[1] Yet the dedication of *Daphnaida* is dated "London this first of Januairie, 1591" (*i.e.,* 1592 n.s.). No convincing explanation of this discrepancy has been offered. On the whole it is easiest to believe that Spenser, writing on New Year's Day, used the new style, *i.e.,* that his 1591 means our 1591.

Alexander when he went to Ireland to seek his fortune under the protection of their kinsman Richard Boyle, afterwards earl of Cork. The view that she was a widow, having been married to one Tristram Peace in 1588 or 1589, at present lacks documentary confirmation, and is hard to reconcile with Burke's statement that she bore seven children to her third—on this view her fourth—husband, Sir Robert Tynte, after 1612 or 1613.

**Amoretti; Epithalamion.**—The *Amoretti* are love-sonnets, all but one in a form which Spenser made his own, consisting of three *linked* quatrains and a couplet. It had already been used in Scots, but Spenser may have got it direct from Marot. Though it lacks the pyramidal strength of the Petrarchan form, and the freedom of the Shakespearean, its "linked sweetness" suits Spenser's style. Many of these sonnets are imitated from French or Italian, especially from Desportes and Tasso: for one a Spanish original has been found. They are all graceful, but only the famous sonnet on Easter can be called great. The *Epithalamion,* on the other hand, is by common consent the greatest of all wedding-songs; rich in poetic allusions and in echoes from his own earlier poems, as if Spenser had gathered up all the fruits of his study and all the flowers of his fancy to present them to his bride. Here for once his whole nature speaks, flesh and spirit reconciled in the sacrament of marriage. The stanza, suggested by the Italian canzone, is magnificent far beyond anything previously heard in English. The structure of the whole poem is as perfect as that of its parts.

Towards the end of 1595 Spenser, having finished three more books of the *Faerie Queene,* came to London to publish them. During this year he also published his *Prothalamion* and *Fowre Hymnes,* and composed or revised his *Veue of the Present State of Ireland,* which, though entered at Stationers' Hall in 1598, was not allowed to be printed without further authority, and, in fact, did not see the light till 1633.

**Prothalamion; Hymnes; Veue of the Present State of Ireland.**—The *Prothalamion* graced the wedding of two of the Earl of Worcester's daughters, who were married together from Essex house. Though it lacks the glow and sweep of the *Epithalamion,* it is, if possible, even more perfect in metre and diction.

The hymns of *Heanvenlie Love* and *Heavenly Beauty* were written in 1596 to propitiate two pious noblewomen and counteract the hymns in *Honour of Love* and in *Honour of Beautie* written in his youth. So Spenser avers; but to print the earlier hymns was scarcely the way to ensure their oblivion.

In the *Veue of the Present State of Ireland* Irenaeus expounds to Eudoxus the causes of the Irish troubles and propounds a cure. Irish laws, customs and religion must all be reformed on the English model. But subjugation must precede reform. Vacillation has been the curse of the Government. Let them now bring over 10,000 foot and 1,000 horse, plant these in six convenient garrisons, give the rebels 20 days in which to surrender, and then hunt down relentlessly all who stand out. Two winter campaigns will break their spirit. Let a fresh offer of pardon then be made, and rebellion will be at an end. There follows a detailed scheme, supported by statistics, for the administration of the pacified areas, ending with a proposal for the appointment of a lieutenant-general, Essex being clearly indicated. Political antagonism and racial antipathy combined with religious hatred to blind Spenser to the Irish cause.

During this second visit to England Spenser's hopes of preferment were centred in the Earl of Essex, but again he sued in vain. He returned to Kilcolman, probably in 1597, and resumed the *Faerie Queene.* In Sept. 1598 he was recommended for the sheriffdom of Cork. But preferment came too late: in October Tyrone's rebellion had broken out, the Munster Irish rose, Kilcolman Castle was burned and Spenser fled with his family to Cork. From Cork he was sent to London with a dispatch which bears date Dec. 9, 1598. Along with it he brought a brief note of his own in which he reiterated the policy of the *View.* On Jan. 16, 1599 he died. He was buried in Westminster Abbey close to Chaucer; many nobles attended his funeral, and his fellow-poets brought elegies which they threw into his grave with the pens that had written them. Spenser's tragic reversal of fortune and sudden death gave rise to a crop of legends. Ben Jonson told Drummond that one of Spenser's children perished in the flames of Kilcolman Castle and that he himself died "for lack of bread." It is only too likely, after all he had gone through, that Spenser collapsed on reaching London, and was a dying man before his friends could learn of his condition and come to his aid. Two more cantos of the *Faerie Queene* with two stanzas of a third were published in 1609; if more was written, as is probable, after 1596, it is irrecoverably lost.

**The Faerie Queene.**—Spenser's place among the great poets depends on the *Faerie Queene,* a fragment of a great poem which was to have been "disposed," as the title informs us, "into XII. bookes fashioning XII. morall vertues," each virtue embodied in a knight, and the whole designed "to fashion a gentleman or noble person in vertuous and gentle discipline"—at once a chivalric romance and a handbook of morals and manners; nay more—for Spenser would emulate Virgil as well as Ariosto—a national epic to the glory of England's Elizabeth. Such a threefold cord is not easily twined. Yet the task seemed feasible to Spenser, because to him the eternal war of good and evil, which was his essential theme, was embodied in the struggle of Protestant England against her Catholic foes. Book I. indeed may be read not inconsistently either as a mere romance, or as the spiritual experience of an elect Christian, or as a history of the English Church in the sixteenth century. But in Book II. the story stands still for nearly two whole cantos; the tale of Hellenore in Book III. is told with a gusto ill calculated to fashion a gentleman in virtuous discipline; in Book IV. the poet grows so careless of his characters that he lets the long-parted lovers come together without recognizing one another; the recent history of Book V. has little allegorical or romantic interest; and Book VI. ends in a burst of sheer pastoralism in which the poet forgets his allegory as completely as the hero forgets his quest. Only Spenser's contemporaries could fully appreciate the historical element, and some of it even to them can only have had the interest of a *roman à clef;* yet it strengthens the texture of the poem, and gives figures like Arthegall and Satyrane some firmness of outline.

The allegory was treated with respect for two centuries; Milton thought "our sage and serious poet" a better teacher than Scotus or Aquinas; modern criticism has too often followed Hazlitt in commending the poem to readers with the assurance that the allegory won't bite them. But to ignore the allegory is to ignore the informing purpose of the whole, without which the story would be a mere series of ill-joined episodes, and much of the imagery meaningless, some of it grotesque or even repulsive. The ethical, as distinct from the structural, value of the allegory must depend on the worth of the ideas it embodies, as its poetical value depends on the imaginative force of their embodiment. Spenser was not an original nor a systematic thinker. His philosophy is a blend of Platonism refracted through Ficino, Aristotelianism of the scholastic tradition, and Christianity with a Calvinistic bias. And the elements do not perfectly combine. Thus the doctrine of love and beauty, by which Ficino thought to reconcile the love of woman with the love of God, this doctrine, brilliantly expounded in the first two Hymns, is fundamentally irreconcilable with the scheme of salvation through the atoning sacrifice of Christ which is expounded in the third Hymn. The poet was a sincere and militant Christian, but also a man sensitive to the allurements of the world and the flesh; he knew self-distrust, and weariness, and regret for evanescent youth, and is never so moving as when he writes out of such experiences or turns from this unstable life in longing for the eternal rest.

Of the romance itself, with its wealth of imagery and melody, there has never been but one opinion. Like all Spenser's work, it is highly imitative. He rifled romantic literature for incidents and situations. The descriptions in which he excels constantly recall works of art—picture, tapestry, pageant or masque. But he owed much also to real life; he was recommended for his sheriffdom as "not unskilful or without experience in the wars"; and his journeys through the wild woods of Munster and his intercourse with soldiers like Grey and Norreys yielded many a hint for the background and characters of the *F.Q.* Its diction,

archaic but not rustic, and rich in strange coinages and terms of chivalry, is in keeping with its remote and old-world air. Not less appropriate is the stanza which he invented, *not* by "extending" the ottava rima or the rhyme royal, but by adding to the linked quatrains which he had used in the *S.C.* an Alexandrine such as Ferrars had employed to tip his sestets. The elements are not new; the miracle lies in their combination. It is not a perfect stanza for narrative, nor indeed is Spenser a perfect story-teller; but its amplitude fits the slow *tempo* of his thought, as he unrolls his leisurely pageants or ponders on time and change. Its power must not be judged by single stanzas, but by the cumulative effect as stanza after stanza rolls in, each ninth wave breaking higher than the rest.

Spenser has not Chaucer's genial breadth, nor Milton's art, nor Wordsworth's vision; but in the purely poetic gifts he is inferior to Shakespeare alone. The "school of Spenser" was small and short-lived, quite eclipsed in the next generation by Jonson and Donne; but in a wider sense all later English poets have been his scholars.

Beeston described Spenser to Aubrey as a little man, with short hair, little band and little cuffs—a description that fits the Pembroke College portrait better than the beruffled exquisite of the Dupplin portrait. These two portraits, whether genuine or not, do aptly illustrate the two sides of Spenser, scholar and Puritan on the one hand, courtier and man of affairs on the other; fundamentally a poet, sensitive and fastidious, yet responsive to the claim of affection or of honour. "Entire affection hateth nicer hands"; "No service loathesome to a gentle kind"; "The noblest mind the best contentment has"—in such lines we hear his authentic voice.

BIBLIOGRAPHY.—Dates of first issues are given above. Folios in 1609 (*F.Q.* only), 1611–13, 1617, 1670 (said to have been "overseen" by Dryden). Editions by J. Hughes (1715), H. J. Todd (1805), F. J. Child (1855), J. P. Collier (1862), R. Morris and J. W. Hales (1869), A. B. Grosart (1882–84), R. E. N. Dodge (1908), J. C. Smith and E. de Sélincourt (1909–10). *F.Q.* only by R. Church (1758), J. Upton (1758), K. M. Warren (1897–1900). *S.C.* by C. H. Herford (1895). *Fowre Hymnes* by L. Winstanley (1907). Commentaries and criticisms by J. Jortin (1714), T. Warton (1752), G. L. Craik (1845), R. W. Church (1879), J. J. Higginson (*S.C.* only) (1912), E. Legouis (1923), W. L. Renwick (1925). Much of the recent work on Spenser has been done by American scholars: F. I. Carpenter, E. A. Greenlaw, J. Erskine, J. B. Fletcher, P. W. Long, C. G. Osgood, F. M. Padelford, C. H. Whitman, etc. Most of it is available only in periodicals. Carpenter's *Reference Guide* (1923), Osgood's *Concordance* (1915), and Whitman's *Subject Index* (1918) are indispensable for detailed study.

(J. C. SM.)

**SPENSERIAN STANZA,** a verse-form so called from its invention by Edmund Spenser for his *Faerie Queene* (1590). Its origin is disputed; Schipper derives it from the Old French ballade (*q.v.*), others from the Italian *ottava rima.* Probably, however, it is Chaucer's eight-line *Monk's Tale* stanza, with a ninth line (an alexandrine) added, a feature which gives the stanza its beauty. The rhyme-scheme is a b a b b c b c c + (the + denoting the extra foot in the last line). Spenser's sonnet-scheme is somewhat similar. The stanza was hardly used in the 17th century, though Giles and Phineas Fletcher made for themselves adaptations of it. About 1740 it was revived, by Akenside (*Virtuoso,* 1737), Shenstone (*Schoolmistress,* 1742) Thomson (*Castle of Indolence,* 1748); followed by Beattie (*Minstrel,* 1771) and Mrs. Tighe (*Psyche,* 1805). Since 1850 it has been rarely employed. It is a purely English form.

**SPERANSKI, COUNT MIKHAIL MIKHAILOVICH** (1772–1839), Russian statesman, the son of a village priest, spent his early days at the ecclesiastical seminary in St. Petersburg (Leningrad), where he rose to be professor of mathematics and physics. His brilliant intellectual qualities attracted the attention of the government, and he became secretary to Prince Kurakin. In 1806, the emperor Alexander I. took him to the conference of Erfurt and put him into direct communication with Napoleon, who described him as "the only clear head in Russia." They discussed Russian reforms.

From 1809 to 1812 Speranski was all-powerful; he replaced the earlier favourites, becoming practically sole minister. In 1810 and the first half of 1811 Speranski was still in high favour, and was the confidant of the emperor in that secret diplomacy which preceded the breach of Russia with Napoleon.

On the eve of the struggle with Napoleon, Alexander, conscious of his unpopularity, conceived the idea of making Speranski his scape-goat, and so mobilising Old Russian sentiment against revolutionary France. The grand-duchess Catherine, Karamzin, Rostopchin and the Swedish general Baron Armfield, intrigued to involve him in a charge of treason. Alexander did not credit the charge, but on March 29, 1812 he dismissed him from office. Reinstated in the public service in 1816, he was appointed governor-general of Siberia, for which he drew up a new scheme of government, and in 1821 entered the council of state. He died on Feb. 11, 1839, at St. Petersburg.

*See* the biography (in Russian) by M. Korff (St. Petersburg, 1861) and the works of V. Vagin (St. Petersburg, 1872, Moscow, 1905).

**SPERMACETI,** a wax found in the head cavities and blubber of the sperm whale (*Physeter macrocephalus*), where it is dissolved in the sperm oil while the creature is living (from Lat. *sperma,* seed, and *cetus,* a whale). It also occurs in other Cetacea (*see* WHALE OIL). It is mainly cetin or cetyl palmitate, $C_{15}H_{31}CO_2C_{16}H_{33}$. The substance is used in making candles, in the dressing of fabrics, in medicine and surgery, and in cosmetic preparations. (*See* OILS, FATS AND WAXES.)

**SPERMOPHILE,** a name applied to a group of squirrel-like rodents (*Citellus*), widely distributed in the northern hemisphere. Most spermophiles hibernate and all have internal cheek pouches. In Russia they are known as sousliks and in the United States as ground squirrels or gophers. (*See* GROUND SQUIRREL; SOUSLIK.)

**SPERMOPHYTA** or SPERMATOPHYTA, the name often used in botany to denote the seed-plants, including the true flowering plants, or angiosperms (*q.v.*), and the conifers and their allies or gymnosperms (*q.v.*).

**SPERM WHALE** (*Physeter catodon*), the largest of the toothed whales, called also cachalot, its size being about equal to those of the Arctic right whale. The head is about one-third of the length of the body, massive, high and truncated in front. It owes its size and form to the accumulation of a peculiar form of fatty tissue in the large hollow on the upper surface of the skull. The oil contained in cells in this cavity, when refined, yields spermaceti, and the sperm oil of commerce comes principally from the thick covering of blubber, which envelops the body. Ambergris, used in perfumery, is a concretion formed in the intestine, and found floating on the sea. (*See* CETACEA; SPERMACETI.)

**SPERRY, ELMER AMBROSE** (1860–1930), American inventor, was born at Cortland, N.Y., on Oct. 12, 1860. He began early to experiment with electric arc lights and in 1879 established a factory in Chicago to manufacture an improved model which was highly successful. He then turned his attention to the development of electric mining machinery, invented the electric rotary and the chain undercutting machines, devised and built his own electric mining generator and other mining apparatus and established another factory to manufacture this machinery. He next designed an electric locomotive for industrial work, and developed motor and transmission machinery for street cars, which resulted in the founding of the Sperry Electric Railway Co. of Cleveland. About 1900 he established a research laboratory in electro-chemistry at Washington, D.C., where he invented the chlorine detinning process and also the electrolytic process for producing white lead from impure by-product lead. In 1915 he announced his high-intensity arc searchlight, built upon an entirely new principle, allowing a brilliancy as high as 900 candle-power per square millemetre, whereas 160 was the highest obtainable previously. The electrical and mechanical means of operating, as well as the mechanism to control the high temperatures of the arc, represented a difficult engineering achievement. These searchlights have become the standard for the principal armies and navies of the world and are in use for aircraft and coast beacons, the largest giving a white light of 1,500,000,000 candle-power which can be seen for upwards of 150 miles.

Sperry's most important inventions were based upon the application of the gyroscope in which he was always greatly interested.

Chief of these is the gyro-compass (*q.v.*), first installed on the battleship Delaware in 1911. This compass, unaffected as it is by iron and steel, has entirely superseded the magnetic compass on submarines and battleships and is rapidly being placed on merchant ships. Upon it the whole complicated system of modern naval gunnery has been developed. (*See* GUNNERY, NAVAL.) Sperry also designed and manufactured electrically sustained gyros for torpedoes which enabled them to complete long trajectories with a high degree of accuracy. During the World War he also developed aerial torpedoes with automatic gyro-control which proved effective at a range of 35 miles. Quantity manufacture had begun when the war ended. Further experiments yielded the gyro-pilot for the steering of ships, the automatic gyro-pilot for stabilizing aeroplanes, the gyroscopic roll and pitch recorder for the testing of ships, and, finally, a gyroscopic ship stabilizer, which has been installed on a number of ships in the United States, British, Italian and Japanese navies and promises to find a wider application. The motion of a ship in the waves is almost completely neutralized by automatic counter movements of the gyroscopes. He served after 1915 as a member of the naval consulting board, and has published numerous scientific papers. He died at Brooklyn on June 16, 1930.

*See* "The Engineering and Scientific Achievements of Elmer A. Sperry," in *Mechanical Engineering,* vol. xlix. (1927).

**SPES,** properly *bona spes* ("good expectation," *i.e.,* hope), a goddess worshipped in Rome from an uncertain but doubtless early date (temple in the Forum Holitorium, or vegetable market, vowed during the first Punic War, *cf.* Tibullus, i. 1, 9, *cf.* ii. 6, 21). Possibly she was originally an agricultural deity, not the personification of hope in general.

*See* Wissowa, *Religion und Kultus,* 2nd ed., p. 329.

**SPESSART,** a highland forest district belonging mainly to the Bavarian province of Lower Franconia, but in the north to the Prussian province of Hesse Cassel.

**SPEUSIPPUS** (4th century B.C.), Greek philosopher, son of Eurymedon and Potone, sister of Plato, is supposed to have been born *c.* 407 B.C. He was bred in the school of Isocrates, but when Plato returned to Athens *c.* 387, Speusippus became a member of the Academy. In 361, when Plato undertook his third and last journey to Sicily, Speusippus accompanied him. In 347 the dying philosopher nominated his nephew to succeed him as scholarch, and the choice was ratified by the school. Speusippus held the office until his death in 339.

Of Speusippus's many philosophical writings nothing survives except a fragment of a treatise *On Pythagorean Numbers.* We gather (A) In regard to his theory of being: (1) whereas Plato postulated as the basis of his system a cause which should be at once Unity, Good, and Mind, Speusippus distinguished Unity, the origin of things, from Good, their end, and both Unity and Good from controlling Mind or Reason; (2) whereas Plato recognized three kinds of numbers—firstly, ideal numbers, *i.e.,* the "determinants" or ideas; secondly, mathematical numbers, the abstractions of mathematics; and thirdly, sensible numbers, numbers embodied in things—Speusippus rejected the ideal numbers, and consequently the ideas; (3) Speusippus traced number, magnitude and soul each to a distinct principle of its own. (B) In regard to his theory of knowledge: (4) he held that a thing cannot be known apart from the knowledge of other things; for, that we may know what a thing is, we must know how it differs from other things, which other things must therefore be known; (5) accordingly, in the ten books of a work called Ὅμοια, he attempted a classification of plants and animals; (6) the results thus obtained he distinguished at once from "knowledge" and from "sensation" holding that "scientific observation" though it cannot attain to truth, may, nevertheless, in virtue of a certain acquired tact, frame "definitions." (C) In regard to his theory of ethics: (7) he denied that pleasure was a good, but seemingly was not prepared to account it an evil.

Speusippus and his contemporaries exercised a far-reaching influence upon Academic doctrine. When they rejected their master's ontology and proposed to themselves as ends mere classificatory sciences which with him had been means, they bartered their hope of philosophic certainty for the tentative results of scientific experience.

Brandis, *Geschichte der griechisch-römischen Philosophie* (1853), II. ii. 1; Zeller, *Die Philosophie d. Griechen* (Leipzig, 1875), II. i.; Mullach, *Frag. Phil. Graecorum,* iii. (1881); and Überweg, *Grundriss der Gesch. der Philosophie,* Bd. I. (1926).

**SPEY,** river in the highlands of Scotland, rising in Mt. Clach-a-Cheannaiche in Lochaber, in Inverness-shire. A mile from its source it forms the small Loch Spey, and 31 m. lower down the larger Loch Inch. It falls by several mouths into the Moray Firth at Kingston. It is about 110 m. long. It is a very rapid river, famous for salmon-fishing, and is nowhere navigable.

**SPEYER** (Spires), a town and episcopal see of Germany, capital of the Bavarian palatinate, situated on the left bank of the Rhine, at the mouth of the Speyerbach, 16 m. S. of Mannheim by rail. Pop. (1939) 30,062. Speyer, known to the Romans as *Augusta Nemetum* or *Nemetae,* and to the Gauls as *Noviomagus,* appears under the form of Spira, about the 7th century. Captured by Julius Caesar in 47 B.C., it was repeatedly destroyed by the barbarian hordes in the first few centuries of the Christian era. The town had become an episcopal seat in the 4th century; but heathenism supervened, and the present bishopric dates from 610. In 830 Speyer became part of the Frankish empire. The contentions between the bishops and the citizens were as severe as in any other city of Germany. The situation of the town opposite the mouths of several roads through the Rhine valley early fostered its trade; in 1294 it rose to be a free imperial city. It enjoyed great renown as the seat of the imperial supreme court from 1527 till 1689. Numerous imperial diets assembled here. From 1801 till 1814 it was the capital of a department of France; but it was restored to Bavaria in 1814.

A basilica of sandstone, the cathedral has a peculiar importance in the history of architecture as probably the earliest Romanesque basilica in which the nave as well as the side arcades was vaulted from the first. Built in 1030–1061 by Conrad II. and his successor, this church has had a chequered history, its disasters culminating in 1689, when the soldiers of Louis XIV. burned it to the bare walls, and scattered the ashes of eight German emperors. Restored in 1772–1784 and provided with a vestibule and façade, it was again desecrated by the French in 1794; but in 1846–1853 it was once more thoroughly restored and adorned in the interior with gorgeous frescoes. Speyer, although rebuilt in 1697, has never recovered from the injuries inflicted by the French in 1689. Its manufactures include paper, tobacco and cigars, sugar, machines, lead, vinegar, beer and musical instruments.

**SPEZIA, LA,** a city of Liguria, Italy, 49 ft. above sea-level. Pop. (1936), 80,399 (town); 106,119 (commune). It is the chief naval harbour of Italy; was adopted as such in 1861 though Napoleon I had entertained the idea. The Bay of Spezia (anc. *Portus Lunae*) is sheltered from all except southerly winds, and on its western shore are numerous openings, which afford perfectly safe anchorage in all weathers. The entrance is protected by forts, while a submarine embankment, 2 m. long, renders it secure. Its important arsenal dates from 1870. The establishment of San Vito is devoted entirely to the production of artillery; that of San Bartolomeo is exclusively used for electrical works and the manufacture of submarine weapons, especially torpedoes. The museum contains a unique collection of menhirs from the neighbourhood cut into the form of human figures. Spezia probably arose after the destruction of Luna. It was sold by the Fieschi in 1276 to Genoa. The town was fortified by its new possessors and made the seat of a governor of some importance. It became a city in the 16th century. Spezia and its naval installations were heavily bombed by the Allies in World War II.

**SPHENE** or **TITANITE,** a mineral consisting of calcium titano-silicate, $CaTiSiO_5$, crystallizing in the monoclinic system. The crystals vary considerably in habit, but are generally thin and wedge-shaped; hence the name sphene (Gr. σφήν, a wedge). The colour is green, yellow, brown or black, and the lustre resinous to adamantine; crystals are transparent to opaque. The hardness is

5·5, specific gravity 3·5. Sphene is cut as a gem-stone, though it is rather too soft to stand much wear; owing to its high dispersive power it gives brilliant flashes of prismatic colours. As small crystals, it is found in igneous rocks (granite, syenite, trachyte, phonolite, etc.), and also in gneiss, schist and crystalline limestone.

**SPHENISCIDAE:** *see* PENGUIN.

**SPHENODON:** *see* REPTILES.

**SPHERE,** in Greek geometry, the solid generated by the revolution of a semicircle about its diameter as an axis. In modern elementary geometry it is more generally considered as the spherical surface so generated, or as the locus of points at a constant distance from a fixed point called the *centre*. The constant distance is called a *radius*, and any line segment through the centre and limited at both ends by the sphere is called a *diameter*. In the geometry of surfaces it is defined as the quadric surface passing through the circle at infinity. Any section made by a plane cutting a sphere is a circle, being a *great circle* if the plane passes through the centre, and otherwise a *small circle*. The solid cut off by the plane of a great circle, is a *hemisphere;* that cut off by the plane of a small circle, a *segment*. In analytical geometery, the equation of a sphere in rectangular Cartesian co-ordinates is $x^2+y^2+z^2=a^2$, and in polar co-ordinates it is $r=a$. If the centre is $(\alpha, \beta, \gamma)$, the Cartesian equation becomes

$$(x-\alpha)^2+(y-\beta)^2+(z-\gamma)^2=a^2.$$

The surface of a sphere is found by the formula $S=4\pi r^2$, the area being four times that of a great circle. The volume is $\frac{4}{3}\pi r^3$. Analogous to the propositions of plane geometry and trigonometry is a series of propositions relating to the sphere. (*See* GEODESY; ASTRONOMY; SURFACE; ANALYTIC GEOMETRY; PROJECTIVE GEOMETRY; SOLIDS, GEOMETRIC; TRIGONOMETRY.)

**SPHERES OF INFLUENCE.** "Spheres of influence," "spheres of action, "spheres of interest," "zones of influence," "field of operations," "Machtsphäre," "Interessensphäre," are regions as to which nations have agreed that one or more of them shall have exclusive liberty of action. These phrases became common after 1882, when the "scramble for Africa" began.

Among treaties defining such spheres are the following:

Great Britain and Portugal as to Africa, Aug. 20, 1890, Nov. 14, 1890 and June 11, 1891. Great Britain and France as to Upper Niger, Jan. 20, 1891; Nov. 15, 1893, as to Lake Chad. Great Britain and France as to Siam, Jan. 15, 1896. The two Governments engage to one another "that neither of them will, without the consent of the other in any case or under any pretext, advance their armed forces into the regions, etc." They also engage not to acquire within this region any special privilege or advantage which shall not be enjoyed in common, or equally open to Great Britain and France or their nationals and dependants. Great Britain and Italy as to Africa, April 15, 1891; May 5, 1894, as to region of the Gulf of Aden. Congo and Portugal, May 25, 1891, as to "sphères de souveraineté et d'influence" in the region of Lunda. Great Britain, Belgium and Congo, May 12, 1894, as to the sphere of influence of the independent Congo State. Great Britain and Germany, July 1, 1890 and Nov. 15, 1893, as to East and Central Africa. Great Britain and Russia as to the spheres of influence to the east of Lake Victoria in the Pamir region, March 11, 1895.

Being the result of treaties, arrangements as to spheres of influence bind only the parties thereto. As Olney, in his correspondence with Lord Salisbury in regard to Venezuela, remarked: "Arrangements as to spheres of influence are new departures, which certain great European Powers have found necessary and convenient in the course of their division among themselves of great tracts of the continent of Africa, and which find their sanction solely in their reciprocal obligations" (United States No. 2, 1896, p. 27). Some treaties declare that the arrangement shall not affect the rights of other powers (Stoerck, *Recueil*, xvi. p. 932).

**Hinterland.**—Claims somewhat similar to these embrace hinterland. Sometimes it is called the "doctrine of contiguity," or "droit de vicinité, de priorité, de préemption ou d'enclave." The occupation of the mouth of a river is constructive occupation of all its basin and tributaries.

A State, having actually occupied the coast, may claim to reserve to itself the right of occupying from time to time territory lying inland (hinterland). In the discussions as to the western boundary of Louisiana between the commissions of the United States and Spain, as to Oregon, as to the claims of the Portuguese in East Africa, and as to the boundaries of Venezuela, the question of the extent of the rights of the discoverer and occupier came up. Lord Salisbury referred to "the modern doctrine of hinterland with its inevitable contradictions" (United States, No. 2, 1896, p. 12). Certainly it is inconsistent with the doctrine, more and more received in recent times, that effective possession is necessary to found a title to sovereignty or control. The doctrine of the hinterland is likely to become less important, now that Africa has been parcelled out. *See* MANDATE, PROTECTORATE, SOVEREIGNTY.

**SPHERICAL HARMONICS** are certain functions which occur in the theories of gravitation, electricity, hydrodynamics, and many other branches of mathematical physics.

If a number of particles of masses $M_1, M_2, \cdots, M_m$, attracting according to the inverse-square law, are placed at points $A_1, A_2, \cdots, A_m$, the *potential* of these masses at any point $P$, *i.e.*, the work done by the gravitational attractions in bringing a unit mass from an infinite distance to $P$, is

$$\frac{M_1}{A_1P}+\frac{M_2}{A_2P}+\cdots+\frac{M_m}{A_mP}.$$

If now the points $A_1, A_2, \cdots, A_m$, $P$ are referred to a set of rectangular co-ordinate axes, and the co-ordinates of the points are $(a_1, b_1, c_1), (a_2, b_2, c_2), \cdots, (a_m, b_m, c_m), (x, y, z)$ so that

$$A_1P=\sqrt{\{(x-a_1)^2+(y-b_1)^2+(z-c_1)^2\}}$$

with similar expressions for $A_2P, A_3P, \cdots, A_mP$, and if $V$ denotes the potential, it may be verified by partial differentiations that

$$\frac{\partial^2V}{\partial x^2}+\frac{\partial^2V}{\partial y^2}+\frac{\partial^2V}{\partial z^2}=0.$$

This equation does not involve the masses or the points at which they are placed, and so it is satisfied by the potential produced at a point $(x, y, z)$, in free space, by any gravitating system; it is known as *Laplace's equation*, and it is frequently written in the form

$$\nabla^2V=0,$$

$\nabla^2$ denoting the differential operator $\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}$ for brevity.

Laplace's equation occurs in problems of Gravitation, Electrostatics and Hydrodynamics; the related equation $\nabla^2V=k\partial V/\partial t$ occurs in problems of conduction of heat, $V$ being then a function of the co-ordinates $x$, $y$, $z$, and the time $t$, and $k$ being a constant; and the equation $c^2\nabla^2V=\partial^2V/\partial t^2$ occurs in problems of Vibrations of air and ether, $c$ being the velocity of sound or of light, according to the problem considered.

In order to discuss generally problems concerning the potential, it is found more effective to examine solutions of Laplace's equation than to regard the potential as the sum of a number of terms of the type $M/AP$, each term representing the potential produced by an attracting particle. If $V_1, V_2, V_3, \cdots$ are a number of solutions of Laplace's equation, and if

$$V = V_1+V_2+V_3+\cdots,$$

it is easily verified that

$$\nabla^2V = \nabla^2V_1+\nabla^2V_2+\nabla^2V_3+\cdots = 0,$$

and so the sum of any number of solutions of Laplace's equation

is itself a solution of the equation. It is thus possible to build up a solution of Laplace's equation by adding together simpler solutions.

Now let $V$ be any potential function, and suppose that it can be expanded by Taylor's theorem as a series of positive integral powers of $x, y, z$, thus

$$V = a_0+a_1x+b_1y+c_1z+a_2x^2+b_2y^2 +c_2z^2+d_2yz+e_2zx+f_2xy+a_3x^3+\cdots.$$

Group together all terms which are of the same degree in $x, y, z$, and denote the groups of terms which are of degrees $0, 1, 2, \cdots, n, \cdots$ in the expansion by

$$Y_0(x, y, z),\quad Y_1(x, y, z),\quad Y_2(x, y, z), \cdots,\quad Y_n(x, y, z), \cdots,$$

or, for brevity, by $Y_0, Y_1, Y_2, \cdots, Y_n, \cdots$, so that

$$V = Y_0+Y_1+Y_2+\cdots+Y_n+\cdots.$$

The expression $Y_n(x, y, z)$ is called *a spherical harmonic of degree n*. It may be verified that

$$\nabla^2Y_2+\nabla^2Y_3+\cdots+\nabla^2Y_n+\cdots = \nabla^2V = 0$$

so that the expression on the left vanishes identically; and since the terms written down are of different degrees, $0, 1, \cdots, n-2\cdots$, each must vanish separately, so that spherical harmonics are themselves solutions of Laplace's equation.

If the polar co-ordinates of $(x, y, z)$ are $(r, \theta, \phi)$, so that

$$x = r\sin\theta\cos\phi,\quad y = r\sin\theta\sin\phi,\quad z = r\cos\theta,$$

then $Y_n(x, y, z)$ may be written in the form $r^nf_n(\theta, \phi)$, where $f_n(\theta, \phi)$ is independent of $r$; and $f_n(\theta, \phi)$ is called a *surface harmonic*.

It can be proved that $Y_n(x, y, z)/r^{2n+1}$ is also a solution of Laplace's equation, and it is called a spherical harmonic of degree $-(n+1)$; this function and $Y_n(x, y, z)$ are called *solid* harmonics.

The term spherical harmonics (German, *Kugelfunktionen;* French, *Fonctions sphériques*) is due to Lord Kelvin.

When referred to polar co-ordinates, Laplace's equation becomes

$$\frac{\partial}{\partial r}\left(r^2\frac{\partial V}{\partial r}\right)+\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial V}{\partial\theta}\right)+\frac{1}{\sin^2\theta}\frac{\partial^2V}{\partial\phi^2} = 0;$$

this was the form of the equation originally given by P. S. de Laplace in 1784, in a memoir on Saturn's rings.

**Determination of Harmonics of Given Degree.**—Let $a_{r,s,t}x^ry^sz^t$ be an arbitrary expression of positive integral degree $n$ in $x, y, z$ where $r, s, t$ are positive integers (zero included) such that $r+s+t=n$, and the summation extends over all possible sets of values of $r, s, t$. It is required to find conditions that this expression may be a harmonic.

It is readily proved that the number of terms in the expression is $\frac{1}{2}(n+2)(n+1)$; if the expression is operated on by Laplace's operator, the result is an expression of degree $n-2$ in $x, y, z$, in which the $\frac{1}{2}n(n-1)$ coefficients are linear combinations of the $a_{r,s,t}$. If the last expression is equated to zero, $\frac{1}{2}n(n-1)$ equations connecting the $a_{r,s,t}$ are obtained, which have to be satisfied if the former expression is to be a harmonic. It follows that the number of independent coefficients $a_{r,s,t}$ is

$$\tfrac{1}{2}(n+2)(n+1)-\tfrac{1}{2}n(n-1),$$

*i.e.*, $2n+1$, and the remaining coefficients are expressible linearly in terms of them.

Consequently there are $2n+1$ independent harmonics of degree $n$, and any other harmonic of degree $n$ is expressible as a linear combination of these harmonics.

Take $n=2$ as an illustration; the expression

$$a_2x^2+b_2y^2+c_2z^2+2d_2yz+2e_2zx+2f_2xy$$

is a harmonic if $a_2+b_2+c_2=0$, and 5 independent harmonics of degree 2, in terms of which any harmonic of degree 2 may be expressed, may be taken to be

$$yz,\quad zx,\quad xy,\quad 2z^2-x^2-y^2,\quad x^2-y^2.$$

The next step is to construct $2n+1$ harmonics of degree $n$. This may be effected by considering the condition that

$$(ax+by+cz)^n$$

may be a harmonic, where $a, b, c$, are constants, and deducing the harmonics from it. By actual differentiation it follows that the condition that $(ax+by+cz)^n$ is a harmonic is

$$a^2+b^2+c^2 = 0;$$

and this condition is satisfied by taking

$$a = i\cos u,\quad b = i\sin u,\quad c = 1,$$

where $u$ is any angle and $i$ stands for $\sqrt{(-1)}$; and so

$$(z+ix\cos u+iy\sin u)^n$$

is always a harmonic.

Now suppose this expression to be expanded by the multinomial theorem, and replace $\cos u$ and $\sin u$ by their exponential values $(e^{iu}+e^{-iu})/2$ and $(e^{iu}-e^{-iu})/(2i)$; when the products of powers of $\cos u$ and $\sin u$ are multiplied out in this way, replace expressions such as $e^{miu}$, $e^{-miu}$ by $\cos mu\pm\sin mu$.

It is thus possible to express $(z+ix\cos u+iy\sin u)^n$ in the form

$$(z+ix\cos u+iy\sin u)^n = \tfrac{1}{2}g_0(x, y, z) + \sum_{m=1}^{n}[g_m(x, y, z)\cos mu+h_m(x, y, z)\sin mu],$$

where $g_m(x,y,z)$ and $h_m(x,y,z)$ are polynomials of degree $n$ in $x,y,z$, and are independent of $u$; and since

$$\tfrac{1}{2}\nabla^2g_0(x,y,z)+\sum_{m=1}^{n}[\nabla^2g_m(x,y,z)\cos mu+\nabla^2h_m(x,y,z)\sin mu]\equiv 0,$$

for all values of $u$, it is evident that $g_m(x,y,z)$ and $h_m(x,y,z)$ must be harmonics. As an illustration,

$$(z+ix\cos u+iy\sin u)^2 = z^2-\tfrac{1}{2}x^2-\tfrac{1}{2}y^2+2ixz\cos u +2iyz\sin u+\tfrac{1}{2}(y^2-x^2)\cos 2u-xy\sin 2u.$$

To obtain $g_m(x,y,z)$ and $h_m(x,y,z)$ explicitly, use Fourier's rule for determining the coefficients in a trigonometrical series, *i.e.*, multiply the expansion of $(z+ix\cos u+iy\sin u)^n$ by $\cos mu$ and by $\sin mu$, and integrate with respect to $u$ from $-\pi$ to $\pi$. It follows that

$$\pi g_m(x,y,z) = \int_{-\pi}^{\pi}(z+ix\cos u+iy\sin u)^n\cos mu\ du,$$
$$(m=0, 1, 2, \cdots, n),$$
$$h_m(x,y,z) = \int_{-\pi}^{\pi}(z+ix\cos u+iy\sin u)^n\sin mu\ du$$
$$(m=1, 2, 3, \cdots, n).$$

It will be proved later that these functions $g_m(x,y,z)$ and $h_m(x,y,z)$ are linearly independent, and so they form a set of $2n+1$ independent harmonics.

**The General Solution of Laplace's Equation.**—It has just been seen that any harmonic of degree $n$ may be expressed in the form

$$\sum_{m=0}^{n}a_mg_m(x,y,z)+\sum_{m=1}^{n}b_mh_m(x,y,z),$$

where $a_m$ and $b_m$ are constants. If now, for brevity,

$$\sum_{m=0}^{n}a_m\cos mu+\sum_{m=1}^{n}b_m\sin mu$$

be called $\pi f_n(u)$, it follows that *any* harmonic of degree $n$ is expressible in the form

$$\int_{-\pi}^{\pi}(z+ix\cos u+iy\sin u)^nf_n(u)du,$$

where $f_n(u)$ is a function of $u$; and, conversely, if $f_n(u)$ is an *arbitrary* function of $u$, it may be verified by substituting the expression in Laplace's equation that it is a harmonic of degree $n$.

Next take *any* solution $V$ of Laplace's equation and suppose it to be expansible in a convergent series of positive integral powers of $x,y,z$; group together all the terms of the same degree and replace each group of terms of the same degree $n$ by an expression of the form

$$\int_{-\pi}^{\pi}(z+ix\cos u+iy\sin u)^n f_n(u)du;$$

it follows that

$$V=\sum_{n=0}^{\infty}\int_{-\pi}^{\pi}(z+ix\cos u+iy\sin u)^n f_n(u)\,du;$$

and this value of $V$ is expressible in the form

$$V=\int_{-\pi}^{\pi}f(z+ix\cos u+iy\sin u,\ u)du,$$

where $f$ denotes a function of the two arguments $z+ix\cos u+iy\sin u$ and $u$; and conversely if $f$ denotes an arbitrary function of its two arguments, the expression on the right may be shown to satisfy Laplace's equation.

It is possible to remove the restriction concerning the possibility of expanding $V$ as a series of positive integral powers of $x,y,z$; and hence *the general solution of Laplace's equation may be written in the form*

$$V=\int_{-\pi}^{\pi}f(z+ix\cos u+iy\sin u,\ u)du.$$

This solution was obtained by E. T. Whittaker in 1902; it may be compared with the solution of the equation

$$\frac{\partial^2 W}{\partial x^2}+\frac{\partial^2 W}{\partial y^2}=0,$$

(known as Laplace's two-dimensional equation) namely

$$W=f(x+iy)+g(x-iy)$$

where $f$ and $g$ denote arbitrary functions.

**Zonal, Tesseral and Sectorial Harmonics.**—The $2n+1$ harmonics of degree $n$ which have been constructed take more simple forms when referred to polar co-ordinates; it is, in fact, possible to establish the expansion:

$$(z+ix\cos u+iy\sin u)^n = r^n P_n(\cos\theta) + 2\sum_{m=1}^{n}\frac{n!\,i^m}{(n+m)!}r^n P_n^m(\cos\theta)$$

$(\cos m\phi\cos mu+\sin m\phi\sin mu)$ where $P_n(\cos\theta)$ depends on $\theta$, but not on $\phi$, and $P_n^m(\cos\theta)=\sin^m\theta\dfrac{d^m P_n(\cos\theta)}{d(\cos\theta)^m}$.

From the form of the above expansion, it is evident that $r^n P_n(\cos\theta)$ is identical with $\frac{1}{2}g_0(x,y,z)$ so that

$$P_n(\cos\theta)=\frac{1}{2\pi}\int_{-\pi}^{\pi}\{\cos\theta+i\sin\theta\cos(\phi-u)\}^n du,$$

it follows from the statement that $P_n(\cos\theta)$ is independent of $\phi$ that it is permissible to put $\phi=0$ in the last formula without affecting the result; and so

$$P_n(\cos\theta)=\frac{1}{2\pi}\int_{-\pi}^{\pi}(\cos\theta+i\sin\theta\cos u)^n du,$$

a formula known as *Laplace's integral.*

From the result stated, it follows that $2n+1$ harmonics of degree $n$ are

$$r^n P_n(\cos\theta),\ r^n P_n^m(\cos\theta)\cos m\phi,\ r^n P_n^m(\cos\theta)\sin m\phi,$$
$$(m=1,2,\cdots,n),$$

and, from the manner in which $\phi$ occurs in them, they are obviously linearly independent.

An alternative definition of $P_n(\cos\theta)$ is derived from the fact that the potential produced at $(x,y,z)$ by a unit mass at $(0,0,a)$ is

$$1/\sqrt{\{x^2+y^2+(a-z)^2\}}=1/\sqrt{(a^2-2ar\mu+r^2)},$$

in polar co-ordinates, where $\mu$ denotes $\cos\theta$; when this potential function is expanded in ascending powers of $r$, the result is of the form

$$\frac{1}{a}+\frac{rP_1(\mu)}{a^2}+\cdots+\frac{r^n P_n(\mu)}{a^{n+1}}+\cdots,$$

where $P_n(\mu)$ depends on $\mu$ and $n$ only; and it may be seen from the expression in Cartesian co-ordinates that $r^n P_n(\mu)$ is a harmonic of degree $n$; it is possible to identify $P_n(\mu)$, defined in this manner, with Laplace's integral; and it can be proved that

$$P_1(\mu)=\mu,\quad P_2(\mu)=\frac{3\mu^2-1}{2},\quad P_3(\mu)=\frac{5\mu^3-3\mu}{2},\cdots,$$

$$P_n(\mu)=\frac{(2n)!}{2^n\cdot(n!)^2}\left[\mu^n-\frac{n(n-1)}{2(2n-1)}\mu^{n-2}+\frac{n(n-1)(n-2)(n-3)}{2\cdot 4(2n-1)(2n-3)}\mu^{n-4}-\cdots\right].$$

If a sphere is drawn with centre at the origin, the locus of points on the sphere at which $P_n(\cos\theta)$ vanishes consists of the $n$ parallels of latitude on which the cosine of the co-latitude is a root of the equation $P_n(\mu)=0$; the locus thus divides the sphere into $n+1$ zones, and for this reason $r^n P_n(\cos\theta)$ is called a *zonal* harmonic.

In like manner when $n>m\geqq 1$, $P_n^m(\cos\theta)$ vanishes on $n-m$ parallels of latitude, while $\cos m\phi$ vanishes on $2m$ meridians, and $\sin m\phi$ vanishes on $2m$ other meridians; the sphere is thus divided into $2m(n-m-1)$ rectangular regions, with $2m$ triangular regions round each pole, and for this reason $r^n P_n^m(\cos\theta)\cos m\phi$ and $r^n P_n^m(\cos\theta)\sin m\phi$ are called *tesseral* harmonics ($\tau\acute{\epsilon}\sigma\sigma\epsilon\rho\alpha$ = a square).

For similar reasons $r^n P_n^n(\cos\theta)\cos n\phi$ and $r^n P_n^n(\cos\theta)\sin n\phi$ are called *sectorial* harmonics.

The function $P_n(\cos\theta)$ is called a *Legendre coefficient*, or a *Legendre function*, while $P_n^m(\cos\theta)$ is called an *associated Legendre function.*

**Normal Solutions of Laplace's Equation.**—The zonal, tesseral and sectorial harmonics are of the form $R\cdot\Theta\cdot\Phi$ where $R,\Theta,\Phi$ respectively involve the co-ordinates, $r,\theta,\phi$, only; a solution consisting of the product of three functions each involving only one co-ordinate is called a *normal solution.*

Thus, if $X\cdot Y\cdot Z$ is a normal solution of Laplace's equation in Cartesian co-ordinates, it follows, on substitution and division by $XYZ$, that

$$\frac{1}{X}\frac{\partial^2 X}{\partial x^2}+\frac{1}{Y}\frac{\partial^2 Y}{\partial y^2}+\frac{1}{Z}\frac{\partial^2 Z}{\partial z^2}=0,$$

and so

$$\frac{1}{X}\frac{\partial^2 X}{\partial x^2},\quad \frac{1}{Y}\frac{\partial^2 Y}{\partial y^2},\quad \frac{1}{Z}\frac{\partial^2 Z}{\partial z^2}$$

must be respectively independent of $x,y,z$; hence they are constants. If these constants are called $a^2$, $b^2$, $c^2$, where $a^2+b^2+c^2=0$, we obtain the solutions

$$V=e^{\pm ax\pm by\pm cz}.$$

Similarly, if $R\Theta\Phi$ is a normal solution in polar co-ordinates,

$$\frac{1}{R}\frac{d}{dr}\left(r^2\frac{dR}{dr}\right)+\frac{1}{\Theta\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right)+\frac{1}{\Phi\sin^2\theta}\frac{d^2\Phi}{d\phi^2}=0,$$

and so $\dfrac{1}{R}\dfrac{d}{dr}\left(r^2\dfrac{dR}{dr}\right)$ and $\dfrac{1}{\Phi}\dfrac{d^2\Phi}{d\phi^2}$ must be constants, say $n(n+1)$ and $-m^2$; and so $\Theta$ satisfies the equation

$$\frac{1}{\sin\theta}\frac{d}{d\theta}\left(\sin\theta\frac{d\Theta}{d\theta}\right)+\left(n[n+1]-\frac{m^2}{\sin^2\theta}\right)\Theta=0,$$

while $\dfrac{d}{dr}\left(r^2\dfrac{dR}{dr}\right)-n(n+1)R=0$, $\dfrac{d^2\Phi}{d\phi^2}+m^2\Phi=0$.

Possible values of $R$ are $r^n$ and $r^{-n-1}$; and possible values of $\Phi$ are $\cos m\phi$ and $\sin m\phi$. But now $n$ and $m$ are not necessarily integers, and so the question arises of defining $P_n^m(\cos\theta)$ in such circumstances.

This problem is dealt with by means of the hypergeometric function of Gauss defined by the equation

$$F(\alpha,\beta;\gamma;z)=1+\frac{\alpha\beta}{\gamma\cdot 1}z+\frac{\alpha(\alpha+1)\beta(\beta+1)}{\gamma(\gamma+1)\cdot 1}z^2+\cdots.$$

A solution of the equation which it is convenient to adopt as the definition of $P_n^m(\cos\theta)$ is

$$P_n^m(\cos\theta) = \frac{1}{\Gamma(1-m)}\left(\frac{\mu+1}{\mu-1}\right)^{\frac{1}{2}m} F(-n, n+1; 1-m; \tfrac{1}{2}-\tfrac{1}{2}\mu),$$

where $\Gamma(1-m)$ denotes the gamma function of Euler which reduces to $(-m)!$ when $m$ is a negative integer (when $m$ is a positive integer, this function differs from the associated Legendre function, as previously defined, by a constant factor). The theory of generalized Legendre functions is consequently merged into the wider theory of hypergeometric functions.

**Cylindrical and Ellipsoidal Harmonics.**—The cylindrical co-ordinates $(\rho,\phi,z)$ of a point are defined by the equations

$$x=\rho\cos\phi, \quad y=\rho\sin\phi, \quad z=z.$$

When the solution $e^{k(z+ix\cos u+iy\sin u)}$ of Laplace's equation is expressed in terms of such co-ordinates it becomes:

$$e^{kz}e^{ik\rho\cos(\phi-u)}$$

and this can be expanded in the form

$$e^{kz}\left[J_0(k\rho)+2\sum_{m=1}^{\infty} i^m J_m(k\rho)\,(\cos m\phi\cos mu+\sin m\phi\sin mu)\right]$$

where

$$J_m(k\rho) = \sum_{n=0}^{\infty}\frac{(-1)^n(\frac{1}{2}k\rho)^{m+2n}}{n!(m+n)!}$$

This leads to the consideration of the *cylindrical harmonics*

$$e^{kz}J_0(k\rho), \quad e^{kz}J_m(k\rho)\cos m\phi, \quad e^{kz}J_m(k\rho)\sin m\phi,$$

which may also be derived as normal solutions of Laplace's equation in cylindrical co-ordinates, viz.

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial V}{\partial\rho}\right)+\frac{1}{\rho^2}\frac{\partial^2 V}{\partial\phi^2}+\frac{\partial^2 V}{\partial z^2}=0.$$

The functions $J_m(k\rho)$ are known as *Bessel functions* (*q.v.*). They occur in numerous physical problems of diverse types including F. W. Bessel's investigations of planetary motion, Daniel Bernoulli's problem of a vibrating hanging chain and L. Euler's problem of a vibrating circular membrane.

The functions which occur in a similar manner when Laplace's equation is referred to a system of confocal conicoids as surfaces of reference are known as *Lamé's functions*; these are of a more complicated type than the functions described hitherto, because they cannot be expressed as series with simple coefficients. But when the confocal conicoids are spheroids, the substitution

$$x=(r^2-c^2)^{\frac{1}{2}}\sin\theta\cos\phi, \quad y=(r^2-c^2)^{\frac{1}{2}}\sin\theta\sin\phi, \quad z=r\cos\theta$$

gives a form of Laplace's equation with normal solutions of the type

$$P_n^m(r/c)P_n^m(\cos\theta)\begin{matrix}\cos\\ \sin\end{matrix} m\phi,$$

the spheroids being prolate; with oblate spheroids, $c$ must be replaced by $ic$.

**Recent Researches.**—Some of the main lines along which progress has been made in recent years include methods of transforming the hypergeometric series; obtaining approximate expressions for $P_n^m(\cos\theta)$ when $n$ or $m$ (or both) is large; expanding arbitrary functions of two variables as series of surface harmonics; expanding arbitrary functions $f(\mu)$ in the form $\sum a_n P_n(\mu)$; obtaining approximate formulae for $J_n(z)$ when $z$ or $n$ (or both) is large; obtaining formulae by which the roots of the equation $J_n(z)=0$ may be calculated; expanding arbitrary functions as series of Bessel functions; obtaining integral equations satisfied by ellipsoidal harmonics, and by the harmonic functions associated with confocal elliptic cylinders. These investigations all arose in the first instance out of some problem of Mathematical Physics, though many of them require the most profound methods of Pure Mathematics for their solution.

**SPHEROID,** literally a sphere-like body. In geometry the term is applied to figures generated by an ellipse (q.v.) revolving about either its minor axis (giving an *oblate spheroid*) or its major axis (giving a *prolate spheroid*). If the equation of the generating ellipse is $b^2x^2+a^2y^2=a^2b^2$, and the ellipse revolves about the major axis (the $x$ axis), the volume is $\frac{4}{3}\pi ab^2$; if about the minor axis, it is $\frac{4}{3}\pi a^2 b$. The equation of the prolate spheroid is $b^2x^2+a^2(y^2+z^2)=a^2b^2$, and of the oblate spheroid it is $b^2(x^2+z^2)+a^2y^2=a^2b^2$. (*See* ELLIPSOID.)

**SPHERULITES,** in petrology, small rounded bodies which commonly occur in vitreous igneous rocks. They are often visible in specimens of obsidian, pitchstone and rhyolite as globules about the size of millet seed, with a duller lustre than the surrounding glassy base of the rock, and when they are examined with a lens they prove to have a radiate fibrous structure. Under the microscope the spherulites are of circular outline and composed of thin divergent fibres, which are crystalline and react on polarized light. Between crossed nicols a black cross appears in the spherulite; its axes are usually perpendicular to one another and parallel to the crossed wires; as the stage is rotated the cross remains steady; between the black arms there are four bright sectors. This shows that the spherulite consists of radiate doubly refracting fibres which have a straight extinction; the arms of the black cross correspond to those fibres which are extinguished. The aggregate is too fine grained for us to determine its minerals.

Spherulites are commonest in acid glassy rocks but occur also in basic glasses such as tachylyte. Sometimes they compose the whole mass; more usually they are surrounded by a glassy or felsitic base. When obsidians are devitrified the spherulites are often traceable, though they may be more or less completely recrystallized or silicified. In the centre of a spherulite there may be a crystal (*e.g.*, quartz or felspar) or sometimes a cavity. Occasionally spherulites have zones of different colours, and while most frequently spherical they may be polygonal, or irregular in outline. In some New Zealand rhyolites the spherulites send branching "cervicorn" processes (like stags' horns) outwards through the surrounding glass of the rock. Long, elliptical or band-like spherulites are called *axiolites*.

Spherulites may be $\frac{1}{2}$in. or more in diameter. In composition they are a mixture of quartz and acid felspar.

Very large and cavernous spherulites have been called *lithophysae;* they are found in obsidians at Lipari, the Yellowstone Park, etc. The characteristic radiate fibrous structure is usually conspicuous, but the fibres are interrupted by cavities which are often so arranged as to give the spherulite a resemblance to a rosebud with folded petals separated by arching interspaces. Some of these lithophysae are 1in. or more in diameter. In the crystallization of a glass there must be contraction, and it is supposed that thus the concentric cavities arise. The steam and other vapours in the magma would fill these empty spaces and exert a powerful mineralizing action on the warm rock. Analogous structures may be produced in artificial glasses, salt solutions and melts of organic substances. (J. S. F.)

**SPHINX,** the Greek name for a compound creature with lion's body and human head (Gr. σφίγγειν to draw tight, squeeze). The Greek sphinx had wings and female bust, and the

male sphinx of Egypt (wingless) is distinguished as "andro-sphinx" by Herodotus. The type perhaps originated in Egypt, where a defined type is usually recumbent. The most celebrated example is the Great Sphinx of Giza, 189ft. long, a rock carved into this shape, and from its situation likely to be the work of the IVth Dynasty.

According to inscriptions of the XVIIIth Dynasty in the shrine between the paws, it represented the sun god Harmachis. It has recently been completely excavated and its head restored. Sphinxes of granite, etc., occur of the XIIth Dynasty and later. (*See* EGYPT, *Art and Archaeology*.) The heads of the sphinxes are royal portraits, and apparently they are intended to represent the power of the reigning Pharaoh. The king as a sphinx, in certain religious scenes, makes offerings to deities; and elsewhere he tears his enemies in pieces. Sphinxes in pairs guarded the approach to a temple, and the Great Sphinx at Giza so guards the entrance of the Nile valley.

The great temple avenues at Thebes are lined with recumbent rams, true sphinxes (a few late instances), and with the so-called criosphinxes or ram-sphinxes, having lion bodies and heads of the sacred animal of Ammon. A falcon-headed sphinx was dedicated to Harmachis in the temple of Abu Simbel, and is occasionally found in sculptures representing the king as Horus, or Mont, the war-god. It is distinguishable from the gryphon only by the absence of wings.

In Assyria the sphinx appears with a bearded male head on cylinders; the female sphinx, lying down and furnished with wings, is first found in the palace of Esar-haddon (7th cent. B.C.). Sphinxes have been found in Phoenicia, one at least being winged and another bearded. They are copies of the Egyptian, both in form and posture, wearing the pshent and the uraeus, but distinguished by having the Assyrian wings. The sphinx is common on Persian gems, and the representations are finely executed. On a Persian intaglio are two sphinxes face to face, each wearing a tiara and guarding a sacred plant which is seen between them; but the sphinx, whether of the Egyptian or the Assyrian type, is not found in Persian sculptures (Perrot and Chipiez, *History of Art in Persia,* Eng. trans., London, 1892). In Asia Minor the oldest examples are the "Hittite" sphinxes of Euyuk. They are Egyptian sphinxes treated in the Assyrian style. They are not recumbent, and the hair falling from the head is curled, not straight, as in the true Egyptian sphinx.

In the early art of Cyprus (the half-way house between Asia and Greece) sphinxes of Greek type are not uncommon. On the other hand, on a gem of Phoenician style found at Curium in Cyprus there appear two male (bearded) sphinxes, with the tree of life between them. With regard to Greece proper, in the third tomb on the acropolis of Mycenae (*c.* 1600 B.C.) were found six small golden sphinxes; they are beardless, but the sex is doubtful.

Moreover, the sphinx (generally sejant, in the Greek fashion) was well-known in Minoan art. It occurs in ivory (couchant) among the Mycenean antiquities from Enkomi in Cyprus, in the British Museum. In the ancient tomb discovered in 1877 at Spata near Athens (which represents a kindred but somewhat later art than the tombs at Mycenae) were found female winged sphinxes carved in ivory or bone. Sphinxes on glass plates have been found in graves at Camirus in Rhodes and on gold plates in Crimean graves. Sphinxes were represented on the throne of Apollo at Amyclae and on the metopes at Selinus; in the best period of Greek art a sphinx was sculptured on the helmet of the statue of Athena in the Parthenon at Athens; and sphinxes carrying off children were sculptured on the front feet of the throne of Zeus at Olympia. There have been found in Boeotia terra-cotta figures of wingless sphinxes. Roman sphinxes of a late period have sometimes a man's, sometimes a woman's head with an asp on the forehead.

In Greek mythology the most famous sphinx was that of Thebes in Boeotia, first mentioned by Hesiod (*Theog.* 326), who calls her the daughter of Orthus and Chimaera. According to Apollodorus (iii. 5, 8), she was the daughter of Typhon and Echidna, and had the face of a woman, the feet and tail of a lion and the wings of a bird. She dwelt at the south-east corner of Lake Copais on a bald rocky mountain called Phicium (mod. Fagas), which was derived from Φιξ, the Aeolic form of σφιγξ. The Muses taught her a riddle and the Thebans had to guess it. Whenever they failed she carried one of them off and devoured him. The riddle was this: "What is that which is four-footed, three-footed and two-footed?" At last Oedipus guessed correctly that it was man; for the child crawls on hands and feet, the adult walks upright, and the old man supports his steps with a stick. Then the sphinx threw herself down from the mountain.

Among the remains of the Mayan culture in Yucatan are found examples of sphinxes, male and female, which are not unlike those of Egypt and Asia Minor.

**SPICE-BUSH** (*Lindera aestivalis*), a North American shrub of the laurel family (Lauraceae), allied to the sassafras and Oregon myrtle (*qq.v.*), native to moist woods from Massachusetts to Ontario and Michigan south to North Carolina and Kansas. It grows from 4 to 20 ft. high, with smooth fragrant twigs and foliage, and bears bright yellow flowers, which unfold before the leaves, and scarlet fruit (drupe), maturing in late summer. The similar hairy spice-bush (*L. melissaefolia*) is found in swamps in the southeastern states. The bark of *L. aestivalis* was formerly of high repute in household medicine, being used as a febrifuge.

**SPIDER MONKEY,** a group of tropical American monkeys known to zoologists as *Ateles*. They take their English name from the slimness of the body, the elongated limbs, and the long tail, the under surface of the prehensile extremity of which is naked. The thumb is rudimentary or wanting. Their long coarse hair and the broader partition between the nostrils distinguishes them from the woolly spider monkeys (*Brachyteles*). The species are arboreal. (*See* PRIMATES.)

**SPIDERS,** or Araneae, form a natural order of the class Arachnida (*q.v.*). They are distributed all over the world, from Spitsbergen, Greenland and Alaska in the north, to Tierra del Fuego, Kerguelen and Macquarie in the south, from sea level to 7,300 metres above it on Mt. Everest. They are found on the ground and on vegetation, in forests and in meadows, in swamps and in deserts, in human homes and in subterranean caves. One may see spiders skipping over the surface of stagnant water, running on the beach between tides and in the case of at least one species, living in air-filled tents under water. All spiders are easily distinguished from insects by the subdivision of their body into two portions only: the cephalothorax and the abdomen. The former is the result of a fusion of the head with the thorax. The fusion is so complete that the outlines of the head may be recognized only from the shallow depressions which separate its dorsal surface from that of the thorax. The abdomen is attached to the cephalothorax by a very slender pedicel, a feature which spiders share with some other Arachnida. But by far the most important character of spiders, separating them not only from other Arachnida, but from all other animals, is the presence of spinnerets on the abdomen. The spinnerets are modified appendages of the fourth and fifth abdominal embryonic segments and are supplied with silk-producing glands situated in the abdomen. The ducts of these glands open at the end of specially modified hairs, the so-called spinning tubes situated on the spinnerets. The silk is produced as a fluid which is pressed out of the spinning tubes and solidifies immediately on contact with the air. Among the Arachnida, the Pseudoscorpiones are also able to produce silk, but their spinnerets are at the end of the movable finger of the chelicerae; *i.e.*, of the first pair of appendages situated in front of the mouth and the silk glands are not in the abdomen, but in the cephalothorax. Some Acari are also endowed with the ability to spin silk. In their case the

silk glands are really modified salivary glands, as is also the case in such insects as moths. So the spiders are the only possessors of their type of spinning apparatus.

Besides common spinning tubes with very fine ducts, spiders possess also a few larger spinning tubes, so-called spigots, present in small, but fixed numbers among the hundreds of regular tubes. In some species the total number of spinning tubes was estimated to be as high as a thousand, but in others it is less than a hundred. A spider's silk thread, as seen with the naked eye, is in reality a cable composed

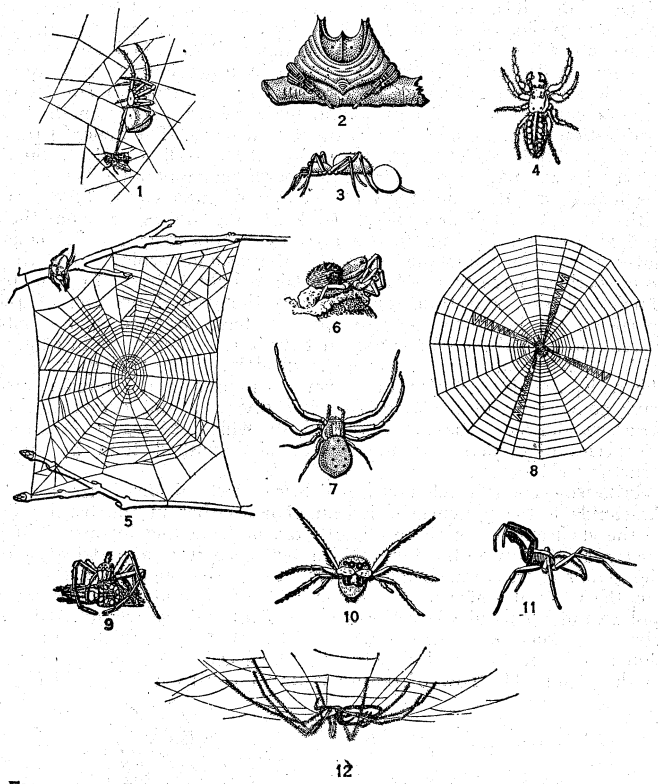

FIG. 1.—TYPES OF SPIDERS, VENOMOUS AND NONVENOMOUS

(1) Theridiid spider, wrapping a fly in sticky threads; (2) Argiopid spider, shown from behind (After Vinson); (3) Female Lycosid spider carrying egg cocoon; (4) Common Attid spider (After Blackwall); (5) Epeirid spider and web (After Lulham); (6) Female Lycosa with egg sac attached to abdomen; (7) Thomasid spider (After Blackwall); (8) Argiopid spider (After Hingston); (9) Grass spider (*Agalena*), pairing (After McCook); (10) Male Attid spider (After Bristowe); (11) Linyphid spider, on under side of her sheet web (After Blackwall); (12) Male Lycosa, in courting attitude (After Bristowe)

of many fine, individual threads. The diameter of such an individual thread is no more than three ten-thousandths of a millimetre, and in some cases, as in the inner lining of the cocoon of *Agalena naevia,* is less than one-tenth of a micromillimetre. Spider silk is finer, lighter and stronger than commercial silk produced by the silkworm; *i.e.,* by the caterpillar of the silkmoth. Naturally, attempts have been made in the past to utilize spider silk, but without success. The reason for the failure lies in the cost of labour involved in the upkeep of a spider colony sufficient to produce large quantities of silk. In captivity each spider has to be kept separately and supplied with food and water, while under natural conditions the size of a garden adequate to accommodate numerous spiders, without danger of loss from overcrowding, is prohibitive from the point of view of reasonable profit. The most promising attempt at keeping spider gardens was made in Madagascar in the 19th century. The species used was the great orb-weaver, *Nephila madagascariensis.* But even in Madagascar the cost of labour proved to be too high. At present spider silk is used only in the construction of optical instruments, because it is the finest thread available. For this purpose cocoons of northern species, such as the American *Argiope aurantia,* seem to be satisfactory. The length of the thread which Nephila uses in the construction of an egg cocoon varies from 1,500 to 4,000 metres.

All spiders have spinnerets, but one must not imagine that all make webs or snares. On the contrary, the majority of species use their silk for purposes other than the capture of insects: they spin egg cocoons, sperm webs, moulting sheets, gossamer threads, attachment discs with cables, lining of burrows, hinges for trap doors, etc., while relatively few species build snares of various types for the capture of prey. In using silk for different purposes, spiders do not use the same glands. Each spider has in its abdomen numerous glands belonging to several different types. Even males and females of the same species differ in this respect, because only females have glands producing silk for egg cocoons. Only spiders which make snares to capture insects produce silk with adhesive droplets. Since spinning of silk is so intimately connected with the activities of all spiders, it is clear that the spinning apparatus is one of the most important features of their anatomy and one of the chief factors which determined the course of their evolution.

**Webs.**—There are several types of webs built by spiders, more or less characteristic of whole families. One can distinguish sheet webs, funnel webs, tube webs, reticular webs, geometric orb webs, etc. In the early days of arachnology spiders were even classified in accordance with the type of web they build. Attempts have been made later to derive one type of web from another and thus to establish trends in their evolution. Unfortunately all such attempts disregard other evidence of spider relationship and of changes involving the anatomical structure of various organs. In many cases comparatively close relatives belonging to the same family build webs of a very different type, while spiders belonging to widely separated families may build webs of the same type. Thus so-called trap-door nests are characteristic of spiders belonging to the family Ctenizidae among the Mygalomorphae, yet some species of the Dipneumonomorph family Lycosidae, notably the European *Lycosa* (*Tarentula*) *opifex,* make trap-door nests of the same type. *Theridiosoma nechodomae* makes a little geometric spiral web, *Epeirotypus gloriae,* a triangular web and *Wendilgarda theridionina* spins a single fine thread across brooks; yet all three belong to the same subfamily of orb-weaving spiders and occur in the same locality on the island of Puerto Rico. *Linyphia marginata,* a species common in Europe and America, builds a dome web, its close relative *Linyphia communis* makes an inverted dome or bowl web and another relative, *Linyphia pusilla,* weaves flat webs.

The most complex snares are undoubtedly those of the typical geometric orb-weavers of the family Argiopidae. A finished web consists usually of three or four outer foundation lines, several inner foundation lines, many radii, a central hub, an intermediate zone and a viscid spiral. Besides this many species build a tent of silk or of a leaf rolled up and held together by threads of silk. In this tent the spider hides during the day, holding in its claws the guy line which is connected with the centre of the web and which transmits the vibrations caused by entangled insects. Before the adhesive spiral is made, the spider makes a corresponding spiral of common silk. When this is finished, the adhesive spiral is attached to the radii in the space between the turns of the common spiral. The latter is now clipped off, rolled up by the chelicerae and dropped to the ground as having no further use. Species of *Argiope* weave additional X-shaped bands called stabilimentum, although they have nothing to do with stabilizing the web. Some weave in the middle of the orb a disc of lacework. *Cyclosa conica,* a little orb-weaver common both in Europe and America, suspends in the vertical diameter of her web a series of silk pellets to camouflage her egg cocoon occupying a place in the same row.

A very unusual web is made by *Hypochilus thorelli,* a peculiar relict species found in the Great Smokies and adjoining mountain ranges in the United States and having close relatives only in Tasmania and China. Its web has the shape of a truncated cone suspended by the smaller, apical end from the underside of horizontal ledges, while the wider, open base of the cone, forming the entrance to the inside of the web, hangs freely down and is held in place by only a few threads. The long-legged spider sits inside the web, flattened against a flat foundation sheet, which is attached directly to the surface of the rock. Another very interesting snare is made by *Dinopis longipes* of Central America. The spider is long, with very long legs, the span of which measures as much as 150 mm. and when the spider hangs fully relaxed with legs and body stretched out in a single line, it looks more like a slightly curved twig than like a spider. It is suspended from a horizontal line by a single vertical thread, holding on to it with its spinnerets and its four posterior legs. With its four anterior legs, it holds the corners of a rectangular net made of special silk produced by so-called cribellar glands. When an insect falls on top of this trap, the spider immediately displays tremendous activity by swinging the trap in a spiral motion with great speed, until the victim is completely enswathed in silk. A new trap has to be built after each capture. *Hyptiotes cavatus* of America and *Hyptiotes paradoxus* of Europe, both belonging to the family Uloboridae, make triangular snares which they swing with the aid of a guy line held in their legs. Their nearest relatives of the genus *Uloborus* construct orb webs of the same type as the Argiopidae, but use cribellar silk for the spiral.

The construction of tents was already mentioned in connection with the building of orb webs. Many spiders of other families build tents which they use as retreats or hiding places in which they find shelter from rain, cold, light and enemies, or from which they can pounce upon unsuspecting victims. The European and Asiatic aquatic spider, *Argyroneta aquatica,* builds her tent under water in the shape of a bell and fills it with air. Special tents are often used for moulting, during which process all spiders, even the most formidable ones, are quite helpless. Some females make complete envelops of tough silk for themselves and their brood and stay inside until the spiderlings become capable of taking care of themselves. Some species winter in special tents made for that purpose under loose bark of trees.

Egg cocoons present a great variety of structure. Some are circular or oval and perfectly flat. Others are globular and smooth. The egg-shaped, pointed cocoons of *Latrodectus geometricus* are covered with numerous little knobs. Some cocoons are white, others are coloured

yellow, brown, pink or green. The cocoon of *Argiope argentata* is a flat, elongated hexagon, often grass-green on one side and golden yellow on the other. The cocoon of *Hypochilus thorelli* is white when made, but the female then camouflages it with pieces of moss which she collects from the surface of the rock or from the ground. Most cocoons are made with at least two walls, an inner and an outer one. First, the spider spins a sheet, deposits the eggs in it, covers them with another sheet and binds the two together, neatly clipping the edge. Then the outer sheath is made, often of much tougher silk. In *Argiope aurantia,* the outer sheath or envelope is almost globular, made of brown, loosely woven silk. The inner sheath is cylindrical, with a round bottom and a strongly constricted neck which protrudes through the top of the outer sheath. The cocoons of *Agalena naevia,* the common American funnel-web spider, are fastened under bark to which their flat base is attached. They are gray, unattractive and dirty looking. The female guards them until she dies.

Attachment, discs or anchors are made by all spiders whenever they want to be safe from injury by falling from an elevation or when they jump from one place to another. An anchor is made instantaneously by pressing the spinnerets against the surface of the object on which the spider happens to be. The pattern of an anchor is characteristic of each species and consists of numerous loops of fine threads brought together to a median line which is then continued as a single cable. On reaching the object of its destination, the spider either breaks off the end of the cable or, if it intends to return, fastens the end and climbs the cable to the point of its anchorage.

Silk is used for enswathing insects captured in a snare. This makes their escape impossible and serves to store them as food for use at a later time. In case the insect is a dangerous adversary, such as a wasp or hornet, silk may be squirted as far as an inch from the spinnerets, a distance sufficient to make the combat safe.

The maximum number of spinnerets which a spider may possess is four pairs. This number, however, is found only in the Liphistiomorphae. In some spiders the anterior median pair is transformed into a flat, perforated plate, the cribellum. In most spiders only six or four spinnerets are present. A few species are known with a single pair of spinnerets, the minimum possible, because the complete loss of spinnerets would require such a readjustment of habits, that the very existence of such creatures would become impossible. The size and shape of spinnerets, on the other hand, may vary considerably and apparently have very little to do with the type and complexity of the web. Spiders belonging to the Mygalomorph family Dipluridae have very long and slender spinnerets. They make large, irregular sheet webs or reticular webs which are usually provided with a funnel-like retreat, whereas spiders of the Dipneumonomorph family Hersiliidae, also with very long and slender spinnerets, make no webs of any kind.

**Reproductive Organs.**—Another character which spiders alone possess and by which they differ from all other animals is of a sexual nature: it consists in a complete separation of the male copulatory apparatus from the reproductive system proper. The latter is situated in the abdomen in both sexes. The female has two ovaries, two oviducts and a single, very short uterus which opens in the median line between the organs of respiration belonging to the second embryonic segment. Another pair of openings is situated in front or at the sides of the genital opening. These openings lead into sperm receptacles. In more highly developed spiders the latter are connected with the uterus by special fertilization ducts. Various chitinous accessory structures, known as the epigynum, are present in many species. These are more or less intimately connected with the genital opening, are characteristic of each species which possess them and in some way, not yet clearly understood, have to do with the act of copulation. The reproductive organs of the male are also in the abdomen. They consist of a pair of sperm glands or testes, a pair of deferent ducts and a short, common ejaculatory duct. The male genital opening is in the identical position described for the female genital opening. But the organs of copulation are in no way connected with the reproductive organs and are instead situated on the terminal joint of the pedipalpi. This is what makes them unique in the entire animal kingdom and what necessitated the development of special instincts, of strictly inherited behaviour of male spiders, peculiar to sexually mature male spiders and only to them. Because the female has a pair of seminal receptacles and the male has a pair of pedipalpi, the males have a pair of copulatory organs. In its simplest form the apparatus consists of a bulb ending in a more or less curved spout or embolus. Inside the bulb a blind receptacle for sperm is situated, with a single duct which opens at the end of the embolus. The receptacles have to be filled with sperm before copulation can take place. This requires the construction of a special sperm web, the ejection of the sperm into the web and its transfer into the palpi through the opening of the embolus. How such an arrangement could have originated remains a mystery. We have something similar in the case of the Ricinulei, another order of Arachnida, in which the metatarsus and tarsus of the third pair of legs in the male is modified as an organ of copulation. We find something similar, but without any structural modification, in the Solifugae, also an order of Arachnida, in which the male transfers the sperm into the genital opening of the female by means of his chelicerae. We do not know in which geological age the pedipalpi of male spiders became modified as an organ of copulation. Oligocene spiders of the Baltic amber and Tertiary spiders of the Florissant shale possess fully developed copulatory organs of the same type and as complicated as recent spiders. The Mesozoic era left a single record of a fossil spider and that so imperfect that nothing can be learned from it. The few fossil spiders from the Upper Carboniferous of Europe and Pennsylvanian of North America, as well as the still fewer fossils found in the Devonian red sandstone of Scotland, are not sufficient to determine whether at that distant age male spiders had as yet unmodified pedipalpi, or whether all available fossil specimens belong to the female sex or at most represent immature individuals. But it is clear that whatever the geological age may be when the pedipalpi became modified into organs of copulation, the change must have involved a corresponding change in sexual habits and this, in its turn, required a change in other habits. It is quite possible and even probable that previous to the development of organs of copulation on the pedipalpi, male spiders used a method of fertilization comparable to that of pseudoscorpions. The males of these small Arachnida attach a spermatophore to a stalk on the ground, grasp with the pincers of their pedipalpi the corresponding pincers of the female and drag her until her genital opening comes in contact with the spermatophore. Since spiders have no pincers on their pedipalpi, or for that matter on any other appendages, males could never grasp a female in the manner of the pseudoscorpions. But they could perhaps have used their pedipalpi to hold a drop of sperm by simple adhesion and transferred it into the genital opening of the female in the best way possible, or may have dropped sperm onto a web and pushed the female until her genital opening came in contact with it. With the development of a special copulatory apparatus in the male, the development of sperm receptacles in the female must have gone apace until the bewildering diversity and complexity of structure and habits has been reached, by which the many thousands of species of spiders are now better distinguished than by other structural characters.

**Poison.**—The third character which is found only in spiders among Arachnida is the presence of poison glands either in the basal joint of the chelicerae or in the cephalothorax and opening by means of a duct near the tip of the fang. With few exceptions the structure of the glands is the same in all spiders. It is an elongated, cylindrical sac, the walls of which have a single layer of glandular epithelial cells and an outer muscular covering composed of spirally wound, striated fibres. A structureless membrane separates the two layers and another thin membrane formed by highly flattened cells protects the outside of the gland. The flow of poison is under control of the spider. In

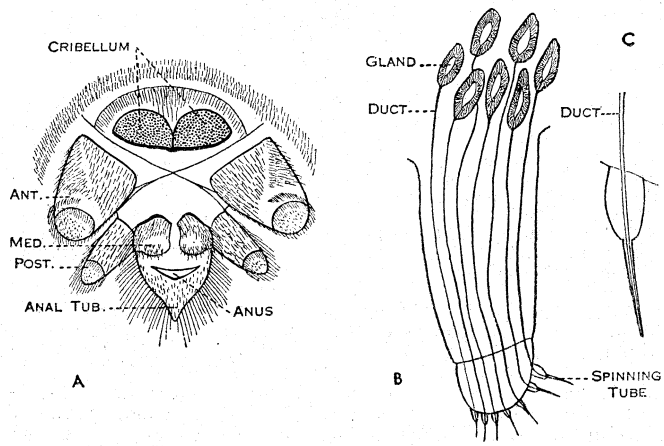

FIG. 2.—SPINNING ORGANS OF SPIDERS

fact, spiders which ensnare their prey do not use their poison, while those who hunt for their prey or hide on flowers and capture insects by grasping them with their fangs when the insects come within their reach, kill their victims with poison. All spiders, however, use their poison in self defense, when escape is impossible. Spiders of two families, Uloboridae and Heptathelidae have no poison glands.

The poison of spiders attracted early attention and was studied many times. Unfortunately, the results of most of such studies are vitiated by the application of wrong and faulty methods. Observations on the effects of bites on man and animals are of very little value even when the species of spider is known and at best may serve only as confirmatory evidence. But experiments conducted in the laboratory have also led to wrong conclusions until ways were found to get the poison in a pure state, without any admixture of other substances such as invariably happens when an entire cephalothorax is used for extraction of poison in a fluid. As now practiced, poison is obtained either by dissecting the cephalothorax and removing the glands, or still better by applying an electric current to the immobilized, live spider and collecting the pure poison as it appears in droplets at the ends of the fangs. Poison obtained in this manner may be dried, weighed and used in measured quantities and known concen-

tration. Few spiders are poisonous to man. Among these the black widow alone is dangerous in the United States, as are other closely related species in Europe, Africa, Asia and Australia. All these species belong to the genus *Latrodectus* of the family Theridiidae and their poison is neurotoxic. The only other spiders known to have a neurotoxic poison belong to the genus *Ctenus* of the family Ctenidae. A Brazilian species, *Lycosa raptoria,* causes a creeping ulceration of the skin. Some observations point to the possibility that other species belonging to various families may be poisonous to man. But the majority—even large tarantulae—are no more dangerous to man than wasps or hornets and a great many spiders do not attempt to bite even when taken in one's hand.

**Respiratory System.**—A fourth feature peculiar to spiders among other Arachnida is the presence of two types of respiratory organs in the same individual: book lungs and tracheal tubes. This peculiarity is restricted to a single suborder among the spiders, the so-called Dipneumonomorphae, but the vast majority of spiders belong to it. It seems certain that originally spiders had two pairs of book lungs and no tracheal tubes; the second pair was later replaced by tracheal tubes and finally the first pair was also replaced by tracheal tubes. Thus we have in spiders a condition unique among the Arachnida. Of late, Tasmanian spiders have been discovered in which only one pair of tracheal tubes remains.

**Digestive System.**—Several features, while not unique among Arachnida, nevertheless are of great importance in the life of spiders. The first of these has to do with the structure of their digestive system. The foregut, consisting of a pharynx, oesophagus and gizzard, is concerned only with the mechanics of ingestion. The pharynx is so structured that it acts both as a pump and a strainer, preventing coarse particles from passing into the oesophagus. The latter is merely a tube connecting the pharynx with the gizzard, but the gizzard is a second, powerful pump. The mid-gut is provided with several branched diverticles, the finest branches ending each in a little spherical ampulla and the whole lot of them held together by interstitial tissue. The mid-gut serves two purposes: it produces digestive enzymes and absorbs the fluid substances into which food is converted after the action of enzymes on its constituents. A pair of maxillary glands situated in the maxillary lobes of the pedipalpi also produce digestive enzymes. The mid-gut forms a large stercoral pouch in which excrements are stored before they are excreted through the hind-gut and anus. Now this arrangement of the digestive system, found also in other Arachnida, makes ingestion of only fluid food possible and necessitates predigestion of food outside the body. It is a mistake to think that spiders suck blood. That is the one thing they never do. Instead, they inflict a wound with their fangs, inject digestive enzymes into the wound and as the tissues of their prey become liquefied, pump the insect dry, leaving nothing but an empty, chitinous shell behind. For some reason which is not quite clear, spiders have never learned to make use of vegetal food or even to feed on dead bodies of animals. They leave in peace even live insects when the latter do not move. Spiders may be fed in captivity by little pieces of raw meat, but the latter must be attached to a thin thread and dragged or dangled in front of the spider to induce the latter to grasp it.

**Sense Organs.**—The second feature which naturally has a great influence on the entire behaviour of spiders, is the structure and function of their sense organs. Spiders belonging to different families differ greatly in this respect. Some have well developed eyes with keen vision. Such spiders have less perfectly developed tactile organs. Other spiders have eyes with much poorer vision and depend more on the perfection of their sense of touch. The latter is the best developed sense even in spiders with good eyes, while in species with poor eyes it is almost unbelievably fine and diversified. The body and legs, the pedipalpi and chelicerae and even the spinnerets of spiders are covered with numerous hairs of various kinds, some stiff and stout, others slender and pliable, some smooth, others provided with serrations. Many spiders have plumelike soft hair. Some hairs lie flat on the surface of the skin, others stand at an angle of 30° or more, some are erect. Not all are sensory hairs, but each sensory hair has its own nerve fibre which conveys impulses to the central nervous system. Especially fine, erect hairs arising from the centre of little drumlike membranes, are sensitive to slow currents of air. Such hairs are called trichobothria and their distribution has systematic value. Once the trichobothria were suspected of being capable of transmitting sound-vibrations, but this proved to be incorrect. Many spiders possess sound-producing organs, but organs of hearing have not yet been discovered, nor is it known how acute hearing is in spiders. It is probable that the range of sounds which they can perceive is quite different from the range of the human ear and presumably much higher.

Except for a few blind species, all spiders possess eyes which are on the carapace. The maximum and most common number is four pairs; but spiders with three, two, or a single pair of eyes are known. Some families have only six eyes, as for example the Dysderidae; but usually the reduction in the number of eyes occurs in different genera of the same family. The so-called anterior median eyes have always a direct retina; *i.e.*, one in which the rods face the dioptric apparatus, consisting of a glass body and a corneal lens. The other eyes have always an inverted retina and are often supplied with a tapetum of pigment cells, reflecting light and giving the eyes a pearly appearance. The disposition of the eyes is characteristic of whole families and is responsible for the diverging directions of the axes of the eyes. Convergent eyes do not occur in spiders. The respective fields of vision are determined by the shape and curvature of the lens, the acuity of vision by their diameter, the size of the image and the distance at which the image of two points falls on a single rod. Each pair of eyes forms images of a size different from that formed by the other eyes and the fields of vision are mostly quite different. Thus a fairly large portion of the horizon is covered, but only small portions are ever covered by overlapping fields of four eyes, still smaller ones by six eyes and scarcely ever by all eight eyes. The best eyes have lenses with spherical surfaces, but the acuity of vision with even the best eyes is far below that of the human eyes.

The olfactory sense is very poorly developed and apparently restricted to what one may call sexual odours. The males of some species are able to follow the invisible spoors left by a female on a smooth surface, such as a sheet of paper. But other scents are not perceived unless the substance is of a highly irritating nature.

**Behaviour.**—Spiders have a highly developed nervous system, possess memory and their reflexes may be conditioned by methods used in such experiments. But since none of the spiders developed a social state comparable to that of insects and only few species at best may be said to be gregarious, the behaviour of spiders is entirely of the type usually spoken of as instinctive. Some of these patterns of inherited behaviour appear early and persist throughout life. Others appear at the time of sexual maturity and disappear rapidly. Generally speaking, the life cycle of a spider may be pictured as follows: A spiderling, on emergence from the egg, is incapable of taking care of itself, because its digestive system is not yet fully developed. The mid-gut is filled with embryonic yolk and ingestion of food is impossible. Consequently spiderlings either stay in a web built by their mother for that purpose before she died, are guarded by their mother inside a brood-cocoon, or are carried by the mother on her back, as the case may be. Their life is restricted to slow digestion of the embryonic yolk. The completion of its digestion coincides with the completion of the digestive system itself and is accompanied by the shedding of the skin and some changes in the proportions of the body. With the mid-gut emptied, hunger sets in and the spiderlings would attack and destroy each other but for the simultaneous emergence of an inherited desire to escape. Dispersal of spiderlings may be accomplished by different methods. In some species, spiderlings simply run away in all directions. But in the majority of species aerial dispersal takes place. This so-called ballooning coincides in temperate zones with the sunny days of autumn or of spring, if the eggs remain quiescent through the winter. Each spiderling climbs to the end of a blade of grass, a twig, a pole or any protruding object, raises its abdomen and spins a thin thread of silk. As this gossamer thread is caught in the breeze, the spiderling lets go of the support on which it sat, climbs to the middle of the thread and is carried by air currents to a considerable height upward and to great distances horizontally. Gossamer threads have been encountered by aeroplanes five miles above sea level and one observer stated in a letter to the author that he saw spider threads in the stratosphere. Spiderlings have been also caught in the rigging of ships several hundred miles from shore. When other currents of air finally bring them down to the ground, the spiderlings enter upon the new phase of their life, which will last until maturity. Each spiderling follows the pattern of behaviour characteristic of the species. Some build a web, orb web, sheet web, reticular web, etc., as the case may be, others make burrows or run about on the ground among leaves, remaining vagabonds without a home. From time to time they moult, shedding the entire skin, including the corneal lens of the eyes and the lining of the fore-gut and the organs of respiration. During this period the spiders are quite helpless and cannot eat nor bite. The number of moults varies in different species and even in the same species, but the usual number is seven or eight and up to 13. Males of all species and most females never moult after maturity, only some Lycosidae and Theraphosidae do so. The usual behaviour of females is not appreciably changed when they become mature, except that sexual excitation becomes manifest and they respond to the advances of a male in a manner different from that which governs their attitude toward their prey or unwelcome intruders. Otherwise they still lead the same life, build the same type of snares, etc.

In the case of males, the entire behaviour pattern changes as soon as they mature. The filling of their palpi with sperm is now their chief concern. The males of some species use the old web for the purpose, merely adding a few threads of silk to which they attach the drop of sperm as it comes out of their genital opening. Other species weave special sperm webs, even if they have never built a web of any kind before. The pumping of the sperm takes from 45 minutes to 2 hours time. When the palpi are charged with sperm the male goes in search of a female. This is a rather hazardous undertaking, considering the fact that no female has ever seen a male in her life and that each female is familiar only with animals suitable for food or those that must be handled as enemies. Courtship is the means by which a male overcomes the hostile attitude of a female. In jumping spiders endowed with a good sense of sight, courtship consists of a love dance in the presence of a watching female, but at some distance

from her. In spiders with a less keen sense of sight, actions involving touch or smell or a combination of these two senses take precedence. Some orb weavers show a discrepancy in the time of maturation, the males maturing considerably earlier than the females. In such cases one or more males get into the web of a female and live in it until she becomes mature. In some species the male builds a tent in which he stays with the immature female, sharing food with her until she moults for the last time. Some males offer a captured insect to the female to appease her hunger. Copulation lasts but a few minutes. The palpi are used one at a time and courtship is sometimes repeated in the interim. When both receptacles of the female are filled, the relationship between her and the male reverts to that between any two spiders of the same or of opposite sex. The male being the smaller of the two and the more agile, seeks safety in escape. The female, with the sexual desire appeased and the feeling of hunger returning, treats the male as an intruder if he persists in remaining in her web or stays too close to her on the ground. But the often repeated stories that female spiders always devour their mate after copulation are based on misinterpretation of observed instances when a male was prevented from escaping and later fell victim to the hungry female. The majority of males die naturally soon after copulation, because the supply of their energy is completely spent. In captivity a male may linger for several weeks if kept alone, but he usually refuses food and dies with the abdomen showing considerable shrinkage of all tissues.

Females live longer. In some species they die soon after egg laying, but in other species they may live several years and copulate annually. To the former group belong the majority of spiders in temperate zones, to the latter the larger Lycosidae and the Theraphosidae. Some large tarantulae are known to have lived in captivity as long as 15 years.

**Enemies.**—Spiders have many enemies among vertebrates and invertebrates. Many lizards, some toads and various birds feeding on insects also eat spiders. The large *Bufo maritima* was observed greedily feeding on hairy tarantulae. Solitary wasps are perhaps the greatest enemies of spiders. Many of them depend entirely on spiders as food for their larvae. Collectors know that the easiest way of getting certain species of spiders is by examining the nests of mud daubers. Species of the genus *Pepsis* among solitary digger wasps paralize Mygalomorph spiders, bury them and lay a single egg on the abdomen of each victim. Some Hymenoptera and Diptera spend their larval life as external parasites of spiders. Nematodes of the family Mermithidae are not uncommon parasites in the body cavity of spiders. Protozoan and helminth intestinal parasites have not as yet been found, perhaps because infection is impossible on account of predigestion and filtering of food.

More than 50,000 species of spiders are known, distributed among more than 2,500 genera and many new species are discovered every year. The spider fauna of Europe is known fairly completely, that of the United States much less so.

**Palaeontology.**—Fossil spiders have already been found in the red sandstone of the Devonian. Many species have been described from the Carboniferous of Europe and America. A single species has been reported from the Mesozoic, but the Tertiary of Europe and America and particularly the Oligocene Amber of the Baltic are rich in fossil species the great majority of which are now extinct.

BIBLIOGRAPHY.—The following short list of books may be of help to the uninitiated. More or less complete bibliography published yearly will be found in the *Zoological Record*. L. **SPIELHAGEN, FRIEDRICH VON** (1829–1911), German novelist, was born at Magdeburg on Feb. 24, 1829. He was brought up at Stralsund, studying also at Berlin, Bonn and Greifswald. He became a master in a gymnasium at Leipzig, but upon his father's death in 1854 devoted himself entirely to writing. After publishing *Klara Vere* (1857) and *Auf der Düne* (1858), he obtained a striking success with *Problematische Naturen* (1860–1861). His powerful *Sturmflut* appeared in 1876. He died Feb. 25, 1911.

Spielhagen's *Sämtliche Werke* were published in 1871 in sixteen volumes, in 1878 in fourteen volumes; his *Sämtliche Romane* in 1898 (22 vols.), and these were followed by a new series in 1902. *See* his autobiography, *Finder und Erfinder* (2 vols., 1890).

**SPIKENARD** or **NARD,** a celebrated perfume which seems to have formed one of the most durable aromatic ingredients in the costly unguents used by the Romans and Eastern nations. The ointment prepared from it is mentioned in the New Testament (Mark xiv. 3–5; John xii. 3–5) as being "very costly," a pound of it being valued at more than 300 denarii (over £10). This appears to represent the prices then current for the best quality of nard, since Pliny (*H.N.* xii. 26) mentions that nard spikes reached as much as 100 denarii per lb. The source of the true or Indian nard is now identified as *Nardostachys jatamansi,* a plant of the family Valerianaceae, the fibrous root-stocks or "spikes" of which are still collected in Bhotan and Nepal.

The great spikenard of the United States is *Aralia racemosa,* and another species of the same genus, *A. nudicaulis,* or wild sarsaparilla, is known as "wild spikenard." In the West Indies *Hyptis suaveolens* is called "spikenard," and in Great Britain the name "ploughman's spikenard" is given to *Inula squarrosa* (*I. conyza*).

**SPILITE,** in petrology, a rock of basaltic character, but possessing in place of the normal labradorite, a felspar of the composition of albite. The ferromagnesian mineral is an augite of pale brown colour; spilites are, however, usually very completely decomposed, augite being represented by chlorite and calcite. They are commonly vesicular or variolitic and show wonderfuly preserved pillow structure, a feature in most cases indicative of a submarine origin of the lavas. The individual pillows are filled with concentric zones of vesicles filled with chlorite and calcite. The formation of pillow structure in volcanic rocks has been directly observed by Dr. Tempest Anderson in the case of the lava poured into the sea from the volcano Matavanu, in Samoa. On the surface of the lava, buds form and expand, giving rise to "pillows" with a glassy crust. The interspaces between the pillows are frequently filled with sediment representing the soft ooze of the sea floor. Not all pillow lavas are spilitic in character.

Some spilites showing pillow structure are not strictly lavas but shallow intrusions into unconsolidated submarine ooze. Excellent examples of such intrusive spilites are provided by the Devonian spilites of Nundle, New South Wales. Though the term spilite was first used by Brongniart for altered basic lavas free from phenocrysts and possessing well marked vesicular textures, a new significance was given to the term by Dewey and Flett, who urged that a special group of rocks—the spilitic suite—should be recognized. According to these authors, a large suite of igneous rocks is genetically associated with the spilites. Their composition varies widely, but they all have some characters in common. They possess a high percentage of soda and are usually extensively altered. These rocks are albite-dolerites, minverites, picrites, keratophyres, soda-felsites and soda-granites. The spilitic suite was originally given a status comparable with that of the alkaline and calc-alkaline suites. The spilitic series is regarded as peculiar to districts that have undergone a long continued and gentle subsidence with few or slight upward movements and no important faulting. The lavas are poured out on the margins of geosynclines while their common sedimentary associates are black shales, limestones and radiolarian cherts. As geosynclines are the centres of subsequent fold movements many ancient spilites have become extensively folded and metamorphosed with production of new minerals, including albite of metamorphic origin. Eruptions having the spilitic facies have occurred repeatedly over a wide area and on a large scale. The analyses of average basalt and spilite are as follows:

| | $SiO_2$ | $Al_2O_3$ | $Fe_2O_3$ | FeO | MgO | CaO | $Na_2O$ | $K_2O$ | $H_2O(+)$ | $TiO_2$ | $CO_2$ |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Average basalt | 49·06 | 15·70 | 5·38 | 6·37 | 6·17 | 8·95 | 3·11 | 1·52 | 1·62 | 1·36 | .. |
| Average spilite | 46·01 | 15·21 | 1·35 | 8·69 | 4·18 | 8·64 | 4·97 | 0·34 | 2·48 | 2·21 | 4·98 |

(C. E. T.)

**SPINA,** an ancient city of Gallia Cispadana, Italy, between Ravenna and the mouths of the Po. In Etruscan times it was the

principal port of Felsina. (*See* BONONIA.) Near Comacchio, in the draining of the lagoon of Valle Trebba, a very extensive necropolis has been found and some 450 tombs have been excavated, ranging from the 6th to the 3rd century B.C. They contained fine Greek, Italic and Etruscan vases.

**SPINACH** (*Spinacia oleracea*) (family Chenopodiaceae), a hardy annual of Asiatic origin, long cultivated for its succulent leaves for use as a pot-herb. When sown in the fall at the proper time it will survive winter temperatures occasionally near 0° F.; when so grown it behaves as a biennial. The prolific rosette of leaves that first develops is harvested in entirety before the appearance of the seed stalks which develop rapidly to 1 to 3 ft. during warm, long days. The plant is sensitive to day length, and temperature; cool weather or short days are conducive to luxurious rosette development and retardation of seed stalk formation; hot weather or long days induce seed stalk formation. Male and female flowers are generally borne on separate plants, the male flowers in terminal spikes and the female flowers (and fruits) in the axils of the branches and leaves. The so-called "seed" is a fruit consisting of a compressed seed together with the surrounding calyx lobes that may be either smooth or prickly.

Spinach can be grown as a summer crop only in distinctly cool climates. It requires very rich, well-watered, well-limed soil. In the United States it is grown very extensively as a fall, winter, or spring crop with plantings to coincide with suitable temperatures. In gardens it is sown thinly in rows 8 to 18 in. apart and the plants thinned to stand 3 to 4 in. apart. In many large fields it is sown in rows 8 in. apart, or even broadcast, and given no thinning or cultivation. Artificial protection is rarely given during winter.

Spinach culture in the United States received an enormous impetus about 1920 when attention was called to its relatively high content of calcium and iron, and further impetus when its relatively high content of vitamins A and C were emphasized. The later discovery of large quantities of oxalates in the plant has cast some doubt upon its true dietary value, but it continues to be a most popular pot-herb. Its culture increased from about 6,000 ac. in 1918 to over 197,000 ac. in 1937, after which it gradually declined to about 75,000 ac. in 1941.

**New Zealand Spinach** (*Tetragonia expansa*) (family Mesembryaceae), a tender annual, native to New Zealand, produces "greens" similar to spinach, when cooked. It is a much-branched, spreading plant 1 to 2 ft. high, with fleshy, triangular leaves and inconspicuous, yellow-green, axillary flowers. The "seed" is a nut-like fruit containing one to two seeds that often germinate very slowly. The plant is frost-tender and heat tolerant, furnishing "greens" at a season when other pot-herbs do not thrive in warm regions. It is sown in rows 2 to 3 ft. apart, with the plants about 1 ft. apart in the rows. The leafy tips of the branches are harvested repeatedly as new growth develops.

**Mountain Spinach or Orach** (*Atriplex hortensis*) (family Chenopodiaceae), of Asiatic origin, is a coarse, hardy annual growing to a height of 6 ft. The leaves are large, triangular-ovate or arrow-shaped, with toothed or wavy margins and colour varying from pale yellow-green to dark red. The leaves are used as a pot-herb, but the plant is of little interest to European or American gardeners except in regions not suited to the culture of the commoner leafy vegetables, as the Great Plains of the United States. (V. R. B.)

**SPINAL COLUMN, SURGERY OF.** Most operations on the vertebral column are designed to relieve some condition of the enclosed spinal cord. The essentially degenerative diseases (tabes dorsalis, disseminated sclerosis, etc.) offer little scope for surgery, which finds its richest field in cases of cord compression. Spina bifida, a congenital defect in development, calls for operation in selected cases only, for most sufferers from this condition die during the first weeks or months of life. There is one fundamental fact which we must grasp if we wish to understand the possibilities of spinal surgery: that regeneration is impossible, so that once the cord, and the long conduction tracts of which it is composed, suffers actual anatomical damage, that damage is permanent and cannot be undone.

