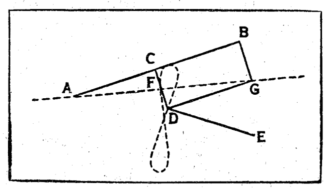

FIG. 1

Watt's Parallel Motion.—The subject of three bar motion appears to have originated in 1784 with the invention by James Watt of his so-called "parallel motion." Writing to his partner, Bolton, in June of that year, he says: "I have started a new hare. I have got a glimpse of a method of causing a piston rod to move up and down perpendicularly by only fixing it to a piece of iron upon the beam without chains or perpendicular guides or untowardly frictions, arch heads or other pieces of clumsiness. I think it a very probable thing to succeed and one of the most ingenious simple pieces of mechanism I have contrived." A visit to the science museum at South Kensington will show the sort of "clumsinesses" which Watt's invention superseded. It was essentially three bar motion, *ACDE* (fig. 1), the links of which were so adjusted in length and disposition as to cause a point *F* on the traversing link *CD* to describe a figure of 8. The portion of the curve near the point of inflexion is nearly straight for an appreciable length. If the two links *AC* and *DE* which rotate about the fixed points *A* and *E* are of equal length and the point *F* is in the middle of *CD,* the figure of 8 is symmetrical; but if they are of unequal lengths, one limb of the curve is straighter than the other and is straightest when the point *F* is taken so that *CF:FD* as *DE:AC.* If the head of the piston rod were fixed at *F* it is clear that the point *E* would be at an inconvenient distance from the rest of the engine; so Watt added two more links, *BG* and *DG,* forming a parallelogram, and it will be seen that *ACDGB* forms a pantograph in which the usual tracing point and fixed centre have changed places; and now if *AC:CB* as *CF:FD,* the point *G* will describe a curve similar to that described by *F.* The head of the piston rod was attached to *G.*

Peaucellier Cell.—Several attempts were made in the early part of the 19th century to improve upon Watt's parallel motion, among which we may mention those of Scott Russell and Kaulbach. The "Grasshopper" engine (now shown in the science museum at South Kensington) was one of them. But it was reserved to Peaucellier, a lieutenant in the French army, to invent the first exact parallel motion. In 1864 he produced his famous Peaucellier cell, consisting of six links, which converts rotatory motion into a truly straight line. It seems, however, to have completely escaped notice. Prof. Tchebichoff of the University of St. Petersburg (Leningrad) had been very interested in parallel motion without having arrived at any solution. But a pupil of his, named Lipkin, rediscovered the Peaucellier cell. The invention was introduced into England where it caused great admiration and interest, forming the subject of an address by Prof. Sylvester at the Royal Institution in 1874 (*Collected Works,* vol. iii.). It consists of four equal bars, *FL, LM, MH, HF,* and two other longer equal bars *KH* and *KL,* jointed together as shown in fig. 2. The outstanding property of this simple mechanism is that during its deformation *KF·KM* remains constant; so that if *K* is fixed, the curves traced out by *F* and *M* are inverse curves. If *F* describes a circle, *M* will describe the inverse circle; but if the centre of the *F* circle is at a distance from

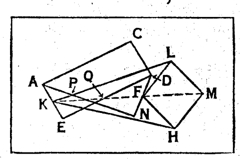

FIG. 2

K equal to its radius, then the radius of the M circle becomes infinite; *i.e.*, M describes a straight line. This form of parallel motion is stated to have been used in an engine installed for the purpose of ventilating the Houses of Parliament before the introduction of electric fans.

Crossed Parallelogram.—After Sylvester's lecture, a period arose in England during which much attention was paid to the subject of linkages, notably by Sir A. B. Kempe and H. Hart. Tchebichoff had proved to his own satisfaction that no linkage of five bars could accurately convert circular motion into rectilinear motion; but in 1877 Hart produced one (*Proc. Lond. Math. Soc.*), thus showing the danger of trying to prove a negative. He had also previously invented one of four links (*Messenger of Mathematics*, 1875). This mechanism consisted of a crossed parallelogram $EAND$ (fig. 2), formed by rotating the triangle ACD about the diagonal AD. If any straight line KF be drawn parallel to AD or EN, cutting the links AN and ED in P and Q, then $KP{\cdot}KQ$ is a constant; so that if K is fixed, the points P and Q describe inverse curves. If the link AE is fixed and K is the midpoint of AE, F will describe the inverse of a conic; and if we add a Peaucellier cell $KLMHF$, M will describe the conic. If $ED{:}EA$ as $1{:}\sqrt{2}$, F describes a lemniscate and M a rectangular hyperbola.

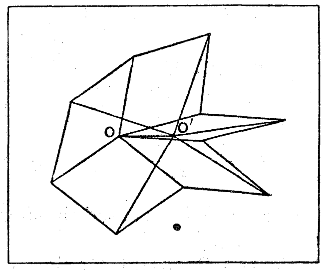

FIG. 3

Other Linkages.—Linkages can thus be made to describe other curves. One of the most interesting is that devised by G. H. Darwin (*Proc. Lond. Math. Soc.*, vol. vi.) for the purpose of drawing the equipotential curves of a system of electrically charged points. If we take two equal Peaucellier cells and pivot their two K points together, and pivot the F point of one and the M point of the other at a fixed distance apart, and ensure (as can be done mechanically in several ways) that the two cells are always equally deformed, then K describes a Cassinian oval with foci at the fixed pivots, for then the product of the focal distance of a point on the curve is constant.

M. Saint Louis showed how the solution of a numerical cubic equation can very simply be found by a three-bar linkage (*Comptes Rendus*, 1874), and as pointed out by Kempe (*Proc. Lond. Math. Soc.*, vol. vii.), an algebraic equation of any degree with numerical coefficients can be solved by linkages of many bars.

The bars AC, AN, DC, DN, DE (fig. 2), with fixed pivots at A and E forms what is called a kite linkage. A great impetus was given to the subject of the three-bar linkages by Darboux (*Bull. des Sci. Mathémat.*, 2° séries, tome iii.). He shows that if a number of kite linkages revolving about the same fixed points are joined together so that the AN of the second coincides with the AC of the first, and so on, and that if the last AC link happens to coincide with the first AN, it will do so in any state of deformation of the compound linkage. The linkage is then said to "close." In his demonstration he employs elliptic functions, the application of which to three-bar motion, originally suggested by Cayley (*Phil. Trans. Roy. Soc.*, 1861) greatly facilitates the solution of problems of closure. Fig. 3 gives a very simple form of closed kite linkages and fig. 4 is a photographic reproduction of one derived from a combination of the innumerable vector formulae which arise from the theorems given by Col. Hippisley in *Proc. Lond. Math. Soc.*, series 2, vol. xiii. In both these linkages all the bars will revolve through 360° when the linkages are deformed, though they both appear to be rigid. (*See* MATHEMATICAL MODELS.) (R. L. H.)

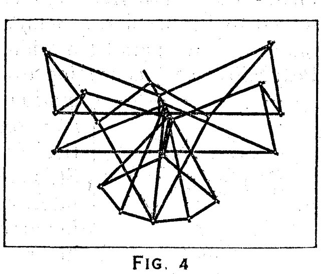

FIG. 4

LINKÖPING, a city of Sweden, the seat of a bishop, and chief town of the district (*län*) of Östergötland. Pop. (1943) 43,463. Linköping was a bishop's see in 1082 and it was at a council held in the town in 1153 that the payment of Peter's pence was agreed to at the instigation of Nicholas Breakspeare, afterwards Adrian IV. The coronation of Birger Jarlsson Valdemar took place in the cathedral in 1251; and in the reign of Gustavus Vasa several important diets were held in the town. It is situated 142 m. by rail S.W. of Stockholm, and communicates with Lake Roxen ($\frac{1}{2}$ m. to the north) and the Göta and Kinda canals by means of the navigable Stångå. The cathedral (1150–1499) is a Romanesque building with a beautiful south portal and a Gothic choir. It contains an altar-piece by Martin Heemskerck (d. 1574). In the church of St. Lars are some paintings by Per Horberg (1746–1816), the Swedish peasant artist. Other buildings of note are the episcopal palace (1470–1500), afterwards a royal palace, and the old gymnasium founded by Gustavus Adolphus in 1627, which contains a valuable library of old books and manuscripts and a museum. There is also the Östergötland Museum. The town has manufactures of tobacco, cloth and hosiery.

LINLEY, THOMAS (1733–1795), English musician and father of a large family of musicians, was born at Badminton on Jan. 17, 1733. He studied music at Bath, and afterwards settled there as a singing-master and conductor. From 1774 he was engaged in the management of the oratorios performed at Drury Lane theatre, London. He composed or compiled the music for many of the dramatic pieces played there, including *The Duenna*, by his son-in-law Richard Brinsley Sheridan. In 1777 he was elected a member of the Royal Society of Musicians. He died in London on Nov. 19, 1795.

LINLITHGOW, a royal and small burgh and the county town of West Lothian or Linlithgowshire, Scotland. Pop. (1938) 3,550. It lies in a valley on the south side of a loch, $17\frac{1}{2}$ mi. W. of Edinburgh by the L.N.E. railway. In the 19th century its antique appearance was much changed by rebuilding. About 4 mi. S. by W. lies the old village of Torphichen where the Knights of St. John of Jerusalem had their chief Scottish preceptory. The parish kirk is built on the site of the nave of the church of the establishment, but the ruins of the transept and of part of the choir still exist. The industries include shoemaking, tanning and currying, manufactures of paper, glue and soap, and distilling. There are shale works and stone quarries in the neighbourhood. An old tower-like structure near the railway station is traditionally regarded as a mansion of the Knights Templars. There are some fine fountains including the Cross Well in front of the town house, originally built in the reign of James V, but rebuilt in 1807; and one surmounted by the figure of St. Michael, the patron saint of the burgh.

The fine ruins of Linlithgow palace rise above the green knolls of the promontory which divides the lake into two nearly equal portions. In plan it is almost square, enclosing a court in the centre of which stands the ruined fountain of which an exquisite copy was erected in front of Holyrood palace by the prince consort. At each corner there is a tower with an internal spiral staircase, that of the northwest angle being crowned by a little octagonal turret known as "Queen Margaret's Bower," from the tradition that it was there that the consort of James IV watched and waited for his return from Flodden. The west side is supposed to date in part from the time of James III, who later took refuge in one of its vaults from his disloyal nobles; but the larger part of the south and east side belongs to the period of James V, about 1535; and the north side was rebuilt in 1619–20 by James VI. The palace was reduced to ruins by General Hawley's dragoons, who set fire to it in 1746. A few yards to the south of the palace is the fine church of St. Michael, a Gothic (Scottish Decorated) building with an embattled tower, probably founded by David I in 1242, but mainly built by George Crichton, bishop of Dunkeld (1528–1536). In it are found some fine stained glass, including a window dedicated to the memory of Sir Charles Wyville Thomson (1830–1882), the naturalist, who was born in the parish. (See *Palace of Linlithgow*, H.M.S.O., Edinburgh, 1933.)

Linlithgow was made a royal burgh by David I. Edward I encamped here the night before the battle of Falkirk (1298), wintered here in 1301, and next year built a castle which in 1313 was captured by the Scots. In 1369 the customs of Linlithgow yielded more than those of any other town in Scotland, except Edinburgh. Robert II granted it a charter of immunities in 1384. The palace became a favourite residence of the kings of Scotland, and often formed part of the marriage settlement of their consorts.

LINLITHGOWSHIRE: *see* WEST LOTHIAN.

LINNAEUS [CARL VON LINNÉ] (1707–1778), Swedish botanist, was born on May 13, O.S. (May 23, N.S.), 1707, at Råshult, in Småland, the son of a pastor. He was educated at Wexiö, Lund and Uppsala, where Olaf Celsius (d. 1756) engaged him to assist in the compilation of his *Hierobotanicon*. A review of S. Vaillant's *Sermo de Structura Florum* (1718) and Wallin's *Gamos Phyton* (1729) led him to examine the stamens and pistils of flowers, and, convinced of the importance of these organs, he formed the idea of basing a system of arrangement upon them. Two years after his appointment as lecturer in botany at Uppsala he explored Lapland in 1732 for the Academy of Sciences and published the scientific results in his *Flora Lapponica* (Amsterdam, 1737); his own account was published in English by Sir J. E. Smith, under the title *Lachesis Lapponica*, in 1811. After a further journey through Dalecarlia, he proceeded to Harderwijk, where he took his M.D. In the same year Jan Fredrik Gronovius (1690–1762), who was visiting him, was so struck by the ms. of the *Systema naturae* that he published it at his own expense. This famous system, artificial as it was, largely made its way by the lucid and admirable laws, and comments on them, which were issued almost at the same time. (*See* BOTANY.) After a visit to England in 1736, Linnaeus published his *Genera Plantarum*, a volume which must be considered the starting-point of modern systematic botany, and in the following year, 1738, his *Classes Plantarum*. Returning to his native country by way of France, he settled as a physician in Stockholm. He was soon appointed naval physician, with minor appointments, and in June 1739 married Sara Moraea. In 1741 he was appointed to the chair of medicine at Uppsala, but in 1742 exchanged it for that of botany. In the same year, previous to this exchange, he travelled through Öland and Gothland, by command of the state, publishing his results in *Oländska och Gothländska Resa* (1745). Its index shows the first use of specific names in nomenclature.

Henceforward his time was taken up by teaching and the preparation of other works. He issued his *Flora Suecica* in 1745 and *Fauna Suecica* in 1746; his two volumes of observations made during journeys in Sweden, *Wästgöta Resa* (1747) and *Skånska Resa* (1751); his *Hortus Upsaliensis* (1748); his *Philosophia Botanica* (1751) and his important *Species Plantarum* (1753), in which the specific names are fully set forth. In 1755 he declined an invitation from the king of Spain to settle in that country, with a liberal salary, and full liberty of conscience. In 1761 he was granted a patent of nobility, antedated to 1757, from which time he was styled Carl von Linné. To his great delight the tea plant was introduced alive into Europe in 1763. An apoplectic attack in 1774 greatly weakened him, and he died on Jan. 10, 1778 at Uppsala, in the cathedral in which he was buried.

Linnaeus delighted in devising classifications, and not only systematized the three kingdoms of nature, but even drew up a treatise on the *Genera Morborum*. He was the first to enunciate the principles for defining genera and species, and to adhere to a uniform use of specific names.

Of his 180 odd works those published during his lifetime were enumerated in R. Pulteney's *General View of the Writings of Linnaeus* (1781). His *epistolae ineditae* appeared at Groningen in 1830. His widow sold his collections and books to Sir J. E. Smith, the first president of the Linnean Society of London. When Smith died in 1828 a subscription was raised to purchase the herbarium and library for the Society, whose property they became.

See T. M. Fries, *Linné, Lefnadsteckning* (2 vols., Stockholm, 1903, Eng. version, 1923, with full bibliography); O. Levertin, *Carl v. Linné* (Stockholm, 1907); J. M. Hulth, *Bibliographia Linnaeana* (Uppsala, 1907); O. Hjelt, *Carl v. Linnés betydelse såsom naturforskare och idkare* (*ib.* 1907, Germ. trs., 1908) and W. Junk, *Linné im Lichte neuerer Forschung* (1925).

LINNET, *Carduelis cannabina*, a common song-bird, frequenting almost the whole of Europe south of lat. 64°, and in Asia extending to Turkestan. It is a winter visitant to Egypt and Abyssinia, and is abundant at all seasons in Barbary, as well as in the Canaries and Madeira. Though the fondness of this species for the seeds of flax (*Linum*) has given it its common name in many European languages, it feeds chiefly on the seeds of Compositae. The males in spring have a handsome crimson-red breast and crown to the head. The song is pleasant but apt to be monotonous. The linnet begins to breed in April, the nest being generally placed in a bush at no great distance from the ground. It is a neat structure of fine twigs, roots or bents, lined with wool or hair. The eggs, four to seven in number, are of a very pale blue marked with reddish or purplish brown. Two broods are raised in a season.

The plumage of this small finch varies much with age, sex and season, some even pied or nearly white; each phase may have a different common name, such as red linnet, gray linnet. The name mountain linnet is applied to the yellow-billed *C. flavirostris*, which never has crimson on crown or breast. Green linnet is a common name for the greenfinch (*q.v.*).

In the southwestern United States linnet is a name for the house finch (*Carpodacus mexicanus frontalis*), familiar, nesting about houses and a good singer; and to the desert house finch (*C. m. solitudinis*), British Columbia to Nevada and eastern California. (G. F. Ss.)

LINOLEUM, a term originally coined by Frederick Walton for material of his own invention, now used indiscriminately to describe any floorcovering having a base of solidified oil adhering to a jute canvas foundation.

Technically there are three distinct classes of floorcovering described commonly as linoleum:—

(*a*) *Floorcloth*, which is made by building up (trowelling) on both sides of the canvas successive layers of paint, until the desired thickness is obtained. It is then printed with a pattern and varnished.

(*b*) *Linoleum proper*, made by rolling or pressing on to the canvas an incorporated mass of linoleum "cement," cork dust, woodflour and pigments.

(*c*) *Cork Carpet and Corticine*, made in the same way as linoleum but with polymerized oil, cork dust and pigments.

Linoleum was first produced in England, in which country most of the subsequent developments of importance have taken place. The earliest patent in 1636, for "Painting with oyle cullers upon wollen-cloath, etc." was followed by the use of various mixtures of oils and resins; and, in 1751, by the incorporation of india-rubber or gum lastic. Three years later Nathan Smith established a factory at Knightsbridge for the manufacture of floorcloth, by applying a mixture of rosin, pitch, Spanish brown, beeswax and linseed oil in a melted state to canvas, and rolling it in by pressure. Subsequent improvements to cheapen the product resulted in modern floorcloth.

Walton's Patent.—It was not until 1844 that the next step towards the manufacture of linoleum proper was taken by Elijah Galloway, who softened india-rubber by heating and incorporating it with cork dust. This was rolled into sheets and marketed as "kamptulicon" which at first was cemented down, but later was rolled on to a canvas backing. Owing to the high price of rubber, however, it proved to be costly; and in 1860 Frederick Walton invented a process (Eng. Pat. 209) for oxidizing linseed oil to produce a cheap rubber-like substitute. In principle, the methods used today are essentially the same as those covered by his inventions.

The manufacture of linoleum involves the following operations:—

(1) The production of solidified linseed oil by "Walton" or other methods (*see* below).

(2) The manufacture of "cement" in the case of "Walton" goods, *i.e.*, true linoleum.

(3) The incorporation of ground cork or woodflour and pigment with the "cement" to produce "linoleum material."

(4) The application of this mixture to a canvas backing of jute.

(5) Seasoning or curing of the sheeted material.

(6) The painting (backing) of the underside to preserve the

canvas.

(7) The trimming of the finished cloth.

Solidified Oil.—The four chief methods for obtaining the solidified oil are:—

(*1*) *"Scrim" Process.*—Linseed oil, boiled with driers, is pumped to the top of sheds kept at 100° F, where it is mechanically flooded every 24 hours over sheets of cotton fabric (scrim). These are usually 3ft. wide by 25ft. long, and are hung about 4in. apart. After some weeks' treatment, when the skins have grown to about 1in. thick, they are cut down.

(*2*) *"Shower Bath" Process.*—The oil is heated with driers (manganese borate) in a steam-jacketed pan, on which there rests a tower about 20ft. high, surmounted by a tank having a perforated bottom. The oil is pumped into the tank and falls in a shower and is re-circulated thus for days. It is then transferred to a "smacker," which is a steam-heated horizontal drum, fitted axially with a rapidly revolving shaft to which blades are attached. It is half filled with the oil, whiting is added and air is blown through. The final product is run out into trays and sets to a dough-like consistency, and is stoved at about 130° F.

(*3*) *"Wood and Bedford" Process.*—The oil is run directly into a machine similar to the "smacker" previously described, and treated in much the same manner, but generally without whiting.

(*4*) *"Taylor Parnacott" Process.*—The oil is boiled with driers and agitated by compressed air until it is thick, at which stage it is transferred to smaller boilers, and the treatment continued until it becomes "stringy." The nature of this product renders unnecessary its conversion into "cement."

Linoleum Material.—The solidified oil obtained by any of the first three processes is ground between rollers and heated in a steam-jacketed pan (cement pot), together with rosin (colophony) and kauri gum. The resulting mass is a dark, homogeneous thick liquid, which, on cooling in thin layers, becomes a sticky rubber-like mass. By incorporating the "cement" with cork dust, woodflour, whiting and pigments, "linoleum material" is obtained. This mixture is intimately ground by passing it through a series of rolls and "germans" (which resemble large sausage machines) or through Pfleiderer mixers as used in paint mixing or bread manufacture. From these it is fed continuously into the "scratcher," a machine consisting of two rolls, one steam-heated and the other cold, to which the material adheres, forming a thick layer. Adjacent to this a third roll, fitted with hundreds of sharp spikes, revolves at high speed and scratches off small particles from the layer, thus converting it to a granular or mealy form.

All types of linoleum pass through these mixing stages—the nature of the finished product being determined by the subsequent treatment of the granulated material.

Linoleum can be divided into two broad classes: (a) Plains, and (b) Inlaids. These can again be further sub-divided, from the manufacturing point of view, into—(1) Plains, Printed, Jaspés, Granites and Moires. (2) Inlaids—Moulded, Straight-line, Granites, Parquetries and Marbles.

Plain and Printed Linoleums.—The granulated material is calendered on to the canvas backing by heavy steam-heated rolls. The same type of material is used for plain and printed goods, but the latter are usually thinner, and have the pattern printed on in oil colours afterwards. Granites, Jaspés and Moires are, with modifications, made in the same way, the variously coloured scratched materials being blended before calendering. Cork Carpet and Corticine too are made similarly, but have a base of polymerized (Taylor) oil incorporated with cork dust and pigments.

Inlaid Linoleum.—When produced by the moulding process, the granulated material of different colours is sifted through stencils on to canvas lying on a table. A separate stencil, having perforations corresponding to the desired position in the pattern, is used for each colour, the scratched material being thrown on and the perforations filled. The completed pattern is afterwards put through a flat hydraulic "making press," to consolidate it, and the face is perfected by passing through a "finishing press." This method gives very fine carpet and floral effects.

Straight-line Inlaids.—For these two processes are used. (a) Hand-made: the stencils in the moulding process are in this case replaced by pieces of previously sheeted material, cut to the desired shape, and laid on to form the pattern required. The rest of the operations are as in the moulding process. Parquetries, Marbles and Tile patterns are made in this way. (b) Machine-made: in this process the scratched material is rolled into a continuous sheet, and led, together with the backing, under a revolving "cutting cylinder." In the periphery of the cylinder steel knives are embedded, forming a complete pattern. Between the knives plungers operate selectively from the inside and place on the canvas the tesserae of the particular part of the pattern required. The pieces not required are carried round between the knives and are ejected.

A series (up to six) of such rolls and cylinders are used to place the different coloured pieces into position, where they are maintained by pins projecting through the backing until the "pressing cylinder" is reached. This machine consolidates the pattern and presses it on to the canvas.

Linoleum obtained by any of the above processes is still in a soft (green) condition, and requires to be hardened by seasoning. This is carried out in drying rooms; the stoves are heated from 90 to 170° F for 2–60 days according to the type of linoleum. Linoleums are usually made 2, 3 and 4 yards wide (metres in European countries) and the thickness may vary from 1·9mm. to 8mm. for plains, and 1·4mm. for inlaids.

It is computed that the world's output of linoleum is in the region of 200,000,000 sq. yds. per annum.

Important developments have taken place in the last few years, in an endeavour to improve the quality of linoleum, by using materials other than linseed oil as a base.

Nitro-cellulose.—In common with all industries using drying oils, great progress has been made in attempting to replace the linseed oil in linoleum with a nitro-cellulose base. In Germany, large quantities of linoleum are being produced containing nitro-cellulose and plasticizers as the binding material. The most recent of these products contains also a proportion of linseed oil "cement." In the U.S., practically all types of linoleum produced are now coated on the surface with a nitro-cellulose composition, which has the advantage of giving a nonmarking, glossy finish, highly resistant to soap and soda.

Felt Base.—Felt, impregnated with bituminous composition, is being used as a substitute for linoleum material. It is coated and then printed with a pattern. Such printed felts are being produced in the United States and Europe on a large scale and rival the production of printed linoleum.

Bibliography.—The literature on linoleum is relatively small, but the following may be consulted:—*Society of Arts Journal* (1862) Walton; *The Society of Chemical Industry Journal,* Reid (1896) 75; Ingle (1904) 1197; Jones (1919) 26T; Martin, *Industrial Organic Chemistry* (1913); *Industrial & Engineering Chemistry Journal,* de Waele (1917) 9.6.18; Livache & McIntosh, *Manufacture of Varnishes,* Vol. I., (1919) 232; Alder Wright, *Oils, Fats and Waxes* (1921); Lewkowitsch & Warburton, *Chemical Technology of Oils, Fat & Waxes,* Vol. III. (1923); Fischer, *Geschichte, Eigenschaften und Fabrikation des Linoleums* (1924); *The Industrial Chemist* (Sept. 1925); *The American Exporter* (Oct. 1925); *Die Tapete* (Aug., Oct. 1925); Walton, *The Infancy & Development of Linoleum Floorcloth* (1925); Morrell & Wood, *The Chemistry of Drying Oils,* 1925; A.-D. Luttringer (1928), *La Linoxyne et le Linoléum.*

LINOTYPE: *see* Printing.

LINSANG, a civet-like carnivorous mammal (*Prionodon linsang*), found from upper Burma through the Malay peninsula to Borneo and Java. Linsangs are slender in build, with short legs and long, banded tail. Their general colour is pale buff, the forehead and muzzle are brown and five broad black or brown transverse bands cross the back. Other longitudinal markings occur on neck and sides. This species is about 30 in. long. (*See* Carnivora.)

(J. E. Hl.)

LINSEED. The seed of the common flax (*q.v.*) or lint, *Linum usitatissimum,* a native of Central Asia. Linseed is chiefly grown to yield oil seeds in Argentina, India, the United States, Canada and Russia. The seeds, the linseed of commerce, are of a lustrous brown colour externally, of an elongated oval form with a slight beak or projection at one extremity. The brown testa contains, in the outer of the four coats into which it is microscopically distinguishable, an abundant secretion of mucilaginous matter; and it has within it a thin layer of albumen, enclosing a pair of large oily cotyledons. The seeds when placed in water for some time become coated with glutinous matter from the exudation of the mucilage in the external layer of the epidermis; and by boiling in sixteen parts of water they exude sufficient mucilage to form with the water a thick pasty decoction. The cotyledons contain the valuable linseed oil referred to below. (*See* Linseed Oil.) Linseed grown in tropical countries is much larger and more plump than that obtained in temperate climes, but the seed from the colder countries yields a finer quality of oil. Linseed formed an article of food among the Greeks and Romans, and it is said that the Abyssinians at the present day eat it roasted. The oil is to some extent used for food in Russia and in parts of Poland and Hungary. The still prevalent use of linseed in poultices for open wounds is entirely to be reprobated. It has now been abandoned by practitioners. The principal objection to this use of linseed oil is that it specially favours the growth of micro-organisms. There are numerous clean and efficient substitutes which have all its supposed advantages and none of its disadvantages. There are now no medicinal uses of this substance. Oil cake (*q.v.*), the mass left after the expression of the oil, is a most valuable feeding substance for cattle. (*See* Flax.)

LINSEED OIL. A most valuable drying oil obtained by expression from linseed, with or without the aid of heat. Preliminary to the operation of pressing, the seeds are crushed and ground to a fine meal. Cold pressing of the seeds yields a golden-yellow oil, which is often used as an edible oil. Larger quantities are obtained by heating the crushed seeds to 160° (71°C.), and then expressing the oil. So obtained, it is somewhat turbid and yellowish-brown in colour. On storing, moisture and mucilaginous matter gradually settle out. After storing several years it is known commercially as "tanked oil," and has a high value in varnish-making. The delay attendant on this method of purification is avoided by treating the crude oil with 1 to 2% of a somewhat strong sulphuric acid, which chars and carries down the bulk of the impurities. For the preparation of "artist's oil," the finest form of linseed oil, the refined oil is placed in shallow trays covered with glass, and exposed to the action of the sun's rays. Numerous other methods of purification, some based on the oxidizing action of ozone, have been suggested, but have not yet superseded the older methods. The yield of oil from different classes of seed varies, but from 23 to 30% of the weight of the seed operated on should be obtained.

Commercial linseed oil has a peculiar, rather disagreeable sharp taste and smell; its specific gravity is given as varying from 0·928 to 0·953, and it solidifies at about −27°. It deposits stearine at 25° and melts at 16°–20°. By saponification it yields a number of fatty acids—palmitic, myristic, oleic, linolic, linolenic and isolinolenic. Appreciable quantities of stearic acid and traces of arachidic acid are also said to be present. Exposed to the air in thin films, linseed oil absorbs oxygen and forms "linoxyn," a resinous semi-elastic, caoutchouc-like mass, of uncertain composition. The oil, when boiled with small proportions of litharge and minium, undergoes the process of resinification in the air with greatly increased rapidity.

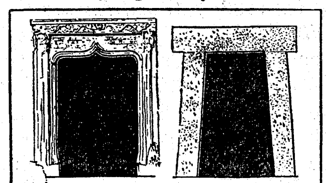
Its most important use is in the preparation of oil paints and varnishes. By painters both raw and boiled oil are used, the latter forming the principal medium in oil painting, and also serving separately as the basis of all oil varnishes. Boiled oil is prepared in a variety of ways—that most common being by heating the raw oil in an iron or copper boiler, which, to allow for frothing, must only be about three-fourths filled. The boiler is heated by a furnace, and the oil is brought gradually to the point of ebullition, at which it is maintained for two hours, during which time moisture is driven off, and the scum and froth which accumulate on the surface are ladled out. Then by slow degrees a proportion of "dryers" is added—usually equal weights of litharge and minium being used to the extent of 3% of the charge of oil; and with these a small proportion of umber is generally thrown in. After the addition of the dryers the boiling is continued two or three hours; the fire is then suddenly withdrawn, and the oil is left covered up in the boiler for ten hours or more. Before sending out, it is usually stored in settling tanks for a few weeks, during which time the uncombined dryers settle at the bottom as "foots." Besides the dryers already mentioned, lead acetate, manganese borate, manganese dioxide, zinc sulphate and other bodies are used.

Linseed oil is also the principal ingredient in printing and lithographic inks. The oil for ink-making is prepared by heating it in an iron pot up to the point where it either takes fire spontaneously or can be ignited with any flaming substance. After the oil has been allowed to burn for some time according to the consistence of the varnish desired, the pot is covered over, and the product when cooled forms a viscid tenacious substance which in its most concentrated form may be drawn into threads. By boiling this varnish with dilute nitric acid vapours of acrolein are given off, and the substance gradually becomes a solid non-adhesive mass the same as the ultimate oxidation product of both raw and boiled oil.

Linseed oil is subject to various falsifications, chiefly through the addition of cotton-seed, niger-seed and hemp-seed oils; and rosin oil and mineral oils also are not infrequently added. Except by smell, by change of specific gravity, and by deterioration of drying properties, these adulterations are difficult to detect. (*See* Oils, Fats and Waxes.)

LINSINGEN, ALEXANDER VON (1850–1935), Prussian general, was born on Feb. 10, 1850 at Hildesheim. From 1909 to 1914 he was in command of the II. Army Corps. In Jan. 1915 he was given command of the German Southern Army, which he exchanged in July of the same year for the Army of the Bug, to which was added in the following Sept. the German-Austrian south-eastern group (Army Group L), with which he foiled the Russian attempts to break through in that and the following two years. In March 1918 Linsingen led the advance into the Ukraine, and in the following June was appointed chief-in-command in the Mark, *i.e.*, the province of Brandenburg including Berlin. On Nov. 9, 1918, the troops under his command made common cause with the revolution.

LINTEL, in architecture, a horizontal beam supported at its two ends, especially the horizontal stone or timber over a door, window or other opening. Post-and-lintel construction is that in which all weights, such as those of roofs or upper storeys, are carried entirely by a simple system of vertical supports and horizontal beams.



Lintel: (left) English half timber type, (right) an example from an Etruscan tomb

LINTH or **LIMMAT,** a river of Switzerland, one of the tributaries of the Aar. It rises in the glaciers of the Tödi range, and has cut out a deep bed which forms the Grossthal that comprises the greater portion of the cantons of Glarus. A little below the town of Glarus the river, keeping its northerly direction, runs through the alluvial plain which it has formed, towards the Lake of Zürich. In order to regulate the flow of the river over this plain it has been canalised and dykes protect the riparian lands. These works were begun in 1807 and the first portion of the undertaking was completed in 1811, and received the name of the "Escher canal," the river being thus diverted into the Walensee. The second portion, known as the "Linth canal," regulated the course of the river between the Walensee and the Lake of Zürich and was completed in 1816. Many improvements and extra protective works were carried out after 1816, the date of the completion of the work being 1911. On issuing from the Lake of Zürich the Linth alters its name to that of "Limmat," and, keeping the north-westerly direction, joins the Aar a little way below Brugg, and just below the junction of the Reuss with the Aar.

LINTON, WILLIAM JAMES (1812–1897), English wood-engraver, republican and author, was born in London. He was educated at Stratford, and in his 16th year was apprenticed to the wood-engraver G. W. Bonner. His earliest known work is to be found in Martin and Westall's *Pictorial Illustrations of the Bible* (1833). After working as a journeyman engraver with two or three firms, losing his money over a cheap political library called the "National," and writing a life of Thomas Paine, he went into partnership (1842) with John Orrin Smith. The firm was immediately employed on the *Illustrated London News,* just then projected. The following year Orrin Smith died, and Linton, who had married a sister of Thomas Wade, editor of *Bell's Weekly Messenger,* found himself in sole charge of a business upon which two families were dependent.

In 1844 he took a prominent part in exposing the violation by the English post-office of Mazzini's correspondence. This led to a friendship with the Italian revolutionist, and Linton threw himself with ardour into European politics. He carried the first congratulatory address of English workmen to the French Provisional Government in 1848. He edited a twopenny weekly paper, *The Cause of the People,* published in the Isle of Man, and he wrote political verses for the Dublin *Nation,* signed "Spartacus." He helped to found the "International League" of patriots, and, in 1850, with G. H. Lewes and Thornton Hunt, started *The Leader,* an organ which, however, did not satisfy his advanced republicanism, and from which he soon withdrew. The same year he wrote a series of articles propounding the views of Mazzini in *The Red Republican.* In 1852 he took up his residence at Brantwood, which he afterwards sold to John Ruskin, and from there issued *The English Republic,* first in the form of weekly tracts and afterwards as a monthly magazine. Most of the paper, which never paid its way and was abandoned in 1855, was written by himself. In 1852 he also printed for private circulation an anonymous volume of poems entitled *The Plaint of Freedom.*

After the failure of his paper he returned to his proper work of wood-engraving. In 1857 his wife died, and in the following year he married Eliza Lynn. In 1864 he retired to Brantwood, his wife remaining in London. In 1867, pressed by financial difficulties, he determined to try his fortune in America, and finally separated from his wife. With his children he settled at Appledore, New Haven, Connecticut, where he set up a printing-press. Here he wrote *Practical Hints on Wood-Engraving* (1879), *James Watson, a Memoir of Chartist Times* (1879), *A History of Wood-Engraving in America* (1882), *Wood-Engraving, a Manual of Instruction* (1884), *The Masters of Wood-Engraving,* for which he made two journeys to England (1890), *The Life of Whittier* (1893), and *Memories,* an autobiography (1895). He died at New Haven on Dec. 29, 1897. As an engraver on wood Linton reached the highest point of execution in his own line. He carried on the tradition of Bewick, fought for intelligent as against merely manipulative excellence in the use of the graver, and championed the use of the "white line" as well as of the black, believing with Ruskin that the former was the truer and more telling basis of aesthetic expression in the wood-block printed upon paper.

See W. J. Linton, *Memories;* F. G. Kitton, article "Linton" in *English Illustrated Magazine* (April 1891); G. S. Layard, *Life of Mrs. Lynn Linton* (1901). (G. S. L.)

LINTON, a city of Greene county, Ind., U.S.A.; 43 mi. S.E. of Terre Haute; served by the Chicago, Milwaukee, St. Paul and Pacific, the Illinois Central and the Pennsylvania railways. The population in 1930 was 5,085; in 1940, 6,263. Linton is in an agricultural and coal-mining region. It was founded about 1850 and was incorporated as a city in 1902.

LINTOT, BARNABY BERNARD (1675–1736), English publisher, was born at Southwater, Sussex, on Dec. 1, 1675, and started business as a publisher in London about 1698. He published for many of the leading writers of the day, notably Vanbrugh, Steele, Gay and Pope. The latter's *Rape of the Lock* in its original form was first published in *Lintot's Miscellany,* and Lintot subsequently issued Pope's translation of the *Iliad* and the joint translation of the *Odyssey* by Pope, Fenton and Broome. Pope quarrelled with Lintot with regard to the supply of free copies of the latter translation to the author's subscribers, and in 1728 satirized the publisher in the *Dunciad,* and in 1735 in the *Prologue to the Satires.* Lintot died on Feb. 3, 1736.

LINUM, a genus of the family Linaceae. There are some 200 species of plants found in temperate and subtropical regions especially the Mediterranean. There are 4 species in the British Flora, *Linum catharticum* (purging flax), with white flowers, which is common, also *L. perenne* (perennial flax), *L. angustifolium* (narrow-leaved flax), and *L. usitatissimum* (flax or linseed) which has been introduced and is cultivated especially in Ireland. Flax is the fibre of the last named species obtained by the removal of the softer tissues by retting; the shorter fibres form tow. The seeds (linseed) yield an oil by pressure and the cake left is a cattle food. About 30 species are native to North America. Among these are *Linum virginianum* (slender yellow flax), of the eastern States; *L. floridanum* (Florida yellow flax), of the south-eastern States; *L. rigidum* (large-flowered yellow flax), of the interior prairie region; *L. Lewisii* (wild blue flax), widely distributed from Wisconsin to Alaska and southward to California and Texas; and *L. californicum* (white-flowered flax), of the Coast ranges. *L. grandiflorum* (flowering flax), a native of North Africa, with large red flowers, and *L. flavum,* with golden-yellow flowers, native to Europe, are grown as ornamental plants. (*See* FLAX.)

LINUS, one of the saints of the Gregorian canon, whose festival is celebrated on Sept. 23. His name appears as the immediate successor of Peter in all ancient lists of the bishops of Rome. Irenaeus (*Adv. Haer.* iii, 3. 3) identifies him with the Linus mentioned by St. Paul in 2 Tim. iv, 21. According to the *Liber Pontificalis,* Linus suffered martyrdom, and was buried in the Vatican.

LINUS. A name abstracted from the ancient ritual cry *αἴλινος,* the refrain of a dirge, supposed Phrygian by Euripides,[1] but probably of Semitic origin (*ai lanu,* "woe to us"). It is as old as Homer,[2] and how much older we do not know. To account for this lament for Linus (Gr. Λίνος), as it was supposed to be, two principal stories were told: (1) *Argive.*—Linus, child of Apollo and Psamathe, was exposed at birth and was torn in pieces by dogs. In revenge, Apollo sent a *Poine* or avenging spirit, which destroyed the Argive children. The hero Coroebus killed her, and a festival, Arnis, otherwise called Dog-killing Day (κυνοφτνίσο), was instituted, in which stray dogs were killed, sacrifice made, and Linus and Psamathe mourned for.[3] (2) *Theban.*—Linus was the son of Urania and Amphimarus, and a great musician. He invented the Linus song, but was put to death by Apollo for setting up as his rival.[4] A later, half-burlesque story, says that he was Heracles' music master, and killed by his pupil, whom he tried to correct.[5] He had a cult on Mt. Helicon. Later tradition rationalized him into an ancient poet, prophet or the like.

This and similar figures (Adonis, Maneros, Narcissus) are plausibly explained as originating ultimately in the ceremonial laments for the dead corn spirit.

LINZ, formerly capital of Upper Austria, was the third largest town in Austria. Pop. (1939) 131,423. On the Danube it lies at the intersection of the east-west routes with the shortest rail connection between Hamburg and Trieste, and is therefore an important railway junction and river port with an active transit trade supplemented by traffic in the products of local industries, *e.g.,* boats, iron and steel goods, agricultural implements, tobacco and cloth. Linz is famous for its examples of Baroque architecture and has a cathedral in the Gothic style.

LION, since the earliest times, one of the best-known animals. In prehistoric times the modern lion (*Panthera leo*) was distributed over the greater part of Europe and within the historic period it inhabited Africa, western Asia, and, very possibly, Greece. At the present day it is found in most parts of Africa, in Mesopotamia, and in Gujarat in northwest India. The Amer-

[4] Paus., ix, 20, 6.
[5] Apollodorus, ii, 63. There are also other variants.

ican "mountain lion" is the puma, *Felis concolor.*

Lions have been divided into local races, depending upon the colour of the fur and the condition of the mane. They differ from the other large Felidae (except the puma, *q.v.*) in the uniform coloration of the adult and in the possession by the male of a mane on the head, neck and shoulders. There is also a tuft of hair on the tail. The usual colour is yellowish gray. In size, the lion is only equalled or excelled among existing Felidae by the tiger; it may measure 10 ft. from nose to tip of tail; the lioness is about a foot less. The internal structure hardly differs from that of the other Felidae (*see* CARNIVORA). The voice is a loud and characteristic roar.

Lions live chiefly in sandy plains and rocky places, where there are thorn thickets; and in the tall grasses and reeds that grow beside streams. They are in the main nocturnal and catch their prey bounding from an ambush or by a careful stalk. Over a short distance they can gallop very rapidly. Their principal food consists of the larger herbivores—buffaloes, antelopes, zebras and giraffes, but they are not above eating carrion. In cultivated districts they frequently take sheep and cattle, and occasionally human beings. Confirmed man-eaters are, however, usually old animals that have not sufficient activity to kill wild creatures. Lions have been known to jump considerable obstacles carrying a goat or other prey in their mouths. Their strength is phenomenal. Very conflicting reports are given as to their courage; the truth seems to be that not only do individual lions differ in this respect, but that the behaviour of a lion depends upon his condition, a hungry, ill-fed animal being bolder than a full-fed specimen. But unless hungry or molested, the lion, like all large animals, thinks discretion the better part of valour. Both parents display the greatest solicitude in training their young.

See Martin Johnson, *Lion* (1929); Cherry Kearton, *In the Land of the Lion* (1929).

LION FISH (*Pterois volitans*), a tropical marine fish of the family Scorpaenidae, reaching a length of about 1 ft., notable for its very high spinous dorsal and large pectoral fins. The spines of the dorsal, and to a less extent rays of the pectoral fin, stand separate from one another. It is marked with an intricate and striking pattern of light and dark cross stripes, the fin rays and spines banded—a sluggish, ornamental creature. Its spines are said to inflict a poisonous sting, though not as severe as that of the poison fish. The lion fish is found in the Indian ocean, East Indies, and eastward into Polynesia (*see* POISON FISH, SCORPION FISHES). (J. T. N.)

LIONNE, HUGUES DE (1611–1671), French statesman, was born at Grenoble on Oct. 11, 1611, of an old family of Dauphiné. Early trained for diplomacy, his abilities attracted the notice of Cardinal Mazarin, who sent him as secretary of the French embassy to the congress of Münster, and, in 1642, on a mission to the pope. From that time he filled high offices. He helped to negotiate the Peace of the Pyrenees (1659), which secured the marriage of Louis XIV to the infanta Maria Theresa. At Mazarin's dying request he was appointed his successor in foreign affairs, and, for the next ten years, continued to direct French foreign policy. Among his most important diplomatic successes were the treaty of Breda (1667), the treaty of Aix-la-Chapelle (1668) and the sale of Dunkirk. He died in Paris on Sept. 1, 1671, leaving memoirs.

See Ulysse Chevalier, *Lettres inédites de Hugues de Lionne . . . précédées d'une notice historique sur la famille de Lionne* (Valence, 1879); J. Valfrey, *La diplomatie française au XVIIIe siècle: Hugues de Lionne, ses ambassadeurs* (2 vols., Paris, 1877–81). For further works *see* Rochas, *Biogr. du Dauphiné* (Paris, 1860), tome ii, p. 87.

LIOTARD, JEAN ÉTIENNE (1702–1789), Swiss painter, was born at Geneva. He began his studies under Gardelle and Petitot. He went to Paris in 1723, studying under J. B. Massé and F. le Moyne on whose recommendation he was taken to Naples by the Marquis Puysieux. In 1735 he was in Rome, painting the portraits of Pope Clement XII and several cardinals. Three years later he accompanied Lord Duncannon to Constantinople, from where he went to Vienna in 1743 to paint the portraits of the imperial family. His eccentric adoption of oriental costume secured him the nickname of "the Turkish painter." Still under distinguished patronage he returned to Paris in 1744; visited England, where he painted the princess of Wales in 1753, and went to Holland in 1756, where, in the following year, he married Marie Fargues. Another visit to England followed in 1772, and in the next two years his name figures among the Royal Academy exhibitors. He returned to his native town in 1776 and died at Geneva in 1789.

Liotard was an artist of great versatility, and though his fame depends largely on his graceful and delicate pastel drawings, of which "La Liseuse," the "Chocolate Girl," and "La Belle Lyonnaise" at the Dresden Gallery are delightful examples, he achieved distinction by his enamels, copperplate engravings and glass painting. He wrote a *Treatise on the Art of Painting,* and was an expert collector of paintings by the old masters. Amsterdam, Berne and Geneva are particularly rich in examples of his paintings and pastel drawings. A picture of a Turk seated is at the Victoria and Albert Museum, London, while the British Museum owns two of his drawings. The Louvre has, besides 22 drawings, a portrait of General Hérault, and a portrait of the artist is in the Uffizi Gallery, Florence.

See *La Vie et les oeuvres de Jean Etienne Liotard (1702–1789), étude biographique et iconographique,* by E. Humbert, A. Revilliod, and J. W. R. Tilanus (Amsterdam, 1897); Band-Bovy, *Peintres génevois* (Geneva, 1903–04); François Tosca *Liotard* (1928).

LIOUVILLE, JOSEPH (1809–1882), French mathematician, was born at St. Omer and died at Paris. He graduated in 1827 from l'École Polytechnique where, in 1833, he became professor. At the unusually early age of 30 he was elected to the Académie des Sciences (Paris), and presently was appointed professor at the Sorbonne and the Collège de France, and director of the Bureau des Longitudes. In 1836 he founded the *Journal des Mathématiques Pures et Appliquées,* of which he was editor for 40 years. This great journal did much to raise and maintain the standard of French mathematics throughout the 19th century. It was saved from extinction after World War I by international effort, largely American.

Liouville was a prolific and boldly original mathematician. His works, never collected, comprise about 400 memoirs and notes, more than 200 on the theory of numbers alone. His earlier work, which proved abortive by current standards, concerned generalized differentiation (fractional) and integration. In 1832–33, he investigated criteria for the analytic character of integrals of algebraic functions. Liouville was the first, in 1844, to prove the existence of transcendental numbers, and he constructed an infinite class of such numbers. He worked also in differential equations and boundary-value problems. His methods in this department became of capital importance in 20th century mathematical physics, as well as in the theory of integral equations. In differential geometry, he contributed notably to the theories of applicability of surfaces and conformal transformations. The concept of geodesic curvature was introduced by Liouville. Nearly all of his work on the theory of numbers (1857–82) was published without indication of the means by which he had obtained his striking results, relating mostly to numerical functions, representation in quadratic forms, and general formulas in parity functions. All have since been proved. In analysis, Liouville was the first to deduce the theory of doubly periodic functions from general theorems, including his own, in the theory of analytic functions of a complex variable. (E. T. B.)

LIPA, a municipality (with administrative centre and 45 *barrios* or districts), of the province of Batangas, Luzon, Philippine islands, about 90 mi. S. by E. of Manila, on high ground at the intersection of old Spanish military roads, east of the lake of Taal and near the railway running to Batangas. Pop. (1939) 45,175. It is one of the largest and wealthiest inland municipalities of the archipelago. Sugar, corn, cacao and tobacco are among the principal products. Coffee was formerly produced in considerable quantity, but many of the trees were destroyed during the insurrection of 1899–1902; others were destroyed by insects. Jusi cloth is woven in Lipa, and tied abacá (Manila hemp) is marketed in considerable volume. Tagalog is the vernacular. Of those aged 6 to 19 inclusive, 32.8% in 1939 attended school, while 52.8% of the inhabitants 10 years old and over were literate.

LIPARI ISLANDS, a group of volcanic islands north of the eastern portion of Sicily (anc. Αἰόλου νῆσοι or *Aeoliae Insulae*),— Lipari (*Lipara,* pop. in 1936, 14,156), Stromboli (Strongyle), Salina (*Didyme,* pop. in 1931, 3,505), Filicudi (*Phoenicusa*), Alicudi (*Ericusa*), Vulcano (*Hiera, Therasia* or *Thermissa*), the mythical abode of Hephaestus, and Panarea (*Euonymus*). The area of the islands is 44 sq.mi. Pop. (1931) 17,606. The island of Aiolie, the home of Aiolos, lord of the winds, has generally been identified with one of this group, and they are now called Isole Eolie. A colony of Cnidians and Rhodians was established on Lipara in 580–577 B.C. The inhabitants, allies of the Syracusans, were attacked by the Athenian fleet in 427 B.C., and by the Carthaginians in 397 B.C., while Agathocles plundered a temple on Lipara in 304 B.C. During the Punic Wars the islands were a Carthaginian naval station until the Romans took possession in 252 B.C. Sextus Pompeius also used them as a naval base. Under the Empire, as under fascism, the islands served as a place of banishment for political prisoners. In the middle ages they frequently changed hands. Lipari contains the chief town (population in 1936, 4,530), which bears the same name and had municipal rights in Roman times. It is the seat of a bishop. The isle contains sulphur springs and vapour baths, which were known and used in ancient times. It has a ruined 16th century castle. Pumicestone is mined and exported, and the obsidian of Lipari was much exported in prehistoric times, and has even been found at Knossos.

Stromboli, 22 mi. N.E. of Lipari, is constantly active, ejecting gas and lava at brief intervals, and always visible at night. Salina, 3 mi. N.W. of Lipari, consisting of the cones of two extinct volcanoes, that on the southeast, Monte Salvatore (3,155 ft.), being the highest point in the islands, is the most fertile of the whole group and produces good Malmsey wine: it takes its name from the saltworks on the south coast. Vulcano, ½ mi. S. of Lipari, contains a still smoking crater, which erupted in 1888–90 and did much damage.

See Archduke Ludwig Salvator of Habsburg, *Die Liparischen Inseln,* 8 vols. (for private circulation) (Prague, 1892–1896); G. Libertini, *Isole Eolie* (Florence, 1921).

LIPETSK, a town in Tambov province, Russia, on the right bank of the Voronezh river, in 52° 37′ N., 39° 35′ E., and on the railway. The river here is not navigable for steamers. Pop. (1939) 66,625. It has flour mills, a brandy distillery and leather and tobacco works. Its chalybeate mineral springs have been famous since the time of Peter the Great. The town has a municipal electricity and water supply.

LIPKA, JOSEPH (1883–1924), U.S. mathematician, was born at Briessin, Poland, in 1883. He emigrated to the U.S. as a child and was educated at Columbia university (A.B., 1905; A.M., 1906; Ph.D., 1912). He was instructor in mathematics at the University of California 1907–08, and afterward instructor 1908–17, assistant professor 1917–23 and associate professor 1923–24 of mathematics at the Massachusetts Institute of Technology. His earlier work, done under the influence of Prof. Kasner of Columbia, was chiefly in the field of applying differential geometry to dynamics and developing in Euclidean spaces of two or three dimensions the geometric properties of dynamical trajectories and related systems of curves. One of his notable earlier achievements was the establishing of the validity in all cases of the Thomson-Tait criterion for a natural family. This was already proved to hold for a Euclidean space of three dimensions, but Lipka established it first for four and then for n dimensions and finally for a general curved space. In 1921 he went abroad for study under various European mathematicians, especially Levi-Civita of Italy. He subsequently published a group of papers revolving about Levi-Civita's notion of parallelism. He generalized Levi-Civita's conception by replacing the geodesics at the basis of it by the trajectories of a natural family, which suggested a new type of parallelism called "conformal parallelism," an idea of great value in the study of problems in dynamics. By introducing conformed parallelism he developed a new set of invariants which yield corresponding results bearing on trajectories. His papers are models of clear thinking and clear expression, and his early death at Boston on Jan. 24, 1924, cut short a career of great promise.

See W. Graustein, "Scientific Work of Joseph Lipka," *Amer. Math. Soc. Bull.,* vol. xxx (1924) and N. Wiener, "In Memory of Joseph Lipka," *Jour. of Math. and Physics,* vol. iii (1924), both of which articles contain bibliographies of his writings.

LI PO or **LI TAI PO** (李白,李太白, 701–762), considered by many critics as China's greatest poet, was born in Pa-hsi (巴西) in Szechwan. He was a descendant, in the ninth generation, of the emperor Hsing-Sheng. At his birth, his mother had a dream in which she saw the planet, Chang-kêng (長庚星, Venus) and because of this omen he was named Po or "The Bright." At ten, he learned the *Book of Odes* and the *Book of History.* He was fond of fencing and developed a taste for drink, a passion for poetry, and a desire for adventure. After the age of 20, he wandered as far as Shantung, and then retired to the Min mountains (岷山) living the life of a *hsien* (仙, an immortal endowed with divine powers as an angelic man) together with five other sympathetic companions, King Chao, Han Chun, Pei Chêng, Chang Shuming and Tao Mien. Their coterie was known as the Six Idlers of the Bamboo Streams (竹溪六逸). Li Po was then summoned by the provincial examination board, who wished to award him governmental preferment, but he made no response. When Su Ting, the governor of Ichou, was introduced to him, he was struck by the poet's genius and said, "This man has conspicuous natural talents. If he had more learning, he would become a second Ssuma Hsiangju" (司馬相如, 126 B.C., the greatest poet of the Han dynasty).

About 742, he reached the capital, Changan (長安), where his poetry aroused the admiration of Ho Chihchang (賀知章), the minister of the emperor and the president of the Hanlin academy (翰林學院). About this time, there was a Korean messenger with an imperial document written in Korean. This nobody could read but Li Po. After being many times summoned by the emperor Ming Huang, Li Po appeared before him to receive promotion. At one time, while Li Po was drinking in low taverns, the emperor sent for him to compose a song; but Li Po was so drunk that his head and face had to be washed repeatedly with cold water before he could go to the pavilion. While the emperor played the flute, Yang Kueifei (楊貴妃), the court mistress, accompanied him on the guitar and Li Po drank and wrote verses, not returning to the Hanlin academy until after midnight.

Once, when Li Po was very drunk the emperor ordered Kao Lishih to take off the poet's shoes; Kao felt humiliated and persuaded Yang Kueifei that some of Li Po's poems were derogatory to her. She therefore dissuaded the emperor whenever he wanted to give high rank to the poet. His official failure was thus brought about. Finally the poet petitioned the emperor that he be allowed to go away, and he was given money and an imperial edict which enabled him to obtain wine free of charge wherever he should go. Li Po, together with Ho Chihchang, Li Shihchih, Li Chin, Tsui Tsungchih, Chu Chin, Chang Hsu and Chio Sui then went away, forming a new coterie called the Eight Immortals of the Wine Cup (酒中八仙).

Afterward Li Po drifted into the service of Prince Lin of Yung who, when he failed in certain of his designs, blamed Li Po. But he forgave him and the poet set out to go to his kinsman, Li Yanping. On his way he fell from the boat in which he was travelling while trying to kiss the reflection of moonlight in the water, and was drowned.

Li Po's style is unmatched for purity. He deals mainly with the themes, wine and women, and where emotions enter his verse they go deep into the heart of the reader. His work has strong imaginative and aesthetic appeal with an exquisite exactness of touch and extreme dexterity. Philosophy, religious or social, has no place in his work; to him the poet is no teacher or prophet, but a creator revealing beauty for its own sake.

LIPPE, one of the smaller of the *Länder* of the German Reich, bounded northwest, west and south by the Prussian province of Westphalia and northeast and east by the Prussian provinces of Hanover and Hesse-Nassau, and Waldeck-Pyrmont. It also possesses three small enclaves—Kappel, Lipperode and Grevenhagen in Westphalia. The area is 469 sq.mi., and the population (1939) 188,596, showing a density of 404 to the sq.mi. The state is hilly and consists chiefly of the basin of the Werre, which from Lage northward flows in a wide valley. From here the land rises to the higher hills which encircle it on the east, south and west (the Teutoburger Wald) borders. The forests of Lippe produce abundance of excellent timber, and consist mostly of deciduous trees, beech preponderating. The valleys contain good arable land, the tillage of which employs the greater part of the inhabitants. Small farms, the larger proportion of which are under 2½ ac., are numerous, and their yield shows a high degree of prosperity among the peasant farmers. The principal crops are potatoes, beetroot (for sugar), hay, rye, oats, wheat and barley. Cattle, horses, sheep and swine are also reared. The industries are small and consist mainly in the manufacture of starch, paper, sugar, tobacco, meerschaum wares, and in weaving and brewing. Salzuflen is famous for its brine-springs. Each year, in spring, brickmakers leave the principality to return home in the late autumn. The roads are good. A railway intersects the country from Herford (on the Cologne-Hanover main line) to Altenbeken; and another from Bielefeld to Hameln traverses it from west to east. About 95% of the population are Protestants. The constitution was drawn up in 1920. It provided for a representative chamber (*Landtag*) of twenty-one members, and an executive chamber (Landes präsidium) of three. The courts of law were centred at Detmold. After 1933 the constitution was superseded by the administration of a National Socialist district leader (*Gauleiter*) appointed by Hitler.