**Spinal Injuries.**—These are generally due to indirect violence, the fracture occurring at a point distant from that at which the force was applied. Thus most injuries of the cervical spine (neck) are due to injuries applied to the head, while forcible flexion of the trunk by a weight falling on the shoulders (the common mechanism in pit accidents from a fall of "roof" or "dirt") causes a fracture at the first lumbar vertebra. The 24 bones which make up the cervical, thoracic and lumbar spine are not equally prone to injury; the three predominant sites where fractures or dislocations occur are at the points where the qualities and range of movement change—at the second cervical, where the compound movements of the head change over into the ordinary movements of the neck, at the disc between the fifth and sixth cervical where the cervical mobility changes into the relative fixity of the chest, and at the first lumbar where the latter joins the rod-like lumbar portion. The bodies of the vertebrae can be compressed or broken without injury to the spinal cord (so-called "Kümmells' disease") provided there is no sliding of the broken parts on one another. A fact which colours our whole attitude towards spinal injury to-day is that when the cord is damaged the lesion is inflicted at the moment of injury. The old teaching was that the cord was being compressed by bone fragments and hence early operation was advised. To-day we treat these cases with conservatism, reduce fractures by manipulation, and operate only when deterioration is setting in or pain is severe. But operation is never done as an immediate urgency. X-Rays are of the greatest help. In summary, the cord lesion associated with most injuries is central haemorrhage or actual laceration, and operation will not often be of service in the worst cases.

**Spinal Tumours.**—Once the diagnosis is reasonably certain it is best to operate early, for these growths are commonly (Elsberg gives 82%) outside the cord and can be dislodged by laminectomy. An incision is made over the spinous processes, the laminae are exposed by clearing the muscles with a rongeur and some three of them are removed. The dura mater is incised, if the tumour has not already been found outside. The results in many cases are dramatic and the palsied may indeed be made to walk upright. When the tumour lies in the cord tissue, nothing of great service can be achieved. Deep X-Ray therapy is the only hope for such conditions, but only a few successes have so far been recorded. Little noticeable weakness follows a laminectomy *per se*.

**Spinal Caries.**—Tuberculosis of the vertebral column is commonest in the very young, and gives good results by fixation on frames or in plaster jackets. Long periods of recumbency (1–3 years) are generally required. In order to render sufferers ambulant at an earlier time, bone-grafting operations have been devised. Albee advised this so-called "internal splinting" and recommended that a long thick graft should be taken from the tibia and inserted into a bed prepared for it over the bared spinous processes and laminae at the region affected, including two healthy vertebrae above and below. Hibbs later introduced the operation of "spinal fusion"; in this no new bone is implanted but the spinous processes and laminae are split and turned up and down to produce a mass of bone which will lock the bones together. The operations are most useful in persons of less tender years than are the majority of sufferers from Pott's disease. In Great Britain and Europe generally, excellent results are obtained by less drastic means, but in those who cannot afford a long convalescence these operations should be considered.

Sometimes a tuberculous abscess forms within the neural canal, extends backwards from the diseased vertebrae, and presses on the cord. Happily most of these patients recover the function of their limbs when perfectly immobilized; laminectomy does not give the good results which one might theoretically expect from it.

**Pain.**—Much can be done for sufferers from agonizing pain by judicious spinal surgery. The chief indications for operation are neuralgia of the body or limbs, often the sequelae of amputations or of herpes zoster, the agonizing pains of spinal syphilis, and hopeless malignant growths. The usual operation heretofore has been section of posterior nerve roots just before they enter the spinal cord. The exposure is the same as for spinal tumours. The results of root sections have been inconsistent, and the operation is being replaced by section of the pain-carrying fibres in the cord itself (Spiller). This tract is the anterior spino-thalamic and lies just sufficiently far away from the motor pathway to the limbs (pyramidal tract) for its division to be effected without inflicting paralysis on the sufferer. As the pain fibres cross in the cord, the tract of the opposite side to that on which the pain is felt is the one to be cut, and of course at a point cephalad to the site of the pain. A cut 2.5 to 3.0 mm. deep is made into the anterolateral aspect of the cord. A very fine and sharp knife is required and the operation must be most delicately and precisely performed. Brilliant results have generally followed, but it is too early to say what the late effects are.

**Spinal Puncture.**—No account of modern spinal surgery can omit some reference to the extended usefulness which is being made of lumbar puncture (puncture into the subarachnoid space and withdrawal of a specimen of cerebrospinal fluid). Our knowledge of the changing chemistry of that fluid in disease conditions is still growing. When a tumour or the like grows in relation to the spinal cord it causes a block in the subarachnoid space, either by its own bulk or by compressing the membranes against one another should it be extradural. The cerebrospinal fluid distal (caudal) to the obstruction is dammed back, for it is chiefly absorbed within the skull and thither it can not now return. A rise in albuminous content and a yellow tinge, xanthochromatosis (Froin's syndrome), are the results. This is of great diagnostic importance. Queckenstedt's test also makes use of the block, for when a normal person's jugular veins are compressed the consequent rise of intracranial venous pressure is transmitted to the cerebrospinal fluid as a whole and can be measured by a manometer attached to a lumbar-puncture needle. If a tumour blocks the spinal canal the manometer records no change or modified changes only. This is most valuable in differentiating between the degenerative and compression groups of paralysis of the lower limbs. Lastly, Lipiodol, a heavy, opaque substance which when introduced into the cerebrospinal fluid above the tumour sinks down through it to rest on the tumour, is proving most useful. It is a 40% solution of inert iodine in poppy-seed oil and is quite opaque to X-Rays so that the precise position and often the shape of the upper end of the tumour becomes definitely recognizable.

**SPINAL CORD,** in anatomy, that part of the central nervous system in man which lies in the spinal canal formed by the vertebrae, and reaches from the foramen magnum to the lower margin of the first lumbar vertebra. It is about 18in. long, and only occupies the upper two-thirds of the spinal canal. The cord is protected by the same three membranes which surround the brain. Outside is the *dura mater,* which differs from that of the brain in not forming a periosteum to the bones, in sending no processes inward, and in having no blood sinuses enclosed within its walls; it is the continuation of only the inner layer of the dura mater of the skull. Inside the dura mater is the *arachnoid,* which is delicate and transparent, while between the two lies the *sub-dural space,* which reaches down to the second or third sacral vertebra. The *pia mater* is the innermost covering, and is closely applied to the surface of the cord into the substance of which it sends processes. Between it and the arachnoid is the *sub-arachnoid space,* which contains the cerebro-spinal fluid. Across this space, on each side of the cord, run a series of processes of the pia mater arranged like the teeth of a saw; by their apices they are attached to the dura mater, while their bases are continuous with the pia mater surrounding the cord. These ligaments, each consisting of twenty-one teeth, are the *ligamenta denticulata,* and by them the spinal cord is moored in the middle of the cerebro-spinal fluid.

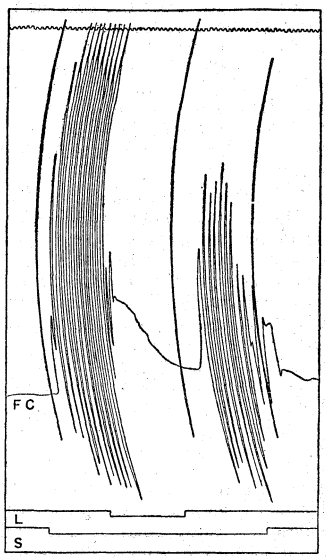

FIG. 1.—SPINAL CORD, SHOWING TRACINGS OF ANTAGONISTIC REFLEXES

The spinal cord itself is a cylinder slightly flattened from before backward. In the cervical region it is enlarged where the nerves forming the *brachial plexus* come off, while opposite the lower thoracic vertebrae the lumbar enlargement marks the region whence the lumbo-sacral nerves are derived. (*See* fig. 2.) Opposite the second lumbar vertebra the cylindrical cord becomes pointed and forms the *conus medullaris,* from the apex of which a glistening membranous thread runs down among the nerves which form the *cauda equina,* and, after blending with the termination of the dural sheath, is attached to the back of the coccyx.

**Details of Structure.**—In a transverse section of the cord (*see* fig. 3) two median fissures are seen; the antero-median is wide, and reaches about a third of the way along the antero-posterior diameter of the cord; it is lined by the pia mater and, in front, lies the single anterior spinal artery.

The postero-median fissure is much deeper and narrower, and has no reflection of the pia mater into it. Where the posterior nerve roots emerge is a depression which is called the *postero-lateral fissure,* while between this and the postero-median a slight groove is seen in the cervical region, the paramedian fissure (*see* also fig. 2). The anterior nerve roots do not emerge from a definite fissure.

The spinal cord, like the brain, consists of grey and white matter, but, as there is here no representative of the cortical grey matter of the brain, the white matter entirely surrounds the grey. In section the grey matter has the form of an H, the cross bar forming the grey *commissure.* In the middle of this the *central canal* can just be made out by the naked eye (*see* fig. 4). The anterior limbs of the H form the *anterior* or *ventral cornua,* while the posterior, which in the greater part of the cord are longer and thinner, are the *posterior* or *dorsal cornua.* At the tips of the latter is a lighter-coloured cap known as the *substantia gelatinosa Rolandi.* On each side of the H is a slighter projection, the *lateral cornu,* best marked in the thoracic region (*see* fig. 4).

The grey matter has different appearances in different regions of the cord, and in the cervical and lumbar enlargements, where the nerves to the limbs come off, the anterior horns are broadened (*see* fig. 4).

Histologically the grey matter is made up of neuroglia, medullated and non-medullated nerve fibres, and nerve cells (*see* NERVOUS SYSTEM). The nerve cells are arranged in three main columns, ventral, intermedio-lateral and posterior vesicular. The *ventral cell column* has the longest cells, and these are again subdivided into antero-mesial, antero-lateral, postero-lateral and central groups. The *intermedio-lateral cell column* is found in the lateral horn of the thoracic region.

The *posterior vesicular* or *Clarke's column* is also largely confined to the thoracic region, and lies in the mesial part of the posterior cornu. It is the place to which the sensory fibres of the sympathetic system (visceral afferents) run. The white matter, as has been shown, surrounds the grey and passes across the middle line to form the *white commissure,* which lies in front of the grey. It is composed of neuroglia and medullated nerve fibres, which are arranged in definite tracts, although in a section of a healthy cord these tracts cannot be distinguished even with the microscope. They have been and are still being gradually mapped out by pathologists, physiologists and embryologists.

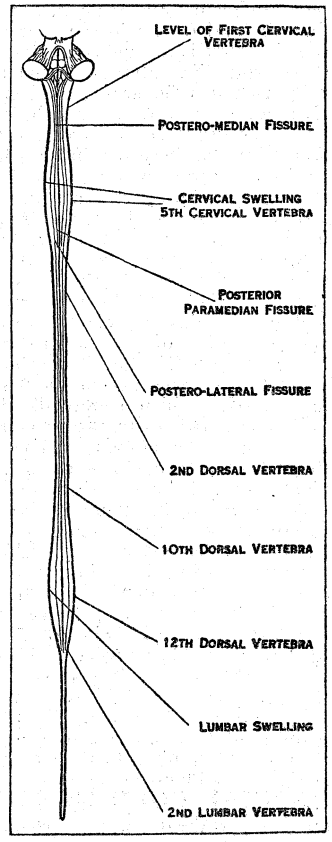

FIG. 2.—DIAGRAM OF DORSAL ASPECT OF SPINAL CORD, SHOWING CERVICAL AND LUMBAR SWELLINGS

A sensory nerve on passing into the cord (fig. 3) through the posterior nerve root lies close to the mesial side of the posterior horn of grey matter, where most of it runs upward. The next root higher up takes the same position and pushes the former one toward the middle line, so that the lower nerve fibres occupy an area close to the postero-median fissure known as the *tract of Goll,* while the higher lie more externally in the *tract of Burdach.* The greater part of each nerve sooner or later enters the grey matter and comes into close relation with the cells of Clarke's column, but some fibres run right up to the nucleus gracilis and cuneatus in the medulla (*see* BRAIN), while a few turn down and form a descending tract, which, in the upper part of the cord, is situated in the inner part of the tract of Burdach and is known as the *comma tract,* but lower down gradually shifts quite close to the postero-median fissure and forms the oval area of Flechsig. It will be obvious that both these tracts could not be seen in the same section, and that fig. 3 is only a diagrammatic outline of their position.

A few fibres of each sensory nerve ascend in a small area known as *Lissauer's tract* on the outer side of the posterior nerve roots, and eventually enter the substantia gelatinosa.

To the outer side of Lissauer's tract and lying close to the lateral surface of the cord is the *direct cerebellar tract,* the fibres of which ascend from the cells of Clarke's column to the cerebellum. As Clarke's column is only well developed in the thoracic region this tract obviously cannot go much lower.

In front of the last and also close to the lateral surface of the cord is another ascending tract, the *tract of Gowers,* or, as it is

sometimes called, the lateral sensory fasciculus. It probably begins in the cells of the posterior horn, and runs up to join the fillet and also to reach the cerebellum through the superior cerebellar peduncle. The *crossed pyramidal tract* lies internal to the direct cerebellar tract, between it and the posterior cornu. It is the great motor tract by which the fibres coming from the Rolandic area of the cerebral cortex are brought into touch with the motor cells in

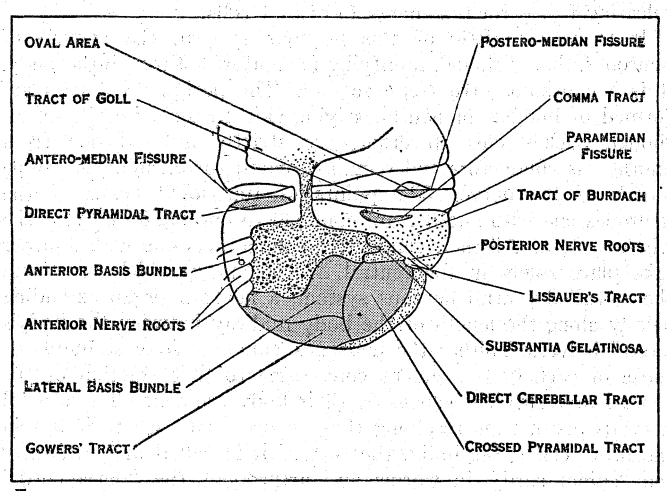

FIG. 3.—TRANSVERSE SECTION OF CORD SHOWING TWO MEDIAN FISSURES AND SCHEMATIC ARRANGEMENT OF COLUMNS OF FIBRES IN THE WHITE MATTER OF ONE HALF

the anterior cornu of the opposite side. This tract extends right down to the fourth sacral nerve.

In front of the crossed pyramidal tract is the lateral basis bundle, which probably consists of association fibres linking up different segments of the cord.

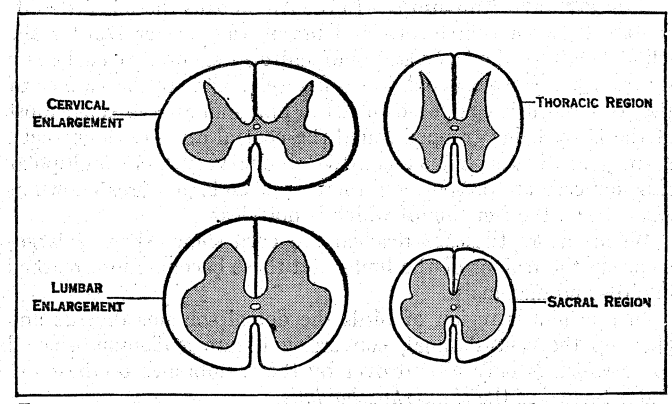
The *anterior basis bundle* lies in front and on the mesial side of the anterior cornu, and through it pass the anterior nerve roots. Like the lateral bundle it consists chiefly of association fibres, but it is continued up into the medulla as the posterior longitudinal bundle to the optic nuclei.

The *direct pyramidal tract* is a small bundle of the motor fibres from the Rolandic area, which, instead of crossing to the other side at the decussation of the pyramids in the medulla, runs down by the side of the antero-median fissure. Its fibres, however, keep on gradually crossing to the opposite side through the anterior white commissure of the cord, and by the time the mid-thoracic region is reached it has usually disappeared.

The roots of the spinal nerves in the upper part of the canal rise from the cord nearly opposite the points at which they emerge between the vertebrae, but the farther one passes down the higher the origin of each root becomes above its point of emergence. Consequently the lumbar and sacral nerves run a long way down from the lumbar enlargement to their spinal foramina and are enclosed in the dural and arachnoid sheaths to form a mass like a horse's tail, which is therefore known as the *cauda equina.*

**Embryology.**—The early development of the neural tube from the ectoderm is outlined in the article on the BRAIN. When the neural groove becomes a tube it is oval in section with a very large laterally compressed central canal (*see* fig. 5). The original ectodermal cells elongate and, radiating outward from the canal, are now known as spongioblasts, while the inner ends of some of them bear cilia and so the canal becomes ciliated. A number of round cells, known as germinal cells, now appear close to the central canal, except at the thin mid-dorsal and mid-ventral laminae (roof-plate and floor-plate). From the division of these the primitive nerve cells or neuroblasts are formed and these later on migrate from the region of the canal and shoot out long processes—the axons. The permanent central canal of the cord was formerly said only to represent the ventral end of the large embryonic canal, the dorsal part being converted into a slit by the gradual closing in of its lateral walls, thus forming the postero-median fissure. A. Robinson, however, does not believe that the posterior fissure is any remnant of the central canal (*Studies in Anatomy,* Owens College, 1891). Probably the fissure is formed partly by an infolding and partly from the original central canal. The antero-median fissure is caused by the ventral part of the cord growing on each side, but not in the mid-line where no germinal cells are.

The anterior nerve roots are formed by the axons of the neuroblasts in the developing anterior cornua, but the posterior grow



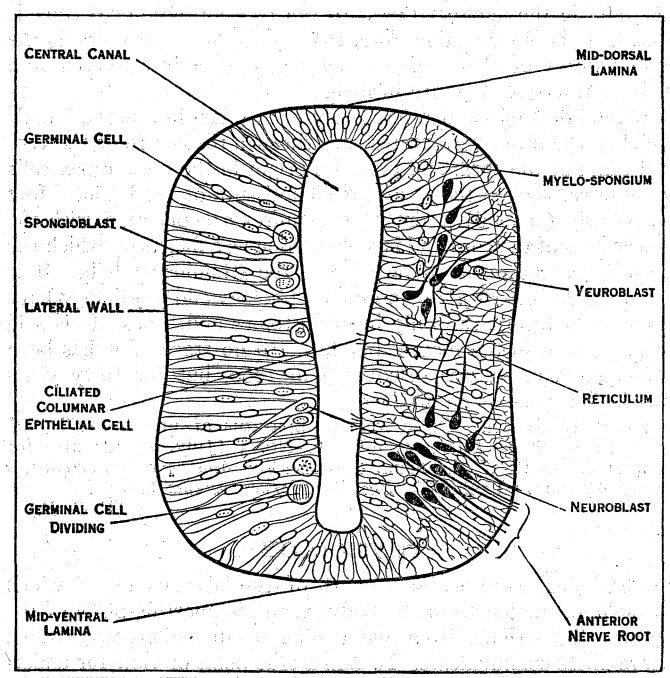


FIG. 4.—SECTIONS OF SPINAL CORD AT DIFFERENT LEVELS (2 X NAT. SIZE)

into the cord from the posterior root ganglia (*see* NERVE: *Spinal*), and, as they grow, form the columns of Goll and Burdach.

In the embryo up to the fifth month there is little difference in the appearance of the grey and white matter of the cord, but at that time the fibres in the columns of Burdach acquire their medullary sheaths or white substance of Schwann, the fatty matter of which is probably abstracted from the blood. Very soon after these the basis bundles myelenate and then, in the sixth month, the columns of Goll. Next follow the direct cerebellar

FIG. 5.—SCHEMATIC REPRESENTATION OF TRANSVERSE SECTION THROUGH EARLY NEURAL TUBE (YOUNG), SHOWING AN EARLIER STAGE ON THE LEFT SIDE THAN ON THE RIGHT

tracts and, in the latter half of the eighth month the tracts of Gowers, while the fibres of the pyramidal and Lissauer's tracts do not gain their medullary sheaths until just before or after birth. At first the spinal cord extends as far as the last mesodermal somite, but neuroblasts are only formed as far as the first coccygeal somite, so that behind that the cord is non-nervous and degenerates later into the filum terminale. After the fourth month the nervous portion grows more slowly than the rest of the body

and so the long cauda equina and filum terminale are produced. At birth the lower limit of the cord is opposite the third lumbar vertebra, but in post-natal development it recedes still farther to the lower level of the first.

For further details *see* standard text books, *e.g.,* Quain's *Anatomy* and J. P. McMurrich, *Development of the Human Body* (1906).

**Comparative Anatomy.**—In the Amphioxus there is little difference between spinal cord and brain; the former reaches the whole length of the body and is of uniform calibre. It encloses a central canal from which a dorsal fissure extends to the surface of the cord and it is composed of nerve fibres and nerve cells; most of the latter being grouped round the central canal or neurocoele, as they are in the human embryo. Some very large multipolar ganglion cells are present, and there are also large fibres known as *giant fibres,* the function of which is not clear.

When the reptiles are reached the cord shows slight enlargements in the regions of the limbs and these become more marked in birds and mammals.

In the lumbar region of birds the dorsal columns diverge and open up the central canal, converting it into a diamond-shaped space which is only roofed over by the membranes of the cord, and is known as the *sinus rhomboidalis.*

In all these lower vertebrates except the Anura (frogs and toads), the cord fills the whole length of the spinal canal, but in the higher mammals (Primates, Chiroptera and Insectivora) it grows less rapidly, and so the posterior part of the canal contains the cauda equina within its sheath of dura mater. In mammals below the anthropoid apes there are no direct pyramidal tracts in the cord, since the decussation of the pyramids in the medulla is complete. Moreover, the crossed tracts vary very much in their proportional size to the rest of the cord in different animals. In man, for example, they form 11·87% of the total cross area of the cord, in the cat 7·76%, in the rabbit 5·3%, in the guinea-pig 3%, and in the mouse 1·14%. In the frog no pyramidal tract is found. It is obvious, therefore, that in the lower vertebrates the motor fibres of the cord are not so completely gathered into definite tracts as they are in man.

A good deal of interest has lately been taken in a nerve bundle which in the lower vertebrates runs through the centre of the central canal of the cord, and takes its origin in the optic reflex cells in close relation to the posterior commissure of the brain. More posteriorly (caudad) it probably acquires a connection with the motor cells of the cord and is looked upon as a means by which the muscles can be made to respond to the stimulus of light. It is known as *Reissner's fibre,* and its morphology and physiology have been studied most carefully in cyclostomes and fishes. It is said to be present in the mouse, but hitherto no trace of it has been found in man. It was discovered in 1860, but for forty years was looked upon as an artifact.

## PHYSIOLOGY

The spinal cord is but a part of the nervous organ which throughout the length of the body forms the meeting-place of the nerve-paths arriving from and issuing to all regions with which nerve fibres communicate. To gain a true point of view for understanding the working of the spinal cord one must refer to the general function of the nervous system in the bodily economy.

**Relation to General Nervous System.**—An animal of microscopic size may continue throughout its life to be constituted entirely by one single cell. Animals of larger bulk, although each begins its existence as a single cell, attain their development by the multiplication of the original single cell, so that from it there comes to be formed a coherent mass of cells very many millions in number. In these multicellular animals each of the constituent cells is a minute self-centred organism, individually born, leading its own life and destined for individual death. The corporate power of the complex animal is the sum of the powers of those manifold individual existences, its cells. Of the agencies which integrate the complex animal, one of the most potent is nervous action. A certain number of the unit cells composing the animal are specially differentiated from the rest to bind the whole together by nervous action. These specially differentiated cells are called "neurones." They constitute living threads along which waves of physico-chemical disturbance are transmitted to act as releasing forces for the energy in distant cells.

It is characteristic of this nervous system, the system of neurones, that, although ramifying far and wide through the body, it is a continuum from end to end. The peripheral nerves are formed of bundles of neurones lying side by side, but these, although packed close together, are strictly isolated one from another as conductors and remain isolated throughout the whole length of the nerve. The points of functional nexus of the neurones one with another are confined to one region only of the whole system. All their conductive connections one with another take place solely in the central nervous mass which constitute the so-called central nervous system, a nervous organ extending axially along the length of the body midway between the body's lateral halves. Thither the neurones converge in vast numbers, those of each body segment converging to that fraction of the central organ which belongs to their body segment. The central nervous organ thus receiving these neurones is, where it lies in the head, called the brain, the rest of it is called in vertebrates the "spinal cord," in worms and arthropods the "nerve-cord." The central organ not only receives neurones which converge to it from outside, but many of its own neurones thrust out their conductive arms from it as nerve fibres carrying nervous influence outwards to regulate the activity of glands and muscles. In the vertebrates the ingoing neurones for each segment and similarly the outgoing neurone fibres are collected into a segmental nerve. To the spinal cord these are each attached by two roots, one dorsal, consisting of the afferent fibres, the other ventral, consisting of the efferent fibres.

**The Reflex.**—The simplest complete reaction of the system is a reflex. There are many reflexes which are extremely complex, being built up of a number of simpler reflexes combined. A reflex is a reaction started by the environment acting as a stimulus upon some nerve which communicates the excitement to other nerves by connections with them in the central nervous organ. The excitement so generated and transmitted finally travels outward from the central organ by one or more of the efferent nerves and through these reaches muscles or glands producing in them its final effect. The muscles and glands are from this point of view termed effector organs. The reaction is therefore "reflected" from the central organ. The nerve structures which include its trajectory are spoken of as a nervous arc. The whole purpose of the central nervous organ is to bring afferent neurones into touch with efferent neurones. The whole purpose of reflex arcs is to bind one part of the organism to another part in such a way that what the environment is doing to the organism at one place may appropriately call forth or restrain movement or secretion in the muscles or glands wherever situated in the organism.

**Receptor Cells.**—There is one condition for the due performance of these reactions which is not provided by the nervous system itself. The afferent neurones are not in most cases so constituted as to be excitable themselves directly by the environment—for instance, they cannot be stimulated by light. Their amenability to the environment, their sensitization to environmental agencies, is effected by special cells adjunct to their peripheral ends. These cells form organs called *receptors.* They are delicately adapted to be stimulated by this or that particular agent and are classifiable into various species, so that each species is easily excited by a particular agent which is "adequate" for it, and is inexcitable or excitable only with difficulty by agencies of other kinds. Thus in the skin some receptors are adapted for mechanical stimuli (touch) and not for thermal stimuli, while others (cold spots, warm spots) are adapted for thermal stimuli and not for mechanical. As far as it is known each afferent neurone is connected with receptors of one species only. The receptors thus confer upon the reflex arcs selective excitability.

Each arc is thus tuned to respond to certain stimuli, while other arcs not having that kind of receptor do not respond. The receptors, therefore, while increasing the responsiveness of the organism to the environment, prevent confusion of reactions (incoordination) by limiting to particular stimuli a particular reaction.

**Proprioceptors.**—The system of neurones is thus made accessible to the play of the external world acting on the body. And in addition to those receptors which are stimulated directly by the external world, are others lying within the mass of the organism itself, which are excitable by actions occurring in the organism itself. These are called *proprioceptors*. They are distributed preponderantly in the muscles and structures functionally adjunct to muscle, such as joints, ligaments, fasciae, etc. The reactions both passive and active induced in such motor structures, reflexly by environmental stimuli, tend therefore secondarily to be followed and accompanied by reflex reactions initiated from proprioceptors.

**Conduction.**—The process by which the excitement generated in the afferent neurone travels along the reflex arc is known as *conduction*. Conduction along afferent and efferent nerves differs in some important respects from that obtaining in the nerve centre, *i.e.*, in the piece of the central nervous system connecting the afferent nerve with the efferent nerve. In a nerve-trunk the excited state set up in it by a stimulus travels along its fibres as wave-like disturbance at a speed of about 100 metres per second, and does not alter in intensity or speed in its travel. A nerve-trunk when excited at some point along its length transmits the "impulse," *i.e.*, the wave-like excited state in both directions, *i.e.*, both up and down each fibre, from the point stimulated. This is true whether the fibre is afferent or efferent. The speed of travel of the nervous impulse along the nerve-trunk is the same whether the nervous impulse is weak or intense. The nerve-trunk shows practically no delay in its response to an effective, even though weak, stimulus and its response ceases practically at once on cessation of the exciting stimulus. When excited by repeated brief stimuli the rhythm of the response corresponds closely with that of the stimuli, even when the frequency of the latter is as high as 500 per second. With momentary stimuli a response even so brief as 20 can be given by the nerve-trunk. Finally, nerve-trunk conduction is singularly resistant to fatigue, to impoverished blood supply, and to many drugs which powerfully affect reflex actions.

Through the central nervous organ the travel of the impulse exhibits departure from these features. Its intensity is liable to be altered in transit. Its time of transit is much longer than for a similar length of nerve-trunk. Its direction of transmission becomes polarized, that is, confined to one direction along the nervous path. To a strong stimulus the central reaction instead of being as brief as an impulse, may endure for a whole second or more. A stimulus not capable of evoking a response from a centre when applied once may by simple repetition become effective (*temporal summation*). It is in the *grey matter* that conduction differs in these respects from conduction in nerve-trunks. In the grey matter each afferent fibre breaks up into branching threadlets which ramify in various directions and terminate in close apposition with other neurones. The point of nexus of one neurone with another is termed the *synapse*. If synapsis occurs by contiguity and not homogeneous continuity, it is fair to suppose that at it the transmission of nervous impulses must be different from that observable in the homogeneous conducting threads of nerve fibres. The conduction must traverse something of the nature of a membrane.

**Reflex Reactions.**—When the spinal cord is severed at any point the reflex arcs of the portion of the body behind the transection are quite cut off from the rest of the nervous system in front, including the brain. The reflex reactions elicited from the thus isolated region cannot therefore be modified by the action of the higher nervous centres. In the head the local centres are overlaid by higher centres which cannot by any simple severance be separated from them. By studying, therefore, the powers of the cord behind a complete spinal transection we can obtain information as to the powers of the purely local or segmental reflex mechanisms.

The so-called "flexion-reflex" of the limb is one of the most accessible of the local reflex reactions which can thus be studied with an isolated portion of the spinal cord as its centre.

Let it be supposed that the limb observed is the hind limb. The three main joints of the limb are the hip, the knee and the ankle. Each of these joints is provided with muscles which flex or bend it, and others which extend or straighten it. It is found that the reflex throws into contraction the flexor muscles of each of these joints. It matters little which of all the various afferent nerves of the limb is stimulated, whichever of these the afferent nerve may be, the centrifugal discharge goes to practically the same muscles, namely, always to the flexors of the joints.

Not only does the reflex action not discharge motor impulses into the nerves of the extensor muscles, but if the spinal cord happens to be discharging impulses into these nerves when the reflex is evoked this discharge is suppressed or diminished (*inhibited*). In this way the latter muscles are prevented from impeding the action of the contracting flexors. This inhibition prevents other reflexes from upsetting for the time being the due action of the flexion-reflex, for it renders the muscles opposing that reflex less accessible to motor discharge through the spinal cord whatever the quarter whence incitation to that discharge may come.

A feature of this reflex is its graded intensity. A weak stimulus evokes in the flexor muscles a contraction which is weak and in the extensor muscles a relaxation which is slight. In the case of the muscle-fibre any strength of stimulus if sufficient to excite it at all excites the fibre totally and evokes its full contraction (Keith-Lucas) and this latter remains the same in amount so long as the mechanical and nutritive conditions of the fibre remain constant. Each muscle-fibre reacting on this "all-or-none" principle and each nerve-fibre similarly responding on that same principle (Kato), different amounts of contraction yielded by the muscle under different strengths of stimulation of its nerve signify differences simply in the number of muscle-fibres which the stimulus excites. In other words the weaker stimuli excite fewer of the nerve-fibres innervating the muscle. When the tension developed by the muscle, *e.g.*, against a stiff spring, reaches the maximal obtainable from it, that fact tells us that all the muscle-fibres are then in contraction; when the tension development is less than maximal some of the muscle-fibres are not in action. A stimulus to the nerve which evokes maximal tension from the muscle is one which succeeds in exciting all the nerve-fibres innervating the muscle, and any stimulus which evokes less than maximal tension is leaving some of the nerve-fibres "idle."

The tension developed by a muscle under reflex excitation falls short of its maximal tension, even when the afferent nerve is stimulated maximally. The reflex activates a proportion only of the total aggregate of the muscle's fibres, and therefore a proportion only of the spinal motor neurones innervating the muscle. But within the range of the limit imposed by the maximal number of muscle-fibres which it *can* activate, the grading of the number activated in accordance with the grading of the strength of stimulation of the afferent nerve is very delicate, much more so than in the case of the motor nerve itself. The actual fractional proportion of the muscle's total aggregate of motor units which an afferent nerve, maximally stimulated, can activate, differs from one afferent nerve to another, and for the same afferent nerve in different experiments. A subconvulsive dose of strychnine raises the size of the fraction. The threshold value of stimulus for the reflex is usually higher than for the contraction of the muscle from the motor nerve. Spinal reflex action no more regards "muscles" than does a motor centre of the cerebral cortex. Both ignore muscles as entities and have in view movements purely. A weak flexion-reflex activates a few fibres of each of the several flexor muscles of the limb. The reflex treats a complex composed from some (*i.e.*, those of similar threshold for the particular afferent nerve) motor-units of hip-flexor, of knee-flexor and of ankle-flexor as functionally more homogeneous than is the total group of fibres composing any one of these muscles alone.

Reflex inhibition has its seat in the grey matter of the spinal centre. It acts at some point in the reflex arc up-stream from

the all-or-none motor unit (motor nerve-fibre with its group of muscle-fibres). The inhibitory reflex is like the excitatory capable of very delicate grading; its effect in diminishing or precluding this or that amount of an excitatory reflex is effected entirely by regulating the number of the motor units thrown out of action or kept out of action. Intensity of contraction or of relaxation is thus in both cases a question simply of number of motor-units reacting. The reflex centre continues discharging impulses for a certain time after its exciting stimulus has ceased. This after-discharge succeeding a strong stimulus may persist even for several seconds.

**Refractory Phase.**—Besides characters common to all or many spinal reflexes certain spinal reflexes have features peculiar to themselves or exhibited by them in degrees not obvious in other reflexes. One of these features is refractory phase. The scratch-reflex exemplifies this. In the dog, cat and many other animals the hind limb often performs a rapid scratching movement, the foot being applied to the skin of the shoulder or neck as if to groom the hairy coat in that region. This movement is in the intact animal under control of the brain, and can be executed or desisted from at will. When certain of the higher centres in the brain have been destroyed, this scratching action occurs very readily and in an uncontrolled way. When the spinal cord has been severed in the neck this scratching movement of the hind limb can be elicited with regularity as a spinal reflex by merely rubbing the skin of the side of the neck or shoulder, or applying there a weak electric current to the skin. In this reflex the stimulus excites afferent nerves connected with the hairs in the skin and these convey impulses to the spinal centres in the neck or shoulder segments, and these in turn discharge impulses into nerve fibres entirely intraspinal passing backward along the cord to reach motor centres in the hind limb region. These motor centres in turn discharge centrifugal impulses into the muscles of the hind limb of the same side of the body as the shoulder which is the seat of irritation. The motor discharge is peculiar in that it causes the muscles of the hind limb to contract rhythmically at a rate of about four contractions per second, and the discharge is peculiar further in that it excites the flexor and extensor muscles of the joints alternately so that at the hip for instance the limb is alternately flexed and extended, each single phase of the movement lasting about an eighth of a second. Now this rhythmic discharge remains the same in rate whether the exciting stimulus applied to the skin be continuous or one of many various rates of repetition. Evidently at some point in the reflex arc there is a mechanism which after reacting to the impulses reaching it remains for a certain brief part of a second unresponsive, and then becomes once more for a brief period responsive, and so on. And this phasic alternation of excitability and inexcitability repeats itself throughout the continuance of the reflex. The phase of inexcitability is termed the *refractory* phase. Its seat lies in the spinal centre. A similar element almost certainly forms part of the co-ordinating mechanism for many other cyclic reflexes, including those of the stepping of the limbs, the movement of the jaw in mastication, the action of the eyelids in blinking, and perhaps the respiratory movements of the chest and larynx.

**Fatigue.**—Nerve trunks do not easily tire out under stimulation even most prolonged. Reflex actions on the other hand relatively soon tire. Some are more resistant, however, than are others. The flexion-reflex may be continued for ten minutes at a time. As a reflex tires, the muscular contraction which it causes tends to become less intense and less steady. The relatively rapid onset of fatigue in reflexes is counterbalanced by speedy recovery in repose. A long flexion-reflex, when from fatigue it has become weak, tremulous and irregular, will recommence after 30 seconds' repose with almost the same vigour and steadiness as if it had not recently been tired out.

The natural movements to which the artificially provoked reflexes seem to correspond do not demand prolonged motor activity, or when they do, demand it in rhythmic repetition with intervening pauses which allow repose.

**Reflex Postures.**—But there are certain reflexes which do persist for long periods at a time. These are reflex postures. The hind limbs of the "spinal" frog assume an attitude which is reflex, for it ceases on severance of the afferent spinal roots. This attitude is one of flexion at hip, knee and ankle, resembling the well-known natural posture of the frog as it squats when quiet in the tank. Similarly in the "decerebrate" dog or cat certain muscles, *e.g.*, the limb extensors, exhibit a persistent contraction. These tonic reflexes are related to attitudes. In the dog and cat they are exhibited by those muscles whose action antagonizes gravity in postures which are usual in the animal, thus the extensors of the knee and hip and shoulder and elbow are in tonic contraction during standing. The postural contraction is accompanied by electrical "action currents" like those of other contraction, though weak and indicative of self-smothering from the rhythms being asynchronous in the contributory fibre-groups. The postural contraction of the extensor muscles in the maintenance of the erect posture is traceable to a reflex, called the *stretch-reflex.* A stretch, *e.g.*, by a pull upon the tendon, lengthening the muscle by even so little as $\frac{1}{2}\%$, excites reflex contraction of some of its fibres. The passive stretch is a mechanical stimulus to some of the proprioceptive organs (perhaps the muscle-spindles) in the muscle. The reflex is therefore unobtainable when the afferent nerve-fibres of the muscle itself have been severed. The essential centre for the stretch-reflex is spinal, but mid-brain and cerebellar centres much reinforce it. In the erect posture the head, neck, tail and jaw would droop and the limbs fold up under their own weight and that of superincumbent parts, were not the "antigravity" muscles checked from yielding by the stretch-reflex which their own passive yield induces in themselves. Hence the reflexly maintained "standing" is a multiple stretch-reflex. Considerable latitude of actual pose is allowed to the individual parts because each muscle involved acts for itself and develops and regulates its own stretch-reflex.

Characteristic of reflex postural contraction is its continuance for long spells at a time without obvious fatigue. Attempts are uniformly unsuccessful to reproduce this feature by electrical stimulation of afferent nerves or of the muscle's motor nerve. The suggestion has therefore been made that the postural contraction of muscle is due to a different process in the muscle-fibre from that of the ordinary contraction executing movements and so easily and often studied under electrical stimulation in the laboratory. Forbes, however, has offered the satisfactory explanation that the postural contraction while the same process as that of ordinary reflex and other contraction involves usually relatively few motor units at a time and these as they fatigue, are replaced by others. The stretch which is the essential stimulus is automatically shifted to fresh motor-units so soon as those already in operation begin to yield and give out. Grafted, as it were, upon the reflex maintenance of the erect-posture are reflexes of locomotion which are also certainly spinal in essence, and essentially proprioceptive. The hind-limbs of the dog, after severance of the cord in the thoracic region, begin to step when released from the ground. Their stepping will go on sometimes quicker and sometimes slower for long periods at a time. Kinematograph analysis of this spinal stepping shows that it is identical with normal stepping except for a slight flexional yield when the limb is vertically on the ground in the normal step. Passively supported mid-flexion of knee and hip even of one hind limb alone at once causes the spinal reflex stepping to cease, in both limbs usually. The proprioceptive stimulus of the spinal stepping may therefore be the passive stretching of the hip and knee-flexor. From observations on stepping under narcosis Graham Brown regards the essential factor in "spinal" stepping to be the intrinsic activity of a "spinal stepping" centre or "centres." Certainly it is not uncommon for an extensor muscle of the limb in isolated attachment to the myograph and after its own afferent nerve fibres have been wholly destroyed and after all the other muscles of the limb have been put out of play by excision of nerve-section to start stepping on its own accord in the bulbospinal preparation. Skin stimuli, for instance, the contact of the sole with the ground, are not necessary for the reflex stepping. On the other hand the ground pressure against the toe pads and plantar cushion seems an important factor in the gallop—indeed the sudden brief

though strong and almost simultaneous extension of all four limbs in the gallop can in the spinal animal be evoked by pressure simulating the ground pressure, and when applied even to one hind foot only.

The eyeballs are eminently organs which, the gaze being a posture, employ active postures throughout the waking day. The proprioception of the neck-muscles excites from the cervical spinal cord reflex influences acting on the nerves of the eyeball muscles. An instance is: turning of the neck toward one side excites turning of the eyeballs toward the opposite side. Or again, a clockwise partial rotation of the neck round its long axis excites from the neck proprioceptor a compensatory anti-clockwise rotation of the eyeballs. These reflex postures of the eyeballs are sometimes called compensatory, because they tend to keep truly vertical the vertical of the retina despite displacements of the head by the movements of the neck.

It may be mentioned here that the spinal and the bulbospinal animal (cat) although its composite stretch-reflex enables it when placed in the erect posture to maintain that attitude, even for hours at a time, is yet not capable of assuming that posture when laid, for instance, on its side. But when the mid-brain is retained in addition to hind-brain and cord the animal has that power of righting itself. These righting reflexes are likewise postural and largely evoked by the otolith organs. Although not truly spinal reflexes their field of nervous operation overruns into the spinal cord.

**The Spinal Reflex Arcs of the Hind Limb.**—When the skin of the limb is stimulated the flexion-reflex already described is evoked. The reflex is excited by nocuous stimuli such as a prick or squeeze applied to the skin anywhere in the limb, but most easily when applied to the foot. The reflex flexion of the ipsilateral hind limb is commonly accompanied by reflex extension of the opposite hind limb.

In the dog and cat extension of the ipsilateral hind limb can, however, be excited by stimulation of the skin in three limited regions. One of these is the sole of the foot; smooth pressure between the pads excites a strong brief extension. This is called the extensor thrust. It is accompanied by a similar sudden brief extension of all three other limbs. This reflex may be related to the action of galloping, and the pressure which excites resembles that which the weight of the body bears on the pads against the ground.

The two other regions are the skin of the front of the groin supplied by the crural branch of the genito-crural nerve, and the skin just below and mesial to the buttock. These always excite the extensor muscles, not the flexors. They may be concerned with sexual acts.

**Reflexes of the Fore Limb.**—The ipsilateral reflex is flexion at shoulder, elbow and wrist. The contralateral fore limb at the same time is extended at shoulder, elbow and wrist.

**The Scratch Reflex.**—The area from which it can be excited extends from the ear to the loin. Each of these reflexes is a co-ordinate reaction. It is seen, therefore, that through the medium of the spinal cord the body behind the head has at command a certain number of reflexes and that each of these manages the skeletal musculature in a co-ordinate way. The muscles worked by these several reflexes are to a large extent common to them all. Some resemble one another in regard to their action upon a particular muscle. Some act in opposite ways upon a particular muscle. In order to follow the co-ordination effected by the spinal cord we have to turn to a certain feature in the scheme of construction of the nervous system. This feature embodies what is termed the *principle of the common path.*

**Interaction Between Reflexes.**—At the commencement of every reflex-arc is a receptive neurone extending from the receptive surface to the central nervous organ. This neurone forms the sole avenue which impulses generated at its receptive point can use whithersoever be their destination. This neurone is therefore a path exclusive to the impulses generated at its own receptive point, and other receptive points than its own cannot employ it. A single receptive point may play reflexly upon quite a number of different effector organs. It may be connected through its reflex path with many muscles and glands in many different regions. Yet all its reflex arcs spring from the one single shank or stem, *i.e.*, from the one afferent neurone which conducts from the receptive point at the periphery into the central nervous organ.

But at the termination of every reflex arc we find a final neurone, the ultimate conductive link to an effector organ (muscle or gland). This last link in the chain, *e.g.*, the motor neurone, differs obviously in one important respect from the first link of the chain. It does not subserve exclusively impulses generated at one single receptive source, but receives impulses from many receptive sources situate in many and various regions of the body. It is the *sole* path which all impulses, no matter whence they come, must travel if they are to act on the muscle fibres to which it leads.

Therefore, while the receptive neurone forms a private path exclusively serving impulses of one source only, the final or efferent neurone is, so to say, a public path *common* to impulses arising at any of many sources of reception. A receptive field, *e.g.*, an area of skin, is analysable into receptive points. One and the same effector organ stands in reflex connection not only with many individual points, but even with many various receptive *fields*. Reflexes generated in manifold sense-organs can pour their influence into one and the same muscle. Thus a limb muscle is the *terminus ad quem* of many reflex arcs arising in many various parts of the body. Its motor nerve is a path common to all the reflex arcs which reach that muscle.

Reflex arcs show, therefore, the general features that the initial neurone of each is a *private* path exclusively belonging to a single receptive point (or small group of points); and that finally the arcs embouch into a path leading to an effector organ; and that their final path is common to all receptive points wheresoever they may lie in the body, so long as they have connection with the effector organ in question. Before finally converging upon the motor neurone the arcs converge to some degree. Their private paths embouch upon *internuncial* paths common in various degrees to groups of private paths. The terminal path may, to distinguish it from internuncial common paths, be called *the final common path.* The motor nerve to a muscle is a collection of final common paths.

Certain consequences result from this arrangement. One of these is the preclusion of essential qualitative difference between nerve-impulses arising in different afferent nerves. If two conductors have a tract in common there can hardly be essential qualitative difference between their modes of conduction.

A second consequence is that each receptor being dependent for final communication with its effector organ upon a path not exclusively its own but common to it with certain other receptors, such nexus necessitates successive and not simultaneous use of the common path by various receptors using it to *different or opposed* effect.

In the simultaneous correlation of reflexes some reflexes combine harmoniously, being reactions that mutually reinforce. These may be termed *allied reflexes,* and the neutral arcs which they employ *allied arcs.* On the other hand, some reflexes, as mentioned above, are *antagonistic* one to another and incompatible. These do not mutually reinforce, but stand to each other in inhibitory relation. One of them inhibits the other.

**Allied Reflexes.**—What happens when trains of impulses, travelling by convergent afferent arcs, meet at the same "common path?" With convergent reflexes which are "allied" in the above sense, this case must be one of extremely frequent occurrence and the management of the interaction between the convergent streams of impulses must be a fundamental factor in nervous co-ordination. The afferent path A embouches upon the intraspinal motor neurones of the knee-flexor and can activate 75% of them. The afferent path B embouches also upon the motor neurones of the same muscle and can activate 75% of them. When the muscle is reflexly contracting to A with a tension 75% of that of the muscle's maximal contraction, stimulation of B is added. The contraction tension in result rises to 85% of the maximal. The inference is that for 65% of the total motor units

of the muscle the excitation from A acts upon the same motor units as would that from B. In other words 65% of the total aggregate of the motor units of the muscle are common to A and to B. The stream of impulses arriving at these common motor-units from B when A's stream is already activating them leaves their activity unchanged, failing either to increase or to diminish it. A's stream, which is engaging them, precludes B's stream from engaging them. This is termed *occlusion.* We may turn from the case of the group to that of the single individual unit. Suppose $\alpha$ to be a train of impulses reaching a central terminal of path A and impinging upon a motor-unit $\mu$ and activating it. Suppose $\beta$ similarly a train impinging by one of path B's terminals upon the same motor unit $\mu$ already activated by $\alpha$. It has been argued that the resultant response of $\mu$ to the double series of impulses impinging on it will show interference and interruption and unsteadiness from "inhibition," the impulses generated by the one train interfering with those generated by the other owing to the refractory phase following in the wake of each impulse. Experiment fails to substantiate such unsteadiness or other evidence of "interference inhibition" even when the impulse trains are each of them at 180 p. sec. Experiment in fact finds the reverse; the resultant contraction being steadier and more durable under the concurrent excitation of A and B than under either alone. An important kind of observation is the following, since it shows clearly that, against the interference view above, "occlusion" is not inhibition. An afferent A activates 50% of a given muscle's motor units. An afferent B activates a still larger percentage of the muscle's motor units. When afferent B is already activating the muscle the stimulation of A causes no outward result on the muscle, but if B's stimulus be then withdrawn A's continuing, the contraction at once falls to and remains at 50% of maximal. A's activation was occluded by B's already existent one, but there was no inhibition. A's activation was occluded throughout the large field amounting to 50% of the total aggregate of the motor units. Yet that not a single motor unit was inhibited, has been experimentally established by taking for B one of the relatively rare afferents which activate 100% of the muscle. Since B is then activating every motor unit it cannot be supposed that lack of A's effect when A is concurrently stimulated is due to inhibition of A's 50% of the motor units; for that would suppose those motor units to be at one and the same time both active and inhibited. The mutual support that the two trains yield each other in the actually observed result argues the immediate replacement of B's effect by A's when B's lapses or intermits; and *vice versa.* That this would be so is borne out by other observations. Where, during the concurrence of A and B, A's effect has been occluding B from activating, on abruptly ceasing to stimulate A, so that B remains under stimulation alone, B which has till then been ineffective owing to occlusion, at once appears as effective and without hesitation or pause replaces that of A step for step as A's after-discharge subsides. The final common path under this competition of allied arcs is comparable with a telephone line already "busy" for one subscriber and for that time "engaged" and non-available to other subscribers. The action of the principle of the final common path may be instanced in regard to "allied arcs" in the scratch-reflex as follows. If, while the scratch-reflex is being elicited from a skin point at the shoulder, a second point distant 10mm. from the other point but also in the receptive field of skin, be stimulated, the stimulation at this second point favours the reaction from the first point. This is well seen when the stimulus at each point is of subminimal intensity. The two stimuli, though each unable separately to invoke the reflex, yet do so when applied both at the same time. The "receptive field" of a reflex is really the common area of commencement of a number of allied arcs.

**Antagonistic Reflexes.**—But not all reflexes connected to one and the same common final path stand to one another in the relation of "allied reflexes." Suppose during the scratch-reflex a stimulus be applied to the foot not of the scratching side, but of the opposite side. The left leg, which is executing the scratch-reflex in response to stimulation of the *left* shoulder skin is cut short in its movement by the stimulation of the *right* foot, although the stimulus at the shoulder to provoke the scratch movement is maintained unaltered all the time. The stimulus to the right foot will temporarily interrupt a scratch-reflex, or will cut it short or will delay its onset; which it does of these depends on the time-relations of the stimuli. The inhibition of the scratch-reflex occurs sometimes when the contraction of the muscles innervated by the reflex conflicting with it is very slight. There is interference between the two reflexes and the one is inhibited by the other.

The reflex from the right foot evokes at the opposite (left) knee extension; in doing this it causes steady excitation of extensor neurones of that knee and steadily inhibits the flexor neurones. But the scratch-reflex causes rhythmic excitation of the flexor neurones. Therefore these flexor neurones in this conflict lie as a final common path under the influence of two antagonistic reflexes, one of which would excite them to rhythmical discharge four times a second, while the other would continually repress all discharge in them.

In all these forms of interference there is a competition, as it were, between the excitatory stimulus used for the one reflex and the excitatory stimulus for the other. Both stimuli are in progress together, and the one in taking effect precludes the other's taking effect as far as the final common path is concerned.

Again, if, while stimulation of the skin of the shoulder is evoking the scratch-reflex, the skin of the hind foot of the *same* side is stimulated, the scratching may be arrested. Stimulation of the skin of the hind foot by any of various stimuli that have the character of threatening the part with damage causes the leg to be flexed, drawing the foot up by steady maintained contraction of the flexors of the ankle, knee and hip. Here, therefore, there is an arc which embouches into a final path, common to it and to the scratch-reflex arc; both these arcs employ the same effector organ, namely, the knee-flexor, and employ it by the common medium of the final path FC. But though the channels for both reflexes embouch upon the same final common path, the excitatory flexor effect specific to each differs strikingly in the two cases. In the scratch-reflex the flexor effect is an intermittent effect; in the noci-ceptive flexion-reflex the flexor effect is steady and maintained. The scratch-reflex is set aside by that of the noci-ceptive arc from the homonymous foot.

The stimulation which previously sufficed to provoke the scratch-reflex is no longer effective, though it is continued all the time. But when the stimulation of the foot is discontinued the scratch-reflex returns. In that respect, although there is no enforced inactivity, there is an *interference* which is tantamount to, if not the same thing as, inhibition. Though there is no cessation of activity in the motor neurone one form of activity that was being impressed upon it is cut short and another takes its place. A stimulation of the foot too weak to cause more than a minimal reflex will often completely suffice to interrupt, or cut short, or prevent onset of, the scratch-reflex.

The kernel of the interference between the homonymous flexion-reflex and the scratch-reflex is that both employ the same final common path FC to different effect—just as in the interference between the crossed extension-reflex and the scratch-reflex. Evidently, the homonymous flexion-reflex and the crossed extension-reflex both use the same final common path FC. And they *use it to different effect.* The motor neurone to the flexor of the knee being taken as a representative of the final common path, the homonymous flexion-reflex inhibits it from discharging. Hence if, while the direct flexion-reflex is in progress, the crossed foot is stimulated, the reflex of the knee-flexor is inhibited. The crossed extension reflex therefore inhibits not only the scratch-reflex, but also the homonymous flexion-reflex.

Further, in all these interferences between reflexes the direction taken by the inhibition is reversible. Thus, the scratch-reflex is not only liable to be inhibited by, but is itself able to inhibit either the homonymous flexion-reflex or the crossed extension-reflex; the homonymous flexion-reflex is not only capable of being inhibited by the crossed extension-reflex, but conversely in its turn can inhibit the crossed extension-reflex. These interferences are therefore reversible in direction. Certain conditions

determine which reflex among two or more competing ones shall obtain mastery over the final common path and thus obtain expression.

As to the intimate nature of the mechanism which thus, by summation or by interference, gives co-ordination where neurones converge upon a common path, it is difficult to surmise. In the central nervous system of vertebrates, afferent neurones A and B in their convergence toward and impingement upon another neurone Z, towards which they conduct, do not make any lateral connection directly one with the other—at least, there seems no clear evidence that they do. It seems, then, that the only structural link between A and B is neurone Z itself. Z itself should therefore be the field of coalition of A and B if they transmit "allied" reflexes.

**Factors Determining the Sequence.**—The formation of a common path from tributary converging afferent arcs is important because it gives a co-ordinate mechanism. There the dominant action of one afferent arc, or set of allied arcs in condominium, is subject to supersession by another afferent arc, or set of allied arcs, and the supersession normally occurs without intercurrent confusion.

Whatever be the nature of the physiological process occurring between the competing reflexes for dominance over the common path, the issue of their competition, namely, the determination of which one of the competing arcs shall for the time being reign over the common path, is largely conditioned by four factors. These are spinal induction, relative fatigue, relative intensity of stimulus, and the functional species of the reflex.

1. Induction occurs in two forms, one of which has been named *immediate induction.* The stimulus which excites a reflex tends by central spread to facilitate and lower the threshold for reflexes allied to that which it particularly excites. A constellation of reflexes thus tends to be formed which reinforce each other, so that a reflex figure results. If the prepotent stimulus shifts, allied arcs are by the induction particularly prepared to be responsive to it or to a similar stimulus.

Immediate induction only occurs between allied reflexes. Its tendency in the competition between afferent arcs is to fortify the reflex just established, or, if transition occur, to favour transition to an allied reflex. Immediate induction seems to obtain with highest intensity at the outset of a reflex, or at least near its commencement.

The other form of spinal induction is *successive induction.* It is in several ways the reverse of the preceding. If the crossed-extension reflex of the limb of the "spinal" dog be elicited at regular intervals, say once a minute, by a carefully adjusted electrical stimulus of defined duration and intensity, the resulting reflex movements are repeated each time with much constancy of character, amplitude and duration. If in one of the intervals a strong prolonged (*e.g.*, 30″) flexion-reflex is reduced from the limb yielding the extensor-reflex movement, the latter reflex is found intensified after the intercurrent flexion-reflex. The intercalated flexion-reflex lowers the threshold for the aftercoming extension-reflexes, and especially increases their after-discharge. This effect may endure, progressively diminishing, through four or five minutes, as tested by the extensor reflexes at successive intervals. Now, as we have seen, *during* the flexion-reflex the extensor arcs were inhibited: *after* the flexion-reflex these arcs are in this case evidently in a phase of exalted excitability. The phenomenon presents obvious analogy to visual contrast. The exaltation after-effect may ensue with such intensity that simple discontinuance of the stimulus maintaining one reflex is immediately followed by "spontaneous" appearance of the antagonistic reflex.

The so-called "mark-time" reflex of the "spinal" dog is an alternating stepping movement of the hind limbs which occurs on holding the animal up so that its limbs hang pendent. It can be inhibited by stimulating the skin of the tail. On cessation of that stimulus the stepping movement sets in more vigorously and at quicker rate than before. This after-increase might be explicable in either of two ways. It might be due to the mere repose of the reflex centre, the repose so recruiting the centre as to strengthen its subsequent action. But a similar period of repose obtained by simply supporting one limb—which causes cessation of the reflex in both limbs, the stimulus being stretch of the hip-flexors under gravity—is not followed by after-increase of the reflex, or the after-increase might result from the inhibition being followed by a rebound to superactivity. This latter seems to be the case. The after-increase occurs even when both hind limbs are passively lifted from below during the whole duration of the inhibitory stimulus applied to the tail. And the reflex inhibition of the knee-extensor by stimulation of the central end of its own nerve is followed by marked rebound to superactivity of the extensor itself. Again, the knee jerk, after being inhibited by stimulation of the hamstring nerve, is more brisk than before the inhibition.

By virtue of this spinal contrast, therefore, the extension-reflex predisposes to and may actually induce a flexion-reflex, and conversely the flexion-reflex predisposes to and may actually induce an extension-reflex. This process is qualified to play a part in linking reflexes together in alternating sequence.

Much of the reflex action of the limb that can be studied in the "spinal" dog bears the character of locomotion. This has been shown recently with particular clearness by the observations of Phillipson. In the stepping of the limb the flexion that raises the foot and carries it clear of the ground prepares the antagonistic arcs of extension, and, so to say, sensitizes them to respond later in their turn by the supporting and propulsive extension of the limb necessary for progression. The reflex "stepping" of the "spinal" dog proceeds without an *external* skin stimulus: it will continue when the dog is held in the air. The cat walks well when all four feet are anaesthetized.

A reflex movement must generate in its progress a number of further stimuli and throw up a shower of centripetal impulses from the moving muscles and joints into the spinal cord. Squeezing of muscles and stimulation of their afferent nerves and those of joints, etc., elicit reflexes. The primary reflex movement might be expected, therefore, of itself to initiate further reflex movement, and that secondarily to initiate further still, and so on. Yet on cessation of the external stimulus to the foot in the flexion-reflex the whole reflex comes usually at once to an end. The scratch-reflex, even when violently provoked, ceases usually within two seconds of the discontinuance of the external stimulus that provoked it. We have as yet no satisfactory explanation of this.

2. Another condition influencing the issue of competition between reflexes of different sources for possession of one and the same final common path is fatigue. A spinal reflex under continuous excitation or frequent repetition becomes weaker, and may cease altogether. This decline is progressive, and takes place earlier in some kinds of reflexes than it does in others. In the "spinal" dog the scratch-reflex under ordinary circumstances tires much more rapidly than does the flexion-reflex.

A reflex as it tires shows other changes besides decline in amplitude of contraction. Thus in the flexion-reflex, the original steadiness of the contraction decreases; it becomes tremulous, and the tremor becomes progressively more marked and more irregular. Finally, an irregular phasic tremor of the muscles is all that remains. It is not the flexor muscles themselves which tire out, for these, when under fatigue of the flexion-reflex contract no longer for that reflex, contract in response to the scratch-reflex which also employs them.

Similar results are furnished by the scratch-reflex, with certain differences in accord with the peculiar character of its individual charge. One of these latter is the feature that the individual beats of the scratch-reflex usually become slower and follow each other at slower frequency. Also the beats, instead of remaining fairly regular in amplitude and frequency, tend to succeed in somewhat regular groups. The beats may disappear altogether for a short time, and then for a short time reappear.

When the scratch-reflex elicited from a spot of skin is fatigued, the fatigue holds for that spot, but does not implicate the reflex as obtained from the surrounding skin. The reflex is, when tired out to stimuli at that spot, easily obtainable by stimulation two or

more centimetres away.

The local fatigue of a spinal reflex seems to be recovered from with remarkable speed. A few seconds' remission of the stimulus suffices for marked though incomplete restoration of the reaction. Fatigue seems a process elaborated and preserved in the selective evolution of the neural machinery. One obvious use attaching to it is the prevention of the too prolonged continuous use of a common path by any one receptor. It precludes one receptor from occupying for long periods an effector organ to the exclusion of all other receptors. It prevents long continuous possession of a common path by any one reflex of considerable intensity. It favours the receptors taking turn about. It helps to ensure serial variety of reaction. The organism, to be successful in a million-sided environment, must in its reaction be many sided. Were it not for such so-called fatigue, an organism might, in regard to its receptivity, develop an eye, or an ear, or a mouth, or a hand or leg, but it would hardly develop the marvellous congeries of all those various sense-organs which it is actually found to possess.

The final efferent-root neurone forms the instrument for many different reflex arcs and acts. It is responsive to them in various rhythms and in various grades of intensity. In accordance with this, it seems from experimental evidence to be *relatively indefatigable*.

3. In the transition from one reflex to another a final common path changes hands and passes from one master to another. A fresh set of afferent arcs becomes dominant on the supersession of one reflex by the next. Of all the conditions determining which one of competing reflexes shall for the time being reign over a final common path, the *intensity* of reaction of the afferent arc itself relatively to that of its rivals is probably the most powerful. An afferent arc that strongly stimulates is *caeteris paribus* more likely to capture the common path than is one excited feebly. A stimulus can only establish its reflex and inhibit an opposed one if it have intensity. This explains why, in order to produce examples of spinal inhibition, recourse has so frequently been made in past times to *strong* stimuli. A strong stimulus will inhibit a reflex in progress although a weak one will fail. Thus in inhibition of micturition in the "spinal" dog a *forcible* squeeze of the tail will do it, but not a weak squeeze. So, likewise, any condition which raises the excitability and responsiveness of a nervous arc will give it power to inhibit other reflexes, just as it would if it were excited by a strong stimulus.

Crossed reflexes are usually less easy to provoke, less reliable of obtainment, and less intense than are direct reflexes. Consequently we find crossed reflexes usually more easily inhibited and replaced by direct reflexes than are these latter by those former. Thus the crossed stepping-reflex is easily replaced by the scratch-reflex, though its stimulus be continued all the time, and though the scratch-reflex itself is not a very potent reflex. But the reverse can occur with suitably adjusted intensity of stimuli.

Again, the flexion-reflex of the dog's leg is, when fully developed, accompanied by extension in the opposite leg. This crossed extensor movement, though often very vigorous, may be considered as an accessory and weaker part of the whole reflex, of which the prominent part is flexion of the homonymous limb. When the flexion-reflex is elicitable poorly, as, for instance, in spinal shock or under fatigue or weak excitation, the crossed extension does not appear. But, where the flexion-reflex is well developed, if not merely one but *both* feet be stimulated simultaneously with stimuli of fairly equal intensity, steady flexion at knee, hip and ankle results in *both* limbs, and extension occurs in neither limb. The contralateral part of each reflex is inhibited by the homolateral flexion of each reflex. In other words, the more intense part of each reflex obtains possession of the final common paths at the expense of the less intense portion of the reflex. But if the intensity of the stimuli applied to the right and left feet be not closely enough balanced, the crossed extension of the reflex excited by the stronger stimulus is found to exclude even the homonymous flexion that the weaker stimulus should and would otherwise evoke from the leg to which it is applied.

It was pointed out above that in a number of cases the transference of control of the final common path FC from one afferent arc to another is *reversible*. The direction of the transference can *caeteris paribus* be easily governed by making the stimulation of this receptor or that receptor the more intense. A factor largely determining whether a reflex succeed another or not is therefore intensity of stimulus.

4. A fourth main determinant for the issue of the conflict between rival reflexes seems the functional species of the reflexes. Reflexes initiated from a species of receptor apparatus that may be termed *noci-ceptive* appear to dominate particularly the majority of the final common paths issuing from the spinal cord. In the simpler sensations we experience from various kinds of stimuli applied to our skin there can be distinguished those of touch, of cold, of warmth and of pain. The pain ending may be regarded as adapted to a whole group of excitants, a group of excitants which has in relation to the organism one feature common to all its components, namely, a *nocuous* character.

With its liability to various kinds of mechanical and other damage, in a world beset with dangers amid which the individual and species have to win their way in the struggle for existence, we may regard nocuous stimuli as part of a normal state of affairs. The skin has evolved a *specific sense of its own injuries*. As psychical adjunct to the reactions of that apparatus we find a strong displeasurable effective quality in the sensations they evoke. This may be a means for branding upon memory, of however rudimentary a kind, a feeling from past events that have been perilously critical for the existence of the individuals of the species. In other words, if we admit that damage to such an exposed sentient organ as the skin must in the evolutionary history of animal life have been sufficiently frequent in relation to its importance, then the existence of a specific set of nerves for skin-pain seems to offer no genetic difficulty, any more than does the clotting of blood or innate immunity to certain diseases. That these nerve-endings constitute a distinct species is argued by their all evoking not only the same species of sensation, but the same species of reflex movement as regards "purpose," intensity, resistance to "shock," etc. And their evolution may well have been unaccompanied by evolution of any specialized end-organ, since the naked free nerve-endings would better suit the wide and peculiar range of stimuli, reaction to which is in this case required. A low threshold was *not* required because the stimuli were all intense, intensity constituting their harmfulness; but response to a wide range of stimuli of *different* kinds was required, because harm might come in various forms. That responsive *range* is supplied by naked nerve itself, and would be cramped by the specialization of an end-organ. Hence these nerve-endings remained free.

It is those areas, stimulation of which, as judged by analogy, can excite pain most intensely, and it is those stimuli which, as judged by analogy, are most fitted to excite pain which, as a general rule, excite in the "spinal" animal—where pain is of course non-existent—the *prepotent* reflexes. The nervous arcs of pain-nerves, broadly speaking, dominate the spinal centres in peculiar degree. Pain is thus the psychical adjunct of an imperative protective reflex. It is preferable, however, since into the merely spinal and reflex aspect of the reaction of these nerves no sensation of any kind can be shown to enter, to avoid the term "pain-nerves." Remembering that the feature common to all this group of stimuli is that they threaten or actually commit damage to the tissue to which they are applied, a convenient term for application to them is *nocuous*. In that case what from the point of view of *sense* are cutaneous pain-nerves are from the point of view of *reflex-action* conveniently termed *noci-ceptive* nerves.

In the competition between reflexes the noci-ceptive as a rule dominate with peculiar certainty and facility. This explains why such stimuli have been so much used to evoke reflexes in the spinal frog, and why, judging from them, such "fatality" belongs to spinal reflexes.

One and the same skin surface will in the hind limb of the spinal dog evoke one or other of two diametrically different reflexes according as the mechanical stimulus applied be of noxious quality or not, a harmful insult or a harmless touch. A needle-prick to the planta causes invariably the drawing up of the limb—the flexion-reflex. A harmless smooth contact, on the other hand,

causes extension—the extensor-thrust above described. This flexion is therefore a noci-ceptive reflex. But the scratch-reflex—which is so readily evoked by simple light irritation of the skin of the shoulder—is relatively mildly noci-ceptive. When the scratch-reflex and the flexion-reflex are in competition for the final neurone common to them, the flexion-reflex more easily dispossesses the scratch-reflex from the final neurone than does the scratch-reflex the flexion-reflex. If both reflexes are fresh, and the stimuli used are such as, when employed separately, evoke their reflexes respectively with some intensity, in my experience it is the flexion-reflex that is usually prepotent. Yet if, while the flexion-reflex is being moderately evoked by an appropriate stimulus of weak intensity, a strong stimulus suitable for producing the scratch-reflex is applied, the steady flexion due to the flexion-reflex is replaced by the rhythmic scratching movement of the scratch-reflex, and this occurs though the stimulus for the flexion-reflex is maintained unaltered. When the stimulus producing the scratch is discontinued the flexion-reflex reappears as before.

In decerebrate rigidity, where a tonic reflex is maintaining contraction in the extensor muscles of the knee, stimulation of the noci-ceptive arcs of the limb easily breaks down that reflex. The noci-ceptive reflex dominates the motor neurone previously held in activity by the postural reflex. And noci-ceptive reflexes are relatively little depressed by "spinal shock."

Besides those receptors attuned to react to direct *noxa,* the skin has others, concerned likewise with functions of vital importance to the species and colligate with sensations similarly of intense affective quality; for instance, those concerned with sexual functions. In the male frog the sexual clasp is a spinal reflex. The cord may be divided both in front and behind the brachial region without interrupting the reflex. Experiment shows that from the spinal male at the breeding season, and also at other times, this reflex is elicited by any object that stimulates the skin of the sternal and adjacent region. In the intact animal, on the contrary, other objects than the female are, when applied to that region, at once rejected, even though they be wrapped in the fresh skin of the female frog and in other ways made to resemble the female. The development of the reflex is not prevented by removal of the testes, but removal of the seminal reservoirs is said to depress it, and their distension, even by indifferent fluids, to exalt it. If the skin of the sternal region and arms is removed the reflex does not occur. Severe mutilation of the limbs and internal organs does not inhibit the reflex, neither does stimulation of the sciatic nerve central to its section. The reflex is, however, depressed or extinguished by strong chemical and pathic stimuli to the sternal skin, at least in many cases. The tortoise exhibits a similar sexual reflex of great spinal potency.

It would seem a general rule that *reflexes arising in species of receptors which considered as sense-organs provoke strongly affective sensation* caeteris paribus *prevail over reflexes of other species when in competition with them for the use of the "final common path."*

Of all reflexes it is those of ordinary posture that are the most *easily* interrupted by other reflexes. Even a weak stimulation of the noci-ceptive arcs arising in the foot often suffices to lower or abolish the knee-jerk or the reflex extensor tonus of the elbow or knee. If various *species* of reflex are arranged, therefore, in their order of potency in regard to power to interrupt one another, the reflexes initiated in receptors which considered as sense-organs excite sensations of strong affective quality lie at the upper end of the scale, and the reflexes that are answerable for the postural tonus of skeletal muscles lie at the lower end of the scale. One great function of the tonic reflexes is to maintain habitual attitudes and postures. They form, therefore, a nervous background of active equilibrium. It is of obvious advantage that this equilibrium should be easily upset, so that the animal may respond agilely to the passing events that break upon it as intercurrent stimuli.

**Results.**—Intensity of stimulation, fatigue and freshness, spinal induction, functional species of reflex, are all, therefore, physiological factors influencing the result of the interaction of reflex-arcs at a common path. It is noticeable that they all resolve themselves ultimately into *intensity of reaction.* Thus, intensity of stimulus means as a rule intensity of reaction. Those species of reflex which are habitually prepotent in interaction with others are those which are habitually intense; those specially impotent in competition are those habitually feeble in intensity, *e.g.,* skeletal muscular tone. The tonic reflexes of attitude are of habitually low intensity, easily interfered with and temporarily suppressed by intercurrent reflexes, these latter having higher intensity.

The high variability of reflex reactions from experiment to experiment, and from observation to observation, is admittedly one of the difficulties that has retarded knowledge of them. Their variability, though often attributed to general conditions of nutrition, or to local blood-supply, etc., seems far more often due to changes produced in the central nervous organ by its own functional conductive activity apart from fatigue. This functional activity itself causes from moment to moment the temporary opening of some connections and the closure of others. The chains of neurones, the conductive lines, have been, especially in recent years, by the methods of Golgi, Ehrlich, Apathy, Cajal and others, richly revealed to the microscope. Anatomical tracing of these may be likened, though more difficult to accomplish, to tracing the distribution of blood vessels after Harvey's discovery had given them meaning, but before the vasomotor mechanism was discovered. The blood vessels of an organ may be turgid at one time, constricted almost to obliteration at another. With the conductive network of the nervous system the temporal variations are even greater, for they extend to absolute withdrawal of nervous influence. Under reflex inhibition a skeletal muscle is relaxed to its post-mortem length, *i.e.,* there may then be no longer evidence of even a tonic influence on it by its motor neurone. The final common path is handed from some group of a *plus* class of afferent arcs to some group of a *minus* class, or of a rhythmic class, and then back to one of the previous groups again, and so on. The conductive web changes its functional pattern with certain limits to and fro. It changes its pattern at the entrances to common paths. The changes in its pattern occur there in virtue of interaction between rival reflexes: occlusion, substitution by equivalence, inhibition, immediate induction, successive induction, fatigue, are factors. As a tap to a kaleidoscope, so a new stimulus that strikes the receptive surfaces causes in the central organ a shift of functional pattern of the linkage. The central organ is a vast network whose lines of conduction follow a certain scheme of pattern, but within that pattern the details of connection are, at the entrance to each common path, mutable. The grey matter may be compared with a telephone exchange, where, from moment to moment, though the end-points of the system are fixed, the connections between starting-points and terminal points are changed to suit passing requirements, as the functional points are shifted at a great railway junction. In order to realize the exchange at work, one must add to its purely spatial plan the temporal datum that within certain limits the connections of the lines shift to and fro from minute to minute. An example is the "reciprocal innervation" of antagonistic muscles—when one muscle of the antagonistic couple is thrown into action the other is thrown out of action. This is only a widely spread case of the general rule that antagonistic reflexes interfere where they embouch upon the same final common paths. And that general rule is part of the general principle of the mutual interaction of reflexes that impinge upon the same common path. *Unlike reflexes have successive but not simultaneous use of the common path; like reflexes mutually reinforce each other on their common path.* Expressed teleologically, *the common path, although economically subservient for many and various purposes, is adapted to serve but one purpose at a time. Hence it is a co-ordinating mechanism and prevents confusion by restricting the use of the organ, its minister, to but one action at a time.*

In the case of simple antagonistic muscles, and in the instances of simple spinal reflexes, the shifts of conductive pattern due to interaction at the mouths of common paths are of but small extent. The co-ordination covers, for instance, one limb or a pair of limbs. But the same principle extended to the reaction of the great arcs arising in the projicient receptor organs of the head,

*e.g.*, the eye, which deal with wide tracts of musculature *as a whole*, operates with more multiplex shift and wider ambit. Releasing forces acting on the brain from moment to moment shut out from activity whole regions of the nervous system, as they conversely call vast other regions into play. *The resultant singleness of action from moment to moment is a keystone in the construction of the individual whose unity it is the specific office of the nervous system to perfect.* The interference of unlike reflexes and the alliance of like reflexes in their action upon their common paths seem to lie at the very root of the great psychical process of "attention."

The spinal cord is not only the seat of reflexes whose "centres" lie wholly within the cord itself; it supplies also conducting paths for nervous reactions initiated by impulses derived from afferent spinal nerve, but involving mechanisms situate altogether headward of the cord in the brain. Many of these reactions affect consciousness, occasioning sensations of various kinds.

Besides the paths followed by headward-running impulses the spinal cord contains paths for impulses passing along it backwards from the brain. These paths lie almost entirely in the ventrolateral columns of the cord. The fibres of which they are composed cross but little in the cord. Their sources are various, some come from the hind brain and some from the mid brain, and in the higher mammalia, especially in man and in the anthropoid apes, a large tract of fibres in the lateral column (the crossed pyramidal tract) comes from the cortex of the neopallium of the fore brain. This last tract is the main medium by which impulses initiated by electrical stimulation of the motor cortex reach the moto-neurones of the cord and through them influence the activity of the skeletal muscles. Of the function of the other tracts descending from the brain into the cord little is known except that mediately or immediately they excite or inhibit the spinal motoneurones by various levels. How they harmonize one with another in their action or what their purpose in normal life may be is at present little more than conjecture. Such terms, therefore, as "paths for volition," etc., are at present too schematic in their basis to warrant their discussion here. (C. S. S.)

**SPINAL MENINGITIS.** Inflammation of the membranes (meninges) surrounding the brain and spinal cord. An equivalent term is cerebro-spinal meningitis.

The meninges, like the pleura, pericardium and peritoneum, are subject to infection with a wide variety of cocci and bacilli. According to the microbic incitant, the infection is termed tubercular, pneumococcal, streptococcal, staphylococcal, influenzal (*B. pfeifferi*), typhoid, etc., meningitis. The precise diagnosis is accomplished by means of the bacteriological examination of fluid (cerebro-spinal) withdrawn by lumbar puncture. The above-mentioned class of bacterial infections of the meninges tends to arise sporadically; as a rule it accompanies the corresponding bacterial infection affecting other parts of the body, the lungs, middle ear, tonsils, etc.

**Epidemic Form.**—In sharp contrast with the sporadic varieties of meningitis is the epidemic form, incited by the diplococcus discovered by Weichselbaum in 1887, now called meningococcus, of which many epidemic outbreaks have been recorded. The meningococcus appears not as a single, sharply defined species, but as a group in which the composing strains, while showing many properties in general, are yet distinguishable by power to ferment carbohydrates, reaction to specific agglutinating agents, etc.

Certain strains of meningococci have greater virulence for man than others and the more virulent strains show greater fixity of biological properties. During epidemics of meningitis virulent strains have the wider distribution; while in interepidemic periods the weaker, less defined strains are more frequently encountered.

A pandemic of meningitis prevailed during the first two decades of the present century. It embraced Europe, America, Asia, Africa and many islands of the seas. This pandemic was characterized by high mortality and by those multiple clinical features which have been noted in previous severe epidemics of the disease. A part only of the cases, usually not a large part, was attended by the visible haemorrhages in the skin and mucous membranes to which the name of spotted fever was applied in earlier times. Usually the very severe and rapidly fatal so-called fulminating cases fell into this category.

The fatality of the epidemic outbreaks, whether in Europe, in America or in more distant countries, in the years between 1904 and 1910 did not vary greatly. In the United States the percentage figures were from 75 to 90; in Great Britain 70 to 80; in Germany 60 to 70; in France, Italy and Belgium 75 to 80; in Palestine 80; in Greece 60; in the Transvaal 75. In other words, the pandemic seems to have been little affected by locality or race. As in all previous epidemics closely observed, the mortality was influenced by the age period of the attacked; the very young and the very old rarely survived attack. Patients between 5 and 30 years of age have the best chance of recovery.

**Serum Treatment.**—The outlook for recovery has been greatly modified by the discovery and use of the antimeningococcic serum since 1904. Attempts to produce a curative serum were carried out simultaneously in Germany by Jochmann and Wassermann, and in America by Flexner. The former failed perhaps because the manner of use was wrong: the serum was injected chiefly subcutaneously. The latter succeeded, because repeated injections were made directly into the inflamed meninges by means of lumbar puncture. Flexner's method was based on an experimental study in which the meninges of monkeys were infected with the meningococcus, and the treatment was applied by lumbar puncture. The serum-treated monkeys survived, while the untreated and those treated by subcutaneous injections of the serum succumbed.

This result agrees with what is known of the anatomical-physiological conditions affecting the passage of chemical substances from the blood into the cerebro-spinal fluid. Such passage, even when the membranes are inflamed, takes place to a very small extent or not at all.

**Results of Serum Treatment.**—The consensus of competent opinion is that given a strong polyvalent antimeningitis serum, its proper employment is capable of greatly modifying the course of the disease, of reducing the mortality, and of preventing crippling consequences.

A number of tabulations have been published showing the effects of the serum according to age groups, days of first injection, etc. The largest compilation is that of Flexner, dealing with about 1,300 cases in which the mortality among those treated in the first three days of illness was 18·1, the second three days 27·2 and after the seventh day 36·5%. The total mortality among these cases was 30·8%, as compared with 75 to 80% among corresponding non-serum-treated cases. Netter's figures for the corresponding three periods are 7·14, 11·1 and 23·5%; and Dopter's 8, 20, 14·4 and 24·1%. Flexner's figures are compiled from the reports of physicians at many places, while Netter's and Dopter's are based on personal experiences largely. Similarly, the influence of age on the results of the treatment is shown as follows: According to Flexner, under one year 50%, one to 20 years 75%, over

20 years 60% recovered; according to Netter, under one year 40%, one to 20 years 79% recovered; and according to Dopter, under one year 53%, one to 20 years 78%, and over 20 years 76% recovered.

Certain important objective effects are produced when anti-meningitis serum is administered. Perhaps the most immediately impressive is the modified character of the clinical course of the disease itself. Briefly stated, this relates to the essential disappearance of the chronic cases slowly moving through weeks and months to a fatal issue, attended by hydrocephalus, extreme emaciation and other sequels. Either the cases fail to respond and terminate quickly, or in a few days the real infection is over and the patient convalescent. The growth and multiplication of the meningococcus within the cerebro-spinal fluid are quickly arrested. Next, epidemic meningitis is a disease from which when recovery occurs spontaneously it tends to take place slowly, gradually, or by "lysis"; under the influence of the serum, sudden termination by "crisis" frequently takes place. Finally, the severe consequences, as of hydrocephalus, impairment of vision and mentality, paralysis and joint affections, are diminished. The one severe complication which has not been influenced is deafness, which occurs in a varying, usually small percentage of the cases, and usually very early in the disease.

**Mode of Infection.**—The meningococcus gains access to the interior of the body by way of the mucous membrane of the nose and throat. The incidence of meningitis bears relationship to the proportion of nasopharyngeal carriers of the meningococcus. When the cases are few in any community or group of persons the carrier rate is low. When the carrier rate rises the cases tend to increase in number. During sharp outbreaks, among an exposed personnel, the carrier rate may reach 20%; ordinarily it is 2 to 3% or less.

Probably the meningococcus passes from the nasal mucous membrane into the blood, with which it is carried to the meninges. Whether it ever passes along the direct lymphatic channels stretching from the nasal membrane to the meninges may be doubted. Instances are known in which meningococci were present in the blood some time before signs of meningitis appeared. The intravenous injection of the anti-meningitis serum has been successful in removing the microbe from the blood and of curing the general or blood infection. No meningitis followed. It is because of the occurrence of meningococci in the blood stream that early intravenous injection of the serum is recommended by certain authorities as a regular part of its intraspinal use in the treatment of epidemic meningitis. To be of value, the intravenous injection should be carried out very early in the disease, and it should not be substituted for the direct injection into the inflamed meninges. As a rule, a number of intraspinal serum injections on successive days is required to control the infection.

The successful employment of the anti-meningococcus serum has led to efforts being made to control other microbic varieties of meningitis in a similar manner, but thus far without notable success.

**SPINDLE-TREE** (*Evonymus europaeus*), so-called from its tough wood being formerly used for spindles, a small tree of the family Celastraceae, native to Europe and sparingly naturalized in eastern North America. The wood furnishes good charcoal. (*See* EVONYMUS; WAHOO.)

**SPINEL,** in mineralogy, the name given to a group of minerals, of the general composition $R''O{\cdot}R_2'''O_3$, where R″=Mg, Fe, Mn, Zn, and R‴=Al, Fe‴, Cr‴. The typical member is $MgO{\cdot}Al_2O_3$, a magnesium aluminate to which the name (Fr. *spinelle,* from the Latin *"spina,"* perhaps in allusion to the sharp angles of the crystals) was originally restricted. All spinels crystallize in the cubic system, typically in octahedra. Twinning is common, the octahedral face being the twin plane, giving a characteristic form known as the spinel twin.

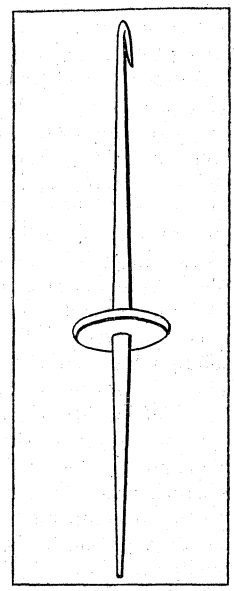
The group of spinel minerals includes the following members:—

| | | | |
|---|---|---|---|
| Magnesia-spinel | $MgAl_2O_4$ | Magnesioferrite | $MgFe_2O_4$ |
| Pleonaste | $(Mg,Fe)Al_2O_4$ | Magnetite | $FeFe_2O_4$ |
| Hercynite | $FeAl_2O_4$ | Gahnite | $ZnAl_2O_4$ |
| Picotite | $(Mg,Fe)(Al,Cr)_2O_4$ | Franklinite | $(Zn,Mn)Fe_2O_4$ |
| Chromite | $FeCr_2O_4$ | | |

Cleavage is typically absent in these minerals with the exception of the zinc spinel (cleavage on 111), but an octahedral parting is observable in magnetite and franklinite. The hardness is variable, in ordinary spinel 7·5–8, but magnetite H=6 and chromite H=5·5. The sp. gr. varies with the composition, from 3·6 (magnesia-spinel) to 5·2 (magnetite). The light refraction shows a range from 1·718 (pure $MgAl_2O_4$), hercynite 1·80, to picotite 2·05, chromite 2·10 and magnetite 2·42. Spinels vary much in colour. Magnesia spinels are pink, red and blue, and are used as gem-stones. The pure magnesia spinel is colourless, hercynite is dark green in thin slices and picotite and chromite are brown in the thinnest sections. Spinels are readily produced artificially. Magnesia spinel melts at 2135° C and between this compound and $FeAl_2O_4$ there is complete miscibility as revealed in spinel analyses, but solid solution between $(Mg, Fe)Al_2O_4$ and magnetite is very limited. The spinels used in jewellery are found mostly in gem gravels, the chief localities being Ceylon, Siam and Upper Burma.

Spinels occur both in igneous and metamorphic rocks. The home of the magnesia spinel is in thermally altered dolomites where it arises by reaction of alumina with dolomite. Here it is usually accompanied by calcite and forsterite. The iron-rich member, pleonaste, is common both in ultrabasic rocks such as dunites and in quartz-less argillaceous hornfelses and gneisses. In these latter it is almost universally accompanied by cordierite and frequently by sillimanite, andalusite or corundum. Hercynite is characteristic of the granulites of Saxony in association with garnet, sillimanite, etc. The chromiferous spinel, picotite, is relegated to the ultrabasic rocks, as dunite, lherzolite and the serpentines derived from them. Gahnite, the zinc spinel, occurs in schists associated with zinc ores, and in pegmatites in Finland and at Broken Hill, New South Wales; while franklinite is associated with zinc and manganese minerals in limestone at Franklin Furnace, New Jersey. (*See* also CHROMITE; MAGNETITE.)

(C. E. T.)



**SPINELLO, ARETINO** (*c.* 1330–1410), Italian painter, the son of a Florentine named Luca, who had taken refuge in Arezzo in 1310 when exiled with the rest of the Ghibelline party, was born at Arezzo about 1330. Spinello was a pupil of Jacopo di Casentino, a follower of Giotto, and his own style was a sort of link between the school of Giotto and that of Siena. In the early part of his life he worked in Florence painting frescoes, nearly all in terra verde in the churches, the Carmine, Sta. Maria Novella and elsewhere. These works are no longer extant. Between 1360 and 1384 he was occupied in painting many frescoes in and near Arezzo, almost all of which have now perished. After the sack of Arezzo in 1384 Spinello returned to Florence, and in 1387–1388 with some assistants covered the walls and vault of the sacristy of S. Miniato near Florence with a series of frescoes, the chief of which represent scenes from the life of St. Benedict. Of his later works the chief are the very fine series of frescoes painted in 1407–1408 in the Salia di Balia in the Palazzo Pubblico at Siena; these are the finest of Spinello's existing frescoes. Spinello died at Arezzo on March 14, 1410.

*See* Sir Dominic Colnaghi, *Dictionary of Florentine Painters* (1928).

**SPINET** or **SPINNET,** names given in England to all small keyboard instruments irrespective of shape, having one string to a note, plucked by means of a quill or plectrum of leather. The earliest name recorded for this instrument is clavicymbalum, which occurs in the rules of the Minnesingers (1404), and also in the *Wunderbuch* (1440), a ms. preserved in what was formerly the grand-ducal library at Weimar. (*See* PIANOFORTE.)

**SPINNING,** the forming of threads by drawing out and twisting various fibres. There is ample evidence of the great antiquity and wide diffusion of the art of spinning, for spinning necessarily precedes weaving (*q.v.*) whenever short fibrous materials

have to be made into threads, and weaving is one of the primal and most universal employments of mankind. No art which has been so long and widely practised remained so unprogressive as that of spinning. On the other hand, since about the middle of the 18th century, when human ingenuity bent itself in earnest to improve the art, there have not been developed in the whole range of mechanical industries machines of greater variety, delicacy of action and capacity than those now in use for spinning.

BY COURTESY OF L. HOOPER AND THE DIRECTOR OF THE VICTORIA AND ALBERT MUSEUM

AN EARLY SPINDLE

Used in primitive thread-making, it was made of wood and was from 9in. to 15in. long

The primitive thread-making implement consisted of a wooden spindle, from 9 to 15in. long, which was rounded and tapered at both extremities, as in the accompanying figure. Near the top there was usually a notch in which the yarn was caught while undergoing the operation of twisting, and lower down a whorl, or wharve, composed of a perforated disk of clay, stone, wood, or other material was secured to give momentum and steadiness to a rotating spindle. Long fibres were commonly attached to a distaff of wood, which was held under the left arm of the operator, but short fibres were spun from carded rolls. After attaching some twisted fibres to the spindle, a rotatory motion was given to the latter either by rolling it by hand against one thigh, or by twirling it between the fingers and thumb of the right hand, after which the fibres were drawn out in a uniform strand by both hands and converted into yarn. When the thread was of sufficient strength, the spindle was suspended by it until a full stretch had been drawn and twisted, after which that portion was wound upon the body of the spindle, and the operation continued until the spindle was filled. The quantity thus rolled up gives the name to a now definite measure of linen yarn, namely "the spindle," or 14,400 yards. Simple as was this primitive apparatus, a dexterous spinner could produce yarn of an evenness, strength and delicacy such as has scarcely been exceeded by elaborate modern appliances. The yarns for the gossamer-like Dacca muslins of India were so fine that 1 lb. weight of cotton was spun into a thread nearly 253m. long. This was accomplished with the aid of a bamboo spindle not much bigger than a darning needle, and which was lightly weighted with a pellet of clay. Since such a tender thread could not support even the weight of so slight a spindle, the apparatus was rotated upon a piece of hollow shell. The spindle as here described was, so far as is known, the sole apparatus with which yarn was spun until comparatively recent times.

**Modern Spinning.**—Modern changes have had for their object: (1) the providing of mechanical means to rotate the spindle, (2) an automatic method of drawing out the fibres, and (3) devices for working a large group of spindles together, at rapid speeds.

The first improvement consisted in cutting a ring groove in the wharve, mounting the spindle horizontally in a frame, and passing a band from a large wheel round the wharve. A rotatory motion was then given to the spindle by turning the wheel with the left hand. After attaching the filaments to the spindle they were attenuated with the right hand, and when fully twisted the thread was moved to form a right angle with the spindle and coiled upon it. Such a wheel has long been known in India, and from a drawing in a 14th-century manuscript in the British Museum it is obvious that it was not unknown, although far from being in general use, in Europe at that early date. It came ultimately to be known in England as the "bobbing wheel," and was in constant use down to the beginning of the 19th century for spinning coarse and fine yarns. But fine yarns received two spinnings; the first consisted in drawing out and slightly twisting the fibres into what is still known as a roving, and by the second spinning the roving was fully attenuated and twisted. In 1533, a citizen of Brunswick is said to have cranked the axis of the large wheel and added a treadle, by which the spinner was enabled to rotate her spindle with one foot and have both hands free to manipulate the fibres.

It is not possible accurately to fix the dates at which all improvements in spinning appliances were made; it is certain that many were known and used long before they were generally adopted. Thus the flyer, which twists yarn before winding it upon a bobbin, is shown in a drawing by Leonardo da Vinci, together with a device for moving the bobbin up and down the spindle so as to effect an even distribution of the yarn. During the 16th century a machine of the foregoing type was widely used, and came to be known as the Saxony wheel. It changed spinning from an intermittent to a continuous operation. The spindle had affixed upon its outer end a wooden flyer, whose forked legs were far enough apart to enclose a double-flanged spool, and at short intervals bent wires, known as the heck, were inserted in each leg for the purpose of guiding the thread evenly upon the spool. This spool was loosely threaded upon the spindle and one of its flanges was grooved to take a driving band from the large wheel, hence the spindle and the spool were separately driven, but the former at a higher speed than the latter. The twisted filaments were drawn through an eye in the flyer, led along one of its legs, and made fast to the spool. By operating the treadle the flyer twisted all the fibres about a common axis once for each revolution, and the spool wound up the length thus spun: the thread being slipped from tooth to tooth of the heck at regular intervals to direct it evenly across the spool.

The remaining part of the problem which lay before inventors was to draw out masses of parallel fibrous material, and twist them into uniform strands by mechanical means. The first stage in the evolution of mechanical spinning was effected by the invention of Lewis Paul, of Birmingham, who obtained a patent in 1738, and who was assisted by John Wyatt. The essential features of this invention consisted in passing carded slivers between pairs of parallel rollers, each succeeding pair of which moved faster than the preceding pair, to attenuate the sliver to the required extent. From Paul's specification it would appear that he attempted to turn the rollers about their horizontal and vertical axes simultaneously, in order to draw out the fibres and twist them at one operation. But he also mentions a plan for which he procured a patent 20 years later, namely, the use of only one pair of rollers working in conjunction with a bobbin which drew off the thread faster than the rollers delivered the sliver, and coiled the thread about itself. The bobbin, therefore, attenuated, twisted and wound the material. Neither plan proved a commercial success. Thomas Highs, of Leigh, and others, laboured upon the problem, but it was left to Richard Arkwright, a barber, of Preston and Bolton, to achieve what his predecessors vainly struggled for. He obtained patents, in 1769 and 1775, for a machine which was subsequently known as the water-twist frame by reason of water-power being applied to drive it. Arkwright's first machine did not contain any really new feature, for it consisted of Paul's drawing rollers, and the spindle, flyer and spool from the Saxony wheel, but the spindles and rollers were grouped in sets of four. Later the water-twist frame was changed into the "throstle" frame, which in turn has almost ceased to be used. In 1829 C. Danforth (1797–1876), an American spinner, invented a dead spindle, on the top of which he placed a hollow cap to serve as the winding point, and inside the cap he rotated a spool: a plan still used by worsted spinners. In 1828 Mr. Thorpe, also an American, invented the ring spinning frame, whose principal feature consisted in the substitution for the flyer of a flanged annular ring, and a light C-shaped traveller. By means of the traveller a thread was held in the best position for winding upon a spool, as well as put under the necessary tension. Later inventors have so altered the construction of the ring, traveller and spindle that a speed of upwards of 11,000 revolutions per minute can now be attained. This represents the highest development of continuous spinning.

Whilst endeavours were being made to perfect continuous spinning, attention was also directed to perfecting the intermittent

process as represented by the bobbing wheel. Between the years 1764 and 1767, James Hargreaves, of Standhill, invented the spinning jenny, by the aid of which 16, or more, threads could be spun simultaneously by one person. All the spindles were placed vertically and rotated from a drum, but the rovings were mounted in a movable carriage and passed between a clamp that opened and shut like a parallel ruler. After securely clamping the rovings and attaching them to the spindles, the carriage was drawn out slowly by one hand and the spindles revolved by the other. The rovings were thus stretched to the proper degree of tenuity, and sufficiently twisted. This was followed by the inward run of the carriage, when the stretch of spun threads was wound upon the spindles, and the operation repeated. Hargreaves therefore returned to the first principles of spinning, viz., simultaneous drawing and twisting. But although the jenny gave a greatly increased output, it was ill adapted for fine spinning. During the years 1774 to 1779, Samuel Crompton, of Bolton, combined, in the mule, the drawing rollers of Paul with the stretching of Hargreaves. But his rollers did not fully attenuate the rovings before twisting them, as is the case with continuous spinning, neither was stretching alone relied upon. From its introduction this machine was able to spin finer and more elastic threads than any of its rivals, but for a time the preparation of suitable rovings was a source of great trouble. The immediate consequence of the decision of the court of king's bench, in 1785, to throw open to the public Arkwright's preparatory machinery, was an enormous increase in the usefulness of the mule. Since Crompton's time a host of inventors have laboured to render all parts of the mule thoroughly automatic; this has led to many changes and additions, but none of its essential features has been discarded. The inventions of Paul, Arkwright, Hargreaves and Crompton are at the foundation of all modern systems of spinning; details regarding them are given in the article on COTTON: *Cotton-Spinning Machinery.* (T. W. F.)

**SPINOLA, AMBROSE,** MARQUIS DE LOS BALBASES (1569–1630), Spanish general, born in Genoa, then practically a protected state under the power of Spain. The family of Spinola was of great antiquity, wealth, and power, and a rival of the house of Doria for authority within the republic. Unsuccessful in a lawsuit against the Dorias, Spinola decided to advance the fortunes of his house by serving the Spanish monarchy in Flanders. In 1602, he and his brother Frederick entered into a contract with the Spanish government. It was a speculation in which Spinola risked the whole great fortune of his house. Frederick, who was to form a squadron of galleys for service on the coast, was killed in action with the Dutch (May 24, 1603). Spinola's first landing in Flanders resulted in nothing definite and he returned at the end of 1602 for more men. On Sept. 29, 1603, he laid siege to Ostend and took it on Sept. 22, 1604, winning thereby a high reputation among the soldiers of his time. A visit to the Spanish court at Valladolid, resulted in his being appointed commander-in-chief in Flanders. The wars of the Low Countries consisted at that time almost wholly of sieges, and Spinola made himself famous by the number of places he took in spite of the efforts of Maurice of Nassau to save them.

On the outbreak of the Thirty Years' War Spinola conducted a vigorous campaign in the lower Palatinate, and was rewarded by the grade of captain-general. The most renowned victory of his career—the capture of Breda after a long siege (Aug. 28, 1624–June 5, 1625)—is the subject of the great picture by Velazquez, known as "Las Lanzas"; the portrait of Spinola is from memory. The taking of Breda was the culmination of Spinola's career. The enmity of Olivares and the want of money paralysed his efforts. Appointed plenipotentiary and general in the war over the succession to the Duchy of Mantua, Spinola landed at Genoa on Sept. 19, 1629. In Italy, Olivares caused him to be deprived of his powers as plenipotentiary, and, broken down in health, he died on Sept. 25, 1630, at the siege of Casale.

**SPINOZA, BENEDICTUS DE** (1632–1677), Dutch philosopher and maker of lenses. The surname occurs in various forms: Espinoza, d'Espinoza, Despinoza, de Spinoza, and simply Spinoza. His first name was Baruch (Hebrew for "Blessed"); but, in accordance with the custom of the time, it was rendered into its Latin equivalent (*Benedictus*).

### THE LIFE AND WRITINGS OF SPINOZA

**Early Years** (1632–1654).—Spinoza was born in Amsterdam on November 24, 1632. The house in which he first saw the light, and in which he passed his early years, occupied the site of what is now No. 41, Waterlooplein. His grandfather (Abraham) and his father (Michael) were Portuguese crypto-Jews, that is, descendants of Jews whom the Inquisition had compelled to embrace Christianity but who remained Jews at heart. When the Netherlands revolted against Spain and the Spanish Inquisition, in 1567, and the Union of Utrecht decreed, in 1579, that "every citizen shall remain free in his religion," many crypto-Jews in Spain and Portugal turned their eyes to Holland in the hope of finding refuge there from their common oppressors. The destruction of the Spanish Armada, in 1588, probably favoured schemes of escape. So in 1593 the first batch of Jewish refugees arrived in Amsterdam. Among these early arrivals were Spinoza's father and grandfather. They hailed from Vidigueira, near Beja, in the South of Portugal, but appear to have stayed for a while in Nantes (France) before settling in Amsterdam. Spinoza's mother came from Lisbon. She died in 1638, when Spinoza was barely six years old.

The Spinozas were fairly well-to-do merchants. Spinoza's grandfather was regarded as the head of the Amsterdam Jewish community from about 1628 onwards, and Spinoza's father was Warden of his synagogue on many occasions, also Warden of the Jewish School, and President of a Jewish Charity which granted loans free of interest. Under the circumstances it may be assumed that Spinoza attended the school for Jewish boys, founded about 1638. The curriculum of this school is well known, so we have a sufficiently clear idea of Spinoza's early education. The school hours were 8 till 11 A.M. and 2 till 5 P.M. The subjects were all Hebrew—the Old Testament, the Talmud, Hebrew Codes, and the works of Ibn Ezra, Maimonides, Crescas and others. Outside school hours the boys had private lessons in secular subjects. The vernacular used in the Jewish school and in Jewish homes was Spanish. Spinoza learned Latin from a German scholar, Jeremiah Felbinger, who may also have taught him German. Spanish and Portuguese Spinoza learned from his father, Dutch from his environment, and he also knew some French and Italian. When exactly he learned mathematics and physics is not known. There were plenty of Hebrew books dealing with these sciences, and the Jewish School had a good lending library, so that Spinoza may have commenced these studies during his school years. Hence probably his choice of the profession of a maker of lenses.

Of Spinoza's teachers at the Jewish School the most eminent were Saul Morteira and Manasseh ben Israel. Morteira was born in Venice in 1596, and studied medicine under Montalto, the crypto-Jewish Court physician of Maria de Medici. He came to Amsterdam in 1616, and in 1638 was elected presiding Rabbi of the Amsterdam synagogues. Manasseh ben Israel was born in Lisbon in 1604. His father was one of 150 Jews whom the Inquisition condemned to the flames in 1605. They managed to save their lives at the expense of their fortunes, and fled at the earliest opportunity. Manasseh's parents brought him to Amsterdam about 1606. In 1622 he became the youthful Rabbi of one of the Amsterdam synagogues (the "Habitation of Peace"). In 1627 he started a Hebrew printing press, and in 1640 he was appointed to one of the senior posts in the Jewish School.

In March 1654 Spinoza's father died. There was some litigation over the estate, as Spinoza's only surviving step-sister claimed it all. Spinoza won the lawsuit, but allowed her to retain nearly everything. Henceforth Spinoza had to fend for himself.

**Critical Years** (1654–1656).—Spinoza was in his twenty-second year when his father died. His studies so far had been mainly Jewish. But he was an independent thinker and he had found more than enough in his Jewish studies to wean him from orthodox theology. In the Biblical commentary by Abraham Ibn

Ezra (1092–1167) one meets with many "a word to the wise" directing attention to some inconsistency in Scripture, to the post-Mosaic authorship of parts at least of the so-called "Five Books of Moses," or to the different authorship of the two parts of *Isaiah*. In the *Guide of the Perplexed* of Moses Maimonides (1135–1204) attention is drawn to various crudities in Biblical theology, and to the provisional character of certain Biblical ordinances. In the writings of Gersonides (1288–1344) rationalism encroaches on miracles and prophecy in an attempt to eliminate the element of supernaturalism. Already Maimonides had insisted on interpreting Scripture in such a way as to harmonize it with reason. Gersonides went further than that. He faced the possibility of a conflict between Reason and Revelation, and maintained that, in such an event, the Bible "cannot prevent us from holding that to be true which our reason prompts us to believe." Again, the popular conception of the world's creation out of nothing was denied by both Ibn Ezra and Gersonides, who believed in the eternity of matter. Maimonides also repudiated the belief that man is the centre of creation, maintaining that each thing exists for its own, not for man's, sake; he also suggested the relativity of good and evil. The Jewish Mystics had taught that Nature is animated. Crescas (1340–1410) ascribed extension to God, denied the validity of the conception of final causes (or the explanation of objects and events by reference to their alleged purposes), and, like Ibn Ezra, maintained a thoroughgoing determinism. Here was food enough for thought, and incentive enough for heresy.

Moreover, the tendency to revolt against mere tradition and authority was very much in the air since the Renaissance, and it affected young Jews as others. There was the tragic figure of Gabriel da Costa, or Uriel Acosta (1585–1640). A crypto-Jewish refugee from Oporto, in Portugal, he settled in Amsterdam. He was opposed to the belief in immortality, and to various Jewish rites, on the ground that they were not Biblical. He was excommunicated by the Jewish authorities, recanted, then returned to the charge, was excommunicated again, recanted again under humiliating conditions, and shot himself. In his naturalistic outlook he was a forerunner of Spinoza. Especially interesting for the understanding of Spinoza is the case of another Jewish doctor of Amsterdam—Daniel de Prado (d. 1663). He too was opposed to supernaturalism and traditionalism, and appears to have influenced young people to adopt similar views. He was persuaded to recant in the synagogue in 1656, but there was no material change in his attitude. The synagogue authorities tried to bribe him to go abroad, but he declined, and was excommunicated in 1657. A contemporary poet, punster and protector of the faith (Isaac Orobio de Castro) wrote an invective in verse against de Prado as a philosophaster who led astray young students, Jewish and non-Jewish. Some of the allusions in this invective most probably refer to Spinoza, the record of whose excommunication faces the page in the communal minute book on which de Prado's recantation is recorded. Some of the writings of Jewish authors of the period (Samuel da Silva, Manasseh ben Israel, Orobio de Castro, etc.) in defence of immortality, revelation and tradition afford considerable evidence of the intellectual ferment in Amsterdam Jewry. And the religious leaders of the day were not particularly tactful or tolerant. They were alarmed by heresies which were at least as anti-Christian as anti-Jewish, and were afraid of giving offence in a country of which they were not yet regarded as citizens. This alarm shows itself in the attempt to bribe de Prado and Spinoza into silence. But they were also imbued with something of the intolerant spirit of the Inquisition, whose victims they had been. In 1640, they actually put the ban on Manasseh ben Israel for some trivial reason, though they rescinded it soon afterwards.

The views which brought Spinoza into collision with the synagogue authorities were essentially the same as those of Farrar, Acosta and de Prado. In conversation with other students he told them that there is nothing in the Bible to support the views that God has no body, that there really are angels (as distinguished from merely imaginative visions of them), and that the soul is immortal. He also expressed his belief that the author of the Pentateuch was no wiser in matters pertaining to physics or even theology than they were. These utterances were reported to the Jewish authorities, who after vainly trying to silence him with bribes and threats excommunicated him in July 1656. The fact of his excommunication was formally reported to the civil authorities—a gesture intended to absolve the Jewish community from all responsibility for Spinoza's heresies. And Spinoza was banished from Amsterdam for a short period.

There is no evidence that Spinoza really wanted to break away from the Jewish community. Such evidence as there is rather points the other way. On December 5, 1655, he attended service in the synagogue and made an offering. In view of his impecuniosity, offerings must have been rare events for him, and it may be assumed that he also went to the synagogue after that date, certainly in March 1656, the anniversary of his father's death. Shortly before or after his excommunication he also addressed an *Apology* (or defence of his views) to the synagogue authorities. Apparently he was not entirely indifferent to their opinions of him. Possibly if Manasseh ben Israel had not been away in London at the critical time, the whole storm would have blown over. As it was, tactlessness, mischief making, alarm and intolerance were in the saddle and rode for a fall. In his 24th year Spinoza stood alone, but unafraid, and uplifted by his destiny to become one of the great lights of humanity.

**Years of Re-Orientation** (1656–1660).—Already before his estrangement from the synagogue Spinoza had become acquainted with a number of Christians. Among these was a certain Francis van den Enden, an ex-Jesuit and ex-bookseller, but an ardent classical scholar and something of a poet and dramatist, who opened a school in Amsterdam in 1652. For a time Spinoza stayed with Van den Enden, assisting with the teaching of the school children, and receiving help in his own further education. In this way Spinoza improved his knowledge of Latin, learned some Greek, was introduced to the Neo-Scholastic philosophy of such writers as Burgersdijck (d. 1632) and Heereboord (d. 1659), and possibly also to the works of Descartes. In any case Spinoza's other Christian acquaintances were mostly Collegiants who were especially interested in the "new philosophy" of Descartes. At the same time he was learning the science and art of making lenses, in which he became a great expert. After his excommunication Spinoza spent some weeks, or possibly months, at Ouwerkerk, a village south of Amsterdam, and then returned to his native city, where he stayed until 1660. He supported himself partly by grinding and polishing lenses for spectacles, telescopes and microscopes, and partly by helping various people with their private studies. Holland was a country of many religious sects whose friction with the predominant Calvinist clergy imparted considerable vitality to theological problems and connected philosophical questions. As all these reformation movements were, or professed to be, "back to the Bible," a knowledge of Hebrew was felt to be necessary, and Hebrew experts like Spinoza were in some demand. The same was true of philosophy as an aid to theology. Accordingly, a number of amateur theologians secured the services of Spinoza to help them with their studies, and through them he also came into contact with others. Of his friends and acquaintances during this period the most important were Pieter Balling, Jarig Jellès, Lodewijk Meyer, Simon Joosten de Vries, and Jan Rieuwertsz. The sincerity of Simon Joosten de Vries's admiration for Spinoza was shown in many ways. At one time he pressed Spinoza to accept a gift of 2,000 florins, at another time he wanted to make Spinoza his sole heir, but in vain. By his will he left Spinoza an annuity of 500 florins, but Spinoza would not accept more than 300. Some or all of these and certain others formed a kind of reading and discussion circle for the study of religious and philosophical problems under the guidance of Spinoza. At first, we may assume, Cartesian philosophy played an important part in these discussions. For at that time there was something like a coalition between the "new philosophy" and liberal, dissenting theology, for they were both opposed by the dominant Calvinists. Most of his Collegiant friends remained Cartesian to the end, though Spinoza himself never followed Descartes in anything

except his science.

To judge from the opening passage of his *Treatise on the Improvement of the Understanding,* which was written shortly afterwards, the years 1656 to 1660 must have been years of storm and stress in Spinoza's mental history. Cut off from kith and kin, and left stranded as the result of his honest attempt to think independently, worldly aims must have seemed at times more alluring than the beck of the spirit. But his higher self won through, partly perhaps with the help of the faith which his unsophisticated friends and disciples placed in knowledge and in him. His new orientation was accomplished by the end of this period. He had learned to view life and its problems from other angles than those of his native environment, and he had acquired a knowledge of a language and a system of concepts more suitable to serve as a vehicle for the great thoughts that were taking shape in his mind, and more suitable, too, for the wider influence which they were destined to exercise. What he needed now was peace and quiet in which to collect his thoughts and reduce them to system. He withdrew accordingly to Rijnsburg, a quiet unworldly village on the old Rhine, about six miles from Leyden.

**Life at Rijnsburg** (1660–1670).—Rijnsburg was the headquarters of the Collegiants. Arrangements for his stay there were no doubt made by his Collegiant friends. He lodged with a surgeon named Hermann Homan, whose humanitarianism is obvious from the inscription on the cottage wall:

> Alas! if all men were but wise,
> And would be good as well,
> The Earth would be a Paradise,
> Where now 'tis mostly Hell.

(From Kamphuysen's *May Morning*). In this cottage (now *Het Spinozahuis*) Spinoza wrote his *Short Treatise on God, Man and his Well-being,* the *Treatise on the Improvement of the Understanding,* the greater part of his *Geometric Version of Descartes' Principia* with the appendix on *Metaphysical Thoughts,* and the first book of his *Ethics.* Part of the *Short Treatise* consists of notes which he had prepared in connection with the study circle in Amsterdam. This circle continued to meet after Spinoza's departure from Amsterdam, and periodically Spinoza sent them the various parts of his *Short Treatise* and other works for study and discussion. This is clear from Letters VIII. and IX. (*The Correspondence of Spinoza,* pp. 101 *seq.*) and from the closing sentences of the *Short Treatise* (pp. 149 *seq.* in A. Wolf's edition). The *Short Treatise* and the *Treatise on the Improvement of the Understanding* were ready in or before April 1662, and were originally intended to be one work, as is clear from Spinoza's third letter to Oldenburg (*Correspondence,* pp. 98 *seq.*). Already in these earlier writings Spinoza's attitude is anti-Cartesian.

During his stay in Rijnsburg Spinoza met various interesting people. Especially noteworthy are Steno, the founder of modern geology, and Oldenburg, one of the first two secretaries of the Royal Society of London. Steno subsequently turned Roman Catholic and tried to persuade Spinoza to do likewise (see *Correspondence,* pp. 324 *seq.*); but he has the merit of having recognized in Spinoza "the reformer of the new philosophy." Oldenburg is of special interest in a biography of Spinoza because the most important part of Spinoza's correspondence passed between him and Oldenburg. Oldenburg visited Leyden in 1661. His countryman Coccejus was professor there. Spinoza must have acquired a reputation somehow, for Oldenburg went out of his way to visit him in Rijnsburg. The deep impression which Spinoza made on Oldenburg (who was about 18 years older than Spinoza) is evident from his first letter to Spinoza (see *Correspondence,* pp. 73 *seq.*). In Rijnsburg also Spinoza first met the brothers Koerbagh whose subsequent tragic fate showed how little freedom of thought there really was even in Holland. Casearius, another student at the University of Leyden, came to spend a year or so in Rijnsburg, and stayed in the same cottage as Spinoza, who instructed him in the philosophy of Descartes. For this purpose Spinoza made a geometrical version of the second part of Descartes' *Principia.* While on a visit to Amsterdam, in 1663, Spinoza showed this to his Cartesian friends, who persuaded him to do the same with the first part of the *Principia.* He did so in a fortnight. These two parts, together with an appendix called *Metaphysical Thoughts,* were accordingly published by his friends in 1663. L. Meyer wrote the introduction explaining that Spinoza did not really share the views expressed in the book; J. Rieuwertsz was the publisher; and J. Jelles defrayed the cost. This was the only book published in Spinoza's life-time with his name on the title-page. P. Balling prepared a Dutch translation of this book, and published it in 1664.

Early in 1662 Spinoza had completed the first draft of his philosophy in one work combining the *Short Treatise* and the *Treatise on the Improvement of the Understanding.* He was not satisfied with its style or with its method of exposition. He had tried the dialogue form without success, so he tried the geometrical method, in the manner of Euclid's *Elements,* which gave him more satisfaction. He therefore decided to lay aside his earlier attempts and make a new start. Thus originated his *Ethics,* the first book of which was finished, and in the hands of his friends, early in 1663. The title of the whole work was not yet intended to be *Ethics,* but "On God, the Rational Soul, and the Highest Happiness of Man," and the work was planned in three parts corresponding to the three parts of the title, instead of the five parts into which it eventually developed. The publication of his version of Descartes' *Principia* was intended to prepare the way for the publication of his own philosophy. For this purpose two things were necessary. He had to secure the patronage of influential men who could shield him and his book from the remorseless hostility of the Calvinist clergy and other fanatics, and he had to show to the more philosophically minded people, who were mostly Cartesians, that his rejection of Cartesianism was not due to ignorance (see *Correspondence,* pp. 123 *seq.,* and *The Oldest Biography of Spinoza,* pp. 57 *seq.,* 147 *seq.*). Spinoza appears to have succeeded so far as to win the interest of a few people belonging to the governing class. These afforded him some protection, but not sufficient to enable him to publish his philosophy in his life-time. Among these were J. Hudde (who subsequently became Sheriff and then Burgomaster of Amsterdam, and a member of the States of Holland), H. Boxel (Pensionary of Gorkum), C. Burgh (who became Treasurer General of the United Netherlands in 1666), possibly also C. van Beuningen (at one time Burgomaster of Amsterdam) and Jan de Witt (Grand Pensionary of Holland).

In June 1663 Spinoza moved from Rijnsburg to Voorburg, near The Hague. Here Spinoza got to know Vossius the philologist, who was subsequently appointed Canon of Windsor, and Christiaan Huygens, the discoverer of Saturn's rings, inventor of the pendulum clock, and originator of the undulatory theory of light.

Though busy with his *Ethics* and his lenses, Spinoza kept up his correspondence with various people, especially with Oldenburg. Oldenburg kept Spinoza informed of the doings of the Royal Society (which had obtained its charter in July 1662) and of the researches of Robert Boyle and others, and solicited news from Spinoza about Huygens and others. But about 1665 the correspondence was interrupted. The Great Fire of London (1666) and the continuation of the war were no doubt responsible for this. In 1667 Oldenburg was suspected of espionage and clapped into the Tower of London for a time. He was released, but became nervous and cautious, so that his correspondence with Spinoza was not resumed until 1675.

From a letter written in June 1665 it appears that Spinoza was then nearing the completion of his *Ethics* (*Correspondence,* p. 202). In the following August or September, however, Spinoza informed Oldenburg that he was engaged on a theological treatise (see *Correspondence,* pp. 204, 206). During the next few years Spinoza was at work on his *Tractatus Theologico-Politicus,* which was published anonymously in 1670. Why did he put aside his *Ethics* in order to write a treatise on the Scriptures? The chief reason is stated on the very title-page of the *Tractatus,* which states that its object is "to show that not only is perfect liberty to philosophize compatible with devout piety and with the peace of the State, but that to take away such liberty is to destroy the public peace and even piety itself." Already in 1665 Spinoza

mentioned this object to Oldenburg. But he also mentioned another, namely, he wanted to clear himself of the charge of atheism which had been brought against him. It would appear that, with the completion of the *Ethics* in sight, Spinoza was considering the question of its publication, but found that such a step was impracticable in the then state of public opinon, which under the increasing influence of the clerics and monarchists became very intolerant and restive, as the troubles caused by the war multiplied. Spinoza consequently conceived the plan of vindicating the cause of freedom of thought in a manner that would at once serve the general interest of the Republic and also prepare the way for the publication of his own philosophy. The chief obstacle was the Calvinist clergy with their constant appeal to Scripture, which they interpreted in any manner that served their fanaticism. So Spinoza set himself the task of showing that the Bible, properly understood, gives no support to the intolerance of the clerics and their interference in civil and political affairs.

**Last Years** (1670–1677).—In May 1670, shortly after the anonymous appearance of the *Tractatus Theologico-Politicus,* Spinoza moved into The Hague, possibly in order to be nearer some of his influential friends. He certainly needed protection. His book created a stir, and went through five editions in as many years. But it stirred a hornet's nest, and denunciations came fast and furious. At first Spinoza stayed on the *Stille Veerkade,* but in 1671 he went to stay with the Van der Spycks in the *Paviljoensgracht* near by, and remained in their house (now *Domus Spinozana*) to the end of his days. His work on the *Tractatus* involved the resumption of his earlier Hebrew studies, and it was about this time that he commenced his *Hebrew Grammar.* He did not, however, finish it, but returned to his *Ethics,* though the prospect of its publication became more and more remote. In 1672 the French invaded Holland, which was unprepared, and so suffered many disasters. The populace, fomented by the monarchists, sought a scapegoat, and murdered the brothers Jan and Cornelius de Witt. Spinoza was beside himself. He prepared a placard expressing his disgust with "the very lowest of barbarians," and was going to post it up on the scene of the crime. Fortunately Van der Spyck locked the door, and saved him from the fate of the De Witts. As it was, his *Tractatus* was denounced as an instrument "forged in hell by a renegade Jew and the devil, and issued with the knowledge of Mr. Jan de Witt." In 1673, while the French army was at Utrecht, Spinoza received an invitation to visit Prince Condé there. It was inspired by a Colonel Stoupe, who was in command of a Swiss regiment under Condé. Stoupe had been a Calvinist minister, and his service with Catholic France against Calvinist Holland evoked the severe censure of some of his countrymen. Stoupe was an unscrupulous adventurer, but was anxious to save appearances. So he conceived the idea of showing that the Dutch were really heretics, and for this purpose he wanted to use Spinoza as his cat's paw. He actually published later in that year a little book in which he denounced the Dutch for tolerating an atheist like Spinoza, and for making no attempt to answer his atheistical treatise. Spinoza only saw in the invitation a possible opportunity of initiating peace negotiations. So he consulted some people of authority, and, armed with the necessary safe-conducts, set out for Utrecht in May 1673. In the meantime Condé had been called away, and Spinoza after waiting for him several weeks in vain, returned to The Hague, where a suspicious rabble greeted him with scowls and stones, but did him no harm. Earlier in the same year another kind of invitation had reached Spinoza. It was an invitation from the Elector Palatine to the Chair of Philosophy in the University of Heidelburg. Spinoza declined the offer with many thanks. He had trouble enough with the clerics and theologians as a recluse, he would not court worse trouble by becoming a public character. So he stayed in The Hague, polishing his *Ethics* and his lenses, and generally practising the art of plain living and high thinking. The impression he made on the people about him may be gathered from the fact that one day his pious Lutheran hostess asked him whether he considered her religion the right way to salvation. Spinoza, of course, reassured her.

In 1675 the *Ethics* was finished finally, and Spinoza went to Amsterdam to see whether it might be published. But rumour had preceded him. Not only the clerics and theologians but even the "stupid Cartesians" were up in arms and brewing mischief. Spinoza, accordingly, abandoned the idea of publishing it. But manuscript copies of it were in the hands of his intimate friends. Once more he turned his attention to political problems, and began his *Political Treatise,* which he did not live to finish.

In 1675 Tschirnhaus visited Spinoza, and also brought about the resumption of the correspondence between Oldenburg and Spinoza. In 1676 Leibniz was staying in The Hague. Already in 1671 he had heard of Spinoza as an authority on optics and had sent him a copy of an optical tract. Since then he had read the *Tractatus Theologico-Politicus,* of which Spinoza then sent him a copy; and he had also learned from Tschirnhaus something about Spinoza's philosophy. He was evidently interested deeply. For, according to his own account, he visited Spinoza frequently and "conversed with him often and at great length."

The days of Spinoza were drawing to an end. The glass dust from the lenses had done its worst. He was in the last stage of consumption. About the middle of February 1677 he sent to Amsterdam for his medical friend Schuller. On Sunday, February 20, about 3 o'clock in the afternoon, Spinoza passed away in the presence of Schuller. Four days later he was buried in the New Church on the Spuy. He was only 44.

In accordance with his previous instructions his manuscripts were sent to Rieuwertsz in Amsterdam. Jelles, Meyer and Schuller prepared them secretly for the press. The *Opera Posthuma* by B. D. S. (and the Dutch version, *De Nagelate Schriften*) were published before the end of 1677. They consisted of the *Ethics,* the *Political Treatise,* the *Treatise on the Improvement of the Understanding,* the *Letters* and the *Hebrew Grammar.* The *Short Treatise* had disappeared, but two copies of a Dutch version were recovered in 1852 and an edition was published in 1862. Two short essays on *The Rainbow* (1687) and *The Calculation of Chances* were also lost for a time, but were found and published, *The Rainbow* in 1862, and both essays in 1883.

For about a century Spinoza's name was anathema. His writings were indeed studied and his ideas were borrowed to a greater extent than is commonly supposed. But people dared not mention his name with respect, much less acknowledge their indebtedness to him. In time, however, things improved. Lessing, Goethe and Coleridge did most to rehabilitate his name, and others followed suit. The monument at The Hague, the *Spinozahuis* at Rijnsburg, and the *Domus Spinozana* in The Hague bear testimony to the reverence in which the memory of Spinoza is now held throughout the civilized world.

## THE PHILOSOPHY OF SPINOZA

**General Account.**—The pioneers of modern thought were inspired by a revulsion from the mediaeval reliance on authority, and the subordination of reason to it. The Humanists of the Renaissance attempted to vindicate the autonomy of reason as against the authority of books and institutions. This rationalist spirit affected some of the Jews of Amsterdam, and, as already remarked, brought them into conflict with established authority. It was the same spirit that brought about the crisis in the early life of Spinoza, who eventually became the prince of rationalists. He insisted that even the Scriptures must be submitted to the test of reason, and produced the most effective protest against the subordination of reason to their authority. This revolt against mere authoritarianism, however, only represented the negative side of rationalism. Important as this was, it was only preparatory to its positive aspect. The positive side of rationalism may be seen in the great classics of science in the 16th and 17th centuries—the works of Copernicus, Vesalius, Galileo, Gilbert, Kepler, Harvey, Boyle, Descartes, Huygens, Pascal, Leibniz and Newton, to mention only a round dozen of the most famous names of the period. Their discoveries were the positive results of reason, whose main function it is to trace the connections between things, to discover their laws, and to display the order which makes things intelligible. It may be said, without any

disrespect for these famous men, that the positive side of rationalism also found its fullest expression in Spinoza. For he attempted a synthesis of the whole of reality. This attempt shocked some of the above-mentioned geniuses, and would have shocked the rest, had they heard of it. For none of them dreamed of the possibility of bridging the chasm between the natural and the supernatural. Spinoza conceived of the whole of reality, including the human and the divine, as an organically interconnected cosmos, in which there is nothing capricious or contingent, but everything happens in an orderly manner according to law.

Spinoza arrived at his conception partly as follows. Whatever object or event be considered, it can only be explained by reference to innumerable others which condition it. Each of these is, in turn, dependent on innumerable others. Each finite thing seems to send out innumerable tendrils and derive support from all directions. Is it conceivable that reality should be composed entirely of such conditional, dependent things? Spinoza, like others, said No. There must be some self-existing, independent or absolute Being as the ground of all that is dependent. But what is the relation of this absolute Being to the world of dependent things and events? The common answer is that this absolute Being is God, an omnipotent supernatural Being who created the world out of nothing, maintains its existence, and occasionally interferes with it in miraculous ways. This conception was almost universal at that time. Newton subscribed to it. And Descartes made a special entry in his diary to record his belief in the three miracles, namely, the creation out of nothing, free-will, and the God-man. But Spinoza rejected the idea of an external Creator suddenly, and apparently capriciously, creating the world at one particular time rather than another, and creating it out of nothing. The solution appeared to him more perplexing than the problem, and rather unscientific in spirit as involving a break in continuity. He preferred to think of the entire system of reality as its own ground. This view was simpler; it avoided the impossible conception of creation out of nothing; and was religiously more satisfying by bringing God and man into closer relationship. Instead of Nature, on the one hand, and a supernatural God, on the other, he posited one world of reality, at once Nature and God, and leaving no room for the supernatural. This so-called *Naturalism* of Spinoza is only distorted if one starts with a crude materialistic idea of Nature and supposes that Spinoza degraded God. The truth is that he raised Nature to the rank of God by conceiving Nature as the fulness of reality, as the One and All. He rejected the specious simplicity obtainable by denying the reality of Matter, or of Mind, or of God. The cosmic system comprehends them all. In fact, God and Nature become identical when each is conceived as the Perfect Self-Existent. This constitutes Spinoza's *Pantheism*.

God or Nature consists of Attributes. God, as the complete system of Attributes, is *absolutely* infinite or complete; each Attribute is only infinite of its kind. By Attribute Spinoza means an ultimate or irreducible quality or energy. He names two such Attributes, namely, Extension and Thought, but he allows for the possibility of an infinity of Attributes. The Attributes do not belong to, but are identical with, Substance. Reality, moreover, is essentially dynamic, not static—to be is to be doing. Thus the Attribute Extension is really the whole of material energy, and the Attribute Thought is the whole of mind-energy. All material things and events are changing modes or states of Extension; and all mental events or experiences are similarly modifications or states of Thought. Each Attribute exhausts its kind of reality, is an ultimate character, activity or "world-line" of Nature, and gives rise to its entire series of objects and events in accordance with its own laws. These finite objects and events are real enough while they last, but as finite modes they change and pass; not, however, into mere nothingness, for the Attribute, of which they are states, abides. The cosmic process never stops.

Spinoza's conception of Extension and Thought, or Matter and Consciousness, as concurrent Attributes or Energies of Reality cast a new light on the problem of the relation between body and soul. Indeed, it was this problem which led him to the conception of concurrent Attributes. Under the influence of Plato and of Christianity, body and soul had come to be regarded as antagonistic to each other, and their apparently intimate relation caused much perplexity to Cartesians and others. Materialists tried to explain away the soul; idealists sought to explain away the body; the Cartesian Occasionalists fell back on the miraculous intervention of God to synchronize body and soul (that is, physical and mental processes) like the wire-puller in a Punch and Judy show. Spinoza realized the *difference* between the mental and the material, but rejected the Cartesian conception of their *antagonism*. So he did not hesitate to attribute to God both Extension and Thought. And man, a finite mode of God, is thus both physical and mental, and functions in both ways concurrently, even if each series of events is self-contained. This solution committed Spinoza to the view that all physical beings are animated, though in very different degrees; and Spinoza accepted this view.

**Theory of Knowledge.**—Spinoza commenced a treatise specially devoted to the problem of Knowledge. But this work, the *Treatise on the Improvement of the Understanding*, was never completed. In his other works epistemological discussions are intimately linked with the rest of his philosophy. Indeed, even in the *Treatise on the Improvement of the Understanding* epistemological views are almost inseparably connected with ethical and religious ones. That is the consequence of his characteristic conception of "Knowledge." For Spinoza "Knowledge" is "life," not in the sense that contemplation is the highest life, but in the sense that knowledge is the means of holding together the threads of life in a systematic unity that can fill its proper place in the cosmic system. In this sense the effort after the highest knowledge becomes part of the cosmic activities by which cosmic unity is maintained, and so part of the very life of God. There are two things which must be borne in mind in connection with Spinoza's conception of knowledge. The first is his insistence on the *active* character of knowledge. The ideas or concepts by means of which thought construes reality are not like "lifeless pictures on a panel"; they are activities by which reality is apprehended; they are part of reality, and reality is activity. The second point is that Spinoza does not divorce knowing from willing. Man always acts according to his lights. If a man's endeavours appear to fall short of his knowledge, that is only because his knowledge is not really what it is held to be, but is wanting in some respect. On the one hand, reason, for Spinoza, is essentially the "practical reason." On the other hand, the highest expression of willing is experienced in that striving for consistency and harmony which is so characteristic of reason. For Spinoza, then, as for Bacon and all the Renaissance thinkers, "Knowledge is power," but in a much deeper sense than Bacon intended.

Spinoza's account of knowledge is particularly interesting as a clue to the way in which he gradually built up his ontology. He distinguishes three ascending grades of knowledge, namely, opinion, reason and intuition. By "opinion" Spinoza means the lowest grade of knowledge in which one assents to what one hears, perceives or imagines. It is the pre-scientific stage of knowledge. Its main characteristic is that objects and events are apprehended as detached things, without any insight into their connections or laws. The second grade, or "reason," is that in which we have an insight into the connections of things and events, and their laws; it is the stage of scientific knowledge. This grade of knowledge is greatly superior to the first, inasmuch as a knowledge of their connections and laws makes things more intelligible. But even this stage is imperfect because rather abstract. It reveals the course of single threads in the fabric of reality, not the whole pattern; it traces "world-lines," but affords no synoptic vision of the cosmos as a whole. It is the function of the third grade of knowledge, "intuition," to complete the scheme. In intuitive knowledge the cosmic system is grasped as a whole. This highest stage is only possible for a mind that has been through the discipline of the rational stage. Unlike the mystics, Spinoza does not regard intuitive vision as a substitute for thought and entirely different from it, but rather as its highest fruit—it is "thoughtfulness matured to inspiration." The three stages of knowledge might be roughly compared with the three stages in the acquisition of the knowledge of a new language.

First come the separate letters of the alphabet; then combinations of letters into words and of words into sentences, etc., in accordance with the laws of grammar; lastly comes the stage when the significance of a whole sentence or paragraph is grasped at a glance. So it is with the great book of Nature. First comes the perception of apparently isolated facts and events; next comes the understanding of their interconnections and laws; finally comes the intuition of the structure and significance of the whole—the vision which sees all things in God, and God in all things.

Spinoza's theory of knowledge appears to make the ontological assumption that reality is an interconnected system. Spinoza himself regarded it as an ultimate intuition. And his theory of knowledge was in some ways a justification of that view. To realize this it is necessary to grasp the fundamental distinction which Spinoza draws between "opinion" and "reason," or perception and understanding. A percept or an image is, for Spinoza, something entirely different from an idea or concept. Conception or understanding is an activity which grasps interconnections, and has nothing to do with images as such. Perception and imagination, on the other hand, are concerned with images and not with connections. And the laws of these two kinds of activities are as different as are their objects. Perception, or imagination, is concerned with images and follows the laws of association; conception or understanding is concerned with connections and follows the laws of logic. Hence Spinoza's insistence that "we can not *imagine* God, but we can *conceive* Him" (*Correspondence,* p. 289). Hence also Spinoza's rejection of Baconian empiricism. From observations of particulars as such it would be impossible, according to Spinoza, to derive laws or necessary connections. The laws or general truths of science rest, in the last resort, not on their correspondence with objects of perception, but on their harmonious interconnection in a system of truths. Spinoza, accordingly, dispenses with an external criterion of truth. "The true," he maintains, "reveals itself and the false." The ultimate test of truth is more truth or more knowledge, or the coherence of all that is known. The false or untrue betrays itself by its incoherence with what is already known. In fact, Spinoza for the most part regards ideas or concepts from the point of view of their *adequacy* rather than their *truth,* in order to avoid the suggestion of a merely external correspondence such as is usually associated with the term "truth." Concepts (or "ideas" in this sense) are acts of thought by which the laws and interconnections of things and events are apprehended. They are *adequate* in so far as they really enable us to systematize a certain range of facts. In that case they are also true, for they agree with the facts. The primacy, however, is with the *adequacy* of the concept, because until we have the adequate concept we can not apprehend the facts in such a way that it can be said to agree with them, or to be *true.*

In the history of philosophy Spinoza was the first to elaborate the coherence theory of truth. In his time mathematics was the only science that could serve as a model of such a coherent system. Hence his addiction to the method of geometry. The significance of his use of this method has been misinterpreted. His sole aim was to express his philosophy in as coherent and objective a manner as possible. Two points should be noted in particular. In the first place, Spinoza did not suppose that science or philosophy can dispense with observation or experience. He fully realized the importance of experience in the very setting of the problems which science and philosophy seek to solve; and it is known from his letters that he carried out many chemical and physical experiments. All that he insisted upon was that science involves much more than mere observation, that it needs concepts not derived from experience. It was his intention to write about scientific method, and to show that Bacon's ideas about it were inadequate; but this was one of several plans which he did not live long enough to carry out. The second point is that Spinoza had no delusions about the conclusiveness of the geometrical method. He himself had expounded the philosophy of Descartes in that method, although he thoroughly disagreed with it.

Above all it is important to note that, for Spinoza, the highest knowledge ("intuitive" or "clear" knowledge) is something much fuller and richer than the abstract assertions usually associated with the term knowledge. In the *Short Treatise* (p. 69 ed. Wolf) he describes it as "feeling and enjoying the thing itself." One must try to realize his meaning by thinking of what happens when a train of thought interests a thinker so deeply as to master him completely, and he gets so absorbed in the object of his thought as to identify himself with it. If we can conjure up all this vividly and warmly, then we may realize how Spinoza came to identify the highest "knowledge" with that "intellectual love of God" in which the individual realizes himself as part of the living Universe. In this state he does not merely picture reality in an external manner, but feels its very heart throb, and feels himself as part of it. But here we are on the verge of the mystical where all but the greatest poets cease to be articulate.

**Substance, Attributes, Modes.**—Spinoza's ideas relating to the character and structure of reality are expressed by him in terms of *substance, attributes,* and *modes.* These terms are very old and familiar; but not in the sense in which Spinoza employs them. To understand Spinoza, it is necessary to lay aside all preconceptions about them, and follow Spinoza closely. Spinoza, as already explained, found it impossible to understand the finite, dependent, transient objects and events of experience without assuming some reality not dependent on anything else but self-existent, not produced by anything else but eternal, not restricted or limited by anything else but infinite. Such an uncaused, self-sustaining reality he called *substance.* So, *e.g.,* he could not understand the reality of material objects and physical events without assuming the reality of a self-existing, infinite and eternal physical force which expresses itself in all the movements and changes which occur, as we say, in space. This physical force he called *Extension,* and described it, at first, as a *substance,* in the sense just explained. Similarly, he could not understand the various dependent, transient mental experiences with which we are familiar without assuming the reality of a self-existing, infinite and eternal consciousness, mental force, or mind-energy, which expresses itself in all these finite experiences of perceiving and understanding, of feeling and striving. This consciousness or mind-energy he called *Thought,* and described it also, at first, as a *substance.* Each of these "substances" he regarded as infinite of its kind (that is, as exhaustive of all the events of its own kind), and as irreducible to the other, or any other, substance. But in view of the intimate way in which Extension and Thought express themselves conjointly in the life of man, Spinoza considered it necessary to conceive of Extension and Thought not as detached realities, but as constituting one organic whole or system. And in order to express this idea, he then described Extension and Thought as *Attributes,* reserving the term *Substance* for the system which they constitute between them. This change of description was not intended to deny that Extension and Thought are substances in the sense of being self-existent, etc. It was only intended to express their coherence in one system. The system of course would be more than any one attribute. For each attribute is only *infinite of its kind;* the system of all the attributes is *absolutely infinite,* that is, exhausts the whole of reality. Spinoza, accordingly, now restricted the term "substance" to the complete system, though he occasionally continued to use the phrase "substance or attribute," or described Extension as a substance. As commonly used, especially since the time of Locke, the term substance is contrasted with its attributes or qualities as their substratum or bearer. But this meaning must not be read into Spinoza. For Spinoza, Substance is not the support or bearer of the Attributes, but the system of Attributes—he actually uses the expression "Substance or the Attributes." If there is any difference at all between "Substance" and "the Attributes," as Spinoza uses these terms, it is only the difference between the Attributes conceived as an organic system and the Attributes conceived (but not by Spinoza) as a mere sum of detached forces. Something is still necessary to complete the account of Spinoza's conception of Substance. We have so far only considered the two Attributes, namely, Extension and

Thought. Spinoza, however, realized that there may be other Attributes, unknown to man. If so, they are all part of the one Substance or cosmic system. And using the term "infinite" in the sense of "complete" or "exhaustive," he ascribed to Substance an infinity of Attributes, that is, all the Attributes there are, whether known to man or not.

Now reality, for Spinoza, is activity. Substance is incessantly active, each Attribute exercising its kind of energy in all possible ways. Thus the various objects and events of the material world come into being as modes (modifications or states) of the attribute Extension; and the various minds and mental experiences come into being as modes of the attribute Thought (or Consciousness). These modes are not external creations of the Attributes, but immanent results—they are not "thrown off" by the Attributes, but are states (or modifications) of them, as air-waves are states of the air. Each Attribute, however, expresses itself in its finite modes not immediately (or directly) but mediately (or indirectly), at least in the sense to be explained now. Galilean physics tended to regard the whole world of physical phenomena as the result of differences of motion or momentum. And, though erroneously conceived, the Cartesian conception of a constant quantity of motion in the world led Spinoza to conceive of all physical phenomena as so many varying expressions of that store of motion (or motion and rest). Spinoza might, of course, have identified Extension with energy of motion. But, with his usual caution, he appears to have suspected that motion may be only one of several types of physical energy. So he described motion simply as a mode of Extension, but as an *infinite* mode (because complete or exhaustive of all finite modes of motion) and as an *immediate* mode (as a direct expression of Extension). Again, the physical world (or "the face of the world as a whole," as Spinoza calls it) retains a certain sameness in spite of the innumerable changes in detail that are going on. Accordingly, Spinoza described also the physical world as a whole as an *infinite* mode of Extension ("infinite" because exhaustive of all facts and events that can be reduced to motion), but as a *mediate* (or indirect) mode, because he regarded it as the outcome of the conservation of motion (itself a mode, though an *immediate* mode). The physical things and events of ordinary experience are *finite* modes. In essence each of them is part of the Attribute Extension, which is active in each of them. But the finiteness of each of them is due to the fact that it is restrained or hedged in, so to say, by other finite modes. This limitation or determination is negation in the sense that each finite mode is *not* the whole attribute Extension, it is not the other finite modes. But each mode is positively real and ultimate as part of the Attribute.

In the same kind of way the Attribute Thought exercises its activity in various mental processes, and in such systems of mental process as are called minds or souls. But in this case, as in the case of Extension, Spinoza conceives of the finite modes of Thought as mediated by infinite modes. The immediate infinite mode of Thought he describes as "the idea of God"; the mediate infinite mode he calls "the infinite idea" or "the idea of all things." The other Attributes (if any) must be conceived in an analogous manner. And the whole Universe or Substance is conceived as one dynamic system of which the various Attributes are the several world-lines along which it expresses itself in all the infinite variety of events.

Having regard to the persistent misinterpretation of Spinozism it may be as well to emphasize the dynamic character of reality as Spinoza conceived it. The cosmic system is certainly a logical or rational system, according to Spinoza, for Thought is a constitutive part of it; but it is not *merely* a logical system—it is dynamic as well as logical. His frequent use of geometrical illustrations affords no evidence at all in support of a purely logico-mathematical interpretation of his philosophy; for Spinoza regarded geometrical figures, not in a Platonic or static manner, but as things traced out by moving particles or lines, etc., that is, dynamically.

**Emergence.**—A few words may be added here to indicate the merits of Spinoza's conception of the Universe in relation to the doctrine of emergent evolution as maintained by C. Lloyd Morgan and S. Alexander. (*See* EMERGENCE and PHILOSOPHY, HISTORY OF.) If reality is considered from the point of view of the finite modes (or *Natura naturata,* in Spinoza's terminology) instead of from that of Substance or the Attributes (or *Natura naturans*), then beginning with the simplest kinds of modes and passing on to more and more complex combinations of them, each such combination will always be something more than the mere sum of its components. To this extent something new emerges at every stage where a system is formed out of simple constituents. At a certain stage we reach the various infinite modes, then the several Attributes, and finally God. For Spinoza, however, God or the Attributes and the Infinite Modes are eternal, so that the process of evolution can only concern the world of finite modes. This kind of emergent evolution Spinoza can be said to recognize when he identifies moral progress with ever widening synthesis—"the more perfection (*i.e.,* reality) anything has, the more does it participate also in Deity" (*Correspondence,* p. 151). But Spinoza's conception has an advantage over the new conception of "emergence" (including the emergence of Deity). For the new doctrine involves the conception of the emergence of something out of nothing, inasmuch as the "emergent" is not contained in the sum of its conditions, but is something new. For Spinoza, on the other hand, the fulness of reality in all its essentials is always there, and the emergence of higher modes with the increasing synthesis or "holism" (*q.v.*) of lower modes does not involve a miraculous emergence of something out of nothing, but merely a rearrangement of what is already real.

**Moral Philosophy.**—For Spinoza, reality means activity, and the reality of anything expresses itself in a tendency to self-preservation—to exist is to persist. In the lowest kinds of things, in so-called inanimate matter, this tendency shows itself as inertia; in living organisms, it shows itself as a "will to live." Regarded physiologically this effort is called *appetite;* when we are conscious of it, it is called *desire.* The moral categories, good and evil, are intimately connected with desire, though not in the way commonly supposed. Man does not desire a thing because he thinks it is good, or shun it because he considers it bad; rather he considers anything good if he desires it, and regards it as bad if he has an aversion for it. Now whatever is felt to heighten vital activity gives pleasure; whatever is felt to lower such activity causes pain. Pleasure coupled with a consciousness of its external cause is called love, and pain coupled with a consciousness of its external cause is called hate—"love" and "hate" being used in the wide sense of "like" and "dislike." All human feelings are derived from pleasure, pain and desire. Their great variety is due to the differences in the kinds of external objects which give rise to them, and to the differences in the inner conditions of the individual experiencing them. Spinoza gives a detailed analysis of the whole gamut of human feelings, and his account is one of the classics of psychology. For the present purpose the most important distinction is that between "active" feelings and "passive" feelings (or "passions"). Man, according to Spinoza, is active or free in so far as any experience is the outcome solely of his own nature; he is passive, or a bondsman, in so far as any experience is due to other causes besides his own nature. The active feelings are all of them forms of self-realization, of heightened activity, of strength of mind, and are therefore always pleasurable. It is the passive feelings (or "passions") which are responsible for all the ills of life, for they are induced largely by things outside us and frequently cause that lowered vitality which means pain. Spinoza next links up his ethics with his theory of knowledge, and correlates the moral progress of man with his intellectual progress. At the lowest stage of knowledge, that of "opinion," man is under the dominant influence of things outside himself, and so is in the bondage of the passions. At the next stage, the stage of "reason," the characteristic feature of the human mind, its intelligence, asserts itself, and helps to emancipate him from his bondage to the senses and external allurements. The insight gained into the nature of the passions helps to free man from their domination. A better understanding of his own place in the cosmic system and of the place of all the objects of his likes and dislikes, and his insight into the neces-

sity which rules all things, tend to cure him of his resentments, regrets and disappointments. He grows reconciled to things, and wins peace of mind. In this way reason teaches acquiescence in the universal order, and elevates the mind above the turmoil of passion. At the highest stage of knowledge, that of "intuitive knowledge," the mind apprehends all things as expressions of the eternal cosmos. It sees all things in God, and God in all things. It feels itself as part of the eternal order, identifying its thoughts with cosmic thought and its interests with cosmic interests. Thereby it becomes eternal as one of the eternal ideas in which the Attribute Thought expresses itself, and attains to that "blessedness" which "is not the reward of virtue, but virtue itself," that is, the perfect joy which characterises perfect self-activity. This is not an easy or a common achievement. "But," says Spinoza, "everything excellent is as difficult as it is rare."

Two things at least must be added to prevent a misunderstanding of this slight sketch of Spinoza's ethics. The first is that he did not teach asceticism. Circumstances compelled him to be extremely frugal and live on a few pence a day; but he affected no contempt for the joys of life. On the contrary, he urged that "it is the part of a wise man to use the world and delight himself in it as best he may, though not to satiety, for that is no delight." The second point is that Spinoza, though compelled by circumstances to live the life of a recluse more or less, laid great stress on the social character of the moral life. "Men," he says, "will find that their needs are best satisfied by mutual help, and that only by uniting their strength can they escape the dangers that beset them everywhere." He insists further that the good pursued by reasonable men is a good that may be enjoyed by all, and that the virtuous man wants no special privileges, but desires also for his fellow men whatever he desires for himself. The third point is that Spinoza's contention that the conception of goodness, like that of purpose, is inapplicable to the cosmic system as a whole does not mean that he denied the validity of the distinction between good and evil in the realm of human conduct. The notions "good" and "evil" involve the conception of an ideal that is desired but not yet realized, and the realization of which is helped by some things, hindered by others. Now the cosmic system, or God, is completely real or perfect, and therefore "beyond good and evil." But with finite modes like men it is quite different. Much can be done that really heightens or lowers human life. Whatever enriches it really is good; whatever impoverishes it really is bad, even if its badness is something negative, a defect, rather than something positive.

**Political Philosophy.**—Spinoza agreed with Hobbes that if each man had to fend for himself, with nothing but his own right arm to rely upon, then the life of man would be "nasty, brutish and short." The truly human life is only possible in an organized community, that is, a state or commonwealth. The state ensures security of life, limb and property; it brings within reach of every individual many necessaries of life which he could not produce by himself; and it sets free sufficient time and energy for the higher development of human powers. Now the existence of a state depends upon a kind of implicit agreement on the part of its members or citizens to obey the sovereign authority which governs it. In a state no one can be allowed to do just as he pleases. Every citizen is obliged to obey its laws; and he is not free even to interpret the laws in a special manner. This looks at first like a loss of freedom on the part of the individuals, and the establishment of an absolute power over them. Yet that is not really so. In the first place, without the advantages of an organized state the average individual would be so subject to dangers and hardships of all kinds and to his own passions that he could not be called free in any real sense of the term, least of all in the sense in which Spinoza used it. Man needs the state not only to save him from others but also from his own lower impulses and to enable him to live a life of reason, which alone is truly human. In the second place, state sovereignty is never really absolute. It is true that almost any kind of government is better than none, so that it is worth while bearing much that is irksome rather than disturb the peace. But a reasonably wise government will even in its own interests endeavour to secure the good will and co-operation of its citizens by refraining from unreasonable measures, and will permit or even encourage its citizens to advocate reforms, provided they employ peaceable means. In this way the state really rests, in the last resort, on the united will of the citizens, on what Rousseau, who read Spinoza, subsequently called the "general will." Spinoza sometimes writes as if he upheld absolute sovereignty. But that is due mainly to his determined opposition to every kind of ecclesiastical control over the state. Though he is prepared to support what may be called a state religion, as a kind of spiritual cement, yet his account of this religion is such as to make it acceptable to the adherents of any one of the historic creeds, to deists, pantheists and all others, provided they are not fanatical believers or unbelievers. It is really in the interests of freedom of thought and speech that Spinoza would entrust the civil government with something approaching absolute sovereignty in order to effectively resist the tyranny of the militant churches.

One of the most striking features in Spinoza's political theory is his basic principle that Right is Might. This principle he applied systematically to the whole problem of government, and seemed rather pleased with his achievement, inasmuch as it enabled him to treat political theory in a scientific spirit, as if he were dealing with applied mathematics. The identification or correlation of right with power has caused much misunderstanding. People supposed that Spinoza reduced justice to brute force. But Spinoza was very far from approving *Realpolitik*. In the philosophy of Spinoza the term "power" (as should be clear from the above account of his moral philosophy) means a great deal more than physical force. In a passage near the end of his *Political Treatise* he states explicitly that "human power chiefly consists in strength of mind and intellect"—it consists in fact, of all the human capacities and aptitudes, especially the highest of them. Conceived correctly, Spinoza's whole philosophy leaves ample scope for ideal motives in the life of the individual and of the community.

Spinoza discusses the principal kinds of states, or the main types of government, namely, Monarchy, Aristocracy and Democracy. Each has its own peculiarities and needs special safeguards, if it is to realize the primary function of a state. Monarchy may degenerate into Tyranny unless it is subjected to various constitutional checks which will prevent any attempt at autocracy. Similarly, Aristocracy may degenerate into Oligarchy, and needs analogous checks. On the whole, Spinoza favours Democracy, by which he meant any kind of representative government. In the case of Democracy the community and the government are more nearly identical than in the case of Monarchy or Aristocracy; consequently a democracy is least likely to experience frequent collisions between the people and the government, and so is best adapted to secure and maintain that peace which it is the business of the state to secure.

**Bible Criticism.**—Spinoza was not only the real father of modern metaphysics and moral and political philosophy, but also of the so-called higher criticism of the Bible. This part of his work was incidental to his plea for freedom of thought and speech. His *Tractatus Theologico-Politicus* undertook to show that the Scriptures properly understood gave no authority for the militant intolerance of the clergy who sought to stifle all dissent by the use of force. To achieve his object, Spinoza had to show what is meant by a proper understanding of the Bible. And this gave him occasion to apply criticism to the Bible. To appreciate his services in this connection it must be remembered that his age was remarkably lacking in historical sense, especially in matters relating to religion. Saintly contemporaries like John Bunyan and Mañasseh ben Israel made the most fantastic use of Scripture texts; while militant clerics, relying on the ignorant bibliolatry of the masses, misapplied Bible texts to gain their ends. Spinoza, who permitted no supernatural rival to Nature and no rival authority to the civil government of the state, rejected also all claims that Biblical literature should be treated in a manner entirely different from that in which any other document is treated that claims to be historical. His contention that the Bible "is in parts imperfect, corrupt, erroneous, and inconsistent with itself, and that we possess but fragments of it" roused a

great storm at the time, and was mainly responsible for his evil repute for a century at least. Nevertheless, the intelligent world has gradually come round to his views, and has learned to agree with him that the real "word of God," or true religion, is not something written in books but "inscribed on the heart and mind of man." And many ministers of religion now praise Spinoza's services in the correct interpretation of Scripture as a document of first rate importance in the progressive development of human thought and conduct.

BIBLIOGRAPHY.—*Biographies:* (M. Lucas) *The Oldest Biography of Spinoza,* edited, translated and annotated by A. Wolf (1927); A. Wolf, *Spinoza; His Life and Treatise on God and Man* (1910); J. Freudenthal, *Das Leben Spinozas* (1904, 1927), and *Die Lebensgeschichte Spinozas in Quellenschriften,* etc. (1899); E. Dunin-Borkowski, *Der Junge de Spinoza* (1910). *Works:* The best edition is *Spinoza Opera* (4 vols.) edited by C. Gebhardt (Heidelberg, 1926). *Translations:* An English translation of the complete works of Spinoza (with introductions and commentaries) by A. Wolf is in course of preparation; the volume containing the complete *Correspondence of Spinoza* was published in 1928. Of other English translations the following are the most important: *Spinoza's Chief Works* translated by R. H. Elwes (2 vols., 1883–84, etc.); *Ethics* translated by Hale White and A. H. Stirling (1899); *A Short Treatise on God, Man and his Well-being* translated by A. Wolf (1910). The best French translations are those by E. Saisset (3 vols., 1861) and Ch. Appuhn (4 vols., 1904, etc.). The best German translations are those by B. Auerbach (2 vols., 1871), and by O. Baensch, C. Gebhardt and others (3 vols., 1914–22). *Books on Spinoza's Philosophy,* etc. The following are the most important: F. Pollock, *Spinoza, His Life and Philosophy* (1880, 1899, 1911); J. Martineau, *A Study of Spinoza* (1882, 1883, 1895); J. Caird, *Spinoza* (1888, 1901); H. H. Joachim, *A Study of the Ethics of Spinoza* (1901); R. A. Duff, *Spinoza's Ethical and Political Philosophy* (1903); L. Roth, *Spinoza, Descartes, and Maimonides* (1924); J. A. Gunn, *Benedict Spinoza* (1925) contains a bibliography; R. McKeon, *The Philosophy of Spinoza* (1928); L. Roth, *Spinoza* (1929). Of *German Books* the most important are: D. Camerer, *Die Lehre Spinozas* (1877, 1914); K. Fischer, *Spinoza* (5th ed., 1909); J. Freudenthal, *Spinoza, Leben und Lehre* (1928). Of *French Books* the most important are: L. Brunschvicg, *Spinoza et ses Contemporains* (1923); V. Delbos, *Le Problème moral dans la Philosophie de Spinoza* (1893) and *Le Spinozisme* (1916). Of *Multilingual Books* the following series (edited by C. Gebhardt) are most important: *Chronicon Spinozanum* (since 1921) and *Bibliotheca Spinozana* (since 1922). (A. Wo.)

**SPINY SQUIRREL,** a group of African ground squirrels, characterized by the spiny nature of the fur. They form the genera *Xerus, Euxerus, Atlantoxerus* and *Geosciurus,* being characterized by the small size or absence of the ears, and the long, nearly straight, claws. Typical spiny squirrels live in clefts or holes of rocks, or in burrows. (*See* RODENTIA.)

**SPION KOP,** a mountain in Natal on the N. Tugela river, and 24 mi. W.S.W. of Ladysmith. It was the scene of a battle in the Transvaal War (*see* SOUTH AFRICAN WAR and LADYSMITH).

**SPIRAEA,** a much cultivated genus of shrubs of the rose family (Rosaceae, *q.v.*), comprising about 80 species, natives mostly of the northern hemisphere. They are slender shrubs, 2 to 8 ft. high, usually with simple leaves and small white, pink or reddish flowers arranged in dense showy clusters. *S. salicifolia* (queen of the meadow) occurs in England and Scotland. *S. latifolia* (meadow-sweet), *S. alba* (white meadow-sweet) and *S. tomentosa* (hardhack, *q.v.*) are representative species of E. North America. *S. douglasi* (western meadow-sweet) occurs on the Pacific coast. Among the best-known cultivated forms are *S. prunifolia* (bridal-wreath) and the popular hybrid *S. vanhouttei.* There are dozens of named forms, commonly called spiraeas, and some are forced for early spring bloom.

A few of the so-called spiraeas belong to the genus *Astilbe* of the family Saxifragaceae.

**SPIRE,** in architecture, a steep, pyramidal form, crowning a tower. The origin of the form was the simple, four-sided, pyramidal roof frequently erected over Romanesque towers, as in many crude 11th century examples in Normandy, some of the Italian campaniles of the 11th and 12th centuries, and many German Romanesque towers, mostly of the 12th century. This form is abrupt and stunted and may easily be ungraceful, and various experimental attempts were made to soften the line. Thus the late 11th century tower at Le Puy en Velay has the successive stages of the tower receding and broken up by projecting bays on the sides. Furthermore, the pyramidal roof itself is decorated with corner finials and small, round-headed dormers. In Germany the form was varied by ending each face of the square tower in a gable, the plane determined by adjacent gable slopes establishing the slope of the pyramid, as in the square tower of the abbey church of Laach (*c.* 1156). The pleasanter effect of the octagonal spires over octagonal towers, like another of the towers at Laach, or the older of the two towers at Mainz (late 12th century), led to attempts to combine an octagonal spire with a square tower. This was accomplished in various ways, one of the simplest being the so-called broach spire, in which small, triangular planes of a less steep pitch than that of the spire proper occur at the bottom of the corner spire faces, with their lower points coinciding with the corners of the towers, as seen in the 12th century church of S. Columba at Cologne.

A more developed form of broach spire lies in the substitution of a small pyramid at the bottom of the corner faces, instead of the triangular plane. This is a type which became common in English Gothic spires. It may be described geometrically as the intersection of a four-sided pyramid of low slope by an eight-sided pyramid of steep slope, as in the 14th century spire of St. Mary's at Stamford. A more elaborate method of softening the junction between square and octagon was to carry the corner faces down unbroken to the top of the tower and fill the triangular corners thus left with decorative finials. An early example is the crossing tower of the church of S. Ours, at Loches, France (12th century).

In the south-west tower of Chartres cathedral (end of the 12th century) a further advance is made in connecting tower and spire, by adding high, gabled dormers on the faces of the spire, over the centres of the tower faces, as well as richly developing the corner pinnacles. In the spire at Senlis cathedral (13th century) a vertical, octagonal stage, or lantern, is placed between the square tower and the octagonal spire. The corners of the square tower are occupied by pinnacles and eight slim dormers surround the spire base. The edges of the Chartres and Senlis spires are decorated with projecting roll mouldings, and those at Senlis are further enriched by crockets which form an admirable fretting of the silhouette. It is probable that similar crocketed spires were almost universally intended over the great towers of most of the French cathedrals. The towers at Laon, for instance, were once so crowned and spires at Reims and Amiens were begun.

**Gothic Climax.**—It was in Normandy, England and Germany that Gothic spire design reached its climax. Particularly famous are the spires of S. Sauveur at Caen (14th century); S. Pierre at Caen (1308) and the magnificent group of spires at Coutances cathedral (13th century), in which the spire dormers and the corner pinnacles are treated with the utmost richness and the sense of height and slimness emphasized in every possible manner. The customary lavishness of the French Flamboyant style is magnificently illustrated in its pierced and intricately traceried spires. The two most remarkable examples are the northern spire of Chartres cathedral (1506–13), by Jehan Texier, and the so-called Tour de Beurre (*c.* 1520) of the cathedral at Rouen.

Spires of a simple type crown many of the Italian campaniles, and during the 13th, 14th and 15th centuries, spires and lanterns were frequently added to earlier towers. In neither Italy nor Spain, however, was the highly developed spire a native form, and Italian spires were simple, slate, tile or metal covered, pyramidal or conical roofs of timber. Burgos cathedral is unique in Spain in possessing two western spires of intricate, open-work masonry, which date from the 15th century. These, however, are known to have been designed by a German architect.

German luxuriance, which had already appeared in the numerous varieties of timber spires used on the Rhenish Romanesque churches, found equally congenial expression in the stone spires of the Gothic period. The early, simple type is seen in the solid spires of S. Elizabeth at Marburg (not completed until the middle of the 14th century but probably from a 13th century design). The cathedral at Freiburg has a spire (1270–88) which is of a new and infinitely richer type. The low, square tower carries a high, octagonal lantern, each side of which is capped by a slim gable and filled with delicate tracery, the corners of the square being filled with rich, triangular pinnacles, one of which is con-

tinued up as an open, spiral staircase, giving access to the upper portion. The spire rises above the lantern, a mere cage of open-work tracery, with crocketted edges, amazingly light and delicate in effect. Somewhat similar, although even more intricate in their pierced stone-work are the western spires of Regensburg cathedral (late 15th century), by Roritzer. These open-work spires became the rule in Germany, as illustrated in the intricate cage of Strasbourg cathedral (spire, 1435); the west towers of Cologne cathedral, built in the 19th century from mediaeval drawings; the over-complicated lace-work of the cathedral at Vienna (1433) and the spire at Ulm, over 500 ft. high, built in the last years of the 19th century, from 15th century drawings.

The spire of Oxford cathedral (1220) is a perfect example of the Early English spire type; it is octagonal, has a marked entasis or convex curve, and is decorated with dormers on each face and corner pinnacles. The great spire of Salisbury cathedral (1250), 406 ft. high, shows the tremendous aesthetic advantage of the greater steepness there present, which became the rule in the later English spires. During the Decorated period it became customary to finish the top of the tower with a parapet, either battlemented or of pierced tracery, and to set back the base of the spire behind the face of the wall. With this change the use of broaches disappeared and tall, corner pinnacles, sometimes supported on corner buttresses, filled the tower corners. An early example of the parapeted tower with a spire, in which broaches remain and the corner pinnacles are raised up to the top of the broach, is that of Ashbourne church, Derbyshire (14th century). Among the loveliest of Decorated spires are the two western spires of Lichfield cathedral, with heavy but effective, corner pinnacles. The highly developed type of spire with corner pinnacles and a parapet below can be seen in St. Peter's, Kettering, and Sts. Peter and Paul, Oundle (both in Northamptonshire), both of the Perpendicular period. In other examples a little flying buttress connects the corner pinnacles with the face of the spire, as in the exquisite Perpendicular spire of Louth church, Lincolnshire. Many Perpendicular spires are often ornamented with crockets up the angles.

**Renaissance.**—The spire was a form never thoroughly absorbed by the Renaissance, which preferred domed lanterns crowning towers. Nevertheless, during the 17th century in Germany, most effective, fantastic, spire-like forms were developed. These, based partly on Italian Baroque prototypes, usually had profiles of broken concave and convex lines, crowned at the top with a sort of onion dome, the whole rising to a considerable height, and, in imaginative quality, far surpassing any of the Italian examples. It is such fantastic spires crowning the simple towers of village churches, which give much of their character to the little towns of south Germany and Austria. At the same time, in England, the spire idea was receiving a much simpler and more straightforward, and equally effective, Renaissance expression, through the efforts of Sir Christopher Wren and his followers, particularly in the churches built after the Great Fire of London in 1666, such as St. Martin's, Ludgate hill, St. Mary-le-Bow and St. Bride's, Fleet street, all by Wren. St. Mary-le-Strand (early 18th century) and St. Martin's-in-the-Fields (1721–1726) both by James Gibbs, which simplified and refined upon their Wren prototypes, are very successful.

Even more effective are many American colonial spires, which, although originally based upon the work of Wren and Gibbs, achieved a fresh beauty through still further simplification. Particularly noteworthy is the type in which a small, octagonal, arcaded lantern crowns a simple, square tower and carries, usually above an attic, a simple, slim, white spire, as in the Old South Meeting House, Boston (1729) and the extremely delicate, white, wooden steeple of the church at Farmington, Conn. (*c.* middle 18th century). Such steeples as that of S. Paul's chapel, New York (*c.* 1767), Christ church, Philadelphia (1754) and S. Michael's, Charleston, S.C. (1742, occasionally attributed to James Gibbs himself), although more monumental in treatment and more English in effect, still retain the characteristic American delicacy. This trend toward the more slender and attenuated proportions reached its climax in the exquisitely light spire of Park street church, Boston (1819), by Peter Banner. (For bibliography *see* GOTHIC ARCHITECTURE.) (T. F. H.)

**SPIRE LIGHT,** the term given to the windows in a spire which are found in all periods of English Gothic architecture and are an important feature in French spires. They are not glazed, and, if of large size, sometimes have transoms to strengthen the mullions.

**SPIRES:** *see* SPEYER.

**SPIRITS.** In the chemical sense the word is sometimes applied to acids having a volatile character, as "spirits of salts" or hydrochloric acid. The name is generally restricted to distilled liquors. The *Spiritus Rectificatus* of the British Pharmacopoeia is a mixture of ethyl alcohol and water in the volume proportions of 90 to 10. There are also four standard diluted alcohols recognized by the same authority containing respectively 70, 60, 45 and 20% of ethyl alcohol by volume. The spirits of the British Pharmacopoeia (*e.g.*, Sp. aetheris nitrosi; sp. chloroformi; sp. camphorae) are solutions of various substances obtained either by distilling them with, or dissolving them in, rectified spirit.

According to the British Spirits Act of 1880 "spirits" means spirits of any description and includes all liquors mixed with spirits, and all mixtures, compounds, or preparations made with spirits. The same enactment defines "plain spirits" as "British spirits (except low wines and feints) which have not had any flavour communicated thereto or ingredient or material mixed therewith," and "spirits of wine" as "rectified spirits of the strength of not less than 43 degrees above proof," *i.e.*, 75·36% of alcohol by weight or 81·59% by volume.

In its popular use "spirits" is generally understood to mean alcoholic beverages, *e.g.*, brandy, rum, whisky, distilled from liquids which have undergone a process of fermentation.

While "spirit" has never been a popular term in the United States it does have the same connotation as in Great Britain. But the Federal Government has defined "spirit" to mean an alcoholic distillate of over 190 degrees proof. Alcoholic distillates of lesser proof are termed whisky with qualifying adjectives which identify the proof and type of whisky.

**Proof Spirit.**—The British standard spirit is "proof spirit," which was defined by the Spirits Act of 1816 as "that which at the temperature of 51° F weighs exactly $\frac{12}{13}$ of an equal measure of distilled water." The temperature of the water was not defined, but there is some documentary evidence indicating that it was intended to be 51° F. A mixture of water and ethyl alcohol complying with this condition has, at 60° F, a specific gravity of 0·91976 and contains 49·28% of alcohol by weight and 57·10% by volume. Mixtures in other proportions are said to be "over proof" or "under proof," the expression of strength being based upon the number of volumes of proof spirit which could be obtained from one hundred volumes of the mixture at 50° F. Thus a strong spirit 100 volumes of which would, on the addition of water, give 166 volumes of proof spirit, is described as having a strength of 166% proof, or 66 degrees over proof, whilst one which contains, in 100 volumes, sufficient alcohol to give 45 volumes of proof spirit has a strength of 45% proof, or 55 degrees under proof. The proof gallon equivalent of a mixture, the strength and volume of which have been determined, can be ascertained by multiplying the volume in gallons by the strength and dividing by 100. Absolute alcohol has a strength of 75·35 degrees over proof.

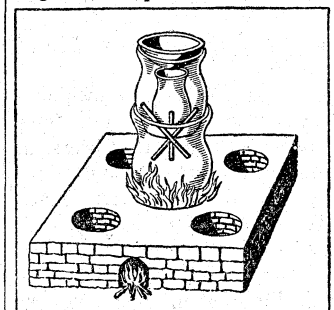

FIG. 1.—ANCIENT FORM OF STILL, USED IN TIBET

This method of assessment of alcoholic strength depends upon the difference in the respective specific gravities of alcohol and water, and the determination of the specific gravities appropriate to mixtures of these two substances is therefore of great importance.

At the request of the British Government the Royal Society undertook an investigation of this problem towards the close of the 18th century.

The work was entrusted to Sir Charles Blagden, the secretary, and George Gilpin, the clerk to the Royal Society.

Results of their experiments were published in the Philosophical Transactions 1790–94 and were of such great merit that they are incorporated in many of the official tables of the present day, including those legalized in Britain in 1915. Tralles in 1911 conducted a similar investigation for the Prussian Government, whilst Gay Lussac (Paris, 1824), McCulloch (Washington, 1848), Baumhauer (Amsterdam, 1860), Mendeléyev (St. Petersburg, 1865), the Kaiserliche Normal Eichungs Kommission (Berlin, 1889), and Bureau of Standards (Washington, 1913 and 1929) were also responsible for considerable work under the auspices of their respective Governments. In the United States a "proof" standard is adopted; Section 3249 of the Revised Statutes provides that "proof spirit shall be held to be that alcoholic liquor which contains one-half its volume of alcohol of a specific gravity of 0·7939 at sixty degrees Fahrenheit." In Holland also a "proof" spirit forms the basis of the revenue charge, the standard being 50% by volume of anhydrous alcohol at 15° C.

In the United States of America the term proof has both a technical and commercial meaning. The proof strength of spirit, therefore, is specified by law and can be used only under certain conditions.

Spirit distilled at over 190 degrees proof is required to be labelled "grain neutral spirit." Spirit distilled at from 160 to 190 degrees proof can be labelled "other whisky" but cannot be identified by the term "whisky" alone. Spirit distilled at under 160 degrees proof can be labelled "whisky" but must be identified in accordance with the grain from which it is distilled.

**Historical.**—The origin of the practice of distillation is lost in antiquity. Olympiodorus, in a commentary on the second book of Aristotle's *Meteors,* states that sailors boiled the sea water and suspended large sponges from the mouth of a brazen vessel in order to imbibe the "sweet water" which is evaporated. According to Fairley the Chinese distilled liquor; *Sautchoo* was known long before the Christian era and *arrack* was made in India as early as 800 B.C. According to this and other evidence accumulated from ancient literature there is little doubt that spirits were manufactured in the East many centuries before Christ. It appears to be well established that about the end of the fourth century A.D. Zosimus described an apparatus for distilling, whilst Geber, who is said to have lived in the seventh century of the Christian era, gave an account of the process, which he described as "the raising of aqueous vapour in any vessel in which it is placed." According to Fairley (*The Analyst,* 1905) the earliest known reference to the preparation of a spirituous liquor by distillation in Great Britain is contained in the "Mead Song" by the Welsh bard Taliesin in the sixth century. Fairley also points out that distillation from fermented grain liquor was practised in Ireland before the distillation of wine was introduced. St. Patrick is credited by an old Irish legend with having first taught the Irish the art of distillation; it is certain that at the time of the first English invasion of Ireland (1170–72) the manufacture of a spirit distilled from grain (*i.e.,* whisky) was known. It is probable also that the distillation of spirit in Scotland dates back to the same early period. Towards the end of the century much home-produced spirit was obtainable in England from apothecaries and vintners. The dissolution of the monasteries under Henry VIII. resulted in many of the disestablished monks setting up in business as distillers, brewers and vinegar makers, and during the Tudor period the distilling trade became firmly established.

The production of a spirit from wine (*i.e.,* brandy) appears to have been known in the ninth century but according to Morewood the first attempt at the distillation of wine in France is attributed to Arnaldus de Villa Nova in the 13th century. As a manufacturing industry the distillation of brandy in France began in the 14th century.

**Official Control of Spirit Trade.**—For centuries the preparation and sale of spirits in Great Britain has been under Government control. During the reign of Elizabeth a royal patent was issued to Candishe and later to Richard Drake to survey "the corrupt sorts of aqua vitae, aqua composita and usquebagh." In 1643 excise duties on spirits were regularly imposed, the tax being collected by the newly constituted excise department. By an act passed in 1657, the excise authorities were given wide powers of control over spirit manufacturers and dealers. Under the Spirits Act of 1880 the conditions imposed upon the trade are exceedingly strict.

A distiller must give notice to the authorities of the erection of any new plant or apparatus and must obtain their approval. He must notify the excise officer of the time of many of his manufacturing operations. He may not upon his distillery or any premises communicating therewith brew beer, refine sugar, deal in wine or make sweets, vinegar, cider or perry. He must keep records in the form prescribed by the Commissioners of Customs and Excise of the quantities of materials used in each operation and of the results of observations to be made at various stages.

There are three methods of assessing duty and whichever gives the highest amount is adopted. The first is the "attenuation charge." This consists of levying the charge due on one gal. of proof spirit for every 100 gal. of worts collected and for every five degrees of attenuation observed, the latter being calculated by taking the difference between the highest specific gravity of the worts and the lowest gravity of the wash after complete fermentation.

The second method is the "low wines" charge calculated upon the bulk quantity at proof strength of the low wines produced by the distillation of the wash. The third is the "feints and spirits" charge, assessed upon the number of proof gallons of feints and spirits produced by the final operations.

All countries exercise control over the spirit trade much in the same manner as does Great Britain. In the U.S., except in that period from 1920 to 1933 when manufacture, transportation or sale of alcoholic beverages was forbidden, the Government has always regulated the production of distilled spirit through actual control of spirit while it was reaching maturity and through excise taxes which in 1939 were $2.50 per proof gallon.

In addition, the Federal Government levies a 30 cents per gallon tax on spirit which is rectified (to rectify distilled spirit means to combine whisky with grain neutral spirit).

The several States of the United States also obtain excise taxes of varying amounts per proof gallon on distilled spirit which is sold within their borders. The State Governments have specific control of the method of distribution and sale to consumers but the Federal Government retains control of the distillation and manufacturing processes.

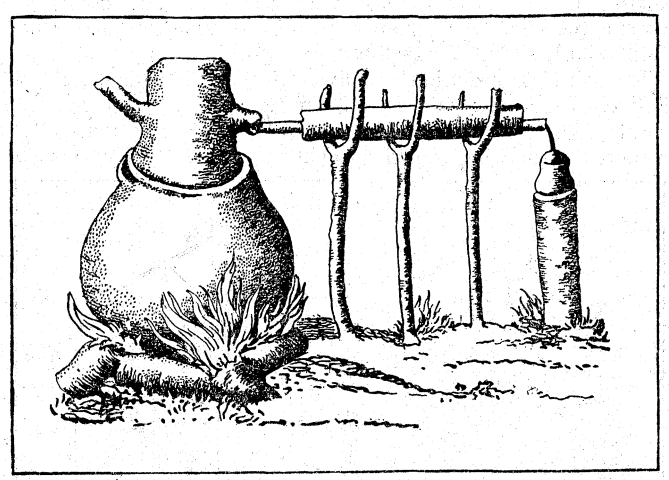

FIG. 2.—STILL OF ANCIENT TYPE AS USED IN TAHITI

**Production and Consumption.**—The development of official control has been coincident with a steady increase in the rate of duty on spirit and the total contribution to the national revenue from this source showed a corresponding growth until other influences affected the consumption of alcoholic beverages. Thus by 1643, in Great Britain the rate of customs or excise duty on

"strong waters or aqua vitae" was 8d. per gallon. The customs duties on spirits imported into Great Britain and Northern Ireland per proof gallon were, in 1929, as follows: Brandy and rum, £3.15.4; Imitation rum, Geneva, £3.15.5; Sweetened spirits, *e.g.*, liqueurs, cordials, etc., £3.15.11; Unsweetened spirits, *e.g.*, liqueurs, cordials, etc., £3.15.5.

There are many modifications of these rates, preferential treatment being accorded, for instance, to goods of Empire origin, while a reduction is also allowed for spirits which can be proved to be of a certain maturity. The corresponding maximum excise duty is £3.14.0 per proof gallon.

The production of spirit in the United Kingdom amounted in 1907 to roughly 50,000,000 proof gallons. In the decade 1880–90 the quantity annually distilled remained practically stationary at about 40,000,000 gal., but during the years 1890–1900 there was a rapid increase, the maximum being attained in 1898 when nearly 64,000,000 gal. were produced. A point had then been reached at which the production considerably exceeded the consumption, due in part to the desire of the spirit trade to meet the increased demand for "matured" spirits and in part to the fact that an excessive amount of capital had, owing to the increased popularity of Scotch whisky, been attracted to the distilling industry. This overproduction led to a vast increase in the quantity of spirit remaining in warehouse. In 1906 production and consumption were about equal and the quantity of spirit in warehouse represented roughly five years' supply.

Of late years the consumption of spirits has shown a marked decline. Whereas in the opening years of the century it reached approximately one gallon per annum per head of the population, in the subsequent decade it fell to 0·75 gallon. This is doubtless due, in part, to the high duties, but in all probability it may be attributed in some measure to a change in popular taste.

The number of distilleries in the British Isles has fluctuated in a manner corresponding to the consumption of spirit, but the variation has been chiefly in Scotland.

In 1906 the respective totals for the three countries were: Scotland 150, Ireland 28, England 8. Since that time there has been a steady decrease, the number for Great Britain and Northern Ireland being 140 in 1923 and 121 in 1926. Of the spirits distilled in the United Kingdom Scotland produces approximately one half, England and Ireland being responsible for the remainder in about equal proportions.

The apparent anomaly between the number of distilleries and the quantity of spirit produced in the different parts of the kingdom is explained by the fact that the great majority of the distilleries in Scotland and Ireland are small pot still distilleries, whereas the English plants are all of considerable capacity. Illicit distillation has almost ceased in Great Britain.

The spirit produced in the United Kingdom is made almost exclusively from malt, unmalted grain (chiefly maize, rye, barley, wheat and oats) and molasses. The relative proportions of malt to unmalted grain have shown a slight upward tendency. On the other hand the quantity of molasses employed has increased very largely, owing mainly to the fact that home made spirit has largely displaced the foreign article for several industrial purposes and particularly for methylation.

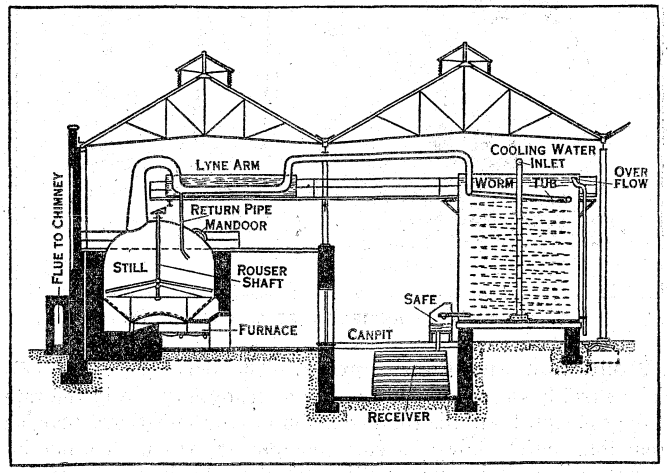

FIG. 3.—DIAGRAM OF SINGLE TYPE OF IRISH POT-STILL PLANT. (JOHN JAMESON'S DISTILLERY, DUBLIN)

In the Dominions the consumption per head of the population shows in some parts a tendency to decrease, thus, for Canada the figure for 1921 was 0·857 gal. and for 1927, 0·323 gal., and New Zealand 0·790 in 1921 and 0·518 in 1925, but in Australia there was an increase from 0·36 gal. in 1921–22 to 0·44 gal. in 1925–26. The sale of alcoholic beverages was prohibited in the United States of America from 1920 to 1933. In other countries the consumption of spirits per head of the population, expressed in litres of absolute alcohol, has been as follows:—

| Year | Denmark | Norway | Sweden | Switzerland | Germany | Holland | Belgium | France |
|---|---|---|---|---|---|---|---|---|
| 1920 | 1·51 | .. | 3·00 | 2·02 | 0·7 | 2·58 | 1·24 | 2·26 |
| 1921 | 1·51 | 0·44 | 2·40 | 2·16 | 1·0 | 1·45 | 0·99 | 2·09 |
| 1922 | 1·70 | 0·44 | 1·90 | 1·95 | 2·0 | 1·44 | 1·21 | 2·42 |
| 1923 | 1·90 | 0·55 | 1·95 | 2·55 | 1·1 | 1·21 | 1·29 | 2·67 |
| 1924 | 2·10 | 0·39 | 2·10 | 2·29 | 0·6 | 1·15 | 1·13 | 2·60 |
| 1925 | .. | 0·26 | 2·20 | 2·32 | 1·0 | .. | 0·97 | 2·70 |

The United States has always been one of the world's largest users of distilled spirits. In 1922 the United Kingdom consumed about 15,000,000 proof gallons as compared with 103,000,000 proof gallons consumed in the United States in 1937. In the four years since Repeal of Prohibition in the United States consumption of distilled spirits has been: 1935, 73,063,000; 1936, 98,858,000; 1937, 103,633,000; 1938, 98,519,000. Of this total consumption approximately 5% was distilled spirits imported from Great Britain and about 2% distilled spirits imported from Canada.

Consumption of distilled spirit has been steadily falling throughout the world. In 1914 the United Kingdom consumed ·71 proof gallons per capita as compared with ·37 proof gallons in 1922. Since 1922 per capita consumption has fallen even lower.

In the United States per capita consumption in 1914 was ·76 proof gallons. In 1939, despite a greatly increased population and a tremendous new group of consumers—women—per capita consumption remained at ·76 proof gallons.

Another indication of the decline in consumption both in the United Kingdom and the United States is found in the number of distilleries. American distilleries in 1939 numbered approximately 150. This total shows a mortality among distilleries in a five-year period of some 100% and even the number 150 will be high if the present rate of bankruptcy among distillers continues.

Distilling has followed other American industries in its development. Many small distilleries came into being in 1933 when the supply of spirit was limited and the demand great. As the better financed distillers increased production and popularized their spirit by national advertising the small producers failed. Testimony before a congressional committee of the United States Congress—the National Economics Committee, 1939—revealed that more than 60% of the spirit sold in the United States was distilled, owned, sold by four major distillers.

**Revenue from Spirit Trade.**—How important is the trade in distilled spirit in the United Kingdom and the U.S. from the standpoint of government revenue is indicated by the fact that in the United Kingdom (1938) £40,000,000 was collected from distillers as excise taxes. In the U.S. (1939) more than $1,000,000,000 was derived from taxes on distilling, distribution, sale of spirit.

**Manufacture.**—The manufacture of spirits can be divided into two or three stages according to the materials used. If they are of a saccharine nature (*e.g.*, grape juice or molasses), the first step is the conversion of the sugar into alcohol, the second operation being the separation by distillation of the alcohol and, incidentally, other volatile substances from solid matter which may be present either in suspension or in solution. If the raw material is of a farinaceous character the preliminary stage is the conversion of the starch into sugar.

*Brandy.*—The manufacture of genuine brandy, although requir-

ing great care in order to obtain a high class product, is not a complicated process. The quality of the brandy produced depends primarily upon the character of the wine employed, whilst the degree of excellence of the spirit offered for sale depends in great measure on the experience of the manufacturers in blending the products of various distillations. The character of the wine is therefore of the first importance and is dependent upon the soil, climate and methods of cultivation. The soil of the Cognac and other districts of France is particularly suitable, and brandy of excellent quality is also distilled from wine of British Empire origin. In France the cultivation of the vine has improved since the replanting of the vineyards after their devastation by the phylloxera epidemic of 1875–78. The best French brandies are obtained from the Charente wines which, although possessing no particular virtue as such, are peculiarly suitable for the production of a spirit of a fine and delicate flavour. The wines of other districts, although more highly flavoured, are not so suitable for the production of brandy. The type of still and method of distillation depend upon the character of the wine employed. In Charente, where as stated above, the most suitable wine is obtained, a simple pot still having a capacity of not more than 200 gal. is usually employed, the distillation being carried out very slowly. The spirit first obtained—*brouillis*—is redistilled to give a product of a higher strength—*bon chauffe*. In other districts where the wine is not so suitable a more complicated apparatus is employed. This includes a distilling column which renders possible a higher degree of rectification and the removal of fractions of the distillate which are considered undesirable.

*Rum.*—This spirit may be divided into two main classes "Jamaica" and "Demerara." The greater proportion of the former is of the type usually imported into Britain. It is prepared by the fermentation of a wash consisting of cane molasses, scum drawn from the solution during the manufacture of cane sugar, "dunder" the viscous mass obtained from the bottom of the still during the previous operation, and "megass," the last, which is the fibrous part of the crushed cane, being added to promote fermentation. The fermentation is slow, extending to 12 days or even longer. When this operation is complete the spirit is distilled off in a pot still. There are two other types of Jamaica rum. That intended for local use is obtained by rapid fermentation and is of comparatively poor quality. The third, known as "German rum" has a very strong flavour and is used for blending purposes or for imparting to plain spirit the characteristics of ordinary rum. Demerara rum is lighter in flavour than the Jamaica varieties and has a lower proportion of secondary ingredients. It is usually prepared by the fermentation of molasses dissolved in water, the spirit being then distilled off in patent stills or in pot stills of a type more complicated than those generally used in Jamaica. For the manufacture of industrial spirit, *see* ALCOHOL.

*Spirits of Farinaceous Origin.*—The raw materials used for these include cereal grains, such as barley, rye, oats, wheat, maize, etc., which produce whisky, "corn brandy," vodka, plain spirit and industrial alcohol. Potatoes are used in the manufacture of industrial alcohol. The first stage in the preparation of spirit from starch is the conversion of the latter into dextrine-maltose and intermediate products. This is accomplished by the action of a diastatic ferment such as that present in malted grain (*see* BREWING) or secreted by certain living organisms, or by an acid such as sulphuric acid. The latter process is little employed at the present time. The materials employed by the distiller and the methods of preparation and treatment to which they are subjected before and after entering the distillery are in some respects similar to those employed by the brewer. The great difference, apart from the actual process of distilling, is that, whereas the object of the brewer is to produce beer, of which alcohol forms only a relatively small proportion, the distiller, broadly speaking, desires to produce alcohol.

**Malting.**—Where malt is employed as the main raw material, as for instance in Scotch pot still and some other whiskies, the process of preparation usually does not differ widely from that used in making brewers' malt. The spirit manufacturer, however, need not be so particular as to the quality and character of the malt, which need only be sound and contain a high percentage of starch to serve his purpose. Barley intended for operations in a patent still is usually "steeped" and "floored" for periods longer than in brewery malting. In distilleries where barley malt is used not as a principal raw material but primarily as a diastatic agent, —for instance in potato and maize distilleries—these two processes are particularly lengthy, the steeping being prolonged until the increase in weight due to the absorbed water is about 40 or 45%. The brewers' malt is almost invariably highly kilned in order to restrict the diastatic power. As the object of the distiller is to produce the highest proportion of alcohol possible he does not desire to restrict the diastatic power in this way, and if possible uses a green malt. The malt whisky manufacturer, however, depends in great measure upon the kilning process to yield the characteristic flavour of his product. For this reason, and also because of the difficulty of obtaining green malt in hot weather, a malt is often used which has undergone a mild kilning process in which a temperature of 130° F is seldom exceeded. In order to reduce the danger of bacterial infection at subsequent stages some antiseptic such as lime is introduced during the steeping.

Although green or low dried barley malt is the saccharifying agent usually employed both in the United Kingdom and on the Continent of Europe, malts prepared from other materials are not infrequently employed.

Oat malt, notwithstanding its low transforming power, possesses certain advantages, inasmuch as it is easily and rapidly prepared, it acts very quickly in the mash tun, and its diastatic power is well maintained during fermentation. Rye is best malted in conjunction with a little barley or oats, as it otherwise tends to superheat and to grow together in a tangled mass.

**Mashing and Fermentation.**—The details of this stage of the process are, in the case of the malting, designed to produce the highest possible yield of alcohol consistent with the commercial requirements, such as flavour and aroma, of the particular trade in which the distiller is engaged. In order to accomplish this the mashing takes place at a low temperature, the wort thus remaining unsterilized and the diastatic action continuing during the fermentation period. The problem for the distiller is to raise the mash to a temperature as high as possible in order to restrict the bacterial fermentation to which the wort is liable, whilst keeping it sufficiently low to prevent the destruction of the diastase. The method employed varies according to the nature of the mash and the quality of the spirit desired, but in general principle is governed by the requirements indicated. The micro-organisms most to be feared are those belonging to the class of fission fungi (*schizomycetes*) such as the butyric, lactic, mannitic and mucic ferments. In order to avoid bacterial fermentation it is necessary either to let the wort "sour" naturally (lactic acid being chiefly formed) or to add a small quantity of acid (formerly sulphuric acid was frequently employed) to it before pitching the yeast. Such a condition is favourable to the free development of the desirable types of distillery yeasts but restrictive to the growth of brewery yeasts and especially of bacteria.

In order to facilitate the proper control of the formation of the acid the souring process is usually carried out in a small separate mash so that when sufficient acid has been produced the temperature of the liquid is increased and the acidifying process stopped. The souring mash is often inoculated with a special variety of lactic acid bacteria—a pure culture of ***B. acidificans longissimus***. The optimum developing temperature of this organism is about 104° F but it is better to keep the wort at 122° F, for at that temperature practically no other bacteria is capable of development. When lactification is complete the temperature is raised to 165° F and after cooling the mass it is pitched with yeast and added to the main wort. Sometimes lactic acid is added instead of being produced naturally. Hydrofluoric acid and its salts are also sometimes used with very satisfactory results.

Much of the yeast used in British and Irish pot still and in some patent still distilleries is obtained from breweries. In order to obtain a more rapid and complete fermentation a special type of "German yeast" is often used. It is usual to "pitch" at about 80° F and then to cool slowly to 60° F. As fermentation develops

the temperature again rises naturally to about 85° F. In malt whisky distilleries the original gravity of the wort is usually about 1·050 to 1·060, but in grain and potato distilleries it is often higher, being sometimes as high as 1·11 in Germany. In the production of industrial alcohol other methods, involving the use of a pure culture of a micro organism in a sterilized wort and then a pure culture of yeast, are adopted. For details of these *see* ALCOHOL IN INDUSTRY.

**Distillation.**—This may be described as a process by which, on the application of heat, one substance can be volatilized from another and recovered by subsequent condensation. Thus, a solvent, such as water, can be separated from solid matter which it holds in solution, or two liquids, boiling at different temperatures, can be freed one from the other. In the case of spirituous liquors the primary object of distillation is the separation, as far as possible, of the alcohol from the non-volatile constituents of the wash. Incidentally other volatile substances, such as water and products of fermentation other than ethyl alcohol are distilled off, but the proportion of these is reduced by further distillation and by various elaborations of the apparatus in which the process takes place. The modifications thus introduced vary according to the materials used and the type of spirit it is desired to produce. The essential parts of a still are the vessel in which the mixture can be heated, a tube or still head to carry off the vapour, a condenser for cooling and thus reducing the vapour once more to the liquid state, and a vessel for receiving the liquid.

**Pot Still.**—This apparatus embodies these features with the minimum of elaboration. Experience has shown that, for wines producing the finest brandies, the most simple form of still is the best. For the distillation of wines which do not produce brandy of the best quality more complicated apparatus is used in order to facilitate higher rectification. In Scotland the pot stills are larger and are adapted more particularly to the requirements of the whisky industry. They vary in size from about 3,000 to 8,000 gal., the usual capacity being 5,000 to 6,000 gallons.

The pot stills used in Ireland differ materially from the Scotch stills. They are very large, ranging up to 20,000 gallons. A characteristic feature is the great length and height of the "lyne arm," *i.e.*, the pipe connecting the still with the condensing coil. This lyne arm generally runs up vertically from the still for a distance of 10 to 20 ft., then horizontally for another 30 to 40 ft., again vertically for 10 to 20 ft., and is then connected to the condenser. The horizontal portion of the lyne arm lies in a shallow trough fitted with a water supply, and the temperature of the spirit vapours prior to their passing to the condenser may thus be regulated at will. According to the length and height of the lyne arm and the temperature of the water jacket, more or less of the vapours condense and are carried back to the still by means of a pipe. This return pipe is fitted with a cock which enables the distiller to regulate the flow. Occasionally there is a further return pipe for the condensing coil, but this is not usual. The advantage of this form of plant is that it is possible to work up far greater quantities of wash and to obtain a much higher rectification in a single operation than is possible in the case of the Scotch pot still. It will be noticed that in the type of Irish pot still shown in fig. 3 there is no return pipe from the lyne arm.

**Patent Still.**—This was designed by Aeneas Coffey in the early part of the 19th century with a view to accomplishing in one process that which necessitates several operations in the pot still, of economizing time, fuel and material, and also of obtaining at will a spirit of higher purity than that which can be produced by the older and more simple form of apparatus. It is the still usually employed for the production of Scotch and Irish grain whiskies. It can, however, be adapted for the distillation of a spirit intended for methylation, or for the production of spirit having a high degree of strength and purity. In the preparation of spirit approximating closely to absolute alcohol, however, the product of the patent still must undergo further treatment and rectification. In certain details the Coffey still since first devised has undergone certain modifications, but in general principle it remains unchanged.

The still shown in the accompanying illustration (fig. 4) is a type designed by Messrs. Robert Willison of Alloa for Scotch grain whisky distilleries. This Coffey still is a double still consisting of two adjacent columns, termed respectively rectifier and analyser. Both columns are subdivided into a number of chambers by perforated copper plates. The main structure is of wood firmly braced with iron. Each compartment communicates with the next by means of a drop pipe standing slightly above the level of the plate and passing downwards into a cup, which forms a water seal or joint. Each compartment is also fitted with a safety valve in case of the plates choking or of the pressure rising unduly. At the beginning of the operation both columns are filled with steam at a pressure of about 5 pounds. The steam at the base of the analyser passes upwards through it, thence to the bottom of the rectifier by means of the pipe B (termed the low wines vapour pipe), and then up through the rectifier. When both columns are filled with steam the wash is pumped up from the wash charger through the copper pipe A nearly to the top of the rectifier, which it enters at the point A. The pipe A runs from the top to the bottom of the rectifier, forming a double bend in each compartment, and the wash (contained in the pipe) travels down in a zig-zag course until it reaches the base of the rectifier at the point C. From here (still remaining in pipe A) it is pumped to the top of the analyser, where it emerges from the pipe and covers the plate of the top compartment. As there is an upward pressure of steam the wash is not able to pass through the perforations of the copper plate forming the base of the compartment, but collects until its level reaches the top of the first drop pipe. Through this is passes into the cup on the plate below and so out on to the next plate. The drop pipes being trapped by the cups, the steam cannot pass upwards through the former. In this way the wash passes through compartment to compartment on the analyser until it reaches the bottom, and then passes out by means of the spent wash siphon. The steam, on its passage up through the analyser, carries with it the alcoholic vapours and other volatile matters contained in the wash. The alcoholic

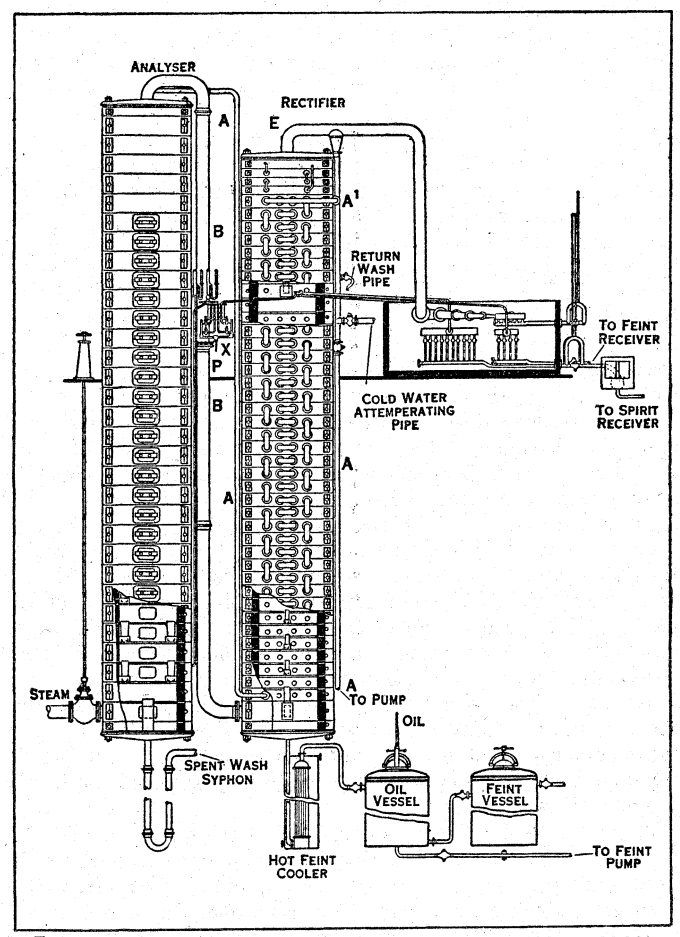

FIG. 4.—DIAGRAM OF COFFEY STILL (R. WILLISON AND CO., ALLOA)

vapours pass from the top of the analyser to the bottom of the rectifier, and then upwards through the latter from compartment to compartment. In so doing they are gradually cooled by the wash flowing down through the pipe A. This gradual cooling causes the less volatile constituents to condense and so to flow downwards through the column until they reach the base of the rectifier. At a certain point in the upper part of the rectifier the bottom of the compartment in question is formed not of a perforated plate, but of a stout copper sheet, pierced by a fairly wide pipe, which stands up about 2 in. above the level of the former. This is termed the spirit plate.

The plate is so placed that the alcoholic vapours condense either on or just above it. The alcohol passes out from the spirit plate chamber from one of the two pipes shown in the illustration (either to the spirits or to the feints receiver as the case may be), and is then further cooled, to complete the condensation, by being run through coils immersed in flowing cold water.

In order to render the condensation still more perfect the upper chambers of the rectifier are fitted with coils through which cold water is passed. The vapours condensed by this fall upon the spirit plate. The vapours which have an appreciably lower boiling point than ethylic alcohol, such as the aldehydes, together with a large volume of carbonic acid gas derived from the wash, pass out of the top of the rectifier by means of the "incondensible gas" pipe E, and thence to a separate condensing coil. The spirit retained is of high strength, generally about 64 over proof. The less volatile constituents of the wash, generally termed "fusel oil," which pass out of the base of the rectifier, are cooled and then passed to the oil vessel. After the apparatus has been worked for some time the fusel oil which floats in a layer on the top of the contents of the oil vessel is skimmed off. The watery layer from the oil vessel, which still contains a little alcohol, is again passed through the apparatus to remove all of the latter.

The distillation is controlled by an operator standing on the platform P. The operator is able by means of the sampling apparatus X to determine the quality and strength of the spirit and of the wash. He is able, by regulating the quantity of steam admitted to the apparatus, by modifying the rate of pumping, and by running the spirit either to the spirit or to the feints receiver, as the case may be, to control the strength and quality of the product in much the same manner as does the pot still distiller.

**By-products of Fermentation and Distillation.**—Although the principal ingredient of all spirits is, of course, ethyl alcohol diluted with different proportions of water, there are present in varying quantities, other substances which impart to each type its individual characteristics and afford a means of determining its origin. These by-products are formed mainly during fermentation, but are also to a certain extent pre-existent in the raw materials or may be generated during the operations preceding and succeeding fermentation. Their nature is complex and varies sensibly according to the raw materials and the methods of malting, mashing, fermentation and distillation. The by-products or secondary ingredients may be classified as follows: (a) higher alcohols, (b) esters, (c) fatty acids, (d) fatty aldehydes and acetals, (e) furfurol, (f) terpene, terpene hydrate and ethereal oils, (g) volatile bases.

The higher alcohols—commonly known as fusel oil—consist of mixtures of fatty alcohols ($C_nH_{2n+1}OH$) containing three or more atoms of carbon. The fusel oil in British pot still spirits is chiefly composed of amyl, butyl and propyl alcohols, their relative proportion being in that order, but in the preparation of British spirits in the patent still the amyl and butyl ingredients are to a great extent removed and the propyl is the predominating higher alcohol in the finished product. The butyl in the grain spirits, as also in brandy, is chiefly the normal, whilst that contained in spirit produced from potatoes is chiefly iso-butyl. The esters, formed by the interaction of alcohols and acids, chiefly during the fermenting and distilling operations, consist almost entirely of fatty acid radicles in combination with ethyl and to a minor extent amyl alcohol. Ethyl acetate (acetic ester) is the chief of these, others being ethyl valerate, butyrate and propionate. Oenanthic ether (ethyl pelargonate) although only representing a small proportion—about one per cent—of the total secondary ingredients present in brandy, is one of that spirit's most pronounced characteristics. The acid present is chiefly acetic—formed by the oxidation of the ethyl alcohol—but small quantities of other acids are also found. Furfurol, which is probably formed chiefly from the pentoses contained in the wort, occurs to a greater or less extent in most spirits, but it is particularly characteristic of pot still products.