History.—Lippe was inhabited in early times by the Cherusii, whose leader Arminius (Hermann) annihilated in A.D. 9 the legions of Varus in the Teutoburger Wald. It was afterward occupied by the Saxons and was subdued by Charlemagne. The founder of the princely family, one of the most ancient in Germany, was Bernard I (1113–1144), who received a grant of the territory from the emperor Lothiar, and assumed the title of lord of Lippe (*edler Herr von Lippe*). From Count Simon VI (1555–1613) descended the Counts of Lippe-Biesterfeld and Lippe-Weissenfeld, and the Princes of Schaumburg-Lippe. On the death of Prince Woldemar of Lippe in 1895, a dispute arose as to the succession between the various branches of the Lippe family, which was only definitely settled in 1905, when Count Leopold of Lippe-Biesterfeld became Prince of Lippe. Lippe, which had been made a principality in 1720 (confirmed in 1789) became a Republic in common with the rest of Germany in Nov. 1918.

LIPPE, a river of Germany, a right-bank tributary of the Rhine. It rises near Lippspringe under the western slope of the Teutoburger Wald, and, after being joined by the Alme, the Pader and the Ahse on the left, and by the Stever on the right, flows into the Rhine near Wesel, after a course of 154 mi. It is navigable, by the aid of 12 locks, downward from Lippstadt, for boats and barges drawing less than 4 ft. of water. The river is important for the transport facilities it affords to the rich agricultural districts of Westphalia.

LIPPI, the name of three distinguished Italian painters of the 15th, 16th and 17th centuries.

I. Fra Filippo Lippi (1406–1469), commonly called Lippo Lippi, one of the most renowned painters of the Italian quattrocento, was born in Florence. In 1421 he was registered in the community of the Carmelite friars of the Carmine in Florence. Here he remained till 1432, and his early faculty for fine arts was probably developed by studying the works of Masaccio in the chapel of the Brancacci. It is not known who his master was. Berenson suggests that he may have been Lorenzo Monaco. The influence of Fra Angelico can be traced in his early work. Between 1430 and 1432 he executed some works in the monastery, which were destroyed by a fire in 1771; they are specified by Vasari, and one was particularly marked by its resemblance to Masaccio's style. Eventually Fra Filippo left his convent, but it appears that he was still bound by some religious vow. In 1452 he was appointed chaplain to the convent of S. Giovannino in Florence, and in 1442 rector (Rettore Commendatario) of S. Quirico at Legnaia.

Except through Vasari nothing is known of Fra Filippo's visits to Ancona and Naples, and his intermediate capture by Barbary pirates and enslavement in Barbary, from which his skill in portrait-sketching availed to release him. This relates to a period, 1431–37, when his career is not otherwise clearly accounted for and modern biographers doubt the accuracy of Vasari's account. Toward June 1456 Fra Filippo was settled in Prato to fulfil a commission to paint frescoes in the choir of the cathedral. Before undertaking this work he set about painting in 1458 a picture for the convent chapel of S. Margherita of Prato, and there saw Lucrezia Buti, a Florentine, who was under the nuns' guardianship. Lippi asked that she might be permitted to sit to him and abducted her to his own house. The fruit of their love was a boy, who became the celebrated painter Filippino Lippi (*see* below). The Virgin in the fine picture in the Pitti gallery is said to be the portrait of Lucrezia Buti.

The frescoes in the choir of Prato cathedral, being the stories of the Baptist and of St. Stephen, represented on the opposite walls, are Fra Filippo's most important and monumental works. At the end wall of the choir are S. Giovanni Gualberto and S. Alberto, and on the ceiling the four evangelists. The close of Lippi's life was spent at Spoleto, where he was commissioned to paint, for the apse of the cathedral, some scenes from the life of the Virgin. In the semidome of the apse is Christ crowning the Madonna, with angels, sibyls and prophets. This series was completed by Fra Diamante after Lippi's death. Lippi died in Spoleto about Oct. 8, 1469. He lies buried in Spoleto, with a monument erected to him by Lorenzo the Magnificent; he was zealously patronized by the Medici family, beginning with Cosimo, Pater Patriae. Jacopo de Sellaio, Francesco di Pesello (called Pesellino) and Sandro Botticelli were among his most distinguished pupils.

In 1441 Lippi painted an altarpiece for the nuns of S. Ambrogio, now in the Uffizi at Florence, which has been celebrated by Browning. It represents the coronation of the Virgin among angels and saints, of whom many are Bernardine monks. One of these, placed to the right, is a half-length portrait of the abbot, pointed out by an inscription upon an angel's scroll "Is perfecit opus." For the church of San Lorenzo he painted an "Annunciation." In the Uffizi is a "Virgin Adoring the Infant Christ" and a "Nativity"; in the National Gallery, London, an "Annunciation" and "Seven Saints"; in the Louvre, Paris, a "Madonna and Angels," painted for S. Spirito in Florence. The museum of Berlin has three early works. There is an early "Adoration of the Magi" in Sir Herbert Cook's collection at Richmond. In the Vatican gallery is a triptych representing "Coronation, Saints and Donors," and in the Palazzo Venezia, Rome, an "Annunciation" from the Hertz collection.

Lippo Lippi's pictures show the naïveté of a strong, rich nature. He approaches religious art from its human side. He was perhaps the greatest colourist of his time, with good draughtsmanship—a naturalist, with much genuine episodical animation. He was fond of ornamenting pilasters and other architectural features. Vasari says that Lippi was wont to hide the extremities in drapery to evade difficulties.

With Vasari's account of Lippo Lippi, the work of Crowe and Cavalcaselle should be consulted. Also E. C. Strutt, *Fra Filippo Lippi* (1906); B. Supino, *Fra Filippo Lippi* (1902) and *Les deux Lippi* (1904); Henriette Mendelsohn, *Fra F. Lippi* (1909); and P. G. Konody, *Fra F. Lippi* (1911).

II. Filippino Lippi (1457–1504), was the natural son of Fra Lippo Lippi and Lucrezia Buti, born at Prato. Losing his father at an early age, the boy was placed in charge of Fra Diamante.

He studied under Sandro Botticelli. His powers developed early, for we find him an accomplished artist by 1480, when he was commissioned to paint an altarpiece, the "Vision of St. Bernard," for the Badia of Florence. Soon afterward (*c.* 1482–90) he began work on the frescoes of the Brancacci chapel in the Carmine, commenced by Masolino and Masaccio many years before. He finished Masaccio's "Resurrection of the King's Son," and was the sole author of "Paul's Interview with Peter in Prison," the "Liberation of Peter," the "Two Saints before the Proconsul" and the "Crucifixion of Peter," modestly adapting his style to that of Masaccio. The portrait of his master Botticelli and those of various others are in this series. In 1485 he executed the great altarpiece of the "Virgin and Saints," now in the Uffizi gallery. Another of his leading works is the altarpiece for the Nerli chapel in S. Spirito—the "Virgin Enthroned," with splendidly living portraits of Nerli and his wife and a fine landscape background.

In 1489 Filippino was in Rome, painting in the church of the Minerva, having first designed the monument for his father in the cathedral of Spoleto. Some of his principal frescoes in the Minerva in celebration of St. Thomas Aquinas are still extant. In 1496 Filippino painted the "Adoration of the Magi" now in the Uffizi. In 1498 he was at Prato; in 1502 he completed the frescoes in the Strozzi chapel, in the church of S. Maria Novella in Florence—"Drusiana Restored to Life by St. John the Evangelist," "St. John in the Cauldron of Boiling Oil" and two subjects from the legend of St. Philip. These are somewhat lively and excited, full of ornate architecture and contrasting colours. The best reputed of his scholars was Raffaellino del Garbo.

Like his father, Filippino had a marked original genius for painting. The father displayed more of sentiment and candid sweetness of motive; the son more of richness, variety and lively pictorial combination. He was admirable in all matters of decorative adjunct, such as draperies, landscape backgrounds and accessories. The National Gallery, London, possesses a good specimen of Filippino, the "Virgin and Child between Sts. Jerome and Dominic." A fine tondo representing the "Holy Family" is in Mrs. Warren's collection at Boston.

Crowe and Cavalcaselle, supplemented by the writings of Berenson, should be consulted as to this painter. An album of his works is in Newnes' Art-library. *See* also A. H. Layard, *The Brancacci Chapel* (Arundel Society, 1868), and B. Supino, *Les deux Lippi* (1904).

III. Lorenzo Lippi (1606–1664), painter and poet, was born in Florence. He studied painting under Matteo Rosselli, the influence of whose style, and more especially of that of Santi di Tito, is to be traced in Lippi's works, which are marked by a strong turn for portrait-like naturalism. His maxim was "to poetize as he spoke, and to paint as he saw." After exercising his art for some time in Florence, Lippi went as court painter to Innsbrück. There he wrote his humorous poem named *Malmantile Racquistato,* published under the anagrammatic pseudonym of "Perlone Zipoli," in 1688. Lippi is more generally remembered by this poem than by his painting.

See Lanzi for Lorenzo Lippi's pictorial work, and Tiraboschi and other literary historians for his writings. Also A. Alterocca, *Lorenzo Lippi* (1914).

LIPPINCOTT, SARA JANE CLARKE (1823–1904), U.S. author and journalist, born Sept. 23, 1823, in Pompey, N.Y., was the daughter of Dr. Thaddeus and Deborah (Baker) Clarke. Educated in public and private schools, she published occasional verse at an early age and at nineteen was a contributor to *Godey's Lady Book.* Best known as "Grace Greenwood," she was the Washington correspondent for the *New York Times* and also the *New York Tribune,* one of the first women to hold such a position. She contributed to many periodicals, including *Godey's, Graham's,* the *New Mirror, Harper's, The Independent* and *The Atlantic Monthly.*

In 1853 she married Leander K. Lippincott and with him edited the *Little Pilgrim* for 12 years. She was the author of 18 books, including children's tales, historical sketches and travel books. Her last work, *Stories and Sketches,* was published when she was 70 years old. Her best known volumes are *Greenwood Leaves* (1850), a collection of articles and stories, and *Haps and Mishaps of a Tour in Europe* (1854) which, as a contemporary reviewer says, "with its freshness of feeling imparts to her letters the charm and fascination of a private conversation."

She lectured during the Civil War, using the proceeds for disabled soldiers and their families, and was a frequent visitor to camp and hospitals, thus earning Lincoln's accolade of "Grace Greenwood, the Patriot." She died at New Rochelle, N.Y., at the age of eighty-one.

LIPPSPRINGE, a town and watering-place in the Prussian province of Westphalia, Germany, near the western slope of the Teutoburger Wald, 5 mi. N.E. of Paderborn. Pop. (1933) 5,160. It is mentioned in chronicles as early as the 9th century, and here in the 13th century the order of the Templars established a stronghold. It received civic rights about 1400. The springs, for which it is famous, are saline waters of a temperature of 70° F., used for bathing and drinking.

LIPPSTADT, a town in the Prussian province of Westphalia, Germany, on the river Lippe, 20 mi. by rail W. by S. of Paderborn, on the main line to Düsseldorf. Pop. (1939) 23,721. Lippstadt was founded in 1168 by the lords of Lippe, the rights over one half of the town passing subsequently to the counts of the Mark, which in 1614 was incorporated with Brandenburg. In 1850 the prince of Lippe-Detmold sold his share to Prussia. The Marien Kirche dating from the 13th century is built in the Transitional style. The manufactures include cigar making, distilling, carriage building and metalworking. During World War II the town was bombed several times by the British R.A.F.

LIPSCHITZ, RUDOLF OTTO SIGISMUND (1832–1903), German mathematician, was born in Königsberg, East Prussia, on May 14, 1832. In 1847 he graduated from the Gymnasium and entered the University of Königsberg. Later he was attracted to the University of Berlin by P. G. Lejeune Dirichlet, and on Aug. 9, 1853 he received his doctor's degree there with a thesis on the magnetic field excited in an ellipsoid by induction. About this time he married Ida Pascha, a childhood playmate. He spent his probationary year at the Gymnasium at Königsberg and then taught at the Gymnasium of Elbing. In 1857 he became privatdocent at Bonn; in 1862 he went to Breslau as ausserordentlicher professor, and in 1864 he returned to Bonn as ordinarius. In 1873 he received an offer from Göttingen, but he declined it and remained at Bonn until his death on Oct. 7, 1903. He devoted himself zealously to the duties of his faculty and for the year 1874–1875 was chosen unanimously as rector. He was a corresponding member of numerous scientific academies, including those at Paris, Berlin, Göttingen and Rome.

The mathematical work of Lipschitz was many-sided, including contributions ranging from the theory of numbers to mathematical physics. He did important work in the calculus of variations, Bessel's functions, Fourier series, potential theory and analytical mechanics. The direction of his thought was determined largely by Dirichlet and by the 1854 *Habilitationsschrift* of G. F. B. Riemann. Fundamentally an algebraist, he was yet interested in the foundations of mathematics, and in his *Lehrbuch der Analysis* (2 vols., Bonn, 1877–1880) he sought to develop the subject from fundamental concepts. Following the lead of A. L. Cauchy, he formulated the well-known Lipschitz (or Cauchy-Lipschitz) condition in connection with the existence theorem for solutions of the differential equation $y'=f\ (x, y)$.

Lipschitz contributed numerous papers to scientific periodicals, especially Crelle's *Journal* and the *Comptes Rendus.* His other works include: *Bedeutung der theoretischen Mechanik* (1866); *Wissenschaft und Staat* (1874); and *Untersuchungen über die Summen von Quadraten* (1886). (C. B. Br.)

LIPSIUS, JUSTUS (1547–1606), the Latinized name of Joest (Juste or Josse) Lips, Belgian scholar, born on Oct. 18 (Nov. 15, according to Amiel), 1547, at Overyssche, a small village in Brabant, near Brussels. He studied at the University of Louvain. In 1567 he published *Variarum Lectionum Libri Tres,* dedicated to Cardinal Granvella, who took him to Rome, where he stayed two years studying mss. and inscriptions. On his return he published *Antiquarum Lectionum Libri Quinque* (1575), which shows an advance forward, a sounder system of emendation by collation. He wandered over Europe a good deal, taught at Jena, Cologne, Louvain and Antwerp and finally became professor of history of Leyden. These changes must have involved some elasticity in the religions he professed, varying between Catholic at Cologne and Calvinist at Leyden. The 11 years at Leyden were his most productive period. It was then that he prepared his *Seneca,* perfected, in successive editions, his *Tacitus* and brought out a series of works, some of pure scholarship, others collections from classical authors, others again of general interest. Of this latter class was a treatise on politics (*Politicorum Libri Sex,* 1589), which caused trouble by his reactionary views on religious toleration, which was with difficulty smoothed down by the university authorities. In the spring of 1590 he went to Mainz, where he was reconciled to the Roman Catholic Church. The event deeply interested the Catholic world, and invitations poured in on Lipsius from the courts and universities of Italy, Austria and Spain. But he preferred to remain in his own country, and finally settled at Louvain, as professor of Latin in the Collegium Buslidianum. He continued to publish dissertations as before, the chief being his *De militia romana* (Antwerp, 1595) and *Lovanium* (Antwerp, 1605; 4th ed., Wesel, 1671), intended as an introduction to a general history of Brabant. He died at Louvain on March 23 (some give April 24) 1606.

Lipsius' knowledge of classical antiquity was extremely limited. His greatest work was his edition of Tacitus. This first appeared in 1575, and was five times revised and corrected—the last time in 1606, shortly before his death. His *Opera Omnia* appeared in 8 vols. at Antwerp (1585, 2nd ed., 1637).

A full list of his publications will be found in van der Aa, *Biographisch Woordenboek der Nederlanden* (1865), and in *Bibliographie Lipsienne* (Ghent, 1886–88). In addition to the biography by A. le Mire (Aubertus Miraeus) (1609), the only original account of his life, *see* M. E. C. Nisard, *Le Triumvirat littéraire au XVI^e siècle* (1852); A. Räss, *Die Convertiten seit der Reformation* (1867); P. Bergman's *Autobiographie de J. Lipse* (1889); L. Galesloot, *Particularités sur la vie de J. Lipse* (1877); E. Amiel, *Un Publiciste du XVI^e siècle. Juste Lipse* (1884); and L. Müller, *Geschichte der klassischen Philologie in den Niederlanden.* The articles by J. J. Thonissen of Louvain in the *Nouvelle Biographie générale,* and L. Roersch in *Biographie nationale de Belgique,* may also be consulted.

LIPSIUS, RICHARD ADELBERT (1830–1892), German Protestant theologian, son of K. H. A. Lipsius (d. 1861), who was rector of the Thomasschule at Leipzig, was born at Gera on Feb. 14, 1830. He studied at Leipzig, and eventually (1871) settled at Jena as professor. He helped to found the Evangelical Protestant Missionary union and the Evangelical Alliance, and from 1874 took an active part in their management. He died at Jena on Aug. 19, 1892. Lipsius wrote principally on dogmatics and the history of early Christianity from a liberal standpoint. His chief works are *Philosophie und Religion* (1885) and *Lehrbuch der evang.-prot. Dogmatik* (1876; 3rd ed., 1893).

His other works include *Die apokryphen Apostelgeschichten* (1883–90), *Hauptpunkte der christl. Glaubenslehre im Umriss dargestellt* (1889), and commentaries on the Epistles to the Galatians, Romans and Philippians in H. J. Holtzmann's *Handkommentar zum Neuen Testament* (1891–92). *See* A. Neumann, *Grundlagen und Grundzüge der Weltanschauung von R. A. Lipsius* (1896).

LIPTON, SIR THOMAS JOHNSTONE, 1ST BART. cr. 1902 (1850–1931), British merchant, was born at Glasgow on May 10, 1850, of Irish parents. He was employed as errand boy to a Glasgow stationer; at fifteen he emigrated to America, where he worked in a grocery store, was a tramcar driver in New Orleans, a traveller for a portrait firm and worked on a plantation in South Carolina. Eventually he returned to Glasgow and opened a small provision shop. In time Lipton had provision shops first all over Scotland and then all over the United Kingdom. To supply his retail shops on the most favourable terms, he purchased extensive tea, coffee and cocoa plantations in Ceylon, and provided his own packing house for hogs in Chicago, and fruit farms, jam factories, bakeries and bacon-curing establishments in England. In 1898 his business was converted into a limited liability company. In 1898 he was knighted, and in 1902 was made a baronet. He was a keen yachtsman, and made repeated attempts to win the "America's" Cup (*see* YACHTING).

LIQUEFACTION OF GASES. It is somewhat uncertain when the idea that gases could be liquefied first arose. Lavoisier certainly expressed the view that if the earth were cooled to the temperature of outer space, part, at least, of its atmosphere would liquefy, but he made no attempt to liquefy any known gas. His associates, Monge and Clouet, were actually the first to succeed in this direction, liquefying sulphur dioxide by passing it into a glass tube cooled with a mixture of ice and salt. About the same time van Marum and Paets van Troostwyk (1790), compressing ammonia to see whether it obeyed Boyle's Law, found that when a certain pressure was reached the volume suddenly decreased rapidly, and drops of liquid appeared. In the year 1799 Guyton de Morveau liquefied ammonia by cooling the gas to the temperature of a mixture of ice and calcium chloride. In 1805 Northmore compressed gases mechanically up to 15 atmospheres, and he appears to have liquefied chlorine.

The Early Work of Davy and Faraday.—No further experimental investigations can be traced till the year 1823, when papers were read before the Royal Society by Sir H. Davy and his assistant M. Faraday (*Phil. Trans.,* 1923), describing experiments carried out at the Royal Institution. In Faraday's first experiments chlorine hydrate, obtained by cooling chlorine water, was heated in a sealed tube to 100° C, when "chlorine was evolved from it under such pressure that it assumed the liquid form, appearing of a bright yellow colour, and sinking in the warm water without any tendency to mix with it." In a second paper he describes experiments with the apparatus shown in figure 1. Compounds which liberated such gases as chlorine, or sulphuretted hydrogen, were placed in the short limb of the glass tube, which was hermetically sealed. The substance was heated, and the long limb of the tube was cooled in ice or in a freezing mixture, and in it the gases liquefied. A few weeks later Davy described the liquefaction of sulphuretted hydrogen, and hydrochloric acid by compression, giving data for the pressures required to liquefy these gases at different temperatures. His paper is of importance, as it shows that in 1823 Davy had already installed apparatus for the compression and liquefaction of gases at the Royal Institution. Ill health prevented him from continuing his researches in this direction.

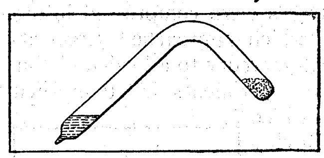

FIG. 1.—FARADAY'S EXPERIMENT

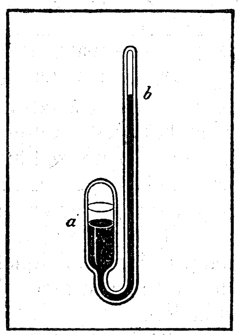
Large Scale Liquefaction.—In 1834 Thilorier developed a method already in vogue for the manufacture of soda water, and applied it to the condensation of carbon dioxide in large quantity. Two stout metal vessels, at first made of cast iron, but, after an accident, of copper, and lined with lead, served as the generator and receiver in Faraday's experiments. One of these was fitted with a cap which could be removed, and a cock, and in it was placed solid bicarbonate of soda and a vessel containing sulphuric acid. The other vessel was fitted with a stopcock only, and the two vessels were joined by a connecting tube which could be detached. The generator was charged, and closed, and then rotated, so as to mix the acid and soda. It was then connected with the receiving vessel, which was cooled in ice, and in this the gas liquefied. The stopcocks were then closed, the vessels were separated, and, by re-charging the generator a second and third charge of gas could be condensed in the receiver. Thilorier observed that the liquid expanded rapidly when heated. He also found that when the liquid was allowed to escape through a jet into a box lined with nonconducting material a snowlike solid was formed. His observation that this solid carbon dioxide mixed with ether was a much more efficient refrigerant than the solid alone was a valuable contribution to the experimental side of the subject.

Faraday's Later Experiments.—The first to apply the results of Thilorier's work, which was carried out from a technical standpoint, to scientific investigations, was Faraday. His method of investigation was as follows. The mixture of solid carbon dioxide and ether was contained in an earthenware vessel of 100 cu.cm. capacity, which fitted into a larger earthenware vessel, three or four folds of dry flannel intervening. The temperature measured by an alcohol thermometer was $-78°$ C, but by placing the apparatus under the receiver of an air pump, and reducing the pressure to 1.2 in. of mercury, a temperature of $-110°$ C was reached.

There seems to be no definite evidence as to when the idea first originated that a pure liquid possessed a definite vapour pressure at a definite temperature. Dalton, early in the 19th century, had shown that the vapour pressure of water was independent of the presence of air in the space above it, and had measured the vapour pressures between the ice point and boiling point. Davy (*loc. cit.*) had observed that "the elasticity of vapours in contact with the liquids from which they are produced, under high pressures increases in higher ratio than the arithmetical one of temperature; but the exact law is not determined," and he had determined the relation of temperature and pressure for certain condensed gases. Faraday now took the subject up at the point at which Davy dropped it, and he determined the vapour pressures of all the gases which could be liquefied at temperatures above $-110°$ C, and at pressures up to 50 atmospheres. (*Phil. Trans.*, 1845.) Faraday was unable to liquefy hydrogen, oxygen, nitrogen, nitric oxide, and carbonic oxide, and the failure of others to succeed by using higher pressures gave rise to the idea that these gases were *permanent,* the term being still used, with recognized qualifications. An interesting investigation with the same object was that of Natterer (*Sitzungsberichte d. Wiener Akad., Ann. d. Phys., 1844–55*). Gases were compressed into a wrought iron vessel, the pressure, which approached 3,000 atmospheres, being transmitted through mercury to a loaded piston, which acted as a manometer. The experiments failed in their object; but indicated the extent to which the permanent gases departed from Boyle's Law regarding the relation between pressure, volume and temperature.

The Critical State.—We must now go back to 1822 when Cagniard de la Tour (*An. de Ch. et de Ph.* 21 and 22) proved that when a liquid was heated above a certain temperature it was completely converted into vapour. He used the glass apparatus shown in fig. 2, the liquid being contained in the wide limb of the U-tube over mercury, the narrow limb serving as a manometer, the pressure being calculated from the volume of the air. The apparatus was heated in an air bath. He obtained the following results:



FROM M. W. TRAVERS, "STUDY OF GASES" (MACMILLAN)

FIG. 2.—CAGNIARD DE LA TOUR'S EXPERIMENT

	Temperature of volatilization	Pressure
Ether	175° C	38 Atms.
Carbon bisulphide . .	258° C	71 Atms.

The experiments of Cagniard de la Tour are an example of the excellent work carried out by French physicists of the period. They were, however, completely lost sight of, and it was not till 1860 that the experiment was repeated by Andrews, and the fundamental principle associated with it was discovered. Andrews' discovery that for each substance there is a critical temperature above which it cannot be liquefied was first made public in the 1863 edition of Miller's *Chemical Physics* and in 1869 formed the subject of a Bakerian lecture under the title, "On the continuity of the gaseous and liquid states of matter."

Research of Andrews.—Andrews had attempted to liquefy the permanent gases by applying high pressures at temperatures down to $-110°$ C. Failing to liquefy them, he turned his attention to the study of the process of liquefying carbon dioxide, with a view to throwing light on the general problem of the liquefaction of gases. For this purpose he used an apparatus, now in the South Kensington museum, of which a diagram is shown in fig. 3. It consisted of twin steel tubes, flanged and capped at both ends, and connected laterally. Through glands in the upper caps glass tubes passed, of capillary bore above and closed at the top, the part inside the steel apparatus being 2.5 mm. bore, and open below. The tubes contained respectively carbon dioxide and air, over mercury with which the steel apparatus was filled, the air tube serving as a manometer, the pressure being assumed to be inversely proportional to the volume. Steel screw plungers passing through glands in the bottom of the apparatus served to regulate the volume and pressure. The glass tubes projecting outside the apparatus were surrounded by a water bath with glass sides. He found that at temperatures below 31° C liquid appeared in the tube containing the carbon dioxide when the air manometer indicated a definite pressure for each particular temperature, and that when liquefaction had commenced, the gas could be completely condensed without increase of pressure, except such as could be attributed to the presence of traces of air in it. Near 31°, which he was the first to call the critical point, the space which had been occupied by the liquid at lower temperatures became filled with a "homogeneous fluid, which, when the pressure was slightly reduced, or the temperature slightly lowered, exhibited a peculiar appearance of moving or flickering striae throughout its entire mass." At temperatures above 31° he found that the gas could be reduced in volume to that which it should occupy as liquid with complete continuity, and without exhibiting a visible surface, hence the title under which the results of the work were published. The results obtained are represented by the simple curves in fig. 4. These curves, called isothermals, representing the relationship of pressure and volume for a series of constant temperatures, are in heavy line. An isothermal for a temperature below the critical temperature represents the volume of the gas as diminishing as the pressure increases till the vapour pressure is reached, and the gas begins to liquefy. The volume then decreases without increase in pressure till the gas is completely liquefied, this part of the curve being a horizontal straight line. As the liquid is only slightly compressible the curve then ascends steeply. The part of the diagram within and below the dotted line represents conditions under which liquid and vapour can co-exist. The critical isothermal has no horizontal portion, since the volumes of liquid and vapour are identical. Above the critical point the curves approach rapidly to the form of the hyperbola.

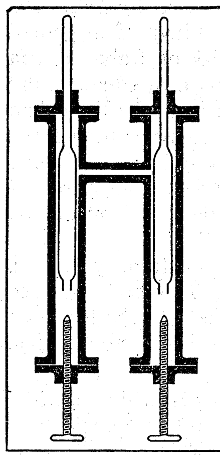


FIG. 3.—ANDREWS' APPARATUS, USED IN INVESTIGATIONS ON THE CRITICAL STATE

The experiments of Andrews fully explained his own failures, and those of Faraday and earlier investigators, to liquefy the so-called permanent gases. The significance of his work, can, however, only be appreciated when we consider the theoretical investigations to which it gave rise. Since the work of Regnault had first shown that the known gases departed more or less from the laws of Boyle and Gay-Lussac as expressed by the equation,

$$\frac{pv}{T}=R, \text{ a constant,}$$

T being the temperature on the scale of a thermometer filled with the gas itself, approximately equivalent to the temperature on the absolute scale, to which reference will be made later. Many attempts had been made to modify the formula to accord with the facts so far as they were known. These, however, only included the volume and pressure relations of the gas, but in view of the discoveries of Andrews it was now obvious that the theoretical investigation must also take into account the existence of the liquid phase.

Van der Waals's Equation of State.—In 1873 there was published in Leyden a dissertation with the same title as Andrews' Bakerian lecture—"On the continuity of the liquid and gaseous states," by J. D. Van der Waals. The title has not, however, the same significance, and is used in a more exact sense than by Andrews. It implies that while the isothermals for temperatures which differ by a very small interval above and below the critical temperature are practically identical in form, the isothermal for the higher temperatures represents the gaseous state only, and that for the lower temperatures relates also to the liquid state. This was the first original paper published by the author who had for some years been engaged upon mathematical investigations, based upon the kinetic theory of gases and Laplace's theory of capillarity, and upon this work he based the theory which made him famous. Assuming the molecules of any particular gas to be all exactly similar hard elastic spheres of radius r, the volume occupied by n molecules in volume v is

$$b' = \tfrac{1}{6} n r^3 \pi$$

In accordance with the assumption as to the form of the molecule, the gas equation thus becomes

$$p(v-b) = RT,$$

where $b = 4b'$.

Now, while the molecules in the interior of a mass of gas are subjected to attractions by other molecules which are equal in all directions, so that the resultant attraction is negligible, the resultant attraction on the molecules in the surface layer is directed inward, and varies as the square of the volume. Allowing for the effect thus produced the equation now becomes:—

$$\left(p + \frac{a}{v^2}\right)(v-b) = RT.$$

This is known as the Van der Waals equation.

It may first be pointed out that the equation may also be written in cubic form

$$v^3 - v^2\left(\frac{RT}{p} + b\right) + \frac{va}{p} - \frac{ab}{p} = 0.$$

One of the three roots of this equation must always be real, and the other two may be real or imaginary, so that for every value of p there may be one or three values of v. In a certain region, for the isothermals below the critical point, there are three real values of v for each value of p, so that the curves do not have the simple form indicated by the heavy lines but follow the sinuous lines.

The latter do not exhibit the discontinuity shown by the former, in which, for one particular value of p only, the vapour pressure, there are two values of v, corresponding to the volumes of saturated vapour and of the liquid. This pressure and the corresponding volumes are indistinguishable on the Van der Waals curve, but at the same time, if the relations of volume, pressure, and temperature under which the liquid and vapour phases are in equilibrium are known, the constants in the Van der Waals equation can be calculated from them with the same accuracy as from the data obtained from the compressibility of the gas. The meaning of the continuous curve has been the subject of much speculation. It has been suggested that the portion of it on the extreme right represents a condition of super-saturated vapour, and that on the left a state in which liquid exists at a pressure below its vapour pressure. The central portion must in any case be without physical significance as it represents the pressure and volume as increasing together and decreasing together. As a matter of fact the Van der Waals equation is based upon the consideration of the behaviour of a single phase, which may change continuously into a second phase, but it does not contemplate discontinuity, or equilibrium between liquid and vapour. The form of the curve has no physical significance at all, but is merely a consequence of the mathematical treatment of the subject.

At the point C, the critical point $\frac{\partial p}{\partial v} = 0$ and a line drawn parallel to the volume axis is tangential to the isothermal. At this point the three values of V are real and equal, and by a simple algebraical process we can obtain the values of the critical temperature, the critical pressure, and the critical volume in terms of the constants of the equation:—

$$T_c = \frac{8a}{27bR}; \quad p_c = \frac{a}{27b^2}; \quad v_c = 3b; \quad p_c v_c = 0{\cdot}375 RT_c.$$

The following are the values of a and b for some of the common gases, when pressures are reckoned in atmospheres, and the volumes in litre-moles:

Gas	a	b
Hydrogen H_2	0.19	0.023
Oxygen O_2	1.36	0.0316
Carbon dioxide CO_2	3.61	0.0428
Sulphur dioxide SO_2	6.69	0.0565

The fundamental ideas which are expressed by the Van der Waals equation are undoubtedly true, but it could hardly be expected that from the simple assumptions upon which it was based it would be possible to develop a complete theory of the gaseous and liquid state. The equation does not enable us to connect in a quantitative manner the properties of gases at low pressures. The ratio $p_c v_c / T_c$ is not 0.375 pv/T, being generally nearer to 0.27 R/R. It is not possible to trace the isothermals

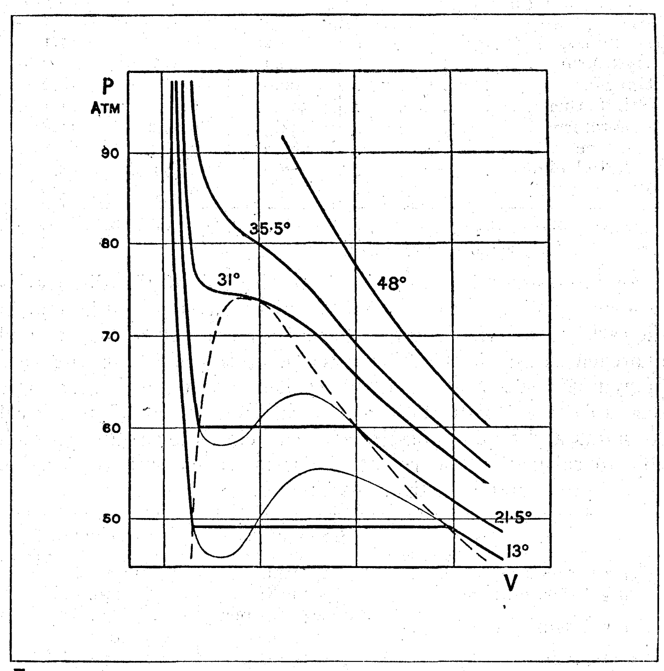

FIG. 4.—P.-V.-T. DIAGRAM FOR CARBON DIOXIDE. ILLUSTRATING THE WORK OF ANDREWS AND OF VAN DER WAALS

for any distances by means of data calculated from the critical constants. However, the Van der Waals equation, even without modification, has been of very great value as a means of calculating the physical constants for gases and liquids approximately.

The Law of Corresponding States.—A second discovery which was made by Van der Waals is known as the law of corresponding states. This is really a mathematical consequence following on the assumption that the properties of the systems with which we are dealing can be represented by an equation with two constants a and b, R depending merely on the quantity of material in this system, molar or otherwise. If then a series of diagrams are drawn like fig. 4, but representing the properties of different materials, such as carbon dioxide, benzene, etc., it will be seen that they are very similar, and they can actually be made identical by altering the vertical and horizontal scales on which they are drawn. This may be done if we change the units from absolute units of temperature, pressure, and volume, and represent these dimensions in terms of fractions or multiples of the values of the critical constants, thus,

for T we write $T/T_c = \theta$ the *reduced temperature*.
" p " " $p/p_c = \pi$ the *reduced pressure*.
" v " " $v/v_c = \phi$ the *reduced volume*.

Equal values of θ, π, and ϕ for different substances represent what are known as corresponding states. By substituting the reduced values in the equation it becomes

$$\left(\pi+\frac{3}{\phi^2}\right)(\phi-\tfrac{1}{3})=\frac{8\theta}{3}.$$

It will be noticed that the constants, a, b, and R have vanished, and therefore all substances in corresponding states should behave alike. For instance, the isothermals of all gases represented in this manner should be identical. The law of corresponding states leads directly to certain useful approximations. The boiling point T_b of most liquids is approximately a corresponding temperature, since

$$T_b/T_c=0.62 \text{ (about)}$$

and as it can be shown that the latent heat of liquefaction L should be identical for liquid-gas systems at corresponding temperatures it follows that

$$L/T_b=\text{constant}.$$

It was found by Trouton (*Phil. Mag.*, 1899) that for many liquids this rule holds good, thus:—

Liquid	T_b	L	L/T_b
†Helium	4.29	22	5.1
†Hydrogen	29.4	214	10.5
†Oxygen	90.6	1,664	18.2
Ethyl ether	307	6,466	21.1
Chloroform	334.5	6,972	20.85
Benzene	353.2	7,370	20.85
‡Ethyl alcohol	357.2	9,972	28.40
‡Water	373	9,660	25.9

Trouton's rule does not hold good for liquids at very low temperatures†, nor for associating liquids‡.

An interesting instance of the application of the discoveries of Van der Waals was that of the Polish physicist Witkowski in the early 1880s. He determined the compressibility of oxygen and hydrogen down to the lowest temperatures which in the case of hydrogen was that of liquid oxygen. From the data, he was then able to calculate the constants in the equation. The critical constants and boiling point of oxygen being known, he was then able to calculate these constants for hydrogen with remarkable accuracy, as later investigations showed.

	Calculated	Experimental
Critical pressure	13 atm.	12.8 atm.
Critical temperature	−240°C	−239.9°C
Critical density	0.033 grams per cu.cm.	0.031 grams per cu.cm.
Boiling point	−250°C	−252.8°C

Later, Kammerlingh Onnes used a similar process to estimate the constants for helium. Again, Ramsay and Young (*Phil. Mag.*, 1886) discovered a simple relationship between the vapour pressures of pairs of liquids, which holds good for associating liquids, but tends to break down at very low temperatures. If T_x and T_y, $T_{x'}$ and $T_{y'}$, are the absolute temperatures at which a pair of liquids have vapour pressures p and p', then

$$T_x/T_y=T_{x'}/T_{y'}+k\,(T_x-T_{x'})$$

when k is a constant for each pair of liquids. This formula enables us to calculate the vapour pressure for any substance over a wide range of temperatures, when the vapour pressures corresponding to two or more temperatures are known. The following is an illustration of the use of the method. The case is taken in which the vapour pressure of krypton was to be determined and water was the reference substance. The values in columns 1 and 2 were the result of observation.

1 P(mm)	2 T_{kr}	3 T_{aq}	4 T_{kr}/T_{aq}
386.6	112.7	353.1	0.3174
11,970	170.9	474.3	0.3603
30,837	201.0	525.1	0.3828

The values in column 3 are the temperatures for water corresponding to the pressures in column 1. The values in column 4 are the ratios of the values 2/3. We then plot the values in column 4 against those in column 3, and draw a straight line through the points set out. Values of T_{aq} in column 6, equivalent to any derived pressure indicated in column 5, are then readily

5 p(mm)	6 T_{aq}	7 T_{kr}/T_{aq}	8 T_{kr}
600	366.5	0.3229	118.35
4,000	427.2	0.3449	147.3
30,000	523.6	0.3801	199.0

selected, and from the graph the corresponding values of T_{kr}/T_{aq} in column 7 are read off. Multiplying the values in column 6 by those in column 7 we obtain the values in column 8. Thus we can calculate the vapour pressures over any range, up to the critical point.

Modifications of Van der Waals' Equation.—Various attempts have been made to modify the Van der Waals' equation, and a very large number of equations, nearly all of which are empirical, have been put forward. Thus Clausius proposed an equation

$$\left\{p+\frac{a}{T(v+c)^2}\right\}(v-b)=RT$$

to represent the experimental results of Amagat at very high pressures. This, and other equations, were carefully examined by Kammerlingh Onnes and all were found to be unsatisfactory. D. Berthelot (*Bureau Int. des Poids et Mesures*, 1907, vol. xiii) proposed an equation which, in the reduced condition, and for low pressures, may be written

$$\left(\pi+\frac{16}{3}\cdot\frac{1}{\theta\phi^2}\right)\left(\phi-\frac{1}{4}\right)=\frac{32}{4}\theta.$$

From this equation we obtain

$$\frac{\partial(\pi\phi)}{\partial\pi}=\frac{1}{4}\left(1-\frac{6}{\theta^2}\right);$$

while from the Van der Waals equation

$$\frac{\partial(\pi\phi)}{\partial\pi}=\frac{1}{3}\left(1-\frac{27}{8\theta}\right).$$

The former expression enables us to calculate the values of $\frac{d(pv)}{dp}$ over a very wide range of temperature with a surprising degree of accuracy, the results showing deviations from experimental values which are comparable with experimental errors. These constants are of importance in evaluating the deviations of the gas scale from the thermodynamic scale of temperature.

Dieterici, whose work has been reviewed by F. H. MacDougall (*J. of Am. Ch. Soc.* 1916), has put forward equations, which, like the equations of Van der Waals, have a true physical meaning. We will consider his second equation, which is based on the following reasoning. In the interior of a fluid the attractive forces between molecules are balanced; at the surface there are unbalanced forces, of which the resultant effect is directed inward. Molecules of low velocity are unable to reach the surface, therefore the surface layer will decrease in density from the interior outward to the surface, where the density will depend on the exterior pressure. Only molecules having a velocity above a certain value will penetrate this inhomogeneous layer, and exert pressure on the walls of the containing vessel. If, now, we determine what fraction of the total molecules has a velocity greater than this value, then the external pressure will be that same fraction of the internal pressure. Omitting the details of the reasoning, from this assumption he arrives at the formula:—

$$p=\frac{RT}{v-b}e^{\frac{-A}{RT}}$$

where e is the base of a natural logarithm, b is a function similar to the Van der Waals b and A is a cohesion function measured by the work done by a molecule in penetrating to the surface. Making the simple assumption that A is proportional directly to the volume, the equation becomes

$$p = \frac{RT}{(v-b)} e^{\frac{-a}{vRT}}$$

This equation differs materially from that of Van der Waals in that a and b are really variable with the volume, which makes it very difficult to apply. In some respects it represents a real advance upon the work of Van der Waals, and from it we can derive the expression:—

$$p_c v_c = 0.27\, RT_c$$

which accords with experiment. Recent attempts to apply modern concepts of atomic structure to the derivation of an equation of state have not led to any noteworthy success.

Thermodynamical Treatment of the Subject.—The experiments of Andrews paved the way for the work of Van der Waals, and after describing those experiments, which open a new period in the history of our subject, it was convenient to describe the theoretical developments to which they gave rise. Before dealing with the next phase in the experimental study of liquid-vapour systems it is convenient to consider the process involved from the standpoint of thermodynamics. The starting point is now the law of conservation of energy, also known as the first law of thermodynamics. To illustrate this law we will suppose that when we supply a quantity of heat Q to a gas, the heat is utilized in increasing the internal energy of the gas by an amount U. If the gas expands it must overcome resistance; in other words it must do work W; and if Q, U and W, are expressed in the same units we may write:—

$$Q = U + W.$$

It is obvious that the heat is drawn from the surroundings, and that work is done on the surroundings, and the energy U, which remains associated with the gas, is now the difference between the quantities W and Q. We will now consider what changes take place in the values of W, Q and U when the gas undergoes changes in temperature, pressure and volume. So long as a system, which may be a gas, or liquid, or may contain both gas and liquid, undergoes no such change its internal energy must remain constant, and under certain conditions the internal energy may remain constant when the system undergoes change. This is illustrated by the well known experiment of Gay-Lussac (1806), afterward perfected by Joule (1844). Two large vessels, connected by a stopcock, are immersed in a water bath, one vessel being exhausted and the other containing gas under pressure. When the temperature is constant, the stopcock is opened, so that the gas can distribute itself between the two vessels. After an interval, the temperature of the water bath is observed, and it is found to be unchanged. The gas has expanded, and though this may be at first sight contrary to experience, its temperature has remained unchanged. Now the experiment is arranged so that the gas expanding into a closed exhausted space, produces no external effect, mechanical or thermal, so that, if we assume the truth of the first law, since

$$W = 0 \text{ and } Q = 0, \text{ it follows that } U = 0.$$

The result obtained in the Gay-Lussac-Joule experiment would always be observed in the case of an ideal gas which obeys the simple law, $pv = RT$, and gases such as air approximate to this very closely at moderate pressures. For the general elementary treatment of problems in thermodynamics it is often convenient, and permissible, to assume that we are dealing with a perfect gas, and that the internal energy at constant temperature is independent of the volume, which is expressed by

$$\left(\frac{\partial U}{\partial v}\right)_T = 0.$$

In the case of an actual gas, which obeys a more complicated law such as that of Van der Waals, the internal energy depends on the distance between the molecules, *i.e.*, on the volume, and a change of temperature is expected when it expands without doing external work. This may be either a cooling or a heating, and can be observed in a modification of the experiment, which will be described later. In any case the internal energy, U, is a unique function of the pressure, p, and temperature, T.

The relation above applies to a perfect gas during any change of volume at constant temperature. Suppose the gas expands in a cylinder with perfectly conducting walls, so that the temperature is kept rigorously constant while the gas does work through the piston. If the volume increases by dv at pressure p we can represent the work done by

$$W = \int p\,dv.$$

Since $pv = RT$
$$W = RT\int_{v_2}^{v_1} \frac{dv}{v} = RT\log_e \frac{v_1}{v_2}$$
$$= RT\log_e \frac{p_2}{p_1}.$$

If W the work done and Q the heat supplied were measured we should find that $Q = W$ and that the gas had served merely as a means of converting heat into work, the internal energy remaining constant. Since the mechanism in this hypothetical experiment is supposed to be perfect, the work done is now the maximum work which can be done by the gas when expanding isothermally.

When a liquid evaporates at constant temperature the volume increases at constant pressure, and the external work done is again expressed by:

$$W = \int p\,dv.$$

The total quantity of heat absorbed in the process is

$$Q = H_2 - H_1 = U_2 - U_1 + \int p\,dv,$$

where U_2 and U_1 are the internal energies of the gas and liquid, respectively. The quantity, $H = U + \int p\,dv$, calculated from some standard initial condition (*e.g.*, liquid at its normal boiling point), is called the total heat. Like the internal energy, it is a definite function of pressure and temperature in the gas phase. It is a convenient quantity in which to express energy changes in refrigeration processes, and has been tabulated for all gases of interest. In the case of the evaporating liquid, the change of internal energy is much larger than the work of expansion. Thus, use of a liquid for refrigeration allows a greater exchange of energy than a gas, for a given change of volume.

Adiabatic Expansion.—We may now consider what happens when a gas is allowed to expand, doing work, but in such a manner that no heat is absorbed, that is to say adiabatically. This actually happens in the high-pressure vessel in the Gay-Lussac-Joule experiment, and it becomes obvious when in a modification of the experiment by Joule, the vessels are contained in separate water baths. Though the temperature of the water in the bath enclosing both vessels has not altered, in the modified experiment, the water around the high-pressure vessel generally becomes cooled, and the water around the low pressure vessel generally becomes equally heated. If the cock is closed the moment expansion has taken place, when the temperature has finally become uniform, the pressure in the high-pressure vessel is found to be less than in the low-pressure vessel. The gas which remains in the high-pressure vessel may be supposed to do work in imparting kinetic energy to that part of the gas which flows into the low-pressure vessel. As the change takes place very rapidly no heat is absorbed. The kinetic energy of the moving mass of gas reappears as heat energy when the gas is brought to rest in the second vessel.

In order to analyze this problem we must first consider the change which takes place when a gas is heated. Suppose that one gram molecule of a gas is heated from T to $T + dT$, so that the pressure remains constant, the heat absorbed by the gas can be represented by: $dQ = C_p dT$, where C_p is the (molar) specific heat at constant pressure. If now we first of all consider the gas to be heated through an interval dT at constant volume, the increase in the internal energy is given by:

$$\left(\frac{\partial U}{\partial T}\right)_v dT = C_v dT,$$

C_v being the specific heat of the gas at constant volume. If now the gas is allowed to expand, doing maximum work, till the original pressure is reached, the work done is:

$$dW = p\ dv = RdT.$$

Then since $dQ = dU + dW$,

$$C_p dT = C_v dT + RdT$$
$$C_p = C_v + R.$$

Now since in any adiabatic process $dQ = O$,

$$C_v dT + p\ dv = O.$$

Substituting $p = RT/v$, and integrating:—

$$C_v \log_e T + R \log_e v = \text{Constant}$$

Writing γ for C_p/C_v, and substituting $C_p - C_v$ for R,

$$\log_e T + (\gamma - 1) \log_e v = \text{Constant},$$

or $$Tv^{(\gamma-1)} = \text{Constant},$$

and writing gas equation in the form:—

$$\log_e P + \log_e v - \log_e T = \text{Constant},$$

we obtain $$\log_e P + \gamma \log_e v = \text{Constant}$$

or $$pv^\gamma = \text{Constant}$$

This equation, which gives the form of the adiabatic curves for a perfect gas, shows that these, when represented on a pv diagram, are steeper than the isothermal curves, indicated by full lines (fig. 5). Suppose that a gas is compressed isothermally, so that the p–v relations are represented by the isothermal ab. When the point bb' is reached the gas is allowed to expand adiabatically. If the adiabatic curve (pv^γ= const.) passes within the region p–v on the diagram which represents conditions under which liquid can exist, as at d, partial liquefaction will result, as happened in the case of the experiments of Cailletet.

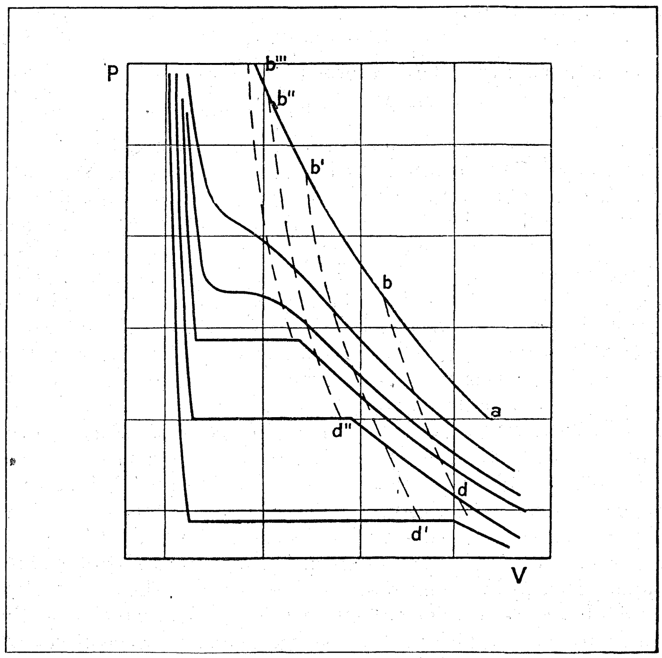

FIG. 5.—ADIABATIC AND ISOTHERMAL CURVES FOR PURE GASES

Liquefaction by Adiabatic Expansion.—When liquefaction does not take place the fall of temperature resulting on expansion from pressure p_1 to pressure p_2 is given by the following expression derived from the above.

$$\frac{T_1}{T_2} = \left(\frac{p_1}{p_2}\right)^{\frac{\gamma-1}{\gamma}}$$

The next experimental work of importance following the work of Andrews, and to which the theory which we have just considered applies, is that of Louis Cailletet. He used an apparatus, similar in principle to that of Andrews. The gas was confined over mercury in a glass tube, the capillary part of which projected outside a steel chamber, the lower part of which also contained mercury to which pressure was transmitted by means of water from a compression pump. The first gas to be investigated was acetylene, which was liquefied by pressure alone at the air temperature (critical temperature 35° C). However, on one occasion when the acetylene had been compressed to a degree insufficient to liquefy it, the release valve on the compression pump was opened, and immediately, as the gas within expanded, the capillary tube was seen to be filled with a dense mist. Cailletet did not at first realize that the cause of the appearance of the mist was the adiabatic cooling and partial liquefaction of the acetylene, and he put it down to the presence of impurity in the gas. As a second experiment with acetylene, prepared with great care, yielded the same result, he next filled the apparatus with nitrous oxide, and again observing the formation of mist on expanding the gas, he came to the conclusion that the phenomenon was due to the actual liquefaction of the gas. It was difficult to realize that such intense cooling could be effected by expanding so small a quantity of gas in a capillary tube, but having realized that this could be done, Cailletet at once proceeded to attack the problem of liquefying the so-called permanent gases. Methane, carbon monoxide and oxygen were in turn compressed to 300 atmospheres in the same apparatus, cooled to −29° C in a bath of sulphur dioxide boiling under reduced pressure, and then allowed to expand by releasing the pressure. In each case the tube was seen to fill with the dense mist, indicating that liquefaction had taken place, though no liquid was actually seen. This is not surprising, for in the case of diatomic gases having the value 1.4 for C_p/C_v, the theoretical cooling would be given by

$$(273-29)/T = 300^{(1\cdot4-1)/1\cdot4};$$
$$T = 48°\ \text{A.,}\quad \text{or}\quad -225°\ \text{C.}$$

This is equivalent to a fall of temperature of just under 200° C.

Early Researches on Mechanical Refrigeration.—At the same time similar experiments were being carried out by R. Pictet, a Swiss engineer, and pioneer of the process of mechanical refrigeration by the continuous liquefaction and evaporation of sulphur dioxide, and other gases which were easily condensed. To this work reference will be made later; for the moment suffice it to say that by condensing sulphur dioxide under three atmospheres pressure and evaporating the liquid *in vacuo* he reached −65° C. At this temperature he condensed carbon dioxide, and by evaporating the solid *in vacuo* he obtained a temperature which he stated to be −130°. To this temperature he cooled oxygen in a steel tube, connected with a steel retort in which it was generated under a pressure of 200 atmospheres by heating potassium chlorate. On allowing the cooled oxygen to escape at a pin valve he observed a jet of liquid oxygen, surrounded by a white cloud, which he took to be solid oxygen. The result was published almost simultaneously with that of Cailletet. Later he generated hydrogen under pressure in the same apparatus by heating potassium formate with caustic potash, and, on opening the pin valve, he thought that he saw a metallic steel blue substance issue from it, and strike the floor making a noise like a discharge of shot. Probably, the gas contained much carbon monoxide, which liquefied on expansion. On the authority of Pictet, many were led to believe that solid hydrogen would prove to be a metal, a suggestion which certain of its chemical properties seemed to support.

Liquefaction of Oxygen.—In 1883 the Polish chemists Wroblewski and Olszewski repeated Cailletet's experiment in a modified form, bending the capillary tube of the compression apparatus so that it could be immersed in a cooling medium. Also they attained an initial temperature lower than that which had been previously used, by cooling and condensing ethylene by means of solid carbon dioxide, and evaporating the ethylene *in vacuo*. The lowest temperature reached was now −136° C, and this temperature was measured by means of a hydrogen thermometer. Liquid oxygen was now seen for the first time in a static condition, and it was possible to measure its vapour pressure between $-136°$ C, and the critical point, $-119°$ C. Two years later, using a more perfect system of heat insulation, and evaporating ethylene under 10 mm. of mercury pressure, a temperature of $-152°$ C was reached, and both nitrogen and carbon monoxide were liquefied.

In 1885, using the same method, but with larger condensation tubes Olszewski liquefied larger quantities of oxygen, nitrogen and carbon monoxide, obtaining as much as 12 to 15 cu.cm. of liquid at the critical points and two to three cu.cm. of liquid at the boiling points. By evaporating a very small quantity of liquid nitrogen *in vacuo* he obtained solid nitrogen, and by reducing the pressure to six mms. of mercury the temperature indicated by the hydrogen thermometer was $-225°$ C, the lowest temperature recorded to a much later date. In 1886 Dewar, at the Royal Institution, obtained 22 cu.cm. of liquid oxygen by compressing the gas into a copper coil, cooled in liquid ethylene, from which it was allowed to expand through a pin valve into a glass vessel, also cooled in liquid ethylene. He then proceeded to construct a plant on the lines of Pictet's original apparatus with cycles for carbon dioxide and ethylene, and in 1892 obtained as much as a pint of liquid oxygen. Reference will be made to this work later. In the meantime Olszewski had extended his investigations, and though he apparently never obtained more than 100

(a) a steel cylinder in which oxygen is compressed and cooled, (b) pressure gauge, (c) compressed oxygen reservoir, (d) expansion valve for oxygen, (e) receiver for liquid oxygen, (f) steel cylinder containing liquid ethylene, (g) coil surrounded by a mixture of carbon dioxide and ether evaporating *in vacuo*, (h) expansion valve for ethylene, (m) vessel surrounding (a) in which ethylene is liquefied and evaporated *in vacuo*

cu.cm. of liquid oxygen, his work is of particular interest on account of the methods used, and also because his investigations provided reliable measurements of critical constants and vapour pressures which are, in some cases, still accepted. His work is described in a paper in the *Philosophical Magazine* for the year 1895. The apparatus is shown in fig. 6. The cylinder *f* contains ethylene, and is cooled in a freezing mixture. The liquid ethylene flows through the coil in the vessel *g*, which contains a mixture of solid CO_2 and ether at $-78°$ C. The cooled liquid flows through a pin valve into a chamber *m*, made up of concentric

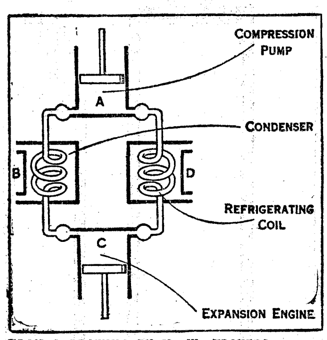
FIG. 7.—OLSZEWSKI'S LIQUID HYDROGEN APPARATUS

(a) steel vessel in which oxygen is compressed and cooled, (b) pressure gauge, (c) reservoir for compressed hydrogen, (d) expansion valve for oxygen, (e) receiver for liquid oxygen which is evaporated *in vacuo*, (f) vessel in which hydrogen is compressed and cooled by liquid oxygen, (l) expansion valve for hydrogen, (i) pipe leading to vacuum pump, (h) vacuum gauge

glass vessels, and in *m* it evaporates at a very low pressure maintained by a large exhaust pump connected with it through the tube *i*. Inside *m* is a steel vessel *a* connected with a cylinder *c* containing compressed oxygen. The oxygen liquefies under pressure in *a* at the temperature of the liquid ethylene boiling *in vacuo*, and the progress of liquefaction is observed by the movements of the gauge *b*. When the gauge comes to rest the vessel *a* is full of liquid. The valve on the steel vessel *c* is then closed, the pin valve *d* is opened, and the liquid runs from *a* into *e*, where it boils under atmospheric pressure, a considerable portion of it evaporating in the process. In this way about 100 cu.cm. of liquid oxygen were obtained, sufficient to enable experiments to be carried on for an hour. Olszewski applied the methods and technique which he had developed in researches on the vapour pressure and critical constants of all important gases, and though the data which they furnished has been largely superseded this work must be placed among the classics. It remains to refer to his attempts to liquefy hydrogen. The apparatus is shown in fig. 7; the lower part of the liquid oxygen vessel is shown at *a*. Both vessels *c* and *k* contained compressed hydrogen, the former communicating with the glass tube *f*, the latter connecting with a copper tube leading to the bottom of the chamber *e*. A stream of hydrogen passed through the liquid oxygen in *e*, and made it boil evenly *in vacuo*. The tube *f* contained a light inner shell to insulate the contents. Hydrogen was compressed into it at a series of increasing pressures up to 140 atmospheres and was then allowed to expand and when the pressure had fallen to 20 atmospheres in each case the phenomenon of liquid in ebullition was observed. Olszewski certainly saw hydrogen in the liquid condition for the first time, but his conclusion that the critical pressure was over 20 atmospheres was not justified.