**Classes and Types of American Spirit.**—There are two great classes of whisky in the United States—*bourbon* and *rye*. Bourbon whisky is whisky distilled from a mash 51 or more per cent of which is corn. Rye whisky is whisky distilled from a mash 51 or more per cent of which is rye. American consumption of whisky with the exception of 5% from the United Kingdom and a little Canadian whisky is of whisky based on these two classes.

The Government permits distillers to classify their product by types. Whiskies, either rye or bourbon, which have been aged in Government warehouses four or more years and are 100 proof are known as *bottled-in-bond* whisky. The term bottled-in-bond derives from the fact that the storing places, warehouses, are insured against removal of whisky of under four years by surety and Government warranty. Bottled-in-bond whisky cannot be blended with other whisky or adulterated with distilled water or grain neutral spirit; otherwise it cannot be labelled bottled-in-bond.

Whisky which is less than or more than 100 proof (although the tendency is to reduce the proof to less than 100) can be labelled *straight* whisky. This whisky cannot be blended with other whisky but its proof can be adjusted by the addition of distilled water. It cannot be less than 2 years old (1939) but it can be aged as long as the distiller wishes. *Blends of straight* whiskies are mixtures of two or more straight whiskies without the addition of other foreign substances. These, too, must be 2 or more years old.

*Spirit blends* or *whisky blends* are whiskies of the other types mentioned to which have been compounded grain neutral spirit and, on occasion, distilled water. These blends usually are composed of from 25% to 40% of straight whisky or whiskies and a balance of grain neutral spirit. These must be labelled as blends and cannot be called whisky without the qualifying adjective.

Of the two classes of whisky, bourbon and rye, about 70% of all American whisky is of the bourbon class; 30% of rye. The bottled-in-bond type, both rye and bourbon, accounts for about 5% of consumption; blends of straight whiskies account for under 2% of consumption; spirit blends or whisky blends for about 30% of consumption; imported whisky for about 5% of consumption and the balance of American consumption is of straight whisky. (If the 1939 gallonage consumption figure be taken at 100,000,000, the gallonage consumption of each type of whisky mentioned can be worked out with reasonable accuracy.)

**Effect of Maturing.**—It is a fact which has been recognized for centuries that alcoholic beverages improve with age. There is little doubt that this improvement is due to changes in the character and relative proportion of the secondary ingredients, although the exact nature of the changes is not fully understood. They are undoubtedly dependent in some manner upon the ventilation of the containing vessel, as no perceptible alteration takes place when the liquid is stored in glass bottles. The degree and rate of maturation depend upon the character of the original spirit, the type of cask and the conditions existing in the place of storage. Generally all the secondary ingredients except furfural tend to increase with age, although, as their proportions are usually expressed in relation to the ethyl alcohol present, the loss of some of the latter by evaporation may result in an apparent increase which is relative rather than actual. Thus in a very damp cellar the spirit will lose very little in volume, but such loss as occurs will be almost completely confined to the alcohol. In a dry cellar the volume decreases more rapidly, and the loss of water as compared with alcohol is relatively greater. Change in the character of the spirit is also caused by extraction of materials from the wood of the cask. There is a limit of time to the beneficial effect of the ageing of the spirit, and when that has been reached the contents of a cask should be immediately bottled, otherwise deterioration will take place.

**Physiological Effects.**—The nature of the physiological effects produced by the ingestion of spirits varies considerably not only according to the class of spirit (*i.e.*, whether whisky, brandy, rum, etc.) consumed but also with its age and general condition, and there is no doubt that the causation of these phenomena is intimately connected with the nature and quantity of the secondary ingredients. Commenting on a statement in Bailey's *Book of Sports* to the effect that wine and brandy had a tendency to make a man fall on his side, whisky to make him fall forward, and cider and perry to make him fall on his back, Sir T. Lauder Brunton in giving evidence before the Spirits Committee in 1891 suggested that these statements, if correct, might indicate definite injury to various parts of the cerebellum. He was inclined to believe that the varying effect of different spirits might be due to the specific action of the different products on the separate nerve centres.

Numerous investigations have been conducted to determine the effects of the various by-products. Thus Dujardin-Beaumetz and Audige found that the pig, whose digestive organs are very similar to those of man, when fed for 30 months with pure alcohol, suffered no ill effects, whereas when similarly treated with imperfectly purified spirit (whether derived from beet, potato or grain) suffered considerably. The same investigators, experimenting on dogs, found that the lethal dose of various alcohols was: ethyl 5 to 6 grammes, per kilo body weight, propyl 3·75 grammes, butyl 1·8 grammes and n-amyl 1·5 grammes. Brunton and F. W. Tunnicliffe demonstrated a poisonous action of furfural upon man and, comparing the after effects upon animals of spirits containing, and freed from, aldehydes, found certain important physiological differences between them.

It is important therefore that the spirit manufacturer should adopt all possible precautions to obtain a product which, whilst satisfying commercial requirements, will ensure the minimum possibility of harm to the consumer. The ordinary precautions which at all times should be followed include clean stills and apparatus, a good water supply, high-class and appropriate materials, and careful control of all operations during mashing, fermentation and distillation. The removal of acids can be effected by neutralization with an alkali in the still, whilst for the elimination of fusel oil treatment with charcoal is the common method.

Many processes have been suggested for the artificial maturing of spirits. The most practical are those embodying the passage of hot or cold air, oxygen or ozone through the liquid. Miels and Barr suggest the maturation of new whisky by the addition of a little sherry and a minute trace of sulphuric acid (subsequently neutralized by lime). Hermite suggests a method which consists essentially of adding an electrolysed solution of common salt to the spirit and subsequently redistilling.

Immediately after the Repeal of the Prohibition Amendment in the United States many processes for the quick ageing of spirit were used. None of the spirit so produced could overcome the tradition of age because for centuries consumers of spirit have placed a premium on the age of spirit.

United States Government regulations forbid the labelling of spirit less than 2 years old as whisky and the incentive to produce an artificially matured spirit has therefore been removed.

(F. G. H. T.; X.)

**SPIRITUALISM,** a name used by some philosophers, instead of "Idealism," to signify a philosophic attitude or point of view about the universe opposed to materialistic philosophy, and to imply that the ultimate reality is more fundamentally on the mental or ideal side of things rather than on that which appeals most directly to the senses as the behaviour and modifications of matter. But the name "Spiritualism," or "Spiritism," is more usually employed to signify a growing persuasion on the part of certain people that the activity of human beings is not entirely limited to the use they make of their bodily or material organisms on this planet. It is held that those organisms were constructed by an animating principle which having entered into relation with matter for the purpose of developing an individuality can continue long after the temporary material body is worn out or otherwise resolved into its elements; and, further, that the personalities thus brought into existence shall carry with them their memory, character, tastes and affection, which they had developed here while in association with matter, and shall be able under certain limitations to guide and influence terrestrial affairs in co-operation with those still living on the earth. This may be taken roughly as the spiritualistic interpretation or explanation of certain obscure phenomena which have occurred sporadically from time immemorial, and which may be said to constitute the phenomena of spiritualism.

**General Principles.**—There is however a group of investigators who, while they accept the phenomena on the grounds of experience, are not prepared to accept the explanation in terms of human survival, and who therefore dislike the term "spiritualism," preferring to employ some non-committal term such as "metapsychics" or "parapsychology"; meaning thereby a study of those obscure phenomena which lie outside the region generally accepted as orthodox psychology, and which suggest a possible extension of human faculty in directions not as yet understood. The object of these investigators is first to verify and then to study the facts, so as to disentangle the laws which regulate them, and seek to bring them within the recognized domain of organized human knowledge, or else to expand that domain so as to include them. This is called psychical research.

A third group of scientific men not only discard the spiritistic hypothesis, but feel a doubt about the facts, regarding them rather as the outcome of savage superstition and folk-lore, and therefore unworthy of scientific attention.

The whole subject therefore at the present time is a debatable one, on which there are many more or less legitimate differences of opinion. On the whole however there is a general consensus of agreement among those who have devoted time and attention to the subject that some of the phenomena are genuine; so that in time they must be accepted and gradually incorporated into the main body of science. They admit however that the investigation is conducted under difficulties, inasmuch as the phenomena cannot be produced at will, and because the facts are largely dependent on the good faith and careful testimony of those who experience them, or who are allowed to witness them under sufficiently strict conditions. In so far as the phenomena appear to be dependent upon the activity of agents whose existence is not generally recognized, and who have the spontaneity and it may be the capriciousness characteristic of live creatures, the phenomena differ in many respects from the purely mechanical behaviour of atomic groupings and material bodies, such as form the customary stock-in-trade of astronomers, physicists and chemists. They appear likely to belong more to the domain of biology, or even of anthropology, when those sciences are sufficiently enlarged to include them. Meanwhile there is a great body of testimony as to their actual occurrences, which cannot properly be ignored.

But, again, this testimony depends on the utilisation of people endowed with exceptional faculties; and these faculties are occasionally imitated by those who do not really possess them—a procedure which must be stigmatized in the strongest terms as fraudulent. There are others who, while possessing the faculties in a small degree, are tempted to enlarge and extend the results by normal supplement: a tendency which has to be constantly guarded against, for, if unchecked, it tends to bring the whole subject into disrepute.

Meanwhile, however, a body of careful investigators, notably those who founded in London the Society for Psychical Research, and others who have joined them or formed similar Societies, have accumulated a great mass of evidence in favour of the phenomena; and the enquiry is still proceeding.

Assuming, on the strength of the evidence, that human faculties are not so limited as was at one time thought, and that these obscure phenomena actually occur, they may be classified into two great groups:—(1) the mental, or purely psychical branch, concerned with the reception of ideas and information,—information which could not have been normally acquired by the operator and therefore has to be styled supernormal; and (2) the physical branch, which concerns the production of effects in ordinary

matter by apparently a supernormal extension of physiological processes.

To the first group belong such subjects as may be summarized under the heads telepathy, clairvoyance (*qq.v.*), lucidity, trance utterance, automatic writing, premonition, xenoglossy, psychometry, and other apparent extensions of receptive faculty occasionally summarized under the rather question-begging term of "cryptesthesia." It is chiefly on the strength of these mental phenomena that the hypothesis about the continued activity of the discarnate has grown up. For most of the communications so received purport to come, and certainly have the superficial appearance of coming, from intelligences no longer in the flesh, who desire to send messages of condolence, sympathy, and assurance to surviving relatives, and to furnish proof of their continued activity. To this group must also probably be added the visual and auditory hallucinations (if that term can be properly used) which many people have experienced in the form of apparitions, or other apparently sensory manifestations, of the people concerned. It has been found that these appearances, or voices, are not limited to those of dead people, as they can be traced sometimes to the unconscious influence of living people, when they are either asleep, or in some danger, or subject to some strong emotion. And these are called phantasms of the living.

The discovery of telepathy, that is to say the transference of thought or of ideas or emotions from one person to another without the use of any of the normal means of communication—a power which has been established by direct experiment as possessed by some people—tends to throw light upon these apparitions, and indeed upon the whole spiritistic hypothesis. For if it is possible for one mind to influence another without the use of the material mechanism commonly employed, it tends to demonstrate an independence between mind and body which cannot fail to have important implications. Though neither the vocal cords nor any other muscles are used for transmission; although neither the eye nor the ear, nor any of the other senses, are used for reception; yet, since some brain process must at least indirectly be involved, it is just possible that telepathy may be due to some unknown method of transmission between brain and brain. But no evidence has ever been adduced, at least none of any trustworthy character, for the existence of what have been called "brain waves." And many circumstances connected with telepathy seem to render it unlikely that a physical method of transmission, even of an etheric kind, could be utilised for the purpose of transmitting information, even though something analogous to brain waves existed. The great distance over which thought-transference occurs, and its apparent independence of obstacles are against such a hypothesis. For although the analogy of wireless telegraphy is often adduced, it must be remembered that we have no means of apprehending etheric waves except by the use of definite instruments (a) for producing such waves in conscious and prearranged manner at one end, and (b) of detecting and transmuting them into sound or other mechanical movements at the other. Telepathy occurs without such instruments (assuming that it occurs at all), and nothing that has been detected in a screened organ like the brain makes it able to act as either a receiving or a transmitting instrument except through the agency of the nerves and muscles. Consequently the most natural hypothesis is that telepathy is a purely mental phenomenon, an action of mind on mind apart from the bodily organs; though the ultimate realization and demonstration of the occurrence must of course depend on the normal methods of testimony and record.

Now mental activity apart from the body is of the essence of the spiritistic hypothesis: and there would be no reason to object to the idea that deceased people can communicate information provided the great and fundamental step is taken of assuming that they still continue to exist. Conversely, the fact, so frequently testified to, that such communications are actually received, whether in the form of apparition or audition, or of automatic writing, or trance speech, or any other way, would, when established, also strongly support or even demonstrate the continued activity of the apparently operating personality. Hence it may be held that the discovery of telepathy rationalises and renders more acceptable many of the asserted occurrences which otherwise would seem absurd and incredible. If an apparition were regarded as an objective reality, all manner of difficulties would arise about the details. But if it is only a mental impression, perhaps roughly analogous to an image in a looking-glass, although produced in some obscure and not in a simply optical manner, difficulties tend to disappear. The image can then be thought of as something not "seen" at all, but mentally reconstructed in accordance with a telepathic impulse which, indirectly through the mind, influences that part of the brain which is accustomed to receive an optical, or it may be an auditory, impression through the nerves. For, on any hypothesis, the brain and mind are closely interrelated; and a mental impression cannot be testified to or realised without the operation of the brain-nerve-muscle system.

## PHYSICAL PHENOMENA

On the spiritistic view—that is to say granted the working hypothesis that individuals once generated and isolated from a cosmic reservoir of life and mind, by means of their association with matter, shall continue to function as mental or psychic entities—it is fairly easy to suppose that they may be able to influence other minds, especially now that telepathy is fairly established as a *vera causa*, and can thus presumably cause inspiration, and convey ideas or information. For it may reasonably be assumed that they have a wider outlook than when limited by the flesh; and, being also less restricted in time, that they may be in occasional touch with greater and higher intelligences on their side. Thus not only could ordinary lucidity and clairvoyance and even premonition be accounted for, but also the more valuable inspirations of genius.

It is not difficult to suppose that the organisms of people thus acted upon could be stimulated to produce such muscular movements as speaking and writing, or any other familiar bodily activity. The influence exerted on such people might still be considered purely mental, and might be thought likely to operate most freely on the recipient organism when the medium or possessor of that organism is normally in a state of unconsciousness or partially suspended mental activity; but it would hardly be expected that the influence would be such as to produce physical phenomena beyond the capacity of the ordinary unstimulated organism. Nevertheless there is a large and growing body of evidence for the occurrence of even physically supernormal phenomena. Undoubtedly this evidence must be scrutinised with extreme care because of its unusual character; so that the further question whether in some cases these phenomena are produced by the latent power of the normal individual, or whether it is dependent on a stimulus received from some other intelligence, may remain an open one, to be considered and classified later when the facts are thoroughly established.

The physical phenomena which have thus been seriously vouched for are such as the following. First, movement of objects without apparent contact; in other words, the displacement of matter at some distance from the boundary of the normal organism, with no perceptible link, and therefore out of the normal reach of the muscles. This is known as telekinesis or locomotion of objects at a distance. A modification of this phenomenon is the moulding or rearrangement of matter so as to produce an imitation of known objects, after the manner of a sculptor or a painter, so as to produce simulacra of hands and faces and other parts of the human organism out of any material available. Another fact which is testified to is the rearrangement of the particles on a photographic plate, so that when the plate is developed in the ordinary way a supernormal image of some kind appears upon it, whether it be writing or a human or animal figure. It is further asserted that if no suitable material is provided, or cannot be collected, some organized material can be drawn, either from the medium or from any of those present, of apparently a living or protoplasmic nature, remaining still associated or connected with the organism from which it is drawn; and that this externalised protoplasm is then independently manipulated so as to display a likeness of some departed person, more or less unsatis-

factory and incomplete, but far beyond the normal power of the medium from which the material is drawn. Such exteriorised protoplasm is now generally known as ectoplasm. It only lasts a short time, and has to be returned to the body whence it came. But meanwhile it is said that it can achieve many odd results, among others that it is able to produce "direct voice," to move about, and also to exert considerable muscular force, thus effecting the locomotion of objects already spoken of as telekinesis.

The testimony of investigators suggests the idea that this extraneous material is worked by an intelligent mind, much in the same fashion as our own bodily organisms are normally worked by our own minds, and that its activities show will and intention analogous to the will and intention of our own movements. We know too little about the relation between mind and matter to stigmatise such an hypothesis as intrinsically absurd: we must be guided by the facts. But the asserted facts are so extraordinary, and physiologically so incredible, that the evidence will have to be of a strong and cumulative character before such an idea can be accepted. Nevertheless it is mainly by physiologists well acquainted with the difficulties of such an hypothesis that it has been most responsibly put forward. And there is considerable testimony from some physiologists in Europe that, however odd they may be, phenomena which suggest this kind of activity are definitely found to occur. The ectoplasm appears to have varying consistency, sometimes being visible only, sometimes tangible only, sometimes neither, and occasionally both. Ectoplasmic formations have been photographed, though it is said that they can sometimes only be photographed in ultra violet light, and with the use of a quartz lens.

One special difficulty surrounding this investigation is that the ectoplasmic material seems to be manipulated or controlled through an etheric connecting link, and that a tremor or vibration in the ether, of the kind which normally excites the retina of the eye, is detrimental to its activity; so that in most ordinary cases operations of this kind have to be conducted, or seem to be easier, in the dark—a circumstance which makes investigation specially difficult and unsatisfactory. It seems to have been found however that red light is not so deleterious as the brighter illumination of higher frequency, and that with due preparation the ectoplasmic formations can be photographed by a flashlight before they are thereby disintegrated. Moreover it is asserted that in the case of some exceptionally strong mediums, some of the effects have been produced in full daylight.

The force exerted by the ectoplasm can be quite considerable. For instance a table can be raised completely off the ground; and the weight of a man clambering on the table need not be sufficient to bring it down. The forces have sometimes been measured by spring-balances: and an attempt has been made to weigh the medium from whom ectoplasm has hypothetically been removed, with the result that the normal organism is said to have lost weight corresponding to that of the material which has been extruded and accumulated on another balance.

In quoting such assertions it is not to be supposed that they are as yet fully accepted; but they indicate the lines on which investigation should proceed. The hypothesis gives a link on which the phenomena can be threaded together, so as to give them a sort of coherence, which further experience may either substantiate or discard.

**Still More Obscure Phenomena.**—All the movements and mouldings hitherto spoken of are within the power of normal individuals, if they are allowed free use of their limbs. There is no difficulty in levitating objects or people, or in moulding images and simulacra. Hence the evidence for the occurrence of these things in a supernormal manner must depend on whether the medium and all those concerned are under complete control. Much of the experimentation is complicated by this necessity.

But there are certain other phenomena asserted which are not of a normal character, and could not be produced normally if the operator were free,—phenomena which might be spoken of as miracles. The one most commonly attested to is the immunity to damage or destruction by extreme heat. It is said that certain people can hold flaming or red-hot coals in their hands without feeling pain and without being singed; that this power can be conveyed to other people under certain conditions; and that even fabrics, such as hair or cambric, can be rendered temporarily immune to fire. Travellers tell us of native races who can walk through fire, or over hot coals, without injury, when in a state of exaltation. Heat is known to be a rapid vibration or tremor among the particles of a body, and it is difficult to see how the molecular or chemical changes normally associated with such tremor can be suspended. But again, when there is sufficient confirmation, we must be prepared to accept the facts, whether we feel able to understand them or not.

Another phenomenon of what is popularly called a miraculous character, has been often asserted to occur, namely the passage of a solid body into or out of a closed cavity; as, for instance, the introduction of an object into a closed room, such object having been previously known to be outside; a phenomenon known as an "apport." Verification of such a fact as that is singularly difficult, especially when the enclosure is, like a room, such as can readily be normally opened; and, like all the rest of the phenomena, it must depend with excessive cogency on the good faith of all concerned. Indeed good faith alone might not be sufficient. Before accepting a thing like that, one would have to allow for hypnotic or other influence.

A modification of this "passage of matter through matter," as it has been called, is the linking of two entire rings together, or the tying of knots on an endless string. These things have been testified to, but are hardly as yet even tentatively accepted. The disintegration and reconstitution of matter has been contemplated as a working hypothesis by the few who do accept them; while others have taken refuge in a fourth dimension of space, in which a globe is no more a complete enclosure than a circle is in three dimensions. A quadruped is fully confined when enclosed in a village pound, but a bird is not. The parable is obvious.

It is however hardly worth while to seek for some mode of conceiving or formulating an explanation until the facts are established. The object of this article has been, first, to show the kind of assertions which are made, and then to indicate the kind of lines on which a rational explanation may be looked for; at least in connection with those for which a prima facie case has been established; and, next, to suggest that an enlarged psychology, and possibly an enlarged physiology,—possibly even an enlarged physics—will have to take into account and rationalize a number of phenomena which so far have been mainly disbelieved or ignored.

**Historical Summary.**—Although spiritualistic phenomena have been testified to by all nations and peoples, although they are spread over the historical documents collected in the Old Testament, and have continued down to the time of John Wesley and later, it is usual to attribute the rise of what is called Modern Spiritualism to occurrences which took place in America about the middle of last century, when they began to attract rational attention; passing through a time of much scepticism and contumely, until they have emerged in the moderate and cautiously sceptical atmosphere of today.

Examples of mediumistic and prophetical incidents are common from the time of the Hebrew Patriarchs downwards. David and the other Kings did not hesitate to consult seers, and, sometimes unwisely, regulated their conduct accordingly. The episode of the infant Samuel is a good example of the phenomenon called the direct voice. In the Graeco-Roman period monitions were experienced, and oracles consulted, as everyone knows. Coming down to recent times, the phenomenon, now fairly common, of intelligent raps, seems to have begun in a family at Hydesville near Rochester, N.Y., about 1848. Stainton Moses, himself a powerful medium, helped to establish the London Spiritualist Alliance, which was joined by the naturalist Alfred Russel Wallace, while the physicist and chemist Sir William Crookes began a series of investigations into a variety of physical phenomena, with the help of the exceptional medium D. D. Home, through whom startling results had been obtained in good light, as narrated by the late Lord Dunraven (*see* "Experiences with D. D. Home" printed by Maclehose for the S.P.R.).

In the seventies of last century Sir William Barrett made preliminary experiments in thought transference; and Cambridge men of letters began to study the various phenomena seriously. In 1882 a special Society was founded by F. W. H. Myers and Edmund Gurney under the Presidency of Henry Sidgwick. This Society for Psychical Research has accumulated a mass of information, critically examined, recorded and discussed in their *Proceedings,* and the work continues to this day.

On the Continent the subject has been taken up by Charles Richet in France, Von Schrenck Notzing in Germany, Morselli, Lombroso and Schiapparelli in Italy, and has been carried on under Dr. Geley and his successors in the Institut Metapsychique of Paris and other organizations; while the American Society for Psychical Research has published an extensive collection of records. In recent times Professor Charles Richet has written what is virtually a text book of the subject under the title *Traité de Metapsychique,* translated into English as *Thirty Years of Psychical Research.* And Dr. Geley has discussed the subject from the medical, biological and philosophic points of view in *From the Unconscious to the Conscious.* Books containing what purport to be records of communications received through mediums in the trance state are too numerous to mention; but the eloquent work of F. W. H. Myers entitled *Human Personality and its Survival of Bodily Death* not only fairly covers the subject up to 1900, but bids fair to become a classic. Selection from other books is difficult. A history of the subject in two volumes by Podmore eschews the spiritistic hypothesis in order to emphasize telepathy. Another history of the subject emphasizing its religious bearings is by Conan Doyle. Older treatises are Hare's *Experimental Investigations of the Spirit Manifestations* (New York 1856), De Morgan's *From Matter to Spirit* (1863), Alfred Russel Wallace's *Miracles and Modern Spiritualism* (1876), Stainton Moses' *Spirit Teachings,* Zöllner's work translated by Massey as *Transcendental Physics.* Also *Reports* of the Dialectical Society in London, and of the Seybert Commission in America, and the *Proceedings* of the Society for Psychical Research in 36 volumes.

BIBLIOGRAPHY.—Books aiming at a philosophical or biological discussion of the subject, in addition to those already mentioned, are:—*Supernormal Faculties in Man* by Osty, *Dissociation of Personality* by Morton Prince, *Body and Mind* by McDougall, *Mind and Personality* by William Brown, *Telepathy and Clairvoyance* by Tischner, *Ectoplasm and Clairvoyance* by Geley, *Occultism and Modern Science* by Oesterreich, *The Facts of Psychic Science and Philosophy* by Campbell Holms is an uncritical summary of a large number of asserted observations.

Books containing detailed evidence are such as the following:—*Phantasms of the Living* (two volumes) by Myers and Gurney (1886), *Man's Survival after Death,* by the Rev. C. L. Tweedale, *Evidence for a Future Life,* by Delanne, *Psychical and Supernormal Phenomena,* by Joire, *After Death* etc., 3 volumes by Flammarion, *On the Threshold of the Unseen,* by Barrett, and many books by J. Arthur Hill, H. A. Dallas, Drayton Thomas and others. (O. J. L.)

**SPITALFIELDS,** a district of London, England, in the western part of the metropolitan borough of Stepney. The name is derived from the fact that the land belonged to the hospital, or "spital," of St. Mary Without Bishopsgate, founded in 1197.

**SPITHEAD,** the name of an important anchorage in the strait known as the Solent which stretches between the Isle of Wight and the mainland of England. The name has often been incorrectly applied to the eastern half of that strait, but is properly restricted to the anchorage extending along the south side of the Spit Sand, which runs from Gillicker point to the Spit fort in an east-south-easterly direction, outside Portsmouth harbour which is the principal station of the British Navy. As a result of this position and of the space available, Spithead has been the scene of many of the great pageants and gatherings of the British Navy on the occasion of coronations, mobilisations, and special occasions, a historic one being that of the funeral of Queen Victoria, who died in the Isle of Wight in 1901.

**SPITSBERGEN** (Norwegian SVALBARD), an Arctic archipelago between Greenland and Novaya Zemlya in 76° 25′ to 80° 50′ N. and 10° 20′ to 35° E., has a total area of 25,000 sq.m. and comprises West Spitsbergen (15,200 sq.m.) North-East Land (about 6,000 sq.m.), Edge island (2,500 sq.m.), Barents island (580 sq.m.), Prince Charles Foreland, the Wiche islands, Hope island and many smaller islands, including Bear island in about 74° 30′ N., 19° E. Norway took possession officially in 1925. The population, largely miners, shifts seasonally: the census of 1930 showed 600; a count in the winter of 1937–38 showed 2,653; in the winter of 1938–39, 2,210. There is no indigenous population.

**Geography.**—The chief island is in the main a much dissected plateau with many deep fjords penetrating far inland. Small plains are found in the north and west. The sharp peaks that gave Spitsbergen its name rise to 4,960 ft. in Horn Sund Tind in the south, 3,450 ft. in Mt. Monaco on Prince Charles Foreland and 4,770 ft. in Mt. Eidsvoll in the north-west. In the middle and east the mountains are flat-topped and seldom over 2,000 ft., but Mt. Newton (5,445 ft.) in New Friesland is the loftiest peak in Spitsbergen. Rocks skirt many stretches of the open coasts but with accurate charting a number of safe harbours have been found. Glaciers fill the valleys except in the southern interior where they have receded. They generally reach the sea, often along broad fronts, but give rise to no large icebergs. Many are in a state of decrepitude, but a few seem to be advancing. An ice covering over New Friesland is the nearest approach to an ice sheet in West Spitsbergen. Barents and Edge islands have glaciers only on the east. The Wiche islands have no large glaciers, but North-East Land and Giles (Gillis) Land are each covered with a dome of ice that almost envelops the island. Prince Charles Foreland has numerous glaciers. Bear Island with an area of 73 sq.mi. rises to 1,630 ft. in Mt. Misery. The northern part is a plain at an elevation of about 150 feet. There are no glaciers. Harbours are small and poor. Hope island lies 125 mi. east of South Cape, Spitsbergen, is 20 mi. long and not more than one mile wide. It rises to 1,200 feet. There is no harbour.

**Structure and Geology.**—The principal features of the geology are known. Most formations from early Palaeozoic, and perhaps Archaean, to recent, occur. The oldest rocks appear chiefly on the west and north, including Prince Charles Foreland and North-East Land. They are the Hecla Hook series of Cambrian and Ordovician dolomites, limestones, shales and quartzites which form the Caledonian folds and overthrusts of the west. The folds can be traced as far east as the west of North-East Land. Granite and gneiss formerly believed to be Archaean probably belong to the same formation and were involved in the Caledonian foldings. Some of these crystalline rocks, however, may prove to be pre-Cambrian. Outside the area of these old rocks Spitsbergen is mainly a plateau of relatively undisturbed strata lying unconformably on a platform of pre-Devonian crystalline rocks. In the north-west there are Devonian rocks. These are unconformably overlain by lower Carboniferous or Culm sandstones and shales with some coal. Middle Carboniferous is rare and the Culm is generally succeeded by upper Carboniferous limestones, Permo-Carboniferous cherts, and Permian sandstones and shales. Next come Triassic, Jurassic and Cretaceous sandstones, limestones and shales. In the Cretaceous beds there is coal. Unconformably there follow Tertiary sandstones and shales with several coal seams. Tertiary folding is obvious in the west against the Hecla Hook beds in places and in the east, but in central Spitsbergen is noticeable only in gentle undulations. Heavy faulting occurred in Tertiary times. Intrusions of dolerites and basalt were probably of Cretaceous (Neocomian) date. An extinct volcano and several hot springs (temp. 82° F) in Bock bay are Quaternary. The strand flat is well developed at 30–60 ft. and post-glacial raised beaches are marked. Glacial and post-glacial débris on low ground generally mask the solid rock and loose screes form fans on the lower slopes. Bear island is built of Hecla Hook, Devonian and Carboniferous beds. The two latter series contain some coal.

**Climate and Ice Conditions.**—The sea around Spitsbergen is shallow, and the ice readily accumulates round the shores. Pack-ice prevents access to most shores except for a few months in the year. However, the warm North Atlantic drift sends a branch to the western shores of Spitsbergen, moderating its climate and leaving an open passage which permits vessels to approach the

western coast during most months of the year. The fjords are frozen from October or November to April or May.

Owing to the warm drift the climate of Spitsbergen is less severe than in the corresponding latitudes of Greenland. January and February means range from 0° to −8° F., and July means from 38° to 40° F. Even in the coldest months of the winter a thaw may set in for a few days, but on the other hand, snow sometimes falls in July and August. Spring comes in June; the snow becomes saturated with water and disappears in places, and scurvy grass and willow open their buds. By the end of June the thermometer has ceased to sink below the freezing-point at night; July, August and September are the best months. In September, however, autumn sets in. The arctic night begins in October and lasts through February.

The annual precipitation at Green harbour is 11.6 in. and less in the interior. Winds are generally light except on the west coast and local winds in the fjords. There is mist on the west and around Bear island in summer.

**Fauna.**—The Greenland whale has disappeared in consequence of the great havoc made by the early whalers. According to Scoresby, no fewer than 57,590 whales were killed between 1669 and 1775. Reckless extermination of seals also took place. Walruses are now rarely seen in the waters of west Spitsbergen. Birds, also, have rapidly diminished in numbers. The fulmar petrel meets ships approaching Spitsbergen far away from the coasts. It makes colonies on the cliffs, as also do the glaucous gull or the "burgomaster." Rotches, black guillemots, ivory gulls, auks, looms and kittiwake gulls breed on the cliffs, while geese, loons and snipe frequent the lagoons and small fresh-water ponds. The eider duck breeds on the islands, but its numbers have become noticeably reduced. These birds, however, are only guests in Spitsbergen, the snowy owl and ptarmigan being the only species which stay permanently. Some 60 species have been recorded from Spitsbergen and Bear island; about half of them breed there. Of land mammals, besides the polar bear, the reindeer and arctic fox have been greatly reduced: Norway has rigorously restricted the slaughter of reindeer; before 1868 from 1,500 to 2,000 were killed by hunters in a few weeks of summer.

**Vegetation.**—The only trees are the polar willow, which does not exceed 2 in. in height, and the rare dwarf birch; and the only bushes are the crowberry and cloudberry. But at the foot of the bird cliffs some loam has been formed notwithstanding the slowness of putrefaction, and there, in contrast with the brownish lichens that cover the rocks, grows a carpet of mosses of the brightest green, variegated with the golden-yellow flowers of the ranunculus, the large-leaved scurvy grass, the cuckoo flower, many saxifrages, fox-tail grass, etc.; while on the driest spots yellow poppies, whitlow grasses and rock roses are found. Even on the higher slopes, 2,500 ft. or more above the sea, the poppy is occasionally met with. In all about 130 species of flowering plants have been found. The distribution is suggestive: most species are found in Europe and 117 are circumpolar; many of the plants common on the west coast are absent in the eastern part because of the greater cold.

**Mining.**—Coal, known since the 17th century, was not mined commercially until the 20th century workings at Advent bay. Progress was slow until 1914, when war curtailed other sources of Scandinavian supplies. The Longyear mine at Advent bay, American-owned since 1905, was sold in 1916 to a Norwegian group. Norwegian mines have also opened at King's bay, Hjorth Haven and other places. Swedish mines were worked from 1917 to 1925 in Lowe sound (Braganza bay); British mining revived after 1919 at Klaas Billen bay, Temple bay and Coles bay; and the Dutch operated mines at Green harbour. In 1938 exports totalled 691,000 tons, used in northern Norway and for the Russian arctic fleet. The product is good steam coal of Tertiary and Cretaceous ages; bituminous coal of Carboniferous age is also available but as yet unmined. Mining continues through the year, but shipping is from late April through September.

**Communication.**—Regular boat sailings are lacking, but contacts are maintained through tourist steamers and the frequent colliers of the summer. A Norwegian radio station was established at Green harbour in 1911, and later stations and post offices were set up at the chief mines.

**Exploration.**—It is probable that Svalbard, discovered by the Vikings in 1194, according to the *Landnamabok*, was Spitsbergen, but the discovery was forgotten. Modern knowledge dates from the discovery by Willem Barents and Jacob Heemskerk, on June 17, 1596. Barents saw parts of the west and north coasts, and he gave the name of Spitsbergen. In 1607 H. Hudson, after visiting Greenland, reached Spitsbergen and reported whales. Bear island, midway between Spitsbergen and the North cape, had been discovered by Barents, and became important as a hunting ground (for walrus, etc.) after Stephen Bennet's visit in 1603. In 1609 Thomas Marmaduke reached Spitsbergen, and in the following year the first hunting expedition was dispatched thither by the Muscovy company under Jonas Poole, whose report resulted in the start of the whaling industry here in 1611. The Dutch quickly came in, causing collisions between the whalers of the two nationalities, and in 1615 the Danes laid claim to "this part of Greenland," as it was then considered. The Russians called the region Grümant, a corruption of Greenland, and well before 1740 were hunting there for walrus, seal, bear, fox, etc. Marmaduke had discovered Hope Island and North-East Land in 1613; Edge saw the Wiche islands in 1617; and C. Gillis found Gillis (Giles) Land in 1707.

Many expeditions have made Spitsbergen their base for polar exploration. The expedition in the "Racehorse" and "Carcass" sent from England in 1773 under C. J. Phipps was the first having a purely geographical purpose. Phipps mapped the north of Spitsbergen and reached 80° 48′ N. In 1818 D. Buchan and J. Franklin reached 80° 34′ to the north of the archipelago. Captain D. C. Clavering and Sir Edward Sabine in 1823 explored the islands, and Sabine made his remarkable magnetic observations, while Clavering reached 80° 20′ N. Sir William Parry in 1827 reached 82° 40′ N. of Spitsbergen on sledges. In the same year the Norwegian geologist, B. M. Keilhau, visited the group. The Swede, Sven Loven, was the first to undertake, in 1837, dredging in Spitsbergen waters. In 1858 Otto Torell, accompanied by A. E. Nordenskiöld and A. Quennerstadt made important observations and brought home rich geological collections. In 1861 a larger expedition led by Torell, Nordenskiöld, A. J. Malmgren and K. Chydenius investigated the possibility of measuring an arc of meridian in Spitsbergen. The work of the measurement of the arc was completed in 1864 by an expedition led by Nordenskiöld, assisted by Malmgren and N. Dunér. In 1868 Nordenskiöld sailed to the north coast, and a German expedition under K. Koldewey circumnavigated west Spitsbergen. In 1870 two young Swedes, Drs. A. G. Nathorst and H. Wilander, examined the phosphoric deposits at Cape Thordsen, and two years later a colony tried unsuccessfully to work the beds. Leigh Smith and the Norwegian Captain E. Ulve visited and mapped parts of east Spitsbergen in 1871 and reached 81° 24′ N. In the same year the first tourist steamer visited the archipelago. In 1872 and 1873 expeditions under Nordenskiöld explored North-East Land and crossed the vast ice-sheet which covers it. In 1882 the Swedish geologists A. G. Nathorst and G. de Geer gathered in Ice fjord data about the geology and flora of the islands. Also in 1882 a Swedish meteorological station was established at Cape Thordsen for carrying on the observations desired by the international polar committee. Expeditions of Gustav Nordenskiöld in 1890 and the circumnavigation by Nathorst in 1898 explored the coasts of the Wiche islands and Giles Land. In 1892 C. Rabot made the first serious attempt to penetrate the interior from the head of Ice fjord, exploring a part of the Sassendal; and in 1896 Sir Martin Conway led an expedition which crossed the island for the first time and surveyed the region between Ice fjord and Bell sound. In 1897 Conway and E. J. Garwood surveyed the glaciated area north of Ice fjord and climbed Horn Sund Tind. In the same year S. A. Andrée made his fatal balloon ascent from Danes island with the intention of floating over the Pole. In 1896 a weekly service of Norwegian tourist steamers was established in summer, with an inn at Advent bay. In 1898, 1899 and 1906 the prince of Monaco made scientific investigations in the archipelago, and in 1898–1902 Swedish and Russian expeditions undertook the measurement of an arc of the meridian. W. S. Bruce, in 1906–07–09, made a complete sur-

vey and scientific investigations of Prince Charles Foreland, and in 1920 J. M. Wordie scaled some of its highest peaks, Monaco, Rudmose and Barents. In 1910 W. Filchner surveyed the glaciated region between Temple and Mohn bays. King's bay was used by R. Amundsen in his unsuccessful flight to the Pole in 1925, and by him and R. E. Byrd in their successful flights in 1926. G. Wilkins alighted in the fjord in April 1928 after his flight from Alaska. The Norwegian government began regular summer expeditions in 1906, in which G. Isachsen, A. Staxrud and A. Hoel surveyed and conducted hydrographic research. Joint Norwegian and Swedish expeditions took place in 1931 and 1934, in the latter of which Prof. H. W. Ahlmann studied glaciology while Prof. H. U. Sverdrup studied the problems of heat, water vapour and momentum in the melting of the snow. In 1936 the Norwegians mapped about two-thirds of the group by aerial photography. (*See* also ARCTIC REGIONS: *Exploration.*)

**Political History.**—Despite diverse interests in and claims to the islands by British, Dutch, Norwegians, Swedes, Danes, Russians and even Americans, the question of sovereignty was long unsolved, and Spitsbergen was a *terra nullius*. Norway initiated a conference on the matter in Christiania (Oslo) in 1910, which was followed by others in 1912 and 1914, all without result. In 1919 Frits Wedel-Jarlsberg persuaded the Allied supreme council to grant to Norway sovereignty over Spitsbergen, Bear island and all the lands lying between 74° and 81° N. and between 10° and 35° E. The act was validated by a treaty of Feb. 9, 1920, signed by Great Britain and the British dominions, the United States, France, Italy, Japan, Holland, Denmark, Norway and Sweden; soviet Russia adhered later. Norway took formal possession on August 14, 1925. Norway then declared the region a part of the kingdom of Norway and appointed a governor (*sysselmann*).

In Aug.–Sept. 1941, a force of Canadians, British and "Free Norwegians" made a sudden landing, destroyed the radio stations, chief mines, some 450,000 tons of mined coal and 275,000 gal. of oil. The Norwegian population was evacuated to England, and some 2,000 Russian miners were transported to a north Russian port. The Allies established a base which was attacked by the Germans in September 1943. (R. N. R. B.; F. D. S.)

BIBLIOGRAPHY.—The literature is voluminous. Sir W. Martin Conway in *No Man's Land* (Cambridge, 1906) details the history of Spitsbergen to 1840, tabulates the principal voyages thereafter until 1900 and gives a full bibliography from the earliest time down to 1902. The observations of the Swedish expedition for the measurement of an arc of the meridian were brought together (in French) in *Missions scientifiques pour la mesure d'un arc de méridien au Spitzberg* . . . (Stockholm, 1903–06), and those of the Russian expedition under the same title in 1904, *seq.* (St. Petersburg [Leningrad]). Other important sources of scientific value are the publication of the Swedish *Vetenskaps Akademie; Ymer* (Stockholm); *Videnskaps Akademi* (Oslo), especially the series of papers on *Resultater av de Norske Statsun. Spits. Ekspeditioner* (1922– ); Albert I., Prince of Monaco's *Résultats des campagnes scientifiques,* 40, 41 and 45 (1889, etc.); and *Spitsbergen Papers* (Oxford, 1925). Two general works are R. N. Rudmose-Brown, *Spitsbergen: its exploration, hunting and mineral riches* (1919) and F. Nansen, *En ferd til Spitsbergen* (1920) or *Spitzbergen* (Leipzig, 1921). G. Isachsen, "Fra Ishavet" in *Det Norske Geografiske Selskabs Aarbok* (1916–19) gives much information about Norwegian hunters. H. M. Cadell, "Coal Mining in Spitsbergen," *Trans. Inst. Min. Eng.*, vol. 60 (1920), A. Hoel, *The Coal Deposits and Coal Mining of Svalbard* (Oslo, 1925) and A. Hoel, "Coal Mining in Svalbard," *Polar Record,* II, No. 16 (1938) describe the coal-bearing areas. F. C. Wieder, *The Dutch Discovery and Mapping of Spitsbergen 1596–1829* (Amsterdam, 1919) has many reproductions of early maps. The meteorological observations at Green harbour are published annually in *Jahrbuch des Norwegischen Meteorologischen Instituts* (Oslo). A. Miethe and H. Hergesell, *Mit Zeppelin nach Spitsbergen* (1911) is noteworthy for the excellence of its illustrations, including colour plates. G. Binney, *With Seaplane and Sledge in the Arctic* (1925), describes recent work in North-East Land. Some of the results of the Norwegian surveys are collected in *Expedition Isachsen au Spitsberg, 1909–10, Résultats scientifiques* (Oslo, 1916). The geomorphology and geology are explained by G. de Geer in "On the physiographical evolution of Spitsbergen," *Geog. Annaler,* vol. i (Stockholm, 1919) and by O. Nordenskjöld in *Handbuch der Regionalen Geologie* IV., 2b. (Heidelberg, 1921) with bibliography. *Spitzbergen-Handbuch* (Berlin, 1916) gives full sailing directions. See also the two Norwegian series *Skrifter om Svalbard og Ishavet* and *Norges Svalbard-og Ishavetsundersökelser Meddelelse.* L. H. Gray, *Spitsbergen and Bear Island* (Washington, 1919) is a good general survey. The Spitsbergen Treaty is published in Treaty Series No. 18, Cmd. 2,092 (1924).

**SPITTA, FRIEDRICH** (1852–1924), German Protestant theologian, was born at Wittingen Jan. 10, 1852. He studied at Göttingen and Erlangen and in 1887 became professor ordinarius and university preacher at Strasbourg. In 1896 he began to edit, with J. Smend, the *Monatschrift für Gottesdienst und Kirchliche Kunst.* From 1919 until his death he taught at Göttingen, where he died June 8, 1924.

**SPITTA, JULIUS AUGUST PHILLIP** (1841–1894), German writer on music, was born at Wechold, Hanover, on Dec. 27, 1841. He was one of the founders of the Bachverein at Leipzig in 1874. In 1875 he became professor of musical history at the university of Berlin and at the conservatoire, of which in 1882 he became a director. His *J. S. Bach* (2 vol. Leipzig, 1873–80, Eng. trans., 3 vol., 1884–5) is one of the great classic musical biographies. Spitta, who was one of the editors of the *Vierteljahrsschrift für Musikwissenschaft* from 1885 onward, died in Berlin on April 13, 1894. His other works include editions of the organ works of Buxtehude (2 vol., Leipzig, 1874–6), and of the works of Heinrich Schuetz.

**SPITTELER, CARL** (1845–1924), Swiss poet and novelist, was born at Liestal, near Basle, April 24, 1845, and died at Lucerne Dec. 28, 1924. In youth he studied theology but he did not pursue a clerical career. After many years of teaching (eight of them in Russia), he published his first important work, *Prometheus and Epimetheus,* in 1880–81, under the pseudonym of "Felix Tandem." This was an epic, written in a rhythmical, quasi-biblical, hieratic prose. A little later appeared *Extramundana* (1883), a volume of apologues in verse. From 1885 to 1892 he engaged in journalism, but published *Schmetterlinge* (1889), a series of short poems. After 1892, when he settled in Lucerne, he was able to devote himself wholly to literature. Three other volumes of short poems were produced between 1892 and 1906—*Literarische Gleichnisse, Balladen* and *Glockenlieder.* In 1900–05 appeared his long epic, *Olympischer Frühling,* which was cited as the main ground for the award of the Nobel prize for literature in 1919. His prose writings include *Imago* (1906) and three other romances; *Lachende Wahrheiten,* a volume of essays (1898; Eng. trans. 1927); *Die Mädchenfeinde* (1907; Eng. trans., 1922), a story founded on a reminiscence of his boyhood; and *Meine frühesten Erlebnisse* (1914), a charming account of his childhood. His last work, published in 1924, shortly before his death, was *Prometheus der Dulder,* a metrical, compacter and maturer treatment of the theme of *Prometheus and Epimetheus.*

Robertson in the *Contemporary Review* (Jan. 1921). *See* also the introductions to the translations of *Lachende Wahrheiten* (Laughing Truths; 1927) and *Selected Poems* (1928). (J. F. M.)

**SPIX, JOHANN BAPTIST VON** (1781–1826), German naturalist, was born in Hochstadt, Bavaria, Feb. 9, 1781. For a time he was curator of the Munich Zoological museum but in 1817 he left there to accompany Karl Friedrich Philipp von Martius, Bavarian naturalist, to Brazil, a mission on which they were sent by the Bavarian government. They remained in Brazil until 1820, Martius studying its flora and Spix its fauna. On their return they collaborated on *Reise in Brasilien,* a three-volume work on the country's natural history. He died in Munich, March 13, 1826.

**SPLEEN,** a vascular organ situated on the left side of the abdomen (*see* DUCTLESS GLANDS).

**SPLIT** or **SPLJET,** the capital of Dalmatia, Yugoslavia (Ital. *Spalato*), has the finest harbour on the Adriatic coast, with a broad bay affording deep, safe anchorage. This, combined with its central position, and good communication with other parts by road, rail and steamer, has made it of great commercial importance, with an extensive trade in cement and marl. Pop. (1931) 43,711, almost entirely Serbo-Croatian. Spalato arose from the palace of Diocletian, who renounced the imperial crown in A.D. 303 and lived here until his death. The palace was then allowed to fall into ruin, but when the incursion of the Avars was over (639) the inhabitants of the ruined city of Salona, near by, took refuge

here, and built up homes within the 9½ acres covered by the palace, incorporating its walls and pillars. Its ground plan is like a Roman camp, *i.e.*, almost a square with four quadrangular towers and four gates, with four streets meeting in the middle. The eastern gate, or Porta Aenea, is destroyed, but the western gate, or Porta Ferrea, and the main entrance to the building, the beautiful Porta Aurea, are still in fairly good preservation. The streets are lined with massive arcades. The vestibule now forms the Piazza del Duomo or cathedral square; to the north-east of this lies the temple of Jupiter, or perhaps the mausoleum. Since the 9th century this has been the cathedral of St. Doimo or Domnius, noteworthy for its finely carved choir stalls. To the south-east is the temple of Aesculapius, long transformed into a baptistery, a beautiful Romanesque campanile having been added in the 14th and 15th centuries.

Excavations have been carried on intermittently at the ruins of Salona, 4 m. north-east, since 1818, and many interesting architectural remains have been discovered together with many smaller relics, now housed in the Split Museum. These include prehistoric objects. Salona was made a Roman colony in 78 B.C. and was one of the chief ports of the Adriatic. Soon after 313 the city became an episcopal see with St. Doimo as its first bishop. The palace was transformed into an imperial cloth factory. The town was captured several times by the Goths and Huns and in 639 was destroyed by the Avars, but was not entirely deserted until the end of the 12th century. In 659 John of Ravenna, the papal legate, was created bishop of Spalato, as the new city was called, the origin of the name being uncertain. A little later it became an archbishopric, and its holders were metropolitans of all Dalmatia until 1033. In 1105 Spalato became a vassal state of Hungary; in 1327 it revolted to Venice, but in 1367 returned to Hungary. It was ruled by the Bosnian king Tvrtko from 1390 to 1391, and in 1402 by the famous Bosnian prince Hrvoje. A large octagonal tower is still known as *Torre d'Harvoye*. In 1420 Spalato fell to Venice and ceased to have an independent history. The castle and walls were erected by the Venetians between 1645 and 1670 and dismantled during the French occupation of Dalmatia (1805–13) in which latter year the province came under Austrian rule and remained there until 1918. In that year Italy occupied the town for a short time, but from 1919 to 1941 the town was Yugoslav. In 1941 it was again occupied by Italians, after the Balkan campaign of the axis.

Lavallée, *Voyage pittoresque et Historique de l'Istrie* (Paris, 1802) illustrated; and G. Lucio, *De Regno Dalmatiae et Croatiae* (Amsterdam, 1666) for chronicles relating to Spalato and Salona.

**SPLÜGEN PASS,** one of the passes across the main chain of the Alps from Switzerland to Italy. The route from Thusis passes first through the celebrated gorge of the Via Mala, then through the Schams basin and past Andeer, beyond which the Rofna gorge gives access to the village of Splügen in the upper reach of the main or Hinter branch of the Rhine (*q.v.*). Leaving to the west the road over the San Bernardino Pass, 6,769 ft., the Splügen road (constructed in 1823) mounts south to the pass (6,946 ft.), which forms the political frontier. On the other side the road avoids the old path through the dreaded Cardinello gorge (here passed Macdonald's army in December, 1800) in order to descend by zigzags to Pianazzo. Thence past Campo Dolcino and Gallivaggio the descent is made to the ancient town of Chiavenna at the junction of the road from the upper Engadine over the Maloja Pass, and 17 m. by rail above Colico, at the northern end of the lake of Como. The distance by road from Splügen village (16 m. above Andeer) to Chiavenna is 25 m.

**SPODUMENE,** a lithium-aluminium silicate ($LiAl[SiO_3]_2$) belonging to the pyroxene group (*see* PYROXENE), named in 1800 from Gr. σπόδιος (ash-coloured), in allusion to its colour, and soon afterwards termed by J. R. Haüy *triphane* (τριφανής, appearing three-fold), because it exhibited certain characteristics equally in three directions. Spodumene crystallizes in the monoclinic system, the crystals having generally a prismatic habit and being often striated longitudinally. It has perfect prismatic cleavage, and imperfect cleavage parallel to the clinopinacoid, whilst a lamellar structure may be developed by parting along the orthopinacoid. The hardness is 6·5 to 7, and the sp.gr. about 3·16. Though generally a dull mineral, some varieties of spodumene are so brightly coloured and transparent as to be valued as gem-stones, *e.g.*, the emerald-green hiddenite (*q.v.*) and the lilac-coloured kunzite (*q.v.*), whilst a yellow or yellowish-green spodumene found as pebbles in the state of Minas Geraes, Brazil, resembles, when cut, some kinds of chrysoberyl. Common spodumene is used as a source of lithium in chemical preparations.

Spodumene occurs in granite and crystalline schists. The original specimens came from the isle of Utö, Sweden, but the finest examples are found in the United States, especially in Massachusetts, fine specimens having also been obtained from the Black Hills of S. Dakota. Some remarkable deposits containing spodumene were discovered many years ago at Branchville, Connecticut, and were exhaustively studied by G. J. Brush and E. S. Dana. The spodumene occurred in large quantity, in a vein of albite-granite, associated with apatite, garnet, columbite, pitchblende and other uranium minerals, with several manganese phosphates.

**SPOFFORTH, FREDERICK ROBERT,** "The Demon" (1853–1926), Australian cricketer, was born at Sydney, N.S.W., on Sept. 9, 1853, and died at Surbiton, Surrey, on June 4, 1926. He was educated at Eglington college, Sydney, and played in Australia up till 1888, when he came to England, and played occasionally in England until 1896. He visited England in the five tours from 1878 to 1886, and in his two great years, 1882 and 1884, took 188 and 218 wickets. Little interest was taken in England in the first Australian tour of 1878 up to his appearance, at Lord's, to play the M.C.C. on May 27. By the end of the day the match was over; the M.C.C. were put out for 33 and 19, and Spofforth had taken 6 wickets for 4 runs and 4 for 16. This one day established Australia as a first-class cricketing power. His other great triumph was during the historic tour of 1882. In the test match at the Oval, England, with 84 to make to win, he lost by 7 runs. In the match Spofforth took 14 wickets for 90 runs. He was badly hurt early in the 1886 tour, and was never the same bowler again.

Of Spofforth's actual pace there are differing opinions. It is perhaps, safe to say that when he first came to England he was really fast, but it is certain that he learnt at once to modify his pace on English wickets, and relied on disguised change of pace, with perhaps one really fast one in an over. Of his supremacy there is no doubt whatever. It may suffice to quote Lord Harris: "Spofforth was the most difficult of them all." Spofforth was above all a man who "bowled with his head"; he got his wickets by variation of pace and flight, combined with a sharp off-break, and maintained an ascendancy by an unquenchable spirit of aggression, displayed in his terrifying run up to the wicket, with his long arms whirling, finishing in a beautifully graceful delivery which made the most of his great height.

Spofforth's bowling is fully illustrated in Beldam and Fry's *Great Bowlers and Fielders* (1907). *See* also *Scores and Biographies* (vol. xiv.); Reminiscences in Wisden's *Cricketers' Almanack* for 1927; H. S. Altham, *History of Cricket* (1925).

**SPOHR, LUDWIG** (1784–1859), German composer and violinist, was born at Brunswick on April 24, 1784. He spent his childhood at Seesen, where in 1789 he began to study the violin, and at six years old was able to take part in chamber-music. He had a few lessons in composition, but, as he himself tells us, he learnt more from studying the scores of Mozart. After playing a concerto of his own at a school concert with marked success, he was placed under Maucourt, the leader of the duke's band; and in 1798 he started on an artistic tour. He made his way to Hamburg, but had to return on foot. The duke then gave him an appointment in his band, and provided for his future education under Franz Eck, with whom he visited St. Petersburg and other European capitals. His first violin concerto was printed in 1803. In 1805 he became violinist to the duke of Gotha. Soon

after this he married, his first wife being Dorette Scheidler, a celebrated harpist.

At Gotha Spohr composed his first opera, *Die Prüfung,* but did not succeed in producing it. *Alruna* was equally unfortunate, though Goethe approved of it at a trial rehearsal at Weimar in 1808. In this year Spohr, hearing that Talma was performing at Erfurt before Napoleon's Congress of Princes, and failing to obtain admission to the theatre, bribed a horn-player to send him as his deputy; and, though he had never touched a horn in his life, he learned in a single day to play it well enough to pass muster in the evening and to get a good view of Napoleon and the princes in a pocket mirror on his desk. Spohr's third opera, *Der Zweikampf mit der Geliebten,* written in 1809, was successfully performed at Hamburg next year. In 1811 he produced his (first) *Symphony in E flat,* and in 1812 composed his first oratorio, *Das jüngste Gericht*[1].

In 1812 Spohr became leader of the orchestra at the Theater an der Wien, Vienna. He then began his dramatic masterpiece, *Faust,* which he completed in 1813, though it was not performed until five years later. He resigned his appointment at Vienna in 1815, and made a tour in Italy, where he performed his eighth and finest violin concerto, the *Scena cantante nello stilo drammatico.* The leading Italian critics called him "the finest singer on the violin that had ever been heard." On Spohr's return to Germany in 1817 he was appointed conductor of the opera at Frankfort; and there in 1818 he first produced his *Faust.* It was followed by *Zemire und Azor,* which, though by no means as fine as *Faust,* soon attained a much greater popularity. *Faust* suffered from its libretto, which is on quite a different plot from Goethe's poem.

Spohr first visited England in 1820, and on the 6th of March played his *Scena cantante* with great success in London at the first Philharmonic concert. At the third he produced a new symphony (*No. 2 in D minor*) and, instead of having it led by the first violinist and a *maestro al cembalo,* conducted it himself with a bâton; a great innovation in London at the time. After a visit to Paris, and a short sojourn in Dresden, Weber recommended him strongly to the elector of Hesse-Cassel as Kapellmeister. Spohr began his duties at Cassel on Jan. 1, 1822, and produced his sixth opera, *Jessonda,* in 1823.

In 1822 Mendelssohn, then a boy of thirteen, visited Cassel; a firm friendship sprang up between the two, which ceased only with Mendelssohn's death in 1847. Spohr's next three operas, *Der Berggeist* (1825), *Pietro von Abano* (1827) and *Der Alchymist* (1830), attained only temporary success. At the Rhenish musical festival held at Düsseldorf in 1826, his oratorio *Die letzten Dinge* (*The Last Judgment*), the most famous of his sacred compositions, was produced. In 1831 Spohr published his admirable *Violin School.* The year 1834 was saddened by his wife's death. Two years later he married a pianist, Marianne Pfeiffer. During 1833 he had been working at an oratorio—*Des Heilands letzte Stunden* (*Calvary* or *The Crucifixion*), which was performed at Cassel on Good Friday 1835, and sung in English at the Norwich Festival of 1839 under Spohr's own direction, with an effect which he afterwards always spoke of as the greatest triumph of his life. For the Norwich Festival of 1842 he composed *The Fall of Babylon,* which also was a perfect success, though the elector of Hesse-Cassel refused Spohr leave of absence to conduct it. His last opera, *Die Kreuzfahrer,* was produced at Cassel in 1845. Of his nine symphonies the finest, *Die Weihe der Töne,* was produced in 1832.

Spohr's compositions for the violin include concertos, quartets, duets and other concerted pieces and solos, and among these a high place is taken by four double quartets (*i.e.,* octets for two antiphonal string-quartet groups), an art-form of his own invention. He was, indeed, keenly interested in experiments, notwithstanding his attachment to classical form; and the care with which he produced Wagner's *Fliegender Holländer* and *Tannhäuser* at Cassel in 1842 and 1853, in spite of the elector's opposition, shows that his failure to understand Beethoven lay deeper than pedantry. He died at Cassel on Oct. 16, 1859.

[1]Not to be confused with *The Last Judgment.*

*See* his *Selbstbiographie* (Eng. trans., 1865); and *Letters of a Leipzig Cantor,* ed. A. D. Coleridge (1892).

**SPOIL FIVE,** once known as "the national card game of Ireland," akin to the British napoleon, the American euchre, the French écarté. Not only spoil five but its variant *forty-five* were carried to the United States and Canada, while the variant *auction forty-fives,* introduced into Newfoundland in 1912, became the principal club game there.

The pack of 52 cards is used in spoil five. Any number from two to ten may play, but four, five or six make the best game. The ace of hearts is always third-best trump, and the rank of the cards is unique:

*As trumps,* spades and clubs rank 5 (high), J (knave), ♡ A, A, K, Q, 2, 3, 4, 6, 7, 8, 9, 10; hearts rank 5 (high), J, A, K, Q, 10, 9, 8, 7, 6, 4, 3, 2; diamonds rank 5 (high), J, ♡ A, A, K, Q, 10, 9, 8, 7, 6, 4, 3, 2.

*When not trumps,* spades and clubs rank K (high), Q, J, A, 2, 3, 4, 5, 6, 7, 8, 9, 10; hearts rank K (high), Q, J, 10, 9, 8, 7, 6, 5, 4, 3, 2; diamonds rank K (high), Q, J, 10, 9, 8, 7, 6, 5, 4, 3, 2, A.

Each player puts an equal number of counters in the pool. Five cards are dealt to each player in rounds of three and two, or two and three, at a time. The next card is turned for trump; if it is an ace, the dealer may discard any card and take the ace (or may refuse to do so). If the turned-up card is not an ace, the player holding the ace of trumps may exchange any card for it or may refuse to do so.

Eldest hand leads, and each player in turn must either follow suit or play a trump if he is able to follow suit. When a lower trump is led, the holder of the five or knave of trumps or the heart ace may *renege* (refuse to follow suit) if he wishes. A trick containing a trump is won by the highest trump it contains, and any other trick by the highest card of the suit led. The winner of each trick leads next. A player who has won three tricks must abandon his hand and take the pool; or *jink it* (play on to win all five tricks and receive the pool plus an extra chip from each other player). If he jinks it and loses a trick, he does not get the pool. A pool not won in one deal is added to the next pool.

**Forty-five** is a variant in which there is no pool; four or six play, in partnerships of two or three to a side respectively. A side winning three tricks scores five points; all five tricks, ten points. As some play, winning four tricks scores 15 points and all five tricks 25 points. The first side to reach 45 points wins.

**SPOILS SYSTEM.** The practice in the United States under which the political party winning an election rewards its campaign workers and other active supporters by appointment to public office. It involves political activity by public employees in support of their party and the consequence of removal from office if their party loses the election. A change in party control of government necessarily brings new officials to those high positions carrying political responsibility, but the spoils system extends personnel turnover to varying proportions of routine or subordinate governmental positions. In the most extreme form of the spoils system the primary test for appointment is excellence of party service, with almost complete disregard of capacity to perform the duties of the public office concerned.

The term spoils system is often applied to the great variety of means by which money may be transferred more or less indirectly from the public treasury to the party coffers, as well as to other abuses of governmental power for partisan advantage. So used, the term includes abuses in the management of public expenditures, irregularities in the granting of franchises and like privileges, partisan favouritism in the administration of criminal law, discrimination in the levy of taxes and other corrupt uses of public power. The term will be limited here to its earlier and narrower usage.

Although patronage existed in colonial times, the spoils system came to full bloom in the period 1800–29. When Jefferson became president in 1801, he found the public offices filled with persons generally hostile to him and to his party. Without espousing the principle of rotation in office, he replaced enough Fed-

eralists with Republicans to assure a more even distribution between the two parties of posts in the civil service. Yet in both appointments and removals partisan considerations were not the sole criterion; it remained for President Jackson to adopt the principle of the spoils system in the national government. Spoils practices were instituted earlier in the governments of states and cities. The system first became firmly rooted in New York; it was established almost as soon in Pennsylvania. By 1828 in all the states of the north and west the system existed or strong groups desired to introduce it.

In his annual message in 1829 Jackson presented a reasoned philosophy of the spoils system. "There are," he said, "perhaps few men who can for any great length of time enjoy office without being more or less under the influence of feelings unfavourable to the faithful discharge of their public duties. Their integrity may be proof against improper considerations immediately addressed to themselves, but they are apt to acquire a habit of looking with indifference upon the public interests and of tolerating conduct from which an unpracticed man would revolt." Rotation in office, then, was not an evil but a positive good. "The duties of all public offices are," he declared, "or at least admit of being made, so plain and simple that men of intelligence may readily qualify themselves for their performance; and I cannot but believe that more is lost by the long continuance of men in office than is generally to be gained by their experience."

The common explanation of the rise of the spoils system is that ways had to be found to support the activities of political parties. With the broadening of the suffrage, the use of elections to choose large numbers of officials and other tendencies toward democratization, political parties had to assume heavy burdens in the conduct of campaigns and leadership of debate on public issues. No class existed with the time or inclination to assume these responsibilities and parties had to be maintained by patronage. Practical considerations of party finance were re-enforced by a democratic dislike of the idea of public office as private property and a hostility toward the rise of an officeholding class.

The spoils system is often said to be peculiar to the United States, but similar practices have existed elsewhere from time to time. In fact, the distribution of public offices to strengthen a regime is an ancient practice of statecraft. At the time of the founding of the United States government, the tests for appointment to the civil service were probity, ability and loyalty to the constitution. The test of loyalty aided in buttressing a new government emerging from controversy. The installation of fascist dictatorships in Germany and Italy was accompanied by considerable partisan dilution of the permanent civil service. If the nature of a government changes radically, a degree of turnover in the civil service is likely to occur. The introduction of the spoils system into the national government of the United States coincided with a veritable revolution as new classes came to power in national affairs. Even systems for the selection of public employees on the basis of merit may reserve by effect the higher positions for members of the dominant groups within the community.

The spoils system flourished unchallenged in the United States until after the Civil War. Bills to reform the civil service were introduced in congress in the 1860s but they attracted little attention and less support. In 1871 congress empowered the president to prescribe regulations to govern the selection of civil servants and to employ persons to aid him in determining the fitness of applicants. President Grant appointed a civil service commission, but it was dissolved in 1875 after congress had failed in 1873 and 1874 to provide funds for its support.

The National Civil Service Reform league, established in 1881, led a reform movement which succeeded gradually in restricting the spoils system by the introduction of the merit system for the selection of civil servants. The movement gained impetus from the assassination of President Garfield by a disappointed office seeker and in 1883, the Pendleton act, largely drafted by leaders of the Reform league, was adopted by congress. It provided for the creation of the United States Civil Service commission and for the merit system in the recruitment of some federal civil servants. In the same year the New York legislature adopted a civil service law—that is, in American usage, a law requiring the selection of civil employees through competitive examination. Massachusetts followed in the next year.

The merit idea spread slowly but steadily. After 1900 other states adopted it, but of 20 state merit systems in 1943, 12 had been adopted after 1920. After 1939, all states were compelled to institute merit systems for those of their employees engaged in security programs aided by federal subsidies. The exact extent of the merit system in municipalities is unknown, but by 1945 probably 75% of municipal workers were under some type of merit system. As the merit system encroached on the spoils system in state and local governments, its application was broadened in the national government by actions of various presidents. A major setback to the principle of merit occurred after World Wars I and II in the extension to veterans of preference in appointments. The coverage of civil service legislation does not indicate accurately the extent to which the spoils system has been superseded. In jurisdictions with civil service laws, spoils practices may prevail. In those lacking formal merit systems, ability may govern selection of employees and their tenure may be permanent. Nevertheless, by 1945 great progress was made toward the elimination of the spoils system.

**SPOKANE** (spō-kăn′), a city of eastern Washington, U.S.A., at the falls of the Spokane river, 50 mi. from its mouth in the Columbia river; a port of entry and the county seat of Spokane county. It has a municipal airport and an airport base of the 5th bombardment wing of the U.S. army, is on federal highways 10, 95, 195 and 395; and is served by the Chicago, Milwaukee, St. Paul and Pacific, the Great Northern, the Northern Pacific, the Spokane International, the Spokane, Portland and Seattle and the Union Pacific railways, and by numerous motor-coach lines. Pop. (1940) was 122,001 (85% native white). Spokane is the metropolis of the "Inland Empire" of 200,000 sq.mi., lying between the Rocky mountains on the east and the Cascade or Coast range on the west, and embracing eastern Washington, northeastern Oregon, northern Idaho, western Montana and southern British Columbia. The city has an area of 41.5 sq.mi. and an altitude of 1,891 ft., and is surrounded by pine-clad mountains, rivers, cascades, waterfalls, lakes (76 within 50 mi.), orchards and fertile fields of grain. It is protected by the mountain ranges from extremes of heat and cold and from the fogs of the coast. The average year has 208 days of sunshine, 16 in. of rainfall, and a "growing season" of 183 days between killing frosts. Through the city, in the heart of the business section, flows the Spokane river, tumbling over cataracts. The city is clean and well built, with substantial business buildings and commodious hotels; well paved, well lighted and well kept streets; and delightful views in every direction. From 1911 it has been under a commission form of government. The park system includes in all 2,720 ac. Mount Spokane (5,808 ft. high), 35 mi. N.E., is maintained by the state as a public recreation ground. Three miles west of the city is Ft. George Wright, headquarters of the 2nd air force, directing all air corps operations for 11 western states, in a reservation of 1,022 ac., presented to the government by the city in 1894. The assessed valuation of property in 1940 was $72,259,098.

**Schools.**—The investment in public school buildings and equipment amounts to over $8,000,000, and the teaching staff in 1940 numbered 653. Gonzaga university (Roman Catholic; opened 1887), Whitworth college (Presbyterian; founded in Tacoma in 1890) and Spokane Junior college and Holy Name normal school (Catholic) are in the city.

**Resources and Commerce.**—The Inland Empire is rich in natural resources (lumber, minerals, fertile soil and water power) and Spokane is its principal market, supply point, manufacturing and distributing centre and financial capital. The wholesale business of the city was $79,081,000 in 1939. Spokane is entitled to

the sobriquet "the power city," for 12 hydroelectric plants of the district have an installed capacity of 266,050 h.p., of which 183,000 h.p. represents the developed capacity of seven plants on the Spokane river in and near the city. This electric power operates mines, maintains extensive irrigation projects, runs transcontinental trains over the Rockies and the Cascades, and supplies current for industrial plants, street lamps and domestic lighting. The product of the city's factories averages $60,000,000 annually.

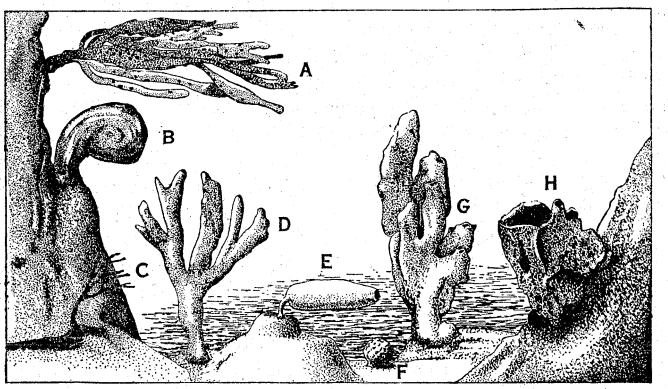
**History.**—The first permanent settlement on the site of Spokane was made in 1874 by James N. Glover, who bought a tract of land from two trappers. The town was incorporated in 1881, as Spokane Falls, received a city charter later in the year, and became the county seat in 1882. In 1890 "Falls" was dropped from the name. Spokan (said to mean "children of the sun") was the name of an Indian tribe of Salishan stock which had formerly occupied the river valley. The Northern Pacific railroad reached the city in 1883, the Union Pacific in 1889, and the Great Northern in 1892. In 1889 (Aug. 4–6) a fire destroyed 30 blocks in the heart of the city, practically the entire business section, at a loss estimated at $5,000,000, but within two years the district was rebuilt, with great improvements. The population was 19,922 in 1890, 36,848 in 1900 and 104,402 in 1910. The pioneer who laid out the town site lived to see a city of over 100,000.

**SPOLETO** (anc. *Spoletium*), a town and archiepiscopal see of the province of Perugia, Italy, 18 mi. N.N.E. of Terni, and 88 mi. N. by E. of Rome by rail. Pop. (1936) 10,579 (town); 32,341 (commune). It is situated on a hill, so that the lowest part is about 1,000, the highest 1,485 ft. above sea level, at the south end of the open valley of the Topino, a tributary of the Tiber, which it joins near Assisi. The principal industries are the collection and preparation of truffles and preserved foods, also tanning and the manufacture of earthenware, cotton and wool spinning. Spoleto is also the centre of an agricultural district, and contains a government experimental olive oil factory. There are few towns of Italy which possess so many Roman remains in good preservation under the mediaeval buildings, and few mediaeval towns with so picturesque an appearance. There are considerable remains of pre-Roman polygonal walls. There are remains of a Roman theatre, over 370 ft. in diameter, and an amphitheatre 390 by 295 ft. A Roman bridge of three arches, 80 ft. long and 26 ft. high, exists at the lower (north) entrance to the town.

The rock above the town was included within the polygonal walls: but Totila fortified, not this rock, but the amphitheatre, which remained the citadel until 1364, when Cardinal Albornoz destroyed it and erected the present Rocca, which was enlarged by Pope Nicholas V; it is now a prison. The Porta Fuga (the name alludes to the repulse of Hannibal) occupies the site of a Roman gate, but is itself mediaeval: while the mediaeval enceinte encloses a somewhat wider area than the ancient. The Piazza del Mercato represents the Roman forum; close by is a triumphal arch of Drusus and Germanicus (A.D. 21), and a temple (?) over which is built the church of S. Ansano. A Roman house in the upper part of the town, with mosaic pavements, probably belonged to Vespasia Polla, the mother of the emperor Vespasian. The Palazzo Municipale, above it, contains the archives and picture gallery. The cathedral of S. Maria Assunta, much modernized in 1634 by Bernini, occupies the site of a church of the Lombard dukes erected about 602. The present church was consecrated in 1198; the façade with eight rose windows belongs to the middle of the 12th century. Over the main entrance is a large mosaic of Christ enthroned, with the Virgin and St. John, by the artist Solsernus (1207). The Early Renaissance vestibule (after 1491) is fine. In the choir and on the half dome of the apse are the finest frescoes of Fra Filippo Lippi (scenes from the life of the Virgin) completed after his death by Fra Diamante: his tomb, erected by Lorenzo de' Medici, with the epitaph by Politian, is on the left of the choir. The fine stalls and panelling in the winter choir date from 1548–54. The Campanile is beautiful.

The church of S. Pietro, outside the town, has a façade richly sculptured with grotesque figures and beasts, of two different dates, about 1000 and about 1200. The little church of SS. Giovanni e Paolo (12th century) contains frescoes of the 12th–14th centuries notably an early representation of the martyrdom of S. Thomas à Becket and a portrait of S. Francis of Assisi. S. Domenico is a fine example of later Italian Gothic with bands of different coloured stone. Both the church and its crypt contain 14th century frescoes. The triple-apsed crypt of S. Gregorio probably dates from the 9th century; the upper church was consecrated in 1146 and the Romanesque work covered with stucco in the restoration of 1744. S. Nicolò is a beautiful example of Pointed Gothic. The basilica of S. Salvatore (*il Crocefisso*) at the cemetery belongs to the 4th century A.D. The fine sculptures of the façade, with its beautiful windows, as also the octagonal dome, all belong to this period. It was restored in 1815. S. Ponziano, not far off, belongs to the 13th century. The city is still supplied with water by an aqueduct, to which belongs the huge bridge called the Ponte delle Torri, crossing the ravine which divides the town from the Monte Luco (2,723 ft.). The bridge is 253 ft. high and 755 ft. long and has ten arches: it was erected in 1364.

After the battle of Trasimenus (217 B.C.) Spoletium was attacked by Hannibal, who was repulsed. It suffered greatly during the civil wars. Sulla, after his victory over Crassus, confiscated the territory of Spoletium (82 B.C.). Under the empire it again became a flourishing town. It was situated on a branch of the Via Flaminia, which left the main road at Narnia and rejoined it at Forum Flaminii. An ancient road also ran hence to Nursia. Martial speaks of its wine. Aemilianus, who had been proclaimed emperor by his soldiers in Moesia, was slain by them here on his way to Rome (A.D. 253), after a reign of three or four months. The foundation of the episcopal see dates from the 4th century. Owing to its elevated position it was an important stronghold during the Vandal and Gothic wars. It was beautified by Theodoric (493) and fortified by Belisarius (536) but its walls were dismantled by Totila (546). Under the Lombards Spoleto became the capital of an independent duchy (from 570), and its dukes ruled a considerable part of central Italy. Together with other fiefs, it was bequeathed to Pope Gregory VII by the empress Matilda, but for some time struggled to maintain its independence. In 1155 it was destroyed by Frederick Barbarossa. In 1213 it was definitely occupied by Gregory IX. During the absence of the papal court in Avignon it was a prey to the struggles between Guelphs and Ghibellines, until in 1354 Cardinal Albornoz brought it once more under the authority of the Church. In 1809 it became capital of the French department of Trasimene. In 1860 it was taken by the Italian troops after a gallant defense.



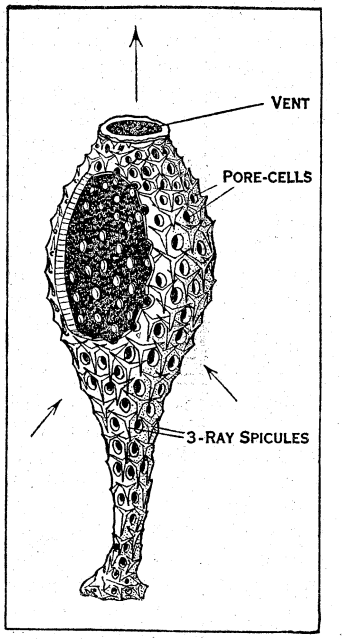
At Monteleone di Spoleto a circular tumulus was found in 1902, with a rectangular chamber in the centre, and in it was the famous *biga* (two horse chariot), the only ancient one found in a complete state, which is now in the Metropolitan Museum at New York. (T. A.)

**SPONGES,** or Porifera (from Latin *porus,* pore, and *fero,* to bear), are the simplest animals of the subkingdom Metazoa, which comprises all the multicellular forms. The body of a sponge consists of a rather loose aggregation of cells supported by a framework of spicules or fibres which form intricate skeletal structure. The differentiation into definite tissues, such as muscular, glandular, nervous, connective, etc., is incomplete and consequently there is but little co-operation and co-ordination among the parts of the body. The majority of sponges are of irregular shape, forming branching or encrusting structures attached to the bottom or to the submerged objects (fig. 1). Some of the sponges have, however, definite form and symmetry.

John Ellis (1765) was the first to demonstrate the animal nature of sponges by observing the water currents produced by a sponge and noticing the contractions on the surface of its body. For a long time sponges were grouped together with the Coelenterates (Linnaeus, Jean Lamarck, Georges Cuvier), until H. M. D. de Blainville (1816) placed them into a special group, Spongiaria, which he considered related to Protozoa. His idea received, however, no recognition from his contemporaries. The present name Porifera was created in 1836 by R. E. Grant, who devoted many years to the study of sponge morphology and anatomy. Separation of sponges from other multicellular forms (Metazoa) was.

proposed by T. H. Huxley (1875) and W. J. Sollas (1884), the view still held in 1945. Modern zoology places the sponges into a special branch of Metazoa called, after Sollas, Parazoa.

**General Characters.**—As the name Porifera implies, the surface of a sponge is covered with a multitude of minute openings or pores through which the current of water is maintained by flagellated cells located inside the sponge body. The water drawn in by the beating of the flagella passes through a complex system of canals and is expelled from several large vents, so-called oscula.

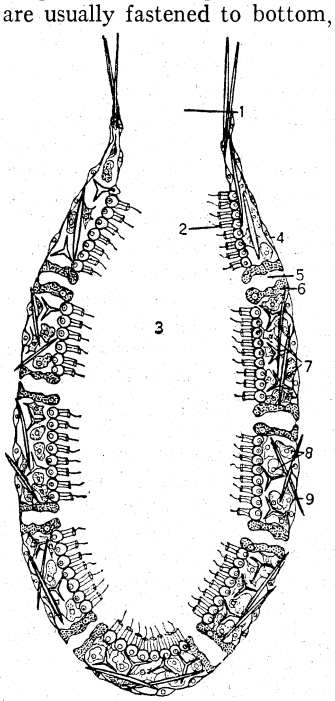


AFTER BIDDER IN "PROCEEDINGS OF THE S.W. NATURALISTS' UNION"

FIG. 1.—COMMON SPONGES OF TEMPERATE SEAS
A. Branched Finger Sponge (*Chalina oculata*); B. Sea Fig (*Suberites ficus*); C. Tow Sponge (*Vibulinus stuposus*); D. *Axinella dissimilis;* E. Common Sponge (*Leucandra fistulosa*); F. Sea Sponge (*Donatia lyncurium*); G. Mermaid's Glove (*Desmacidon fruticosum*); H. Brittle Horny Sponge (*Spongelia fragilis*)

The tissues are kept in place by a skeleton composed of mineral spicules or made of a mesh of elastic fibres (horny sponges). The simplest organization is found in the so-called ascanoid type of sponges represented by a few genera of calcareous sponges, *Leucosolenia* (fig. 2), *Ascute, Ascyssa* and *Dendya.* The latter genus approaches a more complex syconoid type. The vaselike symmetrical body of an ascanoid sponge is made of three layers of tissues forming the walls around a large central cavity (fig. 3). The outside covering consists of epidermis made of a single row of thin and flat cells. The central cavity is lined by a layer of collar cells or choanocytes, recognizable because of the presence of a contractile collar surrounding the base of a single long flagellum (fig. 4). The intermediate layer or mesenchyme (fig. 3, [7]) separating the collar cells from the epidermis consists of gelatinous material with spicules embedded in it and numerous amoeboid cells, the amoebocytes (fig. 3, [8]), freely wandering about. The incurrent pores or ostia are not simple holes in the epidermis but represent intracellular channels passing through special tubular cells, the so-called porocytes (fig. 5). Water is discharged through a large opening known as the osculum (fig. 3, [1]).

In the next more complex type of organization, represented by the genus *Sycon* and called syconoid, the continuous layer of choanocytes is pushed outward at regular intervals to form pouchlike projections or radial canals. The walls of the canals may fuse, leaving between them narrow spaces, the inward-leading canals, lined with the surface epidermis. The spreading of the epidermis and mesenchyme to form a cortex (fig. 6) and the underlying subdermal spaces presents a further advance in the complexity of sponge organization and leads to a final or so-called leuconoid type. The latter type of organization and its numerous variations are represented in a vast majority of sponges. The leuconoid sponge (fig. 6, D) is characterized by clusters of small rounded flagellated chambers formed as a result of the outfolding of a continuous choanocyte layer of the ascanoid sponge. The choanocytes occur only in these chambers. The water is conveyed to the flagellated chambers through the ostia, subdermal spaces, inward-leading channels and pores (prosopyles) and is expelled through the outward-leading pores (apopyles) to the outward-leading canals, larger channels and is finally discharged through the oscula. A large layer of mesenchyme fills up the space between the canals and the flagellated chamber. The large central cavity so prominent in the asconoid type is obliterated and the entire body of the sponge consists of a maze of water channels and flagellated chambers supported by a skeleton made of mineral spicules or spongin fibres. The development of a complex leuconoid type of organization is accompanied by a greater efficiency in producing and maintaining strong currents of water which provide the sponge with food and oxygen for respiration.



**Size, Shape and Colour.**—The size of sponges varies from a fraction of an inch, the usual length of small inconspicuous calcareous sponges of temperate seas (*Sycon, Grantia*), to huge masses of irregular or global shape several feet in diameter found in tropical and subtropical waters (*Hircinia* and many other horny sponges). Some of the sponges have definite symmetrical bodies, but the majority grow as irregular encrusting masses or form large branching colonies. Of particular interest are many deep-sea sponges which display greater regularity of growth not found in their relatives inhabiting shallow waters. This secondary symmetry clearly shown in a remarkable species, *Esperiopsis challengeri* (fig. 7), is probably correlated with life in still water at great oceanic depths, which according to the generally accepted view the sponges invaded only in a comparatively recent time.

AFTER HAECKEL'S "DER KALSCHWAMME" (DE GRUYTER & CO.)

FIG. 2.—YOUNG LACE-CHALK (LEUCOSOLENIA PRIMORDALIS) IN "OLYNTHUS" STAGE, MAGNIFIED

Sponges are completely devoid of organs of locomotion and are usually fastened to bottom, rocks, piles or other submerged objects. Those living on muddy bottoms are anchored by roots consisting of bundles of long spicules (fig. 8).

FIG. 3.—DIAGRAM OF THE ASCANOID SPONGE
1, osculum; 2, layer of choanocytes; 3, central cavity; 4, epidermis; 5, pore through porocyte; 6, porocyte; 7, mesenchyme; 8, amoebocyte; 9, spicule

The colour is greatly variable. The deep water sponges are usually drab or brownish, but many of the inhabitants of shallow water lagoons display brilliant yellow, green, red, scarlet and violet colours. Among the most brilliantly coloured sponges are the scarlet sponge, *Tedania ignis,* of the coral reefs in Bermuda, and the red sponge, *Microciona prolifera,* inhabiting the estuaries along the North American coast. Various species of boring sponge, *Cliona,* frequently are found as large bright-yellow masses overgrowing the shell of an oyster or a clam. The greenish colouration of a fresh-water sponge, *Spongilla viridis,* is due to the presence of unicellular green algae which invade the sponge cells and live and propagate inside the sponge body without injuring their host (*see* SYMBIOSIS).

**Classifications.**—The sponges are classified primarily on the basis of the type of skeleton and shape and size of their spicules.

AFTER BIDDER IN "QUARTERLY JOURNAL OF MICROSCOPICAL SCIENCE"

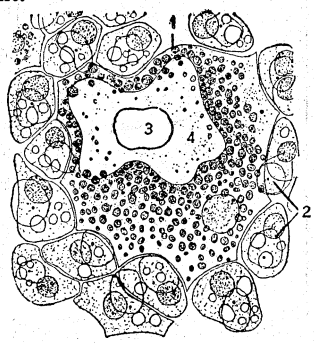
FIG. 4.—WALL OF FLAGELLATE CHAMBER OF THICK WALLED BANANA-CHALK (LEUCANDRA ASPERA); ARROWS SHOW DIRECTION OF CURRENTS

The chemical composition of the skeletal material serves to separate the calcareous, or chalky sponges, with the spicules composed of calcite, from siliceous and horny sponges in which the spicules are composed of silica or the skeleton consists entirely of horny fibres. Some of the classes and orders of siliceous sponges are not, however, clearly defined and no uniform system of classification has yet been agreed upon by zoologists. The classification commonly used in the United States is based on the works of E. Topsent, H. V. Wilson and M. W. deLaubenfels. The phylum Porifera is usually divided into three classes:

*Class I.—Calcarea,* the calcareous sponges. Skeleton is made of one-,three-,or four-rayed spicules of calcite.

*Class II.—Hexactinellida,* the glass sponges. Skeleton consists of a network of separate six-rayed (triaxon) siliceous spicules, finger-shaped flagellated chambers, no surface epithelium.

*Class III.—Demospongiae.* Sponges of leuconoid type with siliceous spicules, not of triaxon type, or of horny fibres or both. Spicules are differentiated into megascleres and microscleres; small flagellated chambers.

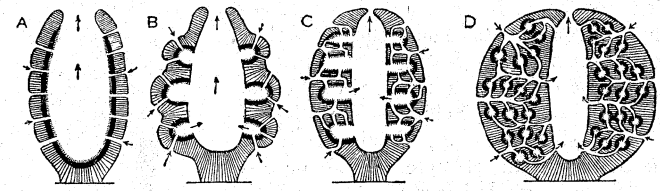


*Subclass I.—Tetractinellida*—with tetraxon spicules and no spongin. Spicules sometimes absent.

*Subclass II.—Monaxonida*—large spicules (megascleres) of monaxonal type, spongin may be present or absent.

*Subclass III.—Keratosa*—the horny sponges. Skeleton consists of a meshwork of spongin fibres. Spicules absent.

For more detailed study of sponge taxonomy, consult monographs and special publications listed by G. C. J. Vosmaer.



**Histology.**—The differentiation of cells in sponge tissues is much less pronounced than in the higher forms which possess various organs or systems such as digestive tracts, musculature, kidneys, etc., lacking in Porifera.

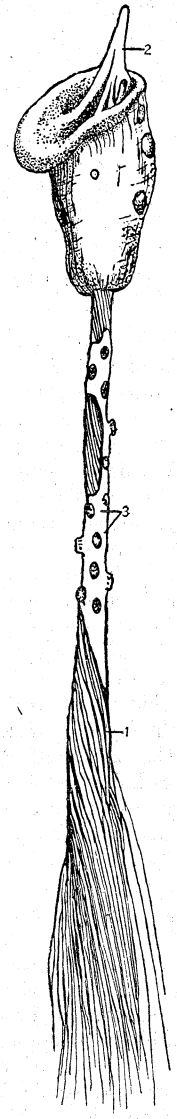
lining of the canals and central cavity. The pinacocytes, as these cells are called, form a single layer of epithelium consisting of flattened platelike elements with a large nucleus in the thicker portion of the cell. Sometimes the pinacocytes are provided with the cilia which help in maintaining the current of water. According to Wilson, in some of the sponges the true epithelium is replaced by a continuous "epithelioid membrane" or syncytium with scattered nuclei. The intake of water is regulated by means of special cells, porocytes, pierced by a canal and supplied with a highly contractile diaphragm consisting of a thin sheet of cytoplasm stretched across the opening (fig. 5). The origin of porocytes, which by some of the investigators are considered as degenerate cells, has not yet been determined.

The flagellated cells or choanocytes lining the flagellated chambers are typical structures of sponge organization. They are easily recognized by transparent contractile collars and long flagella (fig. 4) attached to the cell body by means of a basal granule. In appearance and structure the choanocytes resemble the flagellated Protozoa of the family Craspedomonadidae. One representative of this group, a colonial protozoan *Proterospongia* (fig. 16), is regarded as a probable link between the sponges and flagellates.

The inner layer of a sponge body consists of transparent intercellular ground substance of variable consistency which gives support or acts as a scaffolding for widely separated mesenchyme cells. The latter are represented by different kinds of amoebocytes, or wandering cells, varying in size, character of pseudopodia, and type of inclusions. The mesenchyme also contains a large number of undifferentiated cells called archaeocytes, which may develop into more specialized types and apparently play an important role in regeneration. Mesenchyme cells which secrete spicules and spongin fibres are called scleroblasts. According to the type of skeleton they produce (fig. 12), they are designated as calcoblasts (secreting calcite

FROM RAY LANCASTER, "TREATISE ON ZOOLOGY," PART II, "THE PORIFERA" BY E. A. MINCHIN, ADAM & CHARLES BLACK, LONDON (THE MACMILLAN CO., NEW YORK AGENT) 1900

FIG. 7.—ESPERIOPSIS CHALLENGERI, A DEEP-SEA SPONGE WITH A SECONDARY SYMMETRY



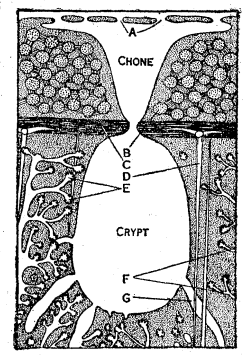
spicules), silocoblasts (producing siliceous spicules) and spongioblasts (forming spongin fibres).

The sex cells, ova and spermatozoa, are apparently derived from choanocytes which lose their flagella and collars and penetrate into mesenchyme. During this stage they look like true amoebocytes. Because of this similarity the old view maintained in the last century by F. E. Schulze, N. Polejaeff and O. Maas that the germ cells arise directly from amoebocytes cannot be discarded without further study.

True muscles in sponges are wanting, but special fusiform contractile cells, the myocytes, somewhat resembling the smooth muscle cells of higher forms have been described. In certain species they form sphincters which regulate the afferent stream of water (fig. 9). Sensory and nerve cells are absent. The contractions of the surface of the body, or of the oscula, noticeable in some of the species, are the result of the direct stimulation of the pinacocytes and myocytes.

**Skeleton.**—Soft tissues are supported by a complex framework of hard spicules made of calcite ($CaCO_3$) in calcareous sponges or of opal ($SiO_2nH_2O$) in siliceous sponges. In horny sponges the skeleton consists of a meshwork of elastic fibres made of spongin, an albuminoid of a highly complex chemical structure. The spicules vary in size, shape, and number of axes. Since the taxonomists use them as principal characters for the identification of sponges, elaborate terminology has been developed for designating various skeletal elements (fig. 10). In general there are two principal types: the large skeletal spicules, the megascleres which form the framework of the sponge body; and the small microscleres of variable and irregular shape scattered throughout the tissues.

Various classes of spicules are distinguished by the number of their axes or rays. Thus, monaxon designates the needle-like spicule with one axis; tetraxon has four rays emerging from one point and extending into different planes; three axes crossing at the right angles typical for Hexactennellid sponges produce an element with six rays (fig. 11) or triaxon; several equal rays emerging from a central point characterize the polyaxons known also as asters. The classification and the corresponding terminology become greatly involved as various modifications caused by the loss of rays, bending of axes, etc., are taken into account and each type denoted by special term.



FROM L. H. HYMAN, "THE INVERTEBRATES: PROTOZOA THROUGH CTENOPHORA" (MCGRAW-HILL, 1940)

FIG. 8.—HYALONEMA, DRY SPECIMEN (AFTER SCHULZE, 1887). A HEXACTINNELID SPONGE WITH ROOT SPICULES; 1, ROOT SPICULES; 2, GASTRAL CONE; 3, SYMBIOTIC ZOANTHIDS ON ROOT TUFT

Mineral substance of a spicule is deposited around a central axis of organic material. In siliceous sponges the silica is laid in the form of concentric cylinders. Usually two scleroblasts (fig. 12) participate in the formation of a monaxon spicule which is laid down by one of them, the founder, while the other, the thickener, deposits additional mineral material. When the spicule is completed the two cells move apart. Several cells combine in secreting more complex spicules and spongin fibres (fig. 12, K, O).

**Chemical Composition.**—Mineral constituents of the skeleton comprise a very large portion of sponge body. From 15% to 97% of the ash of siliceous sponges consists of $SiO_2$, while in calcareous sponges $CaCO_3$ content of ash varies from 84.9% to 86.8%. Other mineral constituents include MgO, $P_2O_5$, $Fe_2O_3Ae_2O_3$, $Na_2O$, $K_2O$, $SO_3$, Sl and minute quantities of Mn, Zn, B, Cu and As.

The presence of relatively large quantities of iodine in dried commercial sponges, first demonstrated in 1819 by Andrew Fyfe, is of considerable scientific interest. It is known that iodine present in various species occurs in a combination with an organic compound of the skeleton known as iodospongin. The percentage of iodine in iodospongin varies from 1.5% to 4.86% in bath sponge (*Euspongia sp.*) to 8%–10% in *Luffaria cauliformis*. More detailed studies identified the iodine compound obtained from spongin as di-iodotyrosine, a complex which also contains bromine. Calcareous and siliceous sponges are, as a rule, poor in iodine; but the red sponge *Microciona prolifera* is apparently an exception, for according to the determinations made in 1933 by W. Bergman its iodine content comprises 0.3% of the total dry weight. The physiological role of the iodine in sponge body is not known.

(A) Dermal pores; (B) Solid-stars; (C) Contractile cells; (D) Grapnel spirule; (E) Flagellate chambers; (F) Inward-leading canals; (G) Afferent canal

**Physiology.**—The water pumping mechanism of sponges consists of thousands of choanocytes which line the flagellated chambers. Because of their position inside the sponge body and small size, their action is difficult to observe. Only in calcareous sponges are the choanocytes relatively large and therefore observable with less difficulty. In action the flagellum of a choanocyte makes an undulating spiral movement which starts at its base and proceeds toward the tip. As the flagellum points toward the outward leading pores, apopyles (fig. 4), each of its strokes draws

a little water and pushes it forward, gradually filling up the chamber. The pressure so produced stretches the walls of the flagellated chamber and is extended to the outward leading canals and central cavity. Apparently there is no co-ordination of the beating of the flagella, each choanocyte working more or less independently of the others. As a result of the movement of thousands of minute flagella the water is sucked into the flagellated chambers through the dermal pores and inward leading canals and escapes through the outward leading canals and oscula. The velocity of current in each flagellated chamber is rather slow, but as thousands of tiny pumps deliver water into a relatively small number of vents, or oscula, the rate of the current increases. G. P. Bidder showed that in *Leucandra aspera* the current velocity at the osculum was about 8 cm. a second, while the velocity at the same moment past collar cells was only from 2 cm. to 4 cm. an hour. The pressure inside the oscula can be measured by inserting a glass tubing of corresponding diameter and observing the height of the water column above the surrounding level. By this method G. H. Parker found that hydraulic pressure in *Stylotella* was about 4 mm. These observations and other indirect methods can be used to compute the rate of pumping water by the whole sponge. According to Bidder, *Leucandra aspera* requires about 5 gal. of water a day and discharges it at a distance of about 9 in. from its body. A fingerlike branching sponge, *Spinosella sororia,* was observed by Parker to filter 1,575 litres of water per day. F. G. Walton Smith, working with cultivated horny sponges in the Bahamas, found that a wool sponge of 500 cu.cm. in volume pumped approximately 2 litres per minute. At this rate its daily requirement may be estimated at about 600 gal., but observations are still lacking to determine whether such a rate of pumping is maintained for 24 hours a day.

The flow of water through the body, maintained by the beating of the flagella, is regulated by the contractions and expansions of the oscula and dermal pores. In spite of the absence of any co-ordinating centre, the pumping mechanism works with great efficiency. The water sucked in by the sponge moves very slowly through the dermal pores, inward leading canals, and flagellated chambers, and provides the tissues with food and oxygen for respiration. Since the outgoing currents discharged through the oscula have much greater velocity, the water filtered by the sponge and contaminated with the products of its metabolism, is discharged far away and cannot be re-used. The presence of toxic or irritating substances dissolved in water is easily detected by the porocytes, which react by contracting their diaphragms and closing the pores. In this way the sponge protects itself against possible injury. Structure and functioning of the pumping mechanism can be regarded as an efficient adaptation of sponges to the sedentary conditions of life in the ocean.

FROM L. H. HYMAN, "THE INVERTEBRATES: PROTOZOA THROUGH CTENOPHORA" (MCGRAW-HILL, 1940)

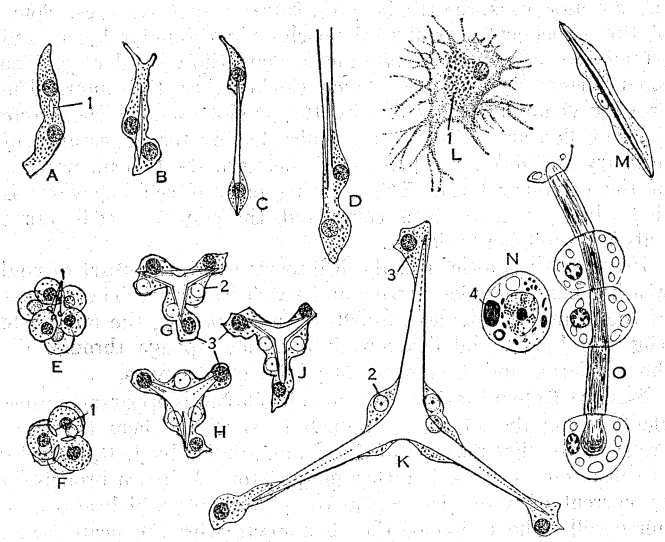

FIG. 11.—SPICULES OF HEXACTINELLID SPONGES

**Food and Nutrition.**—The food of sponges consists of minute organisms suspended in water. Bacteria probably play an important role in the feeding of horny sponges which frequently inhabit waters containing but small numbers of other microorganisms in suspension. Thus, for instance, principal commercial species of sponges in the Bahamas are found on mud bottoms in waters containing very abundant bacterial flora but poor in plankton. The role of bacteria in the feeding of sponges has not been, however, adequately studied and requires further investigation.

Ingestion and digestion of food can be observed by feeding the sponges with easily identifiable materials such as carmine or carbon powder, milk, starch grains or bacteria, and examining their tissues at regular intervals after feeding. As the flow of water passing from the narrow inward leading channels slows down after entering the flagellated chambers, the suspended particles settle and are caught by collar cells. In calcareous sponges the material entrapped in the collars of choanocytes becomes engulfed and digested by the cytoplasm. Some of the particles may be passed, however, to the amoebocytes surrounding the flagellated chambers (fig. 13). More complete division of functions exists in siliceous sponges. Here food is also caught by the choanocytes but digestion is accomplished only by amoebocytes.