Development of Mechanical Refrigeration.—While physicists were endeavouring to liquefy the so-called permanent gases, engineers were developing methods of mechanical refrigeration by the continuous condensation and evaporation of volatile liquids. In the ideal plant the liquid and vapour circulate continuously through a system which is illustrated by the diagram in fig. 8. The cylinders a and c are connected through coils of pipe b and d so that circulation can take place in the direction $abcd$. When the piston in a is operated mechanically, vapour is drawn from the coil d, and on the return stroke the vapour is compressed, we can suppose adiabatically, and enters the condenser coil b, where it is condensed isothermally at temperature T', by water circulating outside the coil at, let us say, the air temperature. The liquid flows into the cylinder c, and here it evaporates, doing work adiabatically, the energy being transmitted by the piston to some machine outside the plant. The gas, now cooled below the air temperature to temperature T, entering the refrigerator coil d, cools the surrounding medium, which may be a solution of brine, as in a refrigerating plant, or a less easily condensable vapour, as in a Pictet gas plant. This machine takes heat from the cold refrigerator coil, and gives up heat to the warm condenser coil. That is, heat is transferred from a low temperature T to a higher temperature T', an action which, by the second law of thermodynamics, requires a net expenditure of work. The process is cyclic, since the working substance returns to its initial condition. If the machine were perfect, that is, if the pistons were frictionless and if there were no exchange of heat except in the coils b and d, it would also be thermodynamically reversible. Reversing the direction of flow, liquid could be drawn from the cold coil d and forced into b under pressure. The warm coil b would then act as the boiler of a steam engine; in it the liquid would absorb heat and evaporate, still under pressure. In this case there would be a net gain of work, at the expense of the heat absorbed in the boiler b.



FROM A DRAWING BY M. W. TRAVERS

FIG. 8.—DIAGRAM ILLUSTRATING CYCLIC PROCESS FOR PRODUCING COLD

Possibly the most important process in which the liquefaction of gases plays a part is mechanical refrigeration, which is the subject of a separate article. Next in importance comes the liquefaction of gases for transport. Easily liquefied gases, such as ethyl chloride, methyl chloride and sulphur dioxide, may be stored and transported in glass containers, metal containers being used for substances which condense at higher pressures at atmospheric temperature. Among these must be reckoned carbon dioxide, nitrous oxide, acetylene (which is condensed with a solvent such as acetone in a steel container filled with an absorbent such as kieselgur), ammonia, chlorine, hydrochloric acid and sulphuretted hydrogen. In the case of gases which exert a corrosive action in presence of water, care must be taken to exclude moisture. The pumps and coils must be made of material which is not attacked by the gas to be condensed.

In a practical mechanical refrigerator, or in the continuous liquefaction of easily condensed gases, the adiabatic expansion in the engine c is omitted. The liquid, condensed under high pressure in the coil b, passes directly to the cold coil d, which it enters through a throttle valve. At this valve the pressure drops nearly to atmospheric, and some of the liquid evaporates, without doing external work. This cools the remainder of the liquid to its boiling point under the lower pressure. The cold liquid collected in d can be used for refrigeration, or can be drawn off in the liquid form. The passage through the throttle valve is not reversible, and there is some waste energy, which is compensated by a gain in simplicity and practicability.

Theory of Continuous Production of Cold.—In the ideal reversible process described above let Q be the amount of heat taken away from the cold coil, which is at absolute temperature T; Q represents the useful cooling. Let Q' be the heat given up to the warm coil, at temperature T', and let W be the net amount of work done on the system. In the ideal process there is no other exchange of energy, and so

$$Q'=W+Q, \text{ or } W=Q'-Q.$$

It can be proved, as a consequence of the second law of thermodynamics, that the reversible process is the most efficient possible for given temperatures T and T'. That is, the ratio Q/W, of useful cooling to work required, is the greatest possible. Further, it can be proved that

$$\frac{Q}{T}=\frac{Q'}{T'}, \text{ or } \frac{Q}{W}=\frac{Q}{Q'-Q}=\frac{T}{T'-T}.$$

T and T' are here temperatures on Kelvin's absolute thermodynamic scale, which is independent of the working substance. This scale cannot be realized directly, but it can be proved that it is the same as that of a thermometer which uses the hypothetical perfect gas. The behaviour of a perfect gas can be determined from that of real gases, such as hydrogen and helium, which obey the gas law closely, by measuring their expansions under different pressures, and extrapolating to zero pressure. Thus the corrections necessary to reduce a hydrogen or helium thermometer to the absolute scale can be determined. The absolute zero, $T=0$, corresponds to a temperature of $-273.16°$ C., or

$$T=t+273.16.$$

It follows from the relation above that the amount of work necessary to effect a certain useful cooling increases very rapidly at extreme low temperatures. It follows also that the absolute zero can never be attained, for no heat can be withdrawn when $T=0$. The efficiency increases if $T'-T$ is kept small; less work is required to attain a given low temperature if the cooling is carried out in several steps, rather than in a single machine.

If heat Q is absorbed or given up by the working substance at absolute temperature T, the quantity

$$\phi-\phi'=Q/T$$

is called the change of entropy. The absolute values of the entropy need not be considered, as it is necessary only to deal with differences. Entropy is a definite thermodynamic function, and tables have been compiled giving the entropy values of most important gases, reckoned from a standard condition, *e.g.*, from liquid at the normal boiling point. Since there is no exchange of heat in an adiabatic expansion, the entropy remains constant; such a change is also called isentropic. Since $Q/T=Q'/T'$ in the ideal reversible refrigerator, there is no net change of entropy in this process. The general condition for any reversible cyclic process, in which the temperature varies continuously, is that the entropy remains constant. This may be written

$$\int\frac{Q}{T}dT=0,$$

the integral being taken around the cycle.

It is convenient to represent changes, such as those which take place in refrigeration machines, on a diagram in which the coordinates are entropy and temperature. In fig. 9, point 1 corresponds to the working substance entering the refrigerator coil at the lower temperature T. In this coil heat Q is taken in at constant temperature, and the change is represented by the line 1–2. The area below this line represents the product $(\phi-\phi')T$, which is equal to Q.

If the values of ϕ are known for the states corresponding to 1 and 2, Q can be calculated. The process of adiabatic compression in the cylinder a involves no heat transfusion, so that entropy is constant, and we pass along the vertical line from 2 to 3. The process of isothermal compression is represented by the horizontal line 3–4, and the heat rejected in the process by $-(\phi'-\phi)T'=Q'$ which is the area of the space below the line. The shaded space between the lines thus represents the work W done in transporting a quantity of heat Q from a lower temperature T to a higher temperature T'. The unshaded space represents the corresponding refrigerating effect, so that overall efficiency of the process is represented by the ratio of the unshaded area to the shaded area. The efficiency of a completely reversible cycle of the kind which we have considered is independent of the nature of the working substance, and the elementary theory would suggest that, by regulating the compression and expansion, the temperature on the cold side could be completely controlled, the quantity of heat transferred being dependent upon the quantity of gas circulated and the absolute temperatures between which the cycle was worked. However, when we deal with problems from the practical standpoint, we at once find that a plant in which the working substance is air must necessarily be larger than one working with ammonia, which circulates mainly as a liquid.

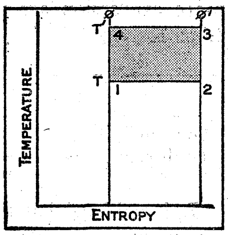


FIG. 9.—TEMPERATURE-ENTROPY DIAGRAM FOR REFRIGERATING CYCLE

The Cascade Process for Liquefaction of Oxygen.—The first process for the continuous production of liquid oxygen or liquid air in quantity, as used by Dewar and by Kammerlingh Onnes, employed a series of gases of successively lower boiling points, as in Olszewski's experimental liquefier. For this reason it is commonly known as a cascade process. The apparatus is illustrated in fig. 10. By the compressor A methyl chloride or carbon dioxide is pumped into the condenser coil B, which is cooled by water circulation. Since the methyl chloride is below its critical temperature, it is liquefied by this isothermal compression. The liquid then passes through the throttle valve C into the evaporator D_1, where its pressure drops to approximately atmospheric. Some of the liquid evaporates, and this cools the remainder to its normal boiling point. The compressor A_1 circulates ethylene, which is liquefied under pressure in the coil B_1, at the temperature of boiling methyl chloride. The liquid ethylene passes through the throttle valve C_1, and is cooled at the expense of partial evaporation. The pressure in the ethylene evaporator D_2 is reduced to 1 to 2 cm. of mercury by a vacuum pump. At this pressure the boiling point of ethylene is less than the critical temperature of oxygen ($-119°$ C.). Thus oxygen compressed by the pump A_2 into the condenser B_2, immersed in the boiling ethylene, is liquefied in its turn. Finally, the liquid oxygen is drawn off through the valve C_2, and is cooled to its normal boiling point by partial evaporation.

Each stage of the cascade liquefier is identical in principle with the simple ammonia refrigerator. As in the latter, there is a non-reversible process involved at each throttle valve, and a consequent loss of efficiency. However, the loss is not serious because the working substance passes through the throttle valve in the form of mixed liquid and vapour. The change of volume is small, and the work which might be saved if the expansion were made adiabatic is also small. Actually the theoretical overall efficiency is high, because the cooling is carried out in steps, with a small temperature drop in each step, so that for each step $T/(T'-T)$ is comparatively large. The cascade liquefier is not used at present for the commercial production of liquid oxygen, but its possibilities should not be forgotten.

The amount of high pressure liquid which has to be evaporated in order to cool the remainder to the temperature of the refrigerator coil is easily estimated. Considering the methyl chloride stage, let q be the fraction of the gas circulated which is yielded as liquid at atmospheric pressure. This fraction is cooled from the temperature T' of the condenser to the temperature T, in the liquid state. It loses heat $qC_l(T'-T)$, where C_l is the average specific heat of liquid in equilibrium with its vapour, over the temperature range concerned. This loss of heat is given up to the fraction $1-q$, which is vaporized in the throttling process. Therefore,

$$qC_l(T'-T)=(1-q)L,$$

where L is the latent heat of vaporization at temperature T. Solving for q gives the result

$$q=\frac{L-C_l\,(T'-T)}{L}.$$

For methyl chloride, with a temperature drop from 20° to $-24°$ C., the yield of liquid is about 83%. In the ethylene and oxygen stages, with higher temperature drops, it is somewhat less. In the first two stages the useful cooling, the amount of heat Q which can be absorbed from the incoming gas of the next stage, is the latent heat of the liquefied fraction:

$$Q=qL=L-C_l(T'-T),$$

per gram of gas circulated.

The Joule-Thomson Effect and Porous Plug Experiment.—It has already been pointed out that the Gay-Lussac-Joule

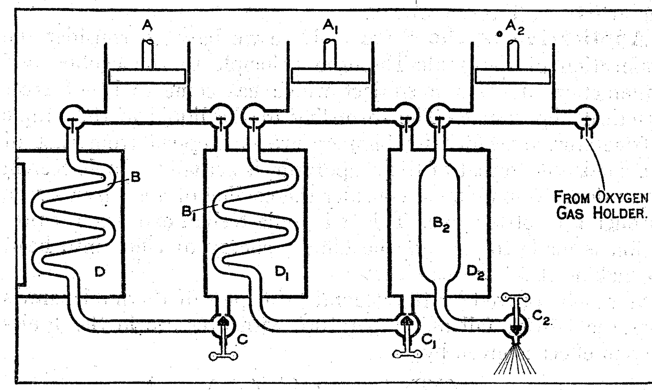

FIG. 10.—DIAGRAM OF THE CASCADE SYSTEM OF LIQUEFYING OXYGEN
The oxygen is compressed into B_2, which is cooled by liquid ethylene, liquefied and evaporated in the cycle A_1 B_1 C_1 D_2. The ethylene is cooled and liquefied by means of carbon dioxide circulated in the system A, B, C, D_1, and the carbonic acid is in turn cooled by water passing through D, and further by expansion and partial evaporation in D_1

experiment was not sufficiently sensitive to detect a change of temperature in a gas expanding without producing external effect, as the heat capacity of the containing vessels and water bath was so large compared with that of the gas that only a change of temperature of several degrees in the gas would produce a noticeable rise in the temperature of the water. The determination of the magnitude of any temperature change which might occur was, however, important. In 1848 Prof. W. Thomson, afterward Lord Kelvin, had shown that the reversible thermodynamic cycle led to a method of defining temperature which was independent of any property of any material. Temperatures measured in this manner are referred to the absolute or Kelvin scale, and the nearest approach to the realization of this scale of temperature is the scale of a thermometer containing a gas whose properties approach to those of the perfect gas. Now in the Gay-Lussac-Joule experiment a perfect gas would undergo no change of temperature, and the change of temperature in any known gas, combined with certain other physical data, would make it possible to determine the departure of the scale of the thermometer containing that gas from the scale of the perfect gas thermometer, and would lead to a practical realization of the absolute scale.

In 1853 Thomson devised his classical porous plug experiment in which the difficulties arising in the Gay-Lussac-Joule experiment were practically eliminated, and he carried it out in conjunction with Joule. The improvement consisted in making the expansion of the gas continuous, instead of intermittent. The gas was pumped through a long coil of pipe immersed in a constant temperature water bath, and passed under pressures of between one and six atmospheres into the expansion apparatus, which consisted of a boxwood tube, a part of the length of which was plugged with cotton wool or silk fibre, slightly compressed between perforated brass plates 2.7 in. apart. The gas expanded to atmospheric pressure in passing through the porous plug. The gas enters at constant pressure p_1, and volume v_1 per unit mass, so that the work done when unit mass is forced through the plug is p_1v_1. Emerging at constant pressure p_2, the gas does work p_2v_2. Therefore the net work done on the gas is $p_1v_1-p_2v_2$, which must appear as an increase in the internal energy U. Thus

$$p_1v_1-p_2v_2=U_2-U_1, \text{ or } p_1v_1+U_1=p_2v_2+U_2,$$

that is, the total heat H is constant. For a perfect gas $p_2v_2=p_1v_1$, and U is independent of volume at constant temperature, so that there is no change of temperature in the porous plug experiment. For real gases there is either an increase or decrease of temperature, according as $pv+U$ decreases or increases in an expansion at constant temperature. At ordinary pressures and temperatures the effect is a heating for hydrogen and helium, a cooling for all other common gases. At very high temperatures or pressures all gases are warmed. In recent years Roebuck and his collaborators have repeated the Joule-Thomson experiment very carefully for a number of gases, in order to correct the gas thermometer scale to absolute temperature. The methods employed are described in the article on THERMOMETRY.

Application of the Effect.—Here we have to consider the application of the Joule-Thomson principle to the cooling and liquefaction of gases, a subject which has come to be of great practical importance. The throttling of the liquid in the simple refrigerator, by which its temperature is dropped from that of the condenser to that of the evaporator, is actually a Joule-Kelvin expansion. Now we must consider the cooling of a gas by passage through a throttle valve. This is a Joule-Kelvin expansion if provision is made to convert the kinetic energy of efflux into heat, by making the flow turbulent.

It can be proved by the general principles of thermodynamics that the rate of fall of temperature with pressure in the Joule-Kelvin effect is given by

$$k=-\left(\frac{\partial T}{\partial p}\right)_H=-\frac{1}{C_p}\left\{T\left(\frac{\partial v}{\partial T}\right)_p-v\right\}.$$

It is simpler, however, to assume that the gas obeys Van der Waals' equation, and to calculate the Joule-Kelvin coefficient k in terms of the constants of that equation. We can write

$$pv=RT-\frac{a}{v}+bp+\frac{ab}{v^2}$$

and by neglecting the last term

$$p_2v_2-p_1v_1=R(T_2-T_1)-a\left(\frac{1}{v_2}-\frac{1}{v_1}\right)+b(p_2-p_1).$$

The change in internal energy for a change in temperature dT is

$$-U=-\int\left(\frac{\partial U}{\partial T}\right)dT-\int\left(\frac{\partial U}{\partial v}\right)dv.$$

For the first term we can substitute $-C_v(T_2-T_1)$. We can obtain an expression for the second in terms of work against cohesion, of which a/v^2 in the Van der Waals equation is a measure, so that

$$\int\left(\frac{\partial U}{\partial v}\right)dv=\int_{v_1}^{v_2}\frac{a}{v_2}dv=-a\left(\frac{1}{v_2}-\frac{1}{v_1}\right).$$

We have therefore

$$-U=C_v(T_2-T_1)+a\left(\frac{1}{v_2}-\frac{1}{v_1}\right),$$

and the whole change is represented by

$$-C_v(T_2-T_1)=R(T_2-T_1)-2a\left(\frac{1}{v_2}-\frac{1}{v_1}\right)+b(p_2-p_1),$$

or approximately

$$C_p(T_2-T_1)=\left(\frac{2a}{RT_1}-b\right)(p_2-p_1);$$

finally, in degrees per atmosphere fall of pressure,

$$k=\frac{1}{C_p}\left(\frac{2a}{RT}-b\right).$$

If the units are litres, atmospheres, gram-moles and calories, the term within the bracket must be multiplied by 24.2, to convert litre-atmospheres into calories. We have then for oxygen and hydrogen the following values for the constants:—

	C_p	a	b
Oxygen	6.97	1.36	.0316
Hydrogen . . .	6.84	0.19	.023

In the following table the values of k calculated from the approximate expression are put down against the results of Joule and Lord Kelvin.

	t°C	k(calc)	k(found)	t°C	k(calc)	k(found)
Oxygen .	17.1°	0.281	0.255	91.6°	0.202	0.203
Hydrogen	6.8°	−0.021	−0.030	90.3°	−0.036	−0.044

It is evident that there should be an inversion of the effect at a temperature t_i given by

$$t_i+273=T_i=2a/Rb.$$

That is, there should be a cooling at temperatures less than t_i and a heating at higher temperatures. For hydrogen the calculated inversion temperature is −73° C., compared with an experimental value of −80° C. For oxygen the inversion temperature is about 620° C. According to the simple theory, the coefficient k and the inversion temperature should be independent of pressure. Actually k decreases with increase of pressure, and for pressures greater than about 12 times the critical pressure, there is no inversion, so that the effect is always a heating.

Cooling and Liquefaction by Free Expansion.—The suggestion to utilize the Joule-Kelvin cooling effect for liquefying gases appears to have been first attempted independently by C. Linde in Germany and W. Hampson in England. The first Linde plant was worked successfully in May 1895, and it produced several litres of liquid air per hour. This may be reckoned as the starting point from which important commercial developments followed. Hampson's apparatus was first exhibited in England in March 1896. His process is the simpler; it is admirably suited for the production of liquid air in small quantity for experimental purposes; and it has been very widely used in university and research institutions.

The success of liquefiers which depend for cooling on the Joule-Kelvin effect is due to the introduction of another equally important principle, that of regenerative cooling in a heat exchanger. The high pressure air enters through a closely wound coil of copper pipe, and expands through a throttle valve at the bottom. The expanding air is cooled by Joule-Kelvin effect, and the cool low-pressure air returns through the spaces between the copper coil, where it cools the incoming high-pressure air. This in turn expands and cools, and the temperature at the bottom of the coil becomes progressively lower. After a time a steady state is reached wherein the temperature at the bottom is low enough that the incoming high-pressure air can condense. Liquid then begins to form, and can be collected after passing through the throttle valve. With a properly designed heat exchanger, the temperature of the low-pressure air leaving the top is only about one degree lower than that of the high-pressure air entering the coil, and nearly all the heat exchange takes place between the two streams of air, very little being absorbed from the surrounding atmosphere.

Hampson's Air Liquefier.—A section of the Hampson apparatus is shown in fig. 11. The compressed gas enters at A and passes to the gauge, shown in elevation, through B to C, where the pipe forms four branches which are wound together to form the regenerator coil. The four pipes unite at D below the valve N, which is controlled by the spindle OO. The compressed air expanding at N is partially liquefied, the liquid collecting in E, and the vapour passing back between the coiled pipes of the regenerator, and escaping through an outlet P. Liquid air is drawn off through the valve G, which is operated by F. The gauge H contains glycerol, and is connected below and above the level of the liquid in E by pipes K and M. The height to which the glycerol rises in M indicates the depth of the liquid in E. The efficiency of the process is of course dependent on the temperature at which the air enters the coil, the pressures at the inlet and at the outlet and the mean value of k for the inlet temperature, and the range of pressure involved. In a well-constructed apparatus the difference of temperature at the inlet and outlet is of the order of one degree, and may be neglected. If the gas were simply allowed to expand without passing back through the coil, the fall in temperature would be given by

$$C_p \times k \times (P_1 - P_2).$$

If the gas returned through the coil and q per cent of it liquefied the heat absorbed in the process would be

$$(C'_p(T'-T)+L)q/100$$

when C'_p is the mean (molar) specific heat between the initial temperature and the boiling point of the gas, and L is the (molar) heat of evaporation. Equating these expressions in the case of oxygen compressed to 180 atmospheres, with $T'-T=200°$ and $k=0.25$, the expected yield is about $9\frac{1}{2}\%$. Bradly and Rowe (*Phys. Review,* 1904) found the yield of a Hampson liquefier to be 8.5% of the air passed through it.

Linde's Air Liquefier.—The Linde system depends upon the same principle as the Hampson system, but differs in that the air is not expanded to the atmospheric pressure, but to an intermediate pressure of about 17 atmospheres. The unliquefied fraction returns through the heat exchanger at this pressure, and re-enters the compressor at the second stage. Thus the work of compression is reduced to a little more than half, because most of the air has only to be re-compressed from 17 to 180 atmospheres, and only enough to replace the fraction liquefied has to be taken in at atmospheric pressure. The yield is about the same, since the reduction in cooling effect caused by the smaller pressure drop is compensated by smaller values of $T'-T$ and L. Hence, there is an important gain in efficiency, as we should expect, since the ratio $T/(T'-T)$ is smaller. If the final product is to be liquid air at atmospheric pressure, there is a loss of liquid in the throttling from 17 to 1 atmosphere, but this does not outweigh the advantages. Many industrial liquid air plants, and plants for the separation of oxygen from air, use the Linde process. In large plants it is usual to precool the compressed air entering the heat exchanger by a methyl chloride or ammonia refrigerator. This further increases the efficiency, because the irreversible Joule-Kelvin cooling is replaced by the relatively efficient refrigeration process over just that part of the temperature range where the coefficient k is smallest. However, there is no advantage in merely cooling the gas at the inlet to the heat exchanger, since the expanded gas would leave the plant at a temperature below that to which the compressed gas was cooled by the carbon dioxide. This difficulty is overcome by utilizing the cold gas to cool the compressed gas before it enters the carbon dioxide refrigerator. The arrangement of the apparatus is illustrated by the diagram (fig. 12). The air is compressed in two stages by the cylinders a and b, and the returned air from the liquefier re-enters the compressor at the intermediate stage at c. The compressed air at 180–200 atmospheres passes through a water separator d, and a purifier e, to the heat exchanger f, in which it is cooled by the cold compressed air from the liquefier. From f the compressed air passes through g, where it is cooled by the circulation of carbon dioxide, as in the cascade system already described. It then enters the main heat exchanger, a short section of which is represented by h. It consists of a triple coil of copper pipes. Through the inner pipe passes the high-pressure air. Through the middle space, the air at 17 atmospheres pressure returns to the compressor, very effective exchange of heat being obtained between these streams of compressed air flowing in opposite directions. Through the outer space flows a stream of the coldest air at atmospheric pressure, serving as a heat insulating layer. At the valve m expansion takes place, and here the pressure falls to 17 atmospheres. When the steady state is reached, partial liquefaction takes place, the liquid collecting in l and the unliquefied air passing by m to the middle pipe of the regenerator coil. The liquid flows through the valve n, and the pressure falling to atmospheric pressure in o, it is partially evaporated, the vapour passing by p to the outer pipe of the heat exchanger, the liquid being drawn off through q. The air returning through the outer pipe of the coil amounts to about one-fifth of the whole; it passes out of the system at r, but actually may be used to cool part of the incoming air by passing it through a subsidiary heat exchanger, similar to f. The air entering the middle section of the regenerator coil by m passes to s, and from there to the heat exchanger f, and to the intermediate pipe of the pump c.

FIG. 11.—DIAGRAMMATIC CROSS SECTION OF LIQUID-AIR MACHINE
Compressed air passes downward through regenerator coil LL, expands at valve N, expanded gas passing upward outside coil. Progressive cooling partially liquefies the air. Liquid air collects in E, and is drawn off at bottom of apparatus

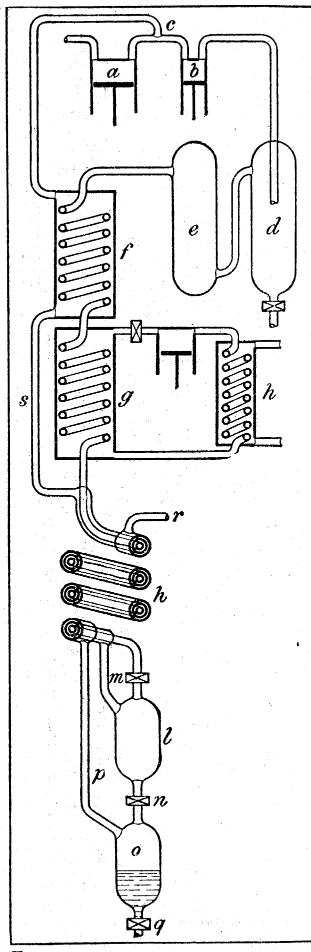

FIG. 12.—THE DIAGRAM ILLUSTRATES THE PROCESS OF LIQUEFYING AIR BY FREE EXPANSION AFTER PRELIMINARY COOLING ON THE CASCADE PRINCIPLE

The immediate result of the development of a process for liquefying air continuously on a large scale was the invention by Linde of a practical method of fractional distillation of the liquid air for the production of oxygen, which will be described later.

Claude and Claude-Heylandt Liquefiers. — Another method of increasing the efficiency of an air liquefier, which was first suggested by Lord Rayleigh, involves a return to the principle of the ideal reversible refrigerator, by the introduction of an expansion cylinder or turbine into the system in place of the expansion valve, thus making the gas do external work. In May 1902, Claude succeeded in building such a machine, and in liquefying air by adiabatic expansion in the cylinder of an expansion engine. The liquid was actually formed inside the engine, and a method was devised for collecting it from the exhaust. However, the method proved impractical because, apart from the difficulty of collecting the liquid, the amount of work done in the expansion engine becomes small when the liquefaction point is reached, and an unwieldy engine is necessary in order to obtain a reasonable yield. Claude's machine was therefore soon modified into what is known as the *Claude-Heylandt liquefier.* Claude-Heylandt and Linde machines, between them, now produce nearly all the liquid air consumed in industry.

The Claude-Heylandt process makes use of an expansion engine for most of the cooling, followed by a throttle valve expansion for the actual liquefaction. The principle is shown in fig. 13. Air at about 40 atmospheres pressure enters the first heat exchanger X_1, where it is cooled to about $-70°$ C. by returning cold air. After leaving X_1 the high pressure stream divides, and about 80% passes into the cylinder of the expansion engine E. The air expanding in the engine does work, and is thereby cooled to about $-125°$ C. The cold air from the exhaust of the engine passes into the bottom of the second exchanger X_2, where it cools the remaining 20% of the incoming air. The exhaust air then continues upward through the first exchanger, to cool the whole mass of incoming air to the temperature of the engine intake. The 20% fraction of the incoming air continues downward through a third exchanger X_3 to the valve V_4, where it expands without doing work, and is cooled to the liquefaction point by the cumulative Joule-Kelvin effect. Unliquefied air from the expansion valve returns through all three heat exchangers, so that its cooling effect will not be wasted. Thus the cooling from intake temperature to $-125°$ C. is effected by the nearly reversible expansion in the engine, and from $-125°$ to the liquefaction point, the range where adiabatic expansion is relatively ineffective, the Joule-Kelvin effect is used. The liquid is collected in a vacuum flask L, from which it can be drawn off through the valve V_3. V_1 and V_2 are valves controlling the proportion of air which passes through the expansion engine; while the column is being cooled down, V_1 is kept closed until the exchanger X_2 has reached its proper temperature. Valve V_5 admits new air to the intake of the compressor, to replace the air liquefied. W is an after-cooler on the compressor, so that air entering the exchangers is cooled at least to the temperature of cold water. T, T, T are gas thermometers attached to the bottom of each exchanger coil. The overall efficiency of the Claude-Heylandt process is high, especially in large plants, as shown by the following figures (from Greenwood, *Industrial Gases*, 1920):—

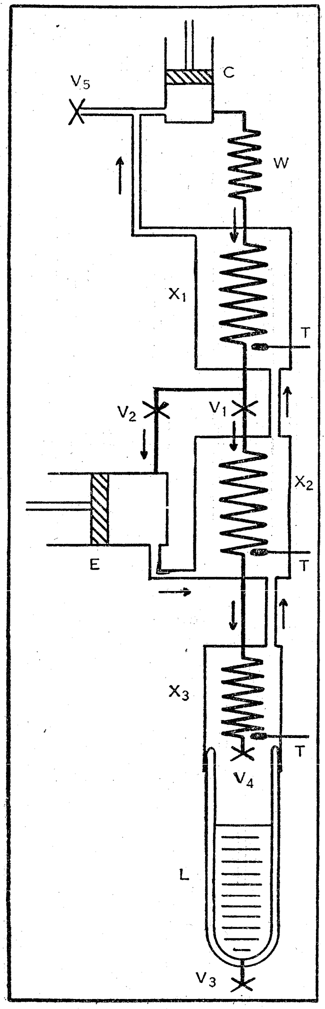

FIG. 13.—CLAUDE-HEYLANDT LIQUEFIER, USING COMBINATION OF ADIABATIC AND FREE EXPANSIONS

Capacity of Machine in Litres per hour		5	50
Output in litres per kilowatt hr.	by Linde process	—	0.45
	by Linde process, with pre-cooling	0.35	0.64
	by Claude-Heylandt process	0.36	0.93

The expansion engine is usually a reciprocating engine, although Kapitza in 1940 described a large experimental plant in Russia, in which a high-speed turbine was used. The amount of work recovered in the expansion engine is small, and it is not practical to return it to help drive the compressor; it is sometimes used to generate electricity for lighting. Lubrication of the engine is a problem on account of the low temperature. Claude first tried light petroleum, and then the liquid air itself. Modern practice is to use an unlubricated piston, with soft leather or graphite rings. During World War II, small Claude-Heylandt liquefiers were brought to a high degree of efficiency, for the production of oxygen gas in small quantities, where transport of gas cylinders was difficult. The low pressure required is an especial advantage in such plants.

Purification of Air Before Liquefaction.—For any continuous liquefaction process the gas entering the heat exchangers must be free from any vapours which would condense and freeze at the cold end of the column. Those usually present in air are water vapour and carbon dioxide, which have to be removed by passing the air through a series of towers containing caustic potash. The purifiers may be located either on the intake of the compressor, or in the high-pressure pipe leading from the compressor to the first exchanger. In order to save as much as possible of the purification, the returning unliquefied air, which is already pure, is re-circulated. In spite of this, the purifiers add greatly to the weight and bulk of a liquid air machine. In some of the small liquefiers mentioned above, the purifiers have been eliminated by using a reversing heat exchanger in the first stage. In this device the incoming and outgoing pipes are of the same size, and are soldered together along their length to ensure good heat conduction. Impure air enters the machine through one pipe, and is cooled by the outgoing cold air in the other pipe. The impurities condense in the pipe, and in time block it. After a certain interval the flow through the pipes is reversed by an automatic valve. The outgoing gas then collects and carries away the impurities which were deposited in the first pipe.

Liquefaction of Hydrogen.—The early attempts to liquefy hydrogen have already been described. The first to obtain liquid hydrogen in quantity for experimental purposes was Dewar at the Royal Institution. His earliest experiments were carried out in 1895, and were described in a paper read before the Chemical Society in 1898. Hydrogen from a cylinder of compressed gas was cooled first by a freezing mixture of solid carbon dioxide and ether, and then by liquid air, to about $-180°$ C. At this temperature, hydrogen is well below the inversion point of the Joule-Kelvin effect ($-80°$ C.). The gas then passed through a heat exchanger to an expansion valve, where it was cooled by free expansion. The cold gas returned through the heat exchanger, to cool the incoming gas. Thus the principle was the same as that of the Hampson air liquefier. Dewar does not seem to have obtained static liquid with this apparatus, but the temperature fell very low. For insulation he used his beautiful invention, the vacuum vessel, which is described later, and which is an outstanding contribution to low temperature technique. Dewar then built a large hydrogen liquefier, of which a description was never published. In referring to it he wrote: "the arrangement appeared so promising that in the next two years there was laid down in the laboratories of the Royal Institution a large plant (it weighs two tons and contains 3,000 ft. of pipe), which is designed on precisely the same principles, though far more elaborate." With this plant he obtained first small quantities and afterward large quantities of liquid hydrogen. In 1898 he published the first quantitative observations on the boiling point and density of the liquid. In 1899 he succeeded in manufacturing a litre of the liquid. In the year 1900 M. W. Travers published an account of a laboratory apparatus, embodying the same principles, but weighing less than 30 lb., and which could be operated in connection with a compressor, or by means of hydrogen compressed into cylinders at 125 atmospheres, and which was capable of producing half a litre of liquid hydrogen after pre-cooling with about five litres of liquid air. Olszewski improved this apparatus, of which a convenient form is shown in diagram (fig. 14). The hydrogen under pressure, after passing through a cylinder containing solid potash, enters the apparatus by the pipe a, which is of solid drawn copper of $\frac{1}{8}$-in. bore. Passing inside the casing o, the pipe divides, one

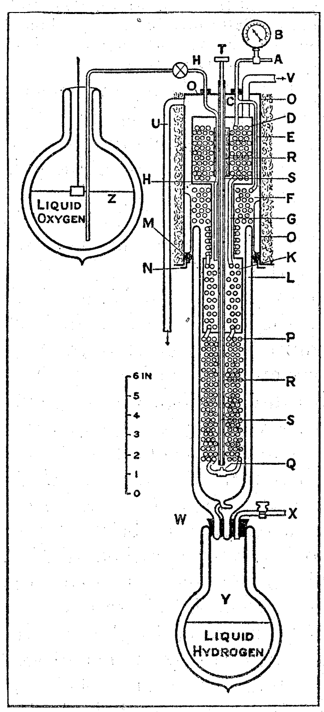

FIG. 14.—TRAVERS' HYDROGEN LIQUEFIER AS MODIFIED BY OLSZEWSKI

Compressed hydrogen cooled to liquid temperature is further cooled by free expansion and partially liquefied branch forming the coil in the chamber *d,* and continuing as *g* to form one of the twin coils in the chamber *k.* The other branch *e* leads through *c* to form the coil *f,* and continues as the other of the twin coils in *k.* Below *k* the tubes are wound closely together to form the regenerator coil *pp,* and unite in the valve *q,* which is operated by the rod *ss* passing right through the liquefier in the casing *r,* and operated by wheel *t.* The lower part of the apparatus is enclosed in the vacuum vessel *ll.* An exhaust pump is connected with the outlet *v* from the chambers *k* and *d,* which are connected by a constricted neck. By this means liquid air or oxygen can be drawn from the vessel *z* through the pipe *h* into *k,* where it evaporates under reduced pressure, the vapour passing upward through the chamber *d.* All the compressed hydrogen passes through the twin coils in *k* and is cooled at least to $-150°$, and economy of liquid air is effected by using its vapour to cool that fraction of the incoming hydrogen which passes through the coil in *d.* After expanding at the valve *q* the unliquefied hydrogen passes upward through the interstices of the regenerator coil, then between the vacuum vessel and the outside of the chamber *k,* and through the interstices of the coil *f,* cooling that part of the hydrogen entering the apparatus by this route, before it enters the other of the twin coils in *g.* The expanded hydrogen leaves the apparatus by the pipe *u.* At *mn* is shown the rubber ring and gland which connect the glass vacuum vessel with the metal parts of the apparatus. Liquid collected in the bottom of *l* passes into the vacuum vessel *y* when the tap *x* is opened to release the gas. Most subsequent hydrogen liquefiers have used Olszewski's method, with only mechanical improvements. One difficulty has always been to obtain sufficiently pure gas. In particular, it is very difficult to remove the last traces of nitrogen, which solidifies and plugs the expansion valve. In 1932 Kapitza and Cockcroft described a hydrogen liquefier in which this difficulty is almost eliminated. Very pure hydrogen is circulated in a system similar to that of Olszewski, and is liquefied. Commercial hydrogen at a pressure a little above atmospheric is passed through a coil immersed in the pure liquid. The impure hydrogen liquefies at the expense of evaporating the pure liquid. The pure gas is then recirculated through the liquefier proper. Since the quantity of impure gas liquefied is practically equal to that of pure liquid evaporated, there is very little loss of efficiency. The impurities collect as solids in the liquid hydrogen container, and settle to the bottom. Liquid hydrogen can be kept for a few hours, and transported, in a vacuum vessel, surrounded by an outer vessel of liquid air. Poured into an open vessel it evaporates very rapidly; and while the vapour can be ignited, solid air condenses and crusts the bottom of the vessel. A litre of the liquid weighs only 60 grams. When the pressure is reduced to 55 mm. of mercury the hydrogen solidifies; the solid having a glassy appearance and melting at $-259°$. Pressure raises the melting point by $0.4°$ per atmosphere.

FIG. 15.—ONNES' HELIUM LIQUEFIER

Helium is liquefied by cooling to liquid hydrogen temperature, followed by free expansion

Liquefaction of Helium.—The liquefaction of helium was ultimately achieved by Onnes in July 1908. His final liquefier is shown in fig. 15. The principle was identical with that of the apparatus used for liquefying hydrogen; and just as the hydrogen in the liquefier was cooled to liquid air temperature before entering the regenerator coil, the helium was precooled to the temperature ($-258°$ C.) of liquid hydrogen boiling *in vacuo.* The helium under a pressure of 30 atmospheres entered from the compression apparatus at the top, and divided so as to pass through two coils *B* and *B′*, which were cooled externally by the currents of cold hydrogen and helium leaving the apparatus. The coils in *B* and *B′* unite at their lower ends, and the pipe through which the helium flows passes to the top of the apparatus, where it again divides, forming two separate coils which pass through the chambers *C* and *C′*, through which flow the cold hydrogen and helium. The coils again unite at the bottom of the chambers *CC′*, and from *D* a single coil enters the chamber *E,* into which liquid hydrogen is drawn from the vacuum vessel shown on the left of the apparatus through the valve *H.* A vacuum is maintained in *E* by an exhaust pump connected with the outlet of the chamber *B,* the hydrogen gas under low pressure following the path indicated by the arrow. The compressed helium now enters the regenerator coil *F,* expands at the valve *K,* passes back through the interstices of the regenerator, through the chambers *C′* and *B′* to the outlet. A single vacuum vessel surrounded the whole of the lower part of the apparatus, and the liquid helium collecting in this vessel was forced (in later experiments), into the receiving vessel shown on the right of the apparatus. This was surrounded by a series of concentric vessels containing in order liquid hydrogen, liquid air and alcohol. The boiling point under atmospheric pressure was found later to be $-268.9°$ C.

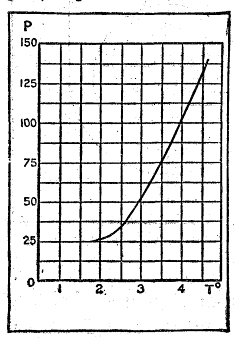

FIG. 16.—MELTING POINT CURVE OF SOLID HELIUM

Onnes immediately set to work to attempt to solidify helium by boiling the liquid under reduced pressure. On the day on which helium was first liquefied (July 1908) the first attempt was made, the pressure being reduced to about 7 mm. Finally using a battery of condensation pumps, the ultimate method for producing a high vacuum, when a pressure of 0.013 mm. and an estimated temperature of $0.82°$ absolute was reached, the "helium still remained a thin liquid." But it was not for Onnes to achieve the final triumph, which was accomplished by his colleague and successor, Prof. Keesom. Just as the melting point of hydrogen is raised by increasing the pressure, it was possible that by increasing the pressure on the helium the melting point might be brought within the range of temperature already attained. Helium was therefore compressed into a glass tube (a metal contrivance was first used) containing a piece of iron rod, which could be moved by a magnet outside the apparatus. The glass tube was cooled to a series of very low temperatures, and, although it was impossible to differentiate visually between solid and liquid helium, it was quite clear that under certain conditions of temperature and pressure the piece of iron became fixed in the tube. Thus, on June 26, 1926, every known substance had been liquefied and solidified. The relationship of these pressures and temperatures is shown in the diagram. It will be seen that the curve does not meet the vapour pressure curve for the liquid, which lies too close to the horizontal axis to be represented. It is now evident that, at pressures less than 22 atmospheres, helium would remain liquid even to the absolute zero. On the other hand, in 1929 Simon produced solid helium under a pressure of 5,800 atmospheres at a temperature of $-231°$ C., far above the critical temperature of the liquid. It appears that the critical state applies to the liquid phase only, since the same has been found true for solid hydrogen and solid neon.

Kapitza's Helium Liquefier.—The necessity of producing large quantities of liquid hydrogen in order to liquefy helium is a great inconvenience, and introduces an element of danger. In 1934 P. Kapitza designed a helium liquefier in which the liquid hydrogen is eliminated by using an adiabatic expansion of helium gas to bridge the gap between the temperature of liquid nitrogen and the inversion point of the Joule-Kelvin effect in helium

($-243°$ C.). Helium at a pressure of 20–30 atmospheres is pre-cooled to $-208°$ C. by liquid nitrogen boiling at reduced pressure. It is then liquefied in a cycle which works on the same principle as the Claude-Heylandt air liquefier. The system of heat exchangers is shown in fig. 17. The compressed helium enters at the top, and passes first through exchanger *A,* where it is cooled by the return flow of evaporated nitrogen and cold low-pressure helium. It then passes through a coil which is attached to the liquid nitrogen chamber *N,* and is cooled to $-208°$ C. Leaving this coil, it is further cooled in exchanger *B* by returning low-pressure helium. The incoming stream is then divided, so that part passes through the expansion engine *E,* where it does work, and is cooled to about $-263°$ C. The cold exhaust helium from the expansion engine cools the remainder of the incoming stream in the exchanger *C.* Finally, this fraction passes through an expansion valve at the bottom, and is partially liquefied by a Joule-Kelvin expansion, combined with regenerative cooling in the heat exchanger *D.* The whole apparatus is surrounded by a vacuum jacket for thermal insulation, and the liquid helium reservoir is further protected by a copper shield which is attached to the liquid nitrogen chamber. The liquid helium is drawn off for use in experiments through another valve, connecting to a double-walled, vacuum insulated delivery pipe. The expansion engine presents some interesting features. The engine cylinder, $1\frac{1}{4}$ inches in diameter, is located in the centre of the apparatus, surrounded by the exchanger coils for protection from atmospheric heat. It is connected by a long rod, which passes up through the centre of the liquefier, to the piston of a small water pump, to absorb the work of expansion. It is designed to have a quick expansion stroke, and a slow return, so that the cold helium gas will not be expelled at a velocity too high to absorb heat from the exchangers. Liquid lubrication is obviously impossible; instead, a small clearance is left between the piston and the cylinder wall, where high-pressure gas accumulates and forms a cushion. The leakage of gas past the piston is reduced by making it relatively long, and by cutting grooves around it, so that the flow will be highly turbulent. The liquefier produces about 2 litres of liquid helium per hour, and requires about 3 litres per hour of liquid nitrogen, with an additional 10 litres for the preliminary cooling.

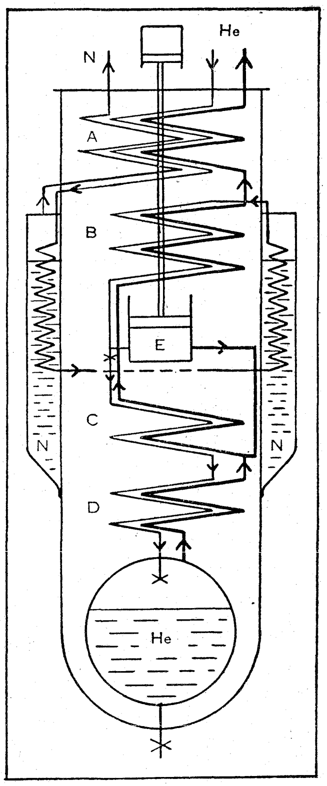

FIG. 17.—KAPITZA'S HELIUM LIQUEFIER

Simon's Method for Liquid Helium.—In 1927 F. Simon described for the first time a simple method of producing liquid helium for experimental purposes. It represents, in fact, a return to the principle of Cailletet's early experiments, in that a single adiabatic expansion is used. However, whereas Cailletet could only produce a mist of liquid oxygen, the fact that liquid helium is comparable in density with the gas at easily attainable pressures makes the yield of liquid very much greater in this case. The method is illustrated in fig. 18. Helium gas at about 150 atmospheres is passed through coils *A* and *F* into a container *B,* which is suspended by fine wires inside an outer vessel *C.* The whole is immersed in liquid hydrogen in a vacuum flask *D,* and the space *C* is filled with helium gas at low pressure. The temperature is reduced as low as possible by pumping off the hydrogen vapour, the gas in *C* allowing the removal of heat from the compressed helium in *B.* When *B* is cooled to the temperature of the liquid hydrogen, *C* is evacuated through the pipe *E* to the best possible vacuum. The helium in *B* is then allowed to expand adiabatically, and part of it liquefies. Starting with helium gas at 150 atmospheres at about $-260°$ C, enough liquid can be condensed to fill up to 80% of the volume of the vessel *B.* The expansion is carried out quite slowly, so that liquid will not be carried away with the gas stream, and the approach to adiabatic conditions is obtained through the excellence of the thermal insulation. This also makes it possible to keep liquid helium in the apparatus for several hours. Simon's method is especially adapted for experiments at liquid helium temperatures when the mass of other material to be cooled is small. The liquefier chamber can be built into the experimental apparatus, and many different forms have been used. On occasion, over a litre of liquid helium has been produced, and transfer to another vacuum vessel is possible if necessary.

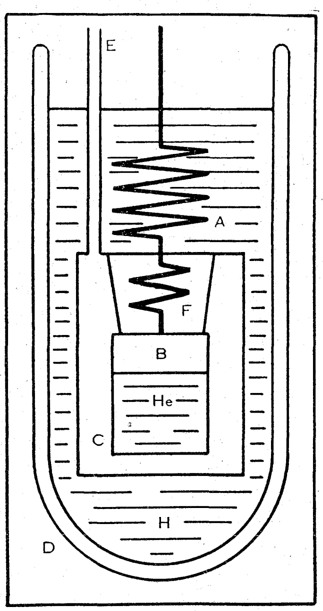

FIG. 18.—SIMON'S SINGLE EXPANSION METHOD FOR LIQUID HELIUM

Liquid Helium II.—In studying the properties of liquid helium, Onnes found a sharp maximum in the density-temperature curve at about 2.2° absolute, and that it was necessary to use different formulae to represent the vapour pressures above and below this point. Keesom found that other physical properties changed at the same temperature, and he came to the conclusion that there are two forms of liquid helium, which he called helium I and helium II. The liquid changes from form I to form II when it is cooled through the temperature 2.19° absolute, but there is no true phase change, since there is no latent heat of transition. Liquid helium II is a truly extraordinary substance, with properties unlike those of any other fluid. Its most striking property, discovered independently by Allen and Kapitza in 1938, is its ability to pass through the finest capillary tubes, with almost negligible resistance, so that it has been described as a superfluid. It wets any solid surface with which it is in contact, and spreads rapidly over the whole surface as a thin film. If an open vessel containing helium II is suspended inside the vacuum flask, the film spreads over the outside as well, and the liquid creeps over the edge, and drops off the bottom of the vessel. When a temperature difference is set up between the ends of a tube containing helium II, a kind of convective flow takes place, by which large quantities of heat energy are transported, producing an apparent thermal conductivity many times that of copper.

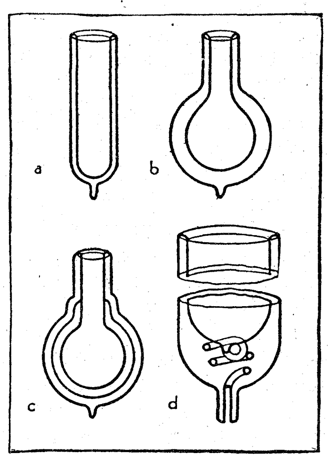

FIG. 19.—DEWAR VACUUM VESSELS

Dewar's Vacuum Vessel.—The invention of the vacuum vessel by Dewar has been of inestimable service to investigation at low temperatures. These pieces of apparatus are double walled vessels of glass or other material, the space between the walls being exhausted, and the walls either polished or silvered. The transfer of heat through a gas-filled space such as that between the walls of a Dewar flask (fig. 19, a) takes place in the following ways: (1) by radiation, which is proportional to $sa(T^4_1 - T^4_2)$ where s is the area and a the emissivity of the surfaces, and T_1, T_2

are the absolute temperatures; (2) by conduction through the gas, proportional to T_1-T_2 for moderate temperature differences; (3) by conduction in the walls of the container; (4) by convection currents in the gas (*see* HEAT: *Conduction in Gases and Liquids*). In a perfect vacuum gas conduction and convection currents would be completely eliminated; they are very small at gas pressures, less than 10^{-6} cm. of mercury. For a polished metal surface, the emissivity a is only a small fraction of its maximum value, that for a dull black body. Thus by polishing or silvering the warm wall the radiation emitted is decreased; by polishing the cold wall also much of the remaining radiation is reflected. There remains conduction by the walls; this can be reduced by using a long narrow neck, made of the thinnest material consistent with adequate strength. Dewar's original vacuum flasks were made of silvered glass, usually of the forms shown at *a* and *b* (fig. 19). Glass flasks are still used for certain scientific purposes, and a great variety of forms have been made. A flask with an extra wall, further to reduce radiation, is shown at *c* (fig. 19), one with a springlike outlet tube is shown at *d*. For most purposes, and especially for the storage and transport of liquefied gases, metal vacuum containers are now used almost exclusively. A form which is common for transport purposes is shown in fig. 20. This consists of two spheres of polished copper, connected only at the top of a long neck. An absorbent, charcoal or silica gel, is placed in a chamber attached to the inner sphere, but open to the vacuum space. When the container is filled, the charcoal is cooled by the cold liquid, and then absorbs much of the air still remaining in the vacuum, so that the efficiency of the insulation is greatly improved. For transport purposes the evacuated sphere is often suspended by heavy steel springs inside a protecting steel jacket. In a properly evacuated flask of this type, of 25 or 50 litres capacity, the loss of liquid air by evaporation is 4 to 6% of the capacity per day.

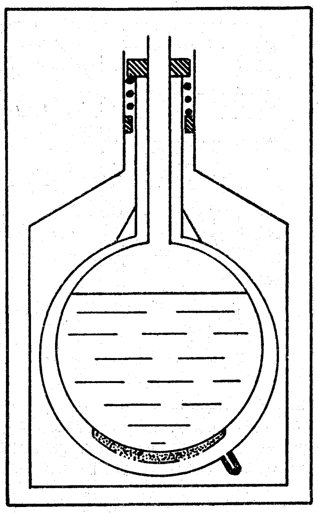

FIG. 20.—METAL VACUUM VESSEL

Physical Measurements at Low Temperatures.—The solution of problems relating to the liquefaction of gases demands the determination of their physical properties at low temperatures, and particularly the following: (1) boiling point and vapour pressures, (2) densities of liquid and vapour, (3) critical constants, (4) compressibilities, (5) specific heats. These investigations demand in the first place the means of maintaining sufficiently large spaces at constant temperature. This may be done conveniently by liquefying pure gases and allowing the liquid to evaporate in vacuum vessels under constant pressure. In this way the following ranges of temperatures may be maintained:—

	C C
Sulphur dioxide	−10° to −73°
Methyl chloride	−24° to −85°
Methyl dichlordifluoride ("Freon")	−28° to −90°
Carbon dioxide and ether constant at	−78.3°
Ethylene	−104° to −150°
Methane	−161° to −184°
Oxygen	−183° to −200°
Nitrogen	−196° to −210°
Hydrogen	−253° to −260°
Helium	−269° to −272°
Paramagnetic salts	below 1° absolute

The study of the physical properties of matter of all kinds down to the lowest possible temperatures has become a matter of prime importance in scientific inquiry. The technique of experimentation at low temperatures was largely developed at the Leyden Cryogenic laboratory, under Kammerlingh Onnes, through the years 1908–23. In 1923 a helium liquefier was built at Toronto; in 1939 there were at least 11 in operation: 4 in the U.S., 3 in Great Britain, and one each in Holland, Canada, the U.S.S.R. and Germany. Low temperature experiments have to be designed so that the apparatus can be enclosed in a cryostat filled with the cooling liquid. For liquid air and lower temperatures the cryostat has to be a vacuum vessel, and for liquid helium temperatures it is usually protected by an outer vessel of liquid air. Liquid air also finds many practical uses, both in the laboratory and in industry; for example, in chemical processes which require the condensation of other gases. It is also used in the production of high vacua, by introducing into the system a tube of charcoal cooled by liquid air, to prevent oil and mercury vapour from diffusing into the vacuum.

The Measurement of Low Temperatures.—In all cryogenic work the aim is to reduce temperature measurements to the absolute scale. Down to the boiling point of hydrogen the standard thermometer is the constant volume hydrogen or helium gas thermometer, with a pressure of 1,000 mm. of mercury at 0° C (*see* THERMOMETRY). The corrections necessary to reduce gas thermometer temperatures to the absolute scale are based on the principle that the latter scale would be realized by a perfect gas. Many experiments have been carried out in standardization laboratories to determine the deviations of hydrogen and helium from the perfect gas law, in order to correct the thermometer. Methods used have been: measurements under different pressures and extrapolation to zero pressure; measurements of the compressibilities; measurements of the Joule-Kelvin effect and calculation of the deviations. These experiments have served to fix the principal boiling and melting points on the absolute scale. For practical purposes electrical resistance thermometers, calibrated at the standard points, are very useful down to −250° C. In the liquid helium region the standard is a helium gas thermometer with a pressure of less than 1 mm. of mercury, the pressure being measured by a hot wire manometer. In the liquid hydrogen and liquid helium regions the usual practice is to use the vapour pressure of the liquid itself as a working thermometer. For this purpose the vapour pressures of hydrogen and helium have been carefully measured at Leyden, in terms of the low pressure gas thermometer.

Temperature, Pressure and Volume Relationships.—The relationship of temperature, pressure and volume for important gases has been determined over a wide range of pressures and down to very low temperatures by workers in the Cryogenic laboratory, Leyden and also in Berlin, and in Boston (Mass.), U.S. The method consists in compressing a known volume of gas into an apparatus similar to a gas thermometer, but much stouter, and measuring the pressure. When the pressure is large a considerable correction must be applied for the extension of the apparatus, and when the temperature of the bulb is far below that of the air, there is also a large correction for the volume of gas in the stem, and in the space above the mercury in the manometer. Owing to difficulty of estimating these corrections accurately the results obtained by different observers do not agree as closely as is desirable.

The volumes of saturated vapours and of the liquefied gases have been determined by a similar method, the liquid from a known volume of gas being condensed in a similar glass apparatus. However, errors are liable to creep in in the neighbourhood of the critical state, where the rate of change of volume with pressure is a maximum. Fortunately, the critical data can be determined by separate experiments. The critical temperature is observed by compressing the gas in a glass tube, and observing the appearance and disappearance of the gas-liquid boundary as the temperature is slowly changed, the volume being varied slightly at the same time. The critical pressure is observed in the same tube, when part of it is below the critical temperature and part above. The critical volume, which is the most difficult to measure, can be determined by measuring the specific volumes of the liquid and of the saturated vapour at temperatures a little below the critical, taking the average of these, and extrapolating the average to the critical temperature.

Measurement of the vapour pressures is also of the utmost importance, and reference has already been made to the comparison of the vapour pressures of hydrogen and helium with the standard gas thermometer. The vapour pressure can usually be represented by a formula of the form

$$\log p = a + bT - c/T,$$

where T is the absolute temperature, and a, b, c are empirical constants. This constant is partly based on integration of the Clapeyron equation (*see* below), and partly on empirical considerations.

Thermal Properties.—Values of the specific heats and latent heats of vaporization and fusion are also required. Specific heats at low temperatures are usually measured by means of a vacuum calorimeter. A sample of known mass is placed in a container, which is insulated from the liquid in the cryostat by a vacuum jacket. A known amount of heat is supplied to the sample electrically, and the rise of temperature is observed, usually by means of a resistance thermometer. The necessary correction for cooling is determined by observing the rate of fall of temperature after the electric current is shut off. The latent heats of vaporization and of fusion can be calculated from the Clausius-Clapeyron equation, which is a direct deduction from the second law of thermodynamics:

$$L=T(V-v)(dp/dT),$$

where L is the latent heat at temperature T, $V-v$ is the change of specific volume in passing from vapour to liquid or liquid to solid, and dp/dT is the slope of the vapour pressure or melting point curve. The latent heat of vaporization can also be measured by observing the amount of liquid vaporized by an electric current. When all these quantities have been determined, tables of entropy and total heat can be drawn up, and are of great value in the design of refrigerating machinery.

The Approach to Absolute Zero.—It is a principle of general thermodynamics that it is impossible to cool a body to the absolute zero of temperature, for an infinite amount of work would be required. However, the approach has been closer and closer with advances in scientific knowledge and experimental technique. In 1908 Onnes attained 0.82° Abs. by the rapid evaporation of liquid helium, and for many years this record was exceeded by only a few hundredths of a degree. In 1926 Debye and Giauque independently suggested that the attainable range of temperatures might be extended much further by making use of the so-called magneto-caloric effect (*see* MAGNETISM). When a substance is magnetized, work is done upon it, and conversely, when the magnetizing field is removed it loses energy, and is cooled if no heat is supplied to it. The effect depends on the rate of change $d\chi/dT$ of the magnetic susceptibility χ with temperature. At ordinary temperatures it is observable only for the ferromagnetic materials, and is of little practical importance. However, there are many paramagnetic materials which have very small susceptibilities at ordinary temperatures, but which obey approximately Curie's law,

$$\chi=\text{constant}/T.$$

If this law is still obeyed at liquid helium temperatures, both the susceptibility and the rate of change become large, and the estimated magneto-caloric cooling is of the order of a degree.

In 1933 Giauque successfully carried out the experiment, using the paramagnetic salt gadolinium sulphate, and reached an estimated temperature of 0.25° Abs. In 1935 De Haas reached the present record of 0.0034° Abs., using potassium chrome alum mixed with a non-magnetic salt, since diluting the salt causes it to follow Curie's law more closely. The salt is enclosed in a double-walled capsule, with a small pressure of helium between the walls. It is cooled to about 1.2° Abs. by liquid helium, and then magnetized in a field of about 25,000 gauss. The helium gas allows the heat generated by magnetization to be conducted away. The external field is then removed, the magnetized salt loses energy, and is cooled. It is not necessary to remove the helium from the capsule, because the temperature promptly falls so low that it is almost completely condensed. The temperature reached is determined by leaving a small magnetic field on the sample, and measuring the susceptibility. This allows the absolute temperature to be calculated if the specific heat is known over the temperature range concerned. The specific heat was therefore one of the first quantities to be measured when the method of cooling proved successful. This can be done by supplying energy to the salt at a known rate, and observing the rate of increase of temperature. One successful method of supplying the energy was irradiation of the salt with γ-rays from radium. A small quantity of added material can be cooled along with the salt in the capsule, so that other materials can be studied below 1° Abs., but technical difficulties have so far prevented any but the simplest experiments. The absolute zero cannot, of course, be reached; it is thermodynamically impossible for Curie's law to hold at the lowest temperatures, and $d\chi/dT$ must become zero eventually.

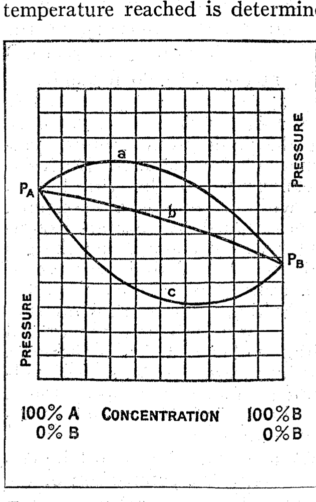

FIG. 21.—VAPOUR PRESSURE-CONCENTRATION CURVES FOR MIXTURES OF TWO LIQUIDS AT CONSTANT TEMPERATURE

Mixtures of Gases.—One of the most important applications of liquefaction of gases is to the separation of mixtures such as air by fractional distillation of the liquid. The vapour pressure of a pure substance depends only on the temperature; that of a mixture depends also on the composition. Further, the composition of the vapour in equilibrium with a mixed liquid is not, in general, the same as that of the liquid. The vapour pressures of a mixture of two gases A and B, at a constant temperature, may be shown on a pressure-concentration diagram (fig. 21), by a curve which terminates in the points P_a, P_b, the vapour pressures of the pure substances. For a certain range of temperatures the curves have the form *b*, lying wholly between horizontals through the end points. Curves can also be drawn showing the equilibrium compositions of the liquid and vapour, at a constant pressure, for various temperatures, as has been done for air at atmospheric pressure (fig. 22, from E. C. C. Baly). This curve shows that the vapour is richer than the liquid in the more volatile constituent *A*. If the liquid is allowed to evaporate, it becomes progressively richer in *B*, and the vapour pressure falls, following the curve *b* (fig. 21) until the residue of liquid is pure *B*; or, at constant pressure the boiling point rises. Thus the constituents of a gas mixture can be separated by liquefying it, and allowing the liquid to evaporate. At certain temperatures, the pressure-concentration curve has a maximum as in *a* (fig. 21), or a minimum as in *c*. In such cases the enrichment of the liquid proceeds only until the maximum or minimum is reached, after which it continues to boil at constant pressure, and the vapour has the same composition as the liquid. Therefore the fractional distillation process succeeds only over that range of temperatures where the curves have the form *b*.

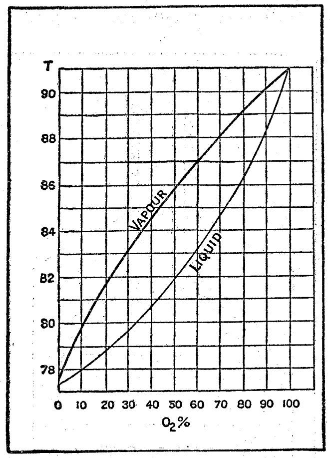

FIG. 22.—DIAGRAM SHOWING RELATIONSHIP BETWEEN TEMPERATURE AND COMPOSITION OF LIQUID AIR

Oxygen from Liquid Air.—The most remarkable result of investigations at very low temperatures has been the development of the process for the separation of oxygen from air. The boiling point of oxygen is —183.0°, while that of nitrogen is —195.8° C, so that unless the liquids form constant boiling mixtures, which is not the case, separation of the gases by liquefaction and subsequent rectification of the liquid presents no difficulties. The separation was first effected successfully by Linde on a technical scale in 1901. He adopted a method long in use by chemists for the separation of volatile liquids by distillation. Liquid air was allowed to trickle down a vertical cylinder, filled with glass balls, into a chamber at the bottom in which it was partially evaporated by cooled compressed air, passing through a coil immersed in it. The vapour passed upward, meeting the descending stream of liquid, which washed out the oxygen, so that the gas leaving the top of the cylinder was mainly nitrogen, with only 7% of oxygen, while liquid containing 96 to 98% of oxygen collected at the bottom. This liquid was drawn off and evaporated, and in this way 70% of the oxygen of the air could be separated with an impurity content of only 2% to 4%. Small oxygen plants of this simple type are in general use, but they are inefficient, as about one third of the oxygen is lost. Much more efficient separation is effected in plants operated on a principle first introduced by Claude in which the gas is fractionated in two stages, the first operated at about four atmospheres, and the second at atmospheric pressure. The working of the system is illustrated by the diagram of the separator (fig. 23). This is incorporated into a unit with an air liquefier of the Claude-Heylandt type, the separated oxygen and nitrogen being used in the return flow through the heat exchangers, in place of the expanded air in a simple liquefier. Sixty to 70% of the high-pressure air passes through the expansion engine, where it expands to 4 atmospheres, with external work. The remainder is partially liquefied by means of the usual heat exchanger and expansion valve. Both the liquid air from

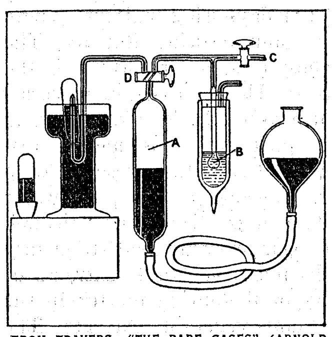
the liquefier and the cold expanded air from the expansion engine enter the chamber *A* at the bottom of the separator, through pipes *P* and *Q*. Here, since we have, at the first moment of condensation, a relatively small quantity of liquid in contact with a large quantity of vapour, a condition of equilibrium exists corresponding to that at the moment when air begins to liquefy, when we have a vapour phase containing rather less than 21% of oxygen, which is in equilibrium with a liquid containing rather less than 47% of oxygen. The air which is not liquefied passes upward through the vertical tubes *B* which traverse the chambers *C* and *D* which, as we shall see later, contain nearly pure liquid oxygen at about —183° C, and at nearly atmospheric pressure. The air, under nearly four atmospheres pressure, partially liquefies in contact with the walls of these tubes, and the liquid running back down the tubes, washes the oxygen out of the ascending stream of air, the liquid collecting in *A* having an average concentration of 40% oxygen. The gas, now poor in oxygen, passes from the top of the outer nest of tubes, down an inner set of tubes where most of it is condensed, its oxygen content being about 4%, and runs into the inner chamber *E*. The greater the quantity of the oxygen-nitrogen mixture which is condensed in *A*, the lower will be its oxygen content, and the richer in nitrogen will be the liquid which passes into *E*. Claude describes this part of the process as antecedent liquefaction and separation by backward flow. The essential feature is condensation at a pressure above atmospheric, and use of the heat of condensation to evaporate the liquid formed in the subsequent atmospheric pressure cycle. The liquids condensed in *A* and *E* are raised to the top of the fractionating column, which consists of a series of perforated trays. The nitrogen-rich liquid from *E*, throttled to 1 atmosphere pressure, enters the top of the column at *H*, at a temperature a little above the boiling point of nitrogen. As it trickles down, nitrogen is evaporated and oxygen is condensed from the rising stream of vapour, so that the liquid becomes progressively richer in oxygen. The oxygen-rich liquid from *A* joins the stream at *K*, where the composition in the column is the same as that of the added liquid. The liquid which finally reaches the bottom of the column is 99% oxygen, the impurity being largely argon. This collects in *C*, where it is used to aid in the condensation of the 4 atmosphere cycle. Finally the evaporated oxygen passes through the heat exchangers to a gas holder. The nitrogen gas from the top of the column is impure; provision is made to collect nearly pure nitrogen from an extra set of tubes connected to the liquid nitrogen chamber *E*. Oxygen plants of this type can produce 4,000 cu.ft. of oxygen per hour at an expenditure of about 180 B.H.P.

Linde has designed a separator similar in many respects to that of Claude, but using a liquefier of the Linde type. These separators are designed to deliver oxygen gas; modifications which deliver liquid oxygen, and use only the nitrogen fraction to cool the liquefier, are also in common use.

Oxygen in Industry.—Large quantities of oxygen gas are consumed in industry, and much of this is produced by one or other of the liquid air processes. The largest use is in conjunction with acetylene or hydrogen for cutting steel plate, and for welding steel and other metals. Plants for the production of oxygen have been established in almost all centres where there is a concentration of heavy industry. The gas is usually compressed into steel cylinders for transport, but these are heavy, and the return of empty cylinders creates a problem. In many large centres, oxygen is now transported in the liquid form, in tank trucks. A large bulk of the liquid can be kept without serious evaporation loss without vacuum insulation, and it is necessary only to cover the tanks well with insulating material. The liquid oxygen is first transferred to an evaporator, where heat is supplied to it, and the evaporated gas is pumped into the consumers' tanks.

In aeroplane flights above 10,000 ft. altitude it is necessary to add oxygen to the rarefied air breathed by the crew and passengers in order to maintain consciousness, or even life. During World War II this use added greatly to the demand for oxygen produced from liquid air, as this process yields gas uncontaminated with noxious impurities. Limited quantities are also used in hospitals, and, mixed with helium, for deep-sea diving. For use in aircraft, the gas is usually carried in cylinders, and is delivered to the crew through face masks, with valves to regulate the flow according to altitude. The cylinders are heavy, and a useful saving in weight can be effected by carrying liquid oxygen. Liquid oxygen systems for aircraft, consisting of vacuum containers and evaporators, have been developed on an experimental basis, but had not come into general use by 1945.



FROM TRAVERS, "THE RARE GASES" (ARNOLD & CO.)

FIG. 24.—APPARATUS USED BY RAMSAY AND TRAVERS FOR LIQUEFYING AND SEPARATING THE RARE GASES BY DISTILLATION

Charcoal impregnated with liquid oxygen is an explosive, and is used to a limited extent in mining operations. The type of charcoal used absorbs about three times its weight of liquid oxygen, approximately the correct amount to ensure complete combustion. The heat developed in the explosion is 1,940 large calories per kg., which is greater than that of blasting gelatine, but the combustion is slower. Where charcoal and liquid oxygen can be used, it has the advantage of comparative safety, since there are no noxious fumes and there is no risk in transport, before the charcoal and oxygen are combined.

The Rare Gases from Liquid Air.—The extraction of argon and neon from air has become a matter of commercial importance. Argon is used for filling the larger sizes of incandescent electric lamps; neon is used in gas discharge tubes, mainly for display purposes, on account of the brilliant red discharge which it produces. Argon boils at —185.7° C, a little below the boiling point of oxygen, and it tends to concentrate in the liquid on the lower trays of an air fractionating column. In some oxygen columns, a portion of the liquid is drawn off at this point, and passed through another column to extract the argon. Neon, which boils at —246° C, is the most volatile of the constituents of air (except for minute and variable amounts of helium), and is left as a gas when all the more plentiful constituents are condensed.

The principal source of helium is natural gas, which always contains small amounts, the proportion in some wells being as high as 3%. The commercial demand is much less than the available supply, and it is extracted only from the richest wells, principally from certain fields in Texas. To extract the helium, the natural gas, consisting mainly of methane and nitrogen with less volatile constituents, is liquefied by cooling to the temperature of liquid nitrogen. The gas left is mainly helium, which can be purified chemically, or by further cooling to the temperature of liquid hydrogen.

The rarer constituents of the atmosphere, krypton and xenon, are not of great commercial importance, but the investigations of Ramsay and Travers which led to the discovery of these gases are another interesting example of the application of low temperatures. By evaporating liquid air they first obtained a residue which consisted mainly of oxygen. The oxygen was removed, leaving argon, with some previously unknown, heavier gas as an impurity. This was introduced into the reservoir *A* of the apparatus shown in fig. 24. This communicated through a stopcock with a bulb *B* immersed in liquid air boiling under reduced pressure. The bulb *B* was exhausted, and then the stopcock *D* was opened, and the impure argon from *A* forced into the bulb *B*, where it liquefied. The liquid was evaporated in small quantities, six fractions of successively higher boiling point being collected. The least volatile portion remained in *B* as a liquid residue. The first two samples were discarded, and the remainder were retreated one by one. After several treatments the most volatile sample was nearly pure argon. The central samples, and final liquid residue were evidently new gases, to which the names krypton and xenon were given. These were also prepared in a nearly pure state by further treatment. A large quantity of the nitrogen fraction from liquid air was treated in the same way, and finally yielded a gas which could not be condensed with liquid air. This gas was named neon, and was purified by condensing the remaining nitrogen and argon with liquid hydrogen.

The melting point of ice on the absolute scale = 273.16° Abs. (International Congress on Refrigeration, 1936). Lowest temperature attained 0.0034° Abs. (De Haas, 1935). (*See* also HEAT; THERMODYNAMICS.)

LIQUEURS, the general term applied to perfumed or flavoured potable spirits, sweetened by the addition of sugar. The term "liqueur" is also used for certain wines and unsweetened spirits of very superior quality, or remarkable for their bouquet, such as tokay or fine old brandy or whisky.

The basis of all the "liqueurs," proper consists of (*a*) relatively strong alcohol or spirit, which must be as pure and neutral as possible; (*b*) sugar or syrup; and (*c*) flavouring matters. There are three distinct main methods of manufacturing liqueurs. The first, by which liqueurs of the highest class are prepared, is the "distillation" or "alcoholate" process. This consists in macerating various aromatic substances such as seeds, leaves, roots and barks of plants, etc., with strong spirit and subsequently distilling the infusion so obtained, generally in the presence of a whole or a part of the solid matter. The mixture of spirit, water and flavouring matters which distils over is termed the "alcoholate." To this is added a solution of sugar or syrup, and frequently colouring matter in the shape of harmless vegetable extracts or burnt sugar, and a further quantity of flavouring matter in the shape of essential oils or clear spirituous vegetable extracts. The second method of making liqueurs is that known as the "essence" process. It is employed, as a rule, for cheap and inferior articles; the process resolving itself into the addition of various essential oils, either natural or artificially prepared, and of spirituous extracts to strong spirit, filtering and adding the saccharine matter to the clear filtrate. The third method of manufacturing liqueurs is the "infusion" process, in which alcohol and sugar are added to various fresh fruit juices. Liqueurs prepared by this method are frequently called "cordials."

The French, who excel in the preparation of liqueurs, grade their products, according to their sweetness and alcoholic strength, into *crêmes, huiles* or *baumes,* which have a thick, oily consistency; and *eaux, extraits* or *élixirs,* which, being less sweetened, are relatively limpid. Liqueurs are also classed, according to their commercial quality and composition, as *ordinaires, demifines, fines* and *sur-fines.* Certain liqueurs, containing only a single flavouring ingredient, or having a prevailing flavour of a particular substance, are named after that body, for instance, *crême de vanille, anisette, kümmel, crême de menthe,* etc. On the other hand, many well-known liqueurs are compounded of very numerous aromatic principles. The nature and quantities of the flavouring agents employed in the preparation of liqueurs of this kind are kept strictly secret, but numerous "recipes" are given in works dealing with this subject. Among the substances frequently used as flavouring agents are aniseed, coriander, fennel, wormwood, gentian, sassafras, amber, hyssop, mint, thyme, angelica, citron, lemon and orange peel, peppermint, cinnamon, cloves, iris, caraway, tea, coffee and so on.

The alcoholic strength of liqueurs ranges from close on 80% of alcohol by volume in some kinds of absinthe, to 27% in anisette. The liqueur industry is a very considerable one in France. Among other well-known trade liqueurs may be mentioned maraschino, which takes its name from a variety of cherry—the marasca—grown in Dalmatia, the centre of the trade being at Zara; kümmel, the flavour of which is largely due to caraway seeds; allasch, which is a rich variety of kümmel; and cherry and other "fruit" brandies and whiskies, the latter being perhaps more properly termed cordials. (*See* also BENEDICTINE, D. O. M.; CHARTREUSE; CREME DE MENTHE; KÜMMEL.)

LIQUID AIR. A pale blue, paramagnetic liquid having a density nearly equal to water. It is chiefly a mixture of liquid oxygen (boiling point—183.0° C) and liquid nitrogen (boiling point—195.8° C). If the liquid is allowed to evaporate the mixture loses nitrogen and becomes much richer in oxygen. Louis Cailletet, in Dec. 1877, succeeded for the first time in liquefying air. Liquid air is prepared in large quantities in connection with the isolation of oxygen from the air. It is an article of commerce and finds many useful applications in the laboratory. (*See* LIQUEFACTION OF GASES.)

LIQUIDAMBAR, LIQUID AMBER or **SWEET GUM,** a product of *Liquidambar styraciflua* (family Hamamelidaceae), a tree native to the United States, Mexico and Central America. The earliest record of the tree appears to be in a Spanish work by F. Hernandez, published in 1651, in which he describes it as a large tree producing a fragrant gum resembling liquid amber, whence the name (*Nov. Plant.,* etc., p. 56). In Ray's *Historia Plantarum* (1686) it is called *Styrax liquida.* It was introduced into Europe in 1681 by John Banister, the missionary collector sent out by Bishop Compton, who planted it in the palace gardens at Fulham. The gum resin yielded by this tree has no special medicinal virtues, being inferior in therapeutic properties to many others of its class. It has long been used in France as a perfume for gloves, etc. It is mainly produced in Mexico. (*See* SWEET GUM.)

LIQUIDATION. A British joint stock company, being a purely artificial body created by law, can only be brought to an end by legal process. This legal process is called *liquidating,* or winding-up, the company.

A company may be wound up (1) *Voluntarily,* by the passing of a special or extraordinary resolution that it be wound up, and the appointment of a person to act as liquidator. The liquidator so appointed has to convene a meeting of creditors, and the creditors may, if they think fit, pass a resolution deputing some named person to apply to the court to appoint another person to act as liquidator, either with or in place of the existing liquidator. Ordinarily, the court would act upon such a request in cases where the company appeared to be insolvent. (2) *Under the Supervision of the Court.* This form of procedure is now practically obsolete. (3) *Compulsorily.* Here the procedure is analogous to that in *bankruptcy.* The official receiver takes charge of the company's affairs in the first instance, and it is the duty of the directors of the company to supply him with a sworn statement of its affairs. This *statement of affairs* is submitted by the official receiver to separate meetings of the creditors and contributories (or shareholders). Each meeting has a right to nominate a liquidator, who may be the official receiver; the official receiver reports the result of the meetings to the court, and the court thereupon appoints a liquidator.

Duties of Liquidator.—Whatever form the liquidation takes, it is the duty of the liquidator (1) to realize the assets of the company to the best advantage; (2) to adjust the rights of contributories *inter se; i.e.,* to determine what calls must be made upon the partly-paid shares of the company (if any) in order to provide for the payment of its debts, and to do justice to the different classes of shareholders; (3) to investigate the causes of liquidation, and if necessary to institute proceedings against any persons who may have contributed to its failure; (4) to distribute the proceeds of the realization of the assets among those entitled to participate, having regard to the priorities provided by law; (5) to close the liquidation, and provide for the final dissolution of the company.

On the appointment of a liquidator, the directors and all the former officers of the company cease to function, and the liquidator becomes the only officer capable of acting in the name of the company and using its *common seal*. In so doing he acts as agent of the company only.

Debenture-holders are secured creditors only to the extent of any specific or general charge that they may hold upon the assets of the company. Usually, a receiver is appointed to look after their special interests; but, in the absence of a receiver, it is the duty of the liquidator to see that, subject to payment of proper costs, the proceeds of the sale of all assets charged in favour of debenture-holders are applied (subject only to the rights of preferential creditors) first in satisfaction of debenture-holders' claims.

In the absence of express provision to the contrary, every share in the company carries equal rights and responsibilities. Thus, if all the shares are not fully-paid, the rights of the respective holders cannot be adjusted until either the partly-paid shares have been fully paid up, or a sum has been returned to the holders of fully-paid shares equal to that uncalled upon the partly-paid shares. But, of course, no return can be made to shareholders until all the debts of the company have been paid. (L. R. D.)

United States.—Although both liquidation and winding-up are terms in use in the United States, the legal process is most frequently called dissolution; and the dual forms refer to voluntary and involuntary dissolution. Liquidation is often used in the narrower sense of the actual disposition of the company's assets.

In a voluntary dissolution the directors usually act as liquidating trustees. In involuntary dissolution the receiver appointed by the court will liquidate the assets. There is no formal creditors' meeting provided for although such meetings are often called and act in an advisory capacity.

In comparing involuntary dissolution with bankruptcy, it should be noted that the bankruptcy statute excludes from its operation railroad, banking and insurance companies. The United States supreme court has further held that in many circumstances a public utility company may be compelled to continue operating even though its stockholders wish to dissolve. In such a case neither bankruptcy nor liquidation would be available to a railroad company. It has, however, been held that when a railroad company is operating at a continuous loss the courts and legislatures must allow it to liquidate. (J. L. We.)

LIQUID OXYGEN EXPLOSIVES: *see* Explosives: *Liquefied Gases.*

LIQUID STATE, THE. The states of aggregation of chemical substances are classified as gas, liquid and solid. Gases and liquids are distinguished from solids by the property of fluidity. Elastic solids resist both tensile and shear deformation with stresses proportional to the strains. They are therefore capable of supporting shearing stress at equilibrium. The representative fluid, obeying the Newtonian law of viscosity, resists shear deformation only with a stress proportional to the rate of strain. Fluids are therefore incapable of supporting shearing stress and, under the action of gravity, flow to adapt their shapes to those of their containers. The mechanical distinction between fluids and solids is not sharp. Many substances, notably certain high polymeric materials, exist in states exhibiting mechanical properties intermediate between those of the elastic solid and the viscous fluid.

Each substance possesses a critical temperature above which there exists but a single fluid phase. Above the critical temperature there is no distinction between gas and liquid. At each temperature below the critical there exists a pressure, called the vapour pressure, at which two fluid phases are capable of coexistence. The more dense is designated as the liquid and the less dense as the vapour. At pressures exceeding the vapour pressure the liquid is stable. At pressures less than the vapour pressure the vapour or gas is stable.

The boiling point of a liquid under constant external pressure is the temperature at which the vapour pressure becomes equal to the external pressure. Heated at constant pressure, a liquid remains stable until its boiling point is reached, when it is transformed to vapour with the absorption of heat. The heat absorbed in the vaporization of unit mass of liquid is called the latent heat of vaporization.

In general, substances possess one or more crystalline solid modifications. Some or all of them may be capable of coexistence with the liquid phase. At a specified external pressure, the temperature at which a crystalline solid and the liquid coexist is called the melting point of the solid or the freezing point of the liquid. When a liquid is cooled to the freezing point, it is transformed into the solid with the liberation of heat. The heat liberated when unit mass of liquid is transformed into solid is called the latent heat of fusion. Noncrystalline solids, for example glassy or vitreous materials, generally do not possess definite melting points, but soften gradually to a liquid phase with increasing temperature. Noncrystalline solids are frequently unstable with respect to transformation to crystalline phases, but the rate of transformation may, as in the case of glasses, be exceedingly slow.

Substances are observed to possess triple points of specified temperature and pressure at which solid, liquid and gas may coexist. At pressures below that of the triple point the liquid is no longer stable. When the solid is heated below the triple point pressure, it sublimes to vapour without passing through an intermediate liquid phase.

Liquids in contact with their own vapours or with air possess a property called surface tension which, unless opposed by external forces, causes the interface to reduce to minimum area. Therefore, in the absence of gravity and other external forces, the stable form of a mass of liquid is spherical. Surfaces between a liquid and a solid or another immiscible liquid are also characterized by interfacial tensions, which determine whether the liquid in question will wet or spread on the other material.

As a rule, substances possess only one liquid modification. Exceptions are found in the case of helium which possesses two liquid forms and in certain substances, for example para-azoxyanisole, which possess optically anisotropic liquid crystalline phases as well as a normal liquid phase.

The Molecular Structure of Liquids.—The structure of substances on the molecular scale is determined by a balance between the ordering influence of intermolecular forces and the disordering influence of thermal motion. At low temperatures the influence of intermolecular forces predominates to give the well-ordered structural characteristics of the crystal lattice. At high temperatures the influence of thermal motion predominates to give the random and featureless structure of a gas. The structure of liquids corresponds to a degree of order intermediate between that of the crystalline solid and that of a gas.

The structure of an ideal crystal is characterized by a high degree of order and organization in the arrangement of the atoms and molecules of which it is composed. This order is described by the theory of space lattices. There exists a fundamental unit of structure composed of a small number of atoms or molecules in a definite geometrical configuration. The crystal lattice is built up as a periodic reproduction of the fundamental unit in the three directions of space. Real crystals possess various types of disorder such as mosaic structure and lattice dislocations as well as thermal disorder associated with lattice vibrations and lattice defects.

When a crystalline solid melts to the liquid, the long-range order of the crystal lattice is destroyed. However, a residue of local order persists in the liquid state. Each molecule maintains a partially ordered arrangement of its neighbours which is a blurred replica of that of the crystal lattice. This vestigial order lacks the long-range character of that of the crystal lattice and becomes imperceptible at distances greater than several molecular diameters.

The local order characteristic of the liquid state is described by the radial distribution function $g(R)$, defined as the ratio of the average local molecular density $\rho(R)$ at a distance R from an arbitrary molecule to the bulk density ρ_0 of the liquid.

$$\rho(R) = \rho_0 g(R) \qquad (1)$$

A radial distribution function everywhere equal to unity corresponds to a completely random or disordered structure. Departures of $g(R)$ from the value unity measure the local order established by a molecule in the arrangement of its neighbours. For the representative liquid, $g(R)$ is a curve which possesses a series of rapidly damped maxima and minima. The positions of the maxima roughly correspond to the first several co-ordination shells of the crystal lattice characteristic of the solid state of the material. The minima correspond to distances intermediate between co-ordination shells. The local order described by the radial distribution function lacks the sharpness of crystalline order and is appreciable only at distances of a few molecular diameters. The resemblance of liquid structure to crystalline structure is therefore limited to a domain of molecular dimensions in the vicinity of any molecule. The radial distribution function specifies only the average local density, from which significant statistical fluctuations must occur as the neighbours of a specified molecule are interchanged with other molecules in the course of thermal motion.

The experimental determination of the radial distribution function is based upon the measurement of angular distribution of intensity of X-rays scattered by the liquid, according to techniques developed by F. Zernicke and J. A. Prins and by P. Debye and H. Mencke. A beam of monochromatic X-rays is allowed to traverse a small sample of the liquid, confined in a glass capillary or in the form of a jet. The intensity of the scattered radiation is recorded as a function of scattering angle on a photographic plate, in an ionization chamber, or with a Geiger-Müller counter. An X-ray scattering photograph of a liquid resembles to a certain extent a Debye-Scherrer powder diagram of a crystalline solid. However, instead of the well-defined rings of maximum intensity of the powder diagram, a liquid gives only a few broad and diffuse rings of rapidly diminishing intensity.

From the intensity $I(\vartheta)$ of the X-rays scattered by a liquid in a direction making an angle ϑ with the incident beam, the radial distribution function may be calculated with the aid of the Fourier integral theorem. The relationship may be expressed in the following manner,

$$\begin{aligned} g(R)-1 &\approx \frac{1}{2\pi^2 R}\int_0^\infty s\,i(s)\sin(sR)ds \\ i(s) &= (I/I_e - Nf^2)/Nf^2 \\ s &= (4\pi/\lambda)\sin\theta/2 \end{aligned} \tag{2}$$

where I_e is intensity of radiation scattered by a single electron, λ the X-ray wave length, and f the form factor of the atoms of which the liquid is composed. The Fourier integral may be evaluated with the aid of an harmonic analyzer or other mechanical computing devices.

Although the X-ray scattering technique is strictly applicable only to a monatomic liquid, it may be employed in an approximate fashion to obtain worthwhile qualitative information concerning the structure of polyatomic liquids when the scattering can be principally attributed to a single type of atom or when the form factors of the several types of atoms composing the molecules are not significantly different in magnitude.

Quasi-crystalline models of local liquid structure may be used to advantage in the interpretation of the radial distribution function. While it is recognized that long-range crystalline order is absent, the local arrangement of the neighbours of each molecule is regarded as a blurred replica of the first several co-ordination shells of a single crystal lattice or of a superposition of several lattice types. The number of neighbours in each diffuse co-ordination shell is estimated as the integral of $4\pi R^2\rho_0 g(R)$ under the corresponding peak of the radial distribution function.

Quasi-crystalline analysis of the radial distribution functions of the liquid metals, for example sodium and mercury, leads to the conclusion that the local structure corresponds to a close-packed arrangement of spheres. J. D. Bernal and R. H. Fowler have employed the quasi-crystalline model with great success in interpreting the structure of liquid water. The liquid is regarded as a three-dimensional net in which each water molecule is linked to four neighbours by hydrogen bonds. By superposing co-ordination structures of the β-quartz, trydymite, and closed-packed types, a radial distribution function, yielding an X-ray scattering curve in substantial agreement with experiment, may be constructed. At low temperatures the β-quartz structure predominates, and at high temperatures the contribution of the closed-packed structure increases. Many of the anomalous properties of water, for example, the maximum density at 4° C., are accounted for by the Bernal-Fowler model.

The structure of the liquid paraffin hydrocarbons has been interpreted along similar lines by B. E. Warren. In these liquids, the structure approximates the arrangement realized in the axial close-packing of slender rods. The X-ray scattering curves of the aliphatic alcohols exhibit inner peaks not observed for the corresponding hydrocarbons. This peak may be qualitatively interpreted, if it is assumed that the alcohol molecules are linked in chains by hydrogen bonds between the hydroxyl groups, while the aliphatic radicals remain approximately close-packed as in the corresponding hydrocarbons. Similar qualitative interpretations of the structures of many organic liquids can be made.

The investigation of the relation between liquid structure and intermolecular forces involves difficult problems in statistical mechanics which have received only partial solution. The statistical mechanical theory of molecular distribution in liquids has been studied by J. E. Mayer and J. G. Kirkwood. An approximate integral equation relating the radial distribution function to the potential of intermolecular forces has been formulated by J. G. Kirkwood and solved by Kirkwood and E. Monroe for a system of rigid spherical molecules without attractive forces. The theoretical distribution function possesses the general characteristics of the experimentally determined radial distribution functions for representative liquids.

The Thermodynamic and Mechanical Properties of Liquids.—The thermodynamic properties of an homogeneous liquid in equilibrium are determined by its equation of state,

$$p = f(T, v) \tag{3}$$

which specifies the pressure p as function of the temperature T and the specific volume v, and by its specific heat as a function of temperature at a constant value of the pressure. The equation of state cannot be expressed in closed form in terms of elementary mathematical functions, but simple analytical approximations may be used for limited ranges of the variables. In general, the compressibilities and thermal expansion coefficients of liquids are not very sensitive to pressure, away from the critical state. However, the compressibility decreases slowly with increasing pressure.

Heterogeneous equilibrium between liquid and vapour or liquid and crystalline solid is described by the Clapeyron equation.

$$\frac{dp}{dT} = \frac{L}{T\Delta v} \tag{4}$$

where L is the heat absorbed and Δv is the specific volume increment in the transition. This differential equation determines the pressure p as a function of temperature T for states of coexistence of the liquid and the contiguous phase. Thus, when applied to liquid-vapour equilibrium, it determines the vapour pressure as a function of temperature.

According to statistical mechanics, the thermodynamic behaviour of a liquid is determined on the molecular scale by the forces acting between the molecules of which it is composed. The intermolecular force between a pair of molecules is one of repulsion at small distances and one of attraction at large distances. The repulsion at small distances prevents molecules from interpenetrating to an appreciable extent and gives them an effective size. The attraction at large distances is called the van der Waals force and is responsible for the general cohesive properties of matter. The potential $V(R)$ of a pair of chemically saturated spherical molecules or atoms, for example argon, situated at a distance R from each other may be approximately represented by the expression, formulated by J. E. Lennard-Jones,

$$V(R) = \frac{\lambda_1}{R^s} - \frac{\lambda_2}{R^6} \tag{5}$$

where λ_1 and λ_2 are constants and s is an exponent in the neighbourhood of 12. The first term, dominating at small intermolecular distances, gives rise to repulsion, and the second, dominating at large distances, gives rise to the van der Waals attraction.

According to J. E. Mayer, the pressure p is related to the potential of intermolecular force $V(R)$ and the radial distribution function $g(R)$ in the following manner,

$$pv = RT - \frac{2\pi N}{3}\rho_0\int_0^\infty R^3\frac{dV}{dR}g(R)dR \tag{5}$$

where V is the molar volume, N is Avogadro's number, R the gas constant, and T the absolute temperature.

The molar heat of vaporization is related to the potential of intermolecular force and the radial distribution function through the formula,

$$L = RT - 2\pi N\rho_0\int_0^\infty R^2 V(R)dR \tag{6}$$

where the symbols have the same significance as in equation (5).

The statistical mechanical theory of liquid structure has been approached from another standpoint by H. Eyring and J. Hirschfelder and by J. E. Lennard-Jones and A. F. Devonshire. In these theories the quasi-crystalline model of local liquid structure is employed to estimate the free volume accessible to each molecule, in which it is supposed to execute gas-like thermal motion. The free volume is much smaller than the total volume per molecule, since each molecule is caged by its neighbours. According to the free volume theories, the equation of state has the form,

$$p = RT\left(\frac{\partial \log v_f}{\partial v}\right)_T - \left(\frac{\partial E}{\partial v}\right)_T \tag{7}$$

where v_f is the free volume and E is the molar internal energy. The several free volume theories prescribe different models upon which to base the calculation of v_f. They have been very successful in reproducing the empirical equations of state of many liquids.

In fluid mechanics the relation between the stress tensor σ and the rate of strain $\dot{\epsilon}$ is of primary importance. For the Newtonian fluid in which the principal shearing stresses are proportional to the corresponding rates of strain, this relation is

$$\sigma = -(p + \tfrac{2}{3}\eta\nabla\cdot\boldsymbol{u})\mathbf{1} + 2\eta\dot{\epsilon} \tag{8}$$

where $\mathbf{1}$ is the unit tensor, u the fluid velocity and η the coefficient of viscosity. The stress law of equation (8) when introduced into the equation of motion leads to the Navier-Stokes equation,

$$\rho\frac{d\boldsymbol{u}}{dt} = \rho\boldsymbol{F} - \nabla p + \eta\nabla^2\boldsymbol{u} + \frac{\eta}{3}\nabla\nabla\cdot\boldsymbol{u} \tag{8}$$

where ρ is the density and $\boldsymbol{F}$ is the external force acting on unit volume of the fluid. The Navier-Stokes equation together with the equation of continuity,

$$\nabla \cdot (\rho \mathbf{u}) = -\partial \rho / \partial t \qquad (10)$$

describes the motion of viscous fluids. The study of the solutions of these equations under appropriate initial and boundary conditions constitutes the science of hydrodynamics.

The coefficient of viscosity of a liquid is related to its structure and the intermolecular forces in a complicated way. According to Eyring, it may be represented in the form,

$$\eta = \frac{a_1 h}{a_2 a_3 a^2} e^{-\Delta F \pm /RT} \qquad (11)$$

where h is Planck's constant and $\Delta F^{\pm}$ is the free energy of activation for the elementary flow process. In this equation, a_1 is the dimension of the unit of flow perpendicular to the direction of flow, a_2 and a_3 the dimensions parallel to the direction of flow, and a the distance moved by the unit of flow in the elementary process.

Electrical and Optical Properties of Liquids.—With the exception of the liquid metals, molten salts, and solutions of salts in ionizing solvents, the electrical conductivities of liquids are very small. In the liquid metals the conductivity is electronic. In molten salts and solutions of salts the conductivity is electrolytic, that is the electric current is carried by the ions of the salt. For example, in an aqueous solution of sodium chloride, the current is carried by the ions Na^+ and Cl^-.

The dielectric constants of nonpolar liquids, for example benzene, the molecules of which do not possess permanent electric dipole moments, do not differ greatly from unity and generally are in the range 1.00 to 3.00. The dielectric constants of polar liquids, for example water, the molecules of which possess orientable electric dipole moments, are generally one or two orders of magnitude larger than those of nonpolar liquids. Thus the dielectric constant of water is approximately 80 at 25° C. With the exception of liquid crystalline phases, liquids are optically isotropic. In nonpolar liquids the refractive indices for the visible spectrum do not differ greatly from the square roots of their dielectric constants measured in the radio or audio frequency spectrum. In polar liquids, the refractive indices for light in the visible spectrum are of the same magnitude as those of nonpolar liquids.

The absorption spectra of liquids in the visible and ultra-violet region of the spectrum reflect the electronic structure of their component molecules and do not differ markedly from the absorption spectra of the substances in the vapour state. However, on account of the perturbing influence of intermolecular forces, changes in frequency and intensity, as well as the broadening and blurring of the band structure of the vapor spectrum, are observed. The infra-red and Raman spectra of liquids may differ markedly from those of their vapours, because of the presence of structural frequencies characteristic of the liquid state. Such structural frequencies are analogous to the lattice vibrational frequencies which give rise to the residual ray spectrum of ionic crystals.

LIQUORICE. The hard and semi-vitreous sticks of paste, black in colour and possessed of a sweet, somewhat astringent taste, known as liquorice paste or black sugar, are the inspissated juice of the roots of a leguminous plant, *Glycyrrhiza glabra,* the *radix glycyrrhizae* of pharmacopoeia. The plant is cultivated throughout the warmer parts of Europe, especially on the Mediterranean shores, and to some extent in Louisiana and California. The roots for use are obtained in lengths of three or four feet, varying in diameter from $\frac{1}{4}$ to 1 in., they are soft, flexible and fibrous, and internally of a bright yellow colour, with a characteristic, sweet pleasant taste. To this sweet taste of its root the plant owes its generic name *Glycyrrhiza* (the sweet-root), of which the word liquorice is a corruption. The roots contain grape-sugar, starch, resin, asparagine, malic acid and the glucoside glycyrrhizin, $C_{24}H_{36}O_9$, a yellow amorphous powder with an acid reaction and a distinctive bitter-sweet taste. On hydrolysis, glycyrrhizin yields glucose and glycyrrhetin.

Stick liquorice is made by crushing and grinding the roots to a pulp, which is boiled in water over an open fire, and the decoction separated from the solid residue of the root is evaporated till a sufficient degree of concentration is attained, after which, on cooling, it is rolled into the form of sticks or other shapes for the market. The preparation of the juice is a widely extended industry along the Mediterranean coasts; but the quality best appreciated in Great Britain is made in Calabria and sold under the names of Solazzi and Corigliano juice. Liquorice enters into the composition of many cough lozenges and other demulcent preparations; and in the form of aromatic syrups and elixirs it has a remarkable effect in masking the taste of nauseous medicines.

LIQUOR LAWS AND LIQUOR CONTROL. Laws to regulate or prohibit the manufacture, sale and transportation of beverage alcohol or intoxicating liquors are of ancient origin everywhere and are growing more numerous and complex in all countries. They are more often found and in greater variety as tax measures ostensibly for the purpose of raising revenue, but even here the dominant motive is usually the social aim to combat the evils of alcoholism and promote public health, public order and social welfare.

Another factor of growing importance since the middle of the 19th century has been the rapid urbanization, industrialization and mechanization of modern life in the leading nations of the world. There is a consequent wider recognition of the need for sobriety in safeguarding public order and physical efficiency.

There are four general methods of legislative control of the liquor traffic:

(1) *Licensing,* the oldest and most widely used method.
(2) *The No-Private-Profit Scandinavian or Company System,* which seeks to secure disinterested management by entrusting a monopoly of sale of liquor to a body of citizens who have no personal interest or profit in it.
(3) *State Monopoly,* where the state retains the wholesale or retail trade, or both, in its own hands, takes the profits as public revenue, and of course retains complete control.
(4) *Restriction or Limited Prohibition,* which is usually a system of high licence with local option or local veto.

Two important distinctions in the licence system as practised more extensively in the United Kingdom and in the United States than elsewhere should be noted. In the United Kingdom we find a single homogeneous system, gradually evolved after centuries of experience with the licensing principle, whereas in the United States before and after the era of national prohibition many different systems are coexistent due to the quasi sovereignty of the individual states. Also American law and legislative practice have never varied the traditional "common law" theory of a licence as a temporary permit, revocable for violation of the conditions upon which it was granted, and terminable at the will of the issuing authority upon the expiration of the brief term—usually one year—for which it was granted, and without vesting any property right in the expectation of renewal. Since 1904, however, a new principle of compensation, as discussed below, has been introduced into the licensing system of England.

I. THE UNITED KINGDOM

The number of public houses, including beerhouses for "on" consumption in England and Wales from 1831 to 1935 decreased in proportion to population, being 1 public house to 168 persons in 1831, 1 to 375 in 1909, 1 to 398 in 1911, 1 to 458 in 1921 and 1 to 538 in 1935 (*see* G. B. Wilson, *op. cit.,* below, p. 236), and 1 to 535 in 1937 (*cf.* Home Office: *Licensing Statistics,* 1937, Parl. Papers, Cmd. 5869, London, 1938). The decrease in the corresponding showing for Scotland is likewise continuous and much more rapid. As a whole, the United Kingdom shows a large and progressive diminution in the number of public houses to population, which has not been counterbalanced by an increase in "off" licences. The Licensing Act, 1904, which became known as the "Balfour act," provided compensation of licences withdrawn on grounds other than misconduct and destroyed the centuries-old unqualified discretion of the justices to refuse the renewal of on-licences, without compensation. This act accelerated greatly the reduction in the number of public houses, but the number of clubs, registered under the Licensing Act, 1902, has increased at a greater rate but apparently represents only 7% of the total amount spent in England and Wales in 1935 for liquors. (*See* Geo. B. Wilson, *Alcohol and the Nation,* London, 1940, p. 143.)

Change in liquor consumption, if we could measure it accurately, and did we know more about the factors affecting it, would of course be the best test of the effectiveness of laws. The two foremost authorities on scientific research in this field, Dr. G. B. Wilson in England (*Op.cit.* c.22), and Prof. E. M. Jellinek of Yale university in *Alcohol Explored* (1942, c.2), and in his study of "Alcohol Consumption Rates" (*Quar. Jour. Studies on Alcohol*, iii, no. 2, pp. 267–80), are agreed that the task is difficult, that we must proceed slowly and cautiously, but that the outlook is good for answers to age-long controversies on the use and abuse of alcohol. Wilson sums up a discussion of liquor consumption during World War I, by saying that the controlling factor over the whole period of the war "was the restriction on the amount of intoxicating liquor available for consumption." Haggard and Jellinek (*Op.cit.* p. 272) tell us that the failure of total prohibition wherever tried need not blind us to the definite effect in decreasing the immoderate use of alcohol which legal measures have had in England, Belgium, Switzerland and Norway—such measures as taxation, regulation of closing hours, licence restrictions, etc. The same authors are cited as authority for the statement (*Information Service*, xxi, no. 40, New York, Dec. 5, 1942) that per capita of "absolute alcohol" from wine, beer and spirits in Great Britain (also in Germany, the Netherlands, Norway and Sweden) tended to decrease from about 1901 to 1930 (war years 1914–18 not included), then rose sharply in 1932 but by last reports available, is "far below the lowest previous figure since the turn of the century." Effective control of the beverage liquor traffic was demonstrated as possible during World War I by Lord D'Abernon, chairman of the Central Control board, through restrictive measures with respect to sale, alcoholic content, taxation, closing hour, limitation of off-premises sales to 2½ hours per day, five days a week, etc. Much of these gains has been retained. Per capita consumption in the United Kingdom was: 1917—27 gal. beer and 6.7 gal. spirits; 1938—14.2 gal. beer and 0.21 gal. spirits, and for the population over 18 years of age, 2.89 and 1.65 respectively.

The important licensing acts since 1904 have been: (1) the Licensing (Consolidation) Act, 1910, which codified all existing licensing laws of England and Wales, repealed almost entirely the Licensing acts of 1828–1904, and remained on the statute book until 1921, though partially superseded during the years 1915–21 by orders of the Central Control board (Liquor Traffic); (2) the Temperance (Scotland) Act, 1913, which limited hours for licensed premises, increased restrictions on clubs supplying liquor, and gave local option to local government electors to vote "no license", "one-fourth reduction", or "no change"; (3) the wartime legislation, 1914–19, (a) Orders under the Defence of the Realm Act, 1914; (b) Intoxicating Liquor (Temporary Restrictions) Act, 1914; (c) Defence of the Realm (Amendment) Act, 1915, under which the Liquor Control board was created as the executive authority. The control by the board was first applied to the Lowlands of Scotland and to important shipbuilding and industrial areas in England; by the end of the war it applied to 29 areas or about three-fourths of England, Scotland and Wales. In 1916 the board tried government monopoly in certain areas, notably in the Carlisle area where this system remained as a permanent institution; (4) the Licensing Act, 1921, which abolished the Liquor Control board, and made permanent some of its regulations, and also applied them to registered clubs; the act also made statutory the state ownership of the Carlisle area, and substituted "permitted hours" for "closing hours" previously in force; (5) the Licensing (Permitted Hours) Act, 1934, which gave the justices authority to extend the hours prescribed in the 1921 act for part of the year, but still contained strict limitation of hours. This principle has been found the most effective measure to reduce drunkenness and the abuse of beverage alcohol.

A Royal Commission on Licensing appointed in 1929 had reported (1932, Parl. Papers, Cmd. 3988) in favour of retention of wartime regulations of hours; other recommendations were: the more rapid reduction of licences; more experimentation with public ownership of the liquor trade; more definite encouragement of specific education on the subject of alcohol; the creation of a National Licensing commission to supervise and assist the proposed reform measures, etc., but no steps had been taken up to 1943 by the government to deal with these recommendations.

II. THE BRITISH COMMONWEALTH OF NATIONS

Canada.—Liquor legislation is based fundamentally on the licence system and practices of the United Kingdom, and also has followed pretty closely that of the United States. While the provinces, like the states, had their own laws which varied in stringency, they usually provided for licence modified by local veto. The Canada Temperance Act, 1878 (Parl. Dom. Can. 41 Vict. c. 16, May 10), known as the Scott act, was a federal law providing for local option in any city or county on petition of one-fourth of the electors at three-year intervals. Under this act a rapid growth of dry areas in the Maritime provinces took place, and Prince Edward Island became completely dry and Nova Scotia nearly so, while in the other provinces where the Scott act was not popular, dry territory also spread rapidly under provincial statutes (*See* L. W. Moffit, "Control of the Liquor Traffic in Canada" in *Annals*, Amer. Acad. P. & S. S., v. 163, Sept. 1932).

This was the situation down to the outbreak of World War I. In the next 15 years, 1916–30, all nine provinces except Prince Edward Island, which had had prohibition for 15 years previously, adopted provincial prohibition (four in 1916, three in 1917, and Quebec, limited to spirituous liquors, in 1919), and repealed these laws (two in 1921, two in 1927, and one each in 1923, 1924, 1925 and 1930) in favour of control by direct government sale.

National prohibition, which received a majority of 13,687 in a total vote of over 500,000, in a plebiscite in 1898, never gained enough support to secure enactment by the dominion government. The constitutional controversy over the respective powers of the dominion and the provinces was settled in 1901 by decision of the privy council that the provinces had complete control of the retail trade in liquor and the dominion, of manufacture and importation. Then followed much legislation analogous to the Wilson and Webb-Kenyon acts in the United States (*q.v.* in article PROHIBITION) to protect dry territory by local option from invasion by liquor from surrounding wet areas. Without a real federal prohibition law, even with these aids to enforcement, provincial prohibition became generally recognized as unenforceable, or at least too difficult, costly and its attendant evils too serious, to warrant its continuance. Unlike the United States, Canada in abandoning total prohibition abandoned also the licence system and went over completely to state monopoly. The Canada Temperance act remained in force, up to 1943, and local option had been little modified, that is, no area that did not want them would have stores or licensed premises established within their borders. While controversies raged and opinions differed as to results, there seemed to be general acceptance of the control system, and nowhere any strong tendency to revert to prohibition, or to the old licence system.

Some advantages accruing from the monopoly of purchase and sale vested in the government, over competitive commercial distribution of beverage alcohol, are: strict limitation of advertising, reduction of inducements to buy, various devices for keeping the quantities bought and amount consumed to ordinary levels without stimulation of profit-seeking vendors and the elimination of the old bar. These results have been achieved by the control system of Canada, and the efforts of the provincial commissions and control boards, and their personnel generally have been of a high order. Yet consumption increased to such an extent that as recently as Dec. 16, 1942, Prime Minister Mackenzie King broadcast an appeal from Ottawa for greater temperance and abstinence as part of the war effort and announced that after Feb. 1, 1943, liquor advertisements would be prohibited throughout Canada for the duration.

Other British Commonwealth Countries.—These have generally followed British models and been less repressive in their policies of licensing and liquor control than Canada. In Australia the existing licence legislation in all six states makes provision for some sort of local option and machinery for the reduction of the number of licences where it seems desirable or where local option votes are in favour of reduction. Local option concerning the sale of fermented and spirituous liquors was in force in South Australia and Tasmania (*Official Year Book*, v. 33, 1940, p. 940), but in New South Wales such polls were suspended after 1913, and in Victoria, Queensland and Western Australia state-wide polls superseded the local polls. In 1928 a special state-wide referendum was taken in New South Wales on state-wide prohibition with compensation. It resulted in a majority of 500,000 against prohibition in a total vote of 1,268,119, being over 88% of the qualified voters (*Official Year Book,* no. 22, 1929, p. 1005). All the states except South Australia have a fixed maximum for licences, above which the licence boards may not go except under special conditions such as demand of increased population. The Licence Reduction boards in New South Wales and Victoria (and similar machinery in all the other states), exist for the reduction of licences where it seems desirable or local option votes so direct. Funds for compensation for licences refused renewal are derived from special taxes usually assessed on the volume of the liquor trade. Provision is made for a poll usually about once every seven years, and in some states total prohibition may be voted on when these polls are taken. Other conditions affecting the Licence Reduction boards vary in the different states, and the reductions effected in the decade 1920–30 were substantial. The per capita consumption, however, does not seem to decrease proportionately. The figures available (*Official Year Book,* 1940) give for Australia: Spirits, 0·2 imp. gal.; wine, 0·36; and beer 8·2; showing little change for each of the years since 1935. The corresponding figures for New Zealand were: 0·3, 0·2, and 8·6; for Canada 0·2, 0·3, and 6; for the United Kingdom: 0·2, 0·3, and 33·1; and for the U.S.A.: 0·9, 0·4, and 13 (according to a comparative table in the *Official Year Book,* 1940, p. 957). In New Zealand three state-wide polls were taken following 1919 on prohibition without compensation, state purchase and continuance of licence. Continuance won by small majorities in all three, though prohibition obtained a plurality in two polls. From the New Zealand 1942 *Official Year Book,* the following statistics are taken of per capita consumption in gallons, for specified years under New Zealand's controlled licence and local option policy: 1926—spirits, 0·47; wine, 0·19; beer, 9·2; 1932—0·21; 0·1; 5·8; 1938—0·28; 0·2; 10·7; and 1940—0·27; 1·9; 11·2. In the Union of South Africa since the License Act of 1928 some reduction in the number of licensed premises has taken place. The Union's *Official Year Book,* no. 22, 1941, p. 191, gives the number of retail liquor licences in 1936 as 1,978 or 1 to 875 Europeans, 15 years of age and over, and in 1940 as 2,051 or 1 to 929; and bottle store licences in 1936 as 552 or 1 to 3,161, and in 1940 as 545 or 1 to 3,498. The corresponding figures for convictions for drunkenness (Europeans) were 6,661 and 5,425. In India the movement which began in 1920 with the introduction of measures to restrict the liquor traffic, and with prohibition and local option in some of the states, seems to have continued down to the outbreak of World War II, but the number of shops licensed for the sale of liquors, etc., increased 13% in the second half of the decade 1929–39 compared with the first half (*Stat. Abstract for Brit. India,* Parl. Papers, Cmd. 6333, p. 780*ff.*, London, 1942).

III. OTHER EUROPEAN COUNTRIES

Prior to World War I, continental European countries gave little legislative attention to the liquor traffic. It was generally licensed for revenue purposes but as for control of beverage alcohol as a means of combatting the evils of alcoholism, that was left to local authorities and to ordinary police regulation. There were notable exceptions. In Russia, Sweden and Norway, Finland and Estonia, important experiments were made with various forms of liquor control and prohibition. A strong and growing temperance and total abstinence movement, in most countries wholly individualistic in character, dated from the latter part of the 19th century in the countries of northern Europe, especially in Finland, Norway, Sweden and Denmark. It was only a little less active in northern central countries like Germany, Switzerland, Belgium and Holland but was weaker in France and Slav countries; and ineffective or non-existent in southern Europe—Italy, Greece, Spain and Portugal. World War I stimulated and greatly increased liquor control, both for food and manpower conservation, but most legislative measures aimed at reducing the consumption of beverage alcohol were weakened or disappeared in the postwar years. After the outbreak of war in 1939 in spite of greater food shortages and need for conservation of alcohol and grains for war uses, there was less governmental interference with beverage alcohol except in Germany, and partially, in Switzerland and France. The individualistic temperance movement gained strength everywhere in Europe, and especially in the northern European countries.

Austria-Hungary and the Balkans.—Prior to 1914 in the Austro-Hungarian empire the liquor licence system followed closely that of Germany. In 1905 the individual temperance movement with government assistance, organized and conducted successfully the 10th International Congress Against Alcoholism with the minister of public instruction as its president. Temperance instruction in the schools was introduced, and in recent years the Hungarian government contributed to the noted Museum of Hygiene and Temperance in Budapest and, by various measures, favoured the nonalcoholic uses of fruits, including grapes, which was a movement stemming from Germany but spreading rapidly in all countries. In the Balkans the individual temperance movement was strong in places but generally less effective and governmental measures for liquor control were either nonexistent or weak and sporadic. The Koran prohibition of the use of wine influenced Moslem peoples but even in Turkey this prohibition, still strictly observed in rural areas, was abolished, and in 1923 an alcohol monopoly was created by law. The widespread use of dried fruits and of unfermented grape juice beverages both in Turkey and elsewhere in Bulgaria and other Balkan countries, exercised greater restriction. Statistics show over half of the grape crop in Turkey is used for dried grapes, about one-third for nonalcoholic beverages, one-sixth consumed as fresh grapes, and less than 2% for alcoholic wine. In Yugoslavia Dr. Stampar as director of social hygiene at the ministry of public health directed an educational campaign against alcohol and enlisted the co-operation of provincial and local hygiene offices, and of the minister of public instruction. But when he recommended state action by legislation there were no results other than minor restrictions, Sunday closing, etc., on liquor establishments. Total abstinence for a time made good progress in connection with the youth movement in recent years. In Bulgaria legislative measures against abuse of alcohol were numerous and probably more effective than elsewhere in the Balkans. Schools were active in temperance instruction which was compulsory and the ministry of public instruction organized a temperance day every year in the schools. All licensed places where alcoholic beverages were sold were required by law to close on Sundays, legal holidays and many church holy days, also they were obliged to sell grape juice or other non-alcoholic beverages which were said to be quite popular in such places. Local option polls were held and women participated though they did not have the suffrage in other matters. In Rumania educational efforts were weaker and the few restrictions the law attempted to put on the number of liquor establishments were feebly enforced. Here too, as elsewhere in the Balkans, new forces were at work, especially among the youth movements which would bring, with peace and greater economic stability, greater control of the liquor traffic, and reduction in the consumption of alcohol.