**Respiration.**—Since special organs of respiration and circulation are lacking, the need for oxygen is supplied through direct exchange between the tissues and the surrounding water. Consequently, the rate of metabolism ($O_2$ consumption) is controlled by the rate of exchange of water. Hyman found that the $O_2$ consumption in *Sycon* may decrease by 80% when the oscula are closed. The observed rates per hour in this sponge vary from 0.04 to 0.16 ml. of oxygen per gram of fresh weight. The figures are of the same degree of magnitude as those observed for many other marine invertebrates. Sponges have no organs of excretion. Products of their metabolism and indigestible material, ejected by the amoebocytes, are discharged with the outgoing currents.

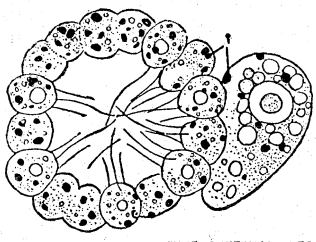
**Poisonous and Injurious Sponges.**—The surface of many sponges is slimy because of the excretion of mucous, which may cause unpleasant but not dangerous irritation of the skin. For instance, the scarlet sponge of the Bermuda islands, *Tedania ignis,* when handled with naked hands, causes painful dermatitis.

The nature of the active substance is not known. Of special interest are the boring sponges of the genus *Cliona,* widely distributed in the coastal water of North America. As the name indicates, the sponge bores through the shells of oysters and other molluscs and in case of severe infestation may destroy them. The method by which the sponge makes its long and branching passages in the shell substance is not known. Secretion of acid has been suggested but not corroborated by observation. Studies conducted by P. S. Galtsoff and V. Pertzoff in 1926 showed, however, that the suspension of cells of *Cliona* behaves as a much stronger acid than that of the nonboring sponge *Microciona.* Mechanical action may also be involved in boring, but the process has not yet been adequately studied.

**Regeneration.**—The power of regeneration, *i.e.,* the ability to restore lost parts, is very high in sponges. Not only is a piece cut off from a body capable of growing into a complete sponge, but the cells separated by squeezing a piece of sponge through fine silk cloth, and suspended in water, reunite and develop into a new sponge. The phenomenon discovered by Wilson in 1907 is of considerable theoretical interest. It was thought first that the development of a new sponge from reunited masses is to a certain extent similar to the development of an embryo, and that the separated cells undergo dedifferentiations and return to the embryonic state. It was shown by P. S. Galtsoff that certain cells retain their morphological characteristics and the first steps in regeneration are accomplished by the sorting out and rearrangement of the old cellular material.

Under unfavourable conditions sponges collapse, disintegrate and leave only small reduction bodies which consist of a mass of amoebocytes covered by epidermis. With the return of normal conditions these bodies are capable of developing into complete sponges.

**Asexual Reproduction.**—All fresh-water and some marine sponges reproduce by means of gemmules, small, hard and rounded bodies consisting of a mass of archaeocytes laden with reserve food and surrounded by a columnar layer of flattened cells (fig. 14). The formation of gemmules in fresh-water sponges begins with the gathering of amoebocytes, which are joined by special nurse cells, the trophocytes, carrying food reserves. Some of the amoebocytes arrange themselves in columnar layers and secrete two concentric membranes around the central core. The inner membrane is usually much thicker than the outer. The growing gemmule is invaded by the screloblasts, which secrete the so-called amphidisks, the spicules having the appearance of ordinary cuff links, and place them between the two membranes of the columnar layer. The amazing part of cell behaviour is that when the gemmule is completed, the columnar cells, nurse cells and screloblasts depart.



Fresh-water sponges usually disintegrate with the onset of cold weather but gemmules survive and hatch in spring. The content of the gemmule emerges through a small opening, the micropyle (fig. 14, [11]), and develops into a new sponge through the differentiation and rearrangement of the archaeocytes.

**Sexual Reproduction.**—Hermaphroditism is apparently prevalent among the sponges, although in some of them the sexes are separate. Fertilization of the ovum, studied by J. B. Gatenby in calcareous sponges, is rather unique, for the sperm brought in by current of water first enters the choanocyte which acts as a nurse cell. The fusion of the choanocyte with the nearest egg, which occupies a position close to the flagellated chamber, sets the sperm free. Insemination is then accomplished in a regular manner.

Similar process was described by O. Tuzet in siliceous sponges, with the only difference that sperm enters the amoebocyte, which in turn transfers it to the egg.

Detailed information about the breeding periods of sponges is lacking. In the commercial sponges of the Bahamas (sheepswool and velvet) breeding takes place all the time, but the greatest proportion of specimen with embryos ready for release were found by F. G. W. Smith in March and April.

**Development.**—The fertilized egg divides into two, four and eight blastomeres which surround a central cavity while they are still arranged in one plane. After the 32-cell stage has been reached the divisions become somewhat irregular. At this time the embryo, called now blastula, has a shape of an oval vesicle, one end of which is flattened and the other rounded. The central cavity of the blastula opens to the exterior at the flattened surface. This opening or pore is surrounded by the cells distinguishable from the others by heavy granular inclusions, while the remaining cells are columnar and have long flagella.

FROM L. H. HYMAN, "THE INVERTEBRATES: PROTOZOA THROUGH CTENOPHORA" (MCGRAW-HILL, 1940)

FIG. 13.—AMOEBOCYTE OF A CALCAREOUS SPONGE RECEIVING CARBON PARTICLES FROM CHOANOCYTES (AFTER POURBOIX, 1933); 1, CARBON PARTICLES

Rapid proliferation of granular cells produces a thick mass which bulges into the central cavity (fig. 15A). By this time the embryo, by means of the flagella, forces its way into the nearest flagellated chamber and escapes through the osculum. Apparently through the absorption of water, the layer of invaginated cells is forced out and the embryo acquires an oval shape.

The sponge larva at this stage is called amphiblastula, from Greek, *amphi,* around or on both sides and *blastos,* germ, (fig. 15, B). One half of it consists of columnar and brightly pigmented cells with long flagella, the other half is made of round granular cells. The amphiblastula type of larvae occurs in all families of sponges and is, therefore, typical of the entire group. The larva swims with its ciliated end forward. After a few days of free life it settles on a smooth surface of a stone or shell, with its ciliated portion directed downward, and almost immediately flattens. The ciliated cells become invaginated and the central cavity of the larva, the blastocoele, reduced to a narrow slit. The larva now becomes attached to the substratum. At this stage it consists of two layers. The granular cells form the outer covering and the flagellated cells line the inside cavity. Very soon the flagellated cells develop characteristic collars and are transformed into choanocytes. The appearance of the granular substance between the two layers, the formation of the pores and osculum, and the secretion of spicules complete the development. At this stage the young sponge is usually referred to as "olynthus." Its final transformation into an adult sponge is a matter of continuous slow growth and rearrangement of cellular elements. Although the details of the development may vary in different classes and families the essential steps are similar in all of them.

**Individuality of Sponges.**—Lack of a central regulatory or co-ordinating organ, great variability in shape or form, and remarkable regenerative power, make it difficult to decide whether sponges are individuals or colonies. This theoretical question, much debated by the zoologists of the last century, has not yet been satisfactorily settled. It is generally considered that the osculum with the contributing part of the canal system is an individual element or a "person," and that several of these units are combined in a colony of individuals grown together and performing common functions. The fact that the osculum controls the flow of water through the adjacent part of the body and is the most conspicuous part of the sponge anatomy, seems to give weight to this view. The boundaries of individual units are, however, indistinct and their individuality is of very vague nature. It is remarkable that, in spite of the absence of central organs, many species of sponges developed very definite shape and symmetry. Their skeletons also show progressive complexity from a rather simple arrangement of spicules to a very complicated symmetrical framework built according to a definite structural pattern.

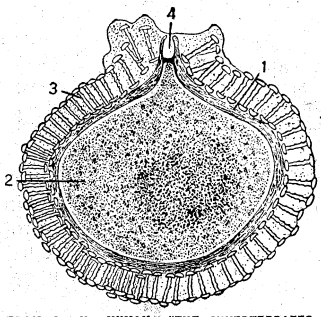
**Relationship.**—On the basis of our knowledge of the anatomy and histology of sponges, it is reasonable to suppose that this group evolved from colonial choanoflagellate Protozoa similar to *Proterospongia* (fig. 16). In the subsequent evolutionary process sponges formed a separate branch of Metazoa which failed to develop higher grades of organization characterized by the formation of a head, nervous system, organs of digestion, circulation and respiration present in other multicellular forms. The sponges

retained their ancestral protozoan features in the structure of choanocytes, in the intracellular digestion, and in the mode of production of the skeleton, the elements of which are secreted by single cells or group of freely moving cells. Progressive evolution in sponges consisted chiefly in the perfection of the canal system and in developing a more complex skeleton. Sponges appeared very early in geological history, for their spicules are found in the upper Cambrian deposits.

TABLE I.—*Common and Scientific Names of Principal Commercial Sponges*

| Common Name | Scientific Name | Fishing Areas |
|---|---|---|
| Turkey cup; Turkey solid, Fine Levant; Silks | *Euspongia officinalis molissima* | Eastern Mediterranean, Tunis |
| Turkey toilet | *Euspongia officinalis adriatica* | Adriatic, Tunisia, Eastern Mediterranean |
| Zimocca | *Euspongia zimocca* | Adriatic, Dardanelles, Greece, Egypt, Tripoli, Tunisia |
| Elephant's ear | *Euspongia officinalis lamella* | Provence, Dalmatia, Egypt, Tunisia, Algeria |
| Honeycomb; bath | *Hippiospongia equina elastica* | Mediterranean |
| Wool; sheepswool | *Hippiospongia lachne* | Florida, West Indies, Honduras |
| Velvet | *Hippiospongia grossypina* | Bahamas, Honduras, Cuba |
| Yellow | *Spongia barbara*. Probably also other species | West Indies, Florida, Cuba, Haiti, Caribbean Sea, Australia, New Zealand |
| Grass | *Spongia graminea* | Florida, Bahamas, Cuba, Mexico, British Honduras |
| Glove | *Hippiospongia canaliculata* var. *flabellum* | Florida, Bahamas |
| Reef | *Spongia obliqua*, and probably *S. agaricina* and other species | Bahamas, Cuba, British Honduras, Florida |
| Hardhead | *Spongia dura*, *S. agaricina corlosia* and probably other species | Bahamas, British Honduras, Haiti |

**Ecology.**—The distribution of sponges is world-wide. They inhabit all the oceans, seas, freshwater lakes and rivers, and grow on all kinds of bottoms from tidal flats to abyssal depths. Their most favoured environment is, however, that of rocky or hard bottom along the seashores and in coral-reef lagoons. The greatest percentage of more than 2,500 known species of sponges is confined to this habitat. Close association with other invertebrates seems to be one of the most interesting features of sponge ecology. Porous structure and numerous cavities of sponge body provide safe abode for hydroids, worms, shrimps, crabs, molluscs and other invertebrates. Some of these animals invade the sponges accidentally, while others form more permanent association. Thus, thousands of shrimps of the family Alpheidae are found in every loggerhead sponge of the British West Indies. The young shrimp of the genus *Spongicola* enter the cavity of glass sponges (Hexactinellida), where they live in pairs and soon become imprisoned because their grown-up bodies cannot escape through the small openings of the sieve plates guarding the oscula of their host. Sponges of the family Suberitidae are often found overgrowing snail shells occupied by hermit crabs. The relation is obviously advantageous for both parties. The crab is well protected by sponge spicules and its repelling taste, while the sponge is carried about by the crab and gets better opportunities for feeding. Crabs of the genus *Dromia* break pieces of sponges with their legs and place them on their backs where the sponge becomes implanted.



Sponges are apparently distasteful to other animals and are usually avoided. They are eaten only by a few species of nudibranch molluscs.

**Diseases.**—Widespread mortalities frequently occur among commercial sponges. In the fall of 1938 a devastating disease which rapidly spread from the Bahamas to Cuba, British Honduras, Mexico and the east coast of Florida almost completely destroyed the velvet sponge and killed more than 70% of wool sponges. The disease was associated with an infection by a funguslike micro-organism tentatively identified as *Spongiophaga*. No control measures were suggested to check the infection except the closing of grounds to commercial fishery.

**Utilization of Sponges.**—Horny sponges (Keratosa) have been in use from the earliest times. In ancient Greece, mothers pacified their crying babies by giving them a piece of sponge soaked in honey. According to Pliny, sponges were employed as paint brushes and mops, and Roman soldiers carried with them a piece of sponge to be used instead of a drinking vessel. This custom makes comprehensible the manner in which vinegar was offered to Christ on the cross—in a soaked sponge (Mark XV, 36). In the 13th century A.D. Arnold of Villascova introduced the "burnt sponge" as medicinal preparation to be used internally in scrofula, a term which usually refers to tuberculosis of lympathic glands, but formerly also covered other diseases. The therapeutic effect, if any, was possibly due to a high content of iodine present in the carbonized sponge in the form of NaI.

In modern times, besides obvious toilet and household uses, sponges are required for scores of purposes such as the manufacture of special surgical and hygienic preparations, leather dressing, application of glaze to fine pottery, scouring and sponging of cloth. They are extensively employed by tile and bricklayers, painters, decorators, lithographers, jewellers and silversmiths. Probably the largest number of sponges is used for washing railroad cars and automobiles.

**Industrial Types.**—The trade recognizes several types which correspond to different species listed in Table I. There is, however, no general agreement regarding the specific names of different varieties of commercial sponges.

FROM L. H. HYMAN, "THE INVERTEBRATES: PROTOZOA THROUGH CTENOPHORA" (MCGRAW-HILL, 1940)

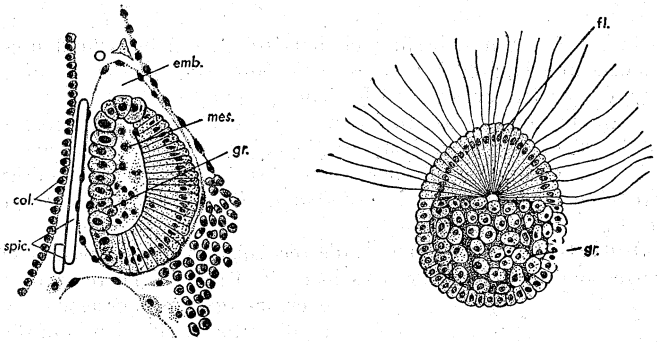
FIG. 14.—THE GEMMULE OF A FRESH-WATER SPONGE, EPHYDATIA, WITH INNER MEMBRANE (AFTER EVANS, 1901); 1, INNER MEMBRANE; 2, MASS OF ARCHAEOCYTES; 3, A LAYER OF AMPHIDISKS; 4, MICROPYLE

Good commercial sponges occur also in the Philippines and in Australia. Contribution to the world trade of sponges from these countries is, however, insignificant. Several varieties of horny sponges of the Hawaiian Islands are not suitable for the trade because of their extreme softness and lack of durability.

The annual world production of sponges in 1938, the last "normal" year before World War II, was estimated at 2,102,400 lb., valued at $2,556,398. The U.S. contributed 28.8% of the total catch and 41.9% of the total value. The contributions of the principal sponge producing countries for the years 1938 and 1939 are shown in Table II.

In 1943 the production of sponges in the U.S. dropped to 325,822 lb., almost one half of that of 1938, but the value increased to $2,305,070.

The most valuable of the commercial sponges are the Turkey Cup and Turkey Toilet. Best specimens of these varieties sometimes are sold as high as $50 per pound. The total quantity of these high priced sponges offered on the world's market is, however, insignificant in comparison with the wool sponge, which in the western hemisphere constitutes about 80% of the catch.



**Fishing Methods.**—Commercial sponges are taken from the bottom of the sea from tidal level to a depth of about 200 ft. In the shallow inshore waters the sponges are picked by means of a two- or three-pronged hook attached to a long pole. The hooker, as the fisherman is called, operates from a small skiff which he pushes by pole. When the sponge is noticed, sometimes at the depth of 25 or even 30 ft., the pole is lowered and the hook

TABLE II.—*Estimated World Production of Sponges*

| Country | 1938 | | 1939 | |
|---|---|---|---|---|
| | Quantity (pounds) | (U.S. dollars) | Quantity (pounds) | (U.S. dollars) |
| United States | 606,000 | $1,070,848 | 484,400 | $1,161,945 |
| Bahamas | 670,000 | 400,000 | 470,000 | 120,000 |
| Cuba | 440,000 | 295,000 | 330,000 | 230,000 |
| Greece | 87,000 | 262,680 | 78,000 | 190,000 |
| Italy‡ | 130,000 | 210,000 | * | * |
| Egypt | † | † | --- | --- |
| Turkey | 75,000 | 180,000 | 55,000 | 150,000 |
| Libya | 70,000 | 120,000 | * | * |
| Caicos Island§ | 19,500 | 11,000 | 6,850 | 2,500 |
| Syria-Lebanon | 3,000 | 4,500 | * | * |
| British Honduras | 1,100 | 1,770 | 1,960 | 2,660 |

placed under the sponge, which is then detached from the bottom by a slight pull and is brought to the surface. This primitive and slow method of fishing can be used only in clear and calm inshore waters. Nude diving, without equipment of any kind, is still practised in Greece, along the Libyan coast and in the Philippines. Fishing in the deeper water near Greece and off the Florida coast requires more elaborate diving equipment consisting of a

FIG. 15.—DEVELOPMENT OF GRANTIA LABYRINTHICA (AFTER DENDY) A, blastula in the embryonic chamber of the mother; B, amphiblastula larva. Col., collared cells lining flagellated chamber; emb., embryonic chamber; fl., flagellated cells; gr., granular cells; mes., mesenchyme cells; spic., maternal spicules. Magnified

regular diving suit, scaphander and boat with mechanically operated air pump. A small dredge, known as "gangave," is used in Libya. The implement is very destructive and its use is prohibited in the western hemisphere. Sponges caught in the Bahamas, Cuba, Turks and Caicos islands are picked exclusively by hookers.

Sponges gathered by divers or hookers are cleaned aboard the boat or placed in "crawls," *i.e.*, small ponds along the shore where the soft parts of sponge tissues rot. The remaining skeletons are taken out, squeezed, rinsed in clear sea water, strung in bunches and dried in air.

FROM L. H. HYMAN, "THE INVERTEBRATES: PROTOZOA THROUGH CTENOPHORA" (MCGRAW-HILL, 1940)

FIG. 16.—PROTEROSPONGIA (AFTER KENT, 1881). A COLONIAL FLAGELLATE CONSIDERED AS A PROBABLE LINK BETWEEN THE FLAGELLATES AND SPONGES

An interesting feature of the sponge industry in the U.S. is a co-operative selling association, the Tarpon Springs Sponge exchange, which auctions all the sponges brought by fishermen. A similar organization, but under direct control of the colonial government, was established in Nassau, Bahamas. The auction is rather unique, for the selling is conducted in complete silence. As the buyers examine the various lots of sponges they write down on a piece of folded paper the highest price they are willing to pay and hand it to the auctioneer. When the auction is over the bids are opened by the representative of the association and the highest bidder is awarded the sponges, provided the price is acceptable to the owner. Before reaching the retail market sponges are sorted, cleaned, bleached and sometimes dyed.

**Conservation.**—At the end of World War II, no system of conservation or management of natural sponge resources was being exercised by any government. The only protection effective in the U.S., Bahamas, Turk and Caicos islands consisted in the enforcement of the size limit laws which prohibit the taking and selling of sponges less than five inches in diameter.

**Sponge Farming or Sponge Culture.**—Because of their high regenerative power, sponges can be grown from small cuttings. Experiments in this method of cultivation were made at the end of the last century by H. F. Moore in Florida and were also conducted on a larger scale in the estuarine waters of Tunisia. The practicability of the method was definitely demonstrated by large scale operations conducted by the British government in the West Indies and British Honduras. From 1935 to 1939 more than 140,000 sponges were growing on government grounds in the Bahamas, and more than 700,000 cuttings were planted at Turneffe, British Honduras. Unfortunately, the mortality of 1938–39 was particularly severe among the cultivated sponges and the beds were almost completely destroyed.

The farming method consists in growing sponges from rectangular slices about 2″ x 4″ x ½″, cut with a very sharp knife from a healthy sponge and attached with a string to a piece of rock or cement disk. The cuttings are immediately placed in water. From 16 to 32 pieces can be cut from one adult wool sponge of six to eight in. in diameter. Regeneration begins immediately and the sponge, firmly adhering to its base, grows as a well-shaped round specimen. In the Bahamas, sponges grown from cuttings reach marketable size in about four years.

If correctly conducted, sponge culture may become a profitable occupation, but because of the scarcity of suitable inshore grounds it cannot replace the fishery on natural grounds. The possibility of propagating sponges through sexual reproduction has not yet been explored.

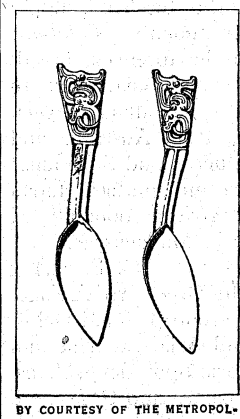
**SPONSOR,** one who stands surety for another (from Lat. *spondere,* to promise), especially in the rite of Christian baptism, a godfather or godmother. The practice originated not in infant baptism, but in the custom of requiring an adult pagan who offered himself for the rite to be accompanied by a Christian known to the bishop, who could vouch for the applicant and undertake his supervision, thus fulfilling the function performed in the Eleusinian mysteries by the *mystagogus*. The Greek word for the person undertaking this function is *ἀνάδοχος*, to which the Latin *susceptor* is equivalent. The word "sponsor" in this ecclesiastical sense occurs for the first time, but incidentally only, and as if it were already long familiar, in Tertullian's treatise *De baptismo* (ch. 18), where, arguing that in certain circumstances baptism may conveniently be postponed, especially in the case of little children, he asks, "For why is it necessary that the sponsors like-

wise should be thrust into danger, who both themselves by reason of mortality may fail to fulfil their promises, and may also be disappointed by the development of an evil disposition [in those for whom they become sponsors]?"

The sponsors here alluded to may have been in many cases the actual parents, and even in the 5th century it was not felt to be inappropriate that they should be so; Augustine, indeed, in one passage appears to speak of it as a matter of course that parents should bring their children and answer for them "tanquam fidejussores" (*Epist. . . . ad Bonif.* 98), and the oldest Egyptian ritual bears similar testimony. Elsewhere Augustine contemplates the bringing of the children of slaves by their masters, and of course orphans and foundlings were brought by other benevolent persons.

The comparatively early appearance, however, of such names as *compatres, commatres, propatres, promatres, patrini, matrinae,* is of itself sufficient evidence, not only that the sponsorial relationship had come to be regarded as a very close one, but also that it was not usually assumed by the natural parents. How very close it was held to be is shown by the Justinian prohibition of marriage between godparents and godchildren. On the other hand, the anciently allowable practice of parents becoming sponsors for their own children, though gradually becoming obsolete, seems to have lingered until the 9th century, when it was at last formally prohibited by the council of Mainz (813). For a long time there was no fixed rule as to the necessary or allowable number of sponsors and sometimes the number actually assumed was large. By the council of Trent, however, it was decided that one only, or at most two, these not being of the same sex, should be permitted.

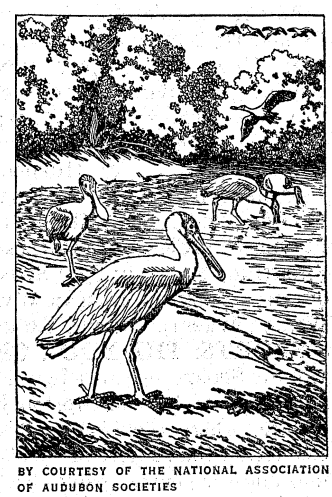


The rubric of the Church of England, that "there shall be for every male child to be baptized two godfathers and one godmother, and for every female one godfather and two godmothers," is not older than 1661; the sponsors are charged with the duty of instructing the child, and in due time presenting it for confirmation. In the Roman Catholic Church the spiritual relationship established between the sponsor and the baptized, and the sponsors and the parents of the baptized, constitutes an impediment to marriage. (*See* MARRIAGE, LAW OF: *Canon Law.*)

**SPONTINI, GASPARO LUIGI PACIFICO** (1774–1851), Italian composer, was born on Nov. 14, 1774, at Majolati (Ancona) in Italy. He was the son of a poor cobbler and was intended for the priesthood. But he obtained lessons from Kapellmeister Quintiliani, and in 1791 went to the Conservatorio de' Turchini at Naples, where he studied under G. Paisiello, D. Cimarosa and Fiorivanti. By 1799 he had already written and produced eight operas. After becoming court composer to King Ferdinand of Naples in this year an intrigue with a princess of the court compelled Spontini to leave Naples in 1800. In 1803 he settled in Paris, where he had no success until the production of *Milton,* a one-act opera, in 1804. Thereafter his powers and ambitions steadily developed, being manifested to the full for the first time in *La Vestale,* produced on Dec. 15, 1807. *Ferdinand Cortez* was received with equal enthusiasm in 1809; but *Olympia* (1819) had less success.

Spontini had been appointed director of the Italian opera in 1810; but his quarrelsome and grasping disposition led to his summary dismissal two years later, and, though reinstated in 1814, he voluntarily resigned his post soon afterward. In 1820 he settled in Berlin by invitation of Frederick William III, commissioned to superintend all music performed at the Prussian court and compose two new grand operas, or three smaller ones, every three years. But he began by at once embroiling himself with the intendant, Count Brühl. *La Vestale, Ferdinand Cortez* and *Olympia*—the last two entirely remodelled—were produced with great success in 1821. But Spontini's fame was entirely eclipsed by the appearance of Carl Weber's *Der Freischütz.* A new opera, *Nourmahal,* founded on Thomas Moore's *Lalla Rookh,* was performed in 1822, and another, entitled *Alcidor,* in 1825; and in 1826 Spontini began the composition of *Agnes von Hohenstaufen,* (produced in 1829), which undoubtedly will rank permanently as his greatest work.

Dismissed from his court position in 1841, he settled in Paris. In 1850 he retired to his birthplace, Majolati, and died there on Jan. 14, 1851.



**SPOON,** a table implement, bowl-shaped at the end, with a handle varying in length and size. From the derivation of the word the earliest northern European spoon would seem to have been a chip or splinter of wood; the Greek κοχλιάριον (Lat. *cochleare*) points to the early and natural use of shells, such as are still used by primitive peoples. Examples are preserved of the various forms of spoons of ivory, flint, slate and wood, many of them carved with the symbols of their religion, used by the ancient Egyptians. The spoons of the Greeks and Romans were chiefly made of bronze and silver, and the handle usually takes the form of a spike or pointed stem. Mediaeval spoons for domestic use were commonly made of horn or wood, but brass, pewter and "latten" spoons appear to have been common about the 15th century. The full descriptions and entries relating to silver spoons in the inventories of the royal and other households point to their special value and rarity. The earliest English reference appears to be in a will of 1259. In the wardrobe accounts of Edward I for the year 1300 some gold and silver spoons marked with the fleur-de-lis, the Paris mark, are mentioned. One of the most interesting mediaeval spoons is the coronation spoon used in the anointing of the sovereign. The sets of spoons popular as christening presents in Tudor times, the handles of which terminate in heads or busts of the apostles, are a special form to which antiquarian interest attaches. (*See* APOSTLE SPOONS.) The earlier English spoon handles terminate in an acorn, plain knob or a diamond; at the end of the 16th century the baluster and seal ending becomes common, the bowl being "fig shaped." At the Restoration the handle becomes broad and flat, the bowl is broad and oval and the termination is cut into the shape known as the *pied de biche,* or hind's foot. In the first quarter of the 18th century the bowl becomes narrow and elliptical, with a tongue or "rat's tail" down the back, and the handle is turned up at the end. The modern form, with the tip of the bowl narrower than the base and the rounded end of the handle turned down, appeared about 1760.

**SPOONBILL,** any one of six species of moderately large wading birds constituting the subfamily Plataleinae and, with the ibises (*q.v.*), the family Threskiornithidae (order Ciconiiformes). The head is partly or entirely bare, the plumage white (except in the roseate spoonbill), often with a rosy tinge, some with a nuptial crest or foreneck plumes. They differ from ibises in having a long nearly straight bill, narrow in the middle and broad and flat at the end, which they immerse in feeding, swinging it from side to side and sifting small animals from the mud and water of estuaries, salt-water bayous and lakes. In flight they flap steadily, usually without sailing. They breed in colonies, often with ibises and herons, build a good nest of sticks sometimes lined with leaves or bark, among reeds or in a low bush or tree about 10 ft. up, and lay three to five white eggs blotched with reddish-brown. The beautiful roseate spoonbill (*Ajaia ajaja*), 32 in., head and throat bare, legs red, is deep pink with neck and upper back white, wing coverts and tail coverts deep

BY COURTESY OF THE NATIONAL ASSOCIATION OF AUDUBON SOCIETIES
THE ROSEATE SPOONBILL (AJAIA AJAJA), FOUND ONLY IN TROPICAL AND SUBTROPICAL AMERICA

carmine and tail and sides of breast tawny-buff. It ranges from the gulf states, West Indies and central Mexico to the Argentine and Chile. In many places it was exterminated by plume hunters. The yellow-legged spoonbill (*Platibis flavipes*) of Australia is white with foreneck straw-coloured, has the forehead, upper throat and bill yellow. The crested white spoonbill (*Platalea leucorodia*), 24 in., with cinnamon-buff on the foreneck, breeds in marshes of central and southern Europe and Asia, south to Egypt, India and Formosa; the black-billed spoonbill (*P. regia*), white with black wing-tips and black legs, from Australia and New Zealand to New Guinea, Celebes, Moluccas and Solomons; the lesser spoonbill (*P. minor*), from Korea and southern Japan to southern China and the Philippines; the African spoonbill (*P. alba*), over Africa south of the Sahara and in Madagascar.

(G. F. Ss.)

**SPORADES,** the scattered islands of the Greek Archipelago, distinguished from the Cyclades, which are grouped round Delos, and from the coastal islands of Europe and Asia. Ancient and modern writers differ as to the list. The Doric Sporades—Melos, Pholegandros, Sikinos, Thera, Anaphe, Astypalaea and Cos—were by some considered a southern cluster of the Cyclades. In modern times the name Sporades is applied to two groups: *The northern Sporades* lie northeast of Negropont (Euboea), Skiathos, Skopelos and Ikos being included in the department of Magnesia, and Scyros (*q.v.*) in that of Euboea. Scyros has a fine harbour. Skiathos is beautifully wooded; the town overlooks an excellent harbour. Skopelos is also well wooded. Almost every householder in both islands is the owner, joint owner or skipper of a sailing ship. *The southern Sporades,* lying off the southwest of Asia Minor, formerly included in the Turkish vilayet of the "Islands of the White Sea," are as follows: Icaria, Patmos (*q.v.*), Leros, Calymnos, Astypalaea (Astropalia or Stampalia), Cos (*q.v.*) (Turk. *Stanko*), Nisyros, Tilos or Episcopi, Syme, Khalki, Rhodes (*q.v.*) and many smaller isles.

*See* C. Bursian, *Geographie von Griechenland* (Leipzig, 1862–71), ii, 348 ff.; L. Ross, *Reisen auf den Griechischen Inseln* (1840–45).

**SPOROZOA,** a group of parasitic Protozoa which produce unicellular spores within a tough envelope or cyst. Since formerly various Protozoa, which had only this character in common and were not truly related to one another, were classed with the Sporozoa, some protozoologists have split up the class Sporozoa into two classes, Amoebosporidia and the true Sporozoa. For further particulars *see* PROTOZOA.

**SPORTS, ARTICLES ON.** Almost all varieties of indoor and outdoor sport have separate articles in this *Encyclopædia.*

Among the chief are: ANGLING; ATHLETIC SPORTS; BASEBALL; BILLIARDS; BOWLING; BOXING; BRIDGE; BULL-FIGHTING; CAMPING; CHARADE; CHESS; CONJURING; COURSING; CRICKET; CYCLING; DRIVING; FALCONRY; FOOTBALL; GAME; GAMES, CLASSICAL; GOLF; GYMKHANA; GYMNASTICS AND GYMNASIUM; HOCKEY; HORSEMANSHIP AND RIDING; HORSE RACING AND BREEDING; HUNTING; HURDLING; JUMPING; LACROSSE; LAWN TENNIS AND TENNIS; MOUNTAINEERING; PATIENCE; PIGEON-FLYING; PIG-STICKING (HOG-HUNTING); PINOCLE; POKER; POLO; PUGILISM; RACKETS; ROLLER-SKATING; ROWING; RUNNING; SHOOTING; SKATING; SKI; SWIMMING; TOBOGGANING; VENTRILOQUISM; WALKING RACES; WATER POLO; WEIGHT THROWING; WHIST; WRESTLING; and YACHTING.

**SPORTS, THE BOOK OF,** or more properly the DECLARATION OF SPORTS, an order issued by James I in 1617 on the recommendation of Thomas Morton, bishop of Chester, for use in Lancashire, where the king on his return from Scotland found a conflict on the subject of Sunday amusements between the Puritans and the gentry, many of whom were Roman Catholics. Permission was given for dancing, archery, leaping, vaulting and other harmless recreations, and of "having of May games, Whitsun ales and morris dances, and the setting up of maypoles and other sports, therewith used, so as the same may be had in due and convenient time without impediment or neglect of divine service, and that women shall have leave to carry rushes to church for the decorating of it." On the other hand, "bear and bull-baiting, interludes, and (at all times in the meane sort of people by law prohibited) bowling" were not to be permitted on any Sunday (Wilkins, *Concilia,* iv, 483).

In 1618 James transmitted orders to the clergy of the whole of England to read the declaration from the pulpit; but so strong was the opposition that he prudently withdrew his command (Wilson, in Kennet, ii 709; Thomas Fuller, *Church History,* v, 452). In 1633 Charles I not only directed the republication of his father's declaration (Rushworth, ii, 193), but insisted upon the reading of it by the clergy.

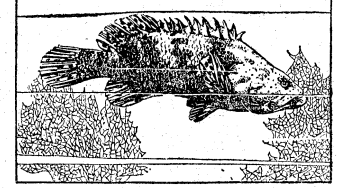
Many of the clergy were punished for refusing to obey the injunction.

With the fall of Laud all attempts to enforce it necessarily came to an end.

**SPOTSWOOD, ALEXANDER** (1676–1740), American colonial governor, was born of an old Scots family, in Tangier, Africa, in 1676.

He served as aide to Marlborough in the War of the Spanish Succession, and was wounded at Blenheim. He was appointed lieutenant governor of Virginia in 1710, and was received with enthusiasm, because he brought to the colony the privilege of *habeas corpus;* his term as governor closed in Sept. 1722, but he remained in Virginia, living near his ironworks in Germanna, a settlement of Germans, on the Rapidan in Spotsylvania county (named in his honour); and he was deputy postmaster general of the colonies from 1730 to 1739.

He was the first representative of the British government in America who fully appreciated the value of the western territory. As governor he recommended the establishment of a Virginia company to carry on trade with the Indians, he urged upon the provincial government and also upon the British authorities the wisdom of constructing forts along the frontier, and he personally organized and conducted in 1716 an exploring expedition into the Shenandoah valley.



He developed the iron industry of Virginia, promoted the religious education of the Indians, and tried to advance the interests of education, especially at the College of William and Mary. He died at Annapolis, Md., June 7, 1740.

*See* R. A. Brock (ed.), "The Official Letters of Alexander Spotswood" (with a memoir), in *The Collections of the Virginia Historical Society* (1882–85).

**SPOTSYLVANIA,** a county of Virginia, U.S.A., so called after Alexander Spotswood (*q.v.*), lieutenant governor of Virginia in 1710–22, who owned extensive estates and mines therein. It is bounded on the north by the Rapidan and Rappahannock rivers and on the south by the North Anna. It is celebrated as containing several of the most famous battlefields of the Civil War—Fredericksburg, Chancellorsville, the Wilderness and particularly that of Spotsylvania courthouse, where the armies of U.S. Grant and Robert E. Lee fought for two weeks (May 8–21, 1864). Pop. (1940) 9,905.

**SPOTTED JEWFISH** (*Promicrops itaiara*), an immense marine bass (fam. Serranidae) found on the coasts of tropical America, which sometimes attains a length of 8 ft. and a weight of about 700 pounds.

The adult is dull olive-brown in colour, with faint spots and bands; the young are yellowish-green, with dark crossbars and spots about the head. The South Pacific jewfish reaches 12 ft.

THE SPOTTED JEWFISH (PROMICROPS ITAIARA)

**SPOTTISWOODE** (SPOTTISWOOD, SPOTISWOOD or SPOTSWOOD), **JOHN** (1565–1639), archbishop of St. Andrews and historian of Scotland, eldest son of John Spottiswood, minister of Calder and "superintendent" of Lothian, was born in 1565. He was educated at Glasgow university (M.A. 1581), and succeeded his father in the parish of Calder in 1583. In 1601 he attended Ludowick, duke of Lennox, as his chaplain, in an embassy to the court of France, returning in 1603. He followed James to England on his accession, but was the same year nominated to the see of Glas-

gow, his consecration in London, however, not taking place until Oct. 1610. On May 30, 1605, he became a member of the Scottish privy council. In 1610 he presided as moderator over the assembly in which presbytery was abolished, in 1615 he was made archbishop of St. Andrews and primate of Scotland, and in 1618 procured the sanction of the privy council to the Five Articles of Perth with their ratification by parliament in 1621. In 1633 he crowned Charles I at Holyrood. In 1635 he was appointed lord chancellor of Scotland, an office which he retained till 1638. He was a spectator at the riot of St. Giles', Edinburgh, on July 23, 1637, endeavoured in vain to avoid disaster by concessions, and on the taking of the Covenant perceived that "now all that we have been doing these thirty years past is thrown down at once." He escaped to Newcastle, was deposed by the assembly on Dec. 4, on trivial charges, and died in London on Nov. 26, 1639, receiving burial in Westminster abbey. His most considerable work was *The History of the Church and State of Scotland* (London, 1655, *seq.*).

*See* the accounts prefixed to the first edition of Spottiswoode's *History of Scotland* and to that published by the Spottiswoode society in 1851; also David Calderwood's *Hist. of the Kirk of Scotland* (1842–49).

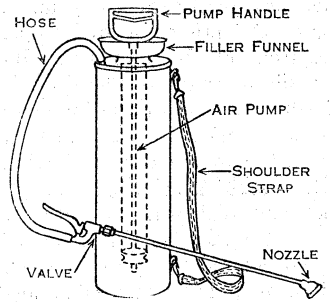
**SPOTTISWOODE, WILLIAM** (1825–1883), English mathematician and physicist, was born in London on Jan. 11, 1825. His father, Andrew Spottiswoode, who was descended from an ancient Scottish family, represented Colchester in parliament for some years, and in 1831 became junior partner in the firm of Eyre & Spottiswoode, printers. William was educated at Laleham, Eton, Harrow and Balliol college, Oxford. His bent for science showed itself while he was still a schoolboy, and indeed his removal from Eton to Harrow is said to have been occasioned by an accidental explosion which occurred while he was performing an experiment for his own amusement. At Harrow he obtained in 1842 a Lyon scholarship, and at Oxford in 1845 a first-class in mathematics, in 1846 the junior and in 1847 the senior university mathematical scholarship. In 1846 he left Oxford to take his father's place in the business, in which he was engaged until his death. In 1847 he issued five pamphlets of original mathematical work; and from this time scarcely a year passed in which he did not give to the world further mathematical researches. In 1856 Spottiswoode travelled in eastern Russia, and in 1860 in Croatia and Hungary; of the former expedition he has left an interesting record entitled *A Tarantasse Journey through Eastern Russia in the Autumn of 1856* (London, 1857). In 1870 he was elected president of the London Mathematical society. In 1871 he began to turn his attention to experimental physics, his earlier researches bearing upon the polarization of light and his later work upon the electrical discharge in rarefied gases. He wrote a popular treatise upon the former subject for the "Nature" series (1874). In 1878 he was elected president of the British association, and in the same year president of the Royal society, of which he had been a fellow after 1853. He died in London of typhoid fever on June 27, 1883, and was buried in Westminster abbey.

**SPRAT, THOMAS** (1635–1713), English divine, was born at Beaminster, Dorsetshire, and educated at Wadham college, Oxford, where he held a fellowship (1657–70). Having taken orders he became a prebendary of Lincoln in 1660. In the preceding year he had gained a reputation by his poem *To the Happie Memory of the most Renowned Prince Oliver, Lord Protector* (London, 1659), and he was afterward well known as a wit, preacher and man of letters. His chief prose works are the *Observations upon Monsieur de Sorbier's Voyage into England* (London, 1665), a satirical reply to the strictures on Englishmen in Samuel de Sorbière's book of that name, and a *History* of the Royal society of London (London, 1667), which Sprat had helped to found. In 1669 he became canon of Westminster, and in 1670 rector of Uffington, Lincolnshire. He was chaplain to Charles II in 1676, curate and lecturer at St. Margaret's, Westminster, in 1679, canon of Windsor in 1681, dean of Westminster in 1683 and bishop of Rochester in 1684. Although he opposed the motion of 1689 declaring the throne vacant, he assisted at the coronation of William and Mary. As dean of Westminster he directed Sir Christopher Wren's restoration of the abbey. He died on May 20, 1713.

**SPRAT,** a marine fish (*Clupea sprattus*), one of the smallest species of the genus *Clupea* or herrings, rarely exceeds 5 in. in length, and occurs in large shoals on the Atlantic coasts of Europe. The sprat spawns in the open sea from February to May. Its eggs are buoyant and pelagic and easily recognized. The sprat is one of the more important food fishes because of the immense numbers in its shoals. In Norway large quantities are tinned in oil, or are eaten fresh, pickled, smoked or prepared as anchovies.

**SPRATT, THOMAS ABEL BRIMAGE** (1811–1888), English vice-admiral, hydrographer and geologist, was born at East Teignmouth on May 11, 1811. He was the eldest son of Commander James Spratt, R.N., and entered the navy in 1827. He was attached to the surveying branch, and was engaged almost continuously until 1863 in surveying the Mediterranean. As commander of the "Spitfire" he rendered distinguished service in the Black sea during the Crimean War, and was appointed C.B. in 1855. At an early date he was associated with the naturalist Edward Forbes with whom he studied the bathymetrical distribution of marine life and later published *Travels in Lycia,* etc. (1847). Spratt investigated the caves at Malta, studied the geology of several Greek islands and the shores of Asia Minor, and made detailed observations on the Delta of the Nile. He was especially distinguished for his *Travels and Researches in Crete* (2 vols., 1865), in which he described the physical geography, geology, archaeology and natural history of the island. He was commissioner of fisheries from 1866 to 1873 and acting conservator of the Mersey from 1879 until his death at Tunbridge Wells on March 10, 1888.

**SPRAYING AND DUSTING MACHINERY.** A great variety of equipment is available for applying certain organic and inorganic substances in solution or dust form to combat insect pests and plant diseases of field, garden and orchard crops, and to kill certain noxious weeds. Spraying is also used for thinning fruit with blossom-killing solutions, and to prevent preharvest drop of fruit.



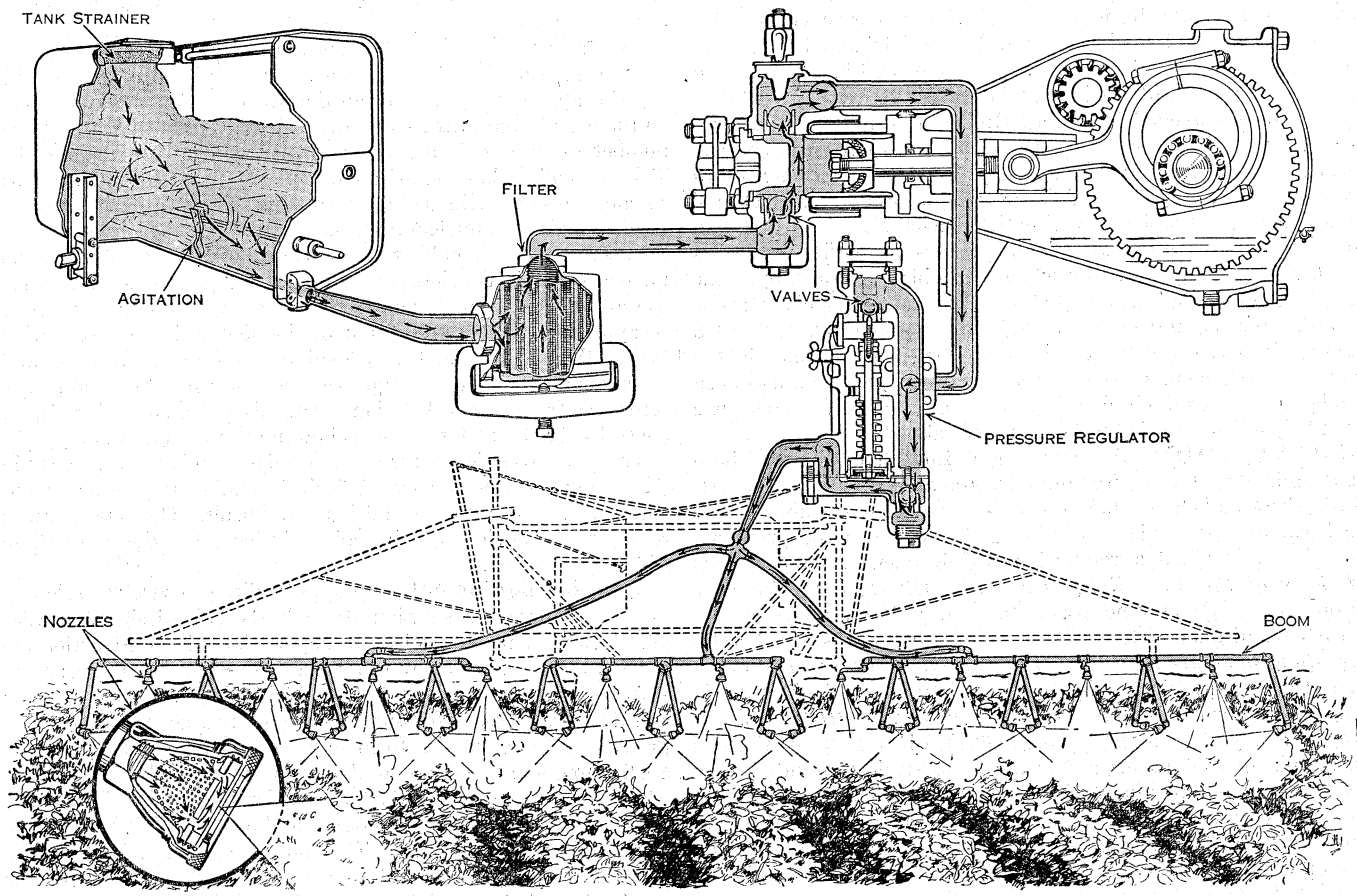
So far, experiments in the application of sprays to prevent preharvest fruit drop have shown their practicability only in the cases of apples and pears. Promising work was underway in 1944 on the use of aerosol fog spraying, which is highly toxic to a large number of insects, is not toxic to man, and is noninflammable. This method makes use of an insecticide such as pyrethrum or rotenone dissolved in a highly volatile substance such as freon (widely used as a refrigerant), the mixture or solution being contained in a steel "bomb" where a constant pressure of about 90 lb. per sq.in. is developed at summer temperatures. When released through a small nozzle the mixture comes out as a fine spray or fog. The entire output of this material was used during World War II by the U.S. armed forces for ridding tents and other quarters of flies, mosquitoes and other insects. Aeroplanes returning from tropical regions were also treated with it, as a control over the malarial and yellow fever mosquitoes.

There was promise in 1944 of hormone spraying, particularly in the case of tomatoes, to set the fruit, instead of relying on pollenizing which under some conditions is difficult. The term sprayer refers to the devices which apply solutions, and duster to those which apply dusts.

**Spraying Equipment.**—Sprayers utilize pressure produced by pumps to force the solution through specially designed nozzles which break it up into mists. Sprayers differ in construction according to make, power by which they are operated, and type.

Accessories such as nozzles are highly important in spraying and dusting. Nozzles for spraying are of two general types; one produces a spray in the form of a cone for medium and close application, and the other produces a comparatively solid stream which breaks into a spray at a considerable height. There are, however, many variations in nozzles and most manufacturers have developed their own designs. The cone-shaped spray is often produced by forcing the liquid into a small eddy chamber of the nozzle through tangential channels in a disk. This action tends to break up the liquid just before it is forced out of the nozzle.

The solid-stream type is generally used in single units and for spraying tall trees. The cone type may be used on a single-jet gun for general purpose spraying or on a multiple-jet gun to produce a foglike spray, desirable in orchard spraying. Except for the simple sprayers, the nozzles are attached singly or in multiple to a rod with cutoff for general purpose or orchard sprayers, and to adjustable pipes of booms for row crop spraying. Grape and hop growers spray with vertical pipes having nozzles fitted on the sides. Weed-killing sprays are applied from a horizontal boom with nozzles attached directly to the under side. The solution supply is controlled by means of suitable valves at the pump.



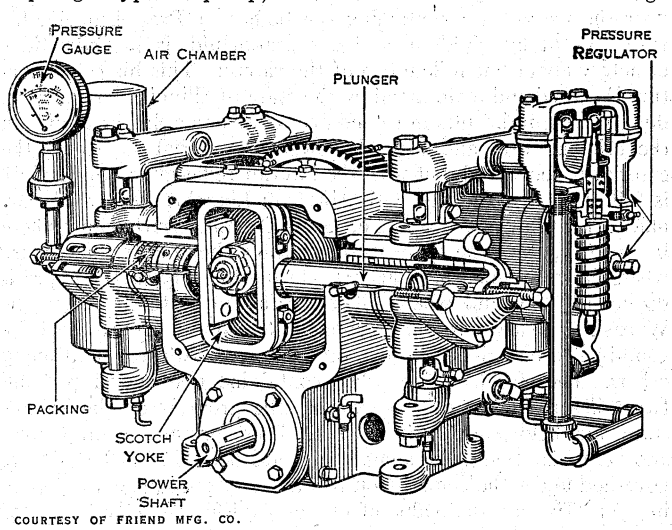
COURTESY, U.S. DEPT. OF AGRICULTURE

FIG. 1.—COMPRESSED AIR SPRAYER

**Manual Sprayers.**—The simplest form of sprayer consists of a bicycle-type hand pump with small container attached, and a suitable nozzle. In another type the hand pump, sometimes with an air chamber, is clamped to a bucket. The knapsack sprayer, as its name implies, is carried on the back of the operator, pressure usually being provided through a diaphragm pump which also actuates an agitator. In the compressed-air sprayer pressure is built up with a plunger-type air pump housed in the container with the solution and air. The one shown in fig. 1 has a capacity of from 1½ to 4 gal. Of this same type but of larger capacity are the wheelbarrow and barrel sprayers. The barrel type may either be stationary or portable.

**Power Sprayers.**—There are three types of power sprayers: those powered with an engine mounted on the frame with the tank, those powered through a power take-off, and those deriving their power from a traction drive. With the first two the same type of sprayer may be used. This consists essentially of a single-acting, plunger-type, reciprocating pump (usually 2- or 3-cylinder), strainer, a pressure regulator which also acts as a safety valve, a metal or wooden tank containing the liquid and an agitator for stirring it, together with such accessories as pressure gauges, cut-off valves, and, frequently, air chambers. Such a sprayer is shown in fig. 2. The pumps obtain their reciprocating motion most commonly from either a crankshaft and connecting rods, eccentric and connecting rods, or a Scotch yoke assembly (fig. 3), and are available in a wide range of sizes and capacities with pressures up to 1,000 lb. per sq.in. Corrosion-resistant valve seats and ball-type valves, usually of hardened stainless steel, are used in the pumps and two types of plunger-cylinder combination; the "plunger-cup," where the cup is fastened to and moves with the plunger rubbing against the cylinder wall, which is usually coated with porcelain; and the "outside-packing" type, in which a stainless steel plunger works back and forth in the stationary packing lining the cylinder walls. The engine-powered sprayer, together with engine, may be mounted on skids for semi-stationary work and supplied with portable pipe lines to conduct the solution; or it may be fixed as a stationary plant and powered either with an engine or electric motor. In this case the conducting pipes are buried in the ground and lead to risers at strategic points for attachment of the spraying equipment. It may also be mounted on a motor truck or on a 2- or 4-wheel chassis and pulled by horses or a tractor.

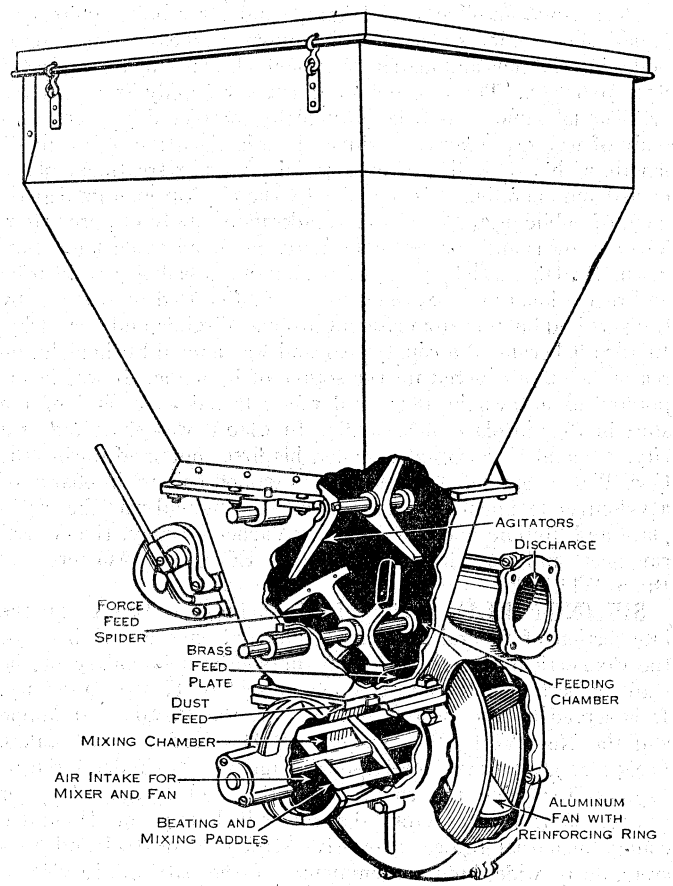
The sprayer with power take-off may be mounted on a 2- or 4-wheel trailer and driven by a power take-off connection from the tractor pulling it, or from the transmission case of the truck transporting it. Occasionally the whole spraying outfit may be mounted on the tractor. While truck-mounted sprayers already have the advantage of pneumatic tires, and tractors are usually thus fitted, pneumatics are being increasingly used on spray-equipment trailers. An important accessory for orchard spraying is an elevated platform or tower. This permits the operator to do a better spraying job on the tops of trees and with less



COURTESY OF JOHN BEAN MFG. CO.

FIG. 2.—TYPICAL POWER SPRAYER

material than from the ground. Traction-driven sprayers derive their power from the transport wheels and their use is limited largely to row crops. This type of sprayer is being replaced by the power take-off or auxiliary-engine drive.



**Dusting Equipment.**—Dusters for applying insecticides and fungicides make use of an air blast produced by means of a fan or plunger-type air pump, which blows the dust into a discharge

COURTESY OF FRIEND MFG. CO.

FIG. 3.—SPRAYER PUMP, CUT AWAY TO SHOW WORKING PARTS

pipe which may be fitted with a straight tube or fan-shaped nozzle. The many makes and models of dusters are of four classes: (1) *hand operated,* in which the air pressure is built up with a plunger pump or with a crank-operated fan; (2) the *traction machine,* in which the power for operating is taken from the ground wheels through chains or gears; (3) the *power duster* (horse or tractor drawn), operated by an auxiliary gasoline engine and suitable for

COURTESY OF MESSINGER MFG. CO.

FIG. 4.—TYPICAL DUSTER

single-spout orchard dusting, or (by changing to a multiple nozzle unit) useful in row-crop dusting; and (4) the *tractor-power duster* mounted on the tractor and driven through the tractor power take-off. The power and traction types consist essentially of a hopper, agitator, feed control, blower fan, mixing chamber, discharge tubes and nozzle or nozzles.

**Aeroplane Dusting.**—In the cotton belt of the United States, dusting of the plants by means of aeroplanes has proved economical. The work is done during daylight, generally in the early morning or late afternoons, when it is considered safest to fly at the low altitudes necessary, and when, too, the moisture on the plants causes the dust particles to adhere better. Commercial firms usually do the dusting on a per-acre basis and commonly dust at a rate of 350 or more acres of cotton per hour.

Dusting by aeroplane has also been employed in California to control insect pests and plant diseases attacking a number of fruit, nut, vegetable and small grain crops. In 1941 the acreage so treated in that state amounted to 176,600.

Experiments have shown the practicability of applying certain dusts to hasten the ripening of certain crops. In the case of cotton, such dusting causes leaves to drop and the rapid ripening of all bolls.

This facilitates mechanical picking of the fibre and permits of a once-over picking job in place of about three pickings otherwise necessary when the bolls ripen unevenly. Likewise with soybeans, if there are indications of an early frost previous to the time the crop should ripen, maturity can be hastened by the application of a defoliating dust. This procedure also causes uniform ripening of the plants.

(R. B. G.)

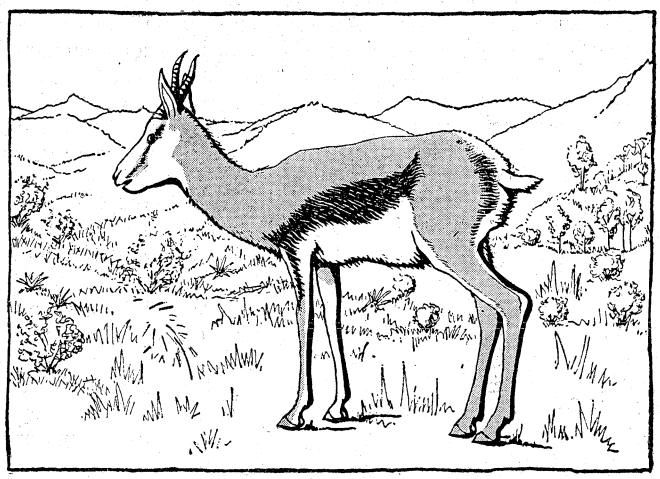
**SPREE** (sprā), a river of Prussia, 227 mi. in length, rising in Saxony, close to the Bohemian frontier, and flowing north past Bautzen, Spremberg and Kottbus, dividing between the first two towns for a time into two arms. Below Kottbus the river splits into a network of channels in the peculiar marshy region known as the Spreewald, then passes Fürstenwalde and Köpenick, threads Berlin in several arms and joins the Havel at Spandau.

More than 100 mi. of it are navigable and it is connected with neighbouring rivers by canals.

**SPREEWALD,** a district of Germany, in the province of Brandenburg, a marshy depression of the middle Spree valley, 106 sq.mi. in extent, 27 mi. long and varying from 1 to 7 mi. in width. The river Spree above Lübben splits into more than 200 arms, and in seasons of flood generally overflows considerable portions of this region.

Part of the region is cultivated, part used as pasture land and wooded like a park especially in the lower districts. Fishing, cattle breeding and the growing of vegetables, more particularly small pickling cucumbers, are the chief occupations of the people, some of whom retain their original Wendish language, customs and costumes. Spreewald is a popular summer resort of the Berlin people, and in winter is popular for skating.

**SPREMBERG,** a town in the Prussian province of Brandenburg, Germany, partly on an island in the river Spree and partly on the west bank, 76 mi. S.E. of Berlin by the railway to Görlitz. Pop. (1939) 14,515.



There are a pilgrimage chapel, dating from 1100 and a ducal château, built about the end of the 16th century (now utilized as government offices). Woollen cloth, bicycles, bricks and cigars are manufactured there.

**SPRING,** the act of springing, or leaping; hence applied in various senses: to the season of the year in which plant life begins

to bud and shoot; to a source of water springing or welling up from below the surface of the earth (*see* WATER SUPPLY); or to an elastic or resilient body or contrivance for receiving and imparting mechanical power.

In architecture, the level of the plane at which an arch or vault begins to curve inward toward the centre; in an arch or vault whose curves are circular or segments of circles, the level of the centre points from which the circular curves are described.

**SPRINGBUCK** or **SPRINGBOK** (*Antidorcas marsupialis*), a small South African gazelle inhabiting the country south

BY COURTESY OF THE N.Y. ZOOLOGICAL SOCIETY

SPRINGBUCK OR SPRINGBOK (ANTIDORCAS MARSUPIALIS), THE SOUTH AFRICAN GAZELLE

of the Zambezi, but ranging northwestwards to Mossamedes. In the more settled parts of Cape Colony, the Transvaal, and the Orange Free State it now only exists within the enclosures of the large farms. Both sexes carry lyrate horns; the shoulder-height of an adult male is about 30 in., and an average pair of horns measures 14 in. along the curve; in the female the horns are more slender. The general colour above is reddish fawn, separated from the white of the underparts by a dark band on the flanks.

**SPRINGER,** the term given in architecture to the stone from which an arch springs (*see* ARCH); in some cases this is the stone resting on the impost or capital, the upper surface of which is a plane directed to the centre of the arch.

**SPRINGFIELD,** the capital city of Illinois, U.S.A., and the county seat of Sangamon county on the Sangamon river, 99 mi. N.E. of St. Louis, 185 mi. S.W. of Chicago. It is served by the Alton, Baltimore and Ohio, Chicago and Illinois Midland, Illinois Central, Illinois Terminal system (electric), and Wabash railroads; has a municipal airport, and is at the intersection of U.S. highways 36 and 66, and in addition state highways 4, 29 and 125. Pop. (1930) 71,864; (1940) 75,503 (U.S. census). The city occupies an area of 9.5 square miles. The state capitol (begun in 1868 and occupied since 1876) is in the form of a Greek cross, surmounted by a massive, symmetrical dome 361 ft. high. Other buildings in the capital group are: the Illinois Centennial building erected 1918–22, to mark the 100th anniversary of the admission of Illinois into the union. In this building are the state historical and general libraries, the state museum, the Hall of Flags, in which are the battle flags of all Illinois regiments since Illinois became a state, and a number of state departments and offices. Facing the capitol building is the Illinois supreme court building. Adjacent to the capitol on the north is the Illinois state armory completed in 1936 at a cost of over $1,000,000; also on the capitol grounds is the state archives building completed in 1939, the second such state archives building to be constructed in the country. A short distance from the capitol grounds is the executive mansion, the residence of governors of Illinois, first occupied in 1856. The old capitol building, begun in 1837 and occupied from 1840 to 1876, is now used as the Sangamon county courthouse. In this building Abraham Lincoln served as a member of the legislature, and made many of his famous pre-Civil War speeches, including the famous "House divided against itself cannot stand" speech. Near the centre of the business section is the Lincoln home, the only one he ever owned, which he bought two years after his marriage, and occupied until his election to the presidency. It is owned and maintained as a state memorial by the state of Illinois. The Lincoln tomb and monument, a granite structure 121 ft. high over the mausoleum containing the bodies of Pres. Lincoln, his wife, two of his children, and one grandchild, is in Oak Ridge cemetery about one mile north of the capitol. This historic structure is owned and maintained by the state of Illinois. In 1930–31, due to structural faults in the edifice, it was completely rebuilt in the original form and with the original material so far as the exterior is concerned, but with the interior redesigned. Springfield is full of spots associated with Abraham Lincoln: sites of his law offices, boardinghouses and homes of friends, courtrooms where he practised, and the old state house now the county courthouse where he maintained headquarters during his campaign for presidency in 1860, and where his body lay in state in 1865; the Wabash station where, on leaving for the White House, he bade good-bye to his friends in his noted Farewell Address, and many others. The city has nine parks containing over 1,000 ac., and two miles northeast of the city are the grounds of the Illinois state fair, held annually in August. These grounds contain over 400 ac. of land, and the annual fairs are held there. The city is governed under the commission form of city government, adopted in 1911. The assessed value of property within the city limits for 1939 was $49,905,110.

Springfield is in the centre of soft-coal mining fields, and numerous coal mines are in and adjacent to the city. The city is also the centre of a rich agricultural area with farming, stock raising and dairying. It is the wholesale and retail centre for over 400,000 persons. Its manufacturing industries are numerous, and in 1940 it made products valued at over $55,000,000. Among the leading products are electric meters, agricultural implements, industrial tractors, road graders and road machinery, flour and cereal products, soybean oil and meal, garage and automobile equipment, ladies' shoes, miners' lamps and equipment, heavy duty steam boiler installations and mattresses. Bank clearings in 1940 totalled $74,476,626.98. The city obtains its water supply from a large artificial lake known as Lake Springfield, completed in 1935. This body of water, the largest artificial lake in the state, is 15 mi. in length, with a shore line of over 45 mi. A water treatment plant, owned and operated, as is the lake, by the city through its department of public property, affords an adequate supply of pure water. The city owns and controls over 4,000 ac. of marginal lands bordering the lake, which are rapidly being developed as a residential and recreational area. Springfield was first settled in 1818–19 by trappers and hunters from North Carolina, Virginia and Kentucky. In 1823 it became the county seat and was named Springfield, no reason being discovered for the source of its name. It was incorporated as a town in 1832, and was selected as capital of the state in 1837 in place of Vandalia. In 1840 it was chartered as a city. General U. S. Grant assumed his first command during the Civil War in Springfield when he was named colonel in charge of a volunteer regiment on July 3, 1861. Springfield was the birthplace and lifetime home of Nicholas Vachel Lindsay, the American poet, and was the early home of Edgar Lee Masters and Brand Whitlock.

**SPRINGFIELD,** a city of Massachusetts, U.S.A., at the intersection of federal highways 5 and 20, on the east bank of the Connecticut river, 6 mi. from the southern boundary of the state; a port of entry and the county seat of Hampden county. It is served by the Boston and Albany, the Boston and Maine and the New York, New Haven and Hartford railways. Pop. (1920) 129,614 (24% foreign-born white); 1940 federal census 149,554, to which the contiguous cities and towns add over 75,000. Four bridges cross the river, including the Hampden county memorial bridge, a massive structure of steel and concrete, 80 ft. wide, built to commemorate the patriotic service of the county's citizens and dedicated in 1923. The area of the city is 38.53 sq.mi. It has many buildings of architectural impor-

tance, and since 1921 its development has been guided by an official planning board. The new Union railroad station, opened in 1926, is one of the most commodious and complete in New England. The courthouse, two churches and other buildings were designed by H. H. Richardson. Facing a public park is the fine "Municipal Group" (designed by Pell and Corbett) which was dedicated in 1913, replacing the city hall erected in 1854 and completely destroyed by fire in 1905. It consists of twin buildings (one an auditorium and the other an administration building; each 115 ft. wide, with a portico formed by ten Corinthian columns 41 ft. high) on either side of a campanile 300 ft. high, which contains a carillon of 12 bells. The city's parks cover 1,268 ac. Forest park has an area of 757 ac., and includes a zoological garden and fine collections of lotus plants. The Art museum (1894–96) contains the valuable collections of George Walter Vincent Smith. Near it is the Science museum (organized 1859); the city library, which has an annual circulation of 11 volumes per caput of the population; the William Pynchon memorial building (dedicated 1927), home of the Connecticut Valley Historical society, and the Museum of Fine Arts. In Merrick park, adjoining the library, stands St. Gaudens's statue of "The Puritan." The public-school system includes commercial, technical and classical high schools, a kindergarten training school, vocational and continuation schools. The American International college (1885) and the International Young Men's Christian Association college (1886) are in Springfield. There are 90 churches in the city, and it is the see of a Roman Catholic and a Protestant Episcopal bishop. The *Springfield Republican* (Independent), a morning newspaper established in 1824 by Samuel Bowles, is still owned by the Bowles family. The city operates under a bicameral form of government. The assessed valuation for 1941 was $261,127,520.

There has been a U.S. arsenal in Springfield since the Revolution, when it was established by the Continental congress; and an armory since 1794, when congress authorized the building of the government's first gun factory on a hill near the present railroad station which had been selected by Washington for the purpose in 1789. Here 800,000 of the famous Springfield muskets were made during the Civil War, and it is still the principal manufactory of small arms for the U.S. army. The Smith and Wesson revolver factory and a plant of the Westinghouse Electric and Manufacturing company are among the commercial manufacturing establishments of special interest.

Springfield is noted for the diversity of its industries, which make nearly 1,500 different products, and employ chiefly skilled mechanics. The aggregate output in 1939 was $83,906,834. The largest groups were electrical machinery, apparatus and supplies; motor vehicles, bodies and parts; foundry and machine shop products; printing and publishing; bread and other bakery products; paper goods and confectionery. Springfield is the transportation centre, both by rail and by highway, of western Massachusetts. The railroad terminal post office at the Union station (one of the three maintained in New England) sorts and forwards over 1,200 carloads of mail each month. A mail-order house sends some 500 tons of catalogues to Springfield by freight, to be mailed on to individual addresses. The city's trade area has a population of 700,000. Two of the largest insurance companies of America have their home offices in Springfield. Bank clearings in 1940 amounted to $176,702,698.

Springfield was founded in 1636 by a dozen families from Roxbury, under the leadership of William Pynchon (1590–1662), one of the original patentees of the Massachusetts Bay Colony, who left Roxbury because he was dissatisfied with its government, hoping to put his own theories into effect in a new colony. The town was incorporated in 1641, and named after Pynchon's birthplace in Essex, England. For several years he ruled it with the power of an autocrat, but in 1652 he was removed from the magistracy in consequence of a tract in which he attacked the Calvinistic doctrine of the Atonement, and returned to England. In King Phillip's War Springfield was a centre of hostilities. After the establishment of the arsenal in 1777 it was an important military supply depot of the Continental army. During Shays' Rebellion there was a riot there in Sept. 1786, and on Jan. 25, 1787, the insurgents, led by Shays, attacked the arsenal, but were dispersed by the militia. Industrial development began with the establishment of the government armory (1794), which brought in skilled workmen and attracted other enterprises. In nine years the population increased 50%. A second impetus was given by the completion of the Boston and Albany railroad in 1839. By 1850 the town had a population of 11,766, and in 1852 it was chartered as a city.

**SPRINGFIELD,** a city of southwestern Missouri, U.S.A., 200 mi. S.E. of Kansas City; the county seat of Greene county. It is on federal highways 60, 65, 66 and 160; has a municipal airport; and is served by the Frisco and the Missouri Pacific railways. Pop. 57,527 in 1930 (93% native white); 61,238 in 1940 by the federal census. The city has a beautiful location on the crest of the Ozark plateau, 1,300 ft. above sea level, and is surrounded by charming scenery. The region is rich in timber, and is known for its poultry, egg production, cheese output and fruit. The creameries of Springfield handle dairy products totalling $18,000,000 annually. Beef cattle and hogs are factors in the $9,000,000 annual business of the stockyards. Annual sales of retail stores total $65,000,000. Flour milling activities have a value of $8,750,000 each year; garment manufactures have a value of $3,500,000; woodworking industries, $2,100,000; the annual pay roll of the Frisco railroad is in excess of $4,000,000. Springfield is the seat of Drury college (1873), the Southwest Missouri state teachers college (1905) and Central Bible institute. Adjoining each other are a National and a Confederate cemetery. Springfield was founded about 1829; laid out in 1833; incorporated as a town in 1838 and again in 1846; and chartered as a city in 1847. It has a commission form of government. At the opening of the Civil War Springfield was an important strategic point. It was occupied alternately by Confederate and Union forces until the spring of 1862, after which the Unionists retained control. The battle of Wilson's Creek (Aug. 10, 1861), 10 mi. S. of the city, was one of the bloodiest engagements of the war. The first railroad reached the city in 1870.

**SPRINGFIELD,** a city of Ohio, U.S.A., the county seat of Clark county; 45 mi. W.S.W. of Columbus, on Lagonda creek, near the Mad river. It is on federal highway 40, has a municipal airport, and is served by the Big Four, the Detroit, Toledo and Ironton, the Erie, and Pennsylvania railways, also by motorbus and truck lines in all directions. Pop. (1930) 68,743; in 1940 it was 70,662 (12% Negroes). The city occupies 15.67 sq.mi. of undulating land, reaching an altitude of 979.27 ft. On hills north of the creek are Wittenberg college (Lutheran; founded 1845), and the state homes of three fraternal orders: the Knights of Pythias (opened 1894), the Masons (1895), and the Odd Fellows (1898). Immediately west of the college campus is beautiful Ferncliff cemetery, in which stands a soldiers' monument on top of a prehistoric mound. The city's parks cover 250 ac. Springfield is an important manufacturing, publishing and horticultural centre. There is a peony farm of 70 ac., and nurseries for ornamental shrubbery. The aggregate output of the city's factories, 1937, was valued at $120,686,925. Among the leading products are agricultural implements, metallic caskets, motor trucks, water wheels, playground equipment, piano plates, gas and steam engines, fans, foundry and machine-shop products, metal signs, iron and steel doors and windows, bumpers, auto parts and motors. Bank debits in 1940 were $214,445,527 and the city's assessed valuation was $84,738,085. Since 1914 it has operated under a commission-manager form of government. In 1799 Simon Kenton and a small party from Kentucky built a fort and 14 cabins 3 or 4 mi. W. of Springfield's present limits. Later in the year James Demint settled on a hill overlooking Lagonda creek. In 1801 he engaged a surveyor to plat a town there, and soon after this Kenton's settlement was abandoned. Trouble from the Indians threatened the new town until 1807, when peace was more firmly established at a council held on a neighbouring hill, where Tecumseh was the principal speaker. In 1818, when Clark county was established, Springfield was made the county seat. It was incorporated as a town in 1828, and in 1850, when

the population was 5,108, was chartered as a city.

**SPRINGFIELD,** a city in Lane county, west central Oregon, U.S.A., on the east bank of the Willamette river, with an altitude of 459 ft. It is on U.S. highway 28, about 4 mi. east of Eugene, and is served by the Southern Pacific railroad. The population was 1,855 in 1920; 2,364 in 1930; and 3,805 by the census of 1940, of whom 3,681 were native white. The chief industry is lumbering (fir), and there is a flax mill and a mill producing Angora wool. Diversified farming is also carried on. Springfield, which was classified as an urban community in 1940, was incorporated in 1885.

**SPRINGFIELD,** the county seat of Robertson county, in northern Tennessee, U.S.A. It is 28 mi. northwest of Nashville at the fork of Carr's creek and a branch of the Red river, with an altitude of 595 ft. and an area of 1.1 sq.mi. It is on U.S. highway 41E and is served by the Louisville and Nashville railroad. The population was 3,680 in 1920; 5,577 in 1930; and 6,668 in 1940, of whom 4,790 were native white and 1,867 Negro. As an important market for loose-leaf tobacco, the town has numerous warehouses for the storage of tobacco. The active season for trading lasts from January through June or July. The chief industry is the manufacture of woollen blankets. There are also flour mills, woodworking plants and stone quarries. Farming is diversified and includes the raising of tobacco, corn and wheat. Springfield has a total assessed valuation of $3,099,322 and a bonded debt of $487,000 (1943). It owns and operates its electric distribution system, sewage treatment plant, and waterworks. Administration is by a commission form of government through direct nonpartisan election. It was incorporated as a town in 1819. A general hospital, owned and managed by the county, was established there in 1934.

**SPRINGFIELD,** a town with a village by the same name, on the Connecticut river, in Windsor county, Vermont, U.S.A., through which the Black river flows with a picturesque falls near the centre of the village. The Boston and Maine railroad serves the town with an electric road from its main line. Pop. (1940), town, 7,720; village, 5,182. It is a machine-tool manufacturing village with a large agricultural area. It was chartered in 1761 and has the town-manager form of government, adopted in 1920, the first town in Vermont to adopt the system.

**SPRING-GUN,** a device formerly in use against poachers and trespassers. Since 1827 spring-guns and all man-traps are illegal in England, except as a protection against burglars.

**SPRING-RICE, SIR CECIL ARTHUR** (1859–1918), British diplomatist, was born in London on Feb. 27, 1859, the second son of the Hon. Charles Spring-Rice (1819–70), and grandson of the 1st Baron Monteagle. Educated at Eton and Balliol college, Oxford, he entered the foreign office in 1882, becoming private secretary to Lord Granville in 1884 and précis writer to Lord Rosebery in 1885. He went to Washington as third secretary in 1886, and in 1895 proceeded to Berlin. In 1898 he became secretary at Teheran, and in 1901 British commissioner on the Caisse de la Dette in Cairo. In 1903 he went to St. Petersburg (Leningrad), first as secretary and later as councillor of embassy, remaining in Russia till the end of 1905. In 1906 he was sent to Persia as minister, having lately been created K.C.M.G. In 1908 he was created G.C.V.O. and went to Sweden as minister, and in 1912 was appointed ambassador to the United States. He died at Ottawa on his way home to England, Feb. 14, 1918.

**SPRINGS** are, in almost all cases, the natural overflow or point of escape from some underground reservoir of water. Their classification may be either according to the geological conditions governing the point of location, or according to the chemical composition of its waters. When considerable chemical impurity is present they are usually termed "mineral springs."

The rocks which constitute the crust of the earth are either permeable or impermeable to water. During most seasons of the year, in temperate climates, a certain amount of rainfall soaks into any crust formed of permeable strata; the part absorbed may be the complete rainfall during winter months, when the air is saturated with moisture, or may fall to near zero during a dry summer, when all the rainfall is returned to the air as evaporation from the surface. That portion of the rainfall which soaks down below the level of plant roots goes to replenish the underground reservoir. The shape of the reservoir varies indefinitely, according to the geological structure of the area; but it is only the shape of its water surface that concerns springs. This surface, known as the water table, divides the fully saturated rocks from those which only hold moisture in their minute pores.

In an area of completely permeable rocks the springs issue at or near the valley bottoms; when, however, the district is made of alternating permeable and impermeable beds, each impermeable bed holds up water on its surface. If the strata are horizontal, small springs may be found all round the outcrops; but if they are tilted or folded the flow of the underground water will be towards the lowest point on the base of the permeable water-bearing bed. At this point the main spring for that local reservoir will be located.

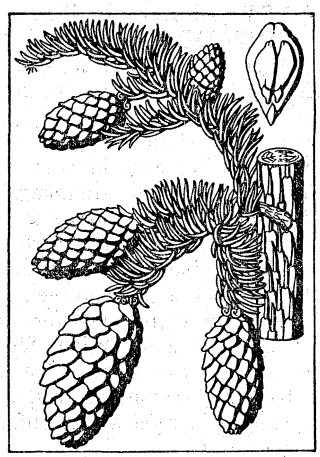
In strata which are, in the main, impermeable, but somewhat brittle the presence of joints and cracks is of prime importance in determining the direction and amount of flow in the underground waters. In jointed rocks the rain water may sink to great depths down one set of joints and rise again along a second, issuing at the surface as a warm or thermal spring; this is the probable cause of the hot springs at Bath. When a permeable bed and an impermeable one are brought into juxtaposition through faulting the flow of water in the permeable one is checked; but since faulting frequently shatters the rock it affords a plane of weakness along which the water will tend to flow. If the water is flowing under pressure due to an overlying impermeable cover, it may reach the surface as an "artesian spring." The water of artesian springs sometimes carries small particles of solid matter in suspension as well as salts in solution. The solid particles are dropped at the point of exit of the spring and may be cemented by the salts deposited from solution. When this takes place a mound is built up, from the summit of which the spring issues. Hence the "mound springs," such as are seen at their best in the great artesian basin of Australia.

Some of the largest springs issue from thick beds of massive limestone. This type of rock is usually well jointed and, being soluble in rain water, the joints and marked bedding planes become enlarged by solution and the whole of the rainfall is absorbed in the mass of the rock and flows underground to issue as large springs. Frequently these springs yield a somewhat hard water of otherwise great purity.

**Mineral Springs.**—All springs containing noticeable quantities of salts in solution, other than the carbonate and sulphate of lime, are known by this name. The commonest minerals found are common salt, giving rise to "bitter springs"; and iron, sulphur, magnesia, etc., giving "medicinal" waters.

**Thermal Springs.**—The springs coming under this heading are derived from two sources. Firstly, meteoric waters which have penetrated down to considerable depths and rise again along well-defined fissures issuing as springs at the surface, but with the temperature of the rocks from which they have come; and, secondly, volcanic waters, either in the form of geysers or hot springs (*see* VOLCANO); in these the water may be either meteoric or in part, at any rate, juvenile—that is, water which is issuing at the surface for the first time. Most of these waters contain much mineral substance in solution, which is deposited on cooling and forms marked basins and terraces of sinter, such as the famous pink and white terraces of New Zealand.

(W. B. R. K.)



**SPRINGTAIL,** any one of the small wingless insects of the order Collembola, so-called because many of them possess a pair of tail-like abdominal appendages adapted for springing. They are widely distributed in the world, and are abundant in the soil and in decaying vegetation. Springtails lay small almost spherical eggs. The newly hatched young are, except for their small size, very similar to the adults. The food of springtails consists largely of decaying bits of vegetation. Some species, however, feed on the tender tissues of growing plants and are of consid-

erable economic importance. (*See* also APTERYGOTA.) (H. E. E.)

**SPRING VALLEY,** a city of Bureau county, Illinois, U.S.A., on the north bank of the Illinois river, 104 mi. S.W. of Chicago. It is served by the Burlington Route, the Chicago and North Western and the Rock Island railways. Pop. 5,270 in 1930; in 1940 it was 5,010. It is a shipping point for coal, zinc, cement and farm products. The city was founded in 1885 and chartered in 1886.

**SPRINKLER.** The automatic sprinkler is a means of combating fire which has the approval of fire insurance companies, who often make a reduction in their premiums when it is employed. The essence of the device is to arrange, under the ceiling of the building to be protected, a series of sprinklers which discharge water as soon as the temperature reaches a certain point. The automatic release of the water is contrived by closing the valves of the sprinklers with fusible metal; the alloy employed being such as to fuse at a temperature of say 150° F. The sprinkler is so devised that the jet spreads the water in a shower, and the distance between the sprinklers is so arranged that every part of the floor is covered. The sprinklers are connected with lines of pipes conveying the water under pressure. In buildings where the water-pipes are likely to freeze, the ceiling connections are filled with air under pressure, so that when the valve opens through the metal fusing, the air escapes and the loss of pressure in the pipes works a lever that opens the valve of the water main. (*See* also FIRE PREVENTION AND EXTINCTION.)

**SPRUCE** (*Picea*), an important genus of evergreen coniferous trees of the pine family (Pinaceae), called also spruce fir, including about 40 species, natives of the cold and temperate regions of the northern hemisphere. They are pyramidal trees, with whorled branches; thin, scaly bark; linear, spirally-arranged leaves, each jointed near the stem on a separate woody base; and ovoid, oblong or cylindrical spreading cones, which become pendent when mature. The spruces are readily distinguished from the pines by their solitary instead of fascicled leaves, which leave peglike projections on the twig when they fall, and from the firs in having pendent cones with persistent scales instead of upright cones with deciduous scales.

BRANCH OF THE NORWAY SPRUCE (PICEA EXCELSA) BEARING CONES
Small figure shows single scale with two winged seeds

In an economic sense the most valuable species is the Norway spruce (*P. excelsa*), native to northern Europe and Asia and well known in plantations in the British Isles and eastern North America, though hardly attaining in cultivation the great height and noble form which it displays in its native woods. In favourable situations it becomes the tallest and one of the stateliest of European trees, sometimes rising to a height of 170 ft. and attaining a trunk diameter of 5 to 6 ft. at the base. It has a nearly straight, tapering trunk, throwing out in somewhat irregular whorls its widespreading branches densely clothed with dark clear green foliage. The boughs and their side branches, as they increase in length, have a tendency to droop, the lower tier, even in large trees, often sweeping the ground, a habit that gives a peculiarly picturesque effect. The slender, sharp, slightly curved leaves are scattered thickly around the shoots; the upper ones pressed toward the stem, and the lower directed sideways, giving a somewhat flattened appearance to the individual sprays. The cylindrical cones, 4 to 7 in. long, grow chiefly at the ends of the upper branches.

The Norway spruce is very widely distributed, growing on most of the mountain ranges of Europe from the Pyrenees northward and extending to 68° N., while in Asia it extends eastward to the Lena river and from the Altai mountains to beyond the Arctic circle. On the Swiss Alps it is one of the most prevalent and striking of the forest trees. In the lower districts of Sweden it is the predominant tree in most of the great forests; in Norway it constitutes a considerable part of the dense woods of the southern valleys, flourishing on mountain slopes up to 3,000 ft. and clothing the shores of some of the fjords to the water's edge.

While less valuable than the pine, the Norway spruce is an important timber tree. When produced in close forests the white wood is of compact and even grain and suitable for a great variety of uses. Immense quantities of spruce lumber are imported into Great Britain from northwestern Europe. Great quantities also of younger trees are imported as poles, used for scaffolding, ladders and mining timber. In Norway the wood is very extensively made by hydroelectric power into wood pulp.

As an ornamental tree Norway spruce has been commonly planted in Great Britain since about 1600. It is also grown as a "nurse" for other trees, for shelter for wall fruit, for cover for game, and for small stakes and poles. As a picturesque tree for park and other ornamental plantation it ranks among the best of the conifers, bearing the smoke of cities better than most of the fir group, though subject to blight, which gives it an unhealthy appearance after a certain age. In North America the Norway spruce is extensively planted in the eastern states and Canada.

In North America there are seven native species of spruce; of these, three are found in the eastern United States and Canada, two occur in the Rocky Mountain region and two are confined to the Pacific coast. The white spruce (*P. glauca*) is found from Maine to Minnesota northward to Labrador and Hudson bay and northwestward to Bering strait in Alaska. It grows to a height of 150 ft. and a trunk diameter of 4 ft., with cylindrical cones 2 in. long. The white spruce is very valuable for lumber and especially for wood pulp, being the chief species utilized in the Canadian wood pulp industry. The red spruce (*P. rubens*) occurs from Nova Scotia to New York and southward in the mountains to Tennessee. It is the dominant spruce in the Adirondack region, attaining a height of 60 to 100 ft., with brownish-red ovoid cones, about $1\frac{1}{4}$ in. long; it is extensively used for lumber and pulp wood. The black or bog spruce (*P. mariana*), native to swamps from Newfoundland to Alaska and southward to Virginia and Minnesota, commonly 20 to 30 ft. but sometimes 90 ft. high, with small globose cones, is utilized for pulp wood and is the source of spruce gum.

The Engelmann spruce (*P. engelmanni*), native to the Rocky Mountain region and extending westward to British Columbia and California, is a handsome tree of high altitudes. It grows from 20 to 150 ft. high, with slender branches and oval cones, sometimes 3 in. long. The blue or Colorado spruce (*P. pungens*), native to the central Rocky Mountain region, is one of the most distinctive American species. It grows from 80 to 150 ft. high, with stiff, horizontal branches, and rigid, bluish-green to silver-white, spiny-tipped leaves, and oblong cones, $2\frac{1}{2}$ to 4 in. long. Several varieties with characteristically blue foliage, as the well-known Koster blue spruce (var. *kosteriana*) are widely grown for ornament.

The Sitka or tideland spruce (*P. sitchensis*) occurs along the Pacific, extending about 50 mi. inland, from Kodiak island, Alaska, southward to northern California. It is the most massive of the spruces, sometimes attaining a height of 190 ft. and a basal trunk diameter of 20 ft., but it usually grows about 100 ft. high, with a trunk 3 ft. in diameter, with widely spreading, rigid branches, stiff, usually prickly-pointed leaves, and oblong cones 2 to 4 in. in length. The Sitka spruce is a valuable timber tree, and is extensively lumbered. The rare weeping spruce (*P. breweriana*), with hanging branches clothing the trunk to the ground and with the few horizontal branches decorated with cordlike hanging branchlets, is confined to the coastal mountains of northern California and adjacent Oregon.

Among the various old world spruces planted as ornamental trees are the Serbian spruce (*P. omorika*); the oriental spruce (*P. orientalis*), of Asia Minor; the Himalayan spruce (*P. smithiana*), the Alcock spruce (*P. bicolor*) and the tiger-tail spruce (*P. polita*), natives of Japan.

Sudworth, "Check List of the Forest Trees of the United States, Their Names and Ranges," *U.S. Dept. Agric., Misc. Cir. 92* (1927).

**SPRUE.** Sprue is a disease of tropical and subtropical regions, and possibly cases arise in temperate climates also.

**Symptoms.**—The symptoms usually begin with dyspepsia and irregularity of bowel action. In a fully declared case the chief signs are the passage of bulky, frothy, pale porridge-like, stools, much flatulence and acidity, a sore, ulcerated mouth, a red, smooth and tender tongue, often with exquisitely painful ulcers on the fraenum and at the sides. Loss of flesh is very rapid amounting perhaps to 40 lb. in two months. Cramps of the fingers and of the feet and calves are common in severe cases. Death occurs from exhaustion and intercurrent disease or, more usually, from intense anaemia, or rarely from perforation of an intestinal ulcer.

**Treatment.**—The treatment is rest in bed for a fortnight on a diet restricted to milk (increasing from 4 to $7\frac{1}{2}$ pints daily) together with calcium lactate (gr. 15 thrice daily) and extract of parathyroid (gr. 1/10th twice daily). The parathyroid *must* be free from admixture with thyroid (most preparations contain some of the latter) for if any of the latter be present, the symptoms become aggravated and palpitation and other indications of thyroid excess are superadded. With a pure preparation, however, the sprue symptoms improve within a fortnight, the ionic calcium increases to about 8 mg. %, the stools are reduced to one a day and the soreness of the mouth disappears. At the end of four weeks in favourable cases, the calcium lactate can be dropped and the parathyroid reduced to half doses. About this time the blood serum will show a normal calcium content, but the parathyroid extract should not be left off entirely for another three to four weeks. Should symptoms recur, a return for a few days to a simpler diet and to the parathyroid extract will restore health.

Many patients treated on these lines have returned to their duties abroad, many others have been treated in the tropics and have recovered. A few years ago the appearance of sprue meant immediate return to a temperate climate and prohibition of future residence in the tropics. (H. H. S.)

**SPUR,** an instrument attached to the heel of a rider's boot for the purpose of goading the horse. (A.S. *spura, spora,* related to *spornan, spurnan,* to kick, spurn.) The earliest form of the horseman's spur armed the heel with a single prick. In England the rowel spur is shown upon the first seal of Henry III, but it did not come into general use until the 14th century. In the 15th century spurs appear with very long shanks, to reach the horse's flank below the outstanding bards. After this time, and until the Restoration, they take many decorative forms, some of which remain in the great spurs worn by Mexican cavaliers. Gilded spurs were reckoned the badge of knighthood, and in the rare cases of ceremonial degradation they were hacked from the knight's heels by the cook's chopper.

In architecture, a spur (Fr. *griffe,* Ger. *Knoll*), is the ornament carved on the angles of the base of early columns; it consists of a projecting claw, which, emerging from the lower torus of the base, rests on the projecting angle of the square plinth; the earliest known example is in Diocletian's palace at Split (Spalato). In Romanesque work the oldest examples are those found on the bases in crypts, where they assumed various conventional forms; being, however, close to the eye, the spur soon developed into an elaborate leaf ornament, which in French 13th-century work and in the early English period is of great beauty.

**SPURGE,** a name applied to plants known botanically as Euphorbia (*q.v.*). The spurge-flax is *Daphne gnidium,* and the spurge-laurel *Daphne laureola,* both found in Great Britain.

**SPURGEON, CHARLES HADDON** (1834–1892), English Nonconformist divine, was born at Kelvedon, Essex, on June 19, 1834. In 1852 he became pastor of Waterbeach. His powers as a boy preacher became widely known, and at the close of 1853 he was "called" to New Park Street chapel, Southwark. Exeter hall was used while a new chapel was being erected, but even that could not contain Spurgeon's hearers. The enlarged chapel at once proved too small for the crowds, and a huge tabernacle was projected in Newington causeway. The Tabernacle was opened for service on March 25, 1861. Spurgeon preached at the Tabernacle on Sundays and Thursdays.

His Sunday sermons were sold literally by tons. They are models of Puritan exposition and of appeal through the emotions to the individual conscience, illuminated by frequent flashes of spontaneous and often highly unconventional humour. Collected as *The Tabernacle Pulpit,* the sermons form some 50 volumes. His book of sayings called *John Ploughman's Talks; or, Plain Advice for Plain People* (1869) found many readers. In 1887 his distrust of modern Biblical criticism led to his withdrawing from the Baptist union. He died at Mentone on Jan. 31, 1892.

*See* the *Life* by Schindler (1892) and Spurgeon's *Autobiography,* compiled by his widow and his private secretary from his diary, sermons, records and letters (1897–1900).

**SPURN HEAD,** foreland of the North sea coast of Yorkshire, England, projecting across the mouth of the Humber. From Kilnsea it is 4 mi. long but seldom exceeds 300 yd. wide. Formed of sand and shingle from the rapidly denuding Holderness coast to the north, it is only a few feet above sea level.

**SPY,** a commune near Namur, Belgium. Pop. (1939) 3,243. Here in 1886, in Betche aux Roches cavern, Maximin Lohest and Marcel de Puydt found two nearly perfect skeletons (man and woman) at the depth of 16 ft., with numerous implements of the early Aurignacian period. All the human remains are in the Lohest collection, Liége. The skulls are of the Neanderthal type.

See *L'Homme Contemporain du Mammouth à Spy* (Namur, 1887); G. de Mortillet, *Le Préhistorique* (1900); Sir A. Keith, *Antiquity of Man,* 2nd ed. (1925).

**SPY:** *see* LAWS OF WAR.

**SQUADRON,** (1) a military term referring to the subdivision of a cavalry regiment, (2) a naval term referring to a detachment of war vessels, and (3) an air force term denoting a unit of a "group." Literally the term means a body of fighting men formed into a square. In 1656 the term was appropriated by horsemen but even in 1810 Scott in *The Lady of the Lake* refers to "squadrons tramping." The earliest use of the word in the military sense appears to be in 1562 and in 1581 Styward in *Martial Discipline* gives a clue to its origin: "The poore Swizers not being able to furnishe themselves with horse, were the first devisers of the pike and the squadrone," from which it is inferred that a body of pikemen formed into a square were employed on the flanks of a formation. This appears to be confirmed by Bullokar who wrote in 1616 that a squadron was a "square form in a battel." Previous to this, Sir John Smyth in 1590 refers to squadrons in reference to infantry, as also does Ward as late as 1639.

Moryson in 1617 mentions "two squadrons of foot 250 men each." In 1702 a squadron of horse was anything between 100 and 200 men but by 1779 the number had been reduced to 80–120. At that date the squadron was composed of three complete troops.

The Cavalry Regulations (British) of 1832 state that "Two or more squadrons compose a regiment." In the modern military sense a squadron is one of the principal units into which a regiment of cavalry is divided, corresponding to a company of infantry, the normal being three or four squadrons, subdivided into "troops." Squadrons are usually between 120 and 200 men. (*See* CAVALRY.)

In the naval sense the term refers to a part of a fleet usually commanded by a flag officer, or it may be applied loosely to any number of vessels less than a whole fleet. For its application to the air force *see* GROUP CAPTAIN and AIR FORCES.

In British military use, "squad" (a shortened form of "squadron") is used of any small detachment of men temporarily formed for drill or fatigue work or other duty. In the U.S. army, however, the squad is the basic infantry unit.

**SQUALL,** the name given to any sudden large increase of wind velocity of less transient character than a "gust." A squall, usually lasting for some minutes at least, is attributable to meteorological causes, while gusts, which may succeed one another every few seconds, are the result of some mechanical interference with the direct flow of air and are thus produced by turbulence. A squall may include a succession of gusts.

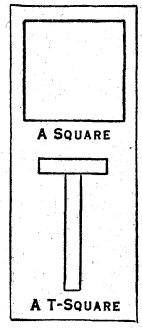
It is difficult to give exact figures for the actual force of the wind during gusts, but 106.5 m.p.h. were recorded at Pendennis castle on March 14, 1905; and 231 m.p.h. on Mt. Washington, New Hampshire, April 12, 1934. Squalls with velocities reaching 55 m.p.h. are not uncommon, and the range of wind velocity during gusts in such a squall may be anything between 40 m.p.h. and upwards of 100 m.p.h.

A squall may be either a rotary wind covering a small area (sometimes called a bull's eye squall) or a straightaway wind. The latter type frequently accompanies the onset of a thunderstorm; as the storm approaches, the wind dies down, then blows gently toward the storm; finally, as the rain is almost at hand, a violent gusty wind abruptly sets in, blowing directly outward from the storm and usually lasting for only a short time. At many places on the earth, local conditions result in the frequent occurrence of squalls of characteristic types, which are called by local names; *e.g.*, the "williwaws" common on many steep coasts in high latitudes, caused by a brief violent drainage of cold air down the steep slopes.

These phenomena are best exhibited in "line squalls." As the name suggests, a number of places arranged, roughly, in a continuous line, often hundreds of miles long, experience simultaneously a similar sequence of events. The course of events in typical line squalls has been worked out by R. G. K. Lempfert and Richard Corless.

The violent winds may be attributed to the breakdown of the dynamical system under the stress of these local but sharp differences of pressure. A line squall commonly marks the "cold front" of an extratropical cyclonic storm; to the rear of the storm, a cold air current is advancing against warmer air, and undercutting the latter.

The boundary between these two air masses is called a cold front; it is the familiar wind-shift line, along which the direction of the wind undergoes a rapid and often considerable change—*e.g.*, from southwest to northwest—usually accompanied by a sharp drop in temperature, an abrupt increase in pressure and a break in the direction of the isobars.



This line has long been known as the squall line, because all along it sudden gusts, squalls and, in summer, thunderstorms, are very common owing to the vigorous ascent of warm air initiated by the lifting caused by the underrunning cold air. (*See* Giblett, "Line Squalls," *Journal of the Royal Aeronautical Society*, vol. 198, 1927.)

In this respect a V-shaped depression may be regarded as a special case of a line squall in which the two currents are from approximately opposite directions, and the line of the trough which sweeps forward, keeping parallel to itself, represents the linear front.

An example of a violent and destructive form of line squall is shown in the records for June 1, 1908. The Kew squall of wind which destroyed a number of the trees of Bushey avenue maintained its violence for a considerable period. Many other famous line squalls, such as those of Feb. 19, 1907, Oct. 14, 1909, etc., have been examined. (*See* Lempfert and Corless, "Line Squalls and Associated Phenomena," *Q.J.R. Met. Soc.*, vol. xxxvi, 1910.) One of historic interest caused the loss of H.M.S. "Eurydice" off the Isle of Wight on March 24, 1878.

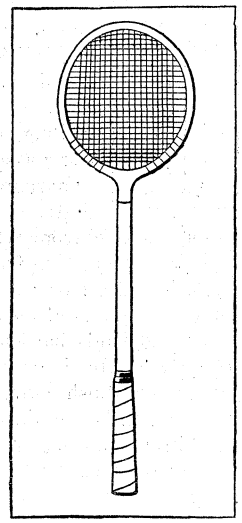
It was among the first to receive special attention and was discussed by Abercromby in 1884 (*Quart. Journ. Roy. Met. Soc.*, x, 172) and previously by Clement Ley (*Symon's Met. Mag.*, April, 1878).

**SQUARE,** a term variously used in mathematics, in technical work and metaphorically. In geometry it designates a rectilinear figure having four equal sides and four equal angles, the angles being right angles. Such a figure is a special kind of rectangle (equilateral) and of parallelogram (equilateral and equiangular). It has four axes of symmetry, and its two finite diagonals (as in the case of any rectangle) are equal. If the side is $s$, the area is $s \times s$, or $s^2$, the name "$s$ squared" being derived from this geometric relation. Hence the analytic square is the product arising from multiplying any algebraic expression by itself; *e.g.* $(a+b)^2 = a^2+2ab+b^2$ (*see* BINOMIAL FORMULA). The Latin writers called the side of a square its *latus* (side), and hence the square root of a number was often called the *latus*. In technical work the word is applied to instruments used for drawing or testing right angles, as in the T-square here shown and the familiar carpenter's square.