Belgium, Denmark and Holland.—After severe wartime restrictions, Belgium in 1918 prohibited the manufacture and sale of spirits, wines with more than 15% alcoholic content, and other beverages (including beer with more than 8%), except necessary alcohol for medicinal, scientific and industrial uses. The next year two measures were enacted by the parliament, one increasing the tax on alcoholic beverages, and prohibiting the consumption of spirits in all places accessible to the public, and authorizing the legal sale of alcoholic beverages only in the minimum quantity of two litres for consumption off the premises; the second was a tax measure for licensed premises providing for increased taxes on alcohol, and repression of illicit distillation, but leaving the trade in fermented liquors of small alcoholic content free. Licensing conditions and restrictions, following the French system, were usually left to local authorities. The number of licensed houses in proportion to population, and the per capita consumption, were still among the highest in Europe, and prohibitive and restrictive measures, chiefly tax measures, were directed against absinthe and spirituous liquors. Available statistics of consumption for the five years ending in 1936 (*Belg. Ann. Stat.* v. 60, 1938) show no significant changes in this period: beer, 15·7 in 1932 and 14·5 in 1936 (100,000 hectolitres), with fluctuations a little higher in 1934 than in 1933 and again in 1936 compared with 1935; beverage alcohol in 1,000 litres, 97 in each of the four years to 1936, and wines, 12·9 in 1933 to 13·9 in 1936.

Denmark had a comprehensive licensing law in force in 1913 with "off" and "on" provisions for sale of spirits, wines and beers (with more than 2·25% of alcohol). An important licensing act of 1925 fixed the maximum number of licences at the number in existence Jan. 1, 1924, with local option as to new licences and permitting local authorities to restrict their issue to a public utility company on the Gothenburg principle. A government handbook entitled *Denmark* (Royal Danish Ministry for Foreign Affairs and the Danish Stat. Dept., 1939, Copenhagen) says that the per capita consumption of pure alcohol prior to 1914 was 6¾ litres of 100%, annually, and in 1938 it was 2½ litres. This publication also states that temperance legislation is "mainly limited to regulations regarding the number of places where alcoholic beverages may be consumed, and to trading in spirits." Efforts at total prohibition generally failed. Alcohol is heavily taxed. A government adviser on temperance was appointed in 1933. There are many temperance societies all over the country with upwards of 118,000 members pledged to abstain from spirituous liquors. The state, however, made little use of legislative powers in combatting alcoholism, but was active in the educational field, both directly through the schools and the public health agencies and in collaboration with the temperance societies. In this connection it may be noted that Iceland, so long associated with Denmark, adopted national prohibition in 1908 by a small majority of the 8,000 votes cast, abandoned it by a referendum vote with 4,000 majority against out of 26,000 votes cast Nov. 13, 1933, and the sale of liquor was legalized in 1935. This was largely due to pressure from other countries, notably Spain, against restrictions on importations of their wines and liquors, and partly, as in Finland, to the difficulty in controlling smuggling.

Holland long had a strong temperance movement under able leadership in Protestant, Catholic and neutral groups, finally united in a loose federation in the national commission against alcoholism in 1909. The fundamental licensing law of 1881 also provided for the limitation of the number of licensed premises to a fixed proportion of the total population, varying according to the size of the town or district. A revision of this law in 1904 gave the communal authorities the right to request the government every five years to reduce the number of public houses or refuse any new licence. The long struggle, nearly 30 years, for local option was finally lost in 1932 when the Dutch parliament voted on an amended licensing measure adopted without the local option feature which at one time had received the signatures of nearly one-tenth of the entire population to a petition in its favour presented to Queen Wilhelmina. No country justified its greater faith in education than in legislation, by more ingenious means and greater perseverance in educational efforts.

France and Switzerland.—Under the basic licensing act of 1880 France moderately restricted places with "on" licences but left their regulation largely to local authorities. The number of public houses increased to 1 to every 81 persons in 1900, and was reported to be 1 to 80 in 1938, a proportion only exceeded by Belgium. The Local Government Act, 1884, empowered municipal authorities to fix the usual conditions, hours of closing, etc., attached to licences. Taxation of the trade, then light, was greatly increased. Manufacture and sale of absinthe was prohibited by the act of March 16, 1915, but the act was weakly enforced and there were many equally deleterious substitutes. The whole tax and regulatory policy as far as there was one, was directed against spirits and to protect the wine industry. Even the consumption of spirituous liquors greatly increased. The per capita consumption of distilled liquor in France in the period 1928–32, the latest for which reliable statistics are available, was 5·52 litres, five times that of Denmark, four times that of Great Britain, more than twice that of Norway or Holland, and 25% higher than Sweden. An investigation by the Academy of Medicine in 1925 showed that the consumption of beverage alcohol had doubled in the period 1918–25. For the period 1928–32 per capita wine consumption was 167 litres per annum and beer 33·7 litres. The total amounted to 20·6 litres of absolute alcohol, a higher annual per capita than that of any other country in the world. Home distillers were said to number 1,500,000, and enjoy a tax exemption on 10 litres of pure alcohol for personal use. Voluntary temperance movements were not lacking, and the Blue Cross in Protestant circles, the Golden Cross in Catholic, the Good Templars' order and other similar bodies kept up an educational campaign against alcoholism, with little government aid but strengthened by the relatively new movement here as elsewhere in Europe for the wider nonalcoholic use of fruits and the increased market for fresh and dried grapes.

In Switzerland the federal government maintained a state monopoly of distilled liquor, extended by referendum on April 6, 1930, to control home distillers (peasants) of fruit alcohol. After 1935 the monopoly took action to promote the nonalcoholic use of fruits, the manufacture of unfermented cider, the taking over of peasants' stills and provision for use of fruit waste for cattle feed, etc. Under a referendum, July 5, 1908, absinthe was prohibited but the enforcement of this prohibition was not too rigid. The cantons regulate retail liquor trade, and determine the number and conditions of licensing. An inquiry in 1931–38 showed 1 licence to 172 inhabitants, and in Italian cantons as high as 1 to 67, and little restriction of fermented beverages and excessively large numbers of licensed places, including grocery stores, for "off" sale of distilled spirits. In 1929 a referendum to give the cantons power to prohibit the manufacture and sale of distilled liquor was rejected by a 2 to 1 vote, with nearly 700,000 votes cast. The Blue Cross and other voluntary temperance movements were active, likewise experiments like the "cafés chocolats" and temperance hotels made steady but slow progress. They retarded but did not halt the increasing per capita consumption of alcohol.

Finland and Estonia.—The early Russian prohibition of vodka, and wartime prohibition, applied to both countries. Estonia repealed wartime prohibition in 1920 for liquor control similar to the "Bratt" system in Sweden. The communal electors from 1927–34 had local option to prevent the opening of liquor shops which resulted in much dry territory, and the Temperance Federation conducts a vigorous educational campaign. Increasing consumption of alcoholic beverages, especially in rural districts, had aroused the government to the need for greater licence restrictions and revival of local option. Finland had long been a leader in vigorous and intelligent experiments in liquor control. For details of the prohibition experience, 1919–32, *see* J. H. Wuorinen's *Prohibition Experiment in Finland* (1931) and his article in *Annals,* Am. Ac. P. & S. S. (Sept. 1932). The parallelism of the 13 years of national prohibition in Finland and the U.S.A. is striking. The act of Jan. 30, 1932, repealed prohibition in Finland and set up a state-owned and directed alcohol company which supervised the manufacture. sale and import of intoxicating beverages. The company was charged with the duty of stamping out "the illegal trade in intoxicants, and will reduce the use of alcoholic beverages to the smallest possible minimum, as well as prevent drunkenness and its harmful consequences." It established liquor shops in cities and towns, fixed hours and closing conditions on Sundays, holidays and at other times so that the shops were actually open less than half the year, and fixed prices for hotels, restaurants, railway cars, steamers, etc., where liquor, beers or wines might be dispensed usually only with meals. The company paid taxes and customs duties, the same as other concerns, and the profits for the first two years went to meet general government expenses, then 35% for temperance work, suppression of illegal liquor trade, and for the national old-age insurance fund; 35% to other public uses, and the balance, 30%, was divided among localities where no liquor was sold. It is said that rum running was practically stamped out by the end of June 1934. The company might declare a dividend not to exceed 7% before profits were distributed as indicated above, and did so for the second year of operation, 1932–33, when the profits were said to have amounted to $1,500,000. The government held 98% of the stock. Home manufacture of malt beverages and wines was permitted. Municipal and communal councils by a two-thirds vote may prohibit sale, manufacture and importation of beverage alcohol within their jurisdiction.

Germany and Italy.—Germany long had a licence system graded to be more restrictive on spirituous liquors, but chiefly intended for revenue purposes only. The wartime restrictions during World War I, which were severe and both general and local, were intended for conservation of food and alcohol for war uses. Administration of licence conditions and variations of the same were left to local authorities. In 1923 the reichstag prohibited the sale of absinthe, and adopted a local option measure requiring a two-thirds vote in any district for no licence. Two years later the reichstag defeated by a vote of 200 to 168 a measure for stricter regulation of licensed premises, and again in 1927 rejected a wider local option bill. Steady growth of the voluntary temperance movement, owing its leadership largely to the Good Templars' order, continued from the beginning of the century down to the advent of Hitler in 1933, since which time the Empire Community to Combat Alcoholism (Reichsfachgemeinschaft zur Bekaempfung des Alkoholismus) federated the temperance societies and eliminated the Jewish members and other, to them, undesirable features. It had other methods than the usual legislative ways of enforcing its policies. In addition to its educational campaign, the empire office against the abuse of alcohol and tobacco, the new name for a further consolidation since July 12, 1939, under the public health department of the old empire community with other organizations dealing with the treatment of inebriates, profited by legislation such as the sterilization law which could be applied to persons suffering from severe alcoholism, and the law providing for the internment of habitual alcoholic delinquents. Blood tests for drunken drivers in traffic accidents, and the absolute prohibition of liquor advertisements recommending alcoholic beverages for young people, were other legislative measures used, but to the sport motive and the able direction of efforts to promote the nonalcoholic use of fruits, the consumption of nonalcoholic beverages (especially unfermented cider) must be attributed credit for whatever progress was made. The acid test of consumption of alcoholic beverages showed little change in the per capita consumption of beer or spirits in 1937–38 compared with that of 1928–29. A per capita of 63.7 for beer, and 1.21 litres of 100% alcohol was very little lower than it was for the previous decade, and quite a bit higher than for several of the intervening years. In Italy the consumption statistics for 1933–36, latest available, show the annual per capita for beer, 1 litre, and for spirits, 0.36 litre, in both cases about one-third of that in 1919–22; wine about the same at 100 litres and total absolute alcohol 1.62 litres less. In 1913 the manufacture and importation of absinthe was prohibited and a licence system introduced limiting licences to 1 to 1,000 population (previously 500) and with greater restrictions on hours, etc. In the postwar period, 1919 to the outbreak of World War II, the Italian government actively co-operated with the temperance movement, and on its own account, did much to promote nonalcoholic use of fruits and the consumption of nonfermented beverages, and recreational facilities for the use of spare time for children and adults. Also "grape day" introduced by Mussolini in 1930 in Milan spread generally and met with some success in diverting the huge grape industry to other uses than wine production.

Russia and Poland.—For Russia liquor control was for a half century, and continued to be, wholly an economic problem. A pioneer in nation-wide prohibition by imperial ukase as a war measure in 1914, Russia gave up one-fourth of the revenue needed to support its national budget. It got in return some social gains in temporary rise in the standard of living of the peasants which appealed to the communists who came into power in 1917, but also an economic dislocation from the illicit manufacture of samogon, and the home distillation of vodka. In 1924 the sale of vodka was again permitted but with restrictions and control exercised through the state alcohol monopoly. In 1929 the council of people's commissars adopted decrees providing for a more thorough regulation of the liquor traffic, prohibition of the sale of vodka, wine and beer on holidays and pay days; included also were the prohibition of the use of alcoholic drinks in window displays, and certain encouragement for nonalcoholic beverages, and the right of municipal and district councils to close any store or restaurant selling wine, beer or vodka. The latter provision was a sort of local option right but it was exercised autocratically from Moscow where the liquor control policy rested on the conviction that drunkenness is the inevitable result of bad living conditions and oppression, that education and regulation may be necessary but only the elimination of the social conditions responsible for the use of alcohol will achieve permanent results (*Cf.* Joseph Barnes: "Liquor Regulation in Russia," in *Annals*, Am. Ac. P. & S. S., Sept. 1932). Poland long had an alcoholism section at its ministry of social affairs but the voluntary temperance movement while ably led was never numerically strong. Its excellent licensing system, dating back to acts of parliament in 1920–21, was highly restrictive and made provision for provincial and local option on no licence which seems to have been voted in many rural areas but poorly enforced.

Sweden and Norway.—The important revision of the basic liquor control law of 1917 enacted by the riksdag, June 18, 1937, (no. 436), after the report of its revising commission which was appointed in 1928 and reported in 1934, went into effect Oct. 1, 1938. The changes are too numerous for even a brief résumé here but on the whole they strengthen, simplify and unify the control (*Cf.* Bengtsson, *op. cit.*, p. 143ff., for excellent comparative summary). The social purpose that "all sale of intoxicating liquors shall be so organized that it is attended by a minimum of harm" is restated and so emphasized in the 1937 law as to give the administrative authorities added powers to shape policies of sales agencies. The communal veto (a sort of local option exercised by the people's representatives, not by direct popular vote) for off-premises trade was abolished but was retained for the bar and retail store trade. Provision was made to reduce the number of system companies, 121 in number in 1937, so that there should be none where there was none in 1937 and in no city or town of less than 5,000 inhabitants. Within a year the number had already been cut to 41. Stricter measures were provided for safeguarding public profits; also a profit quota system for the transferred licences under which many hotels and restaurants were operated. The principle of profit limitation was strictly applied to wholesaling and manufacturing of spirituous liquors, and even to retailing and on-premises sale of Pilsner beer. From 1919 to 1936 the number of control book holders, or spirits permit holders, increased steadily. In 1936 the number was 1,350,000 or 21.6% of the population, and included 150,000 women. One-fifth of them could purchase the maximum quota of 4 litres of spirituous liquors, but the average allotment was only 2.15 litres, 80% of which was actually consumed. The companies were given larger discretionary powers to fix and limit within the legal maximum the purchase rights of private owners of control books. The per capita consumption of alcoholic beverages in 1936 of spirits of 50% was 4.4 litres; wine 0.9; beer (2.25–2.75 max. per cent of alcohol by volume), 22.0; and this showed little change since 1920, but a small steady increase year by year after 1933. Bengtsson says (*Op. cit.*, p. 153): "Sweden, compared with the prewar period (*i.e.*, 1914), has not reduced its alcohol consumption to any greater degree than many other European countries, and perhaps not to the same extent as some of those countries. When the question of the reduction of the most serious and conspicuous social effects of alcohol is considered, however, Sweden occupies a prominent place among the nations."

In Norway prior to the adoption of national prohibition in 1916 the "Samlags" or company system similar to that in Sweden had long been in existence, but with local option to prohibit retail sale of spirits from 1904–16. Two-thirds of the country districts and about half the towns were "dry." In 1919 a popular vote of 5 to 3 in about 800,000 voting decided in favour of maintenance of national prohibition but this was reversed by a similar vote in 1926 when 5 to 4 in a total of 950,000 were against prohibition which was abolished by law, April 5, 1927. Local option, however, was retained and made stricter. Only towns with over 4,000 may vote every six years to permit or prohibit sale of alcoholic beverages. At the last poll held in 1934, out of 67 towns, 21 voted "no sale," 11 beer only, 18 beer and wine, and only 17 authorized sale of spirits. The German invasion prevented the next poll due in 1940 from being held. The government made provision for treatment of inebriates, co-operated through established machinery with the temperance societies, and actively participated in educational work to combat alcoholism. The statistics of per capita consumption for the period 1928–32, were for spirits, 2.12 litres, wine 1.06, beer 17.04, making a total of absolute alcohol of 2.11 which was reduced in 1936 to 1.95 litres.

IV. THE UNITED STATES

The thousands of statutes, state and federal, and local ordinances without number, in the United States prior to and through the era of national prohibition, constitute in themselves the most extensive and illuminating experiment in liquor legislation and social control of the liquor traffic in all history. They are the background of what has taken place since repeal of national prohibition in 1933. (*See* PROHIBITION.)

The post-repeal era began with Executive Order 6474, Dec. 4, 1933, congress not being in session at the time, pursuant to Title I of the National Industrial Recovery act. The order set up the Federal Alcohol Control administration to administer the codes of fair practices for the liquor industry. The codes sought (1) to protect the consumer from false labelling and advertising; (2) to prevent unfair practices such as commercial bribery, control of retail outlets, gifts and prizes to trade or consumer buyers, etc.; (3) to prevent shipments into dry territory in violation of state laws; (4) to prevent sales of distilled spirits in bulk containers; (5) limitation of production and importation to quantity sufficient to meet consumer demands; (6) price control. This lasted until the FACA ceased to function, May 27, 1935, when the NIRA was declared unconstitutional by the supreme court in the Schechter case (295 U.S. 495) but congress continued the same general policy by the Federal Alcohol Administration act in Aug. 1935 (49 Stat. 977, 1935, 27 U.S.C. par. 201ff.) which established the Federal Alcohol administration as a new division in the treasury department. Congress, however, eliminated from the new act the former code provisions with reference to price control, limitation of production and allocation of importations, but it continued and strengthened the basic permit conditioned not only upon observance of fair practices as formerly in the case of the codes but also upon the observance of all federal laws relating to liquor. Thus the FAA has authority to determine who may engage in the liquor business as an importer, distiller, rectifier or wholesaler. Brewers are not included. It enforces the act and regulations thereunder, not only by invoking the penalties imposed for violations but also by revoking or suspending permits for cause after the holder has been notified and given a hearing. The act was amended by the Liquor Administration act of June 26, 1936 (27 U.S.C., Supl. 1940, 201ff.), which abolished the office of administrator and made the FAA an independent agency governed by a three-man board appointed by the president, by and with the advice of the senate; but by Executive Order, April 2, 1940, it was restored to its previous status of a division in the treasury department. The basic permit, considered so essential to the regulation of the character of the industry, the protection of the revenue, and the enforcement of the 21st amendment with its new prohibition of the invasion of the rights of "dry" territory, was upheld by the U.S. court of appeals in the *Arrow* case (109 F., 2d, 397, C.C.A. 7th, 1940) but whether the basic permit, if applied to wholly intrastate transactions, is valid, had not up to 1943 been decided. For full details of federal control as exercised by the alcohol tax unit in charge of a deputy commissioner of internal revenue in the treasury department, since the consolidation of the FAA with this unit in July 1940, *see* John E. O'Neill, "Federal Activity in Alcohol Beverage Control" (*Law and Contemp. Probs.*, Duke University Law School, vol. vii, no. 4, 1940, pp. 570–99).

One of the chief reasons for the breakdown of national prohibition was the unwillingness on the part of the states, and their failure to co-operate with the federal government in its enforcement. Repeal of national prohibition put the problem of liquor control largely back in the hands of the states. Outside of the three states (Kansas, Mississippi and Oklahoma) which in 1943 continued to have state-wide prohibition, all of the 45 others fall under one of two methods of liquor control—monopoly control (17) or licensing control (28). As state-wide or state-administered systems either method is a departure for most of the states. South Carolina in preprohibition days did have a state dispensary, and other southern states made some use of county stores, but elsewhere and where licence prevailed both the licensing and policing of the liquor trade was chiefly a local government matter. In 1943, while the business of manufacturing, distributing, transporting and selling alcoholic beverages was in private hands in the 28 states under licence control, the state exercised control, through licence, in 4 exclusively, in 2 sharing it with the counties, in 6 sharing with the municipalities, and in 15 sharing with counties and municipalities, while in only 1 (Louisiana) the parishes and municipalities rather than the state administered control. In the 17 monopoly states all but one operated retail establishments. Wyoming alone had a monopoly of the wholesale business and left retail business in private hands, but the state, counties and municipalities shared the licensing power. Three others shared that power with the municipalities, and one other, North Carolina, shared it with the counties. In the other 12 states of this group there was exclusive state administration of the control system except in 2 (Alabama and Michigan) where local approval was necessary before the state might issue on-sale licences. Thirty-six states retained some form of local option but 3 of them had no dry areas in July 1942, and 5 more, less than 1%, while North Carolina had 72.7% of its population living in dry areas by local option, and in only 14 states was more than 10% of the population living in dry areas.

The chief aim of state control seems to be to so distribute administrative duties and responsibilities between the state and its local subdivisions, and the state and local police, as to prevent the return of the saloon. Thus three of the licence states prohibit the on-premises sale of spirits, and nine of the monopoly states prohibit such sales by the drink. In general there is a separation of "package" from "on-premises" sale, and the latter is further limited to bona fide restaurants and hotels.

The methods and devices employed in state control to protect the revenue, eliminate the saloon, the bootlegger, and illegal production of alcoholic beverage liquor, to restrict output, unfair trade practices, promotional efforts (undesirable advertising, gifts, prizes, etc., to stimulate demand), and to regulate prices are too numerous to mention here. (Cf. *State Liquor Legislation*, prepared by Marketing Laws Survey, sponsored by U.S. Department of Commerce, WPA, Wash., D.C., 1941, pp. 910; "Alcoholic Beverage Control," in *Law and Contemporary Problems*, vol. 7, no. 4, pp. 600–708, Duke Univ. Law School, 1940.) The public revenue derived from the new liquor legislation was estimated in 1940 to be about $1,500,000,000, 68.5% of which came from federal taxes and import duties. The state governments received 28.8%, and the local governments 2.7%. The per capita return in the 17 monopoly states was about a dollar higher than it was in 27 licence states, though it fluctuated from 0.41 (North Carolina) to 4.79 (Montana) in the monopoly states, and from 0.86 (Arkansas) to 3.28 (New York) in the licence states. Results measured in terms of consumption of alcoholic beverages are a better gauge of the effectiveness of liquor control. Unfortunately the statistics of consumption were in 1943 too incomplete and unreliable for the years since repeal to give a satisfactory basis for judgment even for the prewar years. So many other factors besides liquor laws and their administration such as general economic conditions, price and purchasing power fluctuations, that valid comparison with preprohibition figures are not as significant as they may seem. Culver and Thomas (*State Liquor Administration—A Statutory Analysis*, Univ. of Cal., Berkeley, 1940) estimate that the per capita consumption of distilled spirits and beer in 1938 in the United States was lower than in any year from 1900 to 1917, also that the per capita consumption of distilled spirits in 1938, based on reports from 44 wet states was 1.038 gal.; wine 0.554 gal., based on 40 states; and beer (36 states) 13.81. Later reports of the Distilled Spirits institute, Washington, D.C., give the per capita apparent consumption of distilled spirits for 45 states and the District of Columbia in 1941 as 1.16 gal., and 1942, 1.33. The figures for the separate states show an increase in 44 states and the District of Columbia, varying from 0.1% to 53.5%, and a decrease in only one state of 4.6%. Both sources cited give the gross and per capita figures for the licence and monopoly states separately, but to quote Culver and Thomas (p. 7 *op. cit.* above) "without much more detailed study of other factors affecting consumption no positive statement can be made concerning the relationship of the type of control system to the consumption of alcoholic beverages." Finally it seems from information supplied by Distilled Spirits institute, that the percentage of population in the U.S. under state and local-option prohibition Oct. 1938 was 17.8, and Nov. 1942 was 18.3. (For list of states, both years, and per cent of area "dry" in each, see *Repeal Review*, vol. 7, no. 4, Dec. 1942, p. 23, Repeal Associates, Wash., D.C.)

LIRA. The Italian name (Lat. *libra*, pound) for a silver coin, the Italian unit of value in the Latin Monetary union, originally corresponding to the French, Swiss and Belgian franc (*q.v.*), and the drachma of Greece, etc. The name is sometimes used of the Turkish pound, *medjidie*. (*See* Italy and Currency.)

LIRI or **GARIGLIANO,** a river of central Italy (anc. *Liris*), which rises at Cappadocia, 7 mi. west of Avezzano, and traverses a beautiful valley between lofty mountains, followed by the railway from Avezzano to Roccasecca. At Isola del Liri are two fine waterfalls. Below Ceprano, the ancient Fregellae, after it has issued from the mountains, the Liri is joined by the Sacco (anc. *Trerus*) formed by the union of several torrents between Palestrina and Segni, and the Melfa from the mountains northeast of Atina, and runs through a broader valley. It then turns through the mountains southwest of the Via Latina and falls into the sea just below Minturno, after a course of 104 mi.

LIROCONITE, a rare mineral consisting of hydrous basic copper and aluminum arsenate, with the probable formula $Cu_9Al_4(OH)_{15}(AsO_4)_5 \cdot 20H_2O$. It crystallizes in the monoclinic system, forming flattened octahedra almost lenticular in shape. Characteristic is the bright sky-blue colour, though sometimes, possibly owing to differences in chemical composition, it is verdigris-green. The colour of the streak or powder is rather paler; hence the name liroconite, from the Gr., λειρός, pale, and κονία, powder. The hardness is $2\frac{1}{2}$, and the specific gravity 2·95. The mineral was found at the beginning of the 19th century in the copper mines near Gwennap in Cornwall, where it was associated with other copper arsenates in the upper, oxidized portions of the lodes.

LISBON (*Lisboa*), the capital of Portugal; on the right bank of the river Tagus, near its entrance into the Atlantic ocean, in 38° 32′ 24″ N. and 9° 11′ 10″ W. Pop. (1930) 594,390; (1940) 709,179. Lisbon, westernmost of European capitals, is built on terraces up the sides of a range of low hills. It fronts the Tagus, and the view from the river of its white houses, and its numerous parks and gardens, is comparable in beauty with the approach to Naples or Constantinople by sea. The lower reaches of the estuary form a channel (Entrada do Tejo) about 2 mi. wide and 8 mi. long, which is partially closed at its mouth by a bar of silt, while the Rada de Lisboa is a tidal lake formed by the broadening of the estuary in its upper part to fill a basin 11 mi. long with an average breadth of nearly 7 mi. Lisbon extends for more than 5 mi. along the shores of both channel and lake, and for more than 3 mi. inland. Its suburbs, which generally terminate in a belt of vineyards, parks or gardens, interspersed with villas and farms, stretch in some cases beyond the inner line of defence 25 m. long, supplementary to the forts and other military works at the mouth of the Tagus, on the heights of Cintra and Alverca, and at Caxias, Sacavem, Monsanto and Ameixoeira. The climate of Lisbon is mild and equable, though somewhat oppressive in summer. Extreme cold is so rare that in the twenty years 1856–1876 snow fell only thrice. The mean annual temperature is 60·1° F, the mean for winter 50·9°, the average rainfall 29·45 in. The water supply is conveyed to the city by two vast aqueducts. The older of these is the Aqueducto das Aguas Livres, which was built in the first half of the 18th century and starts from a point near Bellas, 15 m. W.N.W. It is conveyed across the Alcantara valley through a magnificent viaduct of thirty-five arches, exceeding 200 ft. in height. At the Lisbon end of the aqueduct is the Mãe de Agua (*i.e.,* "Mother of Water"), containing a huge stone hall in the midst of which is the reservoir. The Alviella aqueduct, opened in 1880, brings water from Alviella near Pernes, 70 m. N.N.E.

The four municipal districts (*bairros*) into which Lisbon is divided are the *Alfama,* or old town, in the east; the *Cidade Baixa,* or lower town, which extends inland from the naval arsenal and custom house; the *Bairro Alto,* comprising all the high ground west of the Cidade Baixa; and the *Alcantara,* or westernmost district, named after the small river Alcantara, which flows down into the Tagus. Other names commonly used, though unofficial, are "Lisboa Oriental" as an alternative for Alfama; "Lisboa Occidental" for the slopes which lead from the Cidade Baixa to the Bairro Alto; "Buenos Ayres" (originally so named from the number of its South American residents) for the Bairro Alto southwest of the Estrella Gardens and east of the Necessidades Park; "Campo de Ourique" and "Rato" for the suburbs respectively north-west and north-east of Buenos Ayres.

The Alfama represents Roman and Moorish Lisbon; many of its narrow, steep and winding alleys retain the mediaeval aspect which all other parts of the city have lost; and almost rival the slums of Oporto in picturesque squalor. The most conspicuous feature of the Alfama is the rocky hill surmounted by the Castello de São Jorge, a Moorish citadel which has been converted into a fort and barracks. The Sé Patriarcal, a cathedral founded in 1150 by Alphonso I. was wrecked by an earthquake in 1344 and rebuilt in 1380, but the earthquake of 1755 shattered the dome; the roof and belfry were subsequently burned, and after the work of restoration was completed the choir and façade were the only parts of the 14th-century Gothic church unspoiled. In one of the side chapels is the tomb of St. Vincent (d. 304), patron saint of Lisbon; a pair of ravens kept within the cathedral precincts are popularly believed to be the same birds which, according to the legend, miraculously guided the saint's vessel to the city. The armorial bearings of Lisbon, representing a ship and two ravens, commemorate the legend. Other noteworthy buildings in the Alfama are the 12th-century church of São Vicente de Fóra, originally, as its name implies, "outside" the city; the 13th-century chapel of Nossa Senhora do Monte and the 16th-century church of Nossa Senhora da Graça, which contains a reputed wonder-working statue of Christ and the tomb of Afonso de Albuquerque (1453–1515).

Modern Lisbon.—West of the Alfama the city dates chiefly from the period after the great earthquake. Its lofty houses, arranged in long straight streets, its gardens and open spaces, a few of its public buildings, and almost all its numerous statues and fountains, will bear comparison with those of any European capital. The centre of social and commercial activity is the district which comprises the Praça do Commercio, Rua Augusta, Rocío, and Avenida da Liberdade. The Praça do Commercio, or Terreiro do Paço, is a spacious square, one side of which faces the river, while the other three sides are occupied by the arcaded buildings of the custom house, post office and ministries. In the midst is a bronze equestrian statue of Joseph I., by J. M. de Castro, which was erected in 1775 and gives point to the name of "Black Horse Square" commonly applied to the Praça by the British. A triumphal arch on the north side leads to Rua Augusta, originally intended to be the cloth-merchants' street; for the plan upon which Lisbon was rebuilt after 1755 involved the restriction of each industry to a specified area. This plan succeeded in the neighbouring Rua Aurea and Rua da Prata, still, as their names indicate, famous for goldsmiths' and silversmiths' shops. Rua Augusta terminates on the north in the Rocío or Praça de Dom Pedro Quarto, a square paved with mosaic of a curious undulatory pattern (Rolling Motion Square) and containing two bronze fountains, a lofty pillar surmounted by a statue of Pedro IV., and the royal national theatre (Theatro de Dona Maria Segunda), erected on the site which the Inquisition buildings occupied from 1520 to 1836. The narrow Rua do Principe, leading past the central railway station, a handsome Mauresque building, connects the Rocío with the Avenida da Liberdade, one of the finest avenues in Europe. The central part of the Avenida, a favourite open-air resort of Lisbon society, is used for riding and driving; on each side of it are paved double avenues of trees, with flower-beds, statues, ponds, fountains, etc., and between these and the broad pavements are two roadways for trams and heavy traffic. Thus the Avenida has the appearance of three parallel streets, separated by avenues of trees instead of houses. Its width exceeds 300 ft It owes its name to an obelisk 98 ft. high, erected in 1882 at its southern end, to commemorate the liberation of Portugal from Spanish rule (Dec., 1640). North and north-east of the Avenida are the Avenida Park, the Edward VII. Park (so named in memory of a visit paid to Lisbon by the king of England in 1903), Campo Grande, with its finely wooded walks, and Campo Pequeno, with the bull-ring. Other noteworthy public gardens are the Passeio da Estrella, commanding magnificent views of the city and river, the Largo do Principe Real, planted with bananas and other tropical trees, the Tapada das Necessidades, originally the park of one of the royal residences, and the Botanical Gardens of the polytechnic school, with a fine avenue of palms and collections of tropical and subtropical flora hardly surpassed in Europe. There are large Portuguese cemeteries east and west of Lisbon, and an English cemetery, known also as *Os Cyprestes* from the number of its cypresses. This was laid out in 1717 at the cost of the British and Dutch residents and contains the graves of Henry Fielding (1707–1754), the novelist, and Dr. Philip Doddridge (1702–1751), the Nonconformist divine.

Lisbon is the seat of an archbishop who since 1716 has borne *ex officio* the honorary title of patriarch. The Estrella church, with its white marble dome and twin towers, is visible for many miles above the city. The late Renaissance church of São Roque contains two beautiful chapels dating from the 18th century, one of which is inlaid with painted tiles, while the other was constructed in Rome of coloured marbles, and consecrated by the pope before being shipped to Lisbon. Its mosaics and lapis lazuli pillars are exceptionally fine. The 14th-century Gothic Igreja do Carmo was shattered by the great earthquake. Only the apse, pillared aisles and outer walls remain standing, and the interior has been converted into an archaeological museum. The church of Nossa Senhora da Conceição has a magnificent Manueline façade.

The Palacio das Cortes, in which both Houses of Parliament sit, is a 16th-century Benedictine convent, used for its present purpose since 1834. It contains the national archives, better known as the Torre do Tombo collection, because in 1375 the archives were first stored in a tower of that name. The royal palace, or Paço das Necessidades, west of Buenos Ayres, is a vast 18th-century mansion occupying the site of a chapel dedicated to Nossa Senhora das Necessidades.

Suburbs and Environs.—In the extreme west of Lisbon, beyond the Alcantara valley, are Belem (*i.e.,* "Bethlehem"), beside the Tagus, and Ajuda, on the heights above. The Paço de Belem, built in 1700 for the counts of Aveiro, became the chief royal palace under John V. (1706–1750). The Torre de Belem, on the foreshore, is a small tower of beautiful design, built in 1520 for the protection of shipping. The finest ecclesiastical building in Portugal except the monasteries of Alcobaça and Batalha also fronts the river. It is the Convento dos Jeronymos, a Hieronymite convent and church, founded in 1499 to commemorate the discovery of the sea-route to India by Vasco da Gama. It was built of white limestone by João de Castilho (d. 1581), perhaps the greatest of Manueline architects. Parts of the building have been restored, but the cloisters and the beautiful central gateway remain unspoiled. The interior contains many royal tombs, including that of Catherine of Braganza (d. 1705), the wife of Charles II. of England. The supposed remains of Camoens and Vasco da Gama were interred here in 1880. In 1834, when the convent was secularized, its buildings were assigned to the Casa Pia, an orphanage founded by Maria I. Since 1903 they have contained the archaeological collections of the Portuguese Ethnological Museum. The royal Ajuda palace, begun (1816–1826) by John VI. but left unfinished, derives its name from the chapel of N. S. de Ajuda ("Our Lady of Aid"). In the coach-house there is an unsurpassed collection of state coaches, the cars upon which figures of saints are borne in procession, sedan chairs, old cabriolets and other curious vehicles.

The more important towns, Setubal, Cintra, Torres Vedras and Mafra, are described in separate articles. Sines, a small seaport on Cape Sines, was the birthplace of Vasco da Gama. On the left bank of the Tagus, opposite Lisbon, are the small towns of Almada, Barreiro, Aldeia Gallega and Seixal, and the hamlet of Trafaria, inhabited by fishermen. The beautiful strip of coast west of Oeiras and south of Cape Roca is often called the "Portuguese Riviera." Its fine climate, mineral springs and sea-bathing attract visitors at all seasons to the picturesque fortified bay of Cascaes, or to Estoril, Mont' Estoril and São João do Estoril, consisting chiefly of villas, hotels and gardens. Remarkable progress has been made of recent years at Mont' Estoril, where the thermal springs now have magnificent buildings, with a casino and new hotel; the railway to Lisbon has been electrified. The Boca do Inferno ("Mouth of Hell") is a cavity in the rocks at Cascaes resembling the Bufador at Peñiscola. The villages of Carcavellos, Bucellas, Lumiar and Collares produce excellent wines; at Carcavellos is the receiving station for cables, with a large British staff, and a club and grounds where, as at the new Sports Club nearer Lisbon, social and athletic meetings are held by the British colony. Alhandra, on the right bank of the Tagus, above Lisbon, was the birthplace of Albuquerque; fighting bulls for the Lisbon arena are bred in the adjacent pastures.

Population and Communications.—Lisbon has various railway stations—for the lines to Cintra, northern and central Portugal, Madrid via Valencia de Alcántara; and for southern Portugal and Andalusia. In 1902 the railways north and south of the Tagus were connected near Lisbon by a bridge. In the previous year an extensive system of electric tramways replaced the old-fashioned cable cars and mule trams. Electric and hydraulic lifts are used where the streets are too steep for trams. Lisbon is lighted by both electricity and gas; it has an admirable telephone service, and is connected by the Carcavellos cable-station with Cornwall (England), Brazil, Vigo in Galicia, Gibraltar, the Azores and Madeira. There are extensive quays with hydraulic cranes, graving docks and warehouses on both banks of the river, and Lisbon has long been one of the principal ports of debarcation for passengers from Brazil and of embarcation for emigrants to South America. The fisheries have always been important, and in no European fishmarket is the produce more varied.

The population of Lisbon, 187,404[1] in 1878, rose to 301,206 in 1890, 594,390 in 1930 and 709,179 in 1940. It includes a large foreign colony, composed chiefly of Spaniards, British, Germans, French, Brazilians and immigrants from the Portuguese colonies, among whom are many half-castes. The majority of the Spaniards are domestic servants and labourers from Galicia, whose industry and easily gained knowledge of the kindred Portuguese language enables them to earn a better livelihood here than in their own homes. The British, German and French communities control a large share of the foreign trade. The Brazilians and colonial immigrants are often merchants and landowners who come to the mother-country to spend their fortunes in a congenial social environment.

The street life of the city is full of interest. The bare-footed fishwives (*varinas,* women of Ovar) bearing flat trays of fish on their heads; the Galician water-carriers, with their casks; the bakers, bending beneath a hundredweight of bread slung in a huge basket from their shoulders; the countrymen, with their sombreros, sashes and hardwood quarter-staves, give colour and animation to their surroundings; while the bagpipes played by peasants from the north, the whistles of the knife-grinders, and the distinctive calls of the vendors of fruit, lottery tickets, or oil and vinegar, contribute a babel of sound. For church festivals and holidays the country-folk come to town, the women riding on pillions behind the men, adorned in shawls, aprons and handkerchiefs of scarlet or other vivid hues, and wearing the strings of coins and ornaments of exquisite gold and silver filigree which represent their savings or dowries.

History.—The name Lisbon is a modification of the ancient name *Olisipo,* also written *Ulyssippo* under the influence of a mythical story of a city founded by Odysseus (Ulysses) in Iberia, which, however, according to Strabo, was placed by ancient tradition rather in the mountains of Turdetania (the extreme south of Spain). Under the Romans Olisipo became a *municipium* with the epithet of *Felicitas Julia,* but was inferior in importance to the less ancient *Emerita Augusta* (Mérida). From 407 to 585 it was occupied by Alaric, and thenceforward by the Visigoths until 711, when it was taken by the Moors. Under the Moors the town bore in Arabic the name of *Al Oshbūna* or *Lashbūna.* It was the first point of Muslim Spain attacked by the Normans in 844. When Alphonso I. of Portugal took advantage of the decline and fall of the Almoravid dynasty to incorporate the provinces of Estremadura and Alemtejo in his new kingdom, Lisbon yielded only after a siege of several months (Oct. 21, 1147), in which Alphonso was aided by English and Flemish crusaders on their way to Syria. In 1184 the city was again attacked, unsuccessfully, by the Muslims under the powerful caliph Abu Yakub. In the reign of Ferdinand I., the greater part of the town was burned by the Castilians (1373), and in 1384 they again besieged Lisbon. It became the seat of an archbishop in 1390; the seat of government in 1422. During the 16th century it gained much in wealth and splendour from the establishment of a Portuguese empire in India and Africa. From 1580 to 1640 Lisbon was a provincial town under Spanish rule, and it was from this port that the Spanish Armada sailed in 1588.

For many centuries the city had suffered from earthquakes, and on Nov. 1, 1755, the greater part of it was reduced almost in an instant to a heap of ruins. A tidal wave at the same time broke over the quays and wrecked the shipping in the Tagus; fire broke out to complete the work of destruction; between 10,000 and 20,000 persons lost their lives; and the value of the property destroyed was about £20,000,000. The shock was felt from Scotland to Asia Minor. Careful investigation by Daniel Sharpe, an English geologist, has delimited the area in and near Lisbon to which its full force was confined. Lisbon is built in a geological basin of Tertiary formation, the upper portion of which is loose sand and gravel destitute of organic remains, while below these are the so-called Almada beds of yellow sand, calcareous sandstone and blue clay rich in organic remains. The Tertiary deposits, which altogether cover an area of more than 2,000 sq.m., are separated near Lisbon from rocks of the Secondary epoch by a great sheet of basalt. The uppermost of these Secondary rocks is the hippurite limestone. It was found that buildings on the blue clay were destroyed and those on the Tertiary deposits seriously injured, while those on the hippurite limestone and basalt were undamaged.

The French invasion of Portugal in 1807 caused the removal of the court to Brazil, and the subsequent Peninsular war, loss of Brazil through rebellion, and a period of internal warfare and contest for the throne resulted in a decadence of Lisbon from which it recovered slowly. The city suffered damage during revolutions in 1910, 1915, 1917, 1919 and 1927. After 1939 Lisbon assumed a peculiar importance as one of the last accessible loop-

[1]This figure represents the population of a smaller area than that of modern Lisbon, for the civic boundaries were extended by a decree dated Dec. 23, 1886.

holes of escape from Western Europe. A great number of refugees congregated there, with Portuguese emigration records showing that some 200,000 had passed through her ports in the period Nov. 1939–Aug. 1941. (*See* PORTUGAL: *History*.)

LISBURN, a market town, urban district and cathedral city of Co. Antrim, Northern Ireland, on the Lagan, 8 mi. S.S.W. of Belfast by rail. Pop. (1937) 13,042. Area, 1.8 sq.mi. In 1627 it was granted by Charles I to Viscount Conway, who built the castle, and introduced English and Welsh settlers. In 1641 the town was set on fire by insurgents. The troops of Cromwell gained a victory near there in 1648, and the castle surrendered in 1650. Christ church (1622) is the cathedral church of the united Protestant dioceses of Down and Connor and Dromore, and has a monument to Jeremy Taylor, bishop of Down and Connor. The staple manufactures are flax spinning, the manufacture of linen and thread and the weaving of damasks and muslins, originally introduced by Huguenots. There is considerable agricultural trade. The ruins of Castle Robin, 2 mi. N. of the town, on a summit of the White mountains, date from the time of Queen Elizabeth. At Drumbo, $3\frac{1}{2}$ mi. E. of Lisburn, is the Giant's Ring, with a dolmen in the centre. Here are also remains of a round tower. The N. Ireland transmitter of the British Broadcasting company is at Blaris, 2 mi. from Lisburn.

LISIEUX, a town of north-western France, capital of an arrondissement in the department of Calvados, 30 mi. E. of Caen by rail. Pop. (1936) 16,032. In the time of Caesar, Lisieux, under the name of *Noviomagus*, was the capital of the Lexovii. Though destroyed by the barbarians, by the 6th century it had become one of the most important towns of Neustria. Its bishopric, suppressed in 1802, dated from that period. In 877 it was pillaged by the Normans; and in 911 was included in the duchy of Normandy by the treaty of St. Clair-sur-Epte. Civil authority was exercised by the bishop as count of the town. In 1136 Geoffrey Plantagenet laid siege to Lisieux, which had taken the side of Stephen of Blois, but before it fell in 1141 both it and the neighbourhood had been reduced to famine. In 1152 the marriage of Henry II. of England to Eleanor of Guienne, which added so largely to his dominions, was celebrated in the cathedral. Thomas à Becket took refuge there, and some vestments used by him are shown in the hospital chapel. Taken by Philip Augustus and reunited to France in 1203, the town was a frequent subject of dispute between the contending parties during the Hundred Years' War, the religious wars, and those of the League.

Lisieux is in the valley of the Touques at its confluence with the Orbiquet. Towers of the 16th century, old fortifications, and streets of houses of the 14th, 15th and 16th centuries, are features. The church of St. Peter, formerly a cathedral, the oldest Gothic church in Normandy is contemporary with the cathedrals of Canterbury and Sens. Begun in the latter half of the 12th it was completed in the 13th and 16th centuries. There is a lantern-tower over the crossing and two towers surmount the west façade. The church of St. Jacques (late 15th century) contains Renaissance glass, some stalls and old frescoes, and a curious picture on wood, restored in 1681. The old episcopal palace is used for civil purposes and contains a beautiful hall (the salle dorée). Lisieux is the seat of a sub-prefect, and has tribunals of first instance and of commerce, a chamber of arts and manufactures, and a board of trade arbitrators. Its manufactures of woollens are important, and bleaching, wool and flax-spinning, tanning, brewing, timber-sawing, metal-founding, and the manufacture of machinery, hosiery and boots and shoes are carried on; there is trade in grain, cattle, cheese and fruit.

LISKEARD, a market town and municipal borough of Cornwall, England, 18 mi. W.N.W. of Plymouth by rail. Pop. (est. 1938) 4,120. Liskeard was at the time of the Domesday Survey an important manor. Richard, king of the Romans, built the manor house or castle and resided there occasionally. In 1240 he constituted Liskeard a free borough and its burgesses freemen with all the liberties enjoyed by the burgesses of Launceston and Helston. In 1266 he granted fairs at the Feasts of the Assumption and St. Matthew. His son in 1275 granted to the burgesses for a yearly rent of £18 the borough in fee farm with its mills, tolls, fines and pleas, pleas of the crown excepted. Liskeard was made a coinage town for tin in 1304. Queen Elizabeth's charter of 1586, was surrendered to Charles II in 1680 and a new one granted by his brother under which the corporation became a self-elected body, and the parliamentary franchise became vested in the corporation and freemen. Sir Edward Coke was returned for this borough in 1620, and Edward Gibbon the historian in 1774. In 1832 Liskeard was deprived of one of its members and in 1885 it became merged in the county. Liskeard manufactures woollen goods, and there are small iron foundries. The public library contains the Leonard Courtney collection of rare Cornish books. Area of borough, 4.2 sq.mi.

LISLE, ALICE (*c.* 1614–1685), commonly known as Lady Alice Lisle, was born about 1614, and married John Lisle (d. 1664), a member of Cromwell's House of Lords. On July 20, 1685, a fortnight after the battle of Sedgemoor, the old lady consented to shelter John Hickes, a well-known Nonconformist minister, at her residence, Moyles court, near Ringwood. Hickes, who was a fugitive from Monmouth's army, brought with him Richard Nelthorpe, also a partisan of Monmouth, and under sentence of outlawry. The two men passed the night at Moyles court, and on the following morning were arrested, and their hostess, who had denied their presence in the house, was charged with harbouring traitors. Her case was tried by Judge Jeffreys at the opening of the "Bloody Assizes" at Winchester. She pleaded that she had no knowledge that Hickes's offence was anything more serious than illegal preaching, that she had known nothing previously of Nelthorpe (whose name was not included in the indictment, but was, nevertheless, mentioned to strengthen the case for the Crown), and that she had no sympathy with the rebellion. The jury reluctantly found her guilty, and, the law recognizing no distinction between principals and accessories in treason, she was sentenced to be burned. James II. allowed beheading to be substituted for burning. Lady Lisle was executed in Winchester market-place on Sept. 2, 1685. One of the first acts of parliament of William and Mary reversed the attainder on the ground that the prosecution was irregular and the verdict injuriously extorted by "the menaces and violences and other illegal practices" of Jeffreys.

See Howell, *State Trials;* H. B. Irving, *Life of Judge Jeffreys;* Stephen, *History of the Criminal Law of England.*

LISMORE, an island in the entrance to Loch Linnhe, Argyllshire, Scotland, 5 mi. N.W. of Oban, $9\frac{1}{2}$ mi. long and $1\frac{3}{4}$ mi. broad. Pop. (1931) 280. It divides the lower end of the loch into two channels, the Lynn of Morvern on the west and the Lynn of Lorne on the east. The name is derived from the Gaelic *lios mòr*, "great garden," from the fertility of the soil. Several ruined castles stand on the coast, and the highest point is 500 ft. Oats, potatoes and lime are exported. Steamers call at Achnacroish, and there is a ferry to Port Appin. A Columban monastery was founded in Lismore by St. Moluag about 592. About 1200 the see of Argyll was separated from Dunkeld by Bishop John, "the Englishman," and Lismore soon afterwards became the seat of the bishop of Argyll. The small cathedral has been restored, and is used as the parish church. The Rev. John Macaulay, grandfather of Lord Macaulay, and the Rev. Donald M'Nicol (1735–1802), who took up the defense of the Highlands against Dr. Johnson, were ministers of Lismore.

LISMORE, a town in the northeast of New South Wales, Australia, situated on the Richmond river (*q.v.*), 65 mi. from its mouth at Ballina and 22 mi. from the same town by road. Coal occurs in the neighbourhood and the timber reserves were formerly largely exploited. Lismore is the centre of the chief dairy district of the state (av. ann. temps.: 76°–57.6° F; av. ann. rainfall: 34.5 in.), with butter factories which export to the

United Kingdom. The growing of sugar cane, after a decline, has recovered ground.

The town is well built, lies on the main North Coast railway (Sydney and Brisbane), has local branch lines (Ballina, etc.); also connections by motor coach with the northern highlands (Tenterfield, etc.), and, by river steamer, with Ballina and the sea (coastal trade). Pop. (1933), 11,762.

LISMORE, a market town and seat of a diocese in Co. Waterford, Eire, 43 mi. W.S.W. of Waterford by rail. Pop. (1936) 1,194. It is situated on a hill rising steeply from the Blackwater.

The original name of Lismore was Maghsciath. A monastery founded here by St. Carthagh in 633 became celebrated as a seat of learning. The bishopric, said to have originated with this foundation, was united to that of Waterford in 1363. In the 9th and beginning of the 10th centuries the town was repeatedly plundered by the Danes, and in 978 the town and abbey were burned by the men of Ossory. Henry II. received in Lismore castle the allegiance of the archbishops and bishops of Ireland. In 1581 the manor was granted to Sir Walter Raleigh. It was incorporated as a municipal borough in the time of Charles I. In 1800 it ceased to exercise its municipal functions.

The baronial castle, erected by John in 1185, was the residence of the bishops till the 14th century. It was besieged in 1641 and 1643, and in 1645 it was partly destroyed by fire. On the summit of the height is the cathedral of St. Carthagh; portions are probably of the 12th and 13th centuries, but the bulk of the building is of the 17th century, and considerable additions were made in the 19th. There is some river trade and the town is the centre of a salmon fishery district.

LISSA (Serbo-Croatian *Vis;* Lat. *Issa*), an island in the Adriatic sea belonging to Yugoslavia and occupied by Italy in World War II. Lissa lies 31 mi. S. by W. of Spalato, and is the outermost island of the Dalmatian Archipelago. Its greatest length is 10½ mi.; its greatest breadth 4½ mi. In shape it is long, as are most of the islands on this longitudinal coastline. The central plain is fertile. Its culminating point is Mount Hum (1,942 ft.), on the southwest. Lissa, the capital, contains the palace of the old Venetian counts Gariboldi, the former residence of the English governor, the monastery of the Minorites and at a little distance to the west the ruins of the ancient city of Issa.

Lissa is said to have been settled by people from Lesbos, the Issa of the Aegean. The Parians, assisted by Dionysius the Elder of Syracuse, introduced a colony in the 4th century B.C. During the First Punic War (265–241 B.C.) the Issaeans with their beaked ships helped the Roman Duilius; and the great republic, having defended their island against the attacks of Agron of Illyria and his queen Teuta, again found them serviceable allies in the war with Philip of Macedon (*c.* 215–211). As early as 996 the Venetians ruled the island, and, though they retired for a time before the Ragusans, their power was effectually established in 1278. Velo Selo, then the chief settlement, was destroyed by Ferdinand of Naples in 1483 and by the Turks in 1571. The present city arose shortly afterwards. During the Napoleonic wars, the French held Lissa until 1811, and during this period the island prospered greatly, its population increasing from 4,000 to 12,000 between 1808 and 1811. In the latter year the French squadron was defeated by the British (*see* below). In 1812 the British established an administrative system, under native officials, in Lissa and the adjoining islands of Curzola and Lagosta. All three were ceded to Austria in 1815. The islanders gain their livelihood by viticulture, for which Issa was once famous, by sardine fishing and by the distillation of rosemary oil. Pop. about 10,100. After World War I Lissa passed to Yugoslavia.

Battles of Lissa.—Two naval actions have been fought in modern times near this island. The first took place on the 13th of March 1811, and was fought between a Franco-Venetian squadron, under the command of an officer named Dubourdieu (of whom little or nothing else is known), and Captain (afterwards Sir) William Hoste with a small British force. The Franco-Venetian squadron (Venice was then part of the dominions of the emperor Napoleon) consisted of six frigates, of which four were of forty guns, and of five corvettes or small craft. The British squadron was composed of three frigates, the "Amphion," 32 (Captain William Hoste), the "Cerberus" (Captain Henry Whitby) and the "Active," 38 (Captain James A. Gordon). With them was the "Volage," 22 (Captain Phipps Hornby). The action has a peculiar interest because the French captain imitated the method of attack employed by Nelson at Trafalgar. He came down from windward in two lines parallel to one another, and at an angle to the British squadron. Captain Hoste was not compelled to lie still as the allies did at Trafalgar. He stood on, and as the two French lines had to overtake him as he slipped away at an angle to their course, one of them got in the way of the other. Captain Hoste materially forwarded the success of his manoeuvre by leading the foremost French ship, the "Favorite," 40, on to a reef, which was known to himself, but not to the enemy. Both squadrons then turned, and the Franco-Venetians falling into great confusion were defeated in spite of the gallant fighting of the individual ships. Two prizes were taken and Dubourdieu was killed.

The second naval battle of Lissa was fought between the Austrian and Italian navies on the 20th of July 1866. The island, then in possession of the Austrians, was attacked by an Italian squadron from Ancona of 12 ironclads and 22 wooden vessels. One of the ironclads was damaged in a bombardment of the forts, and two were detached on other service, when an Austrian squadron of 7 ironclads, one unarmoured warship the "Kaiser" and a number of small craft which had left Fasano under the command of Admiral Tegethoff came to interrupt their operations. The Italian admiral Persano arranged his ships in a single long line ahead, which allowing for the necessary space between them meant that the Italian formation stretched for more than 2 m. Just before the action began Admiral Persano shifted his flag from the "Re d'Italia," the fourth ship in order from the van, to the ram "Affondatore," the fifth. This made it necessary for the "Affondatore" and the ships astern to shorten speed, and, as the leading vessels stood on, a gap was created in the Italian line. Admiral Tegethoff, who was on the port bow of the Italians, attacked with his squadron in three divisions formed in obtuse angles. The Italians opened a very rapid and ill-directed fire at a distance of 1,000 yds. The Austrians did not reply till they were at a distance of 300 yds. Under Tegethoff's vigorous leadership, and aided by the disorder in the Italian line, the Austrians brought on a brief, but to the Italians destructive, mêlée. They broke through an interval between the third and fourth Italian ships. The unarmed Austrian ships headed to attack the unarmed Italians in the rear. At this point an incident occurred to which an exaggerated importance was given. The Italian ironclad "Re di Portogallo" of 5,600 tons, in the rear of the line, stood out to cover the unarmoured squadron by ramming the Austrians. She was herself rammed by the wooden "Kaiser" (5,000 tons), but received little injury, while the Austrian was much injured. The "Kaiser" and the wooden vessels then made for the protection of fort San Giorgio on Lissa unpursued. In the centre, where the action was hottest, the Austrian flagship "Ferdinand Max" of 5,200 tons rammed and sank the "Re d'Italia." The Italian "Palestro" of 2,000 tons was fired by a shell and blew up. By midday the Italians were in retreat, and Tegethoff anchored at San Giorgio. His squadron had suffered very little from the wild fire of the Italians. The battle of July 20 was the first fought at sea by modern ironclad steam fleets, and therefore, attracted a great deal of attention. The sinking of the "Re d'Italia" and the ramming of the "Portogallo" by the "Kaiser" gave an immense impulse to the then popular theory that the ram would be a leading, if not the principal, weapon in modern sea warfare. This calculation has not been borne out by more recent experience, and indeed was not justified by the battle itself, in which the attempts to ram were many and the successes very few. The "Re d'Italia" was struck only because she was suddenly and most injudiciously backed, so that she had no way on when charged by the "Ferdinand Max."

For the first battle of Lissa *see* James's *Naval History,* vol. v. (1837). A clear account of the second battle will be found in Sir S

Eardley-Wilmot's *Development of Navies* (London, 1892); *see* also H. W. Wilson's *Ironclads in Action* (London, 1896). (D. H.)

LISSA: *see* LESZNO.

LIST, FRIEDRICH (1789–1846), German economist, was born at Reutlingen, Württemberg, on Aug. 6, 1789. Unwilling to follow the occupation of his father, who was a tanner, he became a clerk in the public service, and by 1816 had risen to the post of ministerial under-secretary. In 1817 he was appointed professor of administration and politics at the university of Tübingen, but the fall of the ministry in 1819 compelled him to resign. As a deputy to the Württemberg chamber, he was active in advocating administrative reforms. He was eventually expelled from the chamber and in April 1822 sentenced to ten months' imprisonment from which he was released on promising to emigrate to America, where he lived from 1825 to 1832. Successful both as a journalist and as a speculator in coal and railways, he was employed on a mission to Paris and in 1832 became United States consul at Leipzig.

He strongly advocated the extension of the railway system in Germany, and the establishment of the *Zollverein* was due largely to his enthusiasm and ardour. Ill health and financial difficulties darkened his later days, and on Nov. 30, 1846, he died by his own hand.

List holds historically one of the highest places in economic thought as applied to practical objects. His principal work is entitled *Das Nationale System der Politischen Ökonomie* (1841). Though his practical conclusions were different from those of Adam Müller (1779–1829), he was largely influenced both by him and Alexander Hamilton. It was particularly against the cosmopolitan principle in the modern economical system that he protested, and against the absolute doctrine of free trade, which was in harmony with that principle. He gave prominence to the national idea, and insisted on the special requirements of each nation according to its circumstances and degree of development.

He refused to Smith's system the title of the industrial, which he thought more appropriate to the mercantile system, and designated the former as "the exchange-value system." He denied the parallelism asserted by Smith between the economic conduct proper to an individual and to a nation, and held that the immediate private interest of the separate members of the community would not lead to the highest good of the whole. He maintained that national unity, which is the result of past development, is necessary to the individual whose interests should be subordinated to the preservation of this unity. The nation having a continuous life, its true wealth must consist—and this is List's fundamental doctrine—not in the quantity of exchange-values which it possesses, but in the full and many-sided development of its productive powers. Its economic education should be more important than the immediate production of values, and it might be right that one generation should sacrifice its gain and enjoyment to secure the strength and skill of the future. In the sound and normal condition of a nation which has attained economic maturity, the three productive powers of agriculture, manufactures and commerce should be alike developed. But the two latter factors are superior in importance, as exercising a more effective and fruitful influence on the whole culture of the nation, as well as on its independence. But for the growth of the higher forms of industry, only those countries of the temperate zones are adapted, while the torrid regions have a natural monopoly in the production of certain raw materials; and thus between these two groups a division of labour spontaneously takes place.

List then goes on to explain his theory of the stages of economic development through which the nations of the temperate zone naturally pass, in advancing to their normal economic state. These are (1) pastoral life, (2) agriculture, (3) agriculture united with manufactures; while in the final stage agriculture, manufactures and commerce are combined. The economic task of the state is to bring into existence through legislative and administrative action the conditions required for the progress of the nation through these stages. Out of this view arises List's scheme of industrial politics. Every nation should begin by fostering its agriculture by free trade and when it is economically so far advanced that it can manufacture for itself, a system of protection should be employed to allow the home industries to develop themselves fully. When the national industries have grown sufficiently strong, the highest stage of progress has been reached; free trade should again become the rule, and the nation be incorporated with the universal industrial union. What a nation loses for a time in exchange values during the protective period she gains in the long run in productive power. The practical conclusion which List drew for Germany was that she needed for her economic progress an extended and conveniently bounded territory reaching to the seacoast both on north and south, and a vigorous expansion of manufactures and commerce, and that the way to the latter lay through protective legislation with a customs union comprising all German lands, and a German marine with a Navigation act. List ably represented the tendencies and demands of his time in his own country; his work had the effect of fixing the attention, not merely of the speculative and official classes, but of practical men generally, on questions of political economy; and his ideas were undoubtedly the economic foundation of modern Germany, as applied by the practical genius of Bismarck.

See biographies of List by Goldschmidt (Berlin, 1878), Jentsch (Berlin, 1901) and Hoeltrel (1910); M. E. Hirst, *Life of Friedrich List* (London, 1909) contains a bibliography and a reprint of List's *Outlines of American Political Economy* (1827). *See* also the article by Eheberg in *Handwörterbuch der Staatswissenschaften* vol. vi. (4th ed., 1925).

LISTA Y ARAGON, ALBERTO (1775–1848), Spanish poet, critic and mathematician, was born in Triana, a suburb of Seville Oct. 15, 1775. As a youth he showed unusual mathematical talent, and at the age of twenty he was made professor of mathematics in a nautical college in Seville. He distinguished himself as a poet and critic and was appointed to the chair of rhetoric and poetry in the university of Seville in 1807.

During the French invasion he was exiled in France, where he remained for four years. Among his many published works were, *Lectures on the Dramatic Literature of Spain,* and a *Treatise on Pure and Mixed Mathematics,* which was long considered a standard work. He died on Oct. 15, 1848.

LISTED SECURITIES, securities which have been examined, approved and listed, or admitted for trading, on one of the stock exchanges. Before a security can be listed on an exchange the issuing company must be investigated by a committee of the exchange and must meet many requirements. Each exchange has its own requirements for listing but those of the New York Stock exchange, although more rigid than others, may be taken as representative. The "Committee on Stock List" examines and acts upon the applications for listing but its findings may be reviewed by the governing committee of the exchange. The reason for the investigation of securities and the listing of only those desired is to place upon the exchange only sound securities concerning which there is available sufficient information to permit intelligent analysis and trading. Securities of new and untried corporations are not accepted, and in order to have its securities accepted for listing a company must have operated long enough to establish a satisfactory character and an earning capacity. Corporations with listed securities must publish their balance sheets, statements of earnings, announcements of directors' meetings, and notices of closing and opening of books. It is also required that the listed issues be large and widely held. The fact that a security is listed on an exchange must not, however, be taken as a guarantee of any kind. It does not give assurance that market prices will not decline, that stock will pay dividends, that bonds will pay interest, or be paid at maturity. (J. H. B.)

LISTER, JOSEPH LISTER, 1ST BARON (1827–1912), English surgeon and founder of antiseptic surgery, was born at Upton, Essex, on April 5, 1827. His father, Joseph Jackson Lister, F.R.S., became eminent in optical science by perfecting the achromatic lens and improving the compound microscope. Joseph Lister was educated at the Quaker schools at Hitchin and at Tottenham, and then at University college, London. He received his M.B. and F.R.C.S. in 1852, having been trained under the two noted physiologists, Wharton Jones and William Sharpey. In the autumn of 1853, Lister went to Edinburgh with an introduction from Sharpey to Syme (*q.v.*) whose house surgeon he became. In 1856 he married Syme's daughter, and soon afterwards was made assistant surgeon to the Royal infirmary, where he gave his first course of lectures on surgery. In the following year he produced his classic paper on "The Early Stages of Inflammation," an investigation in which his interests had already been roused by his contact with gangrene and pyaemia in University college hospital, London. About the same time, he began work on the coagulation of blood, a subject related to the early stages of inflammation. In his Croonian lecture to the Royal Society in 1863 on this topic, he concluded that the real cause of coagulation of the blood is "the influence exerted upon it by ordinary matter, the contact of which for a very brief period effects a change in the blood, inducing a mutual reaction between its solid and fluid constituents, in which the corpuscles impart to the liquor sanguinis a disposition to coagulate."

On his appointment to the chair of surgery at Glasgow in 1860, Lister at first busied himself with his articles on amputation and on anaesthetics for Holmes' *System of Surgery.* He then resumed his researches on inflammation, his suspicion that decomposition of the blood in the wound was the main cause of suppuration taking on a new meaning after his attention was drawn in 1865 to the work of Pasteur by his colleague, Dr. Thomas Anderson. Pasteur (*q.v.*) had shown that putrefaction, like other fermentations, was due to microbes growing in the putrescible substance and coming from the air. Lister at once saw that if putrefaction was caused neither by the spontaneous generation of germs nor by the oxygen in the air—two predominating theories of his day—there was some chance of preventing it. But how were the organisms in the air to be destroyed before they entered the wound? Of three possibilities, filtration, heat and chemical agents, he selected the last for experiment.

The first experiment was made in 1865 upon a compound fracture, the agent used being carbolic acid. It was applied to the wound undiluted, so as to form with the blood a dense crust, the surface of which was painted daily with the acid until all danger had passed. The results, after a first failure, were so satisfactory that Lister wrote his paper, "On a New Method of treating Compound Fracture, Abscess, etc.," for the *Lancet* between March and July 1867, and at the British Association in Dublin, in the same year, spoke of the value of his methods. However, the caustic property of undiluted carbolic acid, though insignificant in comparison with the evils to be avoided in compound fracture, made it unsuited for general surgery. It was necessary to mitigate its action by blending it with some inert substance, and the endeavour to find this substance which would provide perfect antiseptic efficiency with the least possible irritation of the tissues formed the subject of experiments continued for many years. Lister found the lac plaster to be most satisfactory. It was a mixture of crystallized carbolic acid and shellac which, when spread on calico and painted with a solution of gutta-percha in benzine, passed through the gutta-percha without adhering to the skin so firmly as to prevent drainage.

Lister now turned his attention to the arrest of haemorrhage in aseptic wounds. It had long been the practice to employ silk or flax for tying arteries, long ends being left to provide escape of the pus together with the portion of the arterial coats included in the knot. Lister hoped that if, by antiseptic means, the thread were deprived of microbes, it would no longer cause suppuration, but might be left with short cut ends to become embedded permanently among the tissues of the wound, which thus would be allowed to heal by first intention. In Dec. 1867 a trial of carbolized silk ligature was so successful that he applied it in a case of femoral aneurysm in a woman. Here again the results were satisfactory. But a year later, the patient having died from other causes, the necropsy showed remnants of the silk incompletely absorbed, with appearances which seemed to indicate that they had been acting as causes of disturbance. Thus he began to seek for a material susceptible of more speedy absorption. He experimented upon the carotid artery of a calf with carbolized catgut, a substance prepared from the small intestine of a sheep. Here again success warranted its use for human subjects, but the difficulty of ensuring its right preparation led him to adopt ultimately a sulphochromic catgut.

In 1869 Lister succeeded his father-in-law, Syme, in the chair of clinical surgery of Edinburgh. There his chief accomplishments were his researches in bacteriology, his substitution of the dressings of absorbent gauze for the non-absorbing lac plaster and his attempt to provide an atmosphere free from microbes by means of a spray of a 1–20 watery solution of carbolic acid. The efficacy of this famous spray, which was used all over the continent, was questioned by Bruns of Tübingen in his paper, *Fort mit dem Spray* of 1880, and Lister himself was beginning to be dubious about the harmfulness of atmospheric dust. At the London Congress in 1881, he narrated experiments which proved both that the serum of the blood is unfavourable for the development of the bacteria swarming in the air and that the cells of an organizing blood-clot have a remarkable power of disposing of microbes and of limiting their advance. Finally, in 1887, Lister abandoned the spray, having come to the conclusion that the air might be disregarded in operations. The spray had served the purpose of maintaining a pure condition of the *entourage* of the operation, and Lister now had to emphasize the necessity for redoubled vigilance on the part of the surgeon and his assistants when his "unconscious caretaker," as he called it, was disregarded.

The relation of Ignaz Semmelweiss, the Hungarian physician, to Lister is of historical importance. Long after Lister's first publication on the antiseptic system (1867) Semmelweiss was unknown or ignored. The French academy pronounced against his opinions as did the highest pathological authority in Germany. In the early 70s Lister's method was in full operation in Hungary as elsewhere, yet none of the surgeons of Budapest ever mentioned Semmelweiss, not even when they gave a great banquet to Lister in 1883. It was after this occasion that Dr. Duka, a Hungarian physician practising in London, wrote a biography of Semmelweiss, which he sent to Lister. Thenceforth Lister regarded Semmelweiss as in some measure his forerunner, though the Hungarian was not aware of the microbic origin of septic poisons, nor were his methods suitable for surgical work.

In 1877 Lister accepted the chair of surgery at King's college, London, which he held for 15 years. While there, the publication of Koch's book on the etiology of traumatic infectious diseases led him to experiment with various mercurial preparations, until he finally adopted a double cyanide of mercury and zinc. In 1896 he retired from practice, but not from scientific study. From 1895 to 1900 he was president of the Royal Society, and in 1896 president of the British Association. In 1883 he was created a baronet, and in 1897 was raised to the peerage as Baron Lister of Lyme Regis. Among the Coronation honours in 1902, he was nominated an original member of the new Order of Merit. He died at Walmer, Kent, on Feb. 10, 1912. The best monument to Lister is the Lister Institute of Preventive Medicine, London—of which he was one of the founders at its inception as the British Institute of Preventive Medicine in 1891. It was modelled on the Pasteur institute in Paris. On the continent he was even more renowned, the German surgeons, especially Thiersch and Volkmann, being the first to adopt his ligature technique and his aseptic treatment, which had banished for ever the prevalent surgical pests—pyaemia, septicaemia, erysipelas and hospital gangrene. Among Lister's contributions to general surgery, Godlee (*see* below) mentions his new amputation through the condyles of the femur, his new operation for excision of the wrist joint and for carcinoma of the breast, his improved surgery of the bladder and urethra and his introduction of such instruments as the aortic tourniquet, the wire needle, the ear hook, the sinus forceps, the urethral bougies and the forceps for extracting stones from the prostatic urethra.

See Lister's *Collected Papers,* 2 vols. (Oxford, 1909); R. J. Godlee, *Lord Lister* (Oxford, 1924); W. Cheyne, *Lister and his Achievement* (1925); and A. Turner, *Joseph, Baron Lister,* centenary vol. (Edinburgh, 1927).

LISTER, JOSEPH JACKSON (1786–1869), English scientist and father of Joseph Lister, was born in London, Jan. 11, 1786. He had only a few years of formal schooling, but even after he no longer attended classes he was diligent in educating himself. He became a wine merchant by trade, taking over his father's shop, but his interest lay in lenses even as a child, and in 1824 he began the work on the compound microscope which was to be his chief contribution to science. In 1830, in a paper, "On the Improvement of Compound Microscopes," which he read before the Royal society, he made public the results of six years' work on the microscope. During that time he had discovered the principle of aplanatic foci, which enabled him to outline to W. Tulley, a noted optician, the methods for constructing a powerful achromatic microscope which would transmit images with almost no distortion. It was excessive distortion of the image which had previously prevented the microscope from taking its proper place in scientific research.

In addition to his work with the microscope, Lister made important studies on mammalian blood and invented the photographer's tripod. He died in Upton, Essex, Oct. 24, 1869.

LISTER, MARTIN (*c.* 1638–1712), English naturalist and physician, was born at Radclive, near Buckingham. He was educated at St. John's college, Cambridge, graduating in 1658–59. He was elected a fellow in 1660 and became F.R.S. in 1671. He practised medicine at York until 1683, when he removed to London. In 1684 he received the degree of M.D. at Oxford and in 1687 became F.R.C.P. He contributed numerous articles on natural history, medicine and antiquities to the *Philosophical Transactions*. His principal works were *Historiae animalium Angliae tres tractatus* (1678); *Historiae Conchyliorum* (1685–92); and *Conchyliorum Bivalvium* (1696).

As a conchologist he was held in high esteem, but while he recognized the similarity of fossil mollusca to living forms, he regarded them as inorganic imitations produced in the rocks. In 1683 he communicated to the Royal society (*Phil. Trans.*, 1684), *An ingenious proposal for a new sort of maps of countries; together with tables of sands and clays, such as are chiefly found in the north parts of England*. In this essay he suggested the preparation of a soil or mineral map of the country, and thereby is credited with being the first to realize the importance of a geological survey. He died at Epsom, Feb. 2, 1712.

LISTER, THOMAS HENRY (1800–1842), English author, was educated at Cambridge university. He held several minor government positions until 1836, when he was made the first registrar-general of births, deaths and marriages of England and Wales, the office having just been created. His best-known literary work was his novel *Granby* (1826), which was well thought of in the early 19th century. He was also the author of six other novels, *Herbert Lacy, Romance of Real Life, Flirtation, Yes and No, Arlington* and *Hulse House;* a play, *Epicharis;* and a biography, *The Life and Administration of Edward, First Earl of Clarendon, with Original Correspondence and Authentic Papers never before published*. He died June 5, 1842, at Knightsbridge.

LISTON, JOHN (*c.* 1776–1846), English actor, was born in Soho, London. He attended school in Soho and for a time taught school but soon turned to the stage, making his public debut at Weymouth as Lord Duberley in *The Heir-at-law*. At first he played serious roles, some of them in support of Mrs. Siddons, but he was badly fitted for them and was far from successful. After he joined Stephen Kemble, however, he began to play low comedy parts and it was in them that he gained his reputation, especially in the representation of old men and country boys. An introduction to Charles Kemble led to his appearance at the Haymarket in 1805 as Sheepface in *The Village Lawyer*, and his association with this theatre continued almost uninterruptedly until 1830. He also performed during his lifetime at Covent Garden, Drury Lane and the Olympic theatre, retiring from the stage in 1837.

Liston played numerous Shakespearean comedy parts, but his best role is almost universally considered to be the part of Paul Pry in John Poole's play of that name. During his last years Liston's mind failed, and he died in London, March 22, 1846. There is some disagreement as to whether he was a real comedian or merely a buffoon, but he was indisputably the most successful comic actor of his day.

LISTON, ROBERT (1794–1847), Scottish surgeon, was born at Ecclesmachan, Linlithgow, Scotland, Oct. 28, 1794. His elementary education was given him by his father, after which he studied at the University of Edinburgh, starting medical work in 1810 under the noted anatomist, John Barclay. Beginning in 1815, he held a number of positions in hospitals, taught anatomy for a time in Edinburgh and in 1827, after some difficulty caused by his tactless methods of criticizing the policies of the Royal infirmary in Edinburgh, was made one of the surgeons to the infirmary.

In 1834 he left Edinburgh for London, becoming shortly after his arrival professor of clinical surgery in University college, University of London, and a surgeon of the North London hospital. He was placed on the council of the Royal College of Surgeons in 1840 and six years later was chosen one of its examiners. He died in London, Dec. 7, 1847.

Liston was an exceptionally skilful surgeon and was famous for the speed and proficiency with which he performed difficult operations never before attempted. He was the inventor of many operative procedures which later became standard surgical technique, and he is particularly noted for the thigh splint which bears his name. In addition to articles in medical journals, he was the author of *Principles of Surgery* (1831–32) and *Practical Surgery* (1837).

LISU (LISAW, YAWYIN), a tribe inhabiting the Salween valley in northern Burma, believed to have migrated southward from the Tibeto-Chinese borders, and still in a migratory condition. They belong to the group called *protomorphus* by Haddon, otherwise described as having Caucasian affinities. They are divided into clans with names suggesting totemism, *e.g.*, fish-, bee-, hemp-people. Some customs suggest Indonesian affinities, viz., spirit- and ancestor-worship; burial in the fields; use of bark or leather cuirasses. They keep hunting dogs, use cross-bows with poisoned arrows and cultivate maize and buckwheat. Houses are built on the ground. The men wear short hair or pigtail, the women two plaits or horns over the ears.

See Litton, *Report on Upper Salween* (Rangoon, 1906); Enriquez, *A Burmese Arcady* (1923). (J. H. H.)

LISZT, FRANZ (1811–1886), Hungarian pianist and composer, was born on Oct. 22, 1811, at Raiding, Hungary. His appeal to musicians was made in a threefold capacity, and we have, therefore, to deal with Liszt, the unrivalled pianoforte virtuoso (1830–48); Liszt, the conductor of the "music of the future," at Weimar, the teacher of Taussig, Bülow and a host of lesser pianists, the eloquent writer on music and musicians, the champion of Berlioz and Wagner (1848–61); and Liszt the prolific composer, who for some 35 years continued to put forth pianoforte pieces, songs, symphonic orchestral pieces, cantatas, masses, psalms and oratorios (1847–82). As virtuoso he held his own for the entire period during which he chose to appear in public; but the militant conductor and prophet of Wagner had a hard time of it; and the composer's place is still in dispute.

Liszt's father, a clerk to the agent of the Esterhazy estates and an amateur musician of some attainment, was Hungarian by birth and ancestry, his mother an Austrian-German. The boy's gifts attracted the attention of certain Hungarian magnates, who furnished 600 gulden annually for some years to enable him to study music at Vienna and Paris. At Vienna he had lessons in pianoforte, playing from Karl Czerny of "Velocity" fame, and from Salieri in harmony and analysis of scores. In his 11th year he began to play in public there, and Beethoven came to his second concert in April 1823. During the three years following he played in Paris, the French provinces and Switzerland, and paid three visits to England. In Paris he had composition lessons from Paër, and a six months' course of lessons in counterpoint from Reicha. In the autumn of 1825 the handsome and fascinating *enfant gâté* of the salons and ateliers—"La Neuvième Merveille du monde"—had the luck to get an operetta (*Don Sancho*) performed three times at the Académie Royale. The score was accidentally destroyed by fire, but a set of studies *à la* Czerny and Cramer, belonging to 1826 and published at Marseille as 12 Études, op. i, is extant and shows remarkable precocity. After the death of his father in 1828 young Liszt gave pianoforte lessons in Paris, got through a good deal of miscellaneous reading and felt the influence of the religious, literary and political aspirations of the time. He attended the meetings of the Saint-Simonists, lent an ear to the romantic mysticism of Père Enfantin and later to the teaching of Abbé Lamennais. He also played Beethoven and Weber in public—a very courageous thing in those days.

The appearance of the violinist Paganini in Paris, 1831, marks the starting point of the supreme eminence Liszt ultimately attained as a virtuoso. Paganini's marvellous technique inspired him to practise as no pianist had ever practised before. He tried to find equivalents for Paganini's effects, transcribed his violin caprices for the piano and perfected his own technique. After Paganini he received a fresh impulse from the playing and the compositions of Chopin, who arrived in 1831, and yet another impulse of equal force from a performance of Berlioz's *Symphonie Fantastique, épisode de la vie d'un artiste,* in 1832. Liszt transcribed this work, and its influence ultimately led him to the composition of his "Poèmes symphoniques" and other examples of orchestral program music.

From 1833 to 1848—when, with characteristic indifference to material considerations, he gave up playing in public—he was the prince of pianists. Five years (1835–40) were spent in Switzerland and Italy, in semi-retirement in the company of the comtesse d'Agoult (*q.v.*), by whom he had three children, one of them afterward Frau Cosima Wagner. These years were devoted to further study and were interrupted only by occasional appearances at Geneva, Milan, Florence and Rome and by annual visits to Paris, when a famous contest with Thalberg took place in 1837. The enthusiasm aroused by Liszt's playing and his personality—the two are inseparable—reached a climax at Vienna and Budapest in 1839–40, when he received a patent of nobility from the emperor of Austria and a sword of honour from the magnates of Hungary in the name of the nation. During the eight years following he was heard at all the principal European centres. He gained much money and gave large sums in charity. His munificence with regard to the Beethoven statue at Bonn made a great stir. The monument was completed at his expense and unveiled at a musical festival conducted by Spohr and himself in 1845.

In 1848 he settled at Weimar with Princess Sayn-Wittgenstein (d. 1887), and remained there till 1861. During this period he acted as conductor at court concerts and on special occasions at the theatre, gave lessons to a number of pianists, wrote articles of permanent value on certain works of Berlioz and the early operas of Wagner and produced those orchestral and choral pieces upon which his reputation as a composer mainly depends. His efforts on behalf of Wagner, then an exile in Switzerland, culminated in the first performance of *Lohengrin* on Aug. 28, 1850. Among other works produced during this period for the first time or revived with a view to the furtherance of musical art were Wagner's *Tannhäuser, Der fliegende Holländer, Das Liebesmahl der Apostel,* and *Eine Faust Overtüre,* Berlioz's *Benvenuto Cellini,* the *Symphonie Fantastique, Harold en Italie, Roméo et Juliette, La Damnation de Faust,* and *L'Enfance du Christ*—the last two conducted by the composer—Schumann's *Genoveva, Paradise and the Peri,* the music to *Manfred* and to *Faust,* Weber's *Euryanthe,* Schubert's *Alfonso und Estrella,* Raff's *König Alfred,* Cornelius' *Der Barbier von Baghdad* and many more.

It was Liszt's habit to recommend to the public such works as he produced not merely by performing them as admirably as possible but also by explanatory articles or essays, such as his two masterpieces of sympathetic criticism, the essays *Lohengrin et Tannhäuser à Weimar* and *Harold en Italie,* which articles found many readers and proved very effective. They are now included together with articles on Schumann and Schubert, Chopin and others in his *Gesammelte Schriften* (6 vol., Leipzig).

The compositions belonging to the period of his residence at Weimar comprise two pianoforte concertos, in E flat and in A, the *Todtentanz,* the *Concerto pathétique* for two pianos, the solo sonata *An Robert Schumann,* sundry *Études,* 15 *Rhapsodies Hongroises,* 12 orchestral *Poèmes symphoniques, Eine Faust Symphonie,* and *Eine Symphonie zu Dante's "Divina Commedia,"* the 13th Psalm for tenor solo, chorus and orchestra, the choruses to Herder's dramatic scenes "Prometheus," and the Missa solennis known as the *Graner Fest Messe.*

Liszt retired to Rome in 1861 and joined the Franciscan order in 1865. The Princess Wittgenstein, it has been said, was determined to marry him, and since neither he nor her family wished their connection to take this form, Cardinal Hohenlohe quietly had him ordained. From 1869 onward he—now the Abbé Liszt—divided his time between Rome and Weimar, where, during the summer months, he received pupils—gratis as formerly—and from 1876 up to his death at Bayreuth on July 31, 1886, he also taught for several months every year at the Hungarian Conservatoire of Budapest.

Liszt's pianoforte technique was based on the teaching of Czerny, who brought up his pupil on Mozart, a little Bach and Beethoven, a good deal of Clementi and Hummel, and a good deal of his (Czerny's) own work. Classicism in the shape of solid, respectable Hummel on the one hand, and Karl Czerny, a trifle flippant, perhaps, and inclined to appeal to the gallery, on the other, these gave the musical parentage of young Liszt. Then appears the Parisian Incroyable and grand seigneur—"Monsieur Lits," as the Parisians called him. Later, we find him imitating Paganini and Chopin, and at the same time making a really passionate and deep study of Beethoven, Weber, Schubert, Berlioz. Thus gradually was formed the master of style—whose command of the instrument was supreme and who played like an inspired poet.

Liszt's strange musical nature was long in maturing its fruits. At the pianoforte his achievements culminated in the two books of studies, twice rewritten, and finally published in 1852 as *Études d'exécution transcendante,* the *Études de concert* and the *Paganini Studies;* the two concertos and the *Todtentanz,* the sonata in B Minor, the Hungarian Rhapsodies and the fine transcriptions of Beethoven's symphonies (the 9th for two pianofortes as well as solo), and of Berlioz's *Symphonie Fantastique,* and the symphony *Harold en Italie.* In his orchestral pieces Liszt was the great apostle of program music (*q.v.*), and in that capacity may be said to have established his most conspicuous claim, apart from his achievements as a pianist, to a place in musical history.

Of his own orchestral works the *Dante* and *Faust* symphonies are generally considered the best. The subject of the *Dante symphony* (1847–55) was particularly well-suited to Liszt's temperament and offered good chances for the display of his peculiar powers as a master of instrumental effect. In the *Faust symphony* (1854–57) the moods of Goethe's characters—Faust, Gretchen and Mephistopheles—are depicted in three instrumental movements, with a chorus of male voices supplying a kind of comment, by way of close. The method of presentation in both symphonies is by means of representative themes (*Leitmotif*), and their combination and interaction. Incidents of the poem or play are illustrated or alluded to as may be convenient, and the exigencies of musical form are not unfrequently disregarded for the sake of special effects. Of the 12 Poèmes symphoniques, *Orphée* is perhaps the most consistent from a purely musical point of view and is exquisitely scored, while *Les Préludes, Tasso* and *Mazeppa* contain many happy pages.

In the choral numbers of the five masses, and in the oratorios *Die Heilige Elisabeth* and *Christus,* there are also fine movements, even if those works as a whole can never be regarded as commensurate with the high aims and genuine religious fervour which went to their making. More truly inspired than most of these larger works are some of Liszt's songs.

Speaking generally of Liszt it may be said that the man was greater than his music. Distinguished by the rarest magnanimity of nature and generosity of soul, he laboured even more energetically to advance the cause of others than his own; most conspicuously of all, of course, in the case of Wagner, and if only for his labours in this regard, and as a fearless champion of all that was noblest in the art, alike ancient and modern, he deserves ever to be held in lasting honour and remembrance.

Bibliography.—Liszt's writings, *Gesammelte Schriften,* were col-

lected by Lina Ramann (6 vols., Leipzig, 1880–83). His correspondence appeared in 9 vol., 1894–1904, edit. by La Mara, and various additional volumes were published later, including *Briefwechsel zwischen Wagner und Liszt,* edit. E. Kloss (2 vol., 3rd ed., 1910). For biographical material *see* L. Ramann, *Franz Liszt als Künstler und Mensch* (3 vol., 1880–94; Eng. trans. by E. Cowdray, 2 vol., 1882); Cosima Wagner, *Franz Liszt* (1912); B. Schrader, *Franz Liszt* (1914); J. Kapp, *Franz Liszt* (1909, 1926); R. Wetz, *Franz Liszt* (1925); A. Hahm, *Franz Liszt, Symphonische Dichtungen erläutert* (1920).

LISZT, FRANZ VON (1851–1919), German jurist, cousin of the composer, Franz Liszt, was born in Vienna on March 2, 1851. He qualified in 1875 as a teacher of criminal law at Graz in Austria, was a professor at Giessen (1879), Marburg (1882), Halle (1889), and in Berlin in 1899. In 1912 he became a member of the Fortschrittliche Volkspartei (Progressive People's party) in the Reichstag.

Liszt's life work was the scientific foundation and reform of the criminal law of which the basic principles are contained in his treatise *Der Zweckgedanke im Strafrecht* (1882). It opposes the principle of regarding punishment as a reprisal and sets up the claim of systematic prevention of a special nature. In the fight against the law-breaker, Liszt, together with the Dutchman Van Hamel and the Belgian Prins, founded the *Internationale Kriminalistische Vereinigung* (International Criminalist Union) in 1889, in which all reforms which became the basis of modern criminal law were initiated.

Liszt's claims in favour of conditional sentence and pardon as well as postponement of punishment later passed into practice. At Marburg he created the Criminalist seminary, at which later in Halle and especially in Berlin students from all lands met. Liszt was also a leading authority on international law. He died at Seeheim on June 22, 1919.

His chief works are *Meineid und falsches Zeugnis* (1876); *Lehrbuch des deutschen Strafrechts* (1881, 21st ed. 1919); *Lehrbuch des Völkerrechts* (1898, 11th ed., 1918); *Strafrechtsfälle zum akademischen Gebrauch* (13th ed. 1922); *Strafrechtliche Aufsätze und Vorträge* (1905). *See* also *Abhandlungen des Kriminalistischen Seminars* (1889, etc.); *Mitteilungen der Internationalen Kriminalistischen Vereinigung* (1890, etc.).

LITANY, a word used by Eusebius and Chrysostom, commonly in the plural, in a general sense, to denote a prayer or prayers of any sort, whether public or private. It is similarly employed in the law of Arcadius (*Cod. Theod.* xvi tit. 5, leg. 30). But some trace of a more technical meaning is found in the epistle (*Ep.* 63) of Basil to the church of Neocaesarea, in which he argues, against those who were objecting to certain innovations, that neither were "litanies" used in the time of Gregory Thaumaturgus. The nature of the recently introduced litanies, which must be assumed to have been practised at Neocaesarea in Basil's day, can only be conjectured. Probably they had many points in common with the *rogationes,* which, according to Sidonius Apollinaris, had been coming into occasional use in France about the beginning of the 5th century, especially when rain or fine weather was desired, and, so far as the three fast days before Ascension were concerned, were first fixed, for one particular district at least, by Mamertus, or Mamercus, of Vienne in A.D. 477. It is assumed that they were penitential and intercessory prayers offered by the community while going about in procession, fasting and clothed in sackcloth.

In the following century the manner of making litanies was to some extent regulated for the entire eastern empire by one of the *Novels* of Justinian, which forbade their celebration without the presence of the bishops and clergy, and ordered that the crosses which were carried in procession should not be deposited elsewhere than in churches, nor be carried by any but duly appointed persons. The first synod of Orleans (A.D. 511) enjoins for all Gaul that the "litanies" before Ascension be celebrated for three days. On these days all menials are to be exempt from work, so that everyone may be free to attend divine service. The diet is to be the same as in Quadragesima; clerks not observing these rogations are to be punished by the bishop. In A.D. 517 the synod of Gerunda provided for two sets of "litanies," the first of which were to be observed with fasting for three days, from Thursday to Saturday in the week after Pentecost; the second for three days from November 1. The second council of Vaison (529), consisting of 12 bishops, ordered the *Kyrie eleison,* first introduced at this time from the eastern Church, to be sung at matins, mass and vespers.

A synod of Paris (573) ordered litanies to be held for three days at the beginning of Lent, and the fifth synod of Toledo (636) appointed litanies to be observed throughout the kingdom for three days from December 14. The first mention of the word litany in connection with the Roman Church goes back to the pontificate of Pelagius I (555–560) but implies it was at that time already old. In 590 Gregory I, moved by the pestilence which had followed an inundation, ordered a "litania septiformis," sometimes called *litania major,* that is to say, a sevenfold procession of clergy, laity, monks, virgins, matrons, widows, poor and children. It must not be confused with the *litania septena* used in church on Easter Even. He is said also to have appointed the processions or litanies of April 25 (St. Mark's day), which seem to have come in the place of the ceremonies of the old Robigalia. In 747 the synod of Cloveshoe ordered the litanies or rogations to be gone about on April 25 "after the manner of the Roman Church," and on the three days before Ascension "after the manner of our ancestors." The latter are still known in the English Church as rogation days. Games, horseracing and junketings were forbidden; and in the litanies the name of Augustine was to be inserted after that of Gregory. The reforming synod of Mainz in 813 ordered the major litany to be observed by all for three days, barefoot and clothed in sackcloth and ashes. The sick only were exempted.

As regards the form of words prescribed for use in these "litanies" or "supplications," documentary evidence is defective. Sometimes it would appear that the "procession" or "litany" did nothing else but chant *Kyrie eleison* without variation. There is no reason to doubt that from an early period the special written litanies of the various churches all showed the common features which are now regarded as essential to a litany, in as far as they consisted of (1) invocations, (2) deprecations, (3) intercessions and (4) supplications. In details, however, they must have varied immensely. The offices of the Roman Catholic Church recognize two litanies, the "Litaniae majores" and the "Litaniae breves," which differ from one another chiefly in the fullness with which details are entered upon in each of the four parts. It is said that in the time of Charlemagne the angels Orihel, Raguhel and Tobihel were invoked, but the names were removed by Pope Zacharias as really belonging to demons. In some mediaeval litanies there were special invocations of S. Fides, S. Spes and S. Charitas.

The litanies, as given in the breviary, are at present appointed to be recited on bended knee, along with the penitential psalms, in all the six week-days of Lent when ordinary service is held. Without the psalms they are said on the feast of Saint Mark and on the three rogation days. A litany is chanted in procession before mass on Holy Saturday. The "litany" or "general supplication" of the Church of England, which is appointed "to be sung or said after morning prayer upon Sundays, Wednesdays and Fridays, and at other times when it shall be commanded by the ordinary," closely follows the "Litaniae majores" of the breviary, the invocations of saints being of course omitted. A similar German litany will be found in the works of Luther. In the Roman Catholic Church there are a number of special litanies peculiar to particular localities or orders, such as the "Litanies of Mary" or the "Litanies of the Sacred Name of Jesus."

There was originally a close connection between the litany and the liturgy (*q.v.*). The ninefold *Kyrie eleison* at the beginning of the Roman mass is a relic of a longer litany of which a specimen may still be seen in the Stowe missal. In the Ambrosian liturgy, the threefold *Kyrie eleison* or Lesser litany occurs thrice, after the *Gloria in excelsis,* after the gospel and at the end of the mass. On the first five Sundays in Lent a missal litany is placed before the *Oratio super populum* and, on the same five Sundays, in the Mozarabic rite before the epistle. In Eastern liturgies, litanies are a prominent feature, as in the case of the deacon's litany at the beginning of the *Missa fidelium* in the Clementine liturgy and immediately before the *Ana-*

phora in the Greek liturgy of St. James.

LITCHFIELD, a town of Connecticut, U.S.A., with a borough of the same name, 28 mi. W. of Hartford and served by the New York, New Haven and Hartford railroad; the county seat of Litchfield county. The population of the town was 4,029 in 1940; of the borough, 1,234.

Litchfield is a region of beautiful scenery, including Mt. Prospect and Lake Bantam (1,001 ac.). The town is a summer resort. Dairying is the principal occupation.

The lands included in the township of Litchfield (originally called Bantam) were bought from the Indians in 1715–16 for £15, the Indians reserving a certain part for hunting. The township was incorporated in 1719, was named Litchfield, after Lichfield in England, and was settled by immigrants from Hartford, Windsor, Wethersfield, Farmington and Lebanon, all within the state of Connecticut, in 1720–21. In 1751 it became the county seat of Litchfield county, and at the same time the borough of Litchfield, which was incorporated in 1879, was laid out. From 1776–80, two depots for military stores and a workshop for the Continental army were maintained there. The leaden statue of George III, erected in Bowling Green in New York city in 1770 and torn down by the citizens on July 9, 1776, was cut up and taken to Litchfield, where, in the house of Oliver Wolcott, it was melted into bullets for the American army by Wolcott's daughter and his sister. Aaron Burr, whose only sister married Tapping Reeve (1744–1823), lived in Litchfield with Reeve in 1774–75. In 1784 Reeve established here the Litchfield law school, the first institution of its kind in America. In 1798 he associated with himself James Gould (1770–1838), who after Reeve's retirement in 1820 continued the work with the assistance of Jabez W. Huntington (1788–1847) until 1833. The school was never incorporated, it had no buildings and the lectures were delivered in the law offices of its instructors, but among its 1,000 or more students were many who afterward became famous, including John C. Calhoun; Levi Woodbury, twice United States senator from New Hampshire, secretary of the navy, secretary of the treasury and a justice of the United States supreme court; John Y. Mason; John M. Clayton; and Henry Baldwin, a justice of the United States supreme court.

In 1792 Mrs. Sarah Pierce made one of the first efforts toward the higher education of women in the United States by opening in Litchfield her Female seminary, which had an influential career of about 40 years and numbered among its alumnae Harriet Beecher Stowe, Mrs. Marshall O. Roberts, Mrs. Cyrus W. Field and Mrs. Hugh McCulloch.

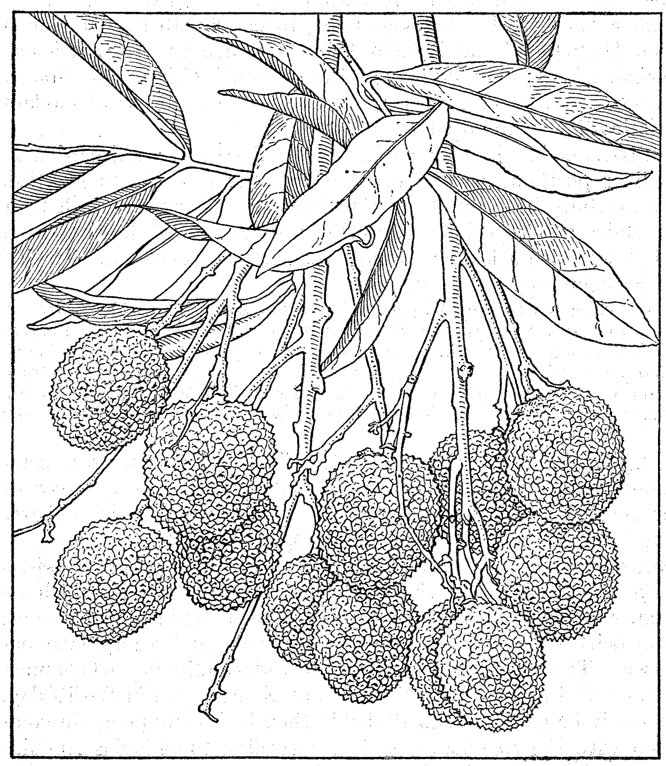
Litchfield was the birthplace of Ethan Allen; of Henry Ward Beecher; of Harriet Beecher Stowe, whose novel *Poganuc People* presents a picture of social conditions in Litchfield during her girlhood; of Oliver Wolcott, Jr.; of John Pierpont, the poet, preacher and lecturer; and of Charles Loring Brace, the philanthropist. It was also the home, during his last years, of Oliver Wolcott; of Colonel Benjamin Tallmadge, an officer on the American side in the War of Independence and later a federalist member of congress; and of Lyman Beecher, who was pastor of the First Congregational church of Litchfield from 1810–26.

LITCHFIELD, a city of Montgomery county, Ill., U.S.A., 52 mi. N.E. of St. Louis, on federal highway 66, and served by the Big Four, the Burlington, the Illinois Central, the Wabash and the Litchfield and Madison railways. The population was 6,612 in 1930; 7,048 in 1940. It is in an agricultural and coal-mining region, and has varied manufactures. Litchfield was incorporated as a town in 1856, as a city in 1859.

LITCHI or LYCHEE, the fruit of *Litchi chinensis,* a tree of the family Sapindaceae, considered indigenous to southern China and adjacent regions, where it has been cultivated for at least 2,000 yrs. The common name is variously written—*litchi, lichee, lychee, leechee, lichi* and so on. According to Yule and Burnell (*Hobson-Jobson*) the pronunciation in northern China is *leechee,* while in the southern part of that country it is *ly-chee.* The latter is generally preferred in the United States.

This is the favourite fruit of southern China. Neither the orange nor the peach is held to equal it. While living in exile at Canton, the poet Su Tung-po declared that litchis would reconcile one to eternal banishment; and Chang Chow-ling, a statesman of the 8th century A.D., composed a poem in which he praised the litchi as the most luscious of all fruits. The first published work devoted exclusively to fruit culture was one on litchi varieties, written by a Chinese scholar in A.D. 1056. In Kwangtung province alone the annual litchi crop is said to be 20,000,000 to 30,000,000 lb. worth $1,000,000 to $1,500,000.

Though introduced into India and several other parts of Asia at an early date, its establishment in the American tropics and subtropics was tardy, because of the fact that the seeds rapidly lose their viability and that the transportation of living plants from one part of the world to another was difficult until modern times. It is said to have been planted in Jamaica about 1775, but did not spread in that island. While the tree may have been grown in Florida as early as 1886, it was not until 1916 that the first fruits were produced in that state. Numerous introductions were made by the U. S. dept. of agriculture between 1900 and



BUREAU OF PLANT INDUSTRY, U.S. DEPARTMENT OF AGRICULTURE

FRUIT OF LITCHI (LITCHI CHINENSIS), ⅔ SIZE

1920, several of which—notably the Brewster variety—proved successful in Florida. A few small commercial plantings were made. In California an occasional tree has borne fruit, but in general it does not appear that conditions are suitable. Numerous trees have fruited in Cuba, in Central America, in Brazil and in other parts of tropical America. Many have been grown successfully in the Hawaiian Islands.

The litchi is subtropical rather than strictly tropical in its requirements, needing a moderate amount of winter chilling to fruit abundantly. At the same time, it tolerates less frost than the orange. The tree is handsome, reaching a height of 35 or 40 ft., with a broad round-topped crown of glossy green foliage, particularly striking when covered with clusters of fruits individually resembling large strawberries. The leaves are compound, with two to four pairs of elliptic-oblong to lanceolate leaflets 2 to 3 in. in length. The flowers, which are small and unattractive, are borne in terminal panicles sometimes a foot long. The fruit is oval to ovate, 1½ in. in diameter in the better varieties, with a brittle rough outer covering, red in colour, enclosing white translucent flesh and a single seed—large in the common forms but small and shrivelled in the better ones. The flavour of fresh litchis resembles that of Bigarreau cherries or Muscat grapes. Dried litchis, commonly called "litchi nuts," are frequently seen in Chinese shops in the United States; they somewhat resemble raisins surrounded by thin shells, and are vastly inferior to the fresh fruit though they have a flavour all their own.

While litchis are easily grown from fresh seed, superior varieties (of which there are a number, including No Mai, Haak Ip and several from northern India) must be propagated vegetatively. Air-layering is the method usually employed. Under greenhouse conditions they can also be grown from tip cuttings. Although the best soil for litchis is perhaps a rich alluvial loam, trees have done well in Florida on sandy loams. Planting distances vary from 20 to 30 ft. and the trees require little pruning. They usually come into bearing at five to eight years of age and are long lived: an early Chinese account mentions one which was cut down when it was 800 yrs. old. (W. Po.)

LITERARY, HISTORICAL AND ARCHAEOLOGICAL SOCIETIES. Owing to the great number of such societies, it is manifestly impossible to include all in this brief list. Only those of paramount importance and of more than purely national appeal will be found here.

Great Britain and Ireland: *The British Academy* (1901, incorp. 1902, under title *British Academy for the Promotion of Historical, Philosophical, and Philological Studies*), *Proceedings; The Royal Society of Literature of the United Kingdom* (1823, incorporated in 1825), *Transactions* (1829–39; 1843, etc.); and the *Royal Asiatic Society of Great Britain and Ireland* have their headquarters in London, as well as the following literary societies, all of which issue publications: *East India Asso.* (1866); *The Irish Literary Soc.; Japan Society; Library Assoc.* (1877); *Malone Soc.* (1906); *Oriental Translation Fund Soc.* (1828); *Pali Text Soc.* (1882); *Philological Soc.* (1842); *Soc. for the Promotion of Hellenic Studies* (1879); *Viking Soc. for Northern Research* (1908, org. 1892 as the *Viking Club*); *Wyclif Soc.* (1882). The *Manchester Literary Club, Trans. and Papers* (1847, etc.), and the *Manx Soc.* (1858) at Douglas, may also be mentioned. In Glasgow are the *Ballad Club* (1876), and the *Scottish Soc. of Literature and Art* (1886), and in Dublin the *National Literary Soc. of Ireland* (1892).

The oldest and most important society in England dealing with history and archaeology is the *Society of Antiquaries of London*, which is said to have been founded by Archbishop Parker in 1572. The meetings were not publicly recommenced until 1707; the present body was incorporated in 1751. It publishes *Vetusta Monumenta* (1747), *Archaeologia* (1770), and *Journal* (quart.). The *Royal Archaeological Institute of Great Britain and Ireland* (1843), *Archaeological Journal* (1844); *British Archaeological Association* (1843), *Journal* (1843); *Royal Numismatic Society* (1836), *Numismatic Chronicle* (1836); *Royal Historical Society* (1868), *Transactions* and the works of the *Camden Society* (1878); and *Institute of Historical Research* (1921), *Bulletin*, belong to London, as well as the following societies, all of which issue publications: *Bibliographical Soc.* (1892); *British School at Athens* (1886); *British School at Rome* (projected 1899; opened 1901, incorp. 1912); *British Record Soc., Ltd.* (1888) amalgamated 1890 with *The Index Library* (1878, incorp. 1893); *Canterbury and York Catholic Record* (1904); *Egypt Exploration Soc.* (1883); *Genealog. and Biogr., Cymmrodorion* (1751–1773), revived in 1820; *Soc. of Dilettanti* (1734); *Folklore Soc.* (1878); *Harleian Soc.* (1869, incorp. 1902); *Huguenot Soc.* (1885); *London and Middlesex Archaeol. Soc.* (1855); *London Topogr. Soc.* (1899); *New Palaeographical Soc.* (1903); *Palestine Exploration Fund* (1869); *Parish Registers Soc.* (1896); *Soc. for Prot. Anc. Buildings* (1877). Outside London are the *Roy. Soc. of Antiquaries of Ireland* (1890), founded as the *Kilkenny Arch. Soc.* (1849), changed to *Roy. Hist. and Arch. Assn.*, 1869; the *Soc. of Antiquaries of Scotland* (1780) at Edinburgh; and the *Irish Archaeol. and Celtic Soc.* (Incorp. 1912) at Dublin.

Canada: Halifax, *Nova Scotia Hist. Soc.* (1878), *Coll.* Montreal, *Société historique* (1857), *Mém.* (1859); *Antiquarian and Numismatic Soc.* (1872), *Journ.* (1872). Ottawa, *Roy. Soc. of Canada* (1883), *Proceed. and Trans.* Quebec, *Lit. and Hist. Soc.* (1824), *Trans.* (1829). Toronto, *Ontario Hist. Soc.* (1888), *Papers and Records* (1899), and the *Royal Canadian Institute* (1914) (1849, as the *Canadian Inst.*), *Trans.*

United States: The central antiquarian body is at Washington: *Archaeological Institute of America* (founded, Boston, 1879, incorp. 1906). It has 44 affiliated societies, maintains 6 schools of archaeology and publishes the *Amer. Journ.* (1897), *Art and Archaeology* (1914), and *Bulletin* (1910). Other important societies are the *American Antiquarian Society*, Worcester, Mass. (1812), *Proceed.* (1843); *American Hist. Assoc.*, Wash., D. C. (1884), *Annual Report* (1884) and *Amer. Hist. Rev.* (1895); *Carnegie Institution of Washington* (1902), *Publications* (1903); *Essex Institute*, Salem, Mass. (1848), *Proceed.* (1846), *Bulletin* (1869), *Hist. Coll.*, (1859); *Amer. Numismatic Soc.*, New York City (1858, revived 1864 under title *Amer. Numis. and Archaeolog. Soc.*, changed to present name, 1907), *Numismatic Notes and Monographs* (1920); *Amer. Oriental Soc.*, Boston (1842), *Journ.* (1842); *Amer. Library Assoc.*, Chicago (1876), *Catalogues, Bulletin, Papers and Proceed.* There are also the various state and local societies including *Mass. Hist. Soc.*, Boston (1791), *Proceed.* (1857) and *Coll.* (1792); *New England Hist. Geneal. Soc.*, Boston (1844), *N.E. Hist. and Geneal. Reg.* (1847); *New York Hist. Soc.*, New York City (1804), *Coll.* (1811); *Maryland Hist. Soc.*, Baltimore (1844), *Md. Hist. Mag.* (1906) and *Archives of Maryland* (1883); *Ohio State Archaeol. and Hist. Soc.*, Columbus (1885), *Ohio Archeol. and Hist. Soc. Quart.* (1887); *Wisconsin Archaeol. Soc.*, Madison (1899), *Wis. Archaeologist* (1901); *State Hist. Soc. of Wis.*, Madison (1849, reorg., 1853), *Wis. Mag. of Hist.* (1917); *Wis. Hist. Coll.* (1855) and *Proceed.* (1887).

Belgium: Antwerp, *Acad. roy. d'Archéol. de Belgique* (1842), *Annales* (1843). Arlon, *Inst. Archéol. de la prov. de Luxembourg* (1847), *Annales.* Bruges, *Soc. pour l'Hist. et les Antiq. de la Flandre* (1839), *Publ.* Brussels, *Soc. de l'Hist. de Belgique* (1858), *Publ.; Soc. Roy de Numism.* (1841), *Revue; Soc. des Bibliophiles Belges, Mons.* (1737), *Publ.; Soc. Roy d'Archéol.* (1887, as *Soc. d'Archéol. de Bruxelles*, title changed 1912), *Annales* (1887); *Inst. Int. de Bibliogr.* (1895), *Répertoire.* Ghent, *Soc. Roy. des Beaux-Arts et de la Litt.* (1808), *Annales* (1844); *Willems Fond* (1851); *Maatschappij de Vlaamsche Bibliophilen* (1839); *Soc. d'Hist. et d'Archéol.* (1893, as *Cercle Hist. et Archéol.*), *Bull.* Liége, *Inst. Archéol.* (1850), *Bull.* (1852). Louvain, *Soc. Litt.* (1839), *Mem.* and *Publ.* Namur, *Soc. Archéol. de Namur* (1845). Tournai, *Soc. Hist. et Archéol.* (1846, as *Soc. Hist. et Litt.*, title changed 1859), *Annales* (1896), superseded *Mém.* (1853–95) and *Bull.* (1849).

Bulgaria: Sofia, *Bulg. Acad.* (1910) (1869, as *Bulg. Lit. Soc.*), *Period.* (1870); *Bulg. Archaeol. Inst.* (1920), *Bull.*

China: Hongkong, *Roy. Asiatic Soc., Trans.* (1848–55). Shanghai, *Roy. Asiatic Soc., Journ.* (1858).

Denmark: Copenhagen, *Dansk Hist. Forening* (1839), *Historisk Tidsskrift; Island. Lit. Selskab* (1780); *K. Danske Selskab* (1745), *Magazin; K. Nordiske Oldskrift Selskab* (1825, reorg. 1865), *Aarböger* (1866–85), *Raekke* (1866), *Kjobenhavn* (1866).

Estonia: Narva, *Archaeol. Soc.;* Tartu, *Selts Kirjanduse Letts* (1907).

Finland: Helsingfors, *Finska Litt. Sällskapet* (1831), *Toimituksia* (1842); *Finnish Archaeol. Soc.* (1870), *Tidskrift* (1874); *Finnish Hist. Soc.* (1875), *Arkisto* (1876); *Finnish Lit. Soc.* (1831), *Suomi; Lang., Hist. and Archaeol. Soc. of Finno-Ugrians* (1883); *Swedish Lit. Soc. in Finland* (1885).

France: *The Congrès Archéologique de la France* first met in 1834. Bordeaux, *Soc. Archéol.* (1873). Paris, *Soc. Nat. des Antiq. de Fr.* (1804, projected; org. 1805 as *Académie celtique;* reorg. 1813 as *Soc. des. Antiq. de Fr.;* 1814, designated *Soc. Roy.*, but suppressed after 1848; 1852 reorg.) *Mém.* (1805); *Soc. de l'Hist. de Fr.* (1833), *Annuaire* (1837); *Soc. de l'École Nat. des Chartes* (1839), *Documents* (1873); *Soc. Asiatique* (1822), *Journ. Asiat.* (1822); *Soc. de l'Hist. du Prot. Fr.* (1853), *Bull.; Soc. de Linguistique de Paris* (1863); *Soc. française de Numism. et d'Archéol.* (1866); *Soc. Bibliogr.* (1868), *Polybiblion; Soc. Philol.* (1867), *Actes* (1869–1907); *Soc. des Études Hist.* (1833), *Revue* (1834); *Soc. d'Hist. Moderne* (1901), *Bull.; Soc. d'Hist.*

Contemp. (1890), *Publ.* (1892); *Soc. d'Hist. Diplomatique* (1876); *Soc. des Bibliophiles Fr.* (1820); *Soc. des Anciens Textes Fr.* (1875), *Bull.*

LITERATURE, a general term which, in default of precise definition, may stand for the best expression of the best thought reduced to writing. Its various forms are the result of race peculiarities, or of diverse individual temperaments, or of political circumstances securing the predominance of one social class which is thus enabled to propagate its ideas and sentiments. In early stages of society, the classes which first attain a distinct literary utterance are priests who compile the chronicles of tribal religious development, or rhapsodes who celebrate the prowess of tribal chiefs. As man feels before he reasons, so poetry generally precedes prose. It embodies more poignantly the sentiment of unsophisticated man. Prose of any permanent value would first show itself in the form of oratory. The development of abstract reasoning would tend to deprive prose of its superfluous ornament and to provide a simpler and more accurate instrument.

CLASSICAL LITERATURE

A survey of this subject, of the preservation or loss of ancient literature, and of the history of classical scholarship will be found under CLASSICS. The history of classical scholarship is further dealt with under the various biographies such as BENTLEY, RICHARD; PORSON, RICHARD; SCALIGER. The method of scholarship is extensively dealt with under TEXTUAL CRITICISM. The two great branches of the subject are handled *in extenso* under GREEK LITERATURE and LATIN LITERATURE. These articles are supplemented by articles on the various schools of writers: ALEXANDRIAN SCHOOL, ANNALISTS, GEOPONICI (*see* also HELLENISM), and on the chief anonymous or pseudonymous works: ANTHOLOGY, CONSTITUTION OF ATHENS, PERVIGILIUM VENERIS, PRIAPEIA and others. All classical writers of any importance have also their own biographies: AESCHYLUS; ARISTOPHANES; BOETHIUS; ANICIUS MANLIUS SEVERINUS, etc., including scientific writers such as EUCLID or PAPPUS OF ALEXANDRIA; but a general guide to the treatment of ancient scientific and artistic knowledge must be sought under the summary articles—ART; MATHEMATICS, FOUNDATIONS OF; MATHEMATICS, HISTORY OF; MEDICINE; MUSIC; etc. The chief legendary figures used as material by classical writers are dealt with separately under such heads as ACHILLES, ARGONAUTS, OEDIPUS, THESEUS. Classical prosody is dealt with under headings such as HEXAMETER; IAMBIC; SAPPHIC METRE; a study of Latin prose rhythm will be found under CICERO, of Greek under ISAEUS and DEMOSTHENES, etc.

Mediaeval and Modern.—The various literatures of the world are surveyed, so far as is possible, on national lines—English, French, American, German, Portuguese, Czecho-Slovakian and so forth. The history of Afrikaans Literature will be found under the heading SOUTH AFRICAN LITERATURE, and under SWISS LITERATURE will be found the literatures written by Swiss authors in German, French and other languages. Then the general surveys are supplemented by long detailed studies of the chief authors—SHAKESPEARE, WILLIAM; DANTE, ALIGHIERI; CERVANTES SAAVEDRA, MIGUEL DE; etc. For the various literary forms—Novel, Drama, Sonnet, Essay, Biography, etc.—*see* the articles under these headings. The chief characters in mediaeval legend are described in their various transformations in such articles as FAUST, TRISTAN, GAWAIN, etc. Journalism is covered in several articles such as NEWSPAPERS and PERIODICAL, and almost everything relating to the history of books is touched on in such articles as BOOKS, BOOK-COLLECTING, BIBLIOGRAPHY, LIBRARIES, INDEX.

Modern developments in literature will be found treated in supplementary articles on BIOGRAPHY; NOVEL; POETRY, as well as in such an article as FREE VERSE.

LITERNUM, an ancient town of Campania, Italy, on the low sandy coast between Cumae and the mouth of the Volturnus. It was probably once dependent on Cumae. It is mainly famous as the residence of the elder Scipio, who withdrew from Rome and died here. His tomb and villa are described by Seneca. The lagoons behind made it unhealthy, though the construction of the Via Domitiana through it must have made it a posting station. Villa Literno, some 7 mi. north-east from its site, is an important junction on the new direct line from Rome, the line for Pozzuoli and the Mergellina station at Naples diverging here.

LITHGOW, WILLIAM (1582–?1650), Scottish traveller and writer, was born and educated in Lanark. He was caught in a love-adventure, mutilated of his ears by the brothers of the lady (hence the sobriquet "Cut-lugged Willie"), and forced to leave Scotland. For 19 years he travelled, mostly on foot, through Europe, the Levant, Egypt and northern Africa, covering, according to his estimate, over 36,000 miles. The story of his adventures may be drawn from *The Totall Discourse of the Rare Adventures* . . . (1614; fuller edition, 1632, etc.). He is the author of a *Present Surveigh of London* (1643). Of his poems "Scotland's Welcome to King Charles, 1633" has considerable antiquarian interest.