**SQUASH** is the fruit of *Cucurbita maxima* and certain varieties of *C. pepo*. (*See* PUMPKIN.) Summer squash is a quick-growing, small-fruited, non-trailing or bush type of *C. pepo*. The plants are upright-spreading, $1\frac{1}{2}$ to $2\frac{1}{2}$ ft. high and produce a remarkable diversity of fruit forms, ranging from flattened through oblong to elongate and crooked. Colours range from white through cream to yellow, also green and variegated. The fruit surfaces or contours may be scalloped, smooth, ridged or warty. The fruits develop very rapidly and must be harvested only a few days after they form, before the seeds and rinds harden. They must be used soon after harvest. The entire fruit is usually cut into pieces, boiled and served with butter. The bush forms are grown about 2 ft. apart in rows 3 to 4 ft. apart. To obtain early yields, seedlings are often started in pots in frames or greenhouses and transplanted into the field after 3 or 4 leaves have developed and after danger of frost is past.

Winter varieties of squash, *C. maxima,* are long-vining, generally large-fruited, long-season kinds, that can be stored many months if kept dry and well above freezing. The fruit stems are greatly enlarged next to the fruits and the fruits show a wide range of sizes, shapes and colours. They are higher in nutritive value than summer squash or so-called pumpkins, and are commonly baked or made into pies. They are extensively grown in the United States in home gardens, market gardens, and on a large field scale for canning. (V. R. B.)

**SQUASH RACKETS.** A game played on exactly the same principle as rackets but in a smaller court and with a ball made of india-rubber. The rules are in most particulars similar to rackets but the scoring is different. In matches in England, hand-in only can win an ace. The rubber is the best of five games of 9 up. If, however, the score becomes 8 all, the player who reached 8 first has the option of a set to two. In America a game consists of 15 points up, and an ace is scored for each rally irrespective of which player is serving, all matches being the best three out of five games. The rotation of service in England is just as in rackets. In the American game, the winner of one rally serves in the next.



**The Court and Implements.**—Squash rackets can be played in courts of many sizes and descriptions, both covered and uncovered, with three or four walls and made of concrete or wood. The first standardization of a court in England was made by the Tennis and Rackets association in 1911. Shortly after World War I the association issued revised standard dimensions, and the great majority of British courts have been built to these dimensions since. The standard court has four walls and can either be covered or uncovered. In length it is 32 ft. and in breadth 21 ft. The front and side walls are 15 ft. in height and the back wall is 7 ft. in height.

The floor in a closed court should be made of wood; in an open court, of cement. In a closed court the front wall should be of composition.

The markings on the floor and front wall of the court are exactly similar to those in a racket court. On the front wall, the top of the play line is 19 in. from the floor and the service line is 6 ft. from the floor. The short line is 14 ft. from the back wall. The service boxes are 5 ft. 3 in. square. In the space between the play-line and the floor is generally placed a strip of tin or some other metal in order to differentiate clearly in sound when the part of the front wall "in play" or "out of play" is hit. The lines on the wall and floor are painted red. Maple is considered a most suitable wood for the floor. The courts should be lighted from the roof, and nearly all modern courts, in addition to this lighting, are fitted with electric light for evening play.

The American standard court is of different size from the English,

being considerably narrower, 31 ft. by 18 ft. 6 in. The racket is precisely similar to the implement used in the game of rackets, only shorter in the handle. The ball is of black rubber. Many different forms of ball have been tried and formerly, when there were no standard courts, the ball which seemed best suited to the particular conditions was generally used. For the present standard English court the association has adopted three standard balls. The ball used in America is larger than that in England.

ENGLISH, BENT ASH FRAME, SQUASH RACKET

Open competitions at squash rackets were unknown in England before the World War. In the years since, several have been started, the most important being the London inter-club tournament (teams of three) for the Bath Club cup; the amateur championship, the royal navy and army championships, and the ladies championships. The winners of the amateur championship were:—April 1923, Capt. T. O. Jameson; Dec. 1923, Capt. Jameson; Dec. 1924, W. D. Macpherson; Jan. 1926, Capt. V. A. Cazalet; Dec. 1926, Capt. J. E. Tomkinson; Dec. 1927, Capt. V. A. Cazalet; Dec. 1928, W. D. Macpherson; 1929 and '30, Capt. V. A. Cazalet; 1931–33 and 1935–38, F. D. Amr Bey; 1934, C. P. Hamilton; 1939, K. C. Gandar-Dower.

The amateur championships are held annually in December at the Bath club. The duke of Windsor is a very keen player and, as prince of Wales, competed several times in the amateur and army championships.

The British professional champion in 1939 was J. Dear (Prince's club) who defeated D. Butcher (St. John's Wood club) in 1937. Leading lady players were Miss Cicely Fenwick, Miss Nancy Cave, Miss Joyce Cave, Miss S. Huntsman, Miss Susan Noel and Miss Margot Lumb, champion from 1936–39. F. D. Amr Bey, an Egyptian, created a sensation in London in the early '30s and was invincible against the best amateurs and professionals for some years.

The development of the game in America was even more rapid than in England, achieving a big vogue in the late '20s and '30s. The large cities of the United States, particularly New York, Boston and Philadelphia, are amply supplied with courts; and the game is also played with much keenness in Canada. British teams visited America after 1924, the late Captain V. A. Cazalet, M. P., leading one of them, and United States teams also toured in England. Among the leading amateur champions were Stanley W. Pearson, 1915–17 and 1921–23; W. Palmer Dixon, 1925–26; Myles P. Baker, 1927; Herbert N. Rawlins Jr., 1928 and 1930; Dr. J. Lawrence Pool, 1929 and 1931; Beekman Pool, 1932–33; Neil J. Sullivan, 1934; Donald Strachan, 1935 and 1939; Germain Glidden, 1936–38; A. Willing Patterson, 1940; Charles Brinton, 1941–42.

The French Squash Rackets association was formed in 1926 and four courts were opened in Jan. 1927. Outside Europe and America courts are to be found in several parts of the British empire, especially in India and the far east. There are courts in New Zealand and in South Africa.

*See* E. H. Miles, *Racquets, Squash Tennis* (1902); C. Arnold, *The Game of Squash Rackets* (1926); E. B. Noel, *The Field Handbook of Squash Rackets* (1926). (E. B. N.; A. Da.)

**SQUIB,** a firework bursting with a flash and a clatter: hence a slight satirical composition put forth on an occasion, which should make a noise by its explosion, not by the possession of any permanent importance. Steele says, in the *Tatler,* that "squibs are those who in the common phrase of the world are call'd libellers, lampooners and pamphleteers," showing that in his time the satirist as well as the satire was called a squib. Swift speaks of the rapidity with which these little literary fireworks flew about, and was himself a proficient in the making of them. A good type of a squib is Gray's *Candidate.* (*See* Lampoon.)

**SQUID,** the popular name given to a large number of cephalopod molluscs which include (*e.g.*) the common squids of the Atlantic (*Loligo, Ommastrephes*), the giant squids (*Architeuthis*) and the fire squids (*Lycoteuthis, Abralia*). They are exclusively marine animals of world-wide distribution and form an important part of the population of marine swimming and floating animals.

A typical squid, e.g., *Loligo vulgaris,* the common squid of the north-east Atlantic and Mediterranean, has an elongate slender body (visceral sac) edged by triangular fins, a short square head provided with well-developed eyes and ten arms. On the under-surface of the latter are arranged rows of suckers which are strengthened by tough horny rings. Two of the arms (tentacles) are longer and more mobile than the other eight (sessile arms) and the suckers are concentrated at the extremity as a "hand." The long tentacles are used for capturing prey, the sessile arms for transferring the latter to the mouth and grasping it while it is being crunched by the horny jaws which are situated around the mouth in the centre of the circlet of arms.

Situated within the muscular tissues of the "mantle" is a long horny structure, the "pen" or gladius. This is the rudiment of a shell and consists actually of a secondary growth (the proostracum) which has replaced the true shell-rudiment. In the genus *Ommastrephes* there is a vestige of the original shell.

The majority of the squids are active, highly mobile animals of aggressive habits and are probably all carnivorous.

Originally the squids were distributed among the two "tribes," Oigopsida and Myopsida, of the ten-armed Cephalopoda (Decapoda). Recently, however, Naef and other students have proposed a more suitable classification of the Decapoda according to which the squids are all placed in a single sub-order, the Teuthoidea.

These forms are divisible into two groups originally called by C. Chun the Oigopsida libera and Oigopsida consuta. The first include the large, active and freely swimming forms (*Architeuthis, Loligo, Ommastrephes,* etc.). The second comprise a smaller assemblage of curious and highly modified forms which are less common than the Libera and are very largely planktonic. The distinction between these two groups is based on the mode of attachment of the ventral edge of the mantle to the head. In the Libera this attachment is effected by a stud and socket junction (*see* Cephalopoda) between the head and the edge of the mantle and can be freed from the head when necessary. In the Consuta the ventral edge of the mantle is permanently fixed to the head.

The Libera are represented by about 65 genera. Among them *Architeuthis* is the most striking on account of its size. The genus includes the largest living invertebrate animals, *Architeuthis princeps* of the north Atlantic attaining a maximum record length of 52 ft. (including the outstretched tentacles). *Sthenoteuthis,* a group of smaller forms, which attain a size of over seven feet, may be also reckoned as "giant squids."

Another interesting group are the phosphorescent squids, *Nematolampas, Thaumatolampas* (*Lycoteuthis*) and *Abralia,* which bear light-organs in certain regions of the body (on the mantle, arms, inside the mantle-cavity and around the eyes). Certain of these when seen alive are very beautiful. *Ommastrephes bartrami,* the so-called "flying squid," is found throughout tropical and temperate seas. Its flight is, strictly speaking, a series of leaps across the surface of the sea which are often strong enough to land it on the deck of a ship. This feat is no doubt rendered easier in high seas. The Consuta are mainly small animals. Their fins are largely reduced and the mantle is swollen and tun-like in *Cranchia, Bathothauma,* etc. In the latter, and in *Sandalops,* and *Corynomma* the arms are much reduced and the eyes are situated on stalks. Unlike the larger swimming squids these animals probably float largely at the mercy of the currents and are thus to be reckoned as "plankton." (*See* Cephalopoda.)

*See* G. Pfeffer, *Die Cephalopoden der Plankton-Expedition* (1912); C. Chun, *Wiss. Ergebn. d. Deutsche Tiefsee Expedn.* Bd. xviii. (1910); G. C. Robson, *A monograph of the recent Cephalopoda,* vol. 1 (1929) and vol. 2 (1932). (G. C. R.)

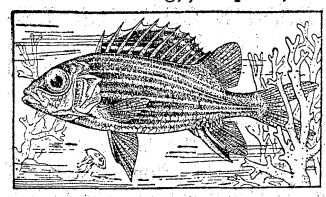
**SQUILL,** the name under which the bulbous root of *Urginea Scilla* (family, Liliaceae) is used in medicine. The medicinal squill is a native of the countries bordering the Mediterranean,

and grows from the sea-level up to an elevation of 3,000ft. The bulbs are globular and often weigh more than 4lb. Two varieties are met with, the one having white and the other pink scales. They are collected in August, when leafless, the membranous outer scales being removed and the fleshy portion cut transversely into slices and dried in the sun.

Three pharmacopoeial preparations of this powerful drug are of importance: the syrup, composed of one part of squill, eight of dilute acetic acid and four of sugar; the *Pilula Ipecacuanhae cum Scilla,* in which ipecacuanha and opium are the chief constituents; and the tincture made by macerating one part of squill with five of alcohol. The drug is a cardiac stimulant. Even in small doses it is a powerful expectorant and a fairly active diuretic. The drug must not be given alone, owing to its irritant action.

An allied species, *Urginea indica,* is used in India in the same manner as the European species. The true squills are represented in Great Britain by two species, *Scilla autumnalis* and *S. verna.* These are confined to the sea-shore. There are 80 species or more in temperate regions of the old world. Several species are grown in gardens, notably *S. bifolia* and *S. sibirica,* originating from the Caucasus region and S.W. Asia. *S. nonscripta* or English bluebell and *S. hispanica* or Spanish bluebell are also widely cultivated.

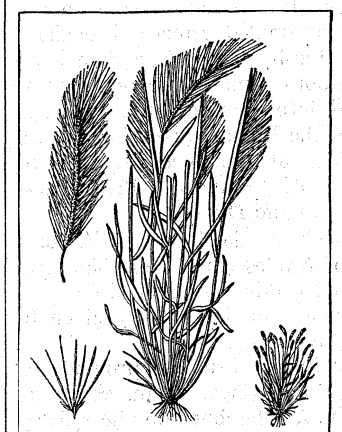
**SQUINCH,** in architecture, a general term for several means by which a square or polygonal room has its upper corners filled in to form a support for a dome: by corbelling out the courses of masonry, each course projecting slightly beyond the one below; by building one or more arches diagonally across the corner; by building in the corner a niche with a half dome at its head, or by filling the corner with a little conical vault which has an arch on its outer diagonal face and its apex in the corner. The arched squinch seems to have been developed almost simultaneously by the Roman builders of the late imperial period and the Sassanians in Persia.



Squinches are often found both in Romanesque and Mohammedan work. In Italy the form is either the conical type as in the church of S. Ambrogio at Milan (crossing 11th or 12th century) or as a succession of arched rings as in the 13th century central tower of the abbey church at Chiaravalle Milanese; more complex forms, with niches and colonnettes are characteristic of the French Romanesque of Auvergne, as in the cathedral of Le Puy en Velay (late 11th and early 12th century); the allied churches of the south-west coast, such as St. Hilaire at Poitiers, use conical squinches of the Italian type. Mohammedan architecture, borrowing from the Sassanian precedent, makes great use of squinch forms, particularly in the Syrian, Egyptian and Moorish phases; the stalactite work, which is so marked a feature of later Muslim architecture, is, in essence, merely a decorative development of a combination of niche squinch forms. In Gothic architecture squinch arches are frequently used on the insides of square towers to support octagonal spires. (*See* BYZANTINE AND ROMANESQUE ARCHITECTURE; DOME; PENDENTIVE.)

**SQUIRREL,** the name of a red, bushy-tailed arboreal rodent, but also extended to include allied species. Typical squirrels are found throughout the tropical and temperate regions except in Madagascar and Australia. The common squirrel (*Sciurus vulgaris*) is found over the whole of Europe and North Asia, though showing great range of colouring in the various parts of its habitat. The ears are tufted, and the animal feeds largely on vegetables and fruits, varied with mice, small birds and eggs. In North America this species is replaced by the gray *S. carolinensis,* a larger and more powerful form, that has been introduced into Great Britain, where it has exterminated the native species in many places. Squirrels vary in size from that of a mouse, as *Nannosciurus minutus* of West Africa, to that of a cat, as the black and yellow *Ratufa bicolor* of Malay. In India the commonest species are the little striped palm squirrels, *Funambulus palmarum* and *F. pennanti,* the latter being the more northern species. One oriental squirrel (*S. caniceps*) assumes a definite breeding dress. Squirrels form the family Sciuridae of the order Rodentia (*q.v.*). (*See* also GROUND SQUIRREL, SPINY SQUIRREL, GROOVE-TOOTHED SQUIRREL, FLYING SQUIRREL.)

GRAY SQUIRREL (SCIURUS CAROLINENSIS), EASTERN NORTH AMERICA



**SQUIRREL FISHES** (*Holocentrus*), a genus of small (less than a foot long), tropical, marine fishes, numerous about coral reefs. They have notably large eyes, a strong backwardly directed spine at the corner of the preopercle (on the lower side of the head), a long spinous dorsal fin contiguous with a shorter one of soft rays behind it, a short anal fin with one of its initial spines notably long and strong, a forked caudal (or tail) fin, and the body covered with firm scales of moderate size. Their colours are bright—red and yellow—and lengthwise stripes on the body predominate. Those with larger mouths (*Flammeo*) are sometimes separated generically from those with smaller mouths (*Holocentrus*).

SQUIRREL FISH (HOLOCENTRUS DIADEMA), ONE OF THE COMMONEST IN THE INDO-PACIFIC, RED IN COLOUR WITH LENGTHWISE WHITE STRIPES

Some 12 species of squirrel fishes inhabit the waters of the East Indies; 9, some of which are the same, those of the Hawaiian Islands; about 7 (of which *Holocentrus adscensionis* is the commonest), the West Indian region. (J. T. N.)

**SQUIRREL MONKEY,** a small golden-haired South American monkey, *Saimiri sciurea;* the name is also applied to the two other species of the genus, whose collective range extends from Costa Rica to Bolivia and Brazil. The squirrel monkeys belong to the Cebinae (*see* CAPUCHIN MONKEY), from the other members of which they differ by their practically non-prehensile tails, smaller size, their large eyes and the backward prolongation of the hinder part of the head. (*See* PRIMATES.)

BY COURTESY OF IOWA GEOLOGICAL SOCIETY
SQUIRREL-TAIL GRASS

**SQUIRREL-TAIL GRASS** (*Hordeum jubatum*), a name widely given in the United States to a species of wild barley, native to Europe, Asia and western North America and naturalized extensively in the eastern States and Canada, often becoming a troublesome weed, especially in alfalfa fields. It is a perennial, with slender stems usually from 1 to 2½ ft. high, bearing nodding, soft, brushlike, long-awned flowering spikes, from 2 to 4 in. long and about as thick, whence the common name. It is also known, locally as barley-grass, foxtail and tickle-grass.

**SRINAGAR,** capital of the state of Kashmir, in Northern India, 5,250 ft. above sea-level, on both banks of the river Jhelum, which winds through the city with an average width of 80 yds. and is crossed by seven wooden bridges. The houses occupy a length of about 3 m. and a breadth of about 1½ m. No two buildings are alike. The curious grouping of the houses, the frail tenements of the poor, the substantial mansions of the wealthier, the curious carving of some, the balconies of others, the irregular embankment and the mountains in the background form a quaint and picturesque spectacle. Pop. (1941) 207,787. The city is exposed to both fire and flood. The artisans of Srinagar enjoy a high reputation. Unfortunately, the historic industry of shawl-weaving has been replaced by carpet manufacture. Other industries are paper, leather, silver and copper ware, and wood-carving.

**SRIRANGAM,** a town of British India, in Trichinopoly district. Madras presidency, 2 m. N. of Trichinopoly city. Pop. (1941), 26,676. It stands on an island of the same name, formed

by the bifurcation of the river Cauvery and by the channel of the Coleroon. The town is celebrated for its great temple, dedicated to Vishnu, composed of seven square enclosures, one within another, and 350 ft. distant from each other. Each enclosure has four gates with high towers, placed one in the centre of each side opposite to the four cardinal points. The outer wall of the temple is not less than 4 m. in circumference. It is a great place of pilgrimage.

**STAAL, MARGUERITE JEANNE CORDIER DELAUNAY,** Baronne de (1684–1750), French author, was born in Paris on Aug. 30, 1684, the daughter of a painter named Cordier. She adopted her mother's maiden name, Delaunay. She was educated at a convent at Evreux, later accompanying Madame de Grieu to the convent of St. Louis where the latter was appointed abbess. Mlle. Delaunay held a little salon there until 1710, and after the death of Mme. de Grieu entered the household of the duchesse du Maine at Sceaux. She helped her mistress to draw up the *Mémoire des princes légitimes,* demanding the meeting of the states-general. After a short imprisonment in the Bastille, on account of her implication in the Cellamare conspiracy (1718), she returned to the service of the duchess. She had had many admirers, and some serious passions, when, in 1735, being then over fifty, the duchess arranged her marriage with the Baron de Staal. She remained a member of the duchess's household, and became the friend and correspondent of Mme. du Deffant. She died at Gennevilliers on June 15, 1750.

Her *Mémoires* appeared about five years later, and have often been reprinted. In these memoirs the humours of the "court of Sceaux" are depicted as hardly any other society of the kind has ever been. "Dans cet art enjoué de raconter," says Sainte-Beuve, "Madame de Staal est classique."

Her *Mémoires* were edited (1877) by M. de Lescure, and translated by S. Bathurst (1877) and by C. H. Bell (1892). Mme. de Staal also left two excellent short comedies, performed at the court of Sceaux, and some letters.

**STABAT MATER,** famous mediaeval Latin hymn on the Crucifixion, which has enjoyed unexampled esteem throughout the ages, believed to have been written by Jacopone, a Franciscan monk of the 13th century. Though not originally intended for this purpose, it was early introduced into liturgical use and was adopted as one of the Sequences of the Roman missal in the 18th century. Among the many settings of the poem by eminent composers may be mentioned those of Josquin des Prés, Palestrina, Pergolesi, Haydn, Rossini, Verdi and Dvořák.

**STABIAE,** an ancient town of Campania, Italy, on the coast at the east extremity of the Gulf of Naples (mod. Castellammare di Stabia). It was dependent upon Nuceria Alfaterna. In 89 B.C. it was taken and destroyed by Sulla, and its territory given to Nuceria as a reward for fidelity to Rome.

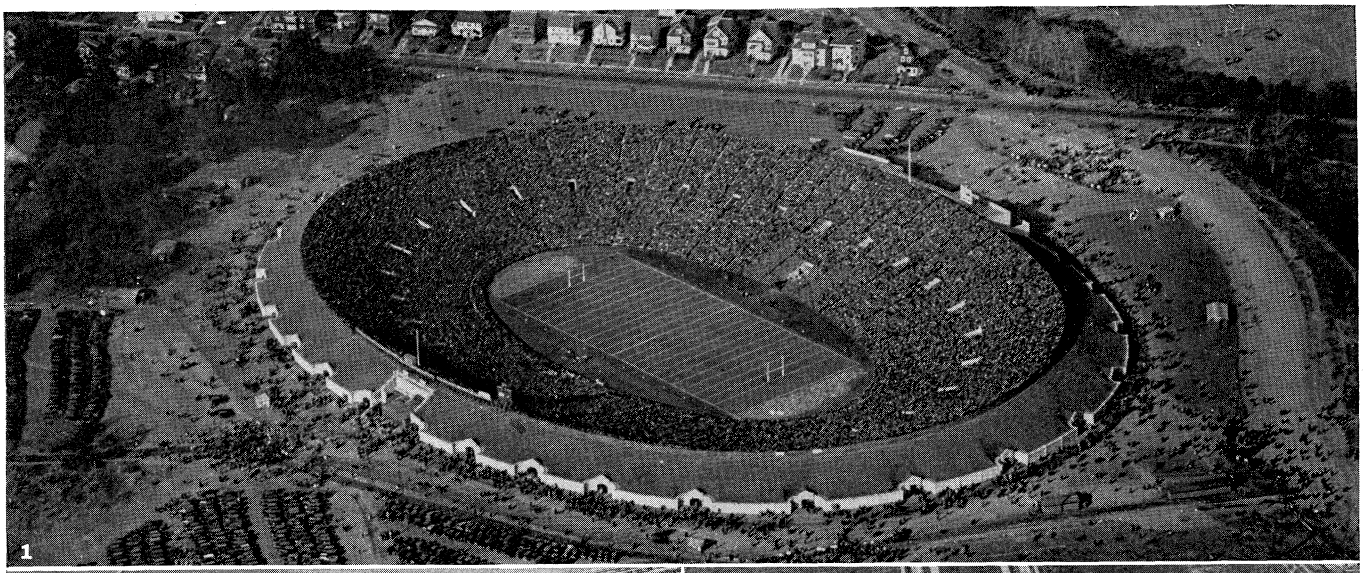
**STADE,** a town of Germany in the Prussian province of Hanover, situated on the navigable Schwinge, 3½ m. above its confluence with the Elbe, 20 m. W. of Hamburg on the railway to Cuxhaven. Pop. (1939) 19,592. The rise of Harburg has deposed it from its former position as the chief port of Hanover.

**STADION, JOHANN PHILIPP KARL JOSEPH** (1763–1824), Austrian statesman, was ambassador in London (1790–93). After some years of retirement he was entrusted (1800) with a mission to the Prussian court, where he endeavoured in vain to effect an alliance with Austria. He had greater success as envoy at St. Petersburg (Leningrad), where he played a large part in the formation of the third coalition against Napoleon (1805). Notwithstanding the failure of this alliance he was made foreign minister, when he helped to prepare archduke Charles for a fresh trial of strength with France. In 1808 he abandoned the policy of procrastination, and with the help of Metternich hastened the outbreak of a new war. The unfortunate results of the campaign of 1809 compelled his resignation, but in 1813 he was commissioned to negotiate the convention which finally overthrew Napoleon.

*See* A. Beer, *Zehn Jahre österreichischer Politik, 1801–1810* (Leipzig, 1877); *Die Finanzen Oesterreichs im 19 Jahrhundert* (Prague, 1877). *See* also AUSTRIA.

**STADIUM,** the Latin form of a Greek word for a standard of length. A stade = 100 *ὀργυιαί* (about 6 ft. or one fathom) = 6 *πλέθρα* (100 Greek or about 101 English feet) = about 606 English feet, or about one-eighth of a Roman mile. The course for the foot race at Olympia was exactly a stade in length, and thus the word for measurement became transferred first to the race and then to the place in which it was run. In modern usage stadium is one of several words applied to a large construction which combines space for games and seats for spectators, such as those erected for football. The Greeks built one of the first at Olympia, for the famous games held there. The Romans built several types of structures for similar purposes: circuses, amphitheatres, also called arenas; and naumachia, which could be flooded for naval engagements. The most famous of the Roman amphitheatres was the Colosseum at Rome. (*See* AMPHITHEATRE; ARENA.)

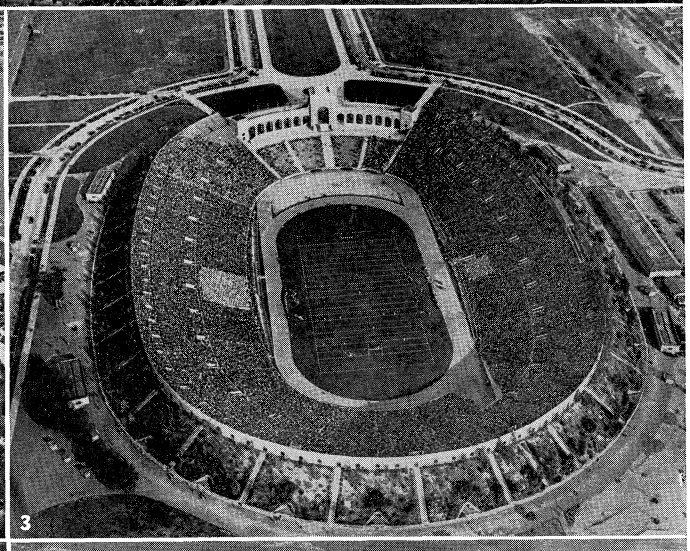
Sports played a minor role in men's lives for many centuries after the fall of Rome, and it was not until modern times that permanent stadia were again needed. In the interim temporary stands such as those built from time to time in the Place des Vosges in Paris for jousting sufficed. An exception should be made of the court of the Belvedere in the Vatican, built in 1500 by Bramante. There the terraces were arranged to accommodate spectators when tournaments were held.



During the 19th century systematic physical exercise was revived. This led to organized athletics, which became as popular as in ancient Greece. Hence the building of large permanent stadia was also revived. The first important stadium of modern times was the reconstruction, in Athens in 1896, of an ancient marble one built about A.D. 170 by Herodes Atticus on the site of a still earlier Greek circus. It seated 66,000 persons, and was undertaken for the first of the modern series of Olympic games.

Although a few other stadia were built before 1900, such as arenas for bullfighting in Spain and Mexico, the great era of modern stadia building was the early 20th century, which by 1930 had seen the construction of more stadia than in any other equal period. In the United States alone more than 100 large stadia had been built. The early 20th century also witnessed the development of a new type of stadia, unknown to the ancients and made possible by modern building techniques, the indoor stadium. This type, completely enclosed and lighted by electricity, could be used night and day the year around. The first important one was the old Madison Square Garden, built in New York city in 1890. It was replaced in 1925 by another of the same name seating 18,000. Others were built in London and Chicago. The Chicago stadium was the largest indoor stadium in the world in 1944. This type was flexible enough to be used for all court sports including those held on ice, and also for public meetings such as conventions, circuses and even concerts.

After 1930 fewer large stadia were built, not only because of the economic depression, but because there were so many in existence, and also because the era of spectator sports had apparently reached a peak, while the popularity of participating sports was increasing. The fascist countries were an exception, however, as great sports fields, of which a large stadium was a feature, were built there during the 1930s.



The following data illustrate the phenomenal increase in stadium building after 1900. Whereas in 1913 there were only 5 large stadia in the United States, by 1930 there were more than 100. During the decade of the 1920s alone 18 huge stadia, each seating more than 50,000 spectators, were erected. Most of these were built for college athletic contests, particularly football. Others were built by private or municipal funds. Four of the largest stadia in the world were built in the United States. The Los Angeles Colosseum, built in 1923, was enlarged in 1932 to accommodate 125,000 persons and renamed the Los Angeles Olympic stadium. The Philadelphia Municipal stadium, built in 1926 for the Sesquicentennial exposition, held 130,000. The Cleveland Public stadium, built in 1931, held over 100,000. In Chicago, Soldier Field, opened in 1926, had permanent seating for 125,000 and could be extended to accommodate more than 200,000. Thus Chicago had the largest permanent stadium of modern times.

## STADIUMS IN THE UNITED STATES

1. The Yale Bowl, first used in 1914, covers 25 acres, has 30 entrances and seats approximately 80,000. Photograph taken just before the start of a Yale-Army game
2. Soldier field, Chicago, with a seating capacity of about 200,000, built as a result of the enormously increasing public interest in sports of various types. Opened in 1926
3. Olympic stadium, Los Angeles, enlarged in 1932 to hold 125,000 spectators. Used for sports contests, concerts and productions of various kinds
4. Chicago stadium, Chicago, largest indoor stadium in the world. The stadium, built in 1928, has a seating capacity of approximately 20,000
5. Ohio State University stadium at Columbus, Ohio, accommodating about 75,000 spectators. The horseshoe shape is a distinctive feature of this stadium. Architect, Howard Dwight Smith; engineer, Clyde T. Morris; built in 1922

## STADIUMS OF EUROPE

The construction of the huge stadium at Athens in 1896 for the revival of the Olympic games, and the subsequent increase of interest in sports throughout Europe, have resulted in the building of many large stadiums and the reconstruction of others

1. Lyon stadium in the old city of Lyon, France, built in 1920
2. Stadium completed in Athens in 1896 for the holding of the Olympic games. There are seats for more than 66,000 spectators
3. Paris, Colombes stadium, strictly practical design, constructed for the Olympic games of 1924
4. Stadium at White City, Shepherd's Bush, London, erected in 1908 for Olympic games
5. "Les Arènes," ancient amphitheatre at Nîmes, France. About 2,000 persons were living within its walls in 1809 when it was cleared by order of the prefect. It is now restored and used as a stadium. Photograph shows a bullfight in progress
6. Helsinki stadium built for the XIIth Olympiad which was to be held in 1940 and was cancelled by the outbreak of World War II. A dramatic expression of modern construction

**Olympic Stadia** have been among the most impressive of stadia. Nearly every country in which the games were held erected a great permanent stadium for the event. The first stadium of the modern type providing for the full range of the modern program of Olympic events, which is much expanded over its classic prototype, was that built in London, at Shepherd's Bush, in 1908 for the IVth Olympiad.

It provided a cinder track, one-third of a mile long, which bounded a turf area for field events 235 yd. by 99 yd. There was also a pool for swimming events, with sufficient depth for diving, and a cycle track. The stands, part of which were roofed, accommodated 50,000 seats. Other Olympic stadia of interest were the Stockholm one of 1912; the severely simple one at Colombes, near Paris, built in 1924; the handsome brick one built at Amsterdam in 1928; and most elaborate of all, that built in Berlin in 1936, for the XIth and last Olympiad to be held before war broke out in 1939.

The nazi government erected the most extensive facilities for sport the world had ever seen. The large stadium, seating 100,000, was only one of several stadia in the group. The group as a whole was of a sombre, brutal massiveness.

The Berlin sports field just described was but one of many great sports fields each with one or more stadia built by the nazis and fascists during the 1930s. These were part of the program to develop strong youth for the future armies. In this respect they were unlike the stadia of the 1920s which had no ulterior purpose. The fascist stadia were also adaptable for party congresses.

The *Deutsche Stadion,* Nürnberg, 1937, was the most colossal. Its large scale and enormous extent, almost double the capacity of the Roman Circus Maximus (reputed to be 225,000), gave a solemn dignity to the ceremonies staged in it.

**Plans.**—The shapes of stadia have varied widely, reflecting the variety of uses for which they have been built. Some were designed for one sport only, such as the Yale Bowl, built in 1914, with a capacity of 80,000, the first modern one to surpass the capacity of the Colosseum. Like its Roman predecessor it is a closed ellipse in plan. The Harvard stadium, built in 1912, was U-shape, open at one end to permit both football and track events. Others have been built to permit baseball as well. Those built for Olympic games have generally been rectangular to enclose a large playing field, and with rounded corners for the track, as in Berlin, 1936. The horseshoe shape has also been used as at Ohio State university in 1922. The most flexible shape was that providing two parallel stands, opposite each other, with the narrow ends open. Some of this type have been built with superimposed tiers of seats, others with crescent-shaped stands (Northwestern university, 1926) so that as many seats as possible were opposite the centre of the field. Still other types have been used for special purposes, such as the Yankee stadium, New York city, 1923, built primarily for baseball, and Forest Hills, Long Island, built for tennis.

**Structure.**—The building of large stadia in the early 20th century was stimulated by the invention of the automobile and the new material-reinforced concrete. This material is relatively cheap for large structures, but has not proved entirely satisfactory in temperate climates as it weathers badly. Nevertheless, in the hands of skilful engineers and careful workmen, especially in Europe, magnificent stadia have been built in reinforced concrete which daringly exploited the potentialities of the material. Some of the fine examples follow: Lyon, built in 1920 by Tony Garnier. Florence, the Giovanni Berta stadium, built in 1933 with fantastic external stair towers expressionistic in style. Bordeaux, built in 1939, remarkable for a roof of graceful arched sections. Helsinki, built for the XIIth Olympiad which was cancelled by the outbreak of war in 1939. The bold tower there was a striking feature. Projects have been designed, though not executed, making use of other structural forms, such as one by Le Corbusier with a roof constructed as the wings of aeroplanes are constructed. Eventually, making use of war-inspired scientific advances, it may be possible to build large stadia completely weatherproof.

(C. L. V. M.)

**STAËL, MADAME DE.** ANNE LOUISE GERMAINE NECKER, BARONNE DE STAËL-HOLSTEIN (1766–1817), French novelist and miscellaneous writer, was born at Paris on April 22, 1766. Her father was the famous financier Necker, her mother Suzanne Curchod, almost equally famous as the early love of Gibbon, as the wife of Necker himself, and as the mistress of one of the most popular salons of Paris. The future Mme. de Staël was from her earliest years a romp, a coquette and passionately desirous of prominence and attention. She was a plain child and a plainer woman, whose sole attractions were large eyes and a buxom figure. She is said to have written her father a letter on his famous *Compte-Rendu* and other matters when she was not fifteen, and to have injured her health by excessive study and intellectual excitement. There is no doubt that her father's dismissal, and the consequent removal of the family from the busy life of Paris, were beneficial to her. During part of the next few years they resided at Coppet, her father's estate on the Lake of Geneva, which she herself made famous. They returned to Paris, or at least to its neighbourhood, in 1785, and Mlle. Necker resumed literary work of a miscellaneous kind, including a novel, *Sophie,* printed in 1786, and a tragedy, *Jeanne Grey,* published in 1790. She married Eric Magnus, Baron of Staël-Holstein, who was first an attaché of the Swedish legation, and then minister. For a great heiress and a very ambitious girl the marriage scarcely seemed brilliant, but the king of Sweden promised the ambassadorship for twelve years and a pension in case of its withdrawal, and the marriage took place on Jan. 14, 1786. The husband was thirty-seven, the wife twenty. Mme. de Staël was accused of extravagance, and after 11 years (1797) an amicable separation of goods was arranged. There was no scandal between them; the baron obtained money and the lady obtained, as a guaranteed ambassadress of a foreign power of consideration, an established position. In 1788 she appeared as an author under her own name (*Sophie* had been already published, but anonymously) with some *Lettres sur J. J. Rousseau.* She stood at this time for a mixture of Rousseauism and constitutionalism in politics. She visited Coppet once or twice, but for the most part in the early days of the revolutionary period she was in Paris taking an interest and, as she thought, a part in the councils and efforts of the Moderates. At last, the day before the September massacres, she fled from France, befriended at this critical juncture by Manuel and Tallien.

She betook herself to Coppet, and there gathered round her a considerable number of friends and fellow-refugees. In 1793 she visited England, and established herself at Mickleham in Surrey as the centre of the Moderate Liberal emigrants—Talleyrand, Narbonne, Jaucourt and others. In the summer she returned to Coppet and wrote a pamphlet (*Réflexions sur le procès de la reine*) on the queen's execution. The next year her mother died, and the fall of Robespierre opened the way back to Paris. M. de Staël (whose mission had been in abeyance and himself in Holland for three years) was accredited to the French republic by the regent of Sweden; his wife reopened her salon and for a time was conspicuous in the motley and eccentric society of the Directory. She also published several small works, the chief being an essay *De l'Influence des passions* (1796), and another *De la Littérature considérée dans ses rapports avec les institutions sociales* (1800). It was during these years that Mme. de Staël was of chief political importance. Benjamin Constant, whom she first met at Coppet in 1794, had a very great influence over her, as in return she had over him. Both personal and political reasons threw her into opposition to Bonaparte. Her own preference for a moderate republic or a constitutional monarchy was quite sincere, and, even if it had not been so, her own character and Napoleon's were too much alike in some points to admit of their getting on together. For some years, however, she was able to alternate between Coppet and Paris without difficulty, though not without knowing that the First Consul disliked her. In 1797 she, as above mentioned, separated formally from her husband. In 1799 he was recalled by the king of Sweden, and in 1802 he died, duly attended by her. They had three children: Auguste-Louis, Albert and Albertine, who married Victor, duc de Broglie.

The exact date of the beginning of what Mme. de Staël's admirers call her duel with Napoleon is not easy to determine. Judging from the title of her book *Dix années d'exil,* it should be put at 1804; judging from the time at which it became pretty clear that the first man in France and she who wished to be the first woman in France were not likely to get on together, it might be put several years earlier. In 1802 she published the first of her really noteworthy books, the novel *Delphine.* In 1803 she returned to Paris. She was directed, by order of Napoleon, not to reside within forty leagues of Paris, and after considerable delay she set out, in company with Constant, by Metz and Frankfort to Weimar, and arrived there in December. There she stayed during the winter and then went to Berlin, where she made the acquaintance of August Wilhelm Schlegel, who afterwards became one of her intimates at Coppet. Thence she travelled to Vienna, where the news of her father's death (April 8) reached her.

She returned to Coppet, and found herself its wealthy and independent mistress, but her sorrow for her father was deep and certainly sincere. She spent the summer at the château with a brilliant company; in the autumn she journeyed to Italy accompanied by Schlegel and Sismondi, and there gathered the materials of her most famous work, *Corinne.* She returned in the summer of 1805, and spent nearly a year in writing *Corinne;* in 1806 she broke the decree of exile and lived for a time undisturbed near Paris. In 1807 *Corinne,* the first aesthetic romance not written in German, appeared. It is in fact, what it was described as being at the time of its appearance, "a picturesque tour couched in the form of a novel." The publication was taken as a reminder of her existence, and the police of the empire sent her back to Coppet. She stayed there as usual for the summer, and then set out once more for Germany. She was again at Coppet in the summer of 1808 (in which year Constant broke with her, subsequently marrying a German lady) and set to work at her book, *De l'Allemagne,* which occupied her for the next two years. She decided to publish the book in Paris. The submission to censorship which this entailed was sufficiently inconsistent and she wrote to the emperor one of the unfortunate letters, at once undignified and provoking, of which she had the secret. The reply to her letter was the condemnation of the whole edition of her book (ten thousand copies) as "not French," and her own exile from France. She retired again to Coppet, where she was not at first interfered with, and she found consolation in a young officer of Swiss origin named Rocca, twenty-three years her junior, whom she married privately in 1811.

The operations of the imperial police in regard to Mme. de Staël are rather obscure. She was at first left undisturbed, but by degrees the château itself became taboo, and her visitors found themselves punished heavily. Mathieu de Montmorency and Mme. Récamier were exiled for the crime of seeing her. On May 23, she left Coppet almost secretly, and journeyed by Bern, Innsbruck and Salzburg to Vienna. There she obtained an Austrian passport to the frontier, and, after some trouble, receiving a Russian passport in Galicia, she escaped from Napoleonic Europe.

She journeyed slowly through Russia and Finland to Sweden, making some stay at St. Petersburg, spent the winter in Stockholm, and then set out for England. Here she received a brilliant reception and was much lionized during the season of 1813. She published *De l'Allemagne* in the autumn, was saddened by the death of her second son Albert, who had entered the Swedish army and fell in a duel brought on by gambling, undertook her *Considérations sur la révolution française,* and when Louis XVIII. had been restored, returned to Paris. She was in Paris when the news of Napoleon's landing arrived and at once fled to Coppet, but a singular story, much discussed, is current of her having approved Napoleon's return. There is no direct evidence of it, but the conduct of her close ally Constant may be quoted in its support, and it is certain that she had no affection for the Bourbons. In October, after Waterloo, she set out for Italy, not only for the advantage of her own health but for that of her second husband, Rocca, who was dying of consumption. Her daughter married Duke Victor de Broglie on Feb. 20, 1816, at Pisa. The whole family returned to Coppet in June, and Byron now frequently visited Mme. de Staël there. Despite her increasing ill-health she returned to Paris for the winter of 1816–1817, and her salon was much frequented. She died on July 14, 1817.

Baron Auguste de Staël (d. 1827) edited the complete works of his mother in seventeen volumes (Paris, 1820–21), with a notice by Mme. Necker de Saussure, and the edition was afterwards republished in a compacter form, and, supplemented by some *Oeuvres inédites,* is still obtainable in three volumes, large 8vo (Didot). The *Considérations* and the *Dix années d'exil* had been published after Mme. de Staël's death. Some *Lettres inédites* to H. Meister were published in 1903. There is no recent reissue of the whole, and the minor works have not been reprinted, but *Corinne, Delphine* and *De l'Allemagne* are easily accessible in cheap and separate forms. Of separate works on Mme. de Staël, or rather on Coppet and its society, besides those of MM. Caro and Othenin d'Haussonville, may be mentioned the capital work of A. Sorel in the *Grands écrivains français.* In English there are biographies by A. Stevens (London, 1880), and Lady Blennerhasset (1889).

G. de Cléron, *Mme. de Staël et M. Necker, d'après leur correspondance inédite* (1925).

**STAFF, MILITARY.** It was not until the time of Cromwell and his "New Model Army" that we find anything comparable to our modern staff system. The organization of the staff of the "New Model Army" was based on that of the Brandenburg army of Gustavus Adolphus, the forerunner of the Prussian staff of later years. It bears little resemblance to the extensive and specialized staff organization of to-day, but was a great improvement on anything which had preceded it and was well suited to the small numbers and narrow battle fronts with which it had to deal. It consisted of a headquarters under a "Sergeant-Major-General" as chief of staff, and an administrative staff for each of the three commands, infantry, cavalry and train. It contained nothing corresponding to our present organization of a general staff responsible for the preparation of plans and the formulation of orders.

At the beginning of the 18th century and during the War of the Spanish Succession the increasing size of armies rendered it impossible for the commander-in-chief to exercise personal control over the whole of his forces. It was therefore found necessary to decentralize command by the grouping of units into permanent fighting formations called "brigades." At the same time the organization of the staff began to develop as a means of co-ordinating the action of these formations. Marlborough remodelled Cromwell's system and gave to his chief of staff, the "Quartermaster General," wider scope and greater responsibility than had his predecessor, the "Sergeant-Major-General," including administrative arrangements, reconnaissance and the collection of information. A large staff of aides-de-camp and gallopers was employed to convey orders on the battlefield, but these were not staff officers in the modern sense: they were rather the forerunners of our present signal service for the transmission of orders.

In 1760 during the Seven Years' War (1756–1763) Frederick the Great instituted the Prussian new academy and organized a body which he called the "Quartermaster General's Staff"; this latter was primarily responsible for the duties of preparing plans of fortifications and collating and publishing topographical information. The French, following the tendency to further decentralization of command, introduced the divisional organization, afterwards developed by both Wellington and Napoleon.

**The Napoleonic Period.**—The increase in the size of armies in the Napoleonic wars led to greater sub-division in organization and still wider decentralization of command. Wellington created a staff organization consisting of three branches, the Quartermaster General's dealing with administration, movements, fortification, topography and intelligence, the Military Secretary's dealing with correspondence of a confidential nature and the Adjutant General's dealing with personnel. The Quartermaster General still acted as chief of staff though as such his functions were limited, because Wellington, like Napoleon, was to a large extent his own chief of staff requiring no advice, but merely the machinery to convey orders and arrange routine.

The staff system used by Napoleon was designed by Louvois in 1687 and adapted in 1796 by Berthier, his chief of staff, to Napoleon's special requirements: it was organized as a writing staff, a fighting staff and a riding or liaison staff. Napoleon himself controlled the preparation of plans, reconnaissance and movements, and the conduct of operations; his autocratic military genius required only a confidential clerk of mechanical perfection and reliability, such as was Berthier, to complement it, and he had no use for a chief of staff, as we understand that term. Napoleon's orders were usually issued in the form of instructions which he expected his generals to carry out in the spirit of his intentions; his control was much less rigid than that of Wellington, whose problem was a more limited one and who was also characteristically more chary of decentralization. Napoleon's army, corps and divisional staffs, like Wellington's, consisted chiefly of aides-de-camp of various grades whose principal duty it was to convey orders on the battlefield and also between theatres of war: one such aide-de-camp rode with despatches from Salamanca to Moscow, a distance of over 2,000 m. They were sometimes given command of troops and appointed to govern provinces.

In the Prussian army, on the other hand, marked progress was made towards the realization of a modern staff system, following the defeat by Napoleon at Jena and the Treaty of Tilsit. Scharnhorst in his reorganization of Prussia's military forces was faced by a new problem; the total strength of these forces had been limited by Napoleon to 42,000 men and to circumvent this restriction it was necessary to resort to a short service system which provided large reserves of trained men for the expansion of the army in war. This new idea of a national militia required a highly trained staff to organize and train the man-power of the nation in peace and to mobilize it in war: with what success the demand was met is shown in the victories of 1864, 1866 and 1870. The Congress of Vienna in 1815 ended a period of 20 years of war and was followed by 40 years of peace in Europe, an era of military stagnation. In England no development resulted from the experience gained in continental campaigns and the country was glad to be quit of things military; in fact Wellington only preserved the nucleus of an army by keeping it abroad and out of sight as far as possible.

The Crimean War of 1854 found the British army, in consequence, unprepared and ill-organized. In 1857 a Council of Military Education was set up under the presidency of the commander-in-chief, the Duke of Cambridge; one of its first tasks was to study and define the qualifications necessary for a staff officer. This was followed by the creation of a Staff College with competitive examination as a condition of entrance, the first examination being held in February 1858 and the first course starting in April of that year.

**Lessons of 1866 and 1870.**—The successes of Prussia in the wars of 1866 and 1870 emphasized the importance of staff work. The development begun under Scharnhorst and Gneisenau had been continued by Clausewitz, Roon and Von Moltke; the latter became Chief of Staff in 1858 and to him is mainly due the organization and training of the Prussian staff of 1866 and 1870. Scharnhorst's rule to the effect that staff officers must return periodically to regimental duty had been adhered to, and this, combined with a sound system of training, had produced a common doctrine throughout the army, which added greatly to its strength and efficiency in war through co-operation and economy of effort.

In France on the other hand there had been a reaction after the Napoleonic wars similar to that which had taken place in England, and the lessons of those wars were neglected. In 1818 an "École d'Etat-Major" was founded, but it provided instruction in the routine of staff duties only, combined with nothing of a higher nature. Officers entered it direct from St. Cyr and the Polytechnique (corresponding to the British Royal Military College and Royal Military Academy) and passed thence to the Staff Corps with which they remained for the rest of their service, a narrow-minded corps apart and out of touch with the troops. Another factor drawing French military thought in a false direction was the conquest of Algeria begun in 1830, a small war against a savage enemy. This kind of fighting came to be considered as typical of all war and the mental outlook and training of the French commanders and staff officers were restricted accordingly. Thus Napoleon had organized corps and grouped corps into an army, but in 1870 the idea of an army did not exist. Napoleon before the battle of Jena in 1806 had moved six corps by three roads at twenty miles a day, billeting in depth; but in 1870 the French corps marched as in savage warfare, closing up on the head at the end of the march, the rate of movement being reduced in consequence to eight miles a day. But fortunately for France there were young men of ability and foresight serving in the army of 1870 and they determined to discover the real cause of the disaster. These men were Bonnal and Lanrezac serving as subalterns, Foch a private in the ranks, and Maillard, later famous for his tactical teaching. They studied deeply the campaigns of Napoleon, and showed how he had applied the principles of war. In 1880 the "Corps d'Etat-Major" was abolished and the "École de Guerre" or Staff College was founded, Maillard being the first professor of strategy. It was recognized that the successes achieved by the Prussians in the wars of 1866 and 1870 had been largely due to their staff organization and training; this led to the adoption, during the last quarter of the nineteenth century, of similar systems by all the military powers except Great Britain and the United States of America.

**British Reorganization.**—In 1895 the Duke of Cambridge resigned his post of commander-in-chief, and the concentration of military responsibility vested in him was dissipated, leaving the new commander-in-chief, Lord Wolseley, with little authority beyond what was involved in the vague term "general supervision." The supreme management of the affairs of the army devolved upon the Secretary of State for War assisted by several officers of equal status *inter se*. But in 1896 a step forward was taken by the formation of the Defence Committee of the Cabinet, which later became the Committee of Imperial Defence.

After the South African war a special committee, known as the "War Office Reconstitution Committee" was set up in 1903 with Lord Esher in the chair. This committee found that the lack of a trained general staff and the fact that some of the most important duties of such a staff were not assigned to any body of officers gravely prejudiced the conduct of operations in South Africa, and that it therefore attached extreme importance to the constitution of a general staff.

The Committee also advocated the abolition of the office of commander-in-chief instituted by the Duke of York in 1795 and its replacement by a Chief of the General Staff and an Army Council, whose function it would be to control and administer the army in accordance with the policy of the government and to act in an advisory capacity to the Secretary of State for War. These recommendations were adopted, and in February 1904 Lord Roberts, the commander-in-chief, retired and the new Army Council came into being. Its first task was the creation of a general staff charged with the duties of advising on the strategical distribution of the army: supervising its training and preparation for war; collecting and collating military intelligence; directing the general policy of the army and securing continuity of action in the execution of that policy. And so for the first time in British military history the staff became a well balanced organization with two clearly defined functions: on the one side the preparation of plans, training and conduct of operations dealt with by the general staff, and on the other the supply of personnel and material, medical arrangements, transportation and quartering dealt with by the administrative staff which also controls the necessary services such as the R.A.S.C., ordnance, medical and veterinary services. But it is important to note that, although the work is divided into separate branches, there is but one staff with a single purpose, namely to assist the commander when framing his plan and the troops and services in carrying it out. The division of staff duties under the two main heads of operations and administration is now the key-note of the British system.

In 1904, in accordance with another and very important recommendation of the Esher Committee, the Defence Committee of the Cabinet was reconstituted as the Committee of Imperial

Defence, whose function it was to act in an advisory capacity to the government, ensure continuity of policy and co-ordinate the work of all government departments concerned in national defence. Prior to the formation of the Committee of Imperial Defence there existed no precedent for the formation of a council of war, or any standing advisory body to assist the Cabinet in time of peace in matters of national defence. An Imperial Defence Conference was held in 1909 at which it was decided that the general staff at the War Office should be made responsible for advising the government on all matters connected with the defence and military preparation of the Empire as a whole; the Chief of the General Staff became Chief of the Imperial General Staff responsible for the preparation of plans and estimates of the imperial forces required to give effect to these plans.

Following the report of the Esher Committee the staff system was modernized and developed, with the result that at the outbreak of the World War the task of mobilizing the expeditionary force and despatching it to France was carried out with extraordinary smoothness and efficiency. In the field also the new system stood the test and strain of war very well in spite of the difficulty of meeting the demands of the largely expanded army. But, as regards the higher direction of the war, matters did not proceed so smoothly. In its conception in 1904 the Imperial General Staff was designed to have responsibility for providing the government with advice; it was however at first mainly occupied in shaping a policy for the direction of affairs within the army itself and thus failed to study at all adequately its main function in relation to the supreme direction of imperial military policy.

**Lessons of the World War.**—The resultant lack of co-ordination as between policy and strategy led to great wastage of effort and man-power, and resort to improvisation in the machinery for the direction of the war. To avoid similar mistakes in future it is necessary that there should be a clear definition and understanding of the respective functions of the statesman and his military advisers. Since the Cabinet alone is qualified to co-ordinate and direct the whole strength of the nation in war, it follows that it must exercise the supreme control. The duty of the head of the government is to formulate policy and to ensure that that policy is suited to available means. The duties of the chiefs of the navy, army and air force are to prepare plans for the execution of the policy of the government, to act as professional advisers and to issue the orders required for carrying out the accepted plan; whilst the co-ordination of plans is now provided for in the Chiefs of Staff Sub-Committee of the Committee of Imperial Defence.

Germany also experienced serious difficulties in regard to the supreme direction of the war owing to the fact that the Kaiser was the nominal commander-in-chief of the army and as such took the field. The result of this was that the machinery for the central control of the war became situated at general headquarters on the western front where it could not work effectively in co-operation with the government, whilst it necessitated headquarters themselves being placed too far from the front to be able to control operations. The growth of armies had long rendered the government of a state, whether vested in a sovereign or exercised through other channels, incapable of direct command and even of formulating a military policy; hence the necessity for a professional head of the military executive who could function for the government in adapting the military to the national policy. So long as war was confined to a single theatre and small armies, the professional head might also exercise command in the field, as did von Moltke in practice in 1866 and 1870. When, however, war is waged simultaneously in more than one theatre and by nations in arms, a further expansion in organization is essential.

The study of the broad aspects of the German staff organization and its functions during the World War leads to the following conclusions. The central government must have in immediate touch with it a professional military executive responsible for controlling military policy both as regards plans and the provision of means in men and material to execute those plans. This military executive must implement a policy formulated on the advice of a single individual, whether he be called chief of staff or commander-in-chief. But in each theatre of war there must be a separate commander-in-chief who is in executive control of such forces as are placed at his disposal, and who regulates his action in accordance with the instructions he receives from the central authority. The staff of the commander-in-chief in each theatre of war must be organized in branches corresponding to those of the central staff organization and in direct touch with them in so far as this does not militate against the control exercised by the commander.

**Special British Problems.**—Continental nations have very clearly defined problems to deal with and can therefore prepare detailed plans and an organization to execute them. With the British, however, it is not possible to do more than provide for the detailed organization of the central authority at home which exists in peace and should not require any change in war; the detailed composition and organization of command and staff in the field must be dependent upon the particular conditions of operations which cannot usually be foreseen. Consequently the system must be such as to be easily adaptable to whatever demands may be made upon it.

That the organization of the British staff in the field during the World War was sound in principle is shown by the fact that it was not necessary to make any material changes in spite of the enormous expansion of the army and the imposition of new duties through the remarkable progress of modern science as applied to war. This organization consisted at general headquarters of a staff divided into three branches, the General Staff branch under a chief of the general staff dealing with operations, intelligence and training, the Adjutant-General's branch dealing with personnel, discipline and the medical service and the Quartermaster-General's branch dealing with supply and transport. Each of these principal staff officers had the right of direct access to the commander-in-chief in all matters appertaining to his branch, whilst the Chief of the General Staff was responsible for co-ordinating the work of the three branches in accordance with the policy laid down by the commander-in-chief. The same system was applied in lower formations except that the functions of the Adjutant-General and the Quartermaster-General were combined in one staff officer.

The alternative to this system is that adopted in other armies including those of the United States of America, France, Germany and Japan, namely a chief of staff responsible not only for co-ordination of the work of the various branches of the staff, but also for its execution. The objections to this system are that the chief of staff becomes a "bottle-neck" prejudicing the right of access to the commander of branches and departments and forced to devote a great deal of his time and attention to administration at the expense of operations and training. The advantages claimed for it are that the commander-in-chief has only one staff officer with whom he deals direct, instead of three or four, as in the British system; and, since the army cannot fight without supplies, that the chief of staff is responsible for both operations and maintenance; in practice, however, there is an inevitable tendency for him to become overloaded with detail.

It will be seen therefore that there is a fundamental difference between the British staff system and that of other armies; in the former, operations and administration are dealt with separately, whereas in the latter they are combined under a chief of staff. Judged by experience, the British system by which the senior staff officer in each branch has direct access to the commander and the senior general staff officer is responsible only for co-ordination of the work and not for its execution, is the one best suited to British requirements and temperament; and that it can be applied successfully was amply proved in the World War; where failures occurred, as in Mesopotamia and Gallipoli, they were due to non-observance of the principles of staff organization rather than to any fault in the scheme of organization itself.

**The control** of the British Army is vested in the Army Council, headed by the civilian Secretary of State for War. The military members are the Chief of the Imperial General Staff, the Vice-Chief of the Imperial General Staff, the Adjutant-General, and

the Quarter-Master-General. In time of peace the Director-General of the Territorial Army is also a member. The Chief of the Imperial General Staff, with the Vice-Chief acting for him in his absence, is charged with the responsibility for operations, intelligence and training, and is adviser to His Majesty's Government in all questions of military policy affecting the security of the Empire. The Adjutant-General is charged with recruitment and mobilization, with discipline, military law and medical service, and with all questions of personnel. The Quarter-Master-General is responsible for the housing of the army, the construction of all fortifications and buildings, and the provision of all water, motor and land transportation. The Deputy Master-General of the Ordnance is no longer a member of the Army Council. While he is still responsible for the design, research and inspection of warlike munitions, his principal functions were all taken from him upon the transfer in 1939 to the independent Ministry of Supply of all responsibility for the manufacture and purchase of supplies and munitions for the army.

A British commander-in-chief in a theatre of operations, such as the British Expeditionary Force, is provided with a staff, the principal officers of which are the Chief of the General Staff, the Deputy Adjutant-General, the Deputy Quarter-Master-General, and the Deputy Master-General of the Ordnance. The addition of the last-named officer was occasioned in large part by the requirements of the extensive motorization and mechanization in the British Army since 1918. The General Staff Branch deals with the employment of the fighting troops, and with all matters connected with the actual execution of military operations. The three other branches deal with the maintenance of troops in the theatre of war, each generally having the same scope of responsibility as the respective branches in the War Office, except that the Deputy Master-General of the Ordnance is charged with the supply and repair of artillery, small arms, ammunitions, tanks and similar munitions. The chiefs of these three maintenance branches correspond directly with their corresponding branches in the War Office and in the lower echelons of command. As before, the heads of all branches have direct access to the commander-in-chief.

In Great Britain the Royal Air Force is a separate combat service, the control of which is vested in the Air Council in the Air Ministry. The military members of the Air Council are the Chief of the Air Staff, the Vice-Chief of the Air Staff, the Air Member for Personnel, the Air Member for Development and Production, and the Air Member for Supply and Organization. Their duties are generally indicated by their titles. Tactical commands of the Air Force are provided with air and administrative staffs based upon their special requirements.

## THE UNITED STATES

The President, by virtue of his office being commander-in-chief of the Army of the United States, exercises control thereof through the secretary of War, who, with the aid and advice of the chief of staff, is responsible for the efficiency of the military establishment. Under the secretary of War, command is exercised by corps area and department commanders, commanders of independent activities and commanders of the various tactical units. The staff does not exercise command. While the army had no general staff prior to 1903, it has invariably had an administrative staff, whose strength and composition have varied according to needs. Under the secretary of War and the various commanders, the administrative staff has performed staff duties pertaining to administration, inspection, discipline, supply, pay, medical attendance and sanitation.

Prior to 1903, the army was commanded, under the secretary of War, by the commanding general of the army. His command did not extend to the supply departments, and the chief of each supply department reported directly to the secretary of War. There was no officer nor body of officers charged with co-ordinating the work of the staff departments with the work of the line, nor was there any officer or body of officers whose principal duty it was to prepare plans for the national defence. The necessity for such a body of officers, charged primarily with co-ordinating and planning, was clearly demonstrated during the Spanish-American War, and, as a result, the act of Feb. 14, 1903, authorized the War Department general staff. Under its initial organization, it consisted of three divisions. From 1903 until 1917, as the result of the limited experience which could be gained in peace-time, many changes were made in the organization during its process of development. During the War of 1914–18, as necessity demanded, many further changes were made in it, and the present general staff, organized under the provisions of the National Defence Act of 1920, is the result of that experience.

The National Defence Act prescribes that the duties of the War Department general staff shall be to prepare plans for national defence and the use of the military forces for that purpose, both separately and in conjunction with the naval forces, and for the mobilization of the manhood of the nation and its material resources in an emergency, to investigate and report upon questions affecting the efficiency of the Army of the United States, and its preparedness for military operations; and to render professional aid and assistance to the secretary of War and the chief of staff. It is the agency for preparing the plans and policies under which the administrative and command agencies operate.

The chief of staff, the immediate adviser to the secretary of War on all military matters, heads the War Department general staff. He is charged by the secretary of War with planning, developing and executing the army's program for national defence. As the agent of, and in the name of the secretary of War, he issues orders to insure that the plans of the War Department are harmoniously executed by all branches and agencies in all components of the army.

The deputy chief of staff assists the chief of staff and acts for him in his absence. He is charged with supervision of the activities of the five divisions of the War Department general staff, each of which is headed by an assistant chief of staff.

The personnel division, known as G-1, prepares plans and policies and supervises activities that concern the officers and enlisted men of the army as individuals. These activities deal with procuring, classifying, assigning, promoting, paying, transferring, retiring and discharging, in peace and in war, all personnel of all components and training activities of the army. This division is also concerned with measures for conserving man power, with replacements of personnel, army regulations, uniform regulations, decorations, religious and recreational work, co-operation with the Red Cross and similar organizations except for medical care and hospitals, regulations concerning enemy aliens, prisoners of war and other matters.

The military intelligence division, known as G-2, has duties that relate to collecting, studying, analyzing and furnishing all kinds of military information. It supervises army activities dealing with military surveys, maps and photographs, codes and ciphers, and translations. Military attachés, observers, foreign-language students and intelligence personnel of all army units, are other matters dealt with by this division. It also directs a public relations branch which prepares and issues War Department press releases and handles other matters concerning relations with the press and with the public at large.

The operations and training division, known as G-3, is charged, in general, with planning and supervising activities with regard to the organized training and operation of the military forces, except for those matters expressly assigned to the war plans division. Other activities dealt with by this division are the location of units of the regular army and the organized reserves, educational and vocational training, training regulations, the special and general service schools, military training in civilian institu-

tions and in civilian training camps, movement of troops, replacement priorities and military police.

The supply division, known as G-4, in general, has duties which relate to supplying the army, and to planning for all equipment, buildings, storage, transportation and distribution of supplies and for other facilities. This division is also concerned with traffic control, hospitalization and evacuation of sick and wounded men and animals, inventions, responsibility and accountability for army property, procurement of real estate, and construction and maintenance of buildings.

The war plans division is, in general, charged with duties relating to plans for the use of military forces in a war. It also supervises the location and armament of coast and land fortifications; and it estimates the military forces that would be required and the times at which they would be needed in all possible circumstances of national defence.

Visualizing, then, the War Department general staff outlined above as the apex of a pyramid formed by the staffs of subordinate units, the staff organization in the American army descends through corps areas, divisions, regiments and battalions. In the lower echelons, the staff sections may be combined and their functions performed by small groups or even individuals.

**STAFF, NAVAL.** All the principal navies of to-day have a body of officers specially charged with war plans, operations, intelligence and the policy to be adopted in such professional matters as training, design of warships, naval aircraft and armament.

In the British Navy the Naval Staff at the Admiralty (*q.v.*) consists of the Chief of the Naval Staff, who is the First Sea Lord, the Deputy Chief of the Naval Staff, the Assistant Chief of the Naval Staff, together with the directors and officers of the various staff divisions. The latter include: operations, plans, intelligence, trade, gunnery, torpedo, training and staff duties, together with the naval air and tactical sections.

At sea, the commander-in-chief has a staff which includes a chief of staff, captain of the fleet, staff officers for operations, gunnery, torpedo, signals, wireless, intelligence, aviation, physical training, engineering, accountancy, medical duties and education. Flag officers in command of divisions or squadrons have a smaller number of staff officers, certain duties being combined or omitted where they are carried out in the fleet flagship. In addition every admiral has a personal staff consisting of his flag lieutenant (A.D.C.) and secretary.

Previous to the World War, although Britain had the largest and most powerful navy of any nation and in consequence was regarded as being a leader in naval enterprise, both the Admiralty and the fleet were singularly deficient in a properly organised staff. This may be attributed in part to the influence of traditions emanating from the days of the sailing navy, when communications were slow and primitive and once an admiral was out of sight of land he was thrown entirely on his own resources and had to act as circumstances arose or as emergency rendered necessary.

Even in more modern times, unfortunately, a school of thought developed which was definitely antagonistic to the idea of a naval staff. As late as the outbreak of the World War there were to be found a number of flag officers of distinction who resented the suggestion that they could be assisted in the execution of their command by comparatively young officers who, it seemed to them, would be usurping some of the functions of an admiral.

The influence of this reactionary school of thought continued to dominate Admiralty policy in this matter until, in 1911, the matter was brought to a head by the discovery that the Admiralty had one lot of war plans and the War Office another, and that these were by no means attuned. In 1912, Winston Churchill, as First Lord, initiated the principle of a Naval Staff. The resignation of the then First Sea Lord, Admiral of the Fleet Sir Arthur Wilson followed. Incidentally this marked the end of the "one-man" régime. With his retirement, too, may be said to have disappeared the habit of intense secrecy, a habit which led to most dangerous ignorance of strategical plans and tactical intentions in the minds of those not in the innermost confidence of the high command.

In spite of the sound decision to create a naval staff, it could not be said that great progress had been made in this direction by August 1914. True there was a Chief of the Naval Staff, a Director of Operations, and from time to time, if the need arose, additional staff appointments were created, while at sea the commander-in-chief of the Grand Fleet and other admirals in important commands, had a number of officers on their staffs. But for the most part the officers in these Admiralty Departments and on the admirals' staffs at sea were untrained in staff work, while many flag officers, both ashore and afloat, had never learned how to use a staff. With traditional adaptability and with that ability to extemporise which comes from sea training, the navy met each and every emergency as it arose, sometimes successfully, but sometimes buying experience at great cost, until ultimately victory came. But one of the outstanding lessons of the World War from a naval point of view was the necessity for not only training officers to fill numerous minor staff appointments, but also to educate those destined for higher command in the use of a staff.

By 1928 the Naval Staff College at Greenwich was engaged in turning out year by year officers trained for duty on admirals' staffs at sea or for the lower staff appointments at the Admiralty, and already this training is beginning to make itself felt as Staff College graduates are beginning to reach more senior rank.

The old antipathy towards a naval staff has died down, and most flag officers to-day make use of their staffs as a matter of course in the same way that general officers in the army have done for many years past. At the Admiralty (*q.v.*) there is a fully-equipped staff, the head of which is the First Sea Lord (Chief of the Naval Staff), whose business it is to study the problems of defence and to prepare in advance for any emergencies which may arise. This staff also forms the nucleus of the far larger organisation which the World War proved to be necessary on the outbreak of hostilities. Incidentally, too, it provides the necessary machinery for close co-operation with the staffs of the other two fighting Services. The three professional heads of those Services meet from time to time as a Chief of Staffs Committee, where matters are discussed and joint proposals formulated in preparation, if need be, for meetings of the Committee of Imperial Defence (*see* NAVAL STRATEGY AND TACTICS).

Apart from its other advantages, the staff system, as it works to-day at the Admiralty, provides a body of officers whose energies are not absorbed by questions of material and supplies, these being dealt with by other departments. Nevertheless, even here there is the necessary co-ordination to ensure that plans, preparations, construction and supplies should march hand in hand.

(E. A.)

**United States.**—An act of Congress of Feb. 14, 1903, created a General Staff Corps and provided for the appointment of a Chief of Staff of the U.S. Army. No similar corps or Naval Staff has ever been authorized for the U.S. Navy, but an act of Congress of March 3, 1915, provided for the appointment of a Chief of Naval Operations specifically charged, under the direction of the Secretary of the Navy, with the operations of the fleet and with the preparation and readiness of plans for its use in war. In a general way the Chief of Naval Operations holds a position in the naval establishment corresponding to that of the Chief of Staff of the Army, but there are many and important differences in the duties and responsibilities of these two officers. The Chief of Naval Operations is appointed by the President by and with the consent of the Senate for a term of four years. The position carries with it the rank of admiral and precedence over all other officers in the naval service.

The Chief of Naval Operations is charged under the Secretary of the Navy with the organization, operation and training of the fleet and its readiness for war. He co-ordinates matters relating to repairs, alterations, docking, manning and outfitting of ships, and determines their military characteristics. He prepares war plans, drill books, signal codes and naval regulations. He directs movements, manoeuvres, strategical and tactical matters, drills and exercises. He advises on the position, capacity and protection of navy yards, naval stations, fuel reserves, radio stations and other reserves and supplies. He handles naval matters touching on foreign relations and performs other duties as set forth by naval regulations, or as directed by the Secretary of the Navy

In order to carry on the varied and detailed duties imposed on the Chief of Naval Operations his office is divided into a number of divisions or sections whose functions are indicated in a general way by their designations as follows: policy and liaison, war plans, naval intelligence, naval districts, fleet training, material, ships' movements, inspection, naval communications and secretarial. Each of these sections or divisions is headed by a flag officer or captain of the line of the Navy except the Secretarial Division which is in charge of the Chief Clerk of Naval Operations. A flag officer is detailed as Assistant Chief of Naval Operations. In addition to the immediate activities outlined above, the Chief of Naval Operations has general cognizance over the Naval War College at Newport, R.I., and is a member of the Joint Army and Navy Board, the Advisory Council of the Secretary of the Navy, and senior member of the General Board.

The Chief of Naval Operations is not the Chief of the General Staff in the sense that such an officer is found in the organization of certain other naval powers, although he performs many of the duties that would ordinarily fall to such an officer. For instance, the Chief of Naval Operations is not superior to the chiefs of bureaux and independent offices of the Navy Department, although he takes precedence over them by virtue of his rank. He is not, in fact, a link in the chain of command between the Secretary of the Navy and the chiefs of the various bureaux of the Navy Department who have the right, and freely exercise it, to consult the Secretary directly on matters concerning their bureaux, as well as to receive instructions directly from him.

When trying to compare the office of the Chief of Naval Operations with that of the U.S. War Department General Staff, it is to be remembered that the Chief of Naval Operations actually directs and controls the Navy and the larger part of his duties are administrative whereas the Chief of Staff of the Army acts largely in an advisory capacity.

The General Staff Corps of the Army is a separate and distinct staff organization whose officers are detailed to duty therein for a term of four years. General Staff officers may serve in the War Department General Staff or on the staff of commanders of troops. There is no similar corps in the Navy, the officers on duty in the Office of the Chief of Naval Operations and serving on the staffs of flag officers ashore and afloat being detailed to this duty in the same manner as to any other duty.

The differences between the staff organizations of army commanders in the field and of naval commanders afloat are even more marked than in the departmental organizations. Officers of naval staffs are usually selected by the flag officer whom they serve, any officer available and acceptable to the flag officer being eligible for such assignment. The number composing a staff depends primarily on the nature of the command, varying from one or more officers to as many as twenty. Quarters and office space required for staffs, being additional to that normally required for the ship's complement, are extremely limited. For this reason the size of a staff must be reduced to a minimum and, therefore, the assignment of duties to individual staff officers is governed to a very large degree by the personal qualifications of the various officers of the staff. This assignment of duties tends to obliterate clear-cut lines of demarcation between fixed divisions of staff cognizance and produces overlapping in the duties of individual officers. Close supervision and co-ordination of staff activities by the Chief of Staff and whole-hearted co-operation between staff officers is essential to the smooth and efficient performance of the work of a large staff. (C. F. H.)

**STAFFA** (Norse for staff, column, or pillar island), uninhabited island of the Inner Hebrides, Argyllshire, Scotland, 54 m. W. of Oban by steamer, about 7 m. from the nearest point of Mull, and 6 m. N. by E. of Iona. It lies almost due north and south, is $\frac{3}{4}$ m. long by about $\frac{1}{3}$ m. wide, and its highest point is 135 ft. above sea-level. In the north-east it shelves to a shore, but otherwise the coast is rugged and much indented with numerous caves. During the tourist season it is visited regularly by steamer from Oban. In section the isle has first a basement of tufa, from which rise, secondly, colonnades of basalt in pillars forming the faces and walls of the principal caves, and these in turn are overlaid, thirdly, by a mass of amorphous basalt. On the south-east coast is the Clam-shell or Scallop cave. It is some 130 ft. long, and on one side of it the ridges of basalt stand out like the ribs of a ship. Near this cave is the rock of Buachaille ("The Herdsman," from a supposed likeness to a shepherd's cap), a pile of columns, fully seen only at low water. On the south-west shore are the Boat cave and Mackinnon's or the Cormorants' cave. Fingal's cave, the most famous, situated in the southern face of the isle, is 227 ft. long. On its western side the pillars are 36 ft. high. The cave is the haunt of seals and sea birds.

**STAFFORD** (Family). This famous English house was founded in England by Robert, a younger brother of Ralf de Tosny (Toeni), of a noble Norman house, who was standard-bearer of the duchy. Robert received at the Conquest a great fief extending into seven counties and became known as Robert de Stafford from his residence at Stafford castle. With his son the male line became extinct, and his sister's husband, Hervey Bagot, one of his knightly tenants, succeeded to the fief in her right (1194); their descendant Edmund de Stafford (that surname having been assumed) was summoned as a baron in 1299. His son, Ralph, conducted the brilliant defence of Aiguillon against the host of France, fought at Crecy and in the siege of Calais. Chosen a Knight of the Garter at the foundation of the order, he was created earl of Stafford in 1351.

His son Hugh, who succeeded as 2nd earl in 1372, served in the French wars. From 1376 he became prominent in politics, probably through his marriage to a daughter of the earl of Warwick, being one of the four lords on the committee in the Good Parliament, and also serving on the committee that controlled Richard II. (1378–80), whom he accompanied on his Scottish expedition in 1385. He died next year on pilgrimage at Rhodes. His son, Thomas, the 3rd earl, married in 1392 the daughter and heiress of Thomas, duke of Buckingham (son of Edward III.), who, on Thomas's death, married in 1398 his brother Edmund, the 5th earl. Their son, Humphrey (1402–1460), the first Stafford duke of Buckingham, was placed by his descent and his possessions in the front rank of the English nobility.

Henry, the 2nd duke, was attainted in 1483, but on the triumph of Henry VII. in 1486 Edward, the 3rd duke (1478–1521), regained the title and estates, and recovered the ancestral office of lord high constable in 1509. He was accused of treason and, after a nominal trial by his peers, was beheaded on May 17, 1521, a subsequent act (1523) confirming his attainder.

Henry (1501–1563), the son of the last duke, was granted by the Crown some of his father's manors for his support, and, espousing the Protestant cause (though married to a daughter of Margaret, countess of Salisbury and sister of Cardinal Pole), was restored in blood on Edward VI.'s accession and declared Lord Stafford, as a new creation, by act of parliament. His second surviving son, Thomas, eventually assumed the royal arms, sailed from Dieppe with two ships in April 1557, landed at Scarborough, seized the castle, and proclaimed himself protector. He was captured and executed for high treason. His father's new barony, in 1637, passed to a cadet in humble circumstances, who was called on, as a pauper, to surrender it to the king, which he did (illegally, it is now held) in 1639. The king thereupon bestowed it on Mary Stafford (the heir general of the line) and her husband, William Howard, in whose descendants it is now vested. Roger, who had surrendered the title, died in 1640, the last heir male, apparently, of the main line of this historic house.

*See* Dugdale, *Baronage* (1675), vol. i.; G. E. C(okayne), *Complete Peerage;* Wrottesley, *History of the Family of Bagot* (1908) and *Crecy and Calais* (1898). The important Stafford mss. in Lord Bagot's possession are calendared in the 4th Report on Historical mss., and the Salt Arch. Soc.'s collections for the history of Staffordshire are valuable for early records. Harcourt's *His Grace the Steward and the Trial of Peers* (1907) should also be consulted. The bishop of Exeter's Register was edited by Hingeston-Randolph in 1886. *Papers relating to the two Baronies of Stafford* (1807), and Campbell's *The Stafford Peerage* (1818) are useful for the pedigree, and there are collections for a history of the family in Add. mss. (Brit. Mus.).

**STAFFORD,** market town, county town, municipal borough, Stafford parliamentary division, Staffordshire, England, on the river Sowe, a tributary of the Trent. Pop. (1938) 32,190. Area

7.91 sq.mi. An important junction on the L.M.S. railway and 132½ mi. N.W. from London, it is also served by the L.N.E. and G.W. railways. While largely modernized, it contains a number of picturesque half-timbered houses. The church of St. Mary, once collegiate, with its canons mentioned in Domesday, shows transitional Norman, Early English and Decorated styles. The complete foundation is attributed to King John. It contains a memorial to Izaak Walton (*q.v.*), a native. The older St. Chad's (much restored) has good Norman details. Since 1909 Stafford has been the seat of a bishopric suffragan in the diocese of Lichfield. The William Salt library, presented in 1872, has many local books and mss.

Stafford (*Stadford, Staffort, Stafforde*) is said to have originally been called Betheney from Berthelin, a hermit who lived there. In later Anglo-Saxon times Stafford contained a royal mint. It is a borough in Domesday Book, and the chief place in the county. The king received all dues, two-thirds as king, the other third as earl of Stafford. From the Domesday Survey it appears that the Conqueror built a castle at Stafford; this was destroyed in the wars of the 17th century. The existing ruin of Stafford Castle is that of an unfinished mansion (1810), which replaced the old stronghold. Beyond it is an early encampment, Bury Ring. A charter from John (1206) constituted Stafford a free borough. The staple industries are the manufacture of boots and shoes and engineering. The town was extended in 1934.

**STAFFORDSHIRE,** a midland county of England, bounded by Derbyshire, Leicestershire, Warwickshire, Worcestershire, Shropshire and Cheshire. The area is 1,154 sq.mi. The county may be divided into three geographical divisions, north, middle and south Staffordshire, depending on the geological structure. The highest land is in the north. Here the southern ends of the Peak folds bring up Lower Carboniferous rocks, with limestones in the north-east and the Pendleside shales and Coal-Measures forming four basins in the north-west and centre. The district is drained by the headwaters of the Trent and its tributaries the Dove, Hamps, Manifold and Churnet and shows a diversity of scenery, the limestone hills being domed and treeless, whilst the Pendleside shales form heather-covered moors, and the grit bands have bold scarp faces. Axe Edge (1,756 ft.), and the Roaches are the highest hills, being formed by Millstone Grit. The four coal-basins are the Pottery, Cheadle, Shaffalong and Goldsitch Moss coalfields. The last two are small and contain only the lowest coal-measures and are no longer worked. The Pottery and the Cheadle basins are more important and contain valuable seams of coal. The Bunter sandstones of the Cheshire plain overlap the coal-measures in the west of the Pottery basin.

Middle Staffordshire is a broad undulating plain, occupied by various members of the Triassic series and drained by the Trent. The plain is divided into an eastern and a western portion by Cannock Chase, formerly a royal preserve, now an important coalfield concealed beneath a cover of glacial sands and gravel which rest upon Bunter sandstone. The high ground rises to about 500 feet. The "Black Country" occupies the greater part of South Staffordshire. Here again the country is low and undulating covered on its margins by the Trias whilst in the middle lies the South Staffordshire coalfield, in which there are several small inliers of Silurian rocks which stand up above the surrounding country to a height of 800 feet. Most of the county is drained by the river Trent, a few streams drain into the Dane which flows into the Mersey, whilst a small area in the west and south-west forms part of the Severn drainage system. The only considerable sheet of water is Aqualate Mere on the Shropshire boundary.

Staffordshire is an important coal-mining county. The Southern coalfield has an estimated reserve of 1,415 million tons and the northern coalfields 4,460 million tons. The latter contains the valuable black-band ironstones which are of commercial importance, and a smaller amount of iron is mined in the south where, however, there are important quarries for road metal.

**History and Early Settlement.**—Although remains of Palaeolithic man have been found in the Derbyshire caves over the border, no finds are known from Staffordshire itself. Neolithic implements, especially round barrows and Beaker pots of later date are found almost entirely and in fairly large numbers in the north-east section of the county. In early times this region must be considered as part of the Peak district of Derbyshire. In the remainder of the county there are isolated finds of Bronze, notably palstaves at Brewood, Biddulph, Bushbury and Stretton, a bronze sword at Alton Castle and a leaf-shaped spear-head at Yarlet. These isolated finds serve to indicate the beginnings of movement along the valley ways and the importance of the roads around the hills into Wales and the west. In Roman times Letocetum just south of Lichfield was the most important settlement.

In the 6th century a tribe of Angles settled about Tamworth, afterwards famous as a residence of the Mercian kings. Later the invaders advanced beyond Cannock Chase. The district was frequently overrun by the Danes, and it was after Edward the Elder had finally expelled the Northmen from Mercia that the land of the south Mercians was formed into a shire around the fortified burgh which he had made in 914 at Stafford. The county is first mentioned by name in the Anglo-Saxon Chronicle in 1016.

The resistance which Staffordshire opposed to the Conqueror was punished by ruthless harrying and confiscation, and the Domesday Survey supplies evidence of the depopulated and impoverished state of the county. The five hundreds of Staffordshire have existed since the Domesday Survey, and the boundaries have remained practically unchanged. The shire court for Staffordshire was held at Stafford, and the assizes at Wolverhampton, Stafford and Lichfield, until by act of parliament of 1558 the assizes and sessions were fixed at Stafford.

In the wars of the reign of Henry III most of the great families of Staffordshire, including those of Basset and Ferrers, supported Simon de Montfort, and in 1263 Prince Edward ravaged the lands of Earl Robert Ferrers and destroyed Tutbury Castle. During the Wars of the Roses, Eccleshall was for a time the headquarters of Queen Margaret, and in 1459 the Lancastrians were defeated at Blore Heath. In the Civil War of the 17th century Staffordshire supported the parliamentary cause, but Tamworth, Lichfield and Stafford were garrisoned for Charles, and Lichfield Cathedral withstood a siege in 1643.

Much of Staffordshire in Norman times was waste land, but the moorlands of the north afforded pasturage for sheep, and in the 14th century Wolverhampton was a staple town for wool. In the 13th century mines of coal and iron are mentioned at Walsall, and ironstone was procured at Sedgeley and Eccleshall. In the 17th century the north of the county yielded coal, lead, copper, marble and millstones, while the rich meadows maintained great dairies; the woodlands of the south supplied timber, salt, black marble and alabaster; the clothing trade flourished about Tamworth, Burton, and Newcastle-under-Lyme; and hemp and flax were grown in the county. The Staffordshire pottery industry is of early origin, but was improved in the 17th century. It has been greatly extended in modern times.

**Architecture.**—The most important churches are the beautiful cathedral of Lichfield, and the churches of Eccleshall, Leek, Penkridge, St. Mary's at Stafford, Tamworth, Tutbury and St. Peter's at Wolverhampton all of which are described elsewhere. Checkley, 4 m. south of Cheadle, shows good Norman and Early English details. Armitage south-east of Rugeley, has a church showing good Norman work. Brewood church, 4 m. south-west of Penkridge, is Early English. Audley church, north-west of Newcastle-under-Lyme, is a good example of Early Decorated work. The remains of the Cistercian abbey of Croxden, north-west of Uttoxeter, are fine Early English, and at Ranton, west of Stafford, the Perpendicular tower and other portions of an Augustinian foundation remain. Among mediaeval domestic remains are the castles of Stafford, Tamworth, Tutbury and Chartley. Beaudesert, south of Rugeley, is a fine Elizabethan mansion in a beautiful undulating demesne. In the south-west, near Stourbridge, are Enville, a Tudor mansion, and Stourton Castle.

**Agriculture and Industries.**—About 75% of the total area of the county is under cultivation, and of this three-quarters is in permanent pasture, cattle being largely kept, and especially cows for the supply of milk to the towns. Staffordshire is well wooded; the National Trust owned 1,964 ac. in 1942.

The southern industrial district, the Black Country (*q.v.*), is

the main seat in England of iron and steel manufacture in all its branches. It covers an area, between Birmingham and Wolverhampton, resembling one great town, and includes such famous centres as Walsall, Wednesbury, Dudley (in Staffordshire) and West Bromwich. The northern industrial district forms the Potteries (*q.v.*); Cheadle east of the Potteries, is the centre of a smaller coalfield; Burton-upon-Trent is famous for its breweries. Chemical works are found in the Black Country and at Tunstall, glassworks at Tutbury; there are also a considerable textile industry, as at Newcastle-under-Lyme, paper mills in that town and at Tamworth, manufactures of boots and shoes at Stafford and Stone, silk and artificial silk at Leek and other manufactures in the county include rubber goods, and motor cars.

**Communications.**—The main line of the L.M.S. railway runs from southeast to northwest by Tamworth, Lichfield (Trent Valley), Rugeley and Stafford. This company and the G.W.R. serve the Black Country by many branches from Birmingham, and jointly work the Stafford-Shrewsbury line. The L.M.S. has branches from Trent Valley to Burton-upon-Trent, and from Rugeley through the Cannock Chase coalfields, from Stafford and from Burton-upon-Trent northward through the Potteries, with a line from Uttoxeter through Leek to Macclesfield.

The west and north line of the L.M.S. (Bristol–Derby) crosses the southeastern part of the county from Birmingham by Tamworth and Burton with a branch to Wolverhampton. The L.N.E. serves Uttoxeter, Burton and Stafford. A considerable amount of coal transport takes place along the canals of the Black Country.

**Population and Administration.**—The area of the geographical county is 1,154 sq.mi., with a population in 1938 of 1,483,650. The area of the administrative county is 1,071 sq.mi.; population (1938) 749,900. Staffordshire contains five hundreds, each having two divisions. It contains 6 county boroughs and 8 municipal boroughs. The county boroughs are:—Stoke-on-Trent, Wolverhampton, Walsall, Smethwick, Burton-on-Trent and West Bromwich; and the municipal boroughs are:—Lichfield, Newcastle-under-Lyme, Stafford (county town), Tamworth, Wednesbury, Bilston, Rowley Regis and Tipton. There were 17 urban districts in 1943, as follows, given in alphabetical order:—Aldridge; Amblecote; Biddulph; Brierley Hill; Brownhills; Cannock; Coseley; Darlaston; Kidsgrove; Leek; Rugeley; Sedgley; Stone; Tettenhall; Uttoxeter; Wednesfield; and Willenhall. Other towns are Abbots Bromley, Brewood, Cheadle, and Eccleshall. There are two cities in the county, Stoke-on-Trent and Lichfield. The county is in the Oxford circuit, and assizes are held at Stafford. It has one court of quarter sessions and there are 20 petty sessional divisions. The county boroughs have separate courts of quarter sessions and commissions of the peace. The county is in the diocese of Lichfield.

Staffordshire is divided into seven parliamentary divisions each returning one member, Burton, Cannock, Kingswinford, Leek, Lichfield, Stafford and Stone. The parliamentary boroughs of Stoke-on-Trent and Wolverhampton return one member for each of three divisions, and the boroughs of Newcastle-under-Lyme, Smethwick, Walsall, Wednesbury and West Bromwich each return one member. The county and parliamentary boroughs return in all 18 members.

**STAGE,** in architecture, an elevated floor, particularly the various storeys of a bell-tower, etc. The term is also applied to the plain parts of buttresses between cap and cap where they set back, or where they are divided by horizontal strings and panelling. It is, too, the floor or platform on which plays are acted, whence the term has come to signify both the theatre (*q.v.*) and the drama (*q.v.*). *See* also STAGE DESIGN, below. From its etymological meaning of a station comes the sense of a place for rest on a journey, the distance between such places, etc.

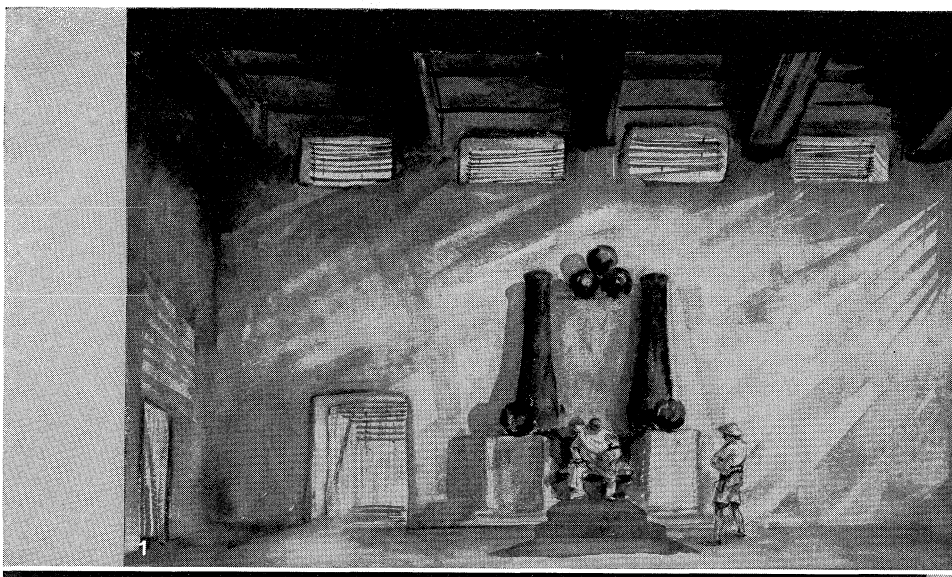
**STAGE DESIGN.** Until about 1900 the pictures created on any stage, generally known as scenery, had no relation to the feeling for form, colour, composition or light which art from 1850 to 1900 had made a common possession. The picture of the world within the theatre was invariably dull, without illusion and rigidly painted,—painted, in fact, with the same merciless and metallic precision which led Manet to exclaim before one of Meissonier's paintings of charging cuirassiers, "Everything is of steel except their breast-plates." Trees stood invariably in regimental rows and their foliage hung in separate parallel layers above their trunks. The walls of hovels or palaces reminded the most careless eye that they were merely painted canvas; the sky flapped, an obviously painted sheet. The ugliness of the total result was all the more glaring because, in an age of realistic playwriting, actors were using every artifice they possessed to make an audience feel that they were Russian or Silesian peasants, Norwegian town councillors, or English clergymen and poets. Every word in the theatre was trying to convince its hearers that what they saw was not actors, but human beings in a world as real as the one they had just left to enter the theatre; that people "were like that"; that life had this significance and that meaning. But everything on the stage reminded the audience that, after all, what they were seeing was a play in a thoroughly artificial place, the theatre, that had no relation to life. Even when a poet held the stage the result was equally ludicrous. It was difficult for the singers of Wagner to transport an audience to the beginning of the world, where the gods were deciding the destiny of men, when everything about them seemed an enlarged landscape done in chromolithograph. Mary Garden wandered in a park that had neither magic nor mystery, in the supposed gloom of palace halls as bland as lithographs of English country houses, current in the '50s. Any symbolism that might have lurked in Maeterlinck's fairy tale of the terror and foreboding of young love was dissipated; and Mélisande's cry "I am not happy" seemed less a comment on the state of her soul than on the preposterous stage settings that surrounded her.

The inadequacy of this type of scenic background, so prevalent at the turn of the century, did not lie alone in its artificiality nor in the fact that it was an obvious and flimsy convention. Artificiality and the conventions of formally painted designs, as proved by the work of Inigo Jones, Bérain and the Bibienas, can breed beauty in the theatre just as easily as the same tradition in the 19th century bred ugliness. The reason for the change which makes painted scenery in one epoch enhance the meaning of the play and in another detract from it, is our changed attitude towards the theatre. The creative dramatists of the past 40 or 50 years, whom for convenience sake we may call modern, such as Ibsen, Shaw, Hauptmann, Chekov and Strindberg, Synge and O'Neill, are modern in the sense that one and all they do not regard the theatre as a place of pure entertainment. And they have succeeded so well that though we may still go to the theatre merely to be amused, we also go to watch a play with the same expectation with which we open a novel treating of modern life—in the hope of seeing more clearly into the springs of character, of getting a fresh sense of human destiny.

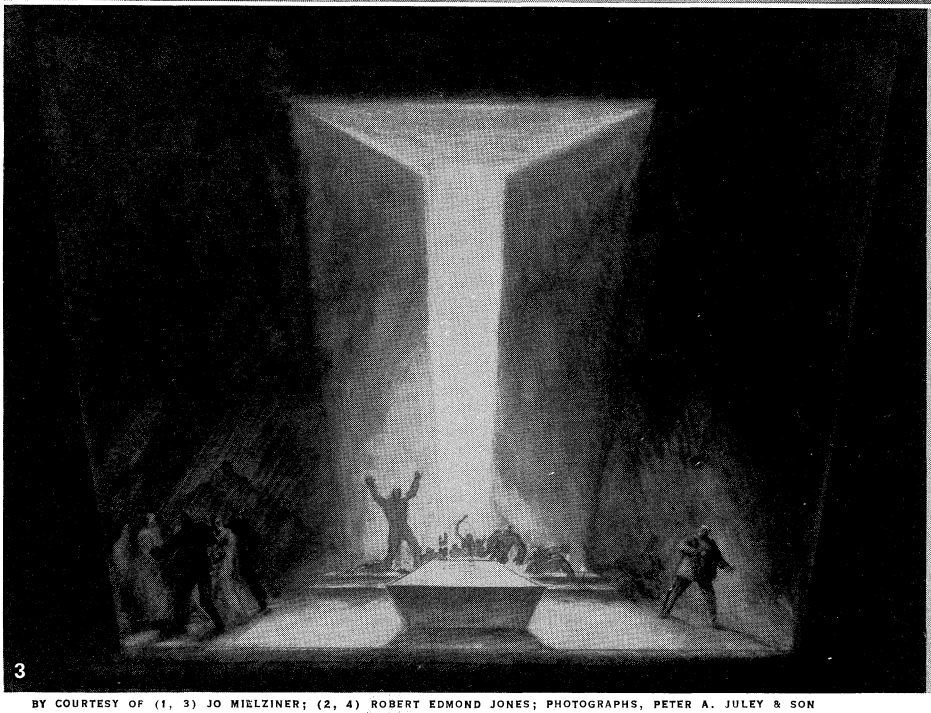
**The Modern Scenic Movement.**—The blatant dissonance between modern plays that were attempting to reconceive a world and scenic backgrounds that merely reflected the conventions of a purely theatrical theatre, was so preposterous that it could not endure. For that reason, directors of modern theatres in every country in Europe, beginning with Germany, and finally in the United States, enlisted painters or designers to make the world on the stage the world of the play. This is the genesis of the so-called modern scenic movement. It arose, not because modern art already existed, but because it became essential to the theatre in order to quicken the reactions of the audience until the world the dramatist asked them to believe in had the plastic reality of a world before their eyes or the imaginative quality of a poet's dream. The source of modern scenery has not been dogma. It did not arise because Gordon Craig prophesied that only screens could back a stage; modern scenery would have occurred whether or not Craig had ever existed or penned a line. He, however, was one of those who prophesied that a change must come and that stage settings must be designed to interpret the play they housed. Every manner and method of modern painting, has, with

the aid of some mechanical device, been put to work in the theatre: the plaster dome, in conjunction with the flexibility of incandescent lamps which made the painted sky seem a heaven and filled the stage with all the ambient light of day; the spot-light, manipulated to create the chiaroscuro of Daumier; light mixed with colour in the manner of Monet and Seurat making colour vibrate, and achieving the atmosphere of the impressionists, or enmeshed in gauze, giving the atmosphere of Whistler's nocturnes. Every technique of modern art has been exploited, whether of impressionism, post-impressionism, cubism or futurism. However, from the point of view of pictures constructed within the proscenium frame of the theatre, almost every method at one time or another, in the hands of a particular director and in conjunction with the methods of his actors, has succeeded in convincing an audience and projecting the interpretation of a dramatist's ideas.

The point needs stressing because the history of modern scenery is usually regarded from the point of view of a mere chronology of begetting, and is continued in the strain of prophecy. A designer reading any of the current histories of his art would feel that the entire problem before him was the choice of a style. And the value to him, as a craftsman, of almost all discussions of the subject, is hereby rendered nil. The theatre, it is supposed, is about to be re-created, purged of evil, saved and given its final form if he, the designer, only makes the right choice; screens, a stage without curtains, scenery made of nothing but curtains, a circus theatre where the actor can mingle with the audience, scenery that is only light, scenery that is merely symbolic colour, scenery that is wooden trestles, and so on, depending upon which method at the moment has had the latest critical success in Europe. It is essential for the scene designer to avoid this critical approach if he wishes to analyse the basis of his craft. For whatever his preferences may be as a painter, he will find that the moment he sets out to design stage settings his problem is everywhere the same. He will find the problem of relating a particular play to a particular audience, the problem, as conceived by the director, of how the meaning of that play can be put over the footlights, and dramatized for that audience. His methods will be deduced not from any abstract aesthetics of the theatre but from the exigencies of that particular situation. For not all his convictions as to why imitation and realism was a defunct method prevented George Bernard Shaw from continuing to write plays so provocative that they must be acted in country-house gardens, Salvation Army barracks and physicians' consulting rooms, for which the designer has to build the walls, find the furniture and even evoke the flowers. On the other hand, not all the dogmas in the world as to the value of realism prevented Shaw, or any other playwright, from reconstructing Antony's adventure in Egypt or Adam's adventure in the Garden of Eden, for which there is an equally avid audience; and the designer will have to find a decorative equivalent for the sphinx, or some symbolic equivalent of the tree of knowledge. And whether theatre audiences are those of London, Prague, Berlin or Warsaw, the designer will find that they came to the theatre to share experiences that are not their own, so that in the course of a single season the designer may have to help in making plausible the romantic scruples of a Hungarian schoolboy or a Hungarian servant, the feudal scruples of Japanese noblemen, the political dogmas of Slavonic revolutionists, the moral codes of American revolutionists and Russian peasants.