The best account of Lithgow and his works is by F. Hindes Groome in the *Dict. Nat. Biog.*

LITHGOW, a town of New South Wales, Australia, lying on the central tableland (altitude 3,000 ft.), 96 mi. by rail N.W. of Sydney. It stands in the heart of the "Western" coal field which possesses steam as well as coking coal. The state coal mine is situated near Lithgow. Large supplies of good iron ore are available at Tallawang (100 mi. N.W.), Carcoar (80 mi. S.W.) and Cadia (100 mi. S.W.). Limestone is quarried 25 mi. away and manganese ore is available at Grenfell (156 mi. W.). It is thus a thriving industrial town (pop. 1933, 13,444). The Hoskins Iron and Steel Co. had large works (blast furnaces with capacity 150,000 tons per ann.; output [1925] 95,500 tons pig iron [£525,000]); these have been moved to Port Kembla on the coast south of Sydney. The Commonwealth Small Arms factory, fire-brick and pipe works, tweed and sawmills, etc., make Lithgow one of the chief industrial centres of Australia. Near by is the famous zigzag railway, an engineering marvel now superseded by tunnels.

LITHIUM, a metallic element belonging to the group of alkali metals and occurring on the earth only in combination, having been first recognised as a separate element by Arfvedson in 1817, symbol Li, atomic number 3, atomic weight 6·94 (two isotopes 6 and 7). It is widely distributed, although in small proportions, in the mineral, vegetable and animal kingdoms. It is found in several characteristic minerals, *e.g.*, lepidolite or lithia mica and in petalite. The ash of many plants contains an appreciable amount of lithium chloride (tobacco ash about 0·44%), and lithium compounds are present in every organ of the human body and especially the lungs. The term "lithia water" recalls the reputation possessed by lithium salts such as the carbonate or citrate for assisting in the elimination of uric acid in gout and in rheumatoid affections, but the potency of lithium compounds in this respect is much exaggerated since the tolerated dose of lithium does not increase the solubility of uric acid in the blood serum. Accordingly, lithium salts have been largely superseded in medicine by organic diuretics such as urotropine (hexamine).

Silicates containing lithium, when heated with calcium oxide, carbonate or sulphate, yield the corresponding soluble lithium compounds which can be extracted with water. The extract, freed from heavy metals, contains lithium and other alkali metals; these are converted into carbonates, and lithium carbonate, being only sparingly soluble, is deposited and separated. The carbonate is converted into lithium bromide and chloride; a mixture of the former salt with 12% of the latter melts at 520° C and is used in the electrolytic production of metallic lithium. The metal has been isolated by electrolysis of a solution of lithium chloride in pyridine, and also by heating lithium hydroxide with magnesium.

Lithium is a silvery white metal tarnishing in moist air. It is harder than the other alkali metals but softer than lead, which it resembles in ductility. Its melting point is variously given 179° to 186° C. It is the lightest of those elements which are solid at the ordinary temperature and it has the highest specific heat, 0·9408, of any solid element. Its spectrum is characterised by a bright red line (6,708 Å.U.) and a fainter orange one (6,104 Å.U.). Lithium decomposes water at the ordinary temperature, liberating hydrogen and forming a caustic solution of lithium hydroxide (lithia). Lithium burns in air or oxygen to the white oxide, Li_2O, and when heated in nitrogen it furnishes the nitride, Li_3N.

Lithium hydride, LiH, produced by direct combination of the metal with hydrogen at bright red heat, is a white, crystalline opalescent mass melting at 680° C; it undergoes electrolytic decomposition, liberating lithium at the cathode and hydrogen at the anode. Lithium fluoride, LiF, is sparingly soluble, but the chloride, LiCl, is soluble in water and also in many organic solvents such as the alcohols, acetone and pyridine. Lithium hydroxide, LiOH, produced by adding water to the oxide, is a white crystalline mass resembling caustic soda or potash but less hygroscopic; it dissolves readily in water and absorbs carbon dioxide to form lithium carbonate, Li_2CO_3. Lithium acetylacetone, $LiC_5H_7O_2$, obtained in colourless needles by the action of acetylacetone on aqueous lithium hydroxide, is soluble in water or alcohol. Lithium phosphate, Li_3PO_4, is very sparingly soluble in water and less so in alkaline solutions, and is sometimes employed in the estimation of lithium; for this purpose the fluoride is also used and the solubility of lithium chloride in amyl alcohol serves to separate lithium from the other alkali metals. Lithium fluoride and fluophosphate are used in ceramics in the production of enamels. The lithium salts employed in medicine are the benzoate, bromide, carbonate, citrate, hippurate, iodide, salicylate, sulphate and hydrogen tartrate. *Lithii citras effervescens* is a mixture of citric acid, lithium citrate and sodium bicarbonate. Since in large or concentrated doses lithium salts cause unpleasant symptoms, they should be freely diluted.

Bibliography.—J. W. Mellor, *A Comprehensive Treatise of Inorganic and Theoretical Chemistry,* Vol. II. (1922); J. N. Friend and A. J. Walker, *A Text Book of Inorganic Chemistry,* Vol. II. (1922).
(G. T. M.)

LITHOGRAPHY is both an art and a method of printing. Lithograph is from the Greek: Litho—stone; Graph—to write or draw—and means "writing on stone," or "drawing on stone." Actually, it embraces the use of stone and of materials other than stone both for art and for commercial printing purposes. As an art it has long been used by some of the most eminent artists—at times by many, at times by very few. As a method of printing it has been employed in a gradually increasing volume.

Lithography—A Form of Art consists of drawing with a greasy substance—both crayon and ink are used—on a special type of stone or metal (aluminium or zinc) or on a special kind of paper to be transferred subsequently to stone or metal. It is the most direct of all the graphic arts because the artist sees the exact value of each line or dot as he draws it, following which his drawing can be reproduced so accurately that it may truly be said to have been multiplied. Lithographic crayon yields broader tones than the etching needle; it makes and retains finer lines than can be obtained in wood block. Moreover, lithographic inks produce as fine lines and dots in pen and stipple drawings as are produced by any other means. All of these print exceptionally well. Lithography as an art has always played some part in lithography as a method of printing and at one time was more important than commercial reproduction.

Now the part played by "art" in lithography is relatively small although many artists are again turning to it as a versatile medium of expression.

Lithography—A Method of Commercial Printing is one of the three basic commercial graphic arts processes—the others being relief or letterpress and intaglio or gravure. Relief, letterpress or typographic printing is the art of printing from movable type, engravings, electrotypes, etc., the impression points or surfaces being raised or in relief. Intaglio or gravure is the reverse of relief printing in that the printing is done from depressions or recesses which have been etched or engraved into the surface of the plate or cylinder. Lithography is a chemical process of printing from a plane surface—the printing portions of the surface being neither raised as in relief printing nor depressed as in gravure or intaglio. The lithographic process is dependent upon the natural repulsion between grease and water; moisture prevents the greasy printing ink from adhering to the stone or plate except where it is covered by design. At present few stones are used for either drawing or printing.

About 1820 it was discovered that zinc possessed most of the essential qualities of lithographic stone. Later on, aluminium came into use. For lithographic printing these metals are today used almost exclusively.

LITHOGRAPHY AS AN ART: THE PROCESS

Drawing Materials.—The best medium on which to draw is Kelheim stone, that on which Senefelder was by chance working when he discovered the art. Three grades of lithographic stone are used: blue (hard), grey (medium), and yellow (soft). The blue is used for engraving, the grey for very fine work, and the yellow for relatively coarse work.

Lithographic stones are grained by rubbing two together with a sifted layer of flint or carborundum between; the resulting grain, consisting of innumerable, minute depressions, can be varied by changing the quality of the graining material (flint, carborundum, sand, etc.). Necessary erasures on such a fine surface are best effected by means of a small piece of lithographic stone rotated with sand and water; defects may be picked out with a needle; a knife may be used to scratch out, but if the grain is removed the part shows scratchy if drawn on again. After being reground and washed thoroughly with clean water the stone is then ready to receive a new drawing.

Zinc and aluminium plates for the artist's use are bought already grained. The disadvantages of using a plate are that its surface easily becomes greasy, corrections are hard to make and its colour may at first confuse values for the artist. In drawings made direct on either a stone or plate a greasy composition known as "tusche" can be applied for solid black lines or large black areas.

Despite its excellence as a drawing surface, the inconvenience connected with carrying the lithographic stone about has caused it to be chiefly used as a receiving surface for drawings transferred from paper. Not only can paper be easily carried in the artist's portfolio, but, since a drawing made on paper has to be transferred to another surface before it can be printed, it appears as it will when printed and does not have to be made in reverse like those made direct on a zinc or aluminium plate or on stone. Good lithographic paper, made by hand in Germany, France, Scotland, and Austria, has a specially prepared chalk surface that is very good to draw on, permits scraping out with a knife and transfers well.

In the United States artists usually employ a fine quality of tracing paper. When making a drawing on paper that is to be transferred to a stone or plate it is not necessary to develop the design with lithographic crayon. A Conté sanguine pencil can be used for the preliminary design over which lithographic crayon is passed later; also charcoal or a lead pencil can be used, since neither these nor the Conté contain grease enough to interfere with transference. The Conté marks, however, being red, can be easily distinguished from those of the black lithographic crayon, while the black marks of charcoal or lead pencil are likely to confuse the artist.

Changes in a drawing on paper can be made by painting out with Chinese white, which, if applied smoothly, can be drawn over; or they can be made on the stone or plate after transference. Since transferring has a tendency to intensify, the drawing should be kept slightly lighter than it is to appear in the finished print.

Lithographic crayon is a composition of soap, wax, oil, and lamp-black. A No. 0 crayon is very soft, No. 1 soft, No. 2 medium, No. 3 hard, No. 4 very hard, and No. 5 copal. In warm weather a No. 3 or No. 4 crayon should be used; in cold weather any may be used but it is advisable never to use a No. 5.

Great care must be taken to keep the drawing surface absolutely clean, free from dust, crumbs, etc. In all cases, the artist must be careful not to touch the surface of the stone, plate or paper with his hand; perspiration, which contains grease, will reproduce in smudges, marring the finished print. A piece of paper or light felt should be kept between the drawing surface and the artist's hand and arm.

Transferring.—Generally, drawings transferred from paper soon after being finished yield the best results, but drawings protected by a film of gum may be preserved indefinitely. Some printers prefer to transfer to a zinc or aluminium plate rather than to stone, believing that the plate reproduces fine tints better. Transferring a drawing on paper to either involves the same method, but a stronger acid solution is used for stone. The drawing is first placed in a "damp book," which consists of damp blotters with a rubber cover. If the paper tends to wrinkle it is stretched with thumb-tacks. It is left between the blotters from 20 to 60 minutes, until the printer believes it ready to transfer, then dropped on the stone or plate, already on the press, and left in the position in which it lands; to move it is to smudge. It is then covered with "backing"—a sheet of clean paper and a sheet of compressed fibre-board whose upper surface is greased to further the passage of the scraper over it. In running the stone or plate through the press care should be taken that the scraper runs entirely across the drawing but not to the edge of the stone or plate, which the scraper slipping off under pressure would damage. To facilitate this a margin of at least one inch should be allowed for every stone or plate; and this holds whether the drawing is made direct on these surfaces or is transferred to them. The bed of the press is slid forward, normal pressure is applied, the bed is turned through the press, the pressure is released and the bed is returned to its original position.

If special transfer paper has been used it should be soaked off; ordinary tracing paper should be pulled off without dampening. The plate or stone is then fanned dry and allowed to stand for about 30 minutes.

The Etch.—What has happened in transferring the drawing to the stone or plate is that some of the greasy lithographic crayon has been forced off the paper onto the plate or stone. If the craftsman is satisfied with the transfer he gives it what is known as an "etch," *i.e.*, a solution of, for a stone, gum arabic and nitric acid, or, for a zinc plate, gum arabic, chromic acid and phosphoric acid, or, for an aluminium plate, gum arabic and phosphoric acid, flowed over the surface with a brush or a piece of absorbent cotton. The gum arabic desensitizes the surface not drawn on, decreasing its affinity for grease; the acid eats away any invisible particles of grease that may be on the surface, but when in the correct solution (*see* formulas appended), does not affect the drawing itself, which is protected by the wax in the lithographic crayon. If the craftsman thinks the transfer poor, he coats the surface of the stone or plate with pure gum arabic, washes it off with water, inks it up until the drawing appears, dusts the inked drawing with rosin, then gives it an "etch."

After the "etch" has dried on the stone the surface is washed with clean water, sponged with a pure solution of gum arabic, rubbed down as smooth as possible with a clean rag and fanned dry. In the case of a plate, the acid solution is washed off without being allowed to dry.

Next the greasy material constituting the image (drawing) is washed off with turpentine, leaving the drawing invisible, apparently destroyed; but it is preserved, of course, in the grease still remaining on the stone or plate. A little asphaltum is rubbed in and fanned dry. The stone or plate is then dampened again with water so that when the ink, which contains grease, is applied it will take only on the grease and be repelled by all parts of the surface not drawn on. It is then dampened with a sponge and inked up with a roller.

It is advisable, finally, to dust the stone or plate with rosin dust, to clean it up, polishing out all dirt, and to repeat the process, after which it is ready for printing.

Drawings made direct on a stone or plate are given an "etch," and then prepared for printing in the manner indicated above. Lithographic engraving, or intaglio printing, is done with a needle on stone desensitized by a solution of gum arabic and nitric acid. Such engravings are inked with a dauber that pushes the ink into the engraved lines; otherwise they are treated like a lithograph drawn direct on stone.

Printing.—Lithographic ink is made from the best dry colour and linseed oil (or synthetic material). It is generally sold stiff so that the craftsman can soften it with varnish to the consistency demanded by his working conditions and the results that he wants. It is available in various colours, but, no matter what colour or combination of colours is wanted in the print, all drawings are made in black, one stone being prepared for each colour desired. The ink is applied by means of a roller made of wood covered with grain leather; during the operation, difficult because the ink must be applied evenly until judged strong enough, the stone or the plate rests on the bed of the press in order that an impression can be made at once.

Sliding pressure is used in printing a lithograph. The scraper, which is made of box or apple wood sharpened to a blunt edge and covered with well greased leather, is set by a screw. Hand-made paper is generally used for lithographic prints, the best grades of which come from Italy, Sweden, France, and Japan; machine-made paper, however, gives good results in practice. The paper is generally moistened to enable it to print very fine tints in full value. It is then placed on top of the plate or stone as it rests in the centre of the press bed, and is covered with backing. Pressure is applied and, the same precautions being taken as in transferring, the stone is cranked through the press; the pressure is released and the bed of the press is returned to its original position.

The first prints pulled have a tendency to be light; the proper strength of the image is built up gradually. If, after a few prints have been pulled, the image has a tendency to grow too dark it is advisable to repeat the "etching" process; if the stone is in colour, before being given an "etch" it is washed with turpentine, rolled up with black ink and dusted with rosin.

As many prints as are wanted can be had, but, when the stone or the plate is taken from the press, it should be rolled up with ink, gummed down with gum arabic and rubbed down very smoothly with a clean rag in order to keep the image intact.

Formulas.—The proportions of gum arabic and acid used in the solution known as the "etch" vary with the quality of the stone or plate, the type and age of the drawing, and the temperature of the room. Only the following approximate proportions can be given: For a stone, one half glass of gum arabic to one teaspoonful of nitric acid. For a zinc plate, one half glass of gum arabic to one teaspoonful of chromic acid to from 12 to 15 drops of phosphoric acid. For an aluminium plate, one half glass of gum arabic to from 15 to 20 drops of phosphoric acid. (*See* also ETCHING.) (G. C. MI.; MA. S.)

LITHOGRAPHY AS AN ART: HISTORY

The history of lithography as a form of art leaves no chance for ingenious theory and learned speculation. Art authorities may argue over the origin of etching and wood-engraving, but the inventor of lithography, Alois Senefelder (1771–1834), himself gave the facts of his invention in *A Complete Course of Lithography—Der Steindruck* (1818)—a book which is half autobiographical, half technical, and wholly absorbing. He was a Bavarian actor and dramatist. Not over successful, he endeavoured to be his own printer and publisher as well and, to that end, experimented with metal plates and Solenhofen stone, acids and inks. According to his often-quoted story, his mother asked him, one day when he was at work, to write her week's washing list and, paper not being handy, he wrote it with his greasy ink on a smooth stone upon which he practised writing in reverse.

Later, instead of cleaning off the writing, he was curious to see what would happen if he etched the stone and pulled a proof. What happened was his discovery of relief engraving on stone (1796). But only after "thousands of experiments" did he make the further, the all-important discovery (1798) that without etching the writing or design in relief, he could prepare the stone so as to get a print from the surface. This is lithography-chemical surface printing.

Germany.—Senefelder did not start out to benefit the artist, nor did the business men who took him up and launched his invention. The first patents were mostly for printing music and calico. However, artists and their patrons quickly saw the possibilities of lithography as an art. In Germany, royalty patronized Senefelder; Baron Aretin went into partnership with him (1806). Less came of royal condescension than of the first work of note issued by the Senefelder-Aretin Press (1808): the reproduction of Dürer's Missal of Maximilian from the copy in the Munich Royal Library, the drawings made by N. Strixner. German artists grew enthusiastic, got to work on stone, less often as original lithographers than as faithful copyists. The Old Masters, Strixner, Piloty, Mitterer, Hanfstängl were the most accomplished. Their reproductions were extraordinary, but no artist of genius or talent can make himself a mere machine, the Old Masters necessarily lost something in their interpretation, and, eventually, photography did away with the artist as copyist.

England.—Already, in 1801, Senefelder had taken out patents in England, where he was personally overshadowed by Philip André and Hullmandel, who seemed inclined to appropriate all the credit, and the profit too. Fortunately he was recognized by the Royal Society of Arts as the inventor, a gold medal was bestowed upon him, and artistic lithography—"Polyautography" the English then called it—was encouraged. The interest of artists was roused, and an album of *Specimens of Polyautography* was published by André in 1803, with Benjamin West, Stothard, Barry, Fuseli among the contributors. For some years, however, little was heard of the new invention. Now and then an experiment was made by artists, notably by Blake and Bewick. But Géricault had made his lithographs in London and Bonington his in France before lithography acquired the least popularity, before royal and titled amateurs, Queen Victoria and Count d'Orsay of the number, began to amuse themselves with it, before albums of "Views" of architecture and landscape were "on the town." Artists like Prout and Harding went to France to work for Baron Taylor's colossal, never-finished *Voyages Pittoresques* which no doubt stimulated the British fancy for such publications as Wilkie's *Tour in the East,* Lewis's *Sketches in Spain and the Orient,* Roberts' *Holy Land.* As a rule, for these English publications, the artists simply supplied sketches from their sketch books which professional lithographers reproduced on stone and printed. Under such conditions it is small wonder that lithography languished as an art, that the artist who practised it for pure love of the medium was the exception. Cattermole's lithotints remain, the few by Cotman, and John Linnell Jr.'s copies, especially one of Mulready's *The Sonnet* which the most skilled German never surpassed. By 1850 lithography in England was really a *Finished Chapter of Illustrative Art,* as it was later described by William Simpson, whose *India* was the last of the big travel books.

France.—Lithography as an art met with the most immediate response in France. There also it received early official recognition and honours, was patronized by amateurs, was for a time the mode in modish drawing-rooms—a fashionable plaything. But in France this period was short. General Baron Lejeune's famous *Cossack* inaugurated the fashion, and was also, no doubt, the first inspiration of the cheaply got up, cheaply priced albums of military subjects that did so much to popularize the Napoleonic legend. Good printers multiplied rapidly—Engelmann, Lasteyrie, Delpech, Gihaut, Motte, Lemercier. The Vernets, Charlet and Raffet were quick to see in Napoleon and his armies a motive for their lithographs. Charlet contributed not only to the subject but to the art, experimenting tirelessly, getting amazing effects out of *la manière noire*—"mezzotint applied to stone." Raffet on a few inches of paper could make a romance of war, turn it into beauty, in such prints as *Le Réveil* and *Ils grognaient mais le suivaient toujours.* Other artists used lithography for portraits, none more notably than Achille Devéria, above all in his renderings of R. J. Lemercier, founder of the great printing house, and of Alexandre Dumas, *Père.* Painters were attracted by the medium and the variety of its resources. There were few who did not give it at least a trial. Géricault went further than a mere trial, his boxers and horses were among the best known prints of those years and, later, the most sought after by collectors. Delacroix mastered the method triumphantly in his *Lion de l'Atlas* and *Tigre Royal,* less strikingly in his illustrations for *Faust* and *Hamlet*. Isabey's triumph was in his little towns for Baron Taylor, his shipping and harbours for himself. But the list is endless—the prints published sometimes separately, sometimes in magazines and papers. Much of the best work came out in *L'Artiste,* the most successful of the magazines, or in Philipon's two papers, *La Caricature* and *Le Charivari* with Daumier and Gavarni for regular contributors. From the beginning French lithographers had devoted themselves to caricature and fashion plates, records of social life and political satire with as much zest as to war, portraits and "picturesque views," but Daumier and Gavarni excelled them all.

Other countries lagged far behind Germany, England and France in the first half of the last century. Spain gave us Goya, the brilliant, the romantic, the grim; Manet, with paint or canvas, did not get more life and colour out of the bull-ring than Goya with greasy chalk on stone. The rest of Europe was practically barren. In America lithography was entirely commercial, with nothing to show that Americans appreciated it as an art save for a stray print by Lafarge or William Morris Hunt and the *Campaign Sketches* of Winslow Homer, made during the Civil War and remembered now because of his fame as a painter. By the middle of the century, the first great period of the art of lithography was everywhere at an end.

Decline of the Art.—Already in 1840, etchings were competing with lithographs in *L'Artiste* and Beraldi was announcing the decline of lithography. In 1864 Burty declared the art *en pleine décadence*. Both were right. The reasons are not far to seek. The swing of the pendulum for one, lithographs had been almost too popular. French lithographers, warned to be serious like the Germans, began to copy pictures which they did, though with distinction, at the sacrifice of original design. Photography became a serious rival in all countries, bringing its disastrous gift of cheapness. Photographic processes replaced lithography, as well as wood-engraving, for the illustration of magazines and papers. In the '60s photo-lithographs were finding their way into Baron Taylor's monumental work. The commercial lithographer soon preferred the camera to the artist. The horrors of chromo-lithography demoralized the public.

A mystery was made of the actual printing. Artists, not allowed near the press—and few had presses of their own—were kept in an outer room waiting for proofs. The earlier transfer papers were abominable. Dealers fought shy of lithographs and collectors hesitated to follow where dealers feared to lead. Under the new conditions the art threatened to disappear.

Later Revival.—But an art with such possibilities for the artist could not altogether die. Adolf Menzel, trained in a Berlin printing shop, was the chief link between the first great period and the revival. In the '40s and '50s, those dark decades for lithography, he was doing his *Uniforms of the Army of Frederick the Great,* issuing his *Sketches on Stone* in a portfolio, bringing out occasional prints, none more famous than his *Christ in the Temple*. His lithographs are marvels of technical knowledge and accomplished drawing, an inexhaustible mine for the intelligent student. In France, the new generation was discovering lithography for itself through the work of the French masters. In the '60s Manet experimented, also Bracquemond, Legros, Fantin-Latour, who began his well-known series with Wagner as inspiration. In London in the '70s the printer Thomas Way interested Whistler, who, enchanted with so autographic a medium, produced little masterpieces that made a talk in the studios. Several appeared in *Piccadilly, The Albemarle, The Whirlwind,* publications which his contributions could not save from an early death. And so, little by little, lithography as an art came into its own again, especially in France where a retrospective exhibition of lithographs was held at the École des Beaux Arts in 1891. Beraldi now talked of the revival in the air and the French, ever leading in such movements, prepared for a more important, more complete exhibition to celebrate the centenary of Senefelder's invention.

The '90s were the years when the Champ-de-Mars *Salon* opened its doors wide to the new school of lithographers, and the black-and-white section was a place to linger in—the years when Toulouse-Lautrec, Steinlen, Odilon Redon, Valloton, Ibels, Anquetin were at work, and Chéret made the walls of Paris gay with his posters. Painters returned to the stone—Besnard, Blanche, Gandara, Puvis de Chavannes and Carrière who never did anything finer in any medium than his portrait of Paul Verlaine. Lithographs again appeared in papers and magazines, again were issued in series, gave the chief interest to such collections as *L'Estampe Originale,* for which Toulouse-Lautrec made the memorable poster in colour. The excitement reached its climax with the wonderful Centenary Exhibition at the Champ-de-Mars, opening in 1895, three years in advance of the actual date as if France could not wait to pay its tribute to Senefelder.

In England only a few shared Whistler's enthusiasm. C. H. Shannon set up his own press, lithographed much the same subjects he painted, with much the same delicacy and grace. Joseph Pennell used lithography for the illustration of Macmillan's new edition of *The Alhambra* and the *Devon and Cornwall* volume in the *Highways and Byways* series. He had no press, the printing was done at Way's where mystery prevailed, and the pale grey prints gave no idea of his powerful Panama and War Work lithographs that were to come later. William Rothenstein published portfolios of portraits. Charles Conder's lithographs, in their subjects, seem like his fans, but even vaguer in design, more elusive in charm. William Strang, like Rothenstein, turned to portraiture—grave serious studies. A few more artists could be named but, in all, so few that when Great Britain was asked to contribute to the Champ-de-Mars Exhibition, Alfred Gilbert, the sculptor who had begun his career in a lithographer's office, and Charles Goulding, the lithographic printer, scattered transfer paper, chalks and washes wholesale among Royal Academicians and prominent outsiders before any sort of contemporary representation could be made. England held a retrospective exhibition at the Victoria and Albert Museum three years later, 1898, the correct date, with not much more to show in the British Section than the collections sent to the Champ-de-Mars.

Düsseldorf chose the same year for its Centenary Exhibition as Paris (1895–96), and German and Austrian artists played their part in the revival. Hans Thoma and Max Liebermann, Greiner, Unger and Fischer, one woman of power and distinction, Kathe Kollwitz, had revived the traditions of the great days in Germany. A few lithographs were published during its short life by the magazine *Pan* and excellent work has been done at the Pan Printing Press in Berlin. *Jugend* opened its pages to the men of the younger generation, reproducing their lithographs. And a number of other magazines and papers have, with more or less success, looked to lithography for their principal attraction. Belgium has contributed to the chronicles of lithography, and Félicien Rops, Henri de Groux, Emil Claus, Fernand Knopf are among the masters. In Holland, Bauer, Von Hoytema, Van Toroop, Van s'Gravesande, Jacob Maris, Veth, are names to be remembered. In New York the Grolier Club arranged an exhibition in 1896 which probably was an influence in awakening American artists, so long lukewarm. Arthur B. Davies, experimenting in colour, Albert Sterner, George Bellows, Charles Locke, a much younger man, are the most prominent of the too small group of artists who have as yet practised the art in America. J. McLure Hamilton also is an American, but his work has been done mostly in England. Factors in arousing this new interest were the improvement of transfer paper, the use of aluminium plates, the growing tendency of the artist to print his lithographs himself on his own press.

Since 1900 lithography has been more alive and active in England than elsewhere. Public interest dwindled after the Victoria and Albert Museum Exhibition but not the interest of artists. Certain magazines even in the '90s opened their pages to lithographers, whose work may be found in *The Pageant, The Savoy, The Studio, The Magazine of Art, The Art Journal.* But 1907–08

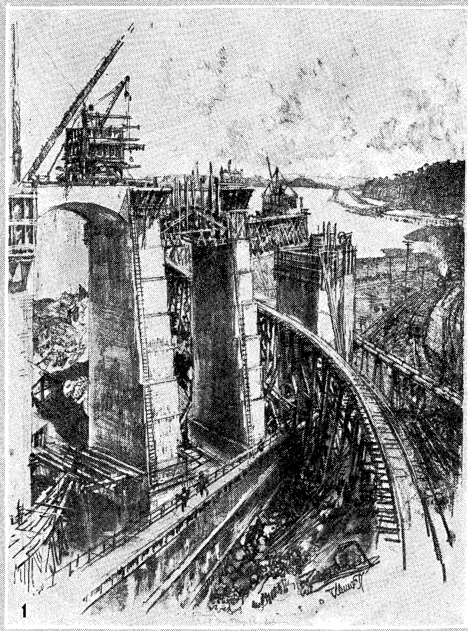
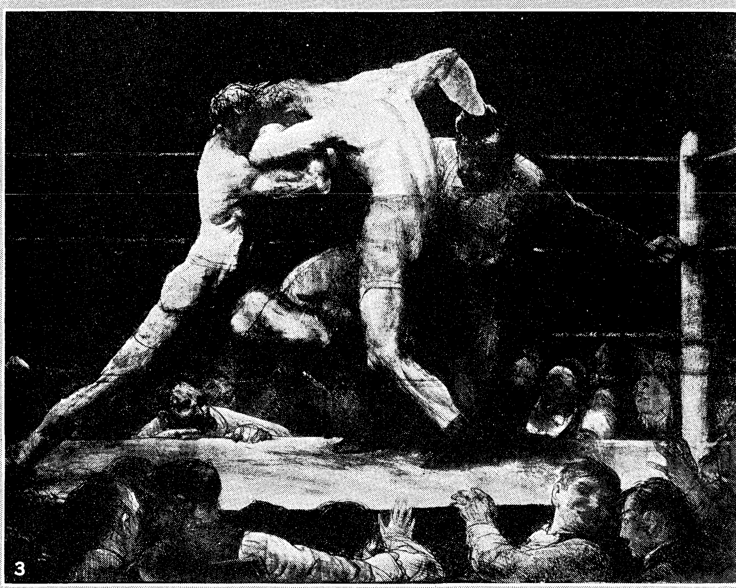
LITHOGRAPHS OF THE 19TH AND 20TH CENTURIES

1. "The Boxers," printed between 1817 and 1821, by Théodore (Jean Louis André) Géricault (1791–1823), French
2. "Christ as a Child in the Temple," 1852, by Adolf von Menzel (1815–1905), German
3. "The Thames," by James A. McNeill Whistler (1834–1903), American
4. "Souvenir de Sainte-Pélagie," by Honoré Daumier (1808–79), French
5. "Il se composa une armée," by Marius A. J. Bauer (1864–1932), Dutch. This is one of a series of illustrations for *La Légende de Saint Julien l'Hospitalier*, by Flaubert
6. "Ils grognaient, et le suivaient toujours," 1836, by Denis Auguste Marie Raffet (1804–60), French
7. "Rome, the Café Greco," 1913, by John Copley (1875–   ), English

LITHOGRAPHY

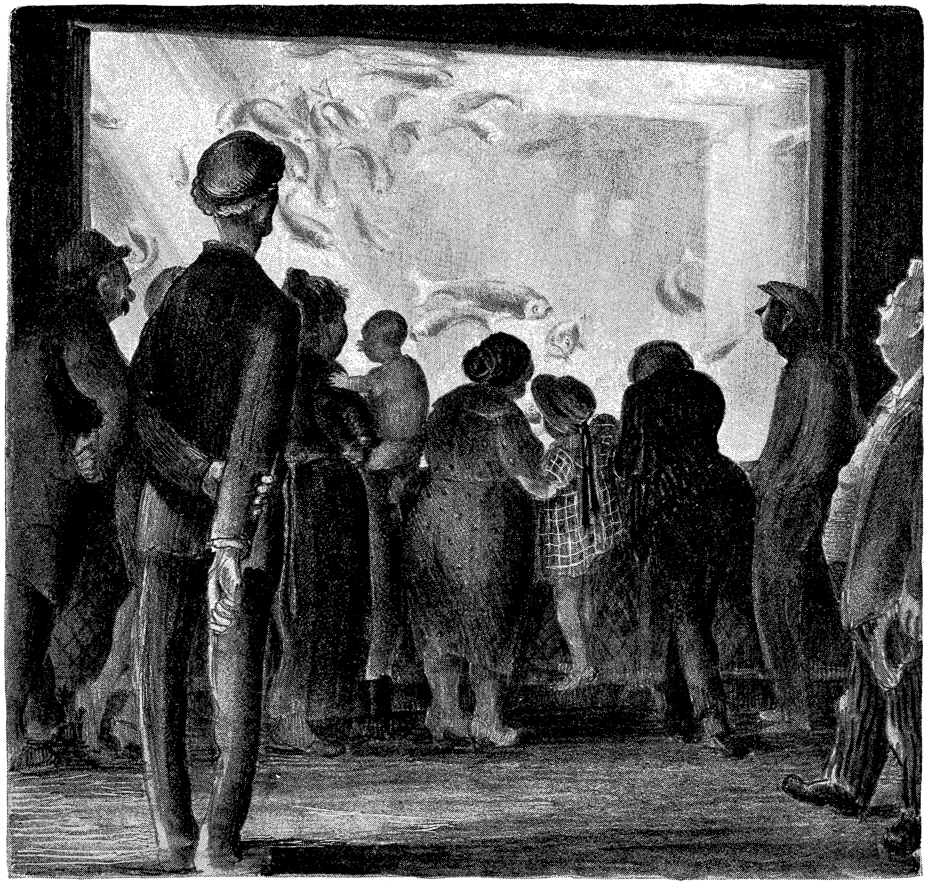




BY COURTESY OF (1) MRS. JOSEPH PENNELL, (2) THE U.S. NAVY RECRUITING BUREAU, (3) EMMA S. BELLOWS, (4) THE TWENTY-ONE GALLERY, LONDON

AMERICAN AND ENGLISH LITHOGRAPHY, 20TH CENTURY

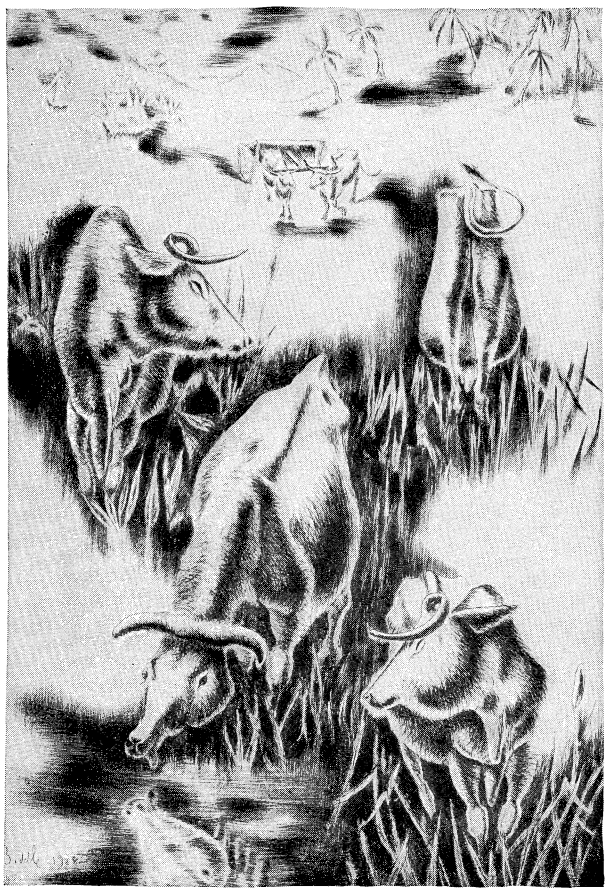
1. "Approaches to Gatun Lock, Panama Canal," by Joseph Pennell (1857–1926), American
2. War Poster by Frank Brangwyn (1867–), English
3. "A Stag at Sharkey's," 1917, by George W. Bellows (1882–1925), American
4. "Hooley's Arches," *c.* 1912, by G. Spencer Pryse (1882–), English

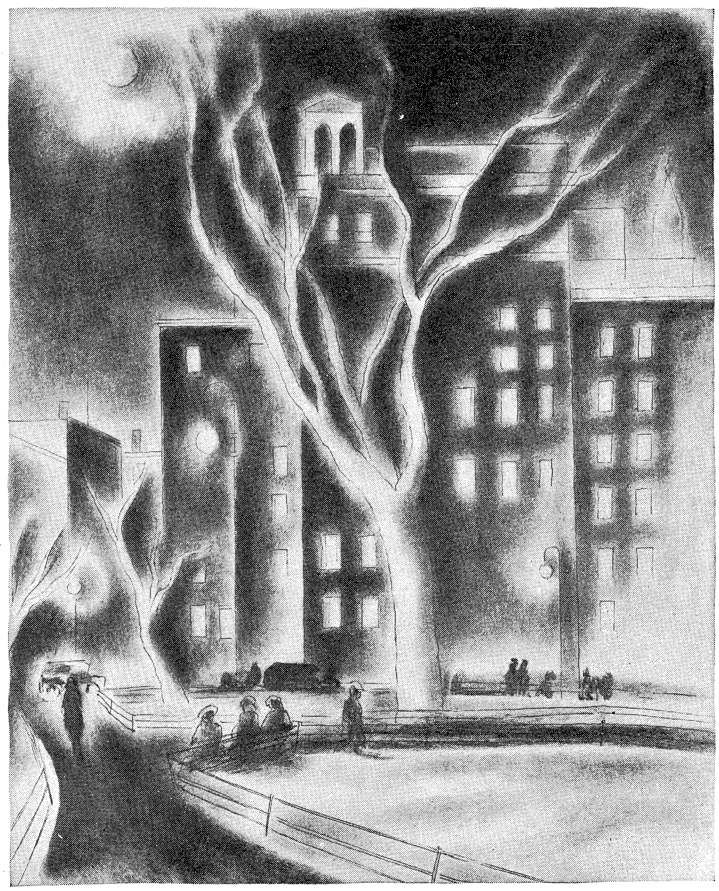


TWO LITHOGRAPHS

1. "Goldfish" by Mabel Dwight, an interesting genre subject taken from the aquarium and showing dark figures silhouetted against a light motif
2. "The Crypt" by Mabel Dwight, showing a suggestive use of black shadows which are cast against a light wall and give relief to the figures

LITHOGRAPHY





THREE MODERN AMERICAN LITHOGRAPHS

1. "Entrance to a Village" by Ernest Fiene. The massing of dark foliage and the angular light areas makes an effective design
2. "Cows" (drypoint on stone) by George Biddle. Strong in design and original in technique
3. "Washington Square" by Ernest Fiene, in which a sense of light is produced by leaving areas exposed, and an impression of mistiness by blurring thin edges

brought the boldest venture of all, *The Neolith,* a quarterly which lithographed text and illustrations alike. It ran for only four numbers. But almost immediately three men associated with it, A. S. Hartrick, F. Ernest Jackson, J. Kerr Lawson, to whose number Joseph Pennell, who had been living in England for years, was promptly added, established the Senefelder Press, which was soon abandoned, and organized the still prosperous Senefelder Club with Pennell as president. The first exhibition was given in the early winter of 1909 and since then annual exhibitions have been held in London and many others throughout Europe and America. Most of the distinguished lithographers of the day became members: J. McLure Hamilton, C. H. Shannon, John Copley its first secretary, E. J. Sullivan, Ethel Gabain, Spencer Pryse, Frank Brangwyn, the second president. The club already in the first quarter of the century did much to restore lithography to its rightful place among the graphic arts, and upon it the future of the art, in a large measure, now rests.

Wagner, *Alois Senefelder, sein Leben und Wirken* (1914); J. and E. R. Pennell, *Lithography and Lithographers* (1915). (E. R. PE.; X.)

LITHOGRAPHY: A METHOD OF COMMERCIAL PRINTING

Lithographic printing—variously referred to by such terms as planography, photo-lithography, offset lithography, photo-offset, offset, offset printing, and others—has forged ahead as a leading commercial graphic arts process. Both because of the versatility of the process itself and because of important new adaptations coupled with basic technological advances, its useful field has steadily widened.

Paper, whether it be of smooth or rough finish, paperboard, cloth, leather, metal—even wood—are all successfully lithographed today. Moreover, through the use of decalcomania, a form of lithographic transfer, referred to below, name plates, brand identifications, and a multitude of colourful decorations may be easily applied in instances where direct printing would be impossible and hand painting would be prohibitive in cost.

The earliest known example of lithography produced in the United States was an illustration for the *Analectic Magazine* published in Philadelphia about 1819. The use of the process spread rapidly to Boston and New York. In the early days the lithographic impressions were taken from the original stone on which the design had been drawn by the artist. All designs were drawn backwards so that when the impression was pulled from the stone it became a normal print. Lithographs were printed only in black, on a hand press. All early coloured lithographs were hand-coloured, a slow, expensive procedure and very uncertain as to results.

The important steps in the development of lithography as a method of commercial printing can be described as follows:

Taking a single impression of a subject from a stone on a hand press was a slow process and necessarily limited the output to the speed of an operator. A real advancement was the discovery that transfer impressions could be taken from the original stone on paper coated with cornstarch and gelatine. These were fastened face up on a large sheet of paper in correct position for printing and the sheet of transfers was then placed face down on a large stone and under pressure the impressions were transferred to the stone. Upon removal of the paper the large stone carried several ink impressions instead of one and the printer could now deal with these multiple impressions as a unit. This development increased the market for certain types of labels and small subjects.

The next important development was the introduction of the power press about 1865. Following the first successful experiment, presses increased in size and speed. There was a constantly increasing demand for larger stones, finally reaching the size of approximately 44x64 inches. The speed of the flat-bed or stone press was limited by its reciprocating motion to approximately 600 sheets per hour.

Next came successful experiments with zinc plates, which made possible the development of the rotary press. Whereas lithographic stones were very heavy and could be handled only in a flat-bed press, the thin, light-weight zinc plate could be strapped around a cylinder. The speed of the rotary press was about 1,100 impressions per hour. This doubling of the output of the press substantially reduced the cost and materially increased the market for lithography. Rotary presses were later built to print, from one feeding, two to five colours which further reduced the cost of manufacturing. A special type of high-speed web rotary press was built about 1895 which printed six colours on one side and one colour on the other side of a roll of paper.

The development of the offset press dates back to about 1875, though the press did not come into extensive use until the early part of the 20th century. The earliest use of the rotary offset press was in tin printing. Later on, more or less by accident, it was discovered that a fine offset impression could be taken on paper and, following the usual experimental stage, the lithographic process called "offset" came rapidly into general use.

The stone press has one cylinder which carries the paper as it comes in contact with the stone, the paper and the stone travelling at exactly the same speed. The single-colour, direct-rotary press has twin cylinders, one carrying the plate and the second carrying the paper, both cylinders rotating at the same speed. Thus, the flatbed and direct-rotary presses are examples of direct printing. The offset press has a third or rubber-blanket cylinder. The printing image is first transferred from the plate to the rubber blanket and thence to the paper which travels around the impression cylinder. Modern offset presses deliver in excess of 4,000 impressions an hour on fine-register, colour work.

Offset presses are built in a variety of sizes from 12x17in. to 50x72in. and print from one to four colours from a single feeding. Also, web offset printing—single and multi-colour—is being rapidly developed.

The above outline has touched principally on the development of presses, but quite as important, if not more so, has been the development of technique in making originals and press plates. In the earlier period, all work was drawn or engraved by the artist on stone. Later on, originals were also drawn or otherwise laid down on zinc and aluminium plates. Discovery and development of the process of hand transfer made possible the simultaneous printing of multiple prints. Then came the development of photo-lithography.

While originally all lithographing was done in black only, experiments in printing colours in perfect register were carried to a successful conclusion, and thus was made possible the faithful reproduction of works of art and other subjects. The procedure in making the original drawing for reproduction in colours was quite simple, a separate stone or plate being required for each colour. To insure perfect register, cross marks were placed in the top, bottom, and side margins of each plate. These register marks served to prevent an overlapping of the colours or a misfitting of the lines as the successive colours were printed.

Photography was invented by Daguerre and Niepce about 1840. Experiments were carried on (about 1851) in Paris on sensitized stone and excellent prints resulted. Continual experimentation in the making of lithographic originals by photography resulted in the development of several photographic processes to be used in colour lithography. These had limited use even in the latter part of the 19th century. One of these, the submarine process, is still employed to some extent.

With the development of colour-separation methods in connection with colour filters, the use of the camera for making both originals and press plates increased rapidly until today much the larger volume of colour lithography is known as "process," meaning photographic. Consequently, work which formerly required from eight to ten colours is now done in four or, at most, six. The speed of the camera, and its elimination of many formerly required steps, has expedited preparation of original plates. Letterheads, bank checks, stock certificates, and other items of commercial stationery which were formerly produced from engravings with an etching needle on stone are now produced photographically from pen and ink sketches with no loss of fine detail.

There has been substantial progress in the making of longer-lived and better printing plates. Original drawings on metal are used as press plates only when the subject approximates the full sheet size of the press. Outdoor posters, which are made up of ten or more large sheets, are an example of work that is printed from the original drawings. In general, however, there are three types of press plates in common use—(1) the hand-transfer plate which is made by pulling impressions from the original plate on specially prepared paper for transfer under pressure to the full-size press plate; (2) the albumin plate, and (3) the deep-etch plate. The latter two are photo-mechanical plates. Albumin plates, being less expensive, are generally used for less exacting short runs; deep-etch plates are generally used for the more exacting jobs, particularly those calling for a wide range of tone values, a large number of impressions and a brilliance in appearance. The product from the deep-etch plate is equal in quality to the best turned out by any other method of printing.

A machine, known as a photo-composer, is often used to prepare photo-mechanical press plates on which the same design is duplicated several times. This precision machine is designed to carry a plate up to 56x72 inches. The photographic plate of the subject to be printed is placed in a movable frame which is then manipulated up and down and across the plate according to a predetermined layout leaving impressions in the multiple positions as required. This machine is capable of such precision that successive plates for the same job can be brought into perfect colour register. Another machine, known as the vacuum frame, is also used for making plates for one-colour, photo-lithographic work and for multi-colour work which does not require close register.

Tin Printing, which was introduced about 1875, is the application of the lithographic process to the decoration of metal plate. A substantial percentage of can-label work formerly done by the paper lithographer has in recent years gone to the tin lithographer. Many of the metal containers one sees, some simply and others elaborately decorated, are the product of tin printing.

The method employed is similar to that already described for paper lithography. The press plates are similarly prepared—largely photo-mechanically—and are run on an offset press. Sheets of prepared tin instead of paper are fed into the press and are then oven dried at high temperature, this procedure being repeated for each additional colour required.

Decalcomania is a lithographic process with certain definite variations. The word "decalcomania" is coined from a Greek root meaning literally "decal"—off the paper; "mania"—craze. In other words, a craze for taking or transferring a picture off a paper background onto another surface. The process originated about 1860 in France but other European nations, particularly Germany, were quick to develop it.

One of the distinguishing variations is the fact that decalcomania, unlike ordinary lithography, is printed on a very absorbent, starch- or dextrine-coated paper. This coating material must afford both a smooth printing surface and one that will prevent the inks, lacquers, or varnishes from penetrating into the paper stock. It must also act as an adhesive where the design is printed face up.

Decalcomania is reproduced from lithographic stone, zinc, copper, and, in more recent years, even by a silk or copper screen method. There are three basic types of decalcomania thus produced—"face-up," "face-down," and a combination of the two carrying copy on both sides of the decalcomania.

In the face-up decalcomania numerous white base-coats are first printed, oftentimes eight or ten whites being applied, until a heavy enough body of ink has been deposited on the decalcomania paper to insure a sturdy support for the actual design. It is necessary to dry thoroughly each white impression before applying the succeeding one. After the base-coats have been applied the other colours follow in order.

In the case of a face-down decalcomania the reverse procedure is followed. All of the tints are successively applied and then followed by the other colours shown in the design after which the backings or base-coats are run. This type of transfer requires unusual skill and experience since it is reverse printing. The artist must know beyond any question how each of the following colours will affect the design.

In printing the combination face-down and face-up design, where copy appears on both sides of the decalcomania, all of the operations involved in both face-down and face-up decalcomanias are performed, the face-up design being printed on top of the face-down design. It will be readily understood that to insure correct register in lithographing decalcomanias full control of press-room temperature and humidity is essential.

Decalcomania is used extensively—in the lettering and decorating of commercial trucks and cars, on railway rolling stock and aeroplanes, as vehicle licences affixed to windshields, as interior decorations on the walls of homes, as revenue or tax stamps on certain commodities, as name-plates or decorative designs on all types of manufactured articles, and as window signs for dealer identification. It is successfully applied to wood, metals, rubber, glass, cloth, and plastics.

Originally merely a plaything or novelty, decalcomania is today an accessory in one form or another to almost every important industry. Recent refinements and improvements indicate still greater usefulness for this highly specialized type of lithography.

Recent Developments.—The lithographic industry, as indicated above, has grown appreciably in the last decade or two. This growth must be attributed to improved techniques, equipment, and materials. Offset presses are more accurate, more adaptable and much faster. Offset rubber blankets last much longer than formerly and give far less trouble to the operator. Photographic procedures have advanced rapidly. The paper negatives, now widely used, were unheard of a few years ago. The use of photographic dry plates, instead of the traditional wet plates, is now the rule rather than the exception. Especially significant is the further development of dry plates which have enabled lithographers to develop the dot etching method successfully. Paper and ink manufacturers have kept pace. Speedier presses required faster-drying inks and papers that would meet more exacting demands.

Established in 1924 through the efforts of the Lithographers National Association Incorporated, the trade association for the lithographers of the United States, the Lithographic Technical Foundation has been an important contributor to this forward movement for the two-fold purpose of basic research and education. Outstanding among its efforts to effect improvements and economies in practice are the "deep-etch" method of making press plates, the improvement and standardization of the albumin method of plate making, the development of a substitute for turpentine which is far less harmful to the worker's hands, the development of the paper hygroscope to ascertain the moisture content of a pile of paper, the register rule to compare the dimensions of the image on the plate in colour work and the print of the same on the sheet, and the inkometer for measuring the tackiness of ink.

The task of passing on to the plants the results of technical research—in other words, of putting them to practical use—is one of the responsibilities of the education department of the Foundation. To this end it has developed and offered a variety of educational courses for meeting the varied needs of all types of employees. *Research Bulletins,* issued from time to time, cover new technological developments of interest to lithographers. (*See* COLLOTYPE; COLOUR PRINTING; PHOTO-ENGRAVING.)

Harrap, *Offset Printing from Stone and Plates* (1927). (MA. S.)

LITHOPONE, a white pigment consisting of a mixture of barium sulphate ($BaSO_4$) and zinc sulphide (ZnS), manufactured in large quantities and used as a substitute for white lead. The essential steps in its preparation are: finely ground barytes (barium sulphate) is calcined at a white heat with coal, coke or charcoal. The BaS thus produced is dissolved from the mass with water and treated by either of two methods: (*a*) a weak solution of $ZnSO_4$ (free from iron) is added in slight excess and the precipitate of $BaSO_4$ and ZnS thus formed is well washed and dried. The crude dry lithopone is calcined at a low red heat, dropped into cold water where it is finely ground and then pressed and dried; (*b*) the BaS is treated with a solution of $ZnCl_2$, producing ZnS and $BaCl_2$. A solution of $ZnSO_4$ is added, precipitating $BaSO_4$. By the fresh addition of BaS solution, the $ZnCl_2$ formed in the latter reaction can be used to precipitate more ZnS. Lithopone is non-poisonous and its cost is only about half that of white lead or zinc oxide. Unlike these latter, lithopone is not discoloured by the H_2S and other sulphurous gases usually present in the atmosphere of all large cities. Unless carefully prepared, due to the presence of impurities, lithopone rapidly darkens in the presence of sunlight. (F. J. G. DU.)

LITHOSPHERE, the solid crust of the earth (Gr. *λίθος*, a stone, and *σφαῖρα*, a sphere). The surface soil, a fluctuating layer of loose earthy material which may extend down for a few hundreds of feet, lies upon a mass of hard rock several miles thick but of varied character and composed mainly of sandstones, mudstones, limestones and various igneous and metamorphic rocks. These two layers form the lithosphere which is constantly affected by the tectonic movements of the solid nucleus below it. Volcanic activity is manifested, mountains are folded, levels change and fresh surfaces are exposed to the cycle of erosion; but through all the changes the lithosphere retains those characteristics which differentiate it from the other spheres of the earth.

LITHUANIA (LIETUVA), a Baltic republic of the soviet union and, for 22 years following the war of 1914–18, an independent state. The people speak the oldest surviving Indo-European language, closely resembling ancient Sanskrit, which, with that of the Letts, comprises the modern remnants of the Aestian or Balt group of languages. In the days of its greatest imperial power the grand duchy of Lithuania stretched from the Baltic to the Black sea and was the last stronghold in Europe against Christianity. Following the union with Poland and the conversion of Lithuania in 1385, Polish influence and language dominated the people for more than 400 years. In 1795 most of ethnic Lithuania was annexed by imperial Russia. Taking advantage of the unstable conditions in eastern Europe following the Russian Revolution, the Lithuanians proclaimed their independence in 1918 and were able to maintain it until June 1940, when soviet troops took over the country. The German army occupied Lithuania 1941–44.

Geography.—Lithuania extends from 53° 53′ to 56° 26′ north and from 21° 3′ to 26° 50′ east. In 1939, after Vilnius (*q.v.*) (Vilna, Wilno) and surrounding territory was ceded to Lithuania, and following the seizure of Klaipeda (Memel [*q.v.*]) by Germany, the area of the republic was 22,958 sq.mi. It is bounded by Latvia on the north, White Russia on the south and east, and the Baltic sea and East Prussia on the west. The country is overlaid with glacial deposits, in some places 400 ft. thick. The typical bottom moraine, with erratics from Finland, extends over most of it, and glacial furrows, striae and elongated troughs run northwest and southeast, as do the eskers. Sand dunes extend along the shores of the Baltic. At one time the region was heavily forested, but in the period previous to the outbreak of war in 1939 only 17% was forested, while 49% was arable, 25% meadows and pastures, 8% turf pits, marshes and swamps, and 1% rivers and lakes. Nearly 2,000 lakes dot the landscape. Lithuania consists chiefly of a low plain watered by the Nemunas (Niemen) and its tributaries. This river system has cut deep valleys in the Baltic hills, which extend roughly from Daugavpils to Kaunas, and empties into Kurisches Haff. In the north numerous streams drain into the Muša river, an affluent of the Aa (Lielupe). The average altitude of Lithuania is 490 ft., with the highest hills being Alsenai (1,112 ft.) and Jakaucizna (961 ft.) in the long-disputed Vilnius area, and Taurapilis (823 ft.).

The climate varies from maritime along the coast to modified continental in the interior. Centrally located Kaunas has an average temperature of 44° F. (Jan., 23.3° F.; July, 65.3° F.), with an average precipitation of 24 in. Four months of the year are usually below freezing and 160 days are rainy, with half of these in late summer. Winds in the summer are predominantly from the N.W., while in the winter they move in from the S.W.

Except for small areas of alluvial soil, principally near the major rivers, most of Lithuania's farmland is low in organic material. The impermeable subsoil and the excess of precipitation over evaporation encourage mould and soil deterioration. Peat bogs have developed in some marshy clay regions, notably in Kobrin and Slanimas, and there are shifting sands in the Pruzenai and Vilkaviškis districts.

Flora and Fauna.—The proportion of Lithuania left in forests is only about half what it was in 1880. The most important trees are fir (40%), pine (28%), aspen (13%), but birch, alder and oak are of some consequence. The great forests are found in the south and east, in the districts of Mariampole and Vilkaviškis.

More than 226 kinds of birds, 35 kinds of wild animals, 12 kinds of amphibians and 7 kinds of reptiles are native. Especially common are rabbits, foxes, wolves, badgers, squirrels, deer, wild hogs and otters. World War I brought about a change in the Lithuanian fauna, with elk, beavers, grouse and black stork becoming almost extinct. More than 40 species of fish can be enumerated in the fresh waters, while Kurisches Haff is rich in brill, trout, whiting, smelt, sole and herring.

Natural Resources.—Although the natural resources have not yet been thoroughly prospected, geologists believe there are no commercial metals, oil or coal. Underdeveloped peat fields, chalk for cement and lime, clay for ceramics, some amber near the East Prussian frontier, and small quantities of quartz have been produced in commercial quantities. There are sulphur springs at Birstonas and brine baths at Druskinikai which contain radium.

Population.—Soviet Lithuania in 1941, including ceded Vilnius districts but excluding Klaipeda, had an estimated population of 2,879,070 and a density of 125.4 per sq.mi. Both the birth rate, 24.8 in 1934, and the death rate, 14.6, showed declining trends. Under 1937 territorial conditions the people were about 81% Lithuanian, 7% Jewish, 4% German, 3% Poles, 2% Russian, White Russian, and 3% Tartars, Letts and others. Acquisition of Vilnius considerably increased the Jewish element. About 80% was Roman Catholic and 5.5% Lutheran; 76.8% lived on isolated farms, and only 15.8% in communities of 2,000 or larger.

Capital and largest city was Vilnius, pop. (est. 1941) 210,000. Other important centres were Kaunas 120,000; Gardinas (Grodno) 51,000; Šiauliai 27,000; and Panevežys 25,000.

Emigration.—During the era of independence the rate of emigration fell to about half its pre-1914 level, averaging 5 per 1,000. It is estimated that a third of the Lithuanians had moved abroad in the 50 years preceding World War I, primarily because of the famines of 1850 and 1867, the insurrections of 1863 and 1905, and the 1874 military service law.

Until the United States applied restrictive legislation in 1924, the bulk of the Lithuanian migration was to American coal mining districts and industrial cities, but by 1930, 80% of the emigrants were settling in Brazil and Argentina, with growing numbers moving to South Africa and Palestine. In 1930 more than a quarter of the emigrants were Jewish.

Although only 193,606 registered as Lithuanians in the 1930 U.S. census, nationalist sources place the figure as high as 750,000. Their rate of naturalization was then 25.6%, and their rate of illiteracy, 24.5%. In addition to a number of Lithuanian cultural and religious movements, many schools have been established, including Marianopolis college and high school in Thompson, Conn. Approximately 80,000 Lithuanians have settled in the United Kingdom, especially in the mining districts of Scotland.

HISTORY

Archaeologists have found evidence that in Neolithic times (3000–1500 B.C.) people closely resembling present-day Lithuanians were living near the shores of the Baltic sea and had reached a relatively high state of culture. But other scholars, studying the close linguistic tie between Lithuanian and Sanskrit as well as the ancient folklore, believe the Lithuanians migrated to their present home about the time of Christ, presumably from the upper reaches of the Dnieper river. Earliest historical records are found in Tacitus, Roman historian of the 1st century A.D., and

Ptolemy, Greek geographer in the following century.