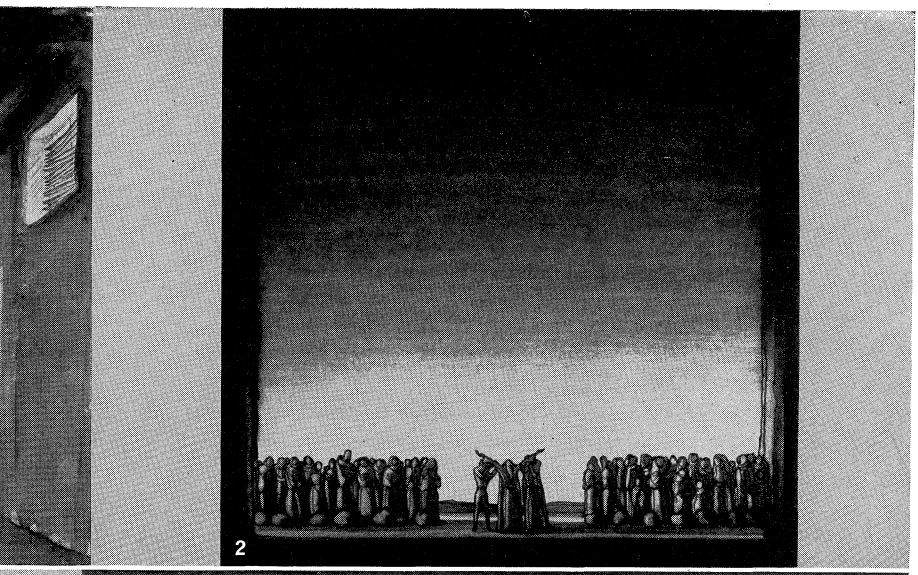
**Staging of "The Faithful."**—Some of the problems of scenic design as worked out by the present writer at the Guild theatre of New York, although not final in any sense as examples of theatre art, are typical of the problems which every stage designer must face in order to evolve design, whatever the pattern he may ultimately adopt. *The Faithful,* by John Masefield, tells the story of 47 Ronin, retainers and henchmen of a Japanese nobleman, tricked by a rival into committing an affront to the emperor's person for which the only expiation was suicide; of the voluntary exile of these Ronin as pariahs, and their final triumph over their dead master's enemy. It is a poet's celebration of the nobleness of loyalty. What is the producer's problem? Obviously something more than to demand poetic background for a poetic play, because the tale of the 47 Ronin, as much of a household story in Japan as Washington and the cherry-tree in America, is totally unfamiliar to Western audiences. He can count on no background in the audience's mind. But Japan is the background which he must create decisively five minutes after the curtain is up, for the reason is that the unforgivable act committed was nothing more than a mistake in ritual, a failure of ceremonial observance, not to the emperor himself, but vicariously to the emperor's person as personified by his envoy. The rigid code of Japanese feudalism is a tradition difficult for Westerners to conceive. The danger is that they will find it, if not preposterous, at least not plausible, so that they cannot identify themselves with the hero. The problem here is that to an audience not composed of orientals or members of Japanese societies, the normal reaction would be "Stab oneself because of a mistake in court etiquette? How preposterous! What a trivial people!"



The playwright cannot solve this problem in the many ways that are offered to the novelist; he has no preliminary chapters or incidental comment to prepare the mind of his audience, as his story proceeds, to make them understand the rigid Samurai code of honour and accept the tragic alternatives imposed on its adherents. Aware of this problem, the designer finds, in making his first researches into the field of Japanese costume and architecture, that ritual ruled not only court etiquette but all Japanese life of the period, to the most trivial detail. Everything is prescribed and ordered; the degree to which the head is shaved, and the degree to which the hair is looped forward on the head; the precise way the obi or white silk belt is tied that holds the pleated skirt in place; the length of the sleeves, as well as the cut of the gown. Everything is ordered ceremonial, even the squares of the matting, the placing of the sword in its rack, the one picture niche where the solitary landscape scroll is shown and the way the single group of flowers is arranged under it. There are in the simplest acts, of receiving a friend and taking tea in his presence, countless opportunities of outraging him by breach of etiquette.

In a world of this sort, it begins to be comprehensible that a mistake in court etiquette could involve the death penalty. Hence every effort—and here the producer co-operates—is made to convey the ceremoniousness of the Japanese feudal world, in the gait of the actors, their gestures, their genuflections, the mode of entering or leaving a room. A Japanese is found to train them; he ties every obi, adjusts every costume, sets every hat and wig. The room which is the opening scene of the play is almost archaeological in its accuracy, and the line of every costume is established with realistic nicety and with an attention to correct cut and material that could hardly be outdone by the Moscow Art theatre. In short, realism as a method is employed in order to make a poetic theme plausible.

On the other hand, once the world of the Samurai is realized, and the tragedy is enacted, there is no further need of such realistic devices. The ragged Ronin wander in the snow, but the snow may be the snow gorges of Japan, painted upon a six-fold Japanese screen, without diminishing either the reality or the suffering of these outlaws. Here a deliberately decorative method seems the inevitable choice. Japanese landscape is known to Western audiences through the popularization of Japanese prints. A screen setting evokes this purely decorative pictorial tradition and suggests the countryside of Japan far more effectively than any attempt to reconstruct it realistically. Thus meticulous realism and deliberate decoration can be employed simultaneously in the same play, and for the same purpose. As pictures the snow scenes are far more effective. But in the theatre the palace scene was far the more important of the two. For if that scene succeeded in conveying Japan effectively to the audience, the world of the Japanese could be taken for granted for the rest of the evening. A white sheet and the shadowgraph of a few pine boughs might have done just as well for the winter hills. This instance reveals how superficial it is to codify stage sets according to purely pictorial principles.



**Staging of "Liliom."**—Molnar's *Liliom* presents an analogous problem of transplantation, not from one century to an-

## THE ABSTRACT SETTING

1. Scene from "Man and the Masses," an example of the formal stage in which mass movement of the actors creates the design
2. Revolution scene in "Man and the Masses," a complete change of mood and design by a change of mass action
3. The miracle in "Tidings Brought to Mary," a play in five acts by Paul Claudel presented throughout on the same platform with changes in lighting only
4. The farewell supper in "Tidings Brought to Mary"

other but from one country to another at the same period. The producer's problem in Liliom was, in essence, that his story deals with the creed of a gangster and a "tough" who is fundamentally romantic. Liliom falls genuinely in love with the servant, Julie, and evinces a belief in "the eternal feminine" worthy of a latter-day Faust. He is transported by the prospect of fatherhood. When he stabs himself rather than be captured by the police in an attempted hold-up that fails, his last cry is "Julie . . . my little girl . . . my little cricket." When, after facing the judgment of heaven and ten years' probation, he returns to earth as a beggar for an opportunity to win redemption, he steals a star to give to his daughter, and then in a moment of exasperation beats her, as he formerly beat her mother. The child cries "he hit me . . . but I didn't feel anything—as though someone had stroked my hand . . ." "Nothing has happened" her mother assures her, divining who the beggar is, "it is possible, my child, for someone to hit you—so that you don't feel any pain." Liliom is not forgiven in heaven; he is redeemed on earth by the persistence of human compassion. The beauty of the final scene made the play at the Guild theatre an allegory, the vindication of a romantic faith, and dictated the scenery. The play was something more than the story of a foreign underworld; its realism was made an ironic cloak for poetic truth. Thus the amusement park where Liliom flourished as a bully was made as authentically Hungarian as possible, so that the audience might accept the reality of a romantic gangster and not reject him as a maudlin invention. On the other hand, precisely because the play seemed important as an allegory because of its poetic truth, the tawdry squalor of Liliom's surroundings had to be invested with beauty, even the tumbledown shack in which he lived. And the railroad embankment, where he attempted his hold-up and met his death, was composed with some of the dignity and severity appropriate to tragedy.

Scene 2 represents the park where Liliom falls in love. The point is that, bully, seducer and braggart though he is, he does fall genuinely in love. He is transfigured and the moment becomes as beautiful for this Hungarian hooligan and a kitchen maid as it does for all lovers. Therefore, the park where they meet must be made beautiful. The hour is dusk, when, as Whistler reminded us, "the evening mist clothes the riverside with poetry as a veil, and the tall chimneys become campaniles, and the warehouses are palaces in the night and the whole city hangs in the heavens"; the "exquisite hour" as Verlaine calls it. Therefore the problem for a designer was to clothe that park with poetry as with a veil; with tree silhouettes which are hung on transparent gauzes; and putting into those tree silhouettes all the grace and the loveliness appropriate to the trees of a pastoral bower destined to arch over young lovers. Had the scene been one of cynical seduction, this quality of tenderness and brooding would have been irrelevant.

Scene 6 represents heaven. Liliom sees heaven in terms of the police courts with which he is familiar. He can conceive of no other bar of judgment; heaven is merely the last police court presided over by a police-court judge; the attendant angels are to his eyes only detectives and policemen. The stage directions emphasize the fact by stating that their costume is the usual police uniform. Nevertheless, Liliom has died; he is in heaven awaiting eternal judgment. If the play is to be properly interpreted this seat of judgment cannot be the proverbial heaven with a celestial throne. On the other hand, if the allegory of the play is to be made plain it cannot be shown simply as a police court. This dilemma was solved by making the scene as far as Liliom's eye ranged a drab room, with the ordinary judge's bench at one end; but the solid walls ended at the wainscoting and window frames. Beyond that was emptiness; the room sat without walls or roof under a blue sky as illimitable as stage light could make it. By this combination of realism and fantasy, the reality of heaven was established for the audience, and at the same time the fact was made clear that to Liliom its judgments were no different from what he had experienced on earth. These four scenes from two plays entirely different in type demonstrate how contradictions of realism and decoration in stage pictures are determined by problems of dramatic interpretation and not primarily by pictorial considerations. The picture is a result of a conviction as to what the meaning of a play is and how it can be reflected in pictorial form.

**The Method of Abstraction.**—Settings that eliminate the stage picture entirely are designed for the same reason and by the same process. *The Tidings Brought to Mary,* by Paul Claudel, was played on the same platform for its entire five acts, which according to the stage directions take place in a barn, a farm kitchen, an orchard and a road at the edge of a forest. Fedor Komisarjevsky, the director, chose the unit platform because he felt that the play was mediaeval not only in its story but in its quality. It was a mystery, couched in the mystic faith of a truly mediaeval catholicism. A single square block served as a bench and, when it was covered with a formal cloth, as a supper-table and an altar. The orchard became eight nuns clothed in Byzantine splendour, each holding a branch of silver flowers, who stood in a remote semi-circle. The sky behind them at this moment became green to suggest the foliage of out of doors. For the road-side scene at night, the same backdrop became the inky blue of a wintry night spangled with a few stars. And a cold steel-blue light thrown over the platform gave the illusion of winter snow. For the miracle the sky blazed forth gold, like the background of a 14th century mosaic, and aureoled the actors. The same intention was carried through the costumes: many were mediaeval French, but others—those of the father and mother—were clad in the traditional robes of early religious paintings, so that the mother had a suggestion of the Mother of Christ, the father, of one of Christ's disciples, and in its formal grouping, the supper of farewell suggested an apostolic meal.

In *Man and the Masses,* by Ernst Toller, the formal platforms became almost invisible. The settings were made wholly by the massing and the movement of the actors. The human beings on the stage provided all the scenery that was needed, for the play was conceived as an abstract allegory. One leader who tries to limit the workers to the bloodless methods of a general strike, is called simply The Woman. The agitator who incites them to revolution is called The Man. Though the workers are supposedly in their union hall, their angry indictments of capitalistic society are chanted in unison as a formal chorus. How could this meeting be placed in a realistic setting of an actual union headquarters, without making such formal choruses seem ridiculous? The title literally translated is "mass-man." The force of Toller's conception is his vision of mass-man. The working-men are a single stubborn unit, welded together in resentment and anger, from which only voices of the young and the old emerge to cry, threaten and lament. If a group of 30 or 40 actors on the stage are to give this feeling of mass power, they cannot be scattered, they cannot move about much; they must be welded. Hence a stage setting was devised for the drama that was a literal cross-section of an amphitheatre; the players never moved from the spot where they were wedged; they rose with waving arms and clenched fists to face The Woman, who pleaded with them; they towered over her; she was below them, supplicating. When this compact mass of 30 actors stood they seemed to represent "the masses"; it seemed that they could sweep down on The Woman and overwhelm her. Then The Man sprang out of their midst and slowly backed up step by step to the top of the amphitheatre. As his eloquence grew they swung slowly round, looking up towards him, turning their backs on The Woman as they ignored her pleas. Finally, at the moment when they were won over to a doctrine of violence, they were a solid mass, crouching under him waiting to spring; as he cried "revolution" they took one step up, the only step they took in the entire act, and lunged together like a huge beast, echoing his cry "revolution." Each one had turned completely round during the scene without once moving from the spot on which he or she stood. They remained a mass, and by a single mass movement expressed their change of faith.

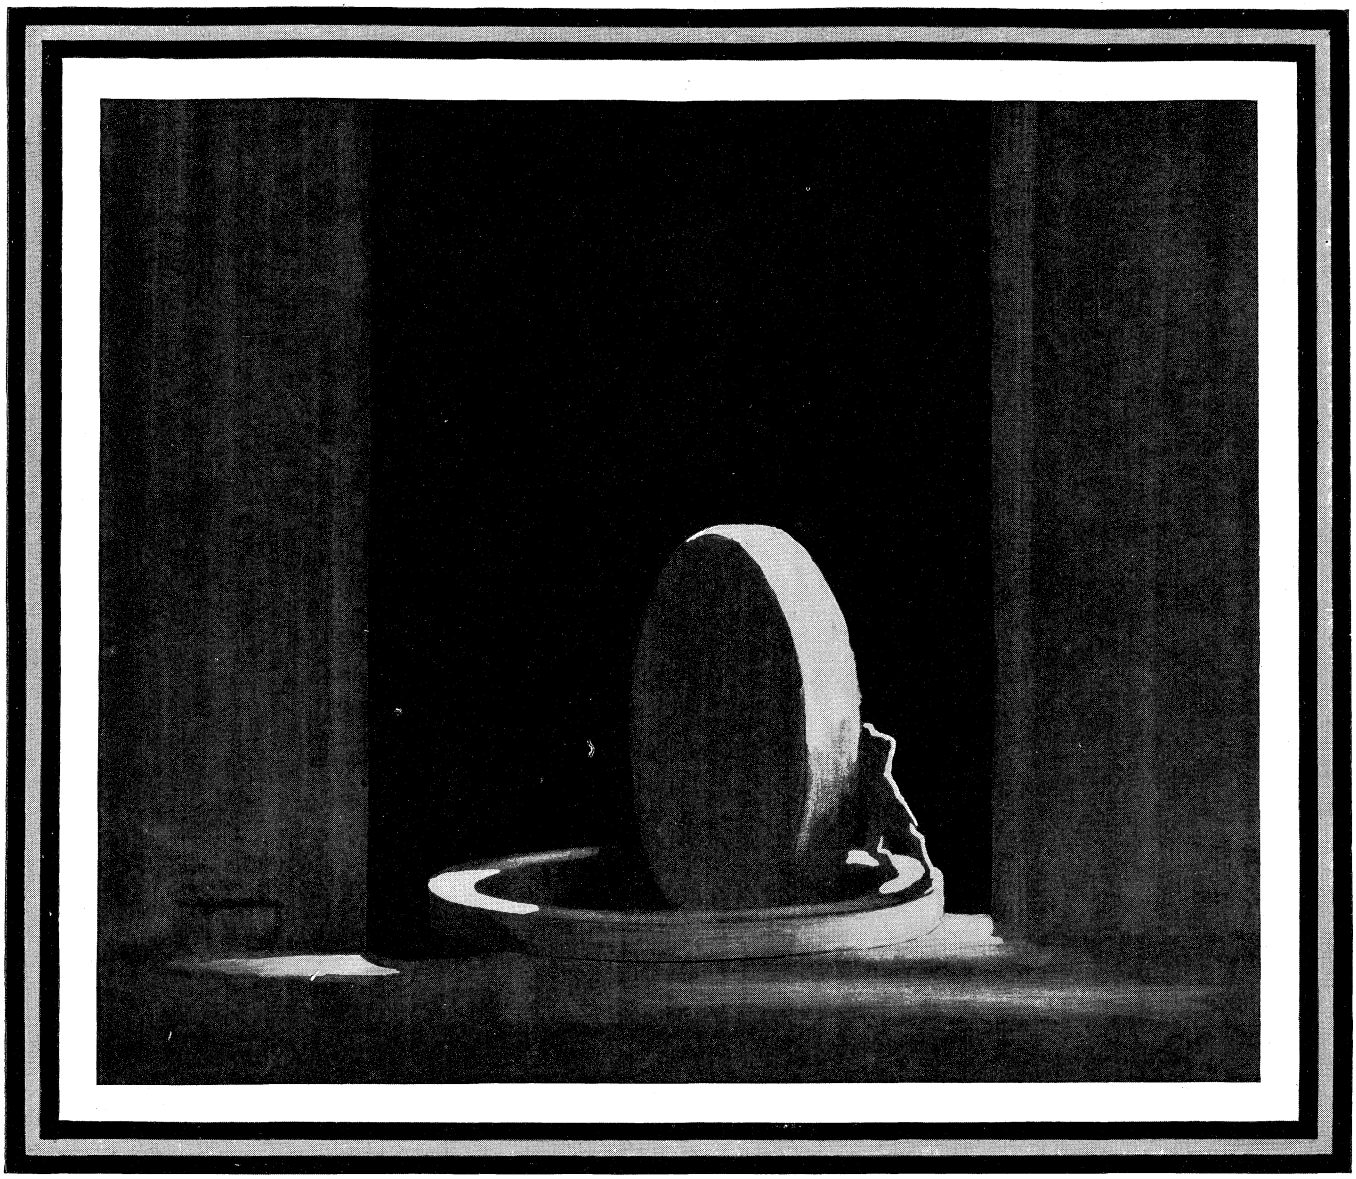
**Varieties of Interpretation.**—The designing of scenery is thus never a purely pictorial problem; it is part and parcel of the act of interpreting a play. Whether a designer chooses abstraction or realism, a picture-stage which imitates the world as we see it

in rooms with the fourth wall knocked out into which we peep, or a formal stage which symbolizes the world, is in itself a relative thing. The method of design chosen is only good even from a pictorial point of view provided it touches the imagination of an audience, and really convinces it of the truth and reality of the play. Setting the play is only part of the process of acting it so as to give it dramatic force; no method, however beautiful it is as a picture, is the right method if it fails to convince an audience; and there are as many types of audience as there are kinds of play. No play has only one meaning; it can mean all things to all men. The imagination of the director must decide and the pictorial imagination of the scene designer must second him. If you can make your audience accept Liliom's story as a modernistic fairy-tale, an allegory from the outset, Pitoev's method of presenting it in clear hard formal outline is the right one. If the play means more as a story in which the allegory is implicit, then the more realistic method of the Theatre Guild is better; similarly with *He Who Gets Slapped*. To compare the two, one would have to sit through the two productions as played by two different casts.

There is no one way of producing any play, even classic masterpieces. In fact every one, whether Euripides or Shakespeare, has to be constantly re-interpreted, in order to become relevant and remain living. If Shakespeare's characters seem important as figures rescued from an actual historic past then the elaborate and exact costuming of the Duke of Saxe-Meiningen or Henry Irving is not only necessary but effective. To one audience, which conceives them primarily as creatures of Shakespeare's time, the bare boards of the Elizabethan stage will make them live more completely. To another audience, particularly sensitive to Shakespeare's word-magic, formal scenery, even a single curtain, is enough. To a German audience, for whom much of the poetry is lost in translation, more pictorial backgrounds are necessary, into which that lost glamour must be projected. But to both German and American audiences for whom Shakespeare's protagonists are imaginative figures living in the world of the imagination, they become most real when part of an unreal world, a forest of dyed strips of tapestry or gauze (Barker's production of *A Midsummer Night's Dream* and Reinhardt's production of the same), or a blood red stairway (Jessner's production of *Richard III.*), or among golden screens (Craig's production of *Hamlet* with Stanislavski at the Moscow Art theatre). And if the tragedy of Hamlet begins to seem too remote and archaic to us, we can make him a human being, for certain audiences, by putting him in modern dress. The art of scene designing is a living art because it can find no final formula. It will live precisely as long as it can discover new meanings in every play of every epoch. Scenery is the background of a play, and as such is part of the continuous adventure of projecting the meaning of a play across the footlights, finding, firing, and then fusing the imagination of an audience. And that adventure will always be a different one in every country and every epoch.

**Structural Innovations.**—The technical and structural changes which determine the design of modern scenery are two: first, the modern theatre, in contrast to the 18th century theatre, has become an extremely shallow box; second, that black box can be completely flooded with electric light, modulated and controlled. The theatres of the late 17th and 18th century fixed the architectural type of theatres, which with changes of ornament and the depth and arrangement of balconies is the type still prevalent to-day. But there is one vital difference: the proportion of the space occupied by the stage in relation to the space occupied by the audience in the auditorium. The 18th century stage averaged in depth 1 to 1½ times the depth of the auditorium pit, and was rarely less than 75 feet. The modern stage, except in opera houses and European state theatres, is rarely more than ⅓ the depth of the auditorium, and averages at the best 25 to 30 feet.

Moreover the 18th century stage was carefully calculated to enhance painting in perspective. The stage floor sloped up. The side flats receded until the rear of the stage was very near the true vanishing point, so that an alley of trees or an avenue of columns receded very much as they would in nature. But on the modern stage the spectators are looking into a space so shallow that any illusion of depth is difficult to attain. In an average production there is rarely more than 8 to 10 ft. from the garden wall to the distant mountains; often there can be only 4 or 5 ft. from a window to the sky.



The early technique of shifting scenery was done by having the side flats on grooved slots, set in pairs, tied to a rod which connected with a series of windlasses in the cellar. At a given moment one turn of these windlasses would shoot the rear flats out like a shutter, and withdraw the front flats out of sight, achieving a complete change of scene with great precision. A beamed gridiron under the ceiling, with another series of windlasses, hoisted and lowered the clouds and the platforms on which gods and goddesses descended. Owing to the shallow space of the modern theatre and the suppression of the apron in front of the curtain, the front rows of spectators can see clear to the roof and to the side walls. The modern stage settings therefore have had to become a three-sided box with a lid over the top, when interiors are called for; for exteriors a curved sky, either of canvas or of plaster is used, instead of a sky in flounces as seen in the 18th century theatres. There is so little room on the stage for stacking scenery that most of it has to be broken apart, or unlashed, for each change of scene, and hoisted into the air where it hangs until it is needed again, and as certain sets may be 24 and sometimes 30 ft. high they have to be hoisted high enough to be out of sight when not in use. Hence the gridiron from which scenery is hung—handling is facilitated by having the lines that haul it attached to counterweights grouped at one side of the stage,—is the most important part of standard stage equipment. The opening which the audience sees, the proscenium frame, is in reality a mouse-trap shutter at the bottom of a tall shaft. The average proscenium opening is 24 to 30 feet. The curtain in actual use is rarely drawn higher than 20 ft. for exteriors, and 12 to 14 ft. for interiors; the remaining space is occupied by flounces and draperies. And the gridiron must be a minimum of 65 ft. in height; for hauling scenery out of sight, 80 to 85 ft. is better. At the Century theatre, New York, it was about 100 ft. above the stage floor.

In any case the space behind the stage opening is mainly storage space for hanging scenery in mid-air. The place occupied by the largest scene is approximately one-seventh of the total stage space, and the proportion will not vary greatly in American theatres or most commercial theatres of Europe.

The system outlined above is not by any means the best either mechanically or aesthetically. It is, in method, as archaic as hoisting sails; indeed the workmen on the stage who shift scenery are known as the crew to this day. The revolving stage introduced by Lautenschläger from Japan was used extensively, and did away with the necessity of a gridiron almost entirely. At Dresden, Linnebach at the State theatre and Hasait at the Opera constructed elevator stages worked by hydraulic power, so that heaviest sets could be set in the cellar, hoisted to stage level and slid into place with extraordinary speed. The cellar being two or three storeys deep, the settings for two or three entire productions could be kept intact indefinitely.

These mechanical marvels have never developed because the economic trend of the time is against them. Land has become too expensive to allow the amount of space and excavation required; rising costs everywhere in Europe make the duplication of any such installation prohibitive. In the United States where a single elevator platform 12 by 30 costs approximately $25,000 to install, an entire stage so equipped would represent a capital investment that only the very wealthiest theatrical producer could carry. Thus theatres tend to become smaller and shallower and the theatre everywhere approximates to American conditions where everything has to be crowded into a standard building site of 100 ft. square.

Important architectural experiments have been made which aim at changing the conventional "peep-show theatre," as its critics have called it, where we look into a stage picture through a more or less gilded frame. Theatres have been projected with the stage as a formal platform, where the actor emphasized in space, picked

## MODERN THEATRICAL PRODUCTION DESIGN

"The Mill," an example of ornamental theatrical setting designed by Isaac Grunewald for the production by the Royal Opera in Stockholm of "Samson et Dalila." The stage is black except for a vivid shaft of light which reflects on the millstone. As the stone slowly turns the reflection gradually widens from a narrow crescent into a circle of brilliant light, against which Samson is silhouetted at just the moment when his aria begins. Here we have a modern setting in which the forms are sublimated into a single dynamic composition

BY COURTESY OF THE ARCHITECTURAL RECORD

## THE USE OF SCENERY "WAGONS" IN REALISTIC SETTINGS

The scenery wagons formed the keystone of this production of Rostand's "Cyrano de Bergerac," reputed to be the most difficult play to set according to the author's direction. Each wagon is rectangular, about 8 ft. by 12, with one floor or platform 18 in. above the stage and a second 7 ft. higher. They are mounted on ballbearing wheels and all four sides covered by 24 ft. "flats" containing doors, windows, arches, balconies, and so forth. By rolling these wagons into different positions and exposing different faces to the audience at different times; by combining them in one scene and separating them in another, and by supplementing them with sections of scenery of the ordinary sort it is possible to meet all the acting requirements and at the same time differentiate the scenes sufficiently to deceive all but the most expert and analytical eye. By this device the high and heavy scenery for all five acts is both set and stored before the rise of the opening curtain and the interiors of the wagons can be utilized for the storage of stage "properties' of which there are more than 200 in the cook-shop scene alone (fig. 2). This principle of the double and triple use of material extends to the minor items of the scene as well. The front of the inner theatre stage in the first act (fig. 1) becomes the counter in the cook-shop scene next following (fig. 2). The stairway which appears in the first, second and third acts is the same stairway, masked differently in each case. The ramparts in the fourth act (fig. 4) become the box hedges in the fifth (not shown in drawings) by the removal of the dyed burlap which has been thrown over them to give them the appearance of earthworks

out by light, can mingle freely with the audience and is partially surrounded by them, a sort of electric contact being the goal sought. The most notable theatres of this sort have been the projects of the American Geddes, the Dutchman Vanderwelde and the Austrian Stranad. Jouvet's platform stage designed for Copeau existed in Paris for a number of years; a circus theatre by Poelzig, "the theatre of the 10,000," was actually built in Berlin, but like Copeau's theatre it was abandoned. Quite apart from economic problems, what thwarts the development of these playhouses is the fact that modern playwrights will not write enough plays that can be given in any such manner. O'Neill and Shaw, Toller, or Werfel, revert to realism quite as often as they depart from it and write plays which require the three-sided box room or the illusion of distance in an actual world which can only be achieved, in the theatre, by looking through a frame. Until modern playwriting achieves some unity of tradition, these formal stages must remain isolated experiments or dreams on paper.

**Lighting.**—The most important effect that the shallow-box stage has had on designing is the fact that perspective planning and painting become preposterous; anything that leads the eye from the front of the stage directly across it to the back wall, makes the eye realize that the picture is only 20 ft. deep. Hence the kind of composition modern scene design employs is not the Renaissance composition of distance into which the eye is led by receding parallel perspective, but distance suggested in the Japanese manner by planes cutting one another like the distant peak of Fujiyama appearing directly over the brink of a hill. The eye, leaping from one to the other, imagines the distance and gets the suggestion of space. Thus a space in modern settings is suggested rather than revealed: the base of one column will suggest an entire temple; one pillar in a gloom pierced by a stained glass window will convey an entire cathedral, and because there is no intermediate form between the pillar and the window, the blackness will seem as deep as the nave of a church. Even the window may not be shown but a shaft of light may be thrown from a point out of the spectator's range of vision in order to increase the scale by the same process of suggestion.

Light is the scene-painter of the modern theatre; light, not paint, draws the scene, and by varying planes of intensity, models it, and makes the corner of a building solid, a hill remote, a sky infinite though it be only two arms' length from the garden wall. If a stage 25 or 30 ft. deep is flooded with even radiance, nothing will persuade the eye that it is anything but a shallow box, however suggestive the arrangement of the setting itself may be. Settings are constructed now as in the Renaissance period, of canvases stretched on wooden frames and hinged or lashed together, but the paint on them is a mere preparation for the light to be thrown on. No setting can be designed until one is certain how one is going to light it; the colour painted is conceived as an undertone of what it will seem when lighted on the stage.

The railway viaduct in *Liliom,* for example, if it is to seem massive and menacing must have the light thrown across it, not at it, otherwise it will become flimsy canvas. Thrown from right to left the single pier casts a sharp shadow which gives a sense of solid masonry. The whole forepart of this scene must have a different quality and intensity of light from the distant silhouette of factory chimneys. With the right balance of light they will recede and seem distant even though they are actually only 8 ft. behind the arch culvert. And both foreground and background must be properly related to the sky if they are not both to fall into it.

So much for the scene; but there are the actors. They must be modelled and emphasized in the areas in which they move; sharply picked out at certain moments, where the action calls for it, at others almost blotted into half shadow, for this scene is one of ambush, of two thieves waiting to rob a cashier, and a rim of shadow into which they can retreat is part of the process of creating the atmosphere of terror and suspense when the crisis comes. Every scene has pools of light waiting for the actors, light which we do not see or know is there until the actor walks into it at a given moment.

Emotionally we react to light far more quickly than to any other medium in the theatre. We react to it even more quickly than to the actor's voice. In fact it sets the key of our emotions, and determines what effect the actor's voice will have on us. Lights not only paint and model the setting, emphasize its planes, and define its form; light also sustains the mood of a scene, and dramatizes its meaning. Crude or blatant lighting can war against the emotions an actor is trying to convey, and often destroy them entirely, all the more so because the lighting of any scene often does not remain static, but is dimmed or heightened, pulses and fluctuates with the action, like an orchestral score.

Change of light alone created every difference essential to the five acts of the *Tidings Brought to Mary.* The park scene of *Liliom* consisted of two gauzes on which the silhouettes of trees were pasted. The entire mood of the scene's poetic dusk was created by a balance of lights. In *Man and the Masses,* the contrast between the mystic dream scenes (not shown) and the sculpturesque force of the mob scenes is entirely a matter of lighting. In the course of the play there were several hundred subtle shifts of lighting timed to coincide with the action of the play. The tree of knowledge in *Back to Methuselah* was entirely made with light, projected from the rear. The sphinx in *Peer Gynt* became a towering form by the same process. The sacred tree on the rim of the Persian desert in *Marco Millions* was merely a silhouette on a semi-transparent back-drop. But it towered in mysterious majesty because of the way light was thrown upon it, from both front and rear.

The technical basis of this important phase of modern theatre art is the spot-light—in contrast to the flood light—which can be controlled and focussed accurately upon one particular spot. To be effective these spot-lights must be separately controlled so that each can be set at any point of intensity from full to dim and fluctuated back and forth if need be during the progress of the play. Hence the rheostats, or dimmer board, that controls these lights, is to the designer's conception what the central nervous system is to the ideas in the brain. Increased subtlety both in design and control of electric light, and particularly the colour of light, is the key to theatrical design of the future. That must wait not only on the playwright and stage designer, but on the lighting engineer, who, more than anyone, holds the key to the modern theatre's destiny. ## STAGE EQUIPMENT

The technical equipment of a modern stage consists of two types of machinery: (1) the mechanical equipment used to facilitate "setting and striking," *i.e.* shifting of scenery; and (2) electrical equipment to control the lighting of the stage.

A house has been described by one modern architect as a machine for living. A stage has always been a machine for giving plays. Even the Greek stage, usually supposed to be indifferent to scenic changes and scenic effects, was equipped, by the 4th century B.C. and probably earlier, with three standard pieces of machinery: (1) the crane used to lower the *deus ex machina* (the god out of the machine) from the roof of the palace façade; (2) the *periaktoi,* triangular prisms placed in the façade of the palace wall, revolving on wooden pins and turned in unison, each face painted

to indicate a different milieu so that three successive indications of place might be achieved, and (3) the *eccyclema,* or rolling platform which emerged from the palace doors after the tragic catastrophe, on which the murdered victim and often the aggressor were shown as a tableau.

The chief mechanical devices of the theatres in the Middle Ages, the Renaissance both in Italy and Elizabethan England, and the European theatres of the 17th and 18th centuries were the trap through which actors appeared and disappeared, often to the accompaniment of effects of smoke and flame; the moving platforms on which Christ was assumpted to the balcony heaven of an open air mediaeval mystery, or the classic gods descended 20 or 30 strong in the *gloire* that concluded so many 17th and 18th century spectacles and opera; and, when mobile scenery was adopted as part of the technique both of playwriting and play production, the windlasses and ropes which hoisted scenery out of the way or dropped it into place.

Until the latter part of the 19th century very little had been added to these basic stage mechanics. The revolving stage of the Japanese popular theatre of the 18th century was copied by Lautenschläger in Munich in 1898; the State and municipal theatres of Germany built in the early 1900s operated the traps mechanically, making them elevator stages which rose from a cellar level as needed. In addition sliding platforms, each carrying a complete setting, known as wagon stages, were utilized and often operated electrically.

In the United States none of these mechanical improvements was generally adopted, the reason being that the conditions of production remained radically different in the American theatre from those that prevailed in Europe. On the Continent theatrical production, particularly in Russia, Germany and the Scandinavian countries, was mainly in the hands of permanent resident companies operating endowed municipal or State theatres which gave a wide repertory of plays ranging from intimate realistic comedies or tragedies to large-scale spectacles and opera. The productions were built on the premises so that workshops as well as a large storehouse were an integral part of the architectural plan, as can be seen in the municipal theatre at Stuttgart with its large theatre at one end, a smaller theatre at the other, and the long façade of the storehouse serving as a connecting link between the two. The complete mechanization of such stages was considered worth the very large investment required in order to facilitate the giving of a different play every night of the week. This type of elaborately mechanized theatre is still standard in Europe, as exemplified by the theatres recently built in Göteborg and Malmö, Sweden.

In the United States, particularly after the decline of the local stock company at the end of the 19th century, the individual company, usually assembled for the occasion, was the producing unit, and much of its income was derived from touring on "the road" through all the principal cities and many of the smaller ones of the entire country. For this reason the mechanical arrangements of the stage remained primitive. Until late in the 19th century the rigging of most stages was exactly like that of a ship. The ropes needed to hoist the scenery up and down were attached to a fly gallery and tied to the belaying-pins on a pin rail, which was an almost exact counterpart of the pin rail of a frigate. Massive or solid scenery was not often built, the entire system of scenic construction consisting of breaking the sets into units not more than 5ft. 9in. wide so that when the settings were dismantled they could be slid through a baggage car door, its standard height being about 6 feet. The American theatre remains very largely an itinerant theatre to this day, the production being assembled usually in New York, then taken for a "tryout" on "the road," then brought back to New York; and, after a New York run, if it is a success, taken on tour again. Instead of being designed and built for the dimensions of a permanent playhouse, it must fit the variable stage dimensions, often exiguous, of any number of theatres.

American theatres have therefore generally been built to rent to travelling productions, either for a percentage of the box-office gross or for a fixed guarantee per week, and it has been the rule to provide as limited mechanical equipment as possible in order to reduce the landlord's overhead expense. The lighting system in these theatres is usually old-fashioned and even primitive, and controls the minimum of apparatus; a few overhead borders and footlights. The company must bring in all its lamps, cables and "dimmer boards," or rheostats, needed to control them. The only mechanical improvement that became common is the substitution of the counterweighted lines operated from the floor, which replace the dead pull of the old rope sets worked from the fly gallery. The houses built in the last century usually had a single trap, known as the Hamlet trap, placed so that Ophelia could be conveniently buried. The trapping of commercial stages is not uniform, and it is under these conditions that even the most modern scenic productions have been made, and to meet these conditions that they have had to be designed and devised. Where revolving stages or sliding stages are needed and used, as is occasionally the case, they also have to be carried on tour and assembled for each opening performance.

Before the deflation of 1929 very few technically adequate theatres had been built, the Century Playhouse, since torn down, a few theatres such as the Martin Beck theatre and the Guild theatre in New York being the exceptions, and a few new opera houses such as those in Chicago and San Francisco. In the main, however, the professional theatres in the United States have been either rudimentary or inadequate in equipment, and except for the houses on "the road" large enough to house musical comedies on tour the stages are too shallow and lack the off-stage space needed to manipulate efficiently and without great waste of time and labour the scenery and properties used during a typical performance.

The technical equipment of American theatres has recently improved due to the fact that they are now being built on college and university campuses for a continued repertory of student productions, and so begin to approximate the rational layout of the repertory houses of Europe. Notable examples are the new theatre at Stanford university, the Wisconsin Union theatre at Madison, Wisconsin, opened in 1939, and the auditorium at the University of Indiana, Bloomington, Indiana, opened in 1940, as well as such small theatres as the recently opened theatre at Amherst and the large playhouse projected for Dartmouth college. In these theatres, not restricted by the size of a conventional city lot, and where the cost of land is not an item of initial expense, stage dimensions are ample, the stage running from 35ft. to 40ft. in depth and 70ft. to 80ft. in width from wall to wall; they are provided with an adequately high gridiron, approximately 70ft., and a complete counterweight system as well as a stage floor that can be trapped over a third of its area. In addition there are workshops where an entire production can be fabricated and painted. At Stanford, at Wisconsin and at Bloomington two auditoriums are provided: a large auditorium with a seating capacity running from 1,300 to 3,000 which can be sub-divided by curtains for smaller audiences, and a smaller theatre for more intimate or experimental productions. At Bloomington and Wisconsin an electrically operated forestage has been provided which can at the touch of a push button be dropped below auditorium level to become an orchestra pit, raised above auditorium level for formal productions, making a forestage for an Elizabethan production if needed, or dropped to auditorium level to hold additional seats.

The funds available for the building of these theatres, running from approximately $500,000 to over $750,000 are, even so, not ample enough to provide for any further mechanization of the stage equipment, such as electrically driven revolving stages or wagon stages; even on a college campus the additional offstage space is rarely available which would be required to house these wagon stages when not in use. The plans for the Dartmouth theatre, however, call for two such reserve wagon stage spaces, and the prize winning design of the William and Mary competition (see *Theatre Arts* for June 1939) also indicate their use.

The more important technical equipment of the modern theatre remains the lighting control system, and the distinguishing feature of a modern production is the subtle variations of light which accompany and dramatize the dramatic action of the play. The

need for these changes, known as "dims," was felt centuries before the mechanical means for their effective use had been invented. The dialogues of Leone di Somi, a Mantuan stage director, written about 1565 (see Appendix B, Allardyce Nicoll's *The Development of the Theatre,* 2nd edition, Harcourt, Brace and Company, 1937) contain the following indications of how variations of light emphasize the mood of the scene:

"Now it has been a custom, both in ancient and modern times, to light bonfires and torches in the streets, on the housetops and on towers, as a sign of joy; and hence arises this theatrical convention—the imitating of such festive occasions. The lights are put there for no other purpose but to imitate, in the very first scene, this mood of gaiety."

"I suppose, then, that these lights would not appear in a tragedy."

"Perhaps they would not be so wholly out of place even in such a play. Quite apart from the fact that there are tragedies with happy endings, we note that nearly all tragedies open in a happy strain; and consequently it will not be unfitting to arouse the mind, so far as we may, to this happiness, although disasters and deaths are to ensue later. I remember once I had to produce a tragedy of this kind. During all the time when the episodes were happy in mood I had the stage brightly illuminated, but so soon as the first unhappy incident occurred—the unexpected death of a queen—while the chorus was engaged in lamenting that the sun could bear to look down on such evil, I contrived (by prearrangement, of course) that at that very instant most of the stage lights not used for the perspective were darkened or extinguished. This created a profound impression of horror among the spectators and won universal praise."

A device for dimming the candlelight of the period can be found in Nicola Sabbattini's well-known treatise, *The Practice of Making Scenes and Machines in Theatres,* printed in 1638.

Di Somi continues:

"It is a natural fact—as no doubt you are aware—that a man who stands in the shade sees much more distinctly an object illuminated from afar; the reason being that the sight proceeds more directly and without any distraction toward this object, or, according to the peripatetic theory, the object impinges itself more directly upon the eye. Wherefore I place only a few lamps in the auditorium, while at the same time I render the stage as bright as I possibly can."

Thus the general scheme and balance of our stage and auditorium lighting was anticipated by nearly 400 years. But the subtleties of modern stage lighting were not finally outlined until Adolphe Appia wrote his epoch making work, *Die Musik und die Inscenierung* (1899), and described in detail a typical light plot for a production, never made, of *Tristan und Isolde,* in the appendix to the volume:

"Picture of the stage at the rise of the curtain: A great torch at stage centre. The somewhat narrow stage space is filled with enough light so that the actors can be distinctly seen, without dimming the brilliance of the torch and above all without dimming the shadows which this source of light casts. The forms which demarcate the stage setting are seen only hazily. The quality of the light veils them in an atmospheric blur. A few barely visible lines in the stage setting indicate the forms of trees. Gradually the eye becomes accustomed to this; above, it becomes aware of the mass of a building in front of which one perceives a terrace.

"During the entire first scene Isolde and Brangaene stay on this terrace and between them and the foreground one senses a declivity, the forms of which one cannot identify clearly. When Isolde extinguishes the torch the entire setting is enveloped in a monotonous half-light in which the eye loses itself without being arrested by a single definite shape. Isolde, as she flies towards Tristan, is enveloped in mysterious shadow which intensifies the impression of death that the right half of the stage has already induced in us. During the first ecstasy of their encounter both remain on the terrace. At its climax (page 112, piano 8°, ff° in orch. *Mein!*) we perceive that they come toward us imperceptibly from the upper terrace and by means of a barely noticeable ramp reach a lower platform further in the foreground. This platform, the ramp leading from the terrace to it and another incline which leads to the forepart of the stage itself, make an uneven terrain on which the glowing dialogue of the scene that follows takes place.

"Then, when their desire is sufficiently appeased, when a single idea possesses them and when we become increasingly aware of the death of time, only then do they reach the foreground of the stage where (pp. 136–37) we perceive for the first time a bench that awaits them. The whole mysterious half-lighted space of the stage becomes still more uniform in tint. The structural forms are blotted out in the shadow of the background and even the different planes of the stage floor are no longer visible.

"Whether as a result of our visual reactions induced by the gleam of the torch and the shadows it casts, or whether because our eye has followed the path that Tristan and Isolde have just traversed, however that may be, we become aware of how tenderly they are enfolded by the world about them. During Brangaene's song the light grows still dimmer. Even the figures of the actors no longer have any clear definition. Finally, when passion awakes once more, grows and threatens by its overwhelming power to annihilate any scenic investiture that might be given it, at this moment (p. 162, first ff° in the orch.) a pale red light strikes at stage right in the background. King Mark and his men-of-arms break in upon the scene. Slowly, cold and colorless, the dawn begins. The eye begins to recognize the general forms of the stage setting and the painted flats that suggest them become clear and hard in quality for the first time. With the greatest effort at self-control Tristan comes back to contact with the world once again, challenging Melot, who betrayed him, to a duel.

"In the setting, now cold in color and hard as bone, only one spot is veiled from the dawning day and remains soft and shadowy: the bench at the foot of the terrace."

These ideas again anticipated the technical means of accomplishing them. It is only in recent years that lighting control systems have been perfected to the point where such fluctuations of atmosphere and light on the stage, to the accompaniment of the changes of dramatic mood and dramatic movement of the script, can be accomplished.

In order to understand this it is important to realize the elaboration of the lighting apparatus needed to light a play and its disposition. The footlights and borders which used to be the principal source of illumination are now unimportant adjuncts of lighting equipment. The focusing lens' spot light with coloured mediums of either glass or gelatin is the essential unit. They are usually assembled on two upright pipe battens on either side of the stage, known as the "light tormentors," and are also hung from one or more pipes overhead, the total often reaching 60 or more spot lights. In addition, in order to illuminate the actors without relying on bright foots which, if used with sufficient strength to light the actors' faces invariably cast distracting shadows on the scenery back of them, spot lights are located in the ceiling beam of the auditorium so that the angle of throw is approximately 60° and hits the actor head-high from the front of the forestage to a point within 6 or 8ft. upstage of the proscenium where the overhead and tormentor lights can illuminate him. These lights are focused in groups to cover various acting areas, and their colour is determined by the nature of the scene: whether daylight or night, whether they are projected to illuminate the actors or give colour and tone to the scenery. They are then successively brought up to a given point of intensity, *i.e.* "dimmed up," or "dimmed down" to a lower point of intensity in overlapping groups, making a light plot which approximates in general scheme and intention Appia's light plot quoted above.

The greatest flexibility of control is therefore essential, and the control board—commonly called the switchboard—remains the nerve centre and the most important single piece of apparatus on the modern stage. Up to recent years the standard rheostat or dimmer consisted of a wound core of resistance wire through which the current was shunted. Thus, when the light was dimmed a major portion of the current was turned into heat. The control was entirely mechanical, each dimmer having a dimmer handle which operated the dimmer from full to out. A certain number of these dimmers could be geared together on a shaft and worked by a master handle. However, as there was a limit to the number that could be geared together without creating too much friction or making the mechanical control extremely difficult to operate, it was usually impossible to select all the lights needed for a particular change and operate them together in a mechanically efficient way. One either needed several operators or often, on a large switchboard, an operator with the reach of an orang-utan. For it must be remembered that in the dimming changes of a modern light plot the light changes start with 50 or more lamps each set at different degrees of intensity—some may be full, some only half bright, others only a quarter up, etc. The change does not take them uniformly either to full or out. Those half-way up may only come down a few points in intensity; others may go to full out; others may come up in the opposite direction from nearly dim to nearly bright. And it is the drawback of the mechanical gearing of dimmer handles on a single shaft that it is impossible to gear them until they are all brought to the same level, so that the task of stopping some when they reach the various predetermined

levels of intensity is an almost impossible one to achieve accurately by hand.

This has been made possible recently by several improvements in the lighting control system. The first is a reactance dimmer in the form of a thyratron tube which directly regulates the voltage of each circuit. The second is a rheostat known as an auto-transformer which automatically transforms the voltage of the lamp to correspond with the desired intensity, the contact being a carbon or copper brush actuated by a motor. Both these dimmers have a variable capacity, the auto-transformer having a wider variable load. The old-fashioned resistance dimmer of 1,000 watts had to be connected with a lamp or lamps of a total 1,000 watts capacity in order to operate smoothly from full to out. The auto-transformer dimmers will take a lamp or circuit of 4,000 watts capacity or a lamp of 10 watts capacity from full to out or to any intermediate point, thus immensely increasing the flexibility of lighting control.

The reactance type of dimming control, though it is in process of being simplified, is much more complicated in wiring layout, more expensive both in initial and installation costs, and occupies more on-stage space than the auto-transformer type. The operating mechanism on the auto-transformer control board consists of a series of potentiometers which actuate, on a 24-volt circuit, the motors attached to the auto-transformers. The control is through a series of small handles over a graduated semi-circular arc which set each circuit at any point between full and out. Without affecting the set-up of the lights then on, a second set of handles controlling these same circuits is pre-set at any number of other points of predetermined intensity from full to out, and the change from the first pre-set to the second is made electrically, each circuit stopping at the point indicated and pre-set. Two master handles are provided which are electrical master controls so that, as on the board at the Wisconsin Union theatre, any of 56 circuits can be connected with one master, the remainder with the other master, and the light change be made on these two sets of selected circuits simultaneously at different speeds either in the same or opposite directions, *i.e.* either from full to out or from out to full, or to any number of pre-selected intermediate points of intensity for each circuit. The system thus gives complete control of any number of lighting units in any number of possible combinations in a way that no mechanical system of dimmer control is able to achieve. This lighting control system in one type or another will undoubtedly become standard in the near future.

It has the further advantage that the control wires can be extended to a point in the auditorium or in the projection booth at the rear of the auditorium, and a portable dimmer board be connected there so that the lights can be as effectively controlled from the auditorium as from backstage if the occasion requires.

An additional feature of modern lighting equipment is the lighting of the cyclorama. The illusion of depth and space in an open air sky is best achieved by a plaster dome, but as this is a heavy and elaborate piece of construction, and requires a great deal of off-stage space if it is not to interfere with the exigencies of scene shifting—more space than can usually be given to it or paid for—a cyclorama made of a textile is the usual substitute. This is a cylinder of cloth or canvas laced to a semicircular pipe above and below, and lighted from overhead and below by lights in parabolic reflectors with glass mediums that are spectroscopically accurate to act as light primaries—red, blue and green. By combinations of these at various intensities in conjunction with the proper painting of the cyclorama itself the colour of the cyclorama can be changed through almost the entire range of the spectrum. As painted canvas is very much affected by changes in humidity and can rarely be made to hang properly, the better practice is to use dyed cotton velour; and in order to facilitate changes of setting during scene intermissions, the up- and down-stage arms are made in the form of travellers, the velour being heavy enough to be drawn back without settling into wrinkles.

The mechanization of the stage for scene shifting seems to offer no further possibilities of practical development differing from what has already been achieved. Future technical developments will undoubtedly be in the electrical field, the development of low voltage high wattage lamps, increased flexibility of focusing lens units, increase in the range of variable load of rheostats and added flexibility of electric master and sub-master control.

BIBLIOGRAPHY.—These devices can be studied in detail in Gustave Cohen's *Histoire de la mise en scène dans le théâtre religieux français du moyen age* (1926) and *Le livre de conduite du régisseur et le compte des dépenses pour le mystère de la Passion joué à Mons en 1501* (1925); W. J. Lawrence's *The Elizabethan Playhouse and Other Studies* (Second Series, 1913); the section of Diderot's *Encyclopaedia* devoted to stage machinery, as well as in G. Bapst's *Essai sur l'Histoire du Théâtre*, and the richly illustrated portfolios of 18th century settings and stage mechanisms *Court Theatres of Drottningholm* (Swedish Architectural Historical Society). ## DEVELOPMENT OF STAGE LIGHTING EQUIPMENT

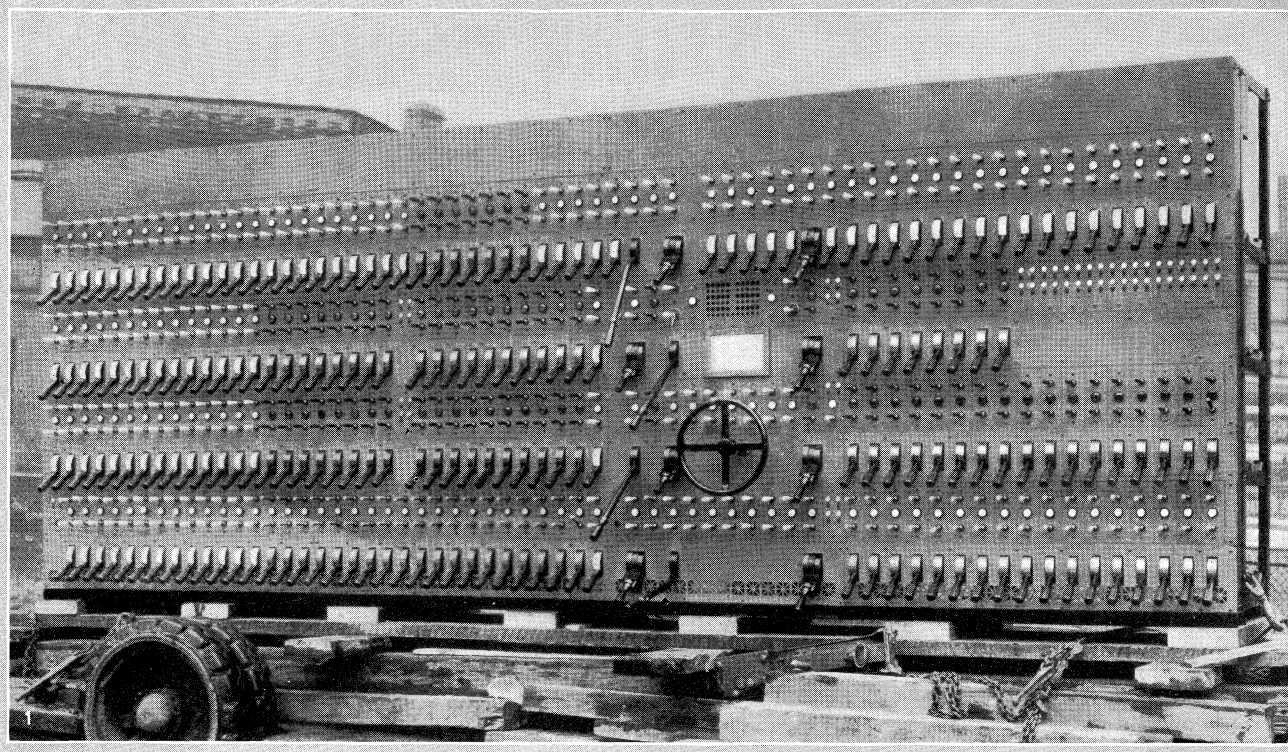
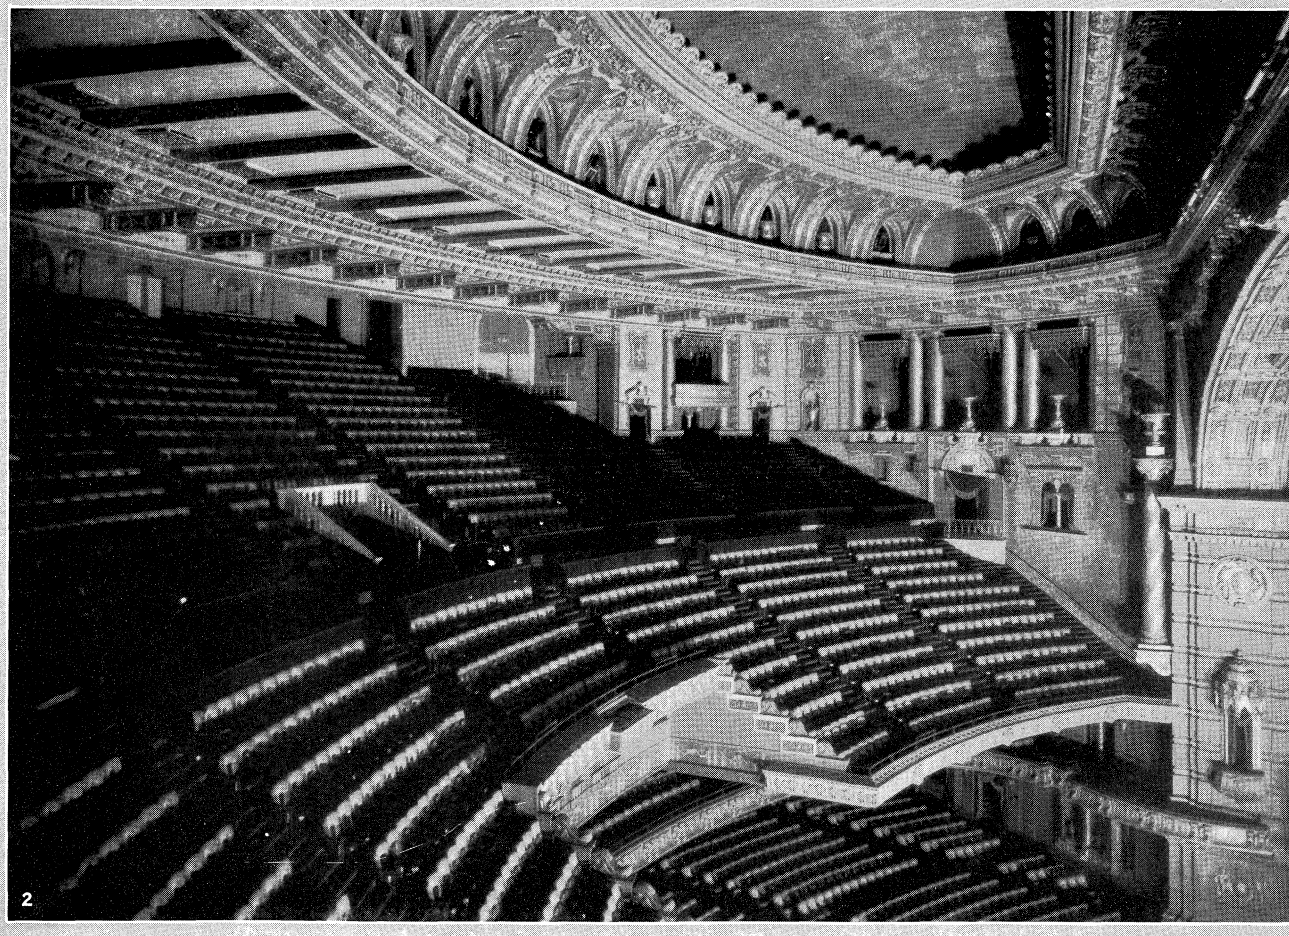
The first authentic description of artificial light as an integral part of a stage presentation is by the Italian Serlio who placed candles and torches behind flasks of coloured water, the light being projected through holes in the scenery. He also used pans and trays as reflectors to intensify the light; but one can imagine that the resulting illumination was never objectionably bright. Even in the early covered theatres the chief light sources were torches or pine knots, open lamps with floating wicks burning vegetable or animal oils, and candles of wax or tallow. "Paladio's theatre" in Italy and "Black Friars Inn" were the first of these indoor theatres and the first indoor productions in England did not take place till 1576.

The removal of the theatre from the open air into buildings was the first active force to bring about better artificial illumination. Inigo Jones brought the Italian theatre influence to England and used the proscenium arch. Gold decorations were applied to the theatre interiors reflecting light from huge clusters of candles. These were hung from the ceiling in a corona above the stage, and supplied all the general illumination. Even with candles, all the writers of the time referred to the lighting as "brilliant."

In 1628 Joseph Furtenbach described the use of oil lamps and candles as "floats" or "footlights," as well as "wing lights" the latter being now known as "borders." In 1775 when David Garrick placed a row of candles below and in front of the stage, masked from the audience by metal screens, they were an innovation in stage lighting. Not till the 18th century did oil lamps generally replace candles. The John Street theatre in New York, erected in 1767, was illuminated by candles for 30 years.



The invention of the Argand lamp in 1783 and the use of camphine, kerosene oil and other higher grade illuminants brought a far superior light to the theatre. The new lamp, which was a simple oil and wick combination provided with a glass chimney, was the first important scientific advance in light sources in 4,000 years. For the first time the illuminant was enclosed rather than being an open flame.



These lamps gradually supplanted the candles. Lamps hung in clusters from the ceilings and projected from walls, balconies and boxes. They were used as footlights, borderlights and wing lights. Despite the improvements, there was still only sufficient illumination to make the actors and scenery recognizable.

Then came gas. In 1781 William Murdock of England claimed a patent for its manufacture, and in 1803 F. A. Windsor completed the first theatre installation in the Lyceum theatre in London. In 1796 it was used in Philadelphia for exterior illumination; and in 1816 a complete gas lighting system was placed in operation in the Chestnut Street Opera house of the same city. Gas was manufactured on the theatre premises for the theatre only. An installation was, therefore, an expensive affair, and gas did not come into general use before 1850.

All of the original gas burners were open flames or flames burning in open glass chimneys. But in 1886 the Welsbach incandescent mantle was invented which increased the efficiency many times. They were used in borders, foots, wings, and bunch lights continuing the old conventions.

Gas for the first time permitted the control of all the lights on the stage from one central location. Elaborate systems were devised with mains sometimes more than 12″ in diameter, and

## A LIGHTING SWITCHBOARD AND THEATRE AUDITORIUM

1. Huge switchboard of the type necessary in large, modern theatres. Each switch plays an important part in the lighting effects achieved
2. Roxy Theatre auditorium. Spotlights, placed in the niches of the ceiling dome, may be regulated in fixed positions or used to follow moving figures on the stage. The dome lights are used to illuminate the orchestra during an overture, and are flexible enough for almost any type of lighting effect. Additional light units from the projection booth at the base of the balcony may be used for the same purpose

## LIGHTING EQUIPMENT FOR THEATRES

1. Spotlight with widely variable spread and soft-edged beam
2. Beam light projector, which throws a beam from three to four times as bright as that of an ordinary spotlight
3. An objective lens and an elliptically shaped reflector enable this lamp to project a beam of high intensity
4. Motor-driven autotransformer dimmer, modulite type
5. Borderlights are used for tone and blending rather than for sharp definition
6. Footlights illuminate the curtain, blend with spotlights, and are occasionally used to provide brilliant lighting from below

thousands of feet of feeder pipe, both flexible and rigid. The Lyceum theatre in London and the Boston theatre in America were two of the first to be equipped with these new controls which were called "gas tables." The first electric control boards were fashioned after these gas tables. They were located near the prompter who could reach a master valve controlling the entire layout. In addition to the master there were series of individual dimmer valves, and on some boards flash buttons by means of which spurts of flame could be made to give quick bursts of light.

Chief among the defects of this system was the risk of fire. Many theatre fires of this time were started by the blazing spirit wads on long poles used for lighting gas jets among the scenic pieces. Dancers with their thin costumes were sometimes set afire by the footlights. Because of these dangers, code regulations were established which fixed the position and number of burners in various locations, and made compulsory the use of guards and screens over open flames.

It became the custom at this time to dim the lights in the auditorium during the play, for at last the theatre had discovered that contrast between light and darkness was as important as light alone for visibility and maintaining interest.

Gas lights also left their impression on the scenic design and painting for many years to come. The light source was not small nor bright enough for small individual units; and the old-fashioned borderlights, footlights, and wing lights were retained, altered only to accommodate the burners replacing the oil floats, chimneys and candles.

Henry Irving experimented with effects of realism, using individual lights to achieve a more plastic illumination and devising an arrangement for drawing thin coloured silks or screens in front of others. He also started the use of sectionalized strips and borders—later employing spot lights—and thus increased the flexibility of existing apparatus. At this time also the cyclorama made its appearance, a piece of equipment still most useful on the stage.

In 1816 the calcium light or "lime light" was invented by Thomas Drummond, and by 1860 had come into general use in the theatre. From this unit came the common expression, "in the limelight" which is frequently used today. This light source was extremely white and concentrated and therefore could be used behind a lens or in front of a parabolic reflector as a spot light. The apparatus was used to "follow" characters about the set and in a few instances for general illumination of the stage. It required the constant attention of an operator.

The beginning of electricity in the theatre was the invention in 1808 of the arc by Sir Humphry Davy, who had also experimented with incandescent lamps as early as 1802. However, this apparatus, although invented before the "lime" lights, did not come into use till many years later. Frequent adjustment was necessary as the carbon was consumed, but the arc was a great advance over the calcium light. Two types of units were built around this source. One used a parabolic reflector behind the carbons, the other was equipped merely with hand operated shutters. The first device was designed in 1846 and used by M. J. Duboseq and M. Foncault in the production of *The Prophet* at the Paris Opera. Five years later M. Duboseq also developed a lightning machine of a type still used today, a rainbow projector, and a luminous fountain—all built about the arc as a light source.

In 1878 Paul Jablochkov introduced his Jablochkov candle, two vertical parallel sticks of carbon separated by a layer of insulating compound. In 1879 the Bellecour theatre in Lyons, France, installed 52 of them. But this method never came into general use for it could not compete with the incandescent lamp invented by Edison in 1879.

This invention brought to the theatre for the first time a clear, relatively high powered, easily controlled light source. For the first time there was light which could be used as a plastic medium, coloured, varied in form and intensity, used in ways which had never before been possible. Wagner in his operas had suggested possibilities in the use of light which stimulated the minds of the producers. He created a demand for technical developments which now began to look possible. Qualities of light were available to those who would use them, and theatre lighting as an art had arrived.

But the invention of the incandescent lamp alone did not immediately bring modern stage lighting to the theatre. However, its advantages over the older types of illuminants were recognized almost at once; and the change-over was more rapid than it had been with any other type of lamp. In 1880 and 1881 a series of experiments in the Paris Grand Opera resulted in the first theatrical installation of incandescent lamps. The greatest impetus was received from a theatre at the Electrotechnische Ausstellung at Munich in 1882. Incandescent and arc lights were used for auditorium as well as stage lighting; and units on the latter were equipped with remotely controlled colour screens. The tracker wire mechanical method was used for this colour changing and still is.

The first completely electrified theatres in Germany were the Landestheater in Stuttgart, the Residenztheater in Munich, the Staatsoper in Vienna, and the Staattheater in Brunn—all in 1883. The Savoy theatre in London and Bijou theatre in Boston installed electric lighting in 1882. The first New York theatre to be equipped was the People's theatre on the Bowery, in 1885. In 1882 a congress of theatrical managers assembled and issued a formal report favouring the illumination of halls and theatres by means of electricity. In 1871 this new method was so well established that a law was passed prohibiting the use of gas in all theatres of Prussia.

The original electric incandescent lighting units were footlights, borderlights, and wing lights, following the old conventions. Arcs were still used wherever concentrated light sources were necessary. The only bulbs available were of the carbon filament type which gave a relatively dull glow of a definitely orange colour.

Gradually, however, materials other than carbon were discovered and osmium, tantalum, moulded tungsten and finally drawn tungsten were used in filament constructions. The use of nitrogen and later nitrogen and argon in the bulbs further increased the efficiency and decreased the size of the lamps. Today, with coiled and coiled-coil filaments, gas filled bulbs, and heat resisting glass jackets, 500-watt lamps only 1½in. in diameter are in general spotlight service, and 5,000-watt lamps, although much larger are not uncommon.

With new light sources available, equipment was developed to use them more effectively. Steel MacKaye, a producer and actor, designed the modern effect machine as well as many other mechanical contrivances for the theatre. Mario Fortuny developed the Kuppelhorizont or dome, still the most perfect means of simulating natural or spectacular sky and background effects. He also developed a system of lighting named after him which utilized reflectors of coloured silk placed behind the lamps to tint and diffuse the light. These silk panels were movable so that the colours could be changed and the illumination softened.

David Belasco and his electrician, Louis Hartmann, abolished footlights—a suggestion made years before by Henry Irving—and began the use of individual sources from the auditorium and above the proscenium for acting area lighting. By means of these instruments as well as special reflector borders and baby lens spots they developed a standard of realism now in general practice in theatres throughout the United States. In Germany Lennebach, Hasait and many others made more contributions to the technical development of the theatre. They invented the rolling cyclorama and made up elaborate systems of light control. The Fortuny system was discarded and used only in rare instances.

Today the development of smaller lamps with hard glass jackets and concentrated filaments, and new types of reflecting surfaces have made possible the design of two new types of spotlights. By reducing the diameter of the lamp bulb and using a Fresnel or stepped lens, an instrument having a high efficiency and giving an even field with soft edges, useful for acting area lighting and easy to blend into a general effect, has been developed. The second type of spotlight differs entirely from this, the light from the lamp being gathered and redirected by a reflector rather than a lens.

An ellipsoidal reflector has the valuable characteristic of re-

directing light which is generated at one of its conjugate foci through the other. This is the principle of the ellipsoidal reflector spotlight. A lamp with tubular glass jacket and concentrated filament, generally of the base-up burning type, is placed with its filament near the focal point within a reflector. A gate or aperture is placed between the reflector and the conjugate focal point and "filled" with the reflected light. One or two lenses acting as an objective then project an image of the aperture on the field to be illuminated. In this way fields of even intensity are produced, the beam may be shaped by means of shutters, iris, or other controls at the aperture, hard or soft edges are possible through focusing of the objectives, and efficiencies comparable to those of the Fresnel lens spotlight are obtained.

The two above mentioned types of spotlights have to a large extent replaced the "standard" plano-convex lens "spots."

Besides the spotlights, three other types of lighting equipment are widely used in stage presentations. First are the striplights—really the first form of apparatus as the old wing or borderlights were strips. The latest development in striplights is the individual reflector type in which each lamp is placed in a spun reflector equipped with either a coloured glass roundel or a gelatin, or glass colour frame.

Floodlights are specially shaped reflectors for individual lamps. They are made in narrow beam or wide beam types and accommodate small or large lamps. Wide angle floodlights are used for illuminating back drops and cycloramas, and, in the U.S., are matte finished ellipsoidal reflectors. Banks of them equipped with three or more filters can give effects which simulate any degree of sky colour from midday to midnight including the brilliant hours of sunset and dawn.

Special effects, the fourth class of lighting equipment, often are built about the spotlight as a base; but they may include anything from painted rainbows and moving clouds to water ripples of cut glass strips, a burst of fireworks, or a waving flag. The effects are generally painted on mica discs enclosed in a sheet metal protective housing and driven by electric or clockwork motors. These "effects" are placed in front of spotlights, an additional lens being added to each to further concentrate the light; and objective lenses project the images of the moving discs.

As opposed to the complicated design of these "projection effects" is the simplicity of the shadow projector. This apparatus is very old in principle but the form now used in stage work is the Linnebach lantern—named after Adolph Linnebach, the designer. It consists of a deep box painted black inside and surrounding a concentrated filament lamp or arc. One side of the box is open, and over this is placed the slide carrying the design to be projected. Because the lamp filament or arc has a definite size, sharp projections such as are obtained with lens units are impossible. But very wide areas can be covered at relatively short projection distances; and, especially for silhouettes of skylines and crude outlines, this method has no equal.

In step with improvements in equipment has been the development of new colour media. Fortuny and other of his contemporaries used coloured silks and reflectors for tinting the light. Lamp dip appeared after the invention of incandescent lamps. Today sheet gelatin is still probably the most widely used colour medium. It is available in large sizes, a great variety of colours, is inexpensive, and most of the colours are relatively fast. Efforts are constantly being made to increase their permanence.

Gelatin, however, is very unsatisfactory in damp climates as it absorbs water readily and proceeds to "melt." In any climate after being subjected to heat from lamps for several hours it becomes very brittle and tends to shrivel. Acetates, such as celluloid, are much stiffer and do not absorb water, but they are very inflammable and the fire hazard precludes their use. Gelatin may be ignited but supports combustion only with difficulty, and tends to smoulder rather than burst into an open flame.

Cellophane has been used with a great degree of success in recent years. It is available in 11 colours besides clear, black, and two degrees of clear diffused. It is thinner than gelatin, is not greatly affected by dampness, and supports combustion only with difficulty. Some of the colours are quite fast, but others rather unstable; and the limited colour selection is, of course, a great disadvantage.

From many standpoints glass is the ideal theatrical colour medium despite its weight, initial cost and fragility. It has come into use only recently and more because new equipment required it than because it was developed to a new degree of perfection. "Gelatins" burned out with alarming rapidity when used in front of high powered spotlights, but when the Fresnel lens and ellipsoidal reflector spotlights came into use with their greater light outputs and concentrated beams, new colour filters had to be found at once. Coloured sheet glass in both "flashed" and "pot" forms was available, but none of it was heat resisting. What to do? Well, the glass, once it cracked under heat, was not likely to break again. Therefore, why not break it in a regular pattern before using it? This system was tested in practice and was successful. Coloured sheet glass is now cut into strips, mounted between sheets of asbestos paper and the whole bound in a substantial metal frame. Some of these frames have been tested in front of 5,000 watt Fresnel lens spotlights and have become so hot that solder melted when placed in contact with the glass, yet there are practically no cases of the glass failing under such conditions. Glass is not the perfect colour medium. It is fragile, heavy and expensive. Its colour range is limited, and sheets of glass often vary in colour and transmission by as much as 50% from one end to the other. The field of plastics at present seems to promise a great advance in colour control in the theatre. But as yet there are no transparent materials which are available in heat resisting quality. But one day in the not too distant future we may expect a material which can be used without a stiffening frame to support it, one which is impervious to heat or moisture, available in a multitude of fast colours. It will be light yet sturdy, and less expensive than glass filters. It is not too much to expect.

For the remote control of all the old gas lighting equipment, the gas table had proved very satisfactory. In the first switchboards only intensity control was thought necessary, although colour controls had already been included in many of the previous gas installations. The first electric dimmers were water barrels with two metal plates put in a weak solution of brine. One plate rested at the bottom of the barrel, the other could be raised or lowered, thus varying the resistance of the circuit by varying the amount of brine between the plates through which the current had to flow. These units were extremely unsatisfactory as the water evaporated rapidly; the heat, if the barrels were overloaded, produced a vile smelling vapour; and the settings for any particular lamp intensity were never twice the same.

The next type of intensity control was a coil of German silver resistance wire tapped at a number of points, these taps being connected by wires to the points of a rotary switch. By turning the switch the resistance in the circuit could be varied at will. The resistance coils were generally mounted in the basement while the switches were located on the stage floor. Because the resistance to current flow uses energy which is transformed into heat, the coils became hot, especially when overloaded—and for that reason were dangerous. A large number of wires leading from the control switches to the coils were also necessary, and this was eliminated by the resistance plate dimmers next developed.

In this type the resistance wire was laid out on a plate, either itself an insulator or coated with an insulating and heat resisting compound. The switchpoints were connected with the wire. The entire assembly was coated with more heat resisting material until only the contact surfaces of the switchpoints were visible. The tapping arms were pivoted directly to the resistance block. This type of control unit is still the most widely used on American stages.

The most obvious fault of the resistance control has already been mentioned:—that energy is used in reducing the current flow and is then dissipated in heat. This fault was recognized as early as 1890 and in 1896 a reactance type of dimmer bank was installed in the Earl's Court theatre in London. Here a double reactance with one coil slipping in and out of the second was used to control each circuit, alternating current being used rather than direct. The plan worked well enough but alternating current was not always available.

Other faults of the resistance dimmer are their large size and weight and the fact that they will control only loads of approximately the same capacity as their own rating. But nearly all types of alternating current control units will operate with lamp loads from their maximum capacity down to zero. They are primarily voltage and not current regulators.

The most modern types of alternating current controls are the auto-transformer dimmer, and the electronic tube and reactance circuit. The first is manufactured in sizes up to 5,000 watts for single phase loads and up to 10,000 watts for three phase loads.

The latest development in theatrical intensity control equipment is the electronic tube and reactor circuit, and, still more recently, electronic tubes which themselves carry a considerable load current. By means of these devices switchboard sizes have been tremendously reduced, and a panel the size of a moderately large radio receiver is now sufficient to control the lights in an entire theatre.

Switching and dimming equipment have been improved and reduced in size, weight and cost. Pre-set and fader circuits have been developed which permit the instant switching of a large number of controls by means of a single master lever, or allow an operator gradually to change the lighting from one predetermined setting to another, some units dimming, some brightening, but all in proportion to their individual readings.

As has been mentioned previously, tracker wires and mechanical link movements are still the standard means of remote colour control in Europe. In the U.S., self-synchronous motors and electromagnetic controls perform the same service. The former permit an operator at the central control panel to move colour frames or lighting units themselves in exactly the same way in which he manipulates levers and dials. Only electric circuits connect the control and the lighting equipment—there are no moving cables or pulleys. Electromagnets perform quick changes, such as colour frame shifts, upon being energized by means of a push button or switch, but cannot be made to control slow movements.

**STAGGER PLAN.** The great congestion of transit facilities in some of the larger cities of the United States, due to a uniformity of opening and closing hours, led to the formulation of a so-called stagger plan. The acuteness of the problem in the city of New York is mainly due to the large number of persons involved, to the fact that business areas are highly concentrated as the result of tall buildings and to the fact that travel is confined largely to two directions, owing to the shape and geographical location of the island which forms the centre of New York's business activity. The department of health, feeling that the congestion of the transit facilities constituted a menace to health, conducted a survey to determine the feasibility of "staggering" or varying the opening and closing hours of firms employing large numbers of persons. As the result of this survey, a plan was determined upon and a considerable number of organizations voluntarily agreed to shift their opening and closing hours in conformity with the recommendations of the health department. Some of the larger companies found it desirable to divide their employees into groups, one group arriving at 8.30, another at 8.45, another at 9, another at 9.15 and another at 9.30. Each of these groups left at correspondingly different times in the afternoon. The groups were chosen in such a manner as to be co-ordinate with the flow of work in the organization. In addition to relieving congestion on the transit lines, this also tended to relieve congestion in the company's building. The plan was first advanced in 1926 and developed only voluntarily thereafter. (O. G. S.)

**STAHL, FRIEDRICH JULIUS** (1802–1861), German ecclesiastical lawyer and politician, was born at Munich on Jan. 16, 1802, of Jewish parentage. At the age of nineteen he entered the Lutheran church. He was professor of law at Würzburg, and of ecclesiastical law and polity at Berlin. Stahl early fell under the influence of Schelling, and at the latter's insistence, began in 1827 his great work: *Die Philosophie des Rechts nach geschichtlicher Ansicht* (an historical view of the philosophy of law), in which he bases all law and political science upon Christian revelation, denies rationalistic doctrines, and, as a deduction from this principle, maintains that a state church must be strictly confessional. This position he further elucidated in his *Der christliche Staat und sein Verhältniss zum Deismus und Judenthum* (The Christian State and its relation to Deism and Judaism). As synodal councillor Stahl made use of his influence to weaken the Evangelical Union (*i.e.,* that compromise between the Calvinist and Lutheran doctrines which is the essence of the Prussian Evangelical Church) and to strengthen the influence of the Lutheran Church. (Cf. *Die Lutherische Kirche und die Union,* 1859.) Frederick William IV. supported Stahl in his ecclesiastical policy, and the Prussian Evangelical Church would probably have been dissolved had not the regency of Prince William (afterwards the emperor William I.) supervened in 1858. Stahl retired into private life and died at Brückenau on Aug. 10, 1861.

**STAHL, GEORG ERNST** (1660–1734), German chemist and physician, was born on Oct. 21, 1660, at Anspach. Having graduated in medicine at Jena in 1683, he became court physician to the duke of Weimar in 1687. From 1694 to 1716 he held the chair of medicine at Halle, and was then appointed physician to the king of Prussia in Berlin, where he died on May 14, 1734. In chemistry he is chiefly known in connection with his doctrine of phlogiston (*see* Chemistry, *History of*), the essentials of which, however, he owed to J. J. Becher; and he also propounded a view of fermentation which in some respects resembles that supported by Liebig a century and a half later.

**STÅHLBERG, KAARLO JUHO** (1865– ), Finnish statesman, was born on Jan. 28, 1865. At the beginning of his public career, he held alternately university and administrative posts until he became a member of the Diet in 1904 and of the Finnish Government in 1905. He resigned in 1907 and in the following year was appointed a professor of administrative law. At the outbreak of the World War, the government was Finnish in name only, being composed entirely of Russian officials. Ståhlberg was then president of the Diet and he had to act as the chief public representative of Finnish opinion. He firmly withstood the increasingly oppressive tendencies of the Imperial Russian Government. After the Russian revolution of 1917 Finland became an independent republic, and in 1919 Ståhlberg was elected to the presidency and as the candidate of the Progressive and Socialist parties he had to fight the unconcealed hostility and distrust of the conservative parties. He pursued, nevertheless, a conciliatory and mitigating policy, and when the time of the next presidential election approached, the country almost unanimously desired him to accept re-election. He refused, however, and retired on the expiration of his presidency.

**STAINED GLASS,** a term that is generally understood to refer only to glass windows that have been coloured by such methods as the fusion of metallic oxides into the glass, the burning of pigment into the surface of white glass, or the joining of white with coloured pieces of glass.

### ORIGINS

The origin of stained glass is obscure. It probably came from the Near East, the home of the glass industry, and mosaic windows of glass set in plaster work, which we know from the 17th century in Egypt and elsewhere, are probably of great antiquity. But it is not likely that the art goes farther back than the 9th century; it is doubtful if before that time glass was made in a sufficient variety of colours to suggest and produce coloured designs. The art would most naturally spread first to Italy, and Venice may have been a centre as early as the 10th century. An Italian panel in the Victoria and Albert Museum, tentatively ascribed to the 13th or 14th century, is fully Italian and Romanesque in style and suggests a native tradition. Actually the earliest reference to stained glass in the accepted sense of the term (that is, windows not merely coloured, but pictorial also) is in a manuscript which records that Adalbéron, bishop of Rheims from 969 to 988, rebuilt the cathedral and redecorated it with windows representing various stories (Richer, vol. ii., lib. 3). An earlier reference, in a 9th century life of St. Ludger, certainly relates to coloured windows, but it is not clear that they were pictorial. Mâle gives, as the earliest mention of leading, a reference to the *Miracles of Saint Benoit* where it is related that in the last years of the 10th century the church of Fleury-sur-Loire was set on fire and it was feared that the leads of the windows would be melted. Which are the earliest windows extant is a matter of dispute, but the evidence, both literary and stylistic, seems to favour certain figures of prophets in Augsburg cathedral, which may date from the middle of the 11th century.

### TECHNIQUE

A stained-glass window is a translucent mosaic held together by lead; that is the simplest conception of its technique. Actually other considerations come into play in the design and execution of a window. The lead is not merely a connecting medium, but in all good design plays a part of its own; it outlines the main constituents of the design, giving definition and rhythm to the masses of colour. From the account given by Theophilus, we can derive a very accurate notion of the technique as practised when the art first came to its perfection in the 12th century. The general scheme for the glazing of a church was, of course, the care of the clerics, and we may assume that the artists among them, the illuminators, would prepare the first drawings. One such series of drawings, the Guthlac Roll, is preserved in the British Museum (Harley Roll, Y 6). But the actual cartoon for the glass was drawn on one end of a whitewashed board supported on trestles. The vacant space at the other end was used for laying out the glass and for the general business of glazing. The cartoon was marked to indicate the various colours, and the next step was to shape a piece of glass to the outline required by the design. This was done, firstly and roughly, with a hot iron and then more carefully with a tool known as the "grozing iron," a flat piece of iron with a notch at one end, rather like a modern spanner. This must have been a slow and laborious process, but the grozing iron seems to have continued in use until about 1500,

when the modern method of diamond cutting began to be employed. The next step, in a fully developed stained-glass window, was to paint the glass with details which the bare design of glass could not give. At first the use of paint was confined to an opaque brown (grisaille, *q.v.*), used, not as colour, but as a means of outlining the design in further detail, reinforcing the effect of the leads. This pigment consisted of powdered glass mixed with a metallic oxide (probably iron), to which was added sufficient gum to make the mixture adhere. If "high lights" were desired, the whole surface of the particular piece of glass was covered with a thin coating of this paint and the lines scratched through with a pointed stick. Shading effects were produced by stippling with a brush. The glass, having been painted, was next fired in the kiln, to fuse the enamels to the glass. In mediaeval times the glass was fired in a pan, which was filled to the top with alternate layers of glass and whiting. When the glass was fused sufficiently, it was brought out and cooled and then rearranged on the glazing table. The next step was the leading. This was (and still is) done by means of strips of lead, in section like the letter H, but with a thicker cross-bar to represent the "core" of the lead; the upright strokes represent the "tapes." At first the leads were cast, but in the 17th century the lead vice was introduced. This is a kind of mangle, with two toothed wheels like coins with milled edges, between which a strip of lead is squeezed, the soft metal emerging in the form already described. Sometimes the wheels had the glazier's name engraved on them, which thus became impressed on the lead as it passed through the machine, and these names are occasionally found on old leading. When the leads, cut to the required length and shape, had been inserted between the pieces of grozed glass, they were next soldered together at the points of junction, and cement or putty was rubbed into the crevices between glass and lead. The window was then ready to move into place, where it was fixed by means of leaden strips soldered to the leads and attached to iron saddle-bars let into the masonry. Larger windows were made in smaller units and these units fitted into an iron framework or "armature" which itself often formed a geometric design contributing to the general effect of the window.

From the 12th to the 15th century the technique of stained glass remained practically unchanged, though one minor innovation had a great effect on the character of design. This was the invention, early in the 14th century, of a yellow stain derived from a solution of silver. It formed a very thin film on the glass and was therefore very transparent; on clear glass it varied in tone from pale lemon yellow to deep orange; but it could also be applied to blue glass to produce a brilliant green. Its effect on design was far-reaching and will be noticed when we come to the history of the craft. In the 16th century the technique of glass-painting became more scientific; the glass itself was thinner and smoother and more transparent; two layers of different colours could be put together to produce a third colour; if these layers were fused together, one layer could be ground away or "abraded" (and by a later process "eaten" away by fluoric acid) to give delicate effects beyond the reach of a leaded mosaic. Finally, towards the middle of the 16th century, the art of painting in enamel on glass appeared, perhaps as a result of economic causes which made a scarcity of pot-metal. Hitherto glass had been coloured throughout its substance and was known as "pot-metal," though to obtain sufficient translucency in a dark colour like ruby the glass was "flashed," that is to say, clear glass whilst still pliant was dipped into molten coloured glass, and so received a translucent film of the desired colour. But now ground glass was mixed with various metallic oxides (copper for green, cobalt for blue, manganese for purple, and so on) and the design was then painted on to a clear sheet of glass and fused on. For some time this technique was continued with the old technique of leaded pot-metal; but in the 17th and 18th centuries the old technique disappeared, and the art of stained glass was virtually dead.

## HISTORY

**Eleventh and Twelfth Centuries.**—The windows at Augsburg, ascribed by Fischer to the middle of the 11th century, have already been mentioned. To the end of the 11th century belongs a window at Le Mans (France) painted with the Ascension. For the 12th century we have in England a figure from a Tree of Jesse in the minster at York, and at Canterbury there is a magnificent series representing the genealogy of Christ which may be dated about 1180. At Chartres there are more important and extensive examples—in the west window is a Tree of Jesse design which is undoubtedly the best surviving stained glass of this century; also the beautiful figure of the Virgin and Child known as La Belle Verrière. Other considerable specimens of 12th century glass exist at Angers, Saint Denis, Châlons-sur-Marne, Bourges, Strasbourg, Poitiers and Le Champ (Isère). The earliest of these windows, such as those at Augsburg and Chartres, are strongly Romanesque in character. The windows at Canterbury come at the end of the Romanesque tradition. They still preserve the monumentality so characteristic of Romanesque design, but the figures are far removed from the rigorously schematic treatment of the Augsburg prophets; there is the first flush of humanism in their bold features. There is a sense of movement in their limbs; a sense of vigour in the formal draperies. The colouring of this Canterbury glass is still typical of the 12th century; the bare flesh is cut in pink glass, whilst the rest of the design is a quiet harmony of blues, pale green, white, brown and yellow, arranged in fairly broad masses with no effort towards "jewel-like" quality. The architectural settings are rudimentary, in most cases representing a simple column on each side of the figure, with an arch spanning the head.

It is probable that most of the early windows were of the single-figure, monumental character of the Augsburg and Canterbury examples. But about the middle of the 12th century a new type of window came into being which consisted, instead of a single representative figure, of a medallion (or several medallions) painted with pictorial subjects, such as incidents from the life of Christ, or from the life of some saint. This change was accompanied by various subsidiary developments. The necessity of telling a story in a series of medallions led to the decorative arrangement of these medallions within an "armature" or iron framework which was itself a subject for pattern, and very beautiful designs were evolved, showing a skilful counterplay of circles, lozenges, quatrefoils and squares, with their appropriate borders and interspaces. This development in its turn necessitated larger windows and this necessity had a profound effect on the development of Gothic architecture itself. A third development was in the actual colour of the glass. The pictorial treatment called for a more detailed and more varied play of colour, and the technical resources of the glass-maker were equal to this demand. The result was that kaleidoscopic or jewel-like glow of colours with which stained glass is always popularly associated. It is in glass of the early 13th century that this property is supremely evident.

**Thirteenth Century.**—With these early 13th century medallions we first become fully conscious of the part played by the actual painting in stained glass. It is true that the earlier figures had a broad effective scheme of drawing, but with the 13th century medallions a fine dramatic sense of line was developed and continued in force throughout the century. And with the sense of line came that superb sense of dramatic composition illustrated in so many of the medallions of this period at Canterbury, Lincoln, Chartres, Sens, Bourges, Le Mans, Rouen, Cologne, Marburg and Klosterneuburg (near Vienna). The highly stylicized motives of the decorative borders of the 12th century were no longer in keeping with this dramatic mode, and as the century advances we accordingly get a naturalizing of these motives. The formal acanthus leaves of classical inspiration give place to more natural plant motives, to scrolls of oak and vine; these coil with a more organic and vigorous movement, until eventually, in the 14th century, the artists begin to copy directly from their own observation—from the ivy and the wild strawberry.

Towards the last quarter of the 13th century, a greyer mood seems to have descended on our glass-painters. It may be that they were required to give more light in the churches, or that the supply of ruby glass, always somewhat precarious, gave out. Whatever the reason, there developed in the latter part of the

13th and early 14th centuries the technique generally known as *grisaille* painting. It implies the use of large areas of clear quarries painted in black or brown enamel with simple and unobtrusive patterns of foliage. Grisaille work at this period is of two kinds: it may consist of geometrical patterns of quarries, often outlined in coloured bands, on which are painted designs of foliage, often in imitation of a trellised plant, or it may be used in combination with subject medallions. The best instance of this latter method is perhaps seen in the windows of the Chapter House at York, which, though now much decayed and obscured, are supreme examples of grisaille work.

These characteristics of 13th century stained glass are general wherever the main stream of Gothic art (*q.v.*) flowed. Distinctions of nationality need not, and indeed cannot, be made. In point of time the medallion windows at Canterbury perhaps come first; then, closest in time and style, come the similar windows at Sens; Chartres comes next and is very impressive in its quantity and scale; at Bourges and Rouen there is glass very similar to that of Chartres; the glass at Lincoln and Beverley in England must be placed somewhere before the middle of the century. But back again in France we find a more distinctive school developing in Paris during the second half of the century, in connection with the building of the Sainte Chapelle and the extension of Notre Dame. The distinguishing feature of this latter style was the general use of a background of trellis-work in blue and red glass, which, in the mass, has a rather unpleasant purple effect. This style scarcely penetrated to England, though an example may be seen in the east window of the south transept of Christ Church, Oxford.

**Fourteenth Century.**—Midway in the 14th century comes the Black Death, and this catastrophe marks the end of the pure Gothic tradition, in this as in all other arts. Its most marked effect was perhaps reflected in the break-up of the inter-community of Christian art. No doubt other forces, economic or political, were operative too; but the disorganization caused by the Black Death among artists and craftsmen all over Europe resulted in the formation of more limited and more local schools. Onward from 1350 the styles of England, France, Austria and Germany diverge more and more from each other. And within all these countries the local differentiations between various centres are often very marked. The disorganization not only affected traditions, but even more so technique. It seems that the ability to manufacture some of the brilliantly coloured kinds of glass was lost at this time, never fully to be recovered until the 19th century. There was also a Cistercian ban on pictorial windows, which no doubt had some influence in this direction, during the 14th century. But the glass-painters were not slow to react to the new situation; the invention of yellow stain early in the century had provided them with one new resource; and the growing taste for line design, as witnessed in the grisaille glass already mentioned, led to the full exploitation of clear white glass. When once the use of white glass had been forced on the glass-painters, its aesthetic value was appreciated. It may be also that the resultant effect on the lighting of the churches was appreciated, and that the glass-painters began consciously to aim at a clearer effect. Architectural developments kept pace with, and even aided, this changing colour-scale. The windows grew higher and wider, the tracery more intricate, demanding of the glass-painter an effect that was not too heavy for the expanse to be filled, or too clumsy for its delicacy.

Further developments were due not so much to economic factors as to a change in spirit. The 14th century saw the full emergence of that movement towards humanism which had found its protagonist early in the 13th century in St. Francis of Assisi. The tendency towards naturalism which we have already seen creeping into the decorative motives of stained glass was a far wider phenomenon, and involved all art and literature. The new spirit of Franciscan naturalism only manifested itself in plastic art by slow degrees, but it culminated in the Renaissance. It involved a transformation of Christian iconography, and the glass-painter, along with other artists, now deserted the fixed types of early Gothic art for the living types before him. Subjects are now given a contemporary setting; for his figures, his costumes and his architecture the painter looked around him and found models before his eyes. A playful freedom of line gradually developed; as the brush-stroke grew lighter, it grew easier. The features are rendered with more grace and verve; there is almost an excess of curve and curl in eyes and lips and locks. An individualization of the features begins to creep in; we begin to feel the presence of real people, friends and contemporaries of the glass-painter, no longer abstracted, no longer idealized. The folds of the garments lose their angular restlessness and sweep and sway in graceful curves. We get, too, the entry of fashion. The garments in the 12th and 13th centuries are formal and of classical derivation, except in so far as they are ecclesiastical or military. They continue to be somewhat non-committal during the first half of the 14th century, but with the growth of naturalistic treatment and the revival of figure-subjects we get the unmistakable evidences of contemporary fashions. The representation of costume then becomes a matter of course, and is of great assistance in the precise dating of stained glass.

But the most typical and expressive development of ornament is seen in the canopy. This form of architectural ornament no doubt originated in the 12th century, when an architectural unit —generally an arch—was introduced to indicate a building or interior scene. This simple unit became more elaborate during the 13th century, but remained essentially illustrative in intention. Then we get as an early characteristic of the 14th century, the elaboration of this detail into purely ornamental features. The architecture is given the value of pure decoration. At first this is rendered in one dimension, and slender pillars and fretted pinnacles, interchanged in colour, form a simple and effective setting for the figures within the framework. But as the architecture itself becomes more elaborate, its representation in the glass develops. By the end of the 14th century we find an elaborate use of perspective. In the 15th century the spirit of play breaks out even here, and the niches are peopled with angels and coy minstrels. As the century advances the canopies grow more complex, though more representational.

**Fifteenth Century.**—With this development of the architectural features of stained glass ornament is perhaps bound up a curious retrogression during the 15th century—the abandonment of natural plant motives for stylicized diapers. Artists forsook the carefully observed ivy, oak and vine, and introduced instead such dreary motives as that usually described as the "seaweed pattern"—an elongated, shapelessly indented leaf, generally painted in reserve on a blue or ruby glass, and seemingly kept as "stock" to be used whenever the design required an indeterminate background. It was a step towards that still more slipshod expedient—the stencilled diaper background of the 16th century. The borders, which had always been an integral part of stained glass design, develop in conformity with the general trend. But their aesthetic function becomes less obvious and they gradually lose decorative value. In the 12th century the border had been the essential framework of the design, enclosing within its definite pattern the otherwise unconfined design. In the 13th century the border existed as a foil for the sequence of separate designs. Then, in the 14th century, when the subject-panel became isolated from its background, the border became a purely decorative feature, contributing a separate unit to the general aesthetic effect; in the 12th century the border framed the design—in the 14th it edged the frame of stonework, its naturalistic form suiting this purpose admirably. Then in the 15th century, with its strange efflorescence of canopy work, the border tended to lose all aesthetic justification; it existed merely as a strip dividing the design from the stonework, and providing, as it were, a transition from one to the other. In this rôle it naturally tended to become more formal in character. Already in the 14th century the typical border of creeping foliage had been varied with alternations of devices such as crowns, chalices, heraldic badges, grotesque animals, small figures of angels, etc.; an exceptional example is to be seen in the famous Bellfounders' window in the north aisle of the nave, York minster, where the border consists of bells (outer lights) and musical monkeys (centre

light). The 15th century saw some recovery of the sense of colour. Coloured glass of a variety of colours, but too even and flat in tone to be quite satisfactory, became available on the Continent and was largely imported into England. Already in 1408 the east window at York minster, made by John Thornton of Coventry, is full of a new vitality and gaiety. The covenants for the execution of the glass in the Beauchamp Chapel, Warwick, which are dated 1447, specifically provide for glazing the windows "with Glasse beyond the Seas, and with no Glasse of England; and that in the finest wise, with the best, cleanest and strongest glasse of beyond the Sea that may be had in England." This window was carried out by John Prudde, one of the greatest of English glass-painters, and the result is versatile in the extreme, the colours, jewelled and counterchanged to the utmost limits of ingenuity, blazing with the greatest richness imaginable.

In Germany also, the development was in consonance with the richness and complexity of late Gothic art in general, and here the development may be particularly associated with the name of Hans Wild, whose principal works date from about 1470 to 1480. His most famous window is in the cathedral at Ulm, and shows great boldness and original fantasy in the use of foliage motives. The window becomes a luxuriant trelliswork of flowering plants and pinnacles in the depths of which the human figures tend almost to disappear.

One characteristic of this period is the development of heraldry in glass. We have practically no knowledge or records of the use of heraldry in stained-glass windows previous to the 14th century, though there are three 13th century shields in the apse windows of Westminster Abbey which serve to indicate an early use of heraldic glass. We know from records that these shields were originally placed in the aisle windows, which were of grisaille. But the particular circumstances which brought heraldic glass into general use are hardly consistent with the spirit of early Gothic art. One of the characteristics of the 14th century is the introduction of the personal element into the windows. Donors began to desire their portraits within the design of their window; memorials to the immediate dead began to assume a representational form. At first no attempt at faithful portrayal could be made; the mode and technique of glass-painting at that time forbade it. The shield of arms had therefore the very definite use of identification. But it was soon realized that heraldry had an aesthetic value of its own, and its use multiplied. Glass proved to be especially suitable to the rendering of the formal patterns of the shields, and the brilliancy doubly attractive in this personal emblem. The ground of the shield, which was usually filled in with a diaper pattern, gave the glass-painter an opportunity to exercise his skill in brushwork and his fertility in the invention of decorative motives. The technique of scratching a design with a point through a dense ground of colour, always a pleasant technique in glass-painting, was encouraged by this development. The glass-painter kept pace with the herald, and did not hesitate to attempt the utmost elaboration of curved shield and exuberant mantling. With the Renaissance heraldic glass took on a more restrained appearance—at least, in England, where the common use of the garter and the wreath tended to confine the design within sober limits. Elsewhere, especially in Switzerland, heraldic glass became, during the course of the 15th and 16th centuries, the most typical use of glass-painting.

The 15th century saw a great growth and intensification of the individualism we have already noted as arising in the 14th century. Such a development naturally gave rise to the dominance of artists of unusual talent, and to the formation of schools dependent on such artists. A distinct style became established as a local tradition and sometimes persisted over two or three generations. Such schools were formed all over Europe, and particularly in the great ecclesiastical cities. In England, for example, definite schools can be associated with York, Coventry, Canterbury, Winchester, Oxford, Gloucester, Wells, Lincoln, Norwich and Westminster.

The different styles are not always easy to distinguish, and the "schools" are rather in the nature of empirical groupings based on the density of distribution.

Towards the end of the 15th century England suffered a general invasion of foreign artists and craftsmen, a growing influx that reached its culmination early in the next century with the arrival of Torrigiano and Holbein. At this time, in the Netherlands, the art of stained glass had reached a development which, in accomplishment and modernity, was far ahead of the insular style in vogue among English glass-painters. The wool and cloth trades flourished in spite of the wars. The new merchants, earnest Lollards as they were, were eager to turn their wealth to some good purpose, and thus they made the 15th century an age of church building and charitable foundations. And these merchants, moreover, were men of some culture, whose business had brought them into contact with foreign luxuries—particularly those of the Netherlands. When, therefore, they required glass for the beautifully furnished churches which they began to construct in various parts of the country, they demanded glass in keeping with their luxurious tastes, and for this they turned to the men from the Netherlands. In answer to the demand these men came across and, in accordance with the regulations, established themselves within a recognized sanctuary such as the liberty of St. Thomas in Southwark, and assumed English names. As time went on, they became a menace to the existence of the London Company or Gild of Glaziers, and a continual series of disputes between the Gild and the foreigners marks the beginning of the 16th century. But the proper tradition of glass-painting was entirely lost. In the middle ages stained glass thrived as an art subordinate to, or in community with, architecture. With the Renaissance, and the shifting of the dominant emphasis of artistic effort from architecture to painting, the glass-painter found himself in a dilemma. He had to adapt his art to the new conditions, or suffer from the general neglect of arts subordinate to architecture. He attempted to save himself by adopting the aesthetics of painting, and the history of stained glass henceforth is the history of this false step and of all the disastrous consequences.