Formation of the Empire.—As early as the 5th century a shadowy theocratic federation was formed among some of the pagan Lithuanian tribes, but not until after 1230, when the Teutonic Knights moved into East Prussia, did the almost isolated tribes band together. Under their leader, Mindaugas (Mindove, Mendog), an effective military organization was built, and in 1251 he and his family were baptized. Two years later he was crowned the first and only king in Lithuanian history by the authority of Pope Innocent IV. But before Mindaugas' death in 1263, during a campaign against the Knights, he had repudiated Christianity and had even sacrificed his prisoners to his ancient gods.

Gediminas (Gedymin [*q.v.*], Gedimin), 1316–1339, was the first great empire builder. In 1321 he took Kiev; in 1323 he founded Vilnius; in 1325 he married his daughter to the prince of Poland. He wrote to Pope John XXII offering to accept Christianity by agreement with him, but the Knights and the Poles objected because they were seeking political as well as spiritual domination. Gediminas introduced western civilization into the grand duchy, granted local autonomy, and made White Russian the official language. Ablest of the dynasty was Algirdas (Olgerd, Olgierd [*q.v.*]), 1345–1377, who ruled with his brother Keitutas (Keijstut). Though at constant war with the Knights, he succeeded in spreading the Lithuanian empire from Vitebsk on the Dvina, Mogilev on the Dnieper, Bryansk on the Desna and the coast of the Black sea from the Dnieper to the Dniester. Before he became a Christian and died as a monk, Algirdas had ruled over 350,000 sq.mi. His son, Jagela (Jagellon, Jagello, Jagiello), succeeded him, and after making a deal with the Knights, killed Keitutas.

Union with Poland, 1385–1795.—The Polish barons and prelates were largely responsible for the Union of Krevo (Krewo) of Aug. 15, 1385, which created an essentially dynastic union between their country and the grand duchy of Lithuania. The Polish queen, Jadwiga (Hedwig), reluctantly married Jagela; Lithuania established the Roman Catholic church; and Jagela was crowned Wladyslaw V (or Ladislas II) of Poland. In Lithuania, Vytautas (Witold, Witowt), son of Keitutas, escaped from Jagela's prison, rallied the nobles, and in 1392 was elected Lithuanian grand duke. His armies fought enemies on all sides, but they achieved their greatest success on July 15, 1410, at Grünewald near Tannenberg, when with Polish, Russian, Czech and Tartar allies, they decisively and finally crushed the German Knights. A crown for Vytautas from Emperor Sigismund was being held up by the Poles when he died in 1430.

The Lithuanian-Polish union was confirmed by the pacts of Vilnius in 1401 and 1434, of Horodlo in 1413, of Gardinas in 1501 and 1512, and Lublin in 1569. This last union also ceded large sections of Lithuania to Poland, doubling its size. From 1501 onward the Lithuanians and Poles were ruled by one sovereign, and from 1569 had a common legislature. The Lithuanians, though sometimes anxious to break away, sank into a state of dependence. Polish language was used by all but the lower classes. Polish laws and customs were adopted. The kings, in order to secure succession, bargained away their rights and eventually became mere puppets for the national assembly (*Sejm and Rada*), which itself was impotent because of the *liberum veto*. Subsequently the dual state was involved in a common downfall, and in the third partition of 1795 ethnic Lithuania fell to Russia except for Suvalkai, which went to Prussia.

Russian Rule and the Renaissance, 1795–1918.—Under Tsar Paul I considerable autonomy was granted to the ceded territories, but Alexander I revoked most of these privileges. When Polonized Lithuanian nobility took part in the Polish rebellion of 1830, Nicholas I retaliated with a ruthless policy of Russification. Russian was made the official language, Polish was proscribed. All monasteries were closed, the number of schools was cut from 394 to 94, even the name "Lithuania" was lost in the new "Northwest Territory." The policy was further extended after the great rebellion of 1863. Muraviev, the governor-general, made religion the test of nationality. He exiled 9,000 of the revolutionists, imported Russians to fill government offices, closed the Roman Catholic schools, and forbade the use of the Lithuanian language in any printed form.

The only real Lithuanian intelligentsia was an extremely small group of *émigrés* and some of the lower clergy. *Aušra* (Dawn), a nationalist paper established in 1883 by Dr. Jonas Basanavičius and printed in Lithuanian, was smuggled in from Tilsit, East Prussia. *Varpas* (Bell), inaugurated six years later, was active until the 1905 revolution. At the turn of the century arose the Social Democrat movement, which was centred almost exclusively in the towns among the White Russians and Jews. The Lithuanians, increasingly conscious of their nationality, joined the 1905 revolution. The Ukase of Oct. 22 granted them free speech, free assembly and right to call a congress at Vilnius. Two months later when this congress met under Basanavičius, it demanded autonomy for Lithuania, the restoration of ethnic frontiers and of the historical capital of Vilnius, and the use of the Lithuanian language in the schools. As the tsardom regained strength, this movement collapsed, though it had at least succeeded in removing the ban on the use of Lithuanian. Subsequently even the electoral franchise for the duma was unfavourable to the Lithuanian nationalists. Russian progressives who favoured autonomy for Poland did not contemplate it for Lithuania.

Era of Independence, 1918–1939.—The German armies which occupied Lithuania in Sept. 1915 remained for more than three years. Requisitioning and destruction were heavy. The use of Lithuanian was severely restricted. Even during the early months of occupation a secret nationalist committee of five was formed, composed of A. Smetona, J. Savlys, Stankevičius, S. Kairys and P. Klimas. German officials, with virtual annexation to Germany as a condition, finally agreed to permit a Lithuanian conference to meet in 1917. This group elected a 20-person national council (*Taryba*) under the leadership of Antanas Smetona, which proclaimed Lithuanian independence, Feb. 16, 1918. The same proclamation agreed to "special relations" with Germany in return for recognition. The crown of Lithuania was subsequently offered to Wilhelm von Urach, a Württemberg duke supposedly related to Mindaugas, but the offer was withdrawn in November. The provisional constitution, adopted in Oct. 1918, vested supreme power in a three-man presidium, which included A. Smetona, who became provisional president in April 1919. Professor Augustinas Voldemaras formed the first cabinet on Nov. 11, 1918.

The newly formed Lithuanian army drove out the Bermondt-Avalov "free corps," but the Poles and Bolsheviks continued to battle through southern and eastern Lithuania. With boundaries still unsettled, the Constitutional assembly met May 15, 1920. Of the 112 delegates, 59 were Christian Democrats, 29 Populists, 14 Social Democrats, 6 Jewish, 3 Polish and 1 German. July 12, 1920 the treaty of Moscow was signed with the Russians recognizing Lithuanian claims to a large portion of Vilnius and Gardinas districts and granting indemnities to Lithuania. On Oct. 7 the Lithuanian-Polish boundary seemed settled when the treaty of Suvalkai was signed, using approximately the Curzon line and granting Vilnius to Lithuania. But two days later the supposedly freebooting army of Gen. Lucian Zeligowski occupied the Vilnius district and set up an independent government, and necessitated the moving of the Lithuanian capital to Kaunas. Subsequent evidence seems to show that this expedition moved under orders from Polish chief-of-state Pilsudski. The council of the League immediately took steps to settle this dispute, but after a futile series of proposed solutions had been offered and after Vilnius had officially been incorporated into Poland in March 1922, the conference of ambassadors on March 15, 1923 accepted the *coup de main*. Full diplomatic and commercial relations were not reestablished between Poland and Lithuania until 1938.

Imitating the Poles, the Lithuanians in Jan. 1923 moved an army in civilian clothes into Klaipeda, which was under a temporary inter-Allied control, and on Jan. 15 formally took over the district. The conference of ambassadors agreed to the union within a month and on May 8, 1924, in Paris, signed a convention setting up Klaipeda as an autonomous unit under Lithuanian sovereignty. Although the German population was slightly greater than the Lithuanian, access to the non-German hinterland almost doubled the trade of Klaipeda. Germany granted Lithuania *de jure* recognition March 23, 1918; soviet Russia on July 12, 1920. France and England did not follow suit until Dec. 1921. The United States delayed until July 25, 1922. Lithuania became a member of the League of Nations on Sept. 22, 1921.

Following a cabinet shift in May 1926, bringing to power a coalition of Socialists, Populists and the national minorities, soviet friendship began to grow. When the Lithuanian-Russian Security pact was signed Sept. 28, the British responded with a temporary financial blockade. By means of a *coup d'etat* on Dec. 17 the Smetona-Voldemaras group took over the government with but 20% of the *Seimas* supporting them (Nationalist and clerical parties). Opposition parties were eliminated and civil liberties curtailed. The constitution of Aug. 1922 was rewritten for the new situation and promulgated on May 15, 1928.

On Jan. 29, 1928, G. Stresemann and A. Voldemaras signed a German-Lithuanian protocol agreeing to conciliate or arbitrate all difficulties between the two countries. In Feb. 1929 Lithuania joined Latvia, Estonia and Poland in signing the Litvinov protocol in Moscow. A long contemplated Baltic pact was completed Sept. 13, 1934 between Estonia, Latvia and Lithuania.

In Sept. 1929 discontent broke out in the dictatorship and Smetona expelled Voldemaras and suppressed his fascist "Iron Wolf" organization. Voldemaras' attempt to return to power in 1934 was effectively thwarted. A third constitution of May 1938 further increased the power of the president.

Poland, taking advantage of the confusion created by German seizure of Austria in 1938 and the shooting of a Polish soldier who had wandered across the frontier, sent an ultimatum to Lithuania demanding establishment of normal relations and the acceptance of the Vilnius cession to Poland. On March 17 the Lithuanian government agreed to accept the terms. A year later, March 22, 1939, after a similar ultimatum incident, Germany seized Klaipeda, the centre through which passed annually three-quarters of Lithuania's exports and two-thirds of her imports. Five days later a new cabinet, composed of the leaders of the banned opposition parties, formed a ministry under General Jonas Černius, formally announcing U.S.S.R. friendship, but with Smetona riding out the change as president.

In the Vortex of World War II, 1939–1944.—After the loss of Klaipeda events moved with devastating rapidity for Lithuania. World War II brought German and Russian armies into Poland in Sept. 1939, and intensified the whole Baltic situation. On Oct. 10 Lithuania signed a pact granting the U.S.S.R. garrison privileges in the country and gaining in return the city and district of Vilnius. In November, however, all Lithuanians were forced to leave Klaipeda. Precarious independence was maintained until June 1940, when Premier Antanas Merkys went to Moscow "to conduct negotiations," and was joined by Juozas Urbsys, foreign minister. On July 14, after opposition had been quieted by protective arrests, the people voted for inclusion in the soviet union; on Aug. 3, Lithuania was admitted formally as the 14th soviet republic. Some 82,000 additional people in the Vilnius district were added to the new republic. President Smetona fled and some 12,000 Jews and war refugees set out for New Guinea via Japan. Reports indicated that during the following year thousands were deported to the east as sovietization continued. Great Britain and the United States refused to recognize the new regime, froze Lithuanian assets, and allowed the old legations in London and Washington to remain.

On June 23, 1941, the day after the German attack on Russia, the Lithuanians staged a revolution and declared independence. The German army reached Kaunas, June 24, but the peoples' hopes in a Germanic liberation were soon dashed. The minister to Berlin, Col. K. Škirpa, was elected prime minister, but he was kept in custody by the nazis. Hence, Juozas Ambrazevičius became chief minister. On July 17, 1941, Hitler announced creation of the "Ostland," including the three Baltic states and White Russia; Heinrich Lohse was named reichscommissar, and Adrian von Renteln became commissioner-general for Lithuania. The position of the provisional government was by this time utterly untenable and it resigned on Aug. 5. On Aug. 10 a national ceremony was held at the tomb of the Unknown Soldier, and thereafter the nazis were left in complete control. The reichscommissar promised "order . . . construction and civilization . . . a supervised economy," but reconstruction was obviously slow. A few Dutch and Danes were colonized, but the sovietized lands were retained by the state, and on March 17, 1943, Lohse proclaimed that individuals could regain land only if they participated in the "war against bolshevism." Universities were closed, and the nazi library "revision" took 27,000 volumes out of two Kaunas libraries, 23,000 from the university library and 40,000 from the Academy of Sciences in Vilnius. In 1943 some 100,000 Lithuanian labourers were reported to be in Germany; demands for troops caused thousands of men and boys to flee to the woods and become guerrillas. The general Russian offensive swept into the country by the summer of 1944 and by mid-October all of Lithuania was retaken. Some Lithuanians welcomed their "communist brothers"; others fled with their "nazi" comrades. Lithuania itself had been devastated in the fighting and much of its Jewish population was said to have been slaughtered. The country was re-established as a soviet republic.

Education.—Until the marriage of Grand Duke Zigmantas (Sigismund I, 1506–48) with the Italian princess, Bona Sforza, brought merchants, artisans and humanist scholars to Lithuania, there was no organized education. The later rivalry between the Protestants and the Catholics brought a rush of school building and the entrance of the Jesuit order. The Vilnius academy (est. 1578) became the centre of the cultural life. Following the rebellion of 1831 all the Catholic schools were closed, leaving only three large Orthodox Russian seminaries open. Not until after the revolution of 1905 was teaching of the Lithuanian language permitted. By 1914 there were more schools in the Baltic area than in any other section of Russia.

Compulsory education was not introduced in the independent republic until 1930, largely because of the lack of trained Lithuanian-speaking teachers. By 1939 Lithuania had 2,335 primary schools, 27 secondary schools, 56 gymnasiums, 5 teachers' training colleges, 21 special advanced training schools and 126 special craft schools. Approximately 250 of the primary schools were established for the benefit of minority groups. Agricultural education was a part of the usual curriculum. University of Vytautas the Great, which was moved from Vilnius and re-established in Kaunas in 1922, had 292 professors and lecturers in 1938 and 3,141 students. There was also an Academy of Agriculture in Dotnuva, Veterinary academy in Kaunas, Institute of Commerce in Klaipeda, Conservatory of Music in Kaunas, School of Arts in Kaunas and Institute of Education in Klaipeda. In 1940 several faculties from the university in Kaunas returned to Vilnius. Illiteracy in 1939 was only 15% of those over 10 years of age, about half the average of 1910–14.

Defense.—The army of independent Lithuania was established during the closing months of 1918 to drive out Bolshevik, German and Polish troops. During the following year an officers' school was established and compulsory military service for all able-bodied men over 21 years of age was instituted. Eighteen months became the usual period of service. Officers were recruited from the military academy (2- or 3-year course), and it was the custom to send 10 to 15 young officers to French, Belgian and Czechoslovakian military schools. The budget effectives numbered about 25,000, including 1,500 officers. The regular army was supplemented by a powerful voluntary riflemen's association (*Šauliai*), organized by districts, with about 55,000 men. The 380-ton former German minesweeper, "Prezidentas Smetona," was the only vessel in the Lithuanian navy and was acquired in 1928 primarily to suppress smuggling.

ECONOMICS AND FINANCE

When independence in 1918 cut off Lithuanian trade with Russia, a fortunate new market was found in Germany. Economic relations between these two countries remained thriving until after 1933 and the magnification of the so-called Memel Question, when increasingly the trade shifted to Great Britain.

Imports and Exports.—Although Lithuania has almost al-

Import and Export of Merchandise

	Value in millions of litai					
	1934	1935	1936	1937	1938	1939
Import	139	129	156	213	224	169
Export	147	152	190	208	233	203
Balance	+8	+23	+34	−5	+9	+34

ways maintained a favourable balance of trade, the total volume of trade showed little tendency to grow. In the face of economic warfare, the government as early as 1932 introduced an import licensing system; in 1935 it was forced to manage the export of currency in order to maintain gold currency coverage; and eventually it virtually monopolized foreign trade through three government-dominated agencies: Maistās, Pienocentras and Lietukis.

The principal items of export by value were butter, live pigs, flax and tow, eggs, poultry, beef, timber, cheese, skins and hides, and wood pulp. The chief imports were cotton and wool cloth and yarn, coal, fertilizers, iron, machinery, liquid fuels, cement, chemicals, sugar and salt.

Distribution of Trade

	Percentage of total trade											
	1923		1926		1929		1932		1935		1938	
	Exp.	Imp.	Exp.	Imp.	Exp.	Imp.	Exp.	Imp.	Exp.	Imp.	Exp.	Imp.
Germany	43.3	80.9	45.8	53.6	59.4	49.3	39.1	40.3	3.6	11.4	26.8	24.5

U.S.S.R.	—	—	.1	.1	—	4.3	3.5	6.1	8.6	10.6	5.7	6.7

Currency and Banking.—The litas, the monetary unit of Lithuania, equalled 100 centas, contained 0.150463 grams of fine gold, and was related to the U.S. dollar (10 litai to a dollar). After dollar devaluation in 1933 the exchange rate was 6 to 1. The soviet government in 1940 substituted the ruble for the litas.

The Bank of Lithuania, established in 1922 as a mixed corporation to serve as a bank of issue, had assets in 1940 of 318,695,503 litai with 175,783,750 litai of notes in circulation. In addition, 8 other banks in Lithuania proper (excluding Vilnius) and 14 mutual credit societies had an aggregate capital of 75,000,000 litai. Co-operative credit societies, especially prevalent among the Jewish population, accounted for an additional 13,000,000 litai capitalization. Under soviet occupation all savings accounts of more than 1,000 litai were confiscated.

Government finance was conservative. The national debt in 1939 was 134,000,000 litai or only 47 litai per capita. The budget, though growing, was traditionally balanced, and in 1939 had a surplus of more than 5,000,000 litai over expenses of 356,000,000 litai. Yield from government and mixed enterprises was a prominent source of revenue. Communications, education and agriculture accounted for three-quarters of the state expenses.

Agriculture and Land Legislation.—Mediocre waterlogged soil and insufficient capital for its development were handicaps to Lithuanian agriculture, but the extensive government program of education, communications and indirect subsidy did much to improve conditions. In tsarist times nearly 40% of the land was held in large estates, but soon after independence the provisional government instituted reforms, which were followed by the Fundamental Agrarian Law of 1922. This confiscated with compensation the portion of estates greater than 197.7 ac. (with a few exceptions); all land seized by the Russian government after 1863; and all commercially-sized forests, peat bogs and mineral claims. The farm land was distributed to landless farm labourers and small landholders, with the head of each family receiving no more than 49.4 ac. By 1936 only 3% of the land remained in estates larger than 197.7 ac. and but 10.6% was operated by nonowners; 45,000 new farms had been established. Under soviet rule all land was nationalized and the former owners were made managers, and each farm was limited to 74 ac. Collectivization was encouraged and most of the farms greater than 197.7 ac. were directly controlled through commissars. The Germans restored the right of ownership but not the confiscated land.

Lithuania is best suited for stock raising. In spite of losses averaging 40% of all the livestock during World War I, the losses were more than made up by 1925. Export of livestock and dairy products climbed from 26.1% of the total value of exports in 1924 to 61.4% in 1939. Butter production expanded tenfold. Pigs became more numerous (1,117,180 in 1938) while cattle were falling off (1,103,550). Scientific animal husbandry and breeding progressed slowly. Sheep, horses, geese and poultry were also important.

Cereal, leguminous and root crops are grown successfully, although the grain is only of fair quality and often must be artificially dried. Winter rye and oats are the most popular crops and occupy about one-third of the arable land. Because of primitive cultivation methods, nearly 15% of the land lies fallow each year. Foreign market demands greatly encouraged wheat production and made Lithuania the third most important flax exporting country in Europe. Co-operatives have been the backbone of agricultural life and stem from the 18th century. By 1939, 401 dealt with credit, 275 with consumer goods, 224 manufacturing, 2 insurance and 430 miscellaneous. The Central Union of Agricultural Co-operatives (Lietukis, est. 1923) united more than 100 local societies and 20,000 members. Through it most of the grain, flax and leguminous crops were exported; and fertilizer, salt, liquid fuel and agricultural machinery imported. In 1926 the dairying societies withdrew, forming the Central Union of Dairy Co-operatives (Pienocentras), which handled almost all milk, butter and eggs for export. In 1926 Lietukis secured 45% of the capital stock of Maistas, in which the government also had a large interest, a company slaughtering and exporting nearly all Lithuanian livestock. The soviets made these organizations government agencies with monopoly rights in their special fields.

Industry.—Including Klaipeda, where half the industry was located, only 6.43% of the Lithuanian working population was engaged in industry and handicraft. Food processing exceeded all others in value (223,400,000 litai), but woodworking, textiles, clothing and metal industries were of some importance. In the period of independence labour unions were superseded by a government-sponsored workers' organization. Disputes were settled by a commission of three; one from this organization, one from government and one from the chamber of commerce. Strikes were uncommon. Government factory inspectors checked on conditions and wages, and supervised the compulsory health insurance program. The average wage for unskilled workers in Kaunas (1934) was 5.3 litai per day.

Communications and Transportation.—In 1920 Lithuania had only one-fifth the railroads and one-twentieth the highways of neighbouring East Prussia. Total railroad mileage in 1937, 1,085 mi., was only about 100 mi. greater than for 1923. Government operation had shown considerable profit. Through use of farmer aid, the highway system was expanded to 20,426 mi., but only 8 mi. were macadamized and 1,193 gravelled. The 417 mi. of navigable waterways, principally the Nemunas and Neris, carried considerable trade. The merchant marine was negligible. In 1938 there were 26,591 telephones, 2 broadcasting stations and 53,667 radios.

(F. D. S.)

LITHUANIAN AND LETTISH LITERATURE. The literary history of the Lithuanians and Letts dates from the Reformation and comprises three clearly defined periods. (1) Up to 1700, when the chief printed books were of a liturgical character. (2) During the 18th century, when a vigorous educational movement began, dictionaries, grammars and other instructive works were compiled, and written poems began to take the place of songs preserved by oral tradition. (3) When the revival of national feeling at the beginning of the 19th century resulted in the establishment of newspapers and the collection and publication of the national folk-poetry. In both literatures, works of a religious character predominate, and both are rich in popular ballads (*dainos*), folk-tales and fables.

The first book printed in Lithuanian was a translation by Mažvydis of Luther's shorter Catechism (Königsberg, 1547); other translations of devotional or liturgical works followed, and by 1701 59 Lithuanian books had appeared, the most noteworthy being those of the preacher J. Bretkun (1535–1602). The spread of Calvinism led to the publication, in 1701, of a Lithuanian New Testament. The first dictionary was printed in 1749. But perhaps the most remarkable work of the second period was *The Four Seasons,* a pastoral poem in hexameters by Christian Donalitius (1714–80), which was edited by Nesselmann (Königsberg, 1869) with a German translation and notes. In the 19th century various collections of fables and folk-tales were published, and an epic, the *Anykščiu Šilelis* ("The Grove of Anykščiai"), was written by Bishop Baranauskas-Baronas. A very famous name is that of Dr. Vincas Kudirka, who wrote both the words and music of the Lithuanian national anthem. He died in 1899. But it was in journalism that the chief original work of the third period was done. F. Kelch (1801–77) founded the first Lithuanian newspaper, a Protestant religious monthly published at Königsberg; and between 1834 and 1895 no fewer than 34 Lithuanian periodicals were published in the United States alone.

Among the more prominent later writers was Jonas Mačiulis (1862–1932), better known as Maironis, popularly styled the "Poet Prophet of the Lithuanian Renaissance," distinguished alike for his dramatic, epic and lyrical poetry. His best-known lyrics are "Voices of Spring," "Young Lithuania" and "Our Sufferings." W. St. Vidunas, born in Lithuania Minor in 1868, is another deeply revered scholar, philosopher, poet and dramatist. Jurgis Baltrušaitis has won fame both as a Lithuanian and a Russian lyric poet of the very first rank. Of the younger men one of the most talented and original is V. Krevé-Mickevičius, who deals with essentially national themes in both prose and poetry. His greatest work in this connection is the historical drama "Skirgaila." Several women also have achieved well-deserved distinction in Lithuanian literature, notably Marija Pečkauskaité (1878–), who writes under the pen-name of the "Witch of Šatrija"; Sophie Ciurlioniené, the realist playwright, and the late Sofija Pšibilauskiené (pen-name, "The Owl of Lazdynai").

Of late western influence has made itself felt, but the inspiration, themes and methods of expression are for the most part fundamentally Lithuanian.

Luther's Catechism (Königsberg, 1586) was the first book printed in Lettic, as in the sister speech. In the 17th century various translations of psalms, hymns and other religious works were published, the majority being Calvinistic in tone. The educational movement of the 18th century was inaugurated by G. F. Stender (1714–96), author of a Lettic dictionary and grammar, of poems, tales and of a *Book of Wisdom* which treats of elementary science and history. Much educational work was subsequently done by the Lettic Literary Society, which publishes a magazine (*Magazin,* Mitau, from 1827), and by the "Young Letts," who published various periodicals and translations of foreign classics, and endeavoured to free their language and thought from German influences. Somewhat similar tasks were undertaken by the "Young Lithuanians," whose first magazine the *Auszra* ("Dawn") was founded in 1883. The famous name of the late Dr. Jonas Basanavičius is closely associated with this publication. From 1890 onwards the literature of both peoples was marked by an ever-increasing nationalism; among the names most prominent during this period may be mentioned those of the dramatist Steperman and the poet Martin Lap, both of whom wrote in Lettic.

LITHUANIAN LANGUAGE. The Lithuanian language belongs, with Lettish and the extinct Old-Prussian language, to the Baltic branch of the Indo-European family. It has preserved until the present day the phonetic system of the hypothetical Indo-European parent-speech with such fidelity as to play a very important rôle in the study of the past history of the other Indo-European languages. It is written in the Latin alphabet, but without *f, h, q, w, x* (*f* and *h* occur in words borrowed from other languages), and with the addition of the following: *č* (=*ch* in *church*), *ē* or *ė* (=*ay* in *pay*), *ū* (=*oo* in *moon*), *š* (=*sh* in *shoot*), *ž* (=*j* in French *jour*). The approximate values of the remaining vowel-letters are: *a* as in English *father, e* as in *bet, where, i* as in *bit, o* as in *go, u* as in *put, y* as *ee* in *seen:* of the remaining consonant-letters, *p, t, k, b, d, g* and *v* are pronounced as in English (*g* always hard as in *get*); *c* is pronounced *ts; s* as in *so; z* as in *zero; j* as *y* in *yet.*

The relation between the phonetic system of the parent Indo-European speech, as reconstructed from Latin, Greek, Sanskrit and the other Indo-European languages (including Lithuanian) and that of Lithuanian is outlined in the following table:—

I.–E.	a	e	o	i	u	ā	ē	ō	ī	ū	p	t	b	d	bh	dh
Lith.	a	e	a	i	u	o	ē	uo	y	ū	p	t	b	d	b	d.

I.–E.	k	ĝ	ĝh	k^w	g^w	g^wh	r	l	m	n	y	w	s
Lith.	š	ž	ž	k	g	g	r	l	m	n	j	v	s

Examples (the words quoted in brackets from cognate languages have in many cases preserved the Indo-European sounds unchanged): *ašis* "axle" (Lat. *axis*), *esti* "is" (Greek *esti*), *avis* "sheep" (Lat. *ovis*), *šuns* "of a dog" (Gr. *kunos,* Sanskrit *śunas*), *moteri* (acc. sg.) "woman" (Gr. [Doric] *mātera*), *mēnesi* (acc. sg.) "month" (Lat. *mēnsem*), *duoti* "to give" (Lat. *dōnum*), *vytis* "willow twig" (Lat. *vitis* "vine"), *pūti* "to rot" (Lat. *pūs* "pus"), *bulis* "buttock" (Skt. *bulis*), *danti* (acc. sg.) "tooth" (Gr. *odonta*), *bijotis* "to fear" (Skt. *bhayate* "he fears"), *dūmai* (pl.) "smoke" (Skt. *dhūmas*), *paršas* "pig" (Lat. *porcus*), *žirnis* "pea" (Lat. *grānum,* Skt. *jīrṇas* "pounded," Engl. *corn*), *vežu* "convey in a cart" (Lat. *veho*), *katras* "which" (Skt. *kataras,* Greek *poteros*), *gija* "thread" (Skt. *jiyā* "bow-string," Gr. *biós* "bow"), *ginklas* "weapon," *genēti* "to prune" (Skt. *hanti*=Hittite *kuenzi,* "he kills" [also "he strikes"], plur. Skt. *ghnanti*=Hittite *kunanẓi* "they kill" [or "strike"]).

Each word has one stressed syllable, the position of which is not determined by any simple general rule, but may be different even in different inflections of the same word. The stressed syllable may be long or short: if long it will have either the acute accent or the circumflex, if short the grave accent. The accents are not written by the Lithuanians; they were not recorded on a great scale until the Lithuanian Kuršaitis (Friedrich Kurschat) marked all the words in his grammar (1876), dictionary (1868–74, 1883) and New Testament edition with the three signs (´), (˜) and (`). The distinctions of which these three marks are the written signs are not in all cases easily audible by a foreigner, but their reality is proved by the absence of any serious contradiction between the testimony of Kuršaitis and that of other native observers. The available data were analysed by the Russian Philip Fortunatov (died 1914) and the Swiss Ferdinand de Saussure (died 1913), who elucidated the principles governing the movement of the accent and also showed, *inter alia,* that certain accentual distinctions in Lithuanian correspond exactly to certain distinctions of a non-accentual nature in some other Indo-European languages (especially Greek and Sanskrit), and that these non-accentual distinctions existed in the Indo-European parent-language.

The inflectional system is of the same type as in Latin, Greek and Sanskrit. The Noun and Adjective have six cases (Nom., Accus., Gen., Dat., Instrumental and Locative). Some stems have also a Vocative. The Dual survives, but the Neuter has been given up (except in certain fossilized relics). A "definite" form of the Adjective is formed by tacking on to it the pronominal stem *ja–*, both being declined, *e.g., geras* "good," gen. *gero, geras–is* "the good man," gen. *gero–jo.* In the Verb there has been a sweeping simplification of the complicated Indo-European system. Given the Pres. Indic., the Preterite Indic., and the Infinitive, all the other parts of a verb can be formed according to simple rules. The types of Present are often archaic; the Future is closely related to the Greek Future (Lith. *duosiu* "I will give" = Gr. *dōseō*), and the Indo-European Participles have survived with little change.

In the vocabulary the native element predominates, but there are also loan-words from Germanic and Slavonic. Some Germanic loans seem to be ancient, *e.g., šarvas* "armour" from Gothic *sarwa* "weapon," *midus* "mead" from the unattested Gothic *midu, kvietys* "wheat," *kliepas* "loaf" from Old Norse *hveiti, hleifr.* The precise source of *kunigas* "priest" (*cf.* primitive Germanic *kuningaz* "king") and *pinigai* "money" (*cf.* Old Norse *penningr,* etc.) is uncertain. Some Germanic words have passed into Slavonic and thence into Lithuanian, *e.g.,* Gothic *biuda-,* Slavonic *bl'udo,* Lithuanian *bliūdas* "dish." The older Lithuanian texts contain numerous loan-words (both Germanic and Slavonic) which have not been given currency in the modern literary language.

Large numbers of Lithuanian (or rather Baltic) words were borrowed by Finnish (or rather by the Finnish-Mordvinian-Tcheremissian speech-community) about the beginning of the Christian era. Some recent writers date these borrowings earlier still, from 1000–500 B.C., but this is doubtful.

Gerullis (Heidelberg, 1923).

(R. McK.)

LITHUANIANS and **LETTS,** two kindred peoples of Indo-European origin, now constituting independent republics, on the shores of the Baltic Sea, and in the basins of the Niemen and the Duna. The two races number about 4,250,000, of whom 2,000,000 are Letts. Ptolemy mentions (iii. 5) two clans, the Galindae and Sudeni, who probably belonged to the western subdivision of this group, the Borussians. In the 10th century the Lithuanians under the name of Litva, with two other branches of the same stem—the Borussians and the Letts—occupied the south-eastern coast of the Baltic Sea, a tract bounded by Finnish tribes in the north, and by Slavs elsewhere.

In this forested, marshy country the Lithuanians maintained their national character notwithstanding the vicissitudes of their history. Their chief priest, *Krive-Kriveyto* (the judge of the judges), under whom were seventeen classes of priests and elders, worshipped in the forests; the Waidelots brought their offerings to the divinities at the foot of oaks; even now, the veneration of great oaks is a widely spread custom in the villages of the Lithuanians, and even of the Letts.

By the 10th century the Lithuanians were divided into three main branches:—the *Borussians* or *Prussians;* the *Letts* (who call themselves *Latvis,* the name given to them in Russian chronicles, *Letygola,* being an abbreviation of *Latvin-galas,* "the confines of Lithuania"); and the *Lithuanians,* or rather *Lituanians, Litva* or *Letuvininkaï*—subdivided into Lithuanians proper, and *Zhmud* (*Zmudz, Samogitians* or *Zemailey*), the "Lowlanders." To this group belong the *Yatvyags,* or *Yadzvings,* a warlike, black-haired people who inhabited the forests at the upper tributaries of the Niemen and Bug. Nestor's chronicle distinguishes also the *Zhemgala,* later known as *Semigallia,* who in the 10th century inhabited the left bank of the Duna. Several authors consider also as Lithuanians the *Kors* of Russian chronicles, or *Cours* of Western authors, who inhabited the peninsula of Courland, and the *Golad,* a clan settled on the banks of the Porotva, tributary of the Moskva river, which seems to have been thrown far from the main stem during its migration to the north. The *Krivichi,* who inhabited what was the government of Smolensk, may belong to the same stem. These peoples are subdivided into numerous independent clans and villages, separated from one another by forests and marshes. The Lithuanians are well built, with elongated faces and fine features, very fair hair, blue eyes and delicate skin. Their chief occupation is agriculture, especially apiculture and cattle breeding. The Letts of Courland are mainly Lutherans. Some are Roman Catholics, others belong to the Greek Church. All Lithuanians have maintained much of their heathen practices and creed; the names of pagan divinities, numerous in the former mythology, are continually mentioned in songs, and in common speech. *See* LATVIA; LITHUANIA.

LITMUS, a colouring matter which occurs in commerce in the form of small blue tablets, which, however, consist mostly, not of the pigment proper, but of calcium carbonate and sulphate and other matter devoid of tinctorial value. Litmus is extensively employed by chemists as an indicator (*q.v.*) for the detection of free acids and free alkalis. An aqueous infusion of litmus, when exactly neutralized by an acid, exhibits a violet colour, which by the least trace of free acid is changed to red, while free alkali turns it to blue. It is manufactured in Holland from certain kinds of lichens (species of *Roccella* and *Lecanora*). The colouring matter results from the action of air and ammonia on orcin during the preparation of litmus from the lichen.

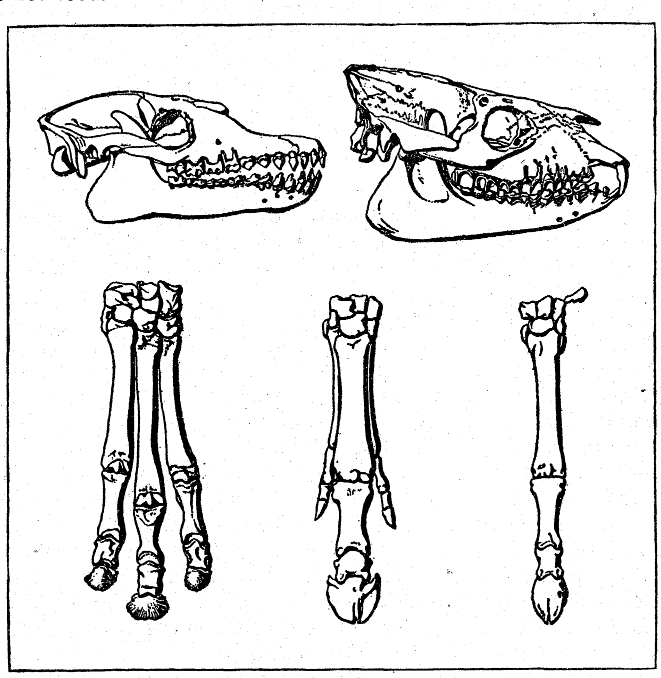
LITOMĚRICE or LEITMERITZ, a town and episcopal see in northern Bohemia girdled by forested hills, on the high right bank of the Elbe, opposite the entry of the Eger. At the limit of steamer navigation on the Elbe, it is the terminus of the Bohemian–Saxon steamship service. Situated in the midst of a very fertile country, the "Bohemian Paradise," which produces large quantities of cereals, fruit, hops and wine, its great weekly corn and cattle markets bind town and country. In addition it has an important brewing industry and a thriving transit trade. By reason of its situation the town has suffered during frontier struggles and during the Thirty Years' War lost most of its Czech population who, as Protestants, left the town and forfeited their property to German immigrants. The population is strongly German. Pop. (1930) 18,509. In 1938 the town came under German rule.

LITOPTERNA, an extinct order of hoofed mammals, confined to South America where, with the Notoungulata or Toxodontia (*q.v.*) they were the typical and abundant hoofed herbivores during the long period when the continent was isolated from all others. They arose from the most primitive ungulates, the

Condylarthra (*see* PHENACODUS), and they retained many unprogressive characters, for instance in the brain and teeth, although some of them became peculiarly specialized in other respects. Even in the Paleocene, the Litopterns were already separated into two families, Proterotheriidae and Macraucheniidae, each of which thereafter had a long history and included highly varied species and genera.

In the earliest Proterotheres, such as *Wainka* in the Paleocene and *Polymorphis* in the Eocene, the teeth were very primitive and barely distinguishable from those of Condylarths. In later forms the teeth remain relatively unprogressive, but some Miocene genera show a remarkable specialization of the feet. Originally five-toed, as in all primitive mammals, in the Miocene these animals had become three-toed or one-toed. Even in the three-toed forms such as *Diadiaphorus,* the weight rested mainly on the large middle hoof and in one genus, *Thoatherium,* the other hoofs were completely lacking. The foot of *Thoatherium* thus closely resembles that of the one-toed modern horse. The vestiges of the other toes are even more reduced than in the horse, and *Thoatherium* is the most completely one-toed of all known mammals. It is also noteworthy that it reached this condition in the Miocene, when all the horses still had three toes. The whole appearance of the animal was quite horselike. Since it is completely certain that the ancestry of *Thoatherium* was very different from that of the horse, this is a remarkably good example of the principle of evolutionary convergence: animals of different ancestry can come to resemble each other closely if their habits are similar.

The specialization of *Thoatherium* did not save it from extinction, and the last surviving Proterotheres, in the Pliocene, were three-toed.



FROM W. B. SCOTT, "REPORTS ON THE PRINCETON EXPEDITIONS TO PATAGONIA"

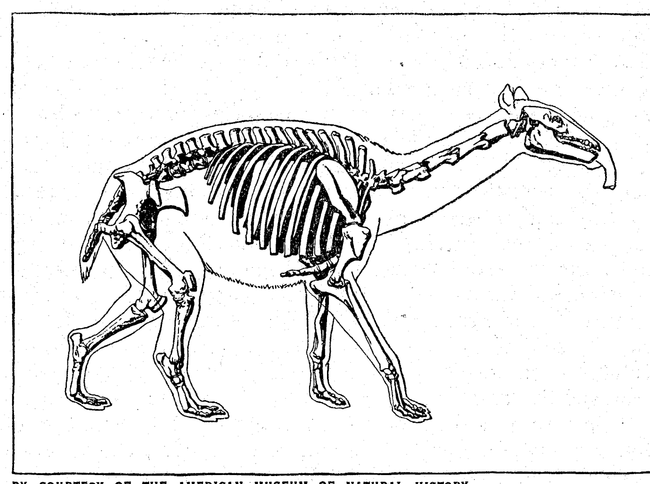
SKULLS AND FEET OF LITOPTERNA FROM THE MIOCENE OF PATAGONIA

Above, skulls of Theosodon and Diadiaphorus; below, forefeet of Theosodon, Diadiaphorus and Thoatherium

In the other family of Litopterns the toes were early reduced to three and remained so, the weight being evenly distributed with little tendency to concentrate on the middle toe. The teeth were in a closed series, with gradual progression from the simple incisors to the complex molars. The molars became high-crowned, with an intricate pattern of crests and valleys in the latest forms. The skull at first had much the same primitive, Condylarth-like structure as in the early Proterotheres. Its progressive modification can be followed in a series of genera that give an example of structural evolution almost as striking as that provided by the fossil horses, although less familiar to nonspecialists. The best-known genera of this series are *Cramauchenia,* Oligocene, *Theosodon,* earlier Miocene, *Scalibrinitherium,* late Miocene and *Macrauchenia,* Pleistocene.

The most obvious change in the skull is the progressive shortening of the nasal bones, accompanied by the development of an inflated, flexible, proboscislike snout.

Macrauchenia, the last member of this group, was as large as a camel. Its long neck and legs and short body and tail must have made it look much like a camel when alive, although its snout and the three toes on each foot, rather than two as in the camel, were striking differences. This is one of the best-known



BY COURTESY OF THE AMERICAN MUSEUM OF NATURAL HISTORY

SKELETON WITH BODY OUTLINE OF THE MACRAUCHENIA, THE LAST SURVIVOR OF THE LITOPTERNA

and first-discovered of South American fossil animals. The first remains, about half of a skeleton, were found in Patagonia by Charles Darwin during his voyage on the Beagle and were named and described by Richard Owen in 1840. Numerous other specimens, including the complete skeleton, have since been found in the Pampean deposits of Argentina.

Of all the hosts of Litopterns, only *Macrauchenia* survived into the Pleistocene and it, too, then became extinct, perhaps from its inability to compete with the more intelligent camels and other herbivores that then invaded South America from the north.

See W. B. Scott, *A History of Land Mammals in the Western Hemisphere,* revised ed. (1937). (G. G. SI.)

LITOTES, a rhetorical figure in which emphasis is secured for a statement by turning it into a denial of the contrary, *e.g.,* "a citizen of no mean city," *i.e.,* a citizen of a famous city, or "A. is not a man to be neglected."

LITTLE ENTENTE. The Little Entente was a political organization, created after World War I, which bound together three Central European states, Czechoslovakia, Yugoslavia and Rumania, for purposes of their common interest.

Origins under the Dual Monarchy.—Those nations had in the past been throttled by the Germanizing, Magyarizing system of the old Austria-Hungary; one of the objects of the Little Entente was to defend the freedom they won after the war against all attempts to restore the former regime. The Little Entente had its roots in a series of political acts and declarations dating back to the days of the old monarchy. In the Austrian half of the Habsburg empire the representatives of the small nations in the parliament at Vienna joined in opposition to the centralizing system which opposed the non-German peoples.

In the Hungarian half the oppressed Slovaks, Serbs, Croats and Rumanians met in 1848 and made a protest against Magyar imperialism; they did so again in 1895 at Budapest; and in 1905 ten non-Magyar deputies of the Budapest parliament formed a club for a like purpose.

During World War I, when the Austro-Hungarian peoples revolted and helped the Western Entente to break the system of militarist imperialism, a common aim again produced common action. In April 1918 a congress of the oppressed Austro-Hungarian peoples was held at Rome, and in the autumn of that year the Central European Democratic Union was formed in America. A year earlier a great meeting of representatives of the Austro-

Hungarian nations had taken place at Kiev in Russia and had established a special committee to fight against German and Austro-Hungarian imperialism. A prominent place was taken in all these actions by the Czechoslovaks, Yugoslavs and Rumanians, supported by Poles, by the Italians of "Italia irridenta" and finally by Ukrainians. The co-operation of the first three nations was particularly close, and toward the end of the war they undertook diplomatic action in common. The Little Entente was formed soon after the peace treaties had been signed, when attempts began to be made by various elements of the prewar regime to bring about a restoration of the Habsburg dynasty.

The Formation of the Little Entente.—The Czechoslovaks, Yugoslavs and Rumanians knew that a return of the Habsburgs would mean the restoration of the German-Magyar absolutism and the destruction of the freedom won by the political revolution of 1918. The Habsburg intrigues were chiefly engineered in Hungary, where the new regime in central Europe was last to be recognized and where intense propaganda was conducted for the recapture of the Slovak, Serbo-Croat and Rumanian territory. The Habsburg menace led to corresponding defensive measures on the part of the threatened States. The Czechoslovak foreign minister travelled on Aug. 13, 1920 to Belgrade where, on the following day, a defense treaty, of which the broad outlines had already been negotiated, was concluded between the kingdom of the Serbs, Croats and Slovenes and the Czechoslovak republic, binding both states, in case of an unprovoked attack by Hungary on either of them, to provide mutual aid the one to the other, and to refrain from making any alliance with a third Power without the consent of both. At Bucharest, whither the Czechoslovak foreign minister proceeded from Belgrade, the basis was negotiated on Aug. 19 for an analogous entente. On Sept. 19, 1920, Rumania informed both those states that it recognized a similar obligation, though it concluded special treaties to that effect with Czechoslovakia on April 23, 1921, and with Yugoslavia on June 7 of that year. The opportuneness of that defensive alliance was proved in April and in Oct. 1921, when two attempts were made to restore the Habsburgs in the person of the former Emperor Charles. Those attempts failed only because they met with the combined armed resistance of Czechoslovakia, Yugoslavia and Rumania.

The European Side of the Entente.—The states which had formed the Little Entente, independently of the European Great Powers, were aware that mere defense measures would not suffice for the maintenance of the new regime if the states concerned were themselves lacking in creative forces, or failed to attain the greatest possible degree of political and economic solidarity and an atmosphere of mutual trust and fruitful co-operation throughout the whole area of Central Europe. The ultimate and wider aim of the Little Entente was therefore to educate central Europe as to the advantages of universal peace and European consolidation. The progress made in the realization of this policy was best seen in the political and economic spheres. The main political object was to persuade all the central European states to work in peaceful co-operation with the new states, and much success was soon achieved. Starting from the treaty of Rapallo between Yugoslavia and Italy and the agreements worked out on the occasion of the visit of the Czechoslovak foreign minister to Rome in Jan. 1921, that policy bore fruit in the Czechoslovak-Austrian agreement of Dec. 16, 1921, which bound both states to abandon hostile propaganda and to settle all disputes by peaceful arbitration. The same principles were the basis of the Czechoslovak-Polish treaty of Nov. 6, 1921, which, although not ratified, created better relations between the two states, and, being followed by the Polish-Rumanian political treaty, materially improved the relations of Poland with the Little Entente.

In the measures taken to save Austria from financial ruin Czechoslovakia had a large share, and did not hesitate to make sacrifices in the interests of mutual confidence. A like policy was followed by the Little Entente towards Hungary, despite the fact that it had been the nationalist elements of Hungary and their Habsburg sympathies that had brought the defensive alliance of the Little Entente into existence. The latter knew from the beginning that correct and, as far as possible, friendly relations between it and Hungary were essential to the complete pacification and consolidation of central Europe. The states forming the Little Entente showed the best of good will in this respect, as was proved by the frequently repeated attempts of Czechoslovakia to negotiate with the Hungarian government, from as early a date as 1921. If those attempts were unsuccessful, it was because Hungary sought by an adventurous policy to avoid an understanding with its neighbours. Under the pressure of economic difficulties, and later on under the influence of the peaceful tendencies of European politics, especially of Locarno, Hungary indeed made several attempts at a central European orientation and even concluded commercial treaties with its neighbours, but there was no immediate and permanent change, though this change would have been nowhere more welcomed than in the countries of the Little Entente, whose only wish was that the change be permanent so that a new Hungary, consolidated both economically and politically, might co-operate in the reconstruction of central Europe.

Economic Policy.—The economic policy of the Little Entente started from the conviction that in central Europe it was necessary not only to overcome the harmful results of the depreciated currency, the obstacles to trade connections and the disturbances in the industrial world, but also to make up for the consequence of the disintegration of the old monarchy, which had constituted a kind of economic whole. The basis of its economic policy, therefore, was the minimizing of these results by the earliest possible establishment of commercial relations with each other and with the rest of the world. The political negotiations were therefore always combined with economic negotiations, which were the basis of a series of commercial treaties, at first between the states of the Little Entente and then with all the neighbouring countries. Questions of common interest to all the states springing from the former Austria-Hungary were discussed with good results at special conferences; *e.g.,* those at Rome and Portorose in 1921, and, later, the special conferences dealing with passport, transport and other problems. The results of this economic co-operation were not of course equally satisfactory in each of the states concerned, nor were they enough in themselves to restore healthy conditions to those states whose economic, financial and currency difficulties left them with no alternative to calling in international financial help.

Expansion of the System.—The increased activity and the determined policy of the states forming the Little Entente outgrew the limits of the simple defense treaties which constituted the original basis. On Aug. 31, 1922, that formal basis was considerably enlarged by the conclusion of a new treaty, in the second article of which both Czechoslovakia and Yugoslavia recognized the treaties concluded by Czechoslovakia with Rumania, Austria and Poland on the one hand, and by Yugoslavia with Rumania and Italy on the other. In the third article both parties agreed to put their economic, financial and transport relations on a firm basis by co-operation; and finally in a further article they undertook to support one another in their international, political and diplomatic relations and to take common measures if their common interests should be threatened.

The principles incorporated in that treaty revealed both the spirit underlying the Little Entente and the basis of its future activity. Emphasis was laid on the importance of economic co-operation and of solidarity in international affairs; the periodical renewal and extension of the existing system of commercial treaties, together with the ever-increasing moral weight of the Little Entente in the councils of Europe, proved that the statesmen of the Little Entente had a firm grasp of both political and economic realities. At international conferences, such as those of the League of Nations, the representatives of the Little Entente regularly spoke as one man, and therefore contributed to a considerable simplification of international relations; their behaviour was particularly noteworthy in that it was not only of a united but of a constructively peaceful character. Essentially the Little Entente was to continue to promote the pacification and the consolidation of central Europe.

The Development of the Little Entente.—In the years which followed its foundation, the Little Entente grew in stature and underwent an interesting development. Dr. Eduard Beneš, the Czechoslovak foreign minister, explained in an address on Feb. 6, 1924 that the members had shown an example of close co-operation. They had preserved central European peace and acted as a moderating influence and brought about a degree of consolidation within the Danubian region. Nevertheless, there were serious problems, even in that period of calm, though the only common bond formally uniting the members of the Little Entente had to do with Hungary. The major problem of Czechoslovakia, however, seemed likely to be Germany, while Italy might constitute Yugoslavia's principal concern, and Russia that of Rumania. Centrifugal, rather than centripetal forces might determine the future of the member states.

The Connections with France.—While French statesmanship had nothing to do with the origins of the Little Entente, and was even opposed to its organization in the beginning, the group had become so well solidified by 1924 that on Jan. 25, 1924, France made an alliance, later implemented by a military pact, with Czechoslovakia. The pact provided for mutual consultation on problems endangering the postwar settlement, and stipulated common action against Habsburg restoration, any attempt against Austrian independence, and any German aggression. In 1926 France signed a similar alliance with Rumania and in 1927 one with Yugoslavia, though these were never genuinely implemented. Together with the French alliance with Belgium in the west and with Poland in the east, the French-Little Entente connection made up the essence of the French postwar system of alliances.

The Consolidation of the Little Entente.—The next several years witnessed a striking consolidation of the Little Entente, which was playing a considerable role in European politics, as Dr. Beneš' part in the drafting of the Geneva protocol of 1924 bore ample testimony. Nevertheless the member states, together with Poland, were disappointed by the failure of the Locarno conference to offer genuinely effective guarantees of their own frontiers on the east of Germany.

The constitutional and organic structure of the Little Entente, which had been built on the foundations of the bilateral treaties of 1920 and 1921, was modified somewhat by an agreement of Czechoslovakia, Rumania and Yugoslavia on May 21, 1929, which provided that renewal of the treaties of alliance should become automatic at the end of each five-year period. Moreover, at the same time, the three states signed the Tripartite treaty for the peaceful settlement of all their differences in accordance with the model treaty of arbitration and conciliation which the League of Nations had adopted in 1928.

A new period of development appeared to have begun in the history of the Little Entente when the era of crisis, beginning with the great world depression, came in the years 1929 and 1930. Despite grave difficulties in industry, commerce and agriculture throughout central and southeastern Europe, optimism seemed to prevail within the circles of the Little Entente, and in the years of crisis which followed, members of the Little Entente took a significant part in the councils of Europe. Men like Dr. Beneš and M. Nicolae Titulescu made their voices felt, especially within the circles of the League of Nations.

While fascist Italy had been an enemy of the Little Entente from the beginning, the advent of Adolf Hitler to power in Germany on Jan. 30, 1933 was an immediate challenge to the whole postwar structure in central Europe. Barely more than two weeks later, on Feb. 16, 1933, Czechoslovakia, Rumania and Yugoslavia proceeded definitely to strengthen the bonds of union and federation against the new and growing menace. Under the able leadership of Eduard Beneš, Nicolae Titulescu and Bogoljub Jevtich, as well as King Alexander of Yugoslavia, the natural evolution toward closer unity was hastened, and a veritable, if short-lived, diplomatic federation was constituted.

The new pact provided for the creation of a permanent council of the states of the Little Entente, composed of the three foreign ministers or their delegates, which was to be the directing organ of the common policy of the Little Entente. The permanent council was to meet at least three times a year. Article VI significantly provided:

> Every political treaty of each state of the Little Entente, every unilateral act changing the present political situation of one of the states of the Little Entente in regard to a third state, as well as any economic agreement implying important political consequences, will thenceforth require the unanimous consent of the council of the Little Entente. Existing political treaties of each state of the Little Entente with third states will be progressively unified as soon as possible.

For the promotion of the economic co-ordination of the three states an economic council was established. The economic council was to meet three times a year, later two. In the interval between meetings, the secretariats were to direct the economic collaboration on the basis of the resolutions adopted by the economic council.

Finally, the Little Entente then established a permanent secretariat, one section of which was to function at Geneva, Switz., the seat of the League of Nations.

As if to lay down the basic principles which were to govern the new organic union of the Little Entente, article X declared:

> The common policy of the permanent council must be inspired by the general principles contained in all the great international acts of the postwar era, such as the covenant of the League of Nations, the pact of Paris, the General Act of Arbitration, the eventual conventions on disarmament and the pacts of Locarno. Moreover, nothing in the present pact can be contrary to the principles and dispositions of the covenant of the League of Nations.

With greater strength and unity the Little Entente seemed on the threshold of much constructive activity. Under Dr. Beneš and Dr. Titulescu, especially, the Little Entente took a lead in urging the application of effective sanctions against Japan in the years 1931 to 1933. Together with Poland, which was equally threatened, the members of the Little Entente successfully protested against the Four-Power pact of March 1933, signed in July by fascist Italy, nazi Germany, Great Britain and France, which would have set up a four-power directory, as outlined by Mussolini, in substitution for the processes of the League of Nations, for the revision of treaties without consultation with and possibly against the interests of the smaller states of Europe. The members of the Little Entente were represented at the London Economic conference in June and July 1933, and on July 4 they signed a nonaggression agreement with the soviet union, represented by Maxim M. Litvinov. The next year Czechoslovakia and Rumania, though not Yugoslavia, entered into diplomatic relations with the government at Moscow. Feb. 9, 1934 witnessed an extension of the principles of regional security embodied in the Little Entente when Yugoslavia and Rumania joined with Turkey and Greece to form the Balkan Entente. Increasing menace on the part of national socialist Germany finally brought about a Czechoslovak-soviet union alliance on May 16, 1935, following the similar French-soviet alliance two weeks earlier.

The Economic Little Entente.—Meanwhile, from its first meeting in Jan. 1934 at Prague, the economic council of the Little Entente, through its resolutions, attempted to lay the foundations for closer economic collaboration among Czechoslovakia, Rumania and Yugoslavia. In view of the similarity in the agrarian structure of Rumania and Yugoslavia and of the fact that Czechoslovakia had a well-balanced agricultural and industrial economy, it was acknowledged that progress could only be made somewhat slowly. Nevertheless, the economic council gradually developed a program calling for closer co-operation among the three countries in the air, river and railway systems, the establishment of a postal union, unification of the customs and commercial codes and abolition of the passport visa. Moreover the council called for collaboration on the part of the banks of issue, agricultural educational institutions, industries and the statistical departments of the governments of the three member states. As the political structure of the Little Entente was to prepare the way for the political organization of the Danubian area, so the economic council of the Little Entente was to attempt to lay the economic foundations of that region, including both Austria and Hungary, though without much success in the case of the latter country.

The Decline of the Little Entente.—By the year 1935, however, at the very time when the Little Entente seemed to be consolidating its structure, its decline was already evident. Europe was in full crisis and had been since the beginning of the Japanese aggression against China in Sept. 1931. On Oct. 9, 1934, King Alexander of Yugoslavia was assassinated, and with him died Jean Louis Barthou, the foreign minister of France. While Yugoslavia did not disintegrate, as Mussolini apparently had anticipated, Prince Paul, the new prince regent of the country, was a weaker character and Dr. Milan Stoyadinovich, who dominated the country as premier from 1935 to 1939, pursued a policy of rapprochement toward Italy, Bulgaria and Germany—a policy which struck at the vitals of both the Little Entente and the Balkan Entente. Moreover the weakness of France, its vacillating foreign policy and the division between France and Great Britain with respect to Italy and Germany, were devastating blows to the unity of the Little Entente.

While there was surprising unity within the ranks of the Little Entente throughout the Ethiopian crisis of 1935–36 and the early phases of the war in Spain, there was distinct evidence of difficulty at the Bratislava conference of the council of the Little Entente in Sept. 1936 when Yugoslavia seemed determined to follow its own path, and the council virtually acknowledged the right of member states to pursue an independent course. Dr. Kamil Krofta, who had become the Czechoslovak foreign minister when Dr. Beneš succeeded to the presidency of the republic, in an important address to the commission on foreign affairs of the Czechoslovak parliament on March 2, 1937, noted the centrifugal forces tearing at the heart of the Little Entente:

> Of late the Little Entente has been brought face to face with a changed situation in Europe caused by the development of the Abyssinian question and the forceful character of Germany's policy. These conditions concern both the individual Little Entente states and the Little Entente as an entity. Yugoslavia has been compelled to occupy herself with the new distribution of power in the Mediterranean sea, Czechoslovakia with the intensive change in the policy of her neighbor on the north, while Rumania is affected by the relations of Europe to the soviet union.

While formal unity remained in the Little Entente, belated French attempts under the government of Leon Blum and of Czechoslovakia to consolidate the Little Entente and generalize the obligations of member states against all aggressions failed—as similar attempts had failed in the effort to attain collective security in western Europe.