**Sixteenth and Seventeenth Centuries.**—But whilst this false aesthetic was developing, there grew up in France and the Netherlands a full-blooded Renaissance style of glass-painting which makes the first half of the 16th century a distinctive epoch in the history of the art. It is a development of the pictorial treatment of the windows on the largest possible scale; the window is regarded as one large canvas; the intersecting mullions are ignored. On this canvas the coloured glass is spread in generous masses and heightened by all the resources of line and shade. The windows gleam with everything that is rich and ornate in colour, design and subject. The glass is thin, but this fault is counteracted by the breadth of the treatment. The Netherlandish type is well represented in England by the work of imported artists, of whom Barnard Flower is the most important. This artist came from the Netherlands, probably encouraged by Henry VII., who made him king's glazier in 1505. Flower executed the whole of the windows for Henry VII.'s chapel at Westminster, and was entrusted with the contract for King's College chapel, Cambridge, but died before he had completed more than four of the windows. It is probable that among the work which may be attributed to Flower are the windows of Fairford church in Gloucestershire, perhaps the most complete unit of stained glass remaining intact in England. King's College chapel, begun by Flower after designs probably by the Flemish artist, Dirick Vellert, was completed by a mixed company of English and Flemish glaziers.

In France, Rouen was the great centre of glass-painting, and that city still offers an incomparable display of the glass of this period, though many other towns, such as Evreux, Châlons-sur-Marne, Dreux, Beauvais, Auch, Troyes and Montmorency, are famous for their windows. In the Netherlands, the most important windows of this period are found in Antwerp, Hoogstraten, Brussels, Liége and Amsterdam, whilst the windows at Gouda, painted by the brothers Dirk and Walter Crabeth and their pupils, towards the end of the 16th century, are of extraordinary range and completeness. In Germany important schools existed at Strasbourg, Augsburg, Munich, Freiburg-im-Breisgau, Nurem-

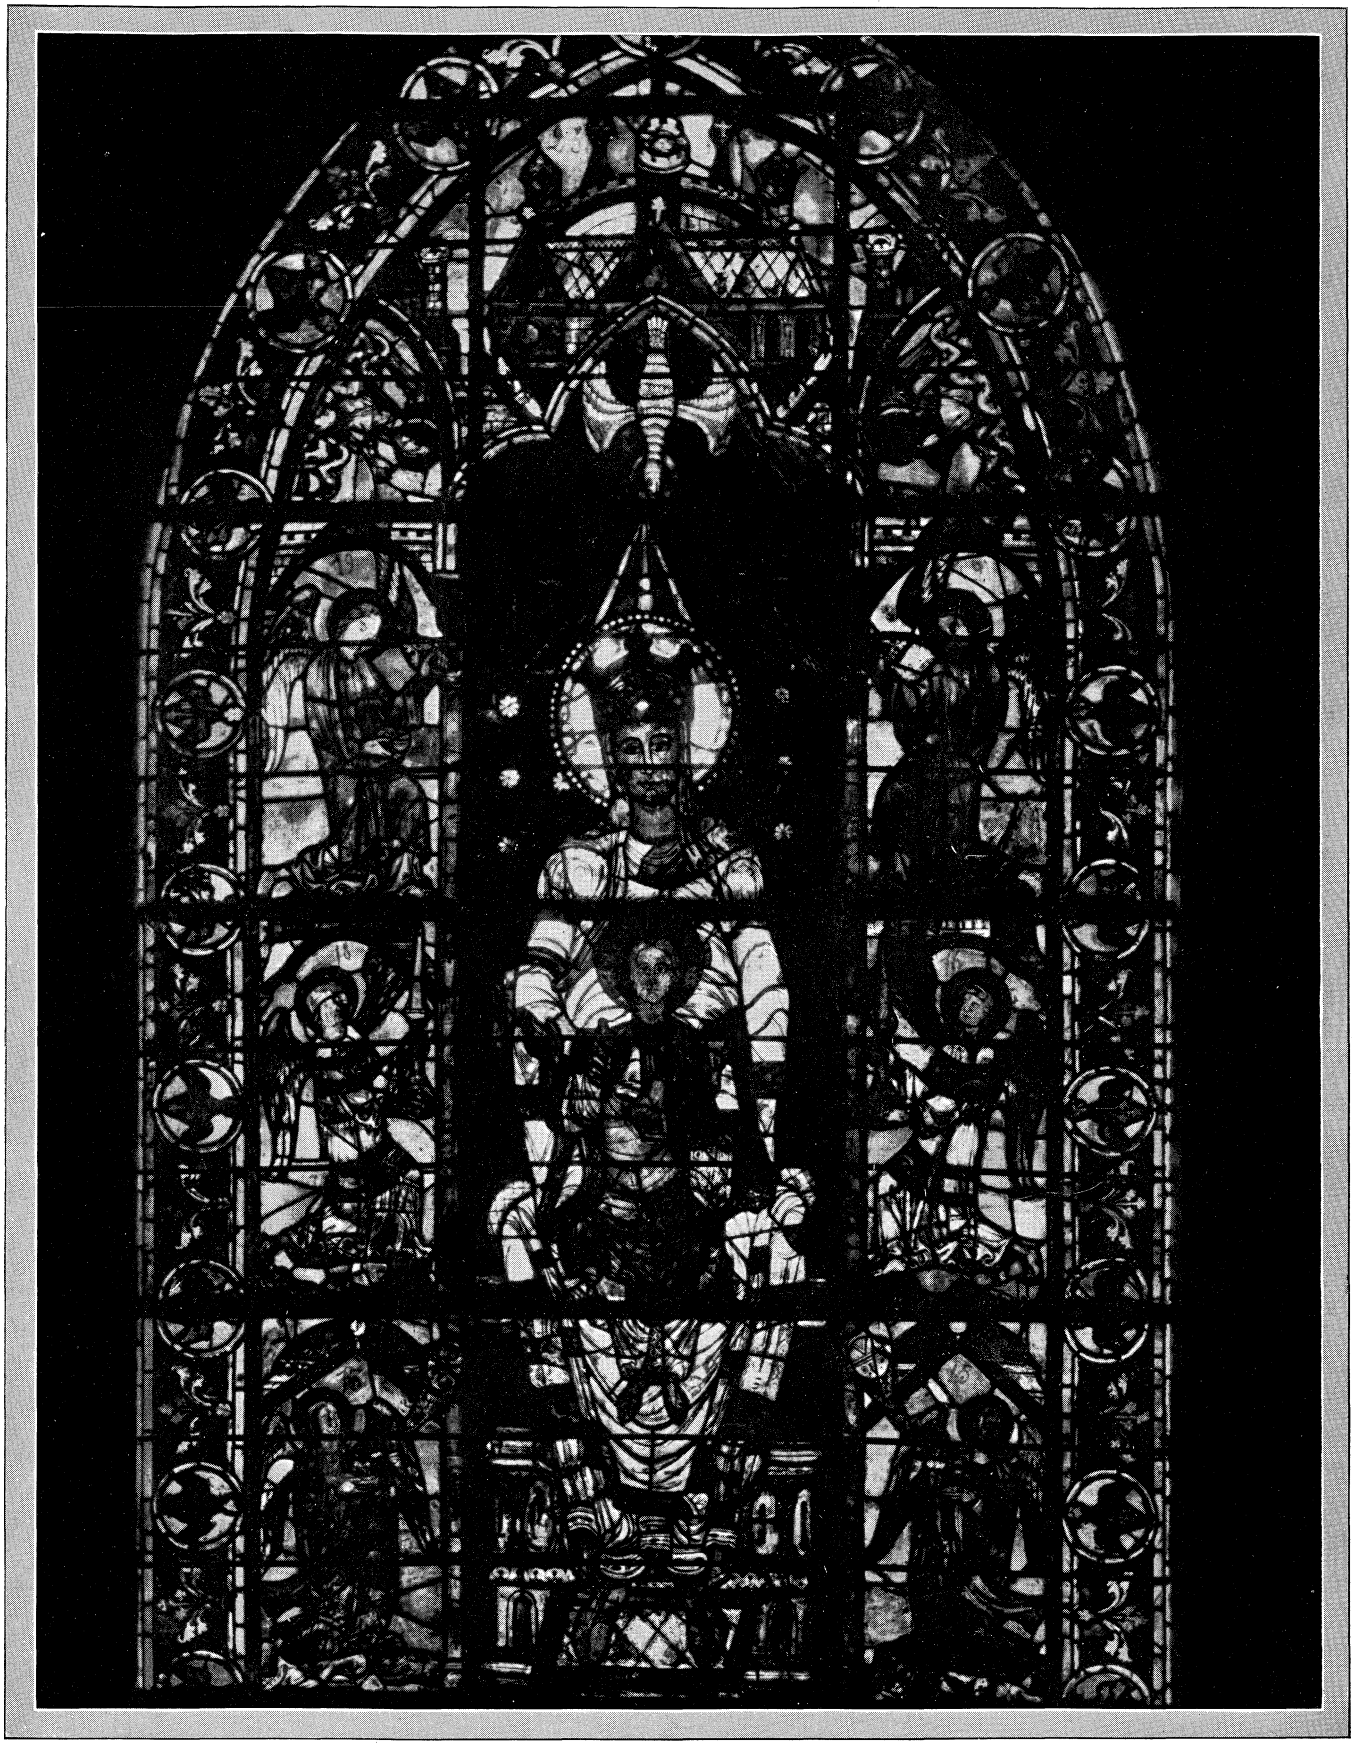
ENGLISH STAINED GLASS

"The Patriarch Jared." 12th century window in the south transept of Canterbury Cathedral. As in much of the mediaeval glass in England, the bare flesh is cut in pink glass, while the rest of the design is a harmony of blues, pale green, white, brown and yellow, arranged in fairly broad masses

ENGLISH STAINED GLASS

"St. Anne Teaching the Virgin." From the east window of All Saints church, York, dated about 1440. The colouring is simple though rich in quality, a characteristic of English glass of this period. St. Anne wears a ruby cloak and bonnet and a blue gown. The Virgin's dress is white, ornamented with a pale yellow pattern, and the background of figures and canopy is blue covered with a diaper. All other parts are white with some yellow stain

berg, and above all at Cologne, the general character of all of which was not essentially different from that of the dominant Flemish or French type. In Italy the period is mainly associated with the name of Guglielmo de Marcillat (1467–1529, sometimes erroneously called William of Marseilles). Windows known to have been made by him exist at Arezzo and Rome, and a very typical example from the cathedral of Cortona, dated 1516, is in the Victoria and Albert Museum. At Florence, where there are also important earlier windows in the cathedral which are said to have been designed by Ghiberti and Donatello, other windows in the style of Marcillat may be seen in the church of Santa Croce. The building of the cathedral at Milan caused an important school of glass-painting to develop there, and the work of Cristoforo de Mottios and Nicolo da Varallo carried out during the second half of the 15th century is of great beauty. The Milan school continued in full activity during the 16th and 17th centuries. In Spain, especially at Seville, León and Avila, magnificent windows of this period exist, but they are in all cases the work of Flemish glass-painters.



In the 17th century we find the highest level of glass-painting in Switzerland, though actually that level had been surpassed in its own country during the 16th century, when Holbein and Burgkmair were leading designers of the panels typical of that country. But the real significance of Switzerland in the history of glass-painting is that there alone was evolved an appropriate technique of enamel-painting. For various reasons of a social kind, glass-painting in that country had acquired a more domestic character; it actually became part of the furniture of the people, and a panel for the window of a room was as natural, and even more usual, than a picture for the wall. Glass-paintings thus became intimate and portable—a kind of *Kleinmalerei* comparable to the development of *Kleinplastik* in sculpture. Within the limits of this littleness, the art of enamelling glass developed an appropriate technique. It was, indeed, the technique of painting—of translucent painting—but then the Swiss panel *was* in all essentials a painting. To the same category belong the roundels painted in grisaille which were produced in large quantities during the first half of the 16th century. In these types of glass-painting the specific problems of distance and architectural harmony did not enter into the question; everything was made for nearness and intimacy. And on this scale stained glass was inappropriate, ungainly and without effect.

The same observations might be made of the Dutch and Flemish glass-paintings of the 16th and 17th centuries, which illustrate the enamel technique in both its good and bad aspects, and it was through these, rather than the Swiss, that the new style penetrated to England. Abraham and Bernard van Linge (who flourished about 1620–40 and painted many windows in Oxford and elsewhere) were the chief of these immigrants, but they were ably imitated by native artists such as Henry Gyles of York (1645–1709), the Price and the Peckitt families of the same city, and by artists like Francis Eginton (1737–1805) and James Pearson (d. 1805), who carried the art right on to the threshold of the 19th century. At their best, the achievements of the glass-painters in this *genre* have a miniature delicacy and a perfection of means beyond reproach. But it must be realized that we have entered on a new art, with its own aesthetic, and we must beware of any confusions of judgment in this respect. The unfortunate truth is that in England (and elsewhere in Europe) it was the glass-painters who were guilty of confusion. Social custom never called upon them for a domestic art comparable with Swiss glass-painting, but nevertheless they attempted to apply the methods of the domestic glass-painters (but without their technical skill) to the quite different needs of ecclesiastical buildings. The result was generally ludicrous, and always inappropriate. The crowning example of this misalliance of two inconsistent arts is to be found in the window designed by Sir Joshua Reynolds for New College chapel, Oxford, which was actually carried out by a china-painter.

The art of glass-painting in England during the 17th and 18th centuries does not offer sufficient material for any comparative criticism or positive judgment. We see nothing but scattered individuals, each expressing his own wayward fancy, displaying some ingenuity, supplying some passing need, but achieving nothing of significance.

**Eighteenth and Nineteenth Centuries.**—The Gothic revival that came as an offspring of the Romantic movement of the late 18th and early 19th centuries was not without its effect on the art of stained glass. The styles and methods of the early Gothic period were reconstructed, but devoid of all inner reason or inspiring sentiment. The art thus reduced to sterile formulas was easily commercialized, and factories for the manufacture of windows, any size, any subject and colours to taste, sprang up all over Europe, but especially in Germany. From this state of things the Pre-Raphaelites and William Morris (*q.v.*), largely inspired by Ruskin, revolted, and whatever faults we may impute to them, we must nevertheless acknowledge that they made a feeling for design once again a vital force in the social life of England—and, indeed, eventually of Europe. We cannot enter here into the general character of Morris's achievements, but the basic fact upon which all his ideals rested was an intense aesthetic appreciation of mediaeval art. As much, perhaps, can be said of the initiators of the Gothic revival, though we may suspect that as an aspect of romanticism their enthusiasm sprang from a sense of the remoteness, the strangeness, and the mysterious gloom of this earlier art rather than from any real understanding of its rational basis or religious significance. But Morris had a more logical appreciation of the Gothic, and his attitude was as free from insincerity as it was devoid of any desire to imitate. He realized that without the spirit, the form could not exist, and his real greatness and overwhelming importance in the history of modern craftsmanship springs entirely from the fact that he attempted to evolve a style and invent a technique appropriate to the expressions of his age. Burne-Jones designed his first cartoons for stained glass as early as 1857, and the St. Frideswide window in Christ church, Oxford, dates from 1859. These early windows were carried out by Messrs. Powell of the Whitefriars Glasshouse, but from 1861 Burne-Jones worked exclusively for Morris. Stained glass was included in the first exhibition of the work of Morris, Marshall, Faulkner and Company in 1862. But the work of this period is weak in design and uncertain in technique. No attempt had been made to work out the proper function of the leads in the design, and the enamels are either poor in quality or badly fired. But even so, there was a certain freshness of attitude and a revolt against the dead conventions of the time. But as the demand for stained glass increased, so more thought was given to these matters and the improvement was rapid. In Morris's fully developed style, as in the cathedral at Birmingham, there is little to complain of in the technique of his glass. Time has yet to show whether the materials will weather so well as the 13th century materials, but in this matter Morris was at the mercy of other people; he did not make his own glass, but obtained the best he could find in the market. In other technical matters Morris need not fear comparison with any age. His selection and disposition of colours is admirable, and he was not afraid of using new colours to achieve effects unknown to previous ages. In the use of leads to emphasize design he is masterly, and we must go back to the 13th century for an adequate comparison. The best examples of windows by Morris and Burne-Jones are to be found in Christ church, Oxford (the St. Cecilia and St. Catherine windows, 1874–75 and 1878), the "Judgment" window at Easthampstead (1875), the two windows in Salisbury cathedral (1879), the east window of St. Peter's, Vere street, London (1881), a window representing the Resurrection at Hopton (1882), the well-known windows in the cathedral at Birmingham, perhaps the finest of all (1887), and (perhaps the most important in London) the windows at Holy Trinity, Sloane street. What is reputed to be one of the finest examples of their work (1882) is a window at Biarritz in France, representing the marriage at Cana. In addition to all the work designed for churches, and confined in the main to Biblical subjects, Burne-Jones and Morris made a good deal of stained glass for domestic or secular purposes. In their choice of subjects for this profane glass, they perhaps unduly confined themselves to the romantic and literary

"Fishing." Example of modern German stained glass, Seewald, executed by G. Heinersdorff. 4. "St. Peter," English, middle 14th century. In Gloucester Cathedral. 5. "God Appearing unto Abram." English, middle 15th century. In Great Malvern Priory. 6. "St. Peter." French, second half of 13th century. From Sées Cathedral, Normandy. 7 and 8. "Prophets." German, 11th century. In Augsburg Cathedral. 9. "The Creation of Eve," in the Cathedral, Chalons-sur-Marne. French, middle 15th century. 10. "St. Michael," German, 14th century. 11. "The Institution of Matrimony" another stained glass window at Chalons-sur-Marne

predilections of their circle; but here again we cannot criticize their stained glass without entering into a discussion of their whole point of view. It is perhaps sufficient to say that it lacked the immediacy and the reality which we are entitled to expect from any contemporary expression of ideals.

The principles which William Morris established and followed give us an adequate criterion for the criticism of modern stained glass. It is sad to confess how little these principles have been followed in England itself. There is no longer any vital contact between the glass-painters and the significant artists of the day. And in all directions there is a relapse into a servile and lifeless imitation of mediaeval mannerisms, due to a natural disregard for those self-sacrificing ordinances which Morris observed. It seems that only the complete filling of every window in every old church will ever terminate this atrocious vandalism. There might be some satisfaction in the prospect if it were certain that that would put a stop to what is known in the trade as "period work"; but these *pastiches* of the art of other epochs find their way into practically every new church that is built, and the only hope of any reform would seem to lie in the final triumph of those principles for which William Morris stood. For these principles are not altogether dead; they have merely migrated, and on the Continent, especially in Germany, there is a school of glass-painting which is not only modern in intention, but is inspired by all that is vital and significant in modern art.

Like the stained glass of William Morris, this modern continental stained glass is both religious and secular. The work of Jan Thorn-Prikker and of Karl Schmidt-Rottluff has given to the symbols and images of Christianity a new intensity and realism for which there is no parallel this side of the Renaissance; and the abstract designs in which these glass-painters have experimented seem to open up infinite possibilities for this art of pure colour and light. These artists work under the direction of Gottfried Heinersdorff for the Berlin firm of Puhl and Wagner. In France, interesting experimental work is being done, for example, by MM. Mauméjean of Paris and Hendaye. Stained glass, which dominates all other arts in this matter of colour, would seem to be peculiarly fitted for those experiments in abstract design and harmony which have been distinctive of a certain phase of modern art. The difficulty in all contemporary glass-painting of a non-ecclesiastical kind, is not so much to extend the possibilities of the art in the direction of design and actuality, but rather to find a function for the art itself. For that we must look, with whatever faith we can summon, to those manifestations of civic and commercial enterprise for which our age is distinguished. At Hagen, in Germany, the railway station has fine modern glass by Jan Thorn-Prikker; in Paris, the offices of a newspaper, *L'Intransigeant*, have windows with appropriate designs by Henri Navarre executed in leaded glass by Gaëtan Jeannin. But these are isolated instances of what seems to be the only chance of a revival of the art commensurate with its possibilities. There is nothing impossible in such a revival; the technical and material resources of the art are greater than they have ever been. All that is lacking is the desire; and to foster this we cannot do better than instil a wider consciousness of the unique and unrivalled beauties of the art as it has existed in the past.

**STAINES,** an urban district in Middlesex, England, 19 mi. from London by the S.R.; served also by the G.W.R. Pop. (est. 1938) 29,920. Area, 12.9 sq.mi. A British village was situated at the Thames on the main road from London, and the crossing was one of the earliest bridged. The existing bridge, designed by George Rennie, was opened in 1831, after three bridges had failed in the previous forty years. The name of Staines appears in Domesday, and has been attributed to a stone marking an early limit of the City of London.

**STAINLESS STEEL** is a term used in a broad sense, particularly in America, to cover all "rustless steels" (*q.v.*) or iron alloys designed to resist atmospheric corrosion, attack by organic solutions, hot or cold acids or chemicals, or scaling at elevated temperatures. In the restricted sense the term applies as a trade name to cutlery steels containing not more than 0·70% carbon and from 9 to 16% of chromium patented in 1916 by the English metallurgist Brearley. Chromium is the principal alloying element in most stainless metals (in the broad sense used above). Stainless or rustless iron contains less than 0·10% carbon and usually from 12 to 18% chromium, the balance being iron. It is inherently stainless to atmospheric corrosion, resists most acids and chemicals fairly well, and can be fabricated and worked cold like mild steel. Most of the possible iron-carbon-chromium compounds up to 3% carbon and 60% chromium have been patented, in addition to the Brearley patent noted above, and many of them containing more than 20% chromium, either in the form of forgings or castings, are non-scaling. Chromium steels containing considerable nickel, for instance 18% chromium and 8% nickel, are non-rusting and are austenitic (*see* STEELS, ALLOY) in structure, very tough, may be hardened by cold work, and are being widely adopted by industry as an "all purpose" alloy (semi-noble). Addition of silicon improves the resistance to scaling of this and plain chromium steels (gas engine valves, for instance, contain 8% chromium and 3% silicon). Other alloying elements are also used for special purposes. Superior resistance to hot or cold hydrochloric acid (until recently unobtainable by any but the noble metals) is given by an alloy of 20% iron, 20% molybdenum and 60% nickel. Alloys based on 35% nickel, 15% chromium, 50% iron make strong, tough, and scale resistant parts for furnaces. While the entire field of iron-carbon-chromium-nickel-silicon alloys is so big that the surface has barely been scratched, to say nothing of possible additions of tungsten, molybdenum, cobalt, copper, manganese, and aluminium, enough is known of the properties of various stainless alloys so that small pieces or large equipment which will corrode or scale no faster than 0.02 in. per year can now be furnished for nearly all commercial liquids or industrial atmospheres. (E. E. T.)

**STAIR, JAMES DALRYMPLE,** 1st VISCOUNT (1619–1695), Scottish lawyer and statesman, was born in May 1619, at Drummurchie in Ayrshire. After seven years as regent of the University of Glasgow he resigned, going to Edinburgh, where he was admitted to the bar on Feb. 17, 1648. In 1649 he was appointed secretary to the unsuccessful commission sent to The Hague to treat with Charles II. by the parliament of Scotland, and was sent in the following year to Breda, where the failure of Montrose's expedition forced Charles to change his attitude and to return to Scotland as the covenanted king. Stair met him on his landing in Aberdeenshire. He refused in 1654 to take the oath of allegiance to the Commonwealth. Three years later (1657), Stair was appointed a commissioner of justice in Scotland, on the recommendation of Monk. After the Restoration he was received with favour by Charles, knighted, and made a judge in the court of session. He refused to take the declaration that the National Covenant and the Solemn League and Covenant were unlawful oaths, and, forestalling deposition, he resigned. The king, however, summoned him to London, and allowed him to take the declaration under an implied reservation. In 1669 a family calam-

ity, the exact facts of which will probably never be ascertained, overtook him. His daughter Janet, who had been betrothed to Lord Rutherford, was married to Dunbar of Baldoon, and some tragic incident occurred on the wedding night, from the effects of which she never recovered[1].

In 1670 Stair served as one of the Scottish commissioners who went to London to treat of the Union. In Jan. 1671 he was appointed president of the court of session. In 1672, and again in 1673, he was returned to parliament for Wigtownshire. When the Test Act was enforced Stair, dreading a fate similar to that of Argyll (*q.v.*), went to London to seek a personal interview with the king; but the duke of York intercepted his access to the royal ear, and when he returned to Scotland he found a new commission of judges issued, from which his name was omitted. He retired to his wife's estate in Galloway, and occupied himself with preparing for the press his great work, *The Institutions of the Law of Scotland,* which he published in the autumn of 1681, with a dedication to the king. He repaired to Holland in Oct. 1684, and took up his residence, along with his wife and some of his younger children, at Leiden, where he published the *Decisions of the Court of Session between 1666 and 1671* and a small treatise entitled *Physiologia nova experimentalis.*

In his absence a prosecution for treason was raised against him and others of the exiles by Sir G. Mackenzie, the lord advocate, but it was dropped, owing to the appointment of his son, the master of Stair, who had made his peace with James II., as lord advocate in place of Mackenzie. Stair returned from Holland in the suite of William of Orange. In 1689 he was again placed at the head of the court of session. He was attacked by an anonymous pamphleteer, perhaps Montgomery or Ferguson the Plotter, in a pamphlet entitled *The Late Proceedings of the Parliament of Scotland Stated and Vindicated.* He defended himself by publishing an *Apology.*

Shortly after its issue he was created Viscount Stair (1690). The massacre of the Macdonalds of Glencoe (Feb. 13, 1692), for which his son, the master of Stair, was largely responsible, naturally reflected on him. On Nov. 29, 1695 Stair died in Edinburgh.

Stair's great legal work, *The Institutions of the Law of Scotland deduced from its Originals, and collated with the Civil, Canon and Feudal Laws and with the Customs of Neighbouring Nations* is important for the historical study of Scottish law. *See* J. Murray Graham, *Annals of the Viscount and First and Second Earls of Stair* (1875); A. J. G. Mackay, *Memoir of Sir James Dalrymple, First Viscount Stair* (1875); and Sir R. Douglas, *Peerage of Scotland,* new ed., by Sir J. B. Paul.

**STAIR,** a series of steps arranged one above the other, occasionally varied by platforms known as "landings." The total height of a stair is the "rise," the total horizontal distance between the top and bottom steps is the "run." A series of steps without a landing is called a "flight." The horizontal surface of a step is called its tread, and the vertical front its riser. The projection of the tread beyond the face of the riser is termed a nosing.

Long use has demonstrated that certain proportions of riser and tread are safe and easy. For interior stairs twice the height of the riser, plus the length of the tread, should be 23, all dimensions being in inches. A variant is that the sum of rise and tread should be between 17 and 17½ in.; a third rule specifies that the product of rise and tread, in inches, should be not less than 70 nor more than 75. In general, English usage advocates a slightly lower rise for a given tread than American usage, while in Europe the rise is frequently greater. For exterior stairs, the general usage is to keep the riser below 6 in., and the tread above 12.

It is uncertain what is the oldest stair in existence. On the sacred road up the mountain of Tai Shan, in Shantung, China, there are many great flights of ancient granite steps. In Egypt stairs in pylons exist which date from the second millennium B.C. Assyria has left massive stairs on the ziggurats (*q.v.*), which date from the 9th and 8th centuries, B.C.; and the palace terrace at Persepolis has a double flight of steps, of great beauty, which shows the skill of the Persians in the 6th century B.C.

Further west, stairs play an important part in the Cretan palaces, as in the palaces at Knossos and Phaistos (both *c.* 1500 B.C.). In Hellenic Greece the monumental stair was of less importance, due to the Greek love of informal and picturesque approaches. Thus in Athens the propylaea of the Acropolis was probably entered by a winding path and the present great flight of stairs, dating from the Roman period, is not part of the original design. In the post Alexandrian period there developed a new love of monumental grandeur, largely Asiatic in origin, which produced such magnificent stairs as those of the altar of Zeus at Pergamon (180 B.C.). A similar monumental sense distinguished Roman stairs. Those of the propylaea at Baalbek (time of Hadrian), over 100 ft. wide, are typical, and again and again stairs are made essential parts of great architectural conceptions, as in the temple of the Sun on the Quirinal hill at Rome, built by Aurelian (A.D. 273), some of the steps of which were taken, in 1348, to build the famous stairs of the Aracoeli on the Capitoline hill at Rome.

Although during the middle ages stairs were used more for utilitarian than aesthetic purposes, where they were necessary they received adequate treatment, usually more direct and informal and more picturesque than those of the Roman tradition. Thus at Le Puy en Vélay, in France, the 11th century cathedral, which was built on a hilltop, is approached by a magnificent stair that provides a superb foreground to the polychrome façade. The steps that mount up to and past the apse of the 14th century cathedral at Erfurt, in Germany, show the direct and beautiful relationship between the building itself and the stairs which is characteristic of the best Gothic usage.

The Renaissance produced a recrudescence of the tradition of Roman formality in stair design. Particularly magnificent are the stairs of the Baroque period, such as the so-called Spanish stairs at Rome in the Piazza di Spagna (1723–26), by F. de Sanctis, those of the Campidoglio, at Rome (begun 1547), by Michelangelo and the infinitely varied terrace stairs of the Italian villas. The inspiration of these Italian Baroque stairs was felt throughout Europe and is largely the foundation of stair design in modern city and garden planning. Thus the enormous stairs of the gardens of Versailles (1667–88), by A. Le Nôtre, owe much to the Italian precedent, and were themselves imitated widely all over Europe. Among modern stairs may be noted the extremely lavish stairs of the monument to Victor Emmanuel II., in Rome (begun 1885), by Giuseppe Sacconi, with the altar of the Patria; the broad flights leading up to the library of Columbia university, New York (1896), by McKim, Mead and White; Waterloo steps in London (1831–34), by Benjamin Wyatt and those of the Lincoln memorial at Washington, D.C. (1924), by Henry Bacon.

In the Orient, the stairs leading down to the river at Benares, in India, of various dates, combine monumentality and picturesqueness; a similar skill is shown in the design of large numbers of temple and palace steps throughout the peninsula. Further east the ruins of Angkor use wide flights of steps with magnificent effect in connecting the various levels of the terraced group. The Chinese have always been superb stair designers and builders, and there is hardly a temple or large house or palace which does not owe some of its effect to its stairs, either monumental and formal, like those of the Forbidden City or the Temple of Heaven, both in Peking, or winding and informal, as in Chinese garden design. Many of the temple stairs have, in the centre, an inclined plane running the entire height of the rise, richly carved with the symbolic dragon—the so-called spirit stairs by which the beneficent powers are supposed to enter. In Japan the tradition is much more informal, but the hilly nature of the country makes stairs an important feature of almost every temple layout. (T. F. H.)

**STAIRCASE,** a term for stairs accompanied by walls. The earliest staircases seem to have been built with walls on both sides, as in Egyptian pylons. Contemporary models of houses, dating back to the Middle Kingdom, show a staircase leading up the side of a court to a roof terrace, with continuous wall below. The origin of such stairs may have been earlier structures in wood, or even ladders cut out of logs. Egyptians may have used the self-supporting staircase in which each step is supported at its front by the step below and prevented from turning by having its end built solidly into a wall.

[1]Sir Walter Scott took the plot of his *Bride of Lammermoor* from this incident, but he disclaimed any intention of making Sir William Ashton a portrait of Lord Stair.

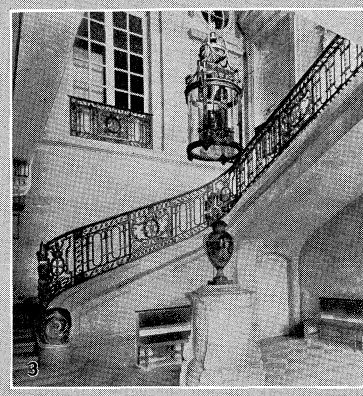
## OLD WORLD STAIRCASES



1. The Scala Regia in the Vatican palace, designed by Bernini and built between 1663–66. Skillful use of exaggerated perspective by the progressive shortening of the columns makes it one of the most impressive of all monumental staircases. 2. The main staircase of the Bavarian State library, designed by Friedrich von Gaertner in the middle of the 19th century, has extreme simplicity as its key note. The contrast of plain wall and colonnade above gives an effective touch. 3. The gorgeous staircase of the Paris Opera, by Charles Garnier, 1861–74. 4. The spiral stairs leading to the jubé or choir loft, in the church of St. Etienne du Mont, at Paris, 1600–05, by Biard, reveal the rich and delicate charm so characteristic of the French early Renaissance. 5. The terrace stairs of the temple of Confucius at Peking have the characteristic Chinese marble balustrades and in the centre a flat ramp, lavishly carved with dragon shapes, to form a spirit way by which beneficent spirits could enter. 6. One of the picturesque and simple stairs in the famous gardens of the Villa d'Este connecting the many levels. 7. The horseshoe staircase in the palace at Fontainebleau, 1634, by J. du Cerceau, noteworthy for the daring Baroque curves of its plan and famous as the place where Napoleon took leave of his troops before going to Elba. 8. The staircase, of flamboyant Gothic, built in the transept of Rouen cathedral, 1477–79, to allow direct entrance to the chapter library

## RENAISSANCE AND MODERN STAIRCASES

1. Staircase by John Russell Pope in the Sloane house in New York, a characteristic modern interpretation of late Georgian delicacy and detail
2. The staircase of the third quarter of the 18th century, in the Moffatt-Yard-Ladd house in Portsmouth, N.H., characterized by the panels, bracketed ends and lavishly turned balusters, so typical of the developed American colonial
3. The famous stairs of the Petit Trianon at Versailles, though built by Gabriel in 1766 under Louis XV., show a simple delicacy and a use of straight lines characteristic of the style known as Louis XVI.
4. Much more typical of Louis XV. work is the lavish and monumental stairs of the Hôtel de Ville at Nancy, France, designed by E. Here, with iron work by Lamour
5. Modern freedom in design, the effort to combine many materials and to contrast straight and curved lines, characterize a stair designed by Patou in a Paris shop (La petite Jeannette)
6. The circular, concrete staircase in the Martel house in Paris, designed by R. Mallet-Stevens, an austere simplification of the more extreme types of modernism
7. In his Paris house, the same architect, Mallet-Stevens, combines concrete stairs with a railing of aluminium whose narrow aluminium supports, set at varying angles, catch varying reflections

**Greece and Rome.**—In classical Greece, interior staircases were common but unimportant; they were placed in out of the way corners, and often built of wood. In Rome, a new treatments for staircases became necessary. Many of the apartment houses indicated on the marble plan of Rome (*c.* A.D. 205), now in the Palazzo dei Conservatori at Rome, seem to have had stair towers built in the centre of a courtyard. The Colosseum (*q.v.*) at Rome (completed A.D. 80) has elaborate and practical entrance and exit stairs, by which the crowds could be readily handled. These, in general, are supported by sloping vaults and roofed by others. Similar staircases were common in the theatres.

**Byzantine and Romanesque.**—Merely inclined planes lead up within enormous buttresses at the ends of the narthex of S. Sophia (532) at Constantinople, so giving access to the galleries. In S. George at Salonica (late 5th century), a spiral staircase surrounds an open well. In the early Romanesque there is a growing use of the spiral staircase. To this development the great thickness of Romanesque walls and buttresses was particularly congenial, as it allowed the staircases to be built in solid masonry. Not only was the open circular well used, but the solid newel, in which each step had cut upon it a cylindrical form to act as part of the newel. This type of spiral staircase is still in use.

**Gothic.**—The Gothic spiral staircase was cut with the utmost cleverness. We have the radial stone cut in two levels, so that the ascent was twice as fast as by the ordinary method, thus allowing the radius to be remarkably decreased. Such circular staircases as lead up in the traceried turrets of the spire of Strasbourg cathedral in Alsace (1435) are miracles of daring design and delicate execution. The late Gothic period also produced a great number of beautiful interior staircases, like the "Stair of the Library" in Rouen cathedral (1477–79), which show that the possibilities of the staircase with straight runs were at last being realized. Of rich interior spiral staircases, the early 16th century staircase leading to the organ in S. Maclou, in Rouen, and the contemporary staircase to the jube (*q.v.*), or rood loft, of S. Étienne du Mont in Paris (in which a certain amount of Renaissance feeling is present) are noteworthy. In the larger houses the lack of communicating passages led to many staircases. Thus in the house of Jacques Coeur at Bourges (*c.* 1450), there are eight separate spiral staircases, whose exterior treatment, in rich, traceried towers, furnishes a great deal of the picturesqueness and varied beauty of such a building.

**Renaissance.**—During the Renaissance, despite such *tours de force* as Vignola's spiral stair in the palace at Caprarola (*c.* 1550), the general practice was to have important staircases run up in a straight flight, sometimes varied by landings, and sometimes with changes in direction between walls often crowned with a slanting vault. The most perfect developments of this type were made chiefly during the Baroque period. The magnificence of the huge interior flights of the Genoese palaces (*e.g.*, the "University," 1623, by Bianco) is famous. The Scala Regia is particularly remarkable in the artificial exaggeration of its perspective, through the gradual diminution of width and height as the steps ascend. In France the spiral staircase added by Francis I. to the château at Blois (1515–24) and the double circular staircase of the château of Chambord (begun 1519) are remarkable. The early Renaissance, however, produced its most remarkable results in the richly ornamented wooden staircases of Tudor and Jacobean houses. The usual arrangement was to have the staircase divided into comparatively short flights, at right angles to each other, around a central open well; the heavy newels at the corners were finished with urn-like finials at the top and carved drops at the bottom, the railing consisted of a large rail supported either by miniature arcades or square balusters, whose mouldings were often sloped to follow the stairs, and the whole was covered with intricate surface ornament of strap work. The staircase at Hatfield house (1611) is typical. The early Renaissance staircases of Spanish palaces are in most cases placed in one corner of the courtyard and run up between walls to a landing with a return flight that opens out onto the upper floor gallery. The walls, and sometimes even the treads and rises, are often cased in brilliant faience tiles. Even in staircases of more Italian type, with balusters, the richness of wall surface remains, as in the staircase of the hospital of S. Cruz at Toledo (1504–14), by E. de Egas. The climax of Spanish Renaissance monumental stair design is reached in the "Escalera Dorada" at Burgos cathedral (1519), by D. de Siloe, with its exquisite metal railing.

The developed classicism combined with the Baroque of the later 16th century to give a new trend to staircase design throughout Europe. Thus in France a gorgeous series of staircases was produced, of which the "Escalier des Princes" of Versailles is typical. The reaction to the lightness and gaiety of the Louis XV. period (*see* LOUIS STYLES) led to the development of many gracious and inviting house staircases of the type known as self-supporting, full of sweeping curves and with railings frequently of metal. In the Louis XVI. period the new, popular classicism restrained the exuberance of the earlier staircases but retained their graciousness and lightness; of these, one of the loveliest is that of the Petit Trianon at Versailles (1766), by Gabriel, with a beautiful iron railing. Meanwhile, the classic trend had expressed itself in England by the substitution of open string for closed string stairs, that is with the balusters coming down to the top of each tread, rather than being supported on a slanting member, or string, which received the ends of the treads. This at once made for a more interesting treatment at the ends of the steps, and led, eventually, to the development of the bracketed step end, in which scrolls and leafage of great richness were carved under the end of each riser. Moreover, the fact that English stairs were largely of wood inspired the design of turned balusters and newels of great variety. During the last half of the 18th century, a growing trend toward lightness and delicacy of design led to the substitution of plain, tapered shafts in place of elaborate balusters, and the use of stairs rising in continuing curves instead of straight flights and landings. The same development took place during the 18th century in the colonial work of North America. Thus certain of the earliest houses, like the Capen house at Topsfield, Mass. (1683), have closed strings and heavy newels of Jacobean type, while the Lee mansion at Marblehead, Mass. (1768), has a magnificent open string staircase, whose steps have panelled and scrolled ends, and whose twisted balusters are as rich as any contemporary work in England. The curved staircase of the Valentine museum at Richmond, Va. (1812), is typical of the later delicacy.

**Modern.**—During the middle and the third quarter of the 19th century, staircase design reached its lowest ebb, not only in England and France, but throughout Europe, except in the case of those monumental and official buildings on the Continent whose design never fell a victim to the current taste. Closed strings again became the fashion and balusters and newels of gargantuan proportions and bulbous and meaningless elaboration. Yet one of the most gorgeous and effective staircases in the world dates from this period, that of the Paris Opéra (1861–74), by Charles Garnier.

Two elements have vastly affected modern staircase design, steel and reinforced concrete. The use of steel has led to simple plans of straight runs and railings delicate and straightforward in design, with newels usually accented, as in the Jacobean wooden stairs. Reinforced concrete, on the other hand, is a material so flexible that the most daring curves and fantastic sweeps become structurally sound. Probably the most brilliant example of this modern type of staircase design is in the new portion of the Galeries Lafayette at Paris (1926), by F. Chanat, a conception of dizzying lightness, with modernist iron railings.

## STRUCTURAL DESIGN

**Stone and Marble Staircases.**—Modern stone and marble staircases are of two main types. In the first the actual exposed treads and rises form, themselves, the structural elements. In the other type the treads and rises are supported upon a separate structural base which may consist of a masonry vault, a steel framework or a reinforced concrete slab. In the first class, in which the steps themselves are structural, the staircase is usually built into a wall at one side. Each step rests for a small distance upon the step below and is built into the wall for a distance sufficient to make the weight of the wall above prevent it from turning.

The undersides of the steps, where exposed, are frequently cut to form an inclined surface, following the slope of the stairs, and may be decorated with panelling or carved or other ornament. This type of stair can be used both for straight and curved runs, and is particularly applicable to monumental entrance halls, where the stair, in a triple run with two landings, or in a continuous, curved sweep, fills a recess opposite the door. In such staircases the railing is usually of metal with the uprights securely dowelled into the ends of the steps. Stairs somewhat similar can be built with the ends of the steps built into the walls on both sides, where a monumental run rises between two walls.

**Wooden Staircases.**—These can be divided into two classes, closed and open string stairs. In both the essential support is given by rough timbers called carriages, which follow the slope of the stairs and are cut roughly to the shape of the under side of the steps. In the case of closed string staircases both sides of the staircase are finished by a sloping, straight-sided plank, approximately an inch and a half thick, on the inner faces of which grooves are cut, whose upper and outer faces exactly fit the top and side of the tread and riser; the under and inner sides are, however, sloped, so that wedges may be driven in to force the tread and riser boards into position and hold them with perfect rigidity. Similar wedges are driven in between the rough carriages and the under sides of treads and risers. To give additional strength, the treads and risers are, themselves, rebated together, so that a small, projecting strip of the tread fits into a groove in the bottom of the riser, and a similar strip on the top of the riser fits into a groove on the bottom of the tread. The projecting portion of the tread is moulded and an additional small cover mould placed below to cover the joint.

In the open string staircase the strings at the end are cut to the shape of the steps, and the vertical cuts are usually mitred at 45°, so that the ends of the risers, also mitred, may form with them an invisible joint. In the ends of the treads dove-tailed sockets are left to receive the dove-tailed ends of the balusters; a moulding, exactly similar to the nosing, is then applied across the end of the step, and covers the bottom of the balusters. At times, bracketed and carved pieces are mitred at the ends of the risers and applied over the face of the string. It is this type of staircase that was the rule during the Georgian period in England and in the developed American colonial and early republic work. Where an open string stair is built against a wall, it is usually finished at the wall end by a closed or housed string, similar to that described, forming a base-board for the wall.

The structural strength for a wooden staircase is usually furnished by framing a heavy member, called a header, at the top and bottom of every run; to these headers the rough carriages are spiked, and the newels, if they exist, firmly fastened. The newels themselves are designed to receive the finished stair strings, and also the finished string member that is occasionally used at the edges of a floor in the stair-well opening. In staircases similar to those of the early 19th century in England and America, in which newels did not exist, except at the bottom, and in which stair rails and balusters were of the most extreme attenuation, and the whole frequently laid out with complex curves, strength was achieved by the most exquisite workmanship, whereby the careful framing of every part made the finished staircase an independently rigid structure. Frequently the curved plan itself furnished a certain amount of lateral rigidity. In modern staircases of this type additional strength is obtained by inserting iron or steel bands into the hand-rail; occasional balusters may be of steel, well fastened to the string.

**Steel Staircases.**—These have become almost universal in modern fireproof buildings of all types, except where unusual monumental effect is desired, and the design of steel staircases is largely standardized. They consist of a steel string on each side, which takes the form of a plate or channel of sufficient rigidity to carry the weight.

Iron spiral staircases are usually formed of cast iron members, each of which forms a tread and riser, and has at its inner end, a collar arranged to slip over a vertical pipe or cylindrical bar forming the central newel. Such spiral staircases are rigid independently of any wall, and are frequently used in open spaces, such as those existing in power houses, gymnasiums and the like. Reinforced concrete, sometimes finished as artificial stone, is used for stairs and permits of infinite variety of form.

**Moving Staircases.**—In many places where continuous transit between floors is necessary, as in large shops, underground railway stations and the like, moving stairs, sometimes known as escalators, are much used. These are of two types. In one, an endless belt carries on its surface links or blocks of sufficient roughness to act as treads. This endless band, at top and bottom, rotates around wheels or pulleys, motor-driven. At the bend the band disappears through the floor into a slot armed with steel arms, so designed as to occur one in each groove between the raised portions of the treads. Another continuous band on each side, geared to the same speed, serves as a hand-rail. The other type has a similar mechanical basis, but the belt, instead of carrying directly upon its upper surface blocks to form the treads, is designed to motivate actual continuous horizontal treads with risers radially shaped, so that at top and bottom the treads slide up on the risers into a continuous moving plane. Moving hand-rails are furnished as in the other type, and in addition, a moving band angularly across the top and bottom, to remove automatically any dropped objects. Moving stairs of the second type are always entered and left at the side, those of the other type directly at top and bottom.

**Legal Regulation.**—As stairs form one of the most necessary methods of exit from a building, their design has formed one of the most important portions of the building legislation of modern municipalities, especially in the case of public, commercial, industrial and educational buildings. Although there is much variation in the detailed requirements of different cities, the methods of regulation are almost the same and state: (1) where fireproof stairs are required; (2) the number of staircases; (3) size; (4) design. Thus, in addition to the universal requirements for structural solidity, the attempt is generally made to furnish at least two stair exits to any large, enclosed, upper floor area; and where fire risk and the danger of panic are unusually great, as in the case of theatres, to demand sufficient stairs to allow the building to be emptied in a very short time, without disorder. Widths of stairs are frequently determined in accordance with the number of people using them. In New York, for instance, each staircase must be designed to contain all the people of the floor area it serves, on the basis of one person to each 21 in. of width and each one and one half treads. Design is controlled by specifying the relationships of tread and riser, the distance apart and size of landings, whether or not curved stairs are allowed, etc., and often, because of the smoke danger, requiring exit stairs to be enclosed in a fireproof tower, with fireproof, self-closing doors at all entrances.

**STALACTITES** are pendent masses formed where water containing mineral solutions drops very slowly from an elevation. (Gr. σταλακτός, from σταλάσσειν, to drip.) They are seen, for example, beneath bridges, arches and old buildings where water percolating through the joints of the masonry has dissolved very small quantities of the lime present in the cement and mortar between the stones. On exposure to the air part of the water evaporates and the solution of calcium carbonate becomes supersaturated; a deposit of this substance ensues and as the drop continues to fall from the same spot a small column of white calcite very slowly grows downwards in a vertical direction from the roof. In the same way stalactites of ice (icicles) are produced in frosty weather as the water dropping from eaves of buildings, elevations, branches of trees, etc., very gradually, freezes. Other minerals often occur in stalactitic growths; thus we find in mines and in the cavities of mineral veins stalactites of limonite, opal, chalcedony and gibbsite. These are never of great size,

usually not more than 2 or 3in. in length, and probably the method of origin is exactly the same as that of the larger and more common stalactites of ice and calcite.

The conditions essential to the perfect development of stalactites appear to be (1) a very slow trickle of water from a fissure; (2) regular evaporation; (3) absence of disturbance, such as currents of air. Hence, ice stalactites form most readily on calm cold nights, and stalactites of ice or calcite are seen in greatest perfection in the interior of caves.

In limestone caves stalactites form in abundance as glimmering white columns covered with a thin film of water. The great caves, such as those of Postumia (in Italy), Jenolan (Australia), the Mammoth Cave (Kentucky), the Causses district in France, and the grottoes of Belgium, are divided into chambers which are richly festooned with stalactites, and fanciful names are given to various groups according to their similarity to different objects, natural or artificial. Ice caves of considerable size occur in the Arctic and Antarctic regions, and are draped with ice stalactites often wonderfully like those of limestone caves.

Where the water drops upon the floor of one of these caves evaporation still goes on and if the air be perfectly still the drop will always land on the same place and a pillar of deposit, called a stalagmite, will rise vertically, till in course of time it meets and joins with the stalactite above. As the stalactites thicken, they assume tapering forms with irregular surfaces. Large stalactites may be 3 or 4ft. thick, but in that case they are usually due to coalescence of adjacent ones. Single stalactites 2ft. in diameter are not rare. From data obtained by measurement of the rate of growth at the present day it has been estimated that as much as 200,000 years may have elapsed since certain thick stalactites began to grow. Caves are of great antiquity but there is, of course, no certainty that the conditions have remained uniform. Sir Archibald Geikie records that stalactites 1½in. in diameter had formed beneath a bridge in Edinburgh which was 100 years old; in caves, however, the rate of formation is rarely so great as this. Inscriptions on stalactites in the Adelsberg cave after 30 years had been covered with a scarcely perceptible film of new deposit. In one of the Moravian caves a stalactite, about as thick as a goose quill, was broken across in 1880, and in 1891 it had grown 3 or 4cm.; from careful observations it has been calculated that one of these stalactites, 7ft. long, may have been formed in 4,000 years. The stalagmitic crust on the floor of caves is usually mixed with blocks which have fallen from the roof, sand, mud and gravel carried in by floods, and the bones of animals and men which have inhabited the cave if it had an accessible entrance.

Stalactites also occur in the interior of the lava caves found in Hawaii, Samoa, etc. Often the upper surface of a lava flow has cooled to form a crust, while the interior is still perfectly fluid, and it sometimes happens that the liquid basalt has made its escape, leaving great cavities below the hollow roof of the lava. The interior of these caves is covered with a black shining film of glassy basalt, and black stalactites of lava hang downwards. Their surface is sometimes changed to brown or red by the action of the acid vapours which filled the cave after the lava retired. These stalactites are tubular, with bluntly rounded ends, and probably their mode of growth is somewhat analogous to that of icicles.

**STALACTITE WORK,** in architecture, one of the most general characteristics of all of the Mohammedan styles, consisting of a series of little niches, bracketed out one above the other, or of projecting prismatic forms in rows and tiers, connected at their upper ends by miniature arches. Its infinite varieties may be classified into three groups, the first consisting of those basically niche-shaped, in which the concave curve is the most important feature; the second group includes those in which the vertical edges between the niches are the most important feature, being set at all sorts of angles and having generally prismatic forms; the last group consists of elaborately intersecting, miniature arches. The first two groups occur commonly in Syrian, Moorish and Turkish work and in their simpler forms, in Persia; the last group is typically Persian and is found also in Mogul work in India.

Stalactites are of comparatively late development in Muslim art, the earliest buildings in Syria, Egypt and north Africa showing no traces of them. They seem to appear suddenly all over the Muslim world toward the beginning of the 12th century. Thus simple forms are found in the mosque at Ani in Armenia, built between 1072–1110, and they are common in Algiers and Sicily during the course of the century, as in the gate at Chella (1118–84), and in the building known as La Ziza at Palermo (1154). In Egypt the stalactite appears in panels flanking the main entrance of the El Akmar mosque at Cairo (1125–50). They reached their highest development in the 14th and 15th centuries, becoming the normal decoration for the heads of door niches and the bracketing under cornices and minaret galleries. The richest examples of the prismatic type are to be found in Moorish work in Spain, especially in the intricate wood and plaster ornament of such palaces as the 14th and 15th century Alhambra in Granada and the 14th century Alcazar at Seville. In Turkey, a peculiar type of faceted crystal shape is found and the form became the most common capital decoration.

**STALIN, JOSEPH VISSARIONOVICH** (DJUGASHVILLI), general-secretary of the Russian Communist Party, was born in 1879, son of a Georgian peasant shoemaker. Young Joseph secured an education through being selected for a course at a Russian religious seminary. However, he was expelled for "unreliability." At 17 he joined a Social Democratic group and agitated among the workers of Georgia.

For organising demonstrations in Batoum in 1902 he was imprisoned, and in 1903 was exiled to Eastern Siberia for three years. In Jan. 1904 he escaped and returned to his political activities, frequently changing his pseudonym. He evaded arrest until 1908, when he was again exiled to Vologda province for three years. He escaped once more in 1909, returning to Baku and renewing his activities, but was speedily arrested and sent to Solvichegodsk for six years. Inside a year he escaped to St. Petersburg, but was arrested a third time after a few months and sent back to Vologda province for a further three years. He escaped in Dec. 1911, was again exiled in April 1912, but was once more in St. Petersburg (Leningrad) in September.

In March 1913 he was arrested and exiled to Turukhansk in Northern Siberia, where he remained until Feb. 1917. He was responsible for the Bolshevik campaign for the State Duma in 1913, directing the Bolshevik group in that Duma from outside, and in 1912–13 acting as one of the editors of the Bolshevik journals "Sviezda" (Star) and "Pravda" (Truth). He belonged to the central committee, and in the Soviet Government he became commissar for nationalities. Stalin fought against Yudenitch, Denikin and the Polish army, in 1919 and 1920 he was commissar for workers' and peasants' inspection, and from 1920 to 1923 was a member of the revolutionary military council. As general secretary of the central committee of the Russian Communist party, after Lenin's death he became the most powerful figure in the U.S.S.R., and held his position when his policy was assailed by other Communist leaders, securing the exile of Trotzky and other opponents.

His *Leninism* was translated (1928) into English.

**STALINGRAD,** a region of the Russian S.F.S.R., lying on both banks of the lower Volga. Area 52,278 sq.mi. Pop. (1939) 2,289,049 (rural 1,396,292; urban 892,757). It is a low-lying area, and the banks of the Volga for some distance on either side of the river are below sea level. The soils on the left bank of the Volga river are salt steppe; on the right, as far as the Don river, they are light brown and gray steppe, with salt efflorescences, while west of the Don is a fertile black-earth region. The climate is continental and the rainfall scanty and variable from year to year. The region lies in an area subject to terrible recurrent famines due to failure of rainfall, and rapid desiccation has been in progress for some time. In years of sufficient rainfall, the harvest is fairly good. The chief crops are summer wheat and winter rye; millet, sunflower seed, barley, oats and potatoes are grown in less quantity, and vineyards are profitable in the south. Maize cultivation is steadily increasing. Irrigation is the only hope for the district. Experimental stations

are working at Stalingrad and at Tingutin.

The most favourable region is the alluvial strip near the Volga and Akhtuba rivers, which is particularly wide near the town of Stalingrad. Here the temperature remains above freezing point for nine months in the year and the combination of alluvial soil, warmth and moisture makes grain, fruit and vegetable growing very profitable. Poplar trees attain a remarkable growth in ten years, and fruit trees bear for five years in succession. The nearness of the oil wells facilitates the use of internal combustion motors for irrigation purposes, and cheap and convenient routes for export are available. The drawback is the frequent change in direction of the main watercourses and their connecting channels, which may convert a fertile garden into a waste of river mud, or even wash it entirely away. Dikes are being built to lessen this danger. Sheep, cattle, pigs and horses are bred, and in the years after World War I made rapid progress toward restoration to prewar level. The 1921 famine, particularly disastrous in this region, following on the civil war centring round the town of Stalingrad, had reduced their numbers catastrophically. There is also some camel breeding in the district. Stalingrad is becoming a centre for timber but apart from Stalingrad (*q.v.*), there are no industrial areas in the region. The chief peasant occupations supplementing agriculture are fishing, flour-milling, oil-pressing, tanning, leather, fur-dressing, textiles and felt making and the making of pottery and household and farm implements. Lake Elton, one of the most productive sources of salt in Russia, is situated in the trans-Volga part of the region, but has no rail connection. The Don approaches the Volga very closely near Stalingrad, and the soviet government in 1928 embarked on a scheme to construct a canal linking the two rivers. This was successfully carried out.

The region was occupied in the 5th century by the Finno-Turkic Bulgars, who were in the 10th century driven northward by the Khazars, a closely related tribe. Later the region formed a part of the empire of the Tatar Golden Horde, one section of which was incorporated in the khanate of Astrakhan. The Russians in 1557 conquered Astrakhan and in 1589 erected the fort of Tsaritsyn on the site of the present town of Stalingrad, but the real absorption of the region into Russia involved a century of struggle with the nomads of the Volga during which there were perpetual Nogai, Kalmuck and Kirghiz raids on the Russian settlements. In the reign of Catherine II, the Russian peasants, the Cossacks and the dissatisfied native tribes rebelled under the leadership of Pugachev (1773–75) and fighting was fierce in the region between Kazan and Stalingrad. After the 1917 revolution, there was much disorder in the region, and considerable opposition to the bolshevists, which was, however, finally overcome.

**STALINGRAD** (formerly Tsaritsyn), a town of the Russian S.F.S.R., the administrative centre of the region. Its position at the point where the Volga most nearly approaches the Don gave it great importance as a transshipment centre, and after the construction of the railway links with the Don at Kalach and with the railway systems of Moscow and Leningrad, its growth was rapid. The town manufactures metal goods and machinery, has a naphtha-refining factory, 20 sawmills, chemical factories, breweries, a confectionery industry and mineral oil works. It is an important centre of tractor construction. Pop. (1939) 445,476.

A fort was erected there in 1589, after the fall of Astrakhan, to prevent the raiding of settlers by Kalmucks, Kirghiz and Circassians, often joined by Cossacks and runaway serfs. The town took part in the rising in favour of the false Demetrius, and was captured by Stenka Razin in 1670. In 1773–75 it took part in the rebellion of Pugachev. After the revolution of 1917, Stalin held the town against the counterrevolutionary White army, and it was renamed in his honour.

Stalingrad was the scene of violent fighting during World War II. The Germans attacked the city in Aug. 1942 and in the next months frequently seemed on the point of taking the city, but the Russians launched a successful counteroffensive in Nov. 1942, and in Feb. 1943 the German army under Field Marshal General Friedrich von Paulus was forced to capitulate. The taking of Stalingrad by the Russians was the turning point in the Russo-German phase of the war. The city was badly damaged during the fighting.

**STALINO,** a town in the Ukrainian S.S.R. Pop. (1939) 462,395. In 1870 a British subject named Hughes received a concession from the Russian government to manufacture iron rails. His company started operations on the site of the present Stalino, formerly known as Hughesovka (Yuzovka). British, French and Belgian capital was freely invested in the development of the industry from 1880 up to 1914. The close conjunction of the Donetz coal field to iron and manganese deposits made the industry very profitable. Following the 1917 revolution the industry was depressed, but from 1924 onward progress was rapid and the population of Stalino doubled between 1923–26.

**STALL,** literally a place where one may stand, and so applied to a separate division in a stable, shed, etc., in which a single horse, cow or other domestic animal may be kept, to a separate booth, bench or table in a market or other building, or in the street, on which goods are exposed for sale, and in England to the higher-priced seats on the ground floor of a theatre. In cathedrals, monastic churches and the larger parish churches the stalls are fixed seats enclosed at the back and separated at the sides by high projecting arms, and placed in one or more rows on the north and south sides of the choir or chancel. In a cathedral the canons and prebendaries have each a stall assigned to them. In the chapels of the various knightly orders the stalls are assigned to the members of the order, thus, in St. George's Chapel, Windsor, are the stalls of the Knights of the Garter, in Henry VII's chapel in Westminster abbey are those of the Knights of the Bath, adorned with the stall plates emblazoned with the arms of the knight occupying the stall, above which is suspended his banner. Architecturally considered, the stalls of a cathedral or church are a marked feature of the interior adornment. They are richly carved, and are frequently surmounted by canopies of tabernacle work. The seats generally can be folded back so as to allow the occupant to stand upright or kneel; beneath the seat, especially in monastic churches, is fixed a small bracket, a *miserere* (*q.v.*), which affords a slight rest for the person while standing. Among beautiful specimens of carved stalls may be mentioned the Early Decorated stalls in Winchester cathedral (1296); the Early Perpendicular ones in Lincoln minster (*c.* 1370); the early 15th-century canopies in Norwich cathedral (15th century), and the towering corner-stalls with their ornate carving filled with figures, in Amiens cathedral (1508–20).

**STALLBAUM, JOHANN GOTTFRIED** (1793–1861), German classical scholar, was born at Zaasch, near Delitzsch in Saxony on Sept. 25, 1793, and died at Leipzig, where he was rector of the Thomasschule, on Jan. 24, 1861. His reputation rests upon his work on Plato, of which he published two complete editions.

*See* C. H. Lipsius in the *Osterprogramm of the Thomasschule* (1861); R. Hoche in *Allgemeine deutsche Biographie,* vol. xxxv.

**STALYBRIDGE,** municipal borough in the Stalybridge and Hyde parliamentary division of Cheshire, England, 7½ mi. E. of Manchester. Pop. (1938) 23,390. Area, 5 sq.mi. The whole district is densely populated. Stalybridge is one of the oldest cotton towns, the first cotton mill having been erected in 1776. It was incorporated in 1857 and was a parliamentary borough from 1867 to 1918. Cotton is the principal industry, but there are also machine works, iron foundries and nail works.

**STAMBOLISKY, ALEXANDER** (1879–1923), Bulgarian statesman, was born at Slavovitsa, Bulgaria, Sept. 1, 1879. He attended the agricultural college of Halle in Germany. On returning to Bulgaria, aged 18, he took up journalism, and in 1902 became editor of the organ of the newly-formed Agrarian league. Six years later he was elected to the Sobranye, where he led the Agrarian party. He now began to organize the peasant masses, who form 80% of the population of Bulgaria, into agricultural associations. In 1911, when the Grand Sobranye met at Trnovo to amend the constitution, his first conflict with King Ferdinand occurred. After the treaty of Bucharest (1913), Stambolisky and the Agrarians were unmerciful in their criticisms of Ferdinand's policy, though deterred from extreme measures by fear of external complications. His opposition to Ferdinand came to a head in 1915 during the negotiations that preceded Bulgaria's entry into World War I. Stambolisky strongly backed the Entente in spite of the king's anger, pressure from the government and the growing influence of the Central Powers. Summoned before the king, Stambolisky threatened him with personal violence if he should fight against the Allies, reminding him that he had a crown to lose. Ferdinand ordered his arrest. He was tried by court martial and condemned to penal servitude for life.

In Sept. 1918, when the resistance of the Bulgarian troops

began to slacken, Ferdinand released Stambolisky, who left for the Macedonian front. He returned at the head of the insurrectionary troops and their arrival at Sofia resulted in Ferdinand's abdication and flight. A partisan of the new ruler, King Boris, Stambolisky became a member of the Cabinet in Jan. 1919 and Prime Minister in Oct.; as head of the Government he went to Paris and signed the Treaty of Neuilly in the same year. In Feb. 1920 he dissolved the Sobranye, and the following month was returned to power at the head of a homogeneous Agrarian majority. From 1920 to 1923, the Agrarians under Stambolisky ruled Bulgaria with a rod of iron. They had the Radoslavov Cabinet, which had brought Bulgaria into the World War, condemned to death by popular vote. Stambolisky also carried measures based on the interest of the peasants (*see* BULGARIA), and declared: "Sofia, that Sodom, that Gomorrah, may disappear. . . . I shall not weep for her." Through his influence post-War Bulgaria loyally carried out the terms of the Peace Treaty, won the esteem of the Allies, and secured a reduction of reparations. Stambolisky also made persistent efforts to improve Bulgaria's relations with Yugoslavia, with which country he concluded an agreement at Niš (1922). His ultimate ideal was probably some kind of federal South Slav State, embracing Bulgaria.

The overthrow of the Government by a military faction on June 9, 1923, was caused partly by dissatisfaction with Stambolisky's domestic policy and partly by the influence of the Macedonian party. The change of régime took place in one night, the Agrarian Ministers being arrested in their homes. Stambolisky, pursued by an armed detachment to his native village of Slavovitsa, escaped and fled across the mountains, hoping to reach the frontier. After being followed by soldiers for three days, he was eventually surrounded and shot on June 12. A formidable personality, attractive in many ways, and made of finer clay than the average Balkan statesman, Stambolisky has been called a modern Rienzi. Tall and broad, his demeanour was fierce and his movements ungainly; his rough-hewn face was crowned by a mass of black hair; he impressed everyone with his strength and the sincerity of his advocacy of a "Green International," to unite the peasants of all countries. Stambolisky published *Authority, Anarchy and Democracy;* and *What a Politician ought to be.*

**STAMBOLOV, STEFAN** (1854–1895), Bulgarian statesman, was born on Jan. 31, 1854, at Trnovo, the ancient Bulgarian capital, where his father kept a small inn. Under Turkish rule it was impossible to obtain a liberal education in Bulgaria, and young Stambolov, after attending the communal school in his native town, was apprenticed to a tailor. During the politico-religious agitation which preceded the establishment of the Bulgarian exarchate in 1870, a number of Bulgarian youths were sent to Russia to be educated at the expense of the Imperial government; among them was Stambolov, who was entered at the seminary of Odessa in order to prepare for the priesthood. He was expelled for his association with Nihilists, and, making his way to Rumania, he entered into close relations with the Bulgarian revolutionary committees at Bucharest, Giurgevo and Galatz. In 1875, though only twenty years of age, he led an insurrectionary movement at Nova Zagora in Bulgaria, and in the following year organized another rising at Orekhovitza. In the autumn of 1876 he took part as a volunteer in the Serbian campaign against Turkey, and subsequently joined the Bulgarian irregular contingent with the Russian army in the war of 1877–78. After the signature of the Berlin Treaty in 1878 Stambolov settled at Trnovo, where he set up as a lawyer, and was soon elected deputy for his native town in the Sobranye, of which he became president in 1884. The revolution of Philippopolis, which brought about the union of Bulgaria with eastern Rumelia, took place on Sept. 18, 1885, and it was largely owing to Stambolov's advice that Prince Alexander decided to identify himself with the movement. War with Serbia followed, and Stambolov served as an ordinary soldier in the Bulgarian army.

After the abduction of Prince Alexander (*q.v.*) (Aug. 21, 1886) Stambolov, who was then at Trnovo, established a loyal government at Trnovo, issued a manifesto to the nation, nominated his brother-in-law, General Mutkurov, commander-in-chief of the army, and invited the prince to return to Bulgaria. These measures resulted in the downfall of the provisional government set up by the Russophil party at Sofia. On the abdication of Prince Alexander (Sept. 8) Stambolov became head of a council of regency, with Mutkurov and Karavelov as his colleagues; the latter, however, soon made way for Jivkov, a friend and fellow townsman of the first regent. Stambolov frustrated the mission of General Kaulbars, whom the Tsar despatched as special commissioner to Bulgaria; suppressed a rising organized by Nabokov, a Russian officer, at Burgas; quelled military revolts at Silistria and Rustchuk; held elections for the Grand Sobranye, despite the interdict of Russia, and eventually secured the election of Prince Ferdinand of Coburg to the vacant throne (July 7, 1887). Under the newly-elected ruler he became prime minister and minister of the interior, and continued in office for nearly seven years.

The aim of his foreign policy was to obtain the recognition of Prince Ferdinand, and to win the support of the Triple Alliance and Great Britain against Russian interference in Bulgaria. He gained the confidence of the Sultan, and obtained concessions for the Bulgarian episcopate in Macedonia (*see* MACEDONIA). With the assistance of Austria-Hungary and Great Britain he negotiated large foreign loans which enabled him to develop the military strength of Bulgaria. He was still the despot. Major Panitza, after a conspiracy, was shot at Sofia in 1890; four political opponents were hanged at Sofia in the following year, and Karavelov was sentenced to five years' imprisonment.

His mood was emphasized by the assassination of his colleague, Beltchev, in 1891, and of Dr. Vlkovitch, the Bulgarian representative at Constantinople, in 1892, and eventually proved intolerable to Prince Ferdinand, who made him resign in May 1894.

He was now exposed to the vengeance of his enemies. On July 15, 1895, he was attacked and barbarously mutilated by a band of Macedonian assassins in the streets of Sofia, and succumbed to his injuries three days later. His funeral was interrupted by disgraceful riots, and an effort was made to perpetrate an outrage on his remains. No attempt was made to arrest his murderers; two persons, however, arraigned for the crime in 1896, were subjected to almost nominal penalties. (J. D. B.; X.)

**STAMFORD,** a municipal borough of Lincolnshire, partly in Northamptonshire, England. Pop. (est. 1938) 10,100. Area, 12.5 sq.mi. It is in the parts of Kesteven and the Rutland and Stamford parliamentary division. It once had 14 parish churches, but now has only six. There are some remains of the 7th century Benedictine monastery of St. Leonard's and a west gate of the Carmelite monastery (1291). To the south of Stamford, in Northamptonshire, is Burghley house, the seat of the marquess of Exeter, a fine quadrangular mansion dating from 1587, containing a noteworthy art collection.

Stamford (Staunford) is a place of great antiquity. The Danes built a fort here on the north bank of the Welland, round which a town existed when in 922 King Edward fortified the opposite side of the stream. It passed again into Danish hands and was one of the five boroughs recaptured by Edmund Aetheling in 941. The priory of St. Leonard was a cell of Durham, and a charter of Edgar dated 972 mentions a market and a mint. In the reign of Edward the Confessor Stamford was a royal borough governed by 12 lawmen. The Norman castle, built before 1086, was thrice besieged by Henry II., but only yielded in 1153. Henry III. gave the town a charter in 1256, and it was incorporated in 1461–62.

Stamford was known for its monastic schools, and in 1333 was chosen as the headquarters of the students who seceded from Oxford, and an Early Decorated gateway remains of Brasenose Hall. The attempt to establish a regular university was prohibited by royal authority. The defeat of the Yorkists here was followed by the decay of the castle in the reign of Richard III., and the history of the place later centred round the family of Cecil.

*See* E. C. Mackenzie-Walcott, *Memorials of Stamford, past and present* (1867); J. Drakard, *The History of Stamford in the County of Lincoln, comprising its ancient progressive and modern state* (1822); C. Nevinson, *History of Stamford* (1879); *Victoria County History: Lincoln.*

**STAMFORD,** a city of Connecticut, U.S.A., on the Boston Post road. Pop. (1930) 46,346 (69% native white); 1940 federal census 47,938. The city lies around a broad bay (2 mi.

across at the entrance and 1½ mi. wide), from which two tidal inlets extend. The city still has the charm of a New England village. It is a residential suburb, with 90 trains daily to and from New York. It is also an important industrial centre with factory products in 1940 valued at about $35,000,000. The town of Stamford (known the first year by the Indian name of Rippowam) was settled in 1641 by 29 persons who seceded from the Wethersfield church. In 1662 it submitted to Connecticut. The borough was incorporated in 1830 and became a city in 1894.

**STAMITZ, JOHANN WENZL ANTON** (1717–1757), the eldest and most important of a family of Bohemian musicians famous in the 18th century. He was born at Deutschbrod on June 19, 1717. He was a solo violinist at the coronation of the emperor Charles VII. (1742), and in 1745 the elector took him to Mannheim as director of the chamber of music. Stamitz and his successors are known as the Mannheim school. Although Phillip Emanuel Bach in Berlin and the young school in Vienna were arriving at similar results, it seems certain that Stamitz was the real pioneer, who not only demonstrated the dramatic value of the "working-out" section of the first movement of a sonata or symphony, but, by incorporating the minuet, definitely established the four-movement form. In addition he demanded of the orchestra a greater independence from the different instruments, singling out the much neglected viola. He died at Mannheim on March 30, 1757. His works include 27 concertos, sonatas and solos for violin; several sets of symphonies, and harpsichord music. Johann's brother ANTON THADDAEUS STAMITZ (1721–1768) was a 'cellist at Mannheim.

Much confusion has arisen between Johann and his eldest son CARL STAMITZ (1746–1801), who sometimes used the name Johann, while the father was frequently called Johann Carl or Carl Johann. He produced an opera, *Der verliebte Vormund,* at Frankfurt and another, *Dardanus,* in St. Petersburg. He died at Jena in 1801. His more elaborated 70 symphonies are chiefly written for larger orchestras than his father's.

An introduction with details of the family, by Hugo Riemann, is included, together with a thematic catalogue of 45 symphonies and 10 orchestral trios, in Series III. i. of *Denkmäler deutscher Tonkunst in Bayern,* and other compositions of Johann and Carl are found in Series VII. i., XV. and XVI. of the same work. *See* also Grove, *Dictionary of Music and Musicians;* Riemann, *Lexikon;* Eitner, *Quellen-Lexikon;* R. Sondheimer, *Die formale Entwicklung der vorklassischen Sinfonie* (*Allgem. Musikztg.* Jan. 1922); P. Bekker, *Musikgeschichte* (1926) p. 126 *et seq.*

**STAMMERING** or STUTTERING, a spasmodic affection of the organs of speech in which the articulation of words is suddenly checked and a pause ensues, often followed by a repetition in rapid sequence of the particular sound at which the stoppage occurred. There are many grades, from a slight inability to pronounce with ease certain letters or syllables, to a condition in which the muscles, not only of the tongue and throat and face, but even of those of respiration are involved in spasm.

In normal speech exquisite co-ordination of muscular movement is necessary in larynx, cheeks, tongue, lips, involving also complicated nervous actions. It is when the co-ordination is not effected with sufficient precision that stammering results. Stammering rarely shows itself before the age of four or five years, and often it develops in a child in a feeble state of health.

Stammerers, as a rule, find the explosive consonants *b, p, d, t, k* and hard *g* the most difficult to articulate, but many also are unable easily to deal with the more continuous consonants, such as *v, f, th, s, z, sh, m, n, y,* and in severe cases even the vowels may cause a certain amount of spasm. Usually the defect is not observed in whispering or singing.

The condition named *aphthongia* totally prevents speech, and may, at intervals, come on when the person attempts to speak; it is only temporary, and is usually caused by nervous excitement.

Stuttering may, it seems, be overcome in some cases by instruction in reading and speaking slowly and deliberately, carefully pronouncing each syllable. When feeling the tendency to stammer, the speaker should pause, and then by a strong voluntary effort attempt to pronounce the word. He should also be taught how to regulate respiration during speech, so that he may not fail from want of breath. In some cases aid may be obtained by raising the voice towards the close of the sentence. Sounds or combinations of sounds that present special difficulties should be carefully studied, and the defect may be largely overcome by a series of graduated exercises in reading. Intoning is often useful. Some maintain that benefit from such education is often merely temporary. In any case the psychical basis of stammering calls for the most pronounced attention in treatment. In very severe cases, where the seizures affect other muscles than those of articulation, medical treatment is necessary.

**STAMP, JOSIAH CHARLES STAMP,** 1ST BARON, cr. 1938 (1880–1941), British economist, was born in London June 21, 1880. Educated at the University of London, he entered the inland revenue department in 1896 and was assistant secretary to the board from 1916 until 1919, when he joined Nobel Industries Ltd., of which he was a director and secretary until he accepted the new post of president of the executive of the London, Midland and Scottish railway in 1925. Stamp sat on the royal commission on income tax (1919); on the finance arbitration committee for Northern Ireland (1923–24); on the committee on taxation and national debt (1924); on the Dawes Committee on German currency and finance (1924); on the court of enquiry into the coal industry (1925); and on the Paris committee of enquiry into the reparations question of 1929. He was created K.B.E. in 1920, G.B.E. in 1924, and G.C.B. in 1935; and was awarded the O.M. in 1936. He was the author of many books. He and Lady Stamp were killed in a German air raid on London, April 16, 1941.

**STAMP ACT,** in American history, an act introduced by George Grenville, and passed by the British parliament in 1765, with the object of raising revenue to pay in part the expenses of the French and Indian Wars (*q.v.*). It involved an extension of the British system of stamp duties to the American colonies and provided for the appointment of officials to distribute the stamped papers. It was passed without debate and with no idea that it would be opposed. Determined opposition, however, was at once shown in all the colonies, the act being looked on as an attempt at taxation without representation. It led to the passage of resolutions of protest by many of the colonial assemblies and to the calling of a Stamp Act Congress in New York attended by delegates from nine of the colonies. So great was the opposition that the proceeds from the duty were less than the expenses of collection. The next year Parliament repealed the act as a matter of expediency but passed another act declaring the right of Parliament to bind the colonies by its enactments. The Stamp Act was one of the important causes of the American Revolution. *See* UNITED STATES: *History.*

**STAMP DUTY,** a tax imposed in Great Britain on written documents which are evidence of legal rights involved. The payment of the tax is denoted by a stamp which is impressed on or affixed to the document. The Stamp Act of 1891 is still the principal act governing stamp duties, though new duties and increases have been authorized by successive Finance Acts.

The sanction of the act is expressed in very wide terms. Except in criminal proceedings, an unstamped instrument executed in Great Britain, or relating, wherever executed, to any matter or thing done or to be done in Great Britain, is not to be given in evidence or to be available for any purpose whatsoever, and it is the duty of all judicial officers before whom such an instrument is tendered in evidence to take notice of the absence or insufficiency of duty. Further, any person whose duty it is to enrol or record an instrument liable to duty is liable to a fine if he enrols or records an instrument insufficiently stamped. In some instances, moreover, parties have no discretion to dispense with written evidence. For example, contracts for insurance (marine, life or general accident) must be expressed in the form of a stamped policy and failure to do this not only vitiates the contract but renders the parties liable to fines. On the other hand, the stamp does not add to or warrant its legality, it merely makes it possible for the legality to be examined. Since 1928 revenue from the duty has varied from £17,070,000 (1932) to £30,060,000 (1929); for the financial year 1938–39 it was £20,980,000.

**STAMPINGS, DROP:** *see* PRESSED METAL.

**STAMPS:** *see* POST AND POSTAL SERVICES and PHILATELY.

**STANCIOFF, DIMITRI** (1864– ), Bulgarian diplomatist, was born at Sistov, Bulgaria, in May 1864, and studied at the Theresianum College, Vienna. In 1887 he entered the Foreign Office, Sofia, and was a member of the delegation entrusted with electing Ferdinand, in due course becoming head of the new King's political Cabinet. Afterwards he was successively Bulgarian representative at Bucharest, Vienna and St. Petersburg. He became Minister of Foreign Affairs in 1906 and was for a time Prime Minister after the murder of Petkoff. In 1908 he resigned and became Minister in Paris, where he remained until 1915 when he was sent to Rome. He was made a member of the Bulgarian Delegation to the Paris Peace Conference, and from 1920 to 1926 was Bulgaria's representative to the Court of St. James. Stancioff was Bulgaria's chief delegate to the first international Peace Conference in 1899 and was a permanent member of the International Court of Arbitration.

**STANDARD.** For the various meanings of this word *see* MEASURES AND WEIGHTS; PHYSICAL UNITS; DIMENSIONAL ANALYSIS; STANDARDS, NATIONAL BUREAU OF; ELECTRICITY and TIME, STANDARD; STANDARDIZATION.

**STANDARD, BATTLE OF THE,** a name given to the battle of Aug. 22, 1138, near Northallerton, in which the Scottish army, largely composed of wild and undisciplined Highlanders and Galloway Picts under King David, was defeated by the English levies of Yorkshire and the north Midlands. The latter formed a single deep line of dismounted men in front of a chariot carrying the consecrated banners of St. Peter of York, St. John of Beverley, St. Wilfred of Ripon and St. Cuthbert of Durham. King David planned to use his nucleus of knights and archers to lead the way and open a gap in the English line, but the fierce pride of the clansmen compelled him to give them precedence. Their headlong onset was repulsed. Left isolated except for his bodyguard of knights, King David retired from the field.

*See* C. Oman, *Art of War in the Middle Ages,* vol. i. 390–396 (1924).

**STANDARDIZATION.** Standardization is the establishing, by authority, custom or general consent, of a rule or model to be followed. In its broadest sense, standardization applies not only to such matters as weights and measures and material objects, but it permeates most fields of human activity. Folkways, taboos, moral codes, ceremonies, religious rituals, educational procedures, social and business customs, industrial practices and law itself, are all forms of standardization. Language is the most important example of standardization that man has brought about. Words are sounds whose meanings have become standardized and so form our principal means of communication. The main use of the term standardization is, however, in connection with technology, industry and business, their products and processes. Among the more important kinds of standards are:

*Standards of Measurement,* such as the metre, kilogram, pound and foot, are as necessary to our national economy as is the alphabet to literature. Some of these, like the cubit and shekel, are of great antiquity. To meet the needs of modern science and technology numerous standards of measurement have been set up in other fields, such as units of time measurement, temperature scales, electrical and magnetic measures, frequency (pitch of musical sounds), hardness, atomic weights, etc. Said Lord Kelvin, "When you can measure what you are speaking about, and express it in numbers, you know something about it." (*See* MEASURES AND WEIGHTS; STANDARDS, NATIONAL BUREAU OF.)

*Money* provides the measure of value. The stability of the monetary unit is of cardinal importance to the stability of the entire national economy of a country.

*Standard Methods of Accounting* have become essential to business management and to governmental bodies as well. Standard cost accounting systems, when adopted by a trade as a whole, make it possible to compare the efficiency of particular operations, and thus provide more effective managerial control than would otherwise be possible.

*Standards for Office, Purchasing and Operating Routines* make possible effective administration of far-flung business enterprises.

*Standards of Size and Shape* provide for interchangeability of parts and supplies. They are essential to present-day large-scale production and to the use of modern manufacturing methods. Examples are bolts and nuts, ball bearings, railway car couplings, automobile tires, screws and pipe thread. Systems of fits and gauges make it possible to control the production of such articles with the necessary accuracy.

*Concentration upon the Optimum Number of Types, Sizes and Grades of Manufacturers' Products* is often referred to as "simplification," a word given it by Herbert Hoover who gave a great impetus to this kind of standardization.

*Safety and Sanitation Standards* for the protection of the public and of employees are frequently given the force of law through legislation or through regulations issued by administrative authorities. Examples are: standards for the purity of drugs contained in the national pharmacopoeias; regulations to assure wholesomeness of food products such as meat and milk; building codes; standard signs and signals for the control of street and highway traffic; industrial safety codes.

*Specifications and Grading Rules* are definitions of materials and products, the purpose of which is to convey the same meaning to buyer and seller. A specification for cement is an elaborate technical definition of just what kind of cement is called for, how a test sample shall be made, how it shall be tested, and what strength it shall have; so that a buyer can telegraph, "Send 100 barrels of cement meeting specification A" with confidence that he will get what he wants. Grading rules are specifications for two or more levels of quality, often of an elementary nature, defining different grades or series of the same class of products, as grade A and grade B milk.

*Methods of Testing* materials and manufactured products are used to determine whether they comply with the specifications upon which they are bought and sold.

*Nomenclature* includes definitions of words and terms used in buying and selling and in technical and trade literature, abbreviations, symbols, etc.

In the last analysis, not only specifications but most other standards, except sizes, are essentially definitions. All buying and selling in which goods do not come under the actual eye of the buyer must necessarily be based upon some sort of standard. Most of such standards are unwritten, simple and crude, often being no more than a two-party understanding, such as "Like the one I bought of you last time." At the other extreme, all of the great commodity markets are dependent upon standards which are, in most cases, well worked out, are nationally accepted and used, and may even be subject to legal definition. In the absence of such standards, the buyer would himself have to judge the wheat, corn, cotton or copper with his own eyes. A safety standard defines just what hazards shall be covered by the safety features of a machine, or by safe practices in an operation. In each case a standard enables buyer and seller, or the parties to any other undertaking with which the standard deals, to speak the same language. Most standards come about through a more or less unconscious evolutionary process. Since the latter part of the 19th century there has, however, been a steadily increasing trend toward the development of industrial standards, through conscious, deliberative action.

Albert W. Whitney has compared the processes of research and standardization to the process of natural selection. "Nature is perpetually creating new variations in plant and animal life. This is precisely analogous to the creative faculty in human thought. This process of nature, uncontrolled, would fill the world with endless variety. Natural selection, however, acting upon this variety, has had the effect not only of choosing certain types as worthy to survive, but of endowing these types with a certain degree of stability. This establishment of a system of discrete and enumerable types in nature is the exact analogue of standardization as a purposeful, human activity. Not only has nature developed types which can be enumerated and classified, but she has standardized for each a multitude of organs and functions. If this were not so, organized life would be practically impossible. Everything would be an individual problem with no possibility of generalizations. Institutions and customs would

be impossible, for institutions and customs and laws depend upon an underlying sameness of reaction. There could be no organized education, because each mind would be an educational problem by itself. An underlying sameness is the basis for every civilization."

The conscious process of standardization in industry was first applied to engineering matters, but has been extended to foods and other agricultural products, in fact to innumerable products of farm, forest, mine and sea. It helps to channel these materials through the many stages of manufacture. It has been concerned predominantly with producer goods. By 1940, however, small beginnings had been made in a number of countries in the use of such standards applied to consumer goods in the retail market.

**Four Stages.**—According to the scale on which it is carried out, standardization may be classified roughly in four stages:

1. By individual companies
2. Group standards developed by associations and government bureaus
3. On a national scale
4. On an international scale.

The number of individuals and organizations interested in any particular piece of standardization work increases greatly from each of these stages to the next. Also the difficulties as well as the importance increase from stage to stage.

Generally two or more stages develop simultaneously. A piece of standardization work which has been carried out by a society or an association may have been put upon so sound a basis that it becomes essentially a national standard. The same is true even of the work of individual companies.

Every industrial plant is carrying on standardization of its own products and processes, and its competitive success largely depends upon the cleverness and thoroughness with which it has studied and solved these problems. Sound plant standards are essential to mass production.

Standardization within individual companies, which got thoroughly under way during the last half of the 19th century, gave rise to collective standardization for entire industries. Such standardization by industries, carried on through their technical societies and trade associations, has for the most part been a product of this century. The use which electric motors and lamps have attained would have been impossible had it not been for the collective standardization carried on in the electrical industry, not only in fundamentals such as voltages and frequencies, but also in such details as the interchangeability of lamp bases and sockets. The adoption of a standard track gauge and of a standard system of interchangeable brakes and couplings was a necessary step in the development of national railway systems.

Just as standardization by individual companies led to standardization by technical and industrial groups so standardization by groups has in turn been found insufficient because so many problems affect numerous diverse industries and require a common solution. This has led to inter-industry or national standardization in behalf of industry as a whole, technical and trade associations and Government bureaus here playing the same role as individual companies play in group standardization.

**National Standardizing Bodies.**—That standardization cannot reach its greatest effectiveness until it is treated as a national problem has been recognized in all the leading industrial countries. By 1939 national industrial standardizing bodies were functioning in the following 27 countries: Argentina, Australia, Belgium, Canada, China, Czechomoravia, Denmark, Finland, France, Germany, Great Britain, Greece, Hungary, Italy, Japan, Latvia, Netherlands, New Zealand, Norway, Poland, Rumania, Spain, South Africa, Sweden, Switzerland, U.S.S.R., United States.

All of these but the British Standards Institution, which began in 1901, were organized during or since the World War of 1914–18. That war gave a great impetus to standardization throughout the world, because of a demand for materials on an unprecedented scale.

Most of these national bodies are predominantly industrial, but all have the active co-operation of their respective national governments. In Japan, Latvia, New Zealand, and the U.S.S.R., the central body is a governmental organization.

The method of work used by these national standardizing bodies in the various countries follows in general the pattern developed by the British. In order that each standard shall represent a national consensus of those concerned with its subject matter (*e.g.*, those who make, sell and use a product), each is formulated by a technical committee made up primarily of accredited representatives of the various bodies concerned with the standard in question.

**International Co-operation** constitutes the fourth and most difficult stage in the standardization process. Naturally, much less has as yet been accomplished internationally than nationally, yet beginnings have been made in several fields and in some of these there has been substantial progress. A large degree of international uniformity has been attained in fundamental scientific nomenclature, as in astronomy, biology, chemistry, geodesy, microscopy and physics, and also in standards of measurement. Parts of this work have been carried out through international congresses, and other parts through specialized international organizations such as the International Electrotechnical Commission, the International Commission on Illumination, and various international scientific unions. In order to further international co-operation, the national bodies maintain the International Federation of the National Standardizing Bodies (ISA) which was set up in 1926 and which has its headquarters at Basle, Switzerland. The national bodies of 22 countries are members of it.

The activities of the ISA cover a broad field. By 1939 work on 47 projects was under way and substantial progress had been made toward securing international uniformity in such diverse fields as photographic and acoustical standards; documentation standards for libraries, including microfilm technique; and limit systems for machine parts to provide for interchangeable fits. World-wide interchangeability had been obtained in some cases, as in metric ball bearings and in 16mm. moving pictures.

International trade and cultural interchange have been greatly facilitated by the large degree of uniformity in fundamental scientific standards that has been attained, and by the much more modest progress in industrial standards.

**Examples in Special Fields.**—The assembly line in the modern automobile factory has become a classical illustration of great reduction in the cost of manufacture through the use of standards and the mass production methods which they make possible. The standardized parts which make up the completed car, or radio set, or refrigerator, are not made for stock and stored in a supply bin as in traditional factory practice, but flow continuously by means of automatic conveyors from the point at which they are fabricated directly to the assembly line. One plant has succeeded in producing, with a force of but 200 workers, 10,000 automobile frames per 24 hours. This involves the manufacture, in different places in the plant, of 125 parts, which must be sure to fit; having these parts meet at one place on schedule; piecing them together at the rate of a complete frame every eight seconds; and doing this accurately 10,000 times a day. Similarly the completed cars do not go into a warehouse, but directly from the assembly line to the dealers. The large automobile manufacturers do not maintain storage facilities for even a single day's production of cars. Under such advanced methods of production, the cost has been reduced to a small fraction of what it would otherwise be. This has made possible the almost universal use of motor vehicles in industrial countries. (*See* MASS PRODUCTION.)

Thorough-going standardization has greatly enlarged the market for citrus fruits and apples. With the assistance of the U.S. Department of Agriculture the growers on the west coast of the United States standardized their horticultural and packing methods, and graded the fruit by size and quality. These western apples soon became predominant in the markets of the country, even in competition with local supplies thousands of miles distant.

A co-ordinated system of paper sizes, originating in Germany, has been adopted in many of the countries of continental Europe.

Specifications for iron and steel, non-ferrous metals, textiles, ceramics, oils, and many other semi-finished materials entering into innumerable manufactured products have been developed in

all industrial countries, and are in extensive use for quality control. In several countries this work, including methods for testing materials, is carried on by special engineering societies organized for the purpose.

The more highly industrialized countries have found it necessary to establish national safety standards for the protection of employees in industry, which are given the force of law. In most countries such standards are administered by the national Government. In the United States the individual States have jurisdiction, and national uniformity is secured through the American Standards Association which serves as a clearing house in this work for industry, insurance, State and Federal Governments.

In the industrialization of their countries, Japan and Soviet Russia have made extensive use of the industrial standards of Europe and America and especially those of Germany, Great Britain and the United States.

**Standards for Consumer Goods.**—Since about 1925 standards for goods and services purchased by families and individuals to fulfil their daily needs and desires have begun to be developed. The world-wide recession in economic activity, which caused widespread unemployment and curtailed incomes of many persons, gave added impetus to this development. Individuals feel that they should have the same opportunities as large industries and Government agencies to judge the relation between price and quality or performance, in order to conserve their incomes by being able to select those things which best suit their needs at prices they can afford to pay. With the bewildering variety and quality of highly fabricated and packaged goods, the individual buyer feels helpless. Consequently a "consumer movement" has been developing in several countries, notably in the United States, where in 1939 a public opinion survey by advertisers indicated that at least 10,000,000 people had some notion of the question. Consumers want standards for consumer goods, and they want these standards expressed in simple language printed on labels affixed to goods, and used in describing products in advertising and selling them.

## ECONOMIC AND SOCIAL SIGNIFICANCE

Language standards enable us to articulate our thoughts; legal standards enable us to live together—all social organization would be impossible without social standards. The growth of technology has made it impossible to maintain a functioning economic life without more and more material standards—the language of commerce.

It is a commonplace that standardization has been an essential factor in the great increase in the real incomes of the populations of industrial countries since the latter part of the 19th century. This is because standards underlie all mass production methods and because they facilitate the integrating processes necessary to large scale production and distribution.

In the flow of products from farm, forest, mine and sea, through processing and fabricating plants, and through wholesale and retail markets to the ultimate consumer, most difficulties are met at transition points—points at which the product passes from department to department within a company, or is sold by one company to another or to an individual. The main function of standards is to facilitate the flow of products through these transition points. Standards are thus both facilitators and integrators. In smoothing out points of difficulty, or "bottle-necks," they provide the evolutionary adjustments which are necessary for industry to be able to keep pace with technical advances. They do this in the individual plant, in particular industries, and in industry at large. They are all the more effective as integrators in that they proceed by simple, evolutionary steps, albeit inconspicuously.

This integrating effect of standards in improving the efficiency of plant operation has been summarized as follows by Howard Coonley, a former president of the National Association of Manufacturers (U.S.A.): "After long experience in company operation, I have been more and more impressed with the fact that the use of effective standards is one of the most reliable tools an executive can have to reduce the pressure under which he lives. Standards cut down on the number of conferences that it is necessary to hold, on the number of misfires, on controversies in the operation of the plant, and on controversies with customers. In most cases this is brought about by solving problems in advance so that they never come before the executive for his consideration. The advantages which my company has reaped from the extensive use that we have made of standardization could, I believe, be summed up in the phrase 'reducing things to simple routine.' It has cut down the pressure on executives from top to bottom of our company, releasing them from the necessity of making many minor decisions. In fact, standardization is a major key to administration. When a company has introduced a well-rounded program of sound standards for office, purchasing and operating routine, as well as for engineering and shop practices, that company is well along toward an effective organization."

**The Human Element.**—In standardization work the human element is far more important than is generally realized. In setting up standards, the human difficulties are usually much more serious than are the technical ones. On the other hand, one of the chief functions of standards is to remove conditions which lead to controversies. As has been indicated, the lack of adequate standards is a prolific cause of controversy—parts that do not fit, supplies and materials that prove unsuitable because they have not been properly specified, goods that do not live up to sales representations. Such transition-point difficulties often result in feelings of resentment or of frustration on the part of the personnel involved, and thus give rise to controversies—often deep-seated ones. Indeed a goodly proportion of present-day industrial standardization, such as that carried on by the national standardizing bodies, is undertaken in the first instance to remove controversies. These controversies are usually resolved, or at least greatly mitigated, by the introduction of standards which solve the mechanics of the difficulty.

In fact, in the broader field of human relations there are many social standards, such as manners, which are devices for "sublimating" into social amenities what would otherwise be irritations resulting from everyday human contacts. For example, when a man who has accidentally bumped against another says, "I am sorry," he is using a standard technique of social behaviour which is usually effective in preventing emotional irritation.

**The Consensus Principle.**—Because of the importance of this human relationship, the national standardizing bodies and other experienced groups take great pains that each standard shall represent a consensus of those concerned with its subject matter. This is accomplished by direct representation of all interested groups upon the committee charged with the formulation of the standard. Each technical committee, made up of representatives of all interested groups, is essentially a miniature legislature organized upon an industrial rather than a geographical basis.

It is instructive to compare this co-operative method with the common-law and the statute-law methods of establishing law, which is a basic type of social standard. The common law has been one of the strongest and most fundamental forces in Anglo-Saxon civilization. Its slow, evolutionary growth has made possible so perfect an adjustment to the conditions of the civilization with which it developed, that few forms of social control have exceeded it in power and effectiveness. Perhaps only the control exerted by folkways has been more powerful. Legislatures have largely replaced the common-law method of law making. In the legislature, powers and problems become so pyramided into national political systems that most specialized problems get lost, or they, and the groups concerned with them, are so remote from the seat of authority that the decisions reached often partake of the nature of autocratic decrees. The significance of the consensus principle lies in the fact that it is more flexible than the legislative method and that it has much of the strength of the common-law method. Its simple directness gives it the vitality of elementary local self-government.

Questions settled by decree often do not stay settled because they have not been solved, but only decided. On the other hand, in the process of setting up a standard by means of the consensus principle, controversial matters usually are threshed out, often with the aid of research, until a solution, and not merely a com-

promise, is reached.

**Standardization and the Machine Age.**—In the extensive discussions of the "machine age" and its relation to the profound economic and political dislocations that have taken place since the World War of 1914–18, much has been said of standardization, which is part and parcel of the machine age and cannot be separated from it.

Advances in technology are continually binding populations as well as industries closer and closer together. With this ever-increasing interchange, the number of transition-point problems is always increasing. As has been seen, the solution of these problems requires more and more standards, which thus perform functions of primary importance.

Most of the criticisms that have been directed against standardization have been based upon a misconception of the nature of the process. These are to the effect that our minds are regimented by the fact that industry is consciously adopting standards; that the world is being reduced to dull mediocrity by standardization; and that it is one of the main "evils" of a civilization dependent upon the machine. One school goes so far as to predict that the machine age, through technologic development, specialization and standardization will either destroy the race, or reduce it to a completely static condition similar to the communal life of ants and bees.

The misconception underlying these views is the idea that standardization means to stand still. To an industrialist a sound standard represents the best way of doing a thing—at the moment. If tomorrow he finds a better way, he will codify it in a new standard. "Were it not for standards," says Whitney, "there would be nothing to stand on to make a fresh advance. All one's energies would be used up in meeting the idiosyncrasies of the immediate moment. In the field of industry each piece of machinery would be an individual problem, even each screw, each bolt and each nut. Standardization is thus the liberator that relegates the problems that have been already solved to their proper place, namely, to the field of routine, and leaves the creative faculties free for the problems that are still unsolved."

Sound standardization is dynamic, not static. It means, not to stand still, but to move forward together. By facilitating the flow of products through industry and commerce, standards help to maintain what an engineer would call *dynamic stability* in industrial processes—just as a motor car in motion or an aeroplane in flight will respond with nicety to the slightest touch on the controls, and will right itself instantly following any slight disturbance—such as a bump in the roadway or a gust of wind—provided the machine has dynamic stability. The danger of stagnation lies, not in the use of standards, but in taking a fixed mental attitude, instead of always keeping the mind receptive to new ideas.

Most students of the subject take the ground that what is wanted is more, not less, science—that the social sciences must be brought up to a level more nearly that which has been attained by the physical sciences, and most important of all, a science of human relations must be developed. They point out that systematic research is something that is new in the world, and it may invalidate all analogies drawn from history or biology.

The relation between research and standardization may be summarized in a word by saying that standardization consists in finding out the best way of doing a thing, and then doing it that way —until a better way is discovered. And standardization is a major factor in conserving the time, the resources, and the mental energy necessary to find a better way. Thus, research and standardization are complementary factors in an advancing industry—more broadly, in an advancing civilization.

**STANDARD OF LIVING.** The term "Standard of Living" has two distinct meanings. As used by the leading economists from Malthus to the present day, it has a strictly technical meaning. It also has a loose, general and semi-popular meaning. In the strictly technical sense it means the scale of living which the average individual of any given group considers preferable to marriage, or which he must be sure of maintaining before he will marry and undertake the support of a family. In the loose and general sense it means merely the list of things which the average individual of any given class happens to be consuming at a given time and place. In the technical sense, it is a dynamic factor in determining the density of population, the labour supply, the rate of wages, and the possibility of future improvement of economic conditions. In the general sense it is merely a description of the way people are actually living in a given time and place. The standard of living, in this popular sense, has little economic significance.

In the strictly technical sense, a man who will marry and beget children without any regard whatsoever to his ability to provide for the needs of wife and children, has, literally, no standard of living at all. It is safe to say that the only creatures who thus thoughtlessly mate and breed are those which, like plants and animals, lack the capacity for thinking of the future. A standard of living, in this technical sense, is something which goes with intelligence and foresight, on the one hand, and responsibility for one's offspring on the other.

Similarly, those who will marry and undertake the support of families as soon as they feel able to provide the bare necessaries of life are said to have a low standard of living. Conversely, those who will not marry until they are reasonably certain of being able to afford a great many luxuries as well as all the necessaries and decencies of life, are said to have a high standard of living. Thus a standard of living is always relative and consists of the number of desirable things which the individual considers more desirable than the domestic satisfactions which come with marriage. A high standard of living may result either from a weakening of sex and domesticity or from a strengthening of the desire for other things, while a low standard may result either from exaggerated sexual and domestic desires or from weakened desires for other things. In any case, the standard of living of workers plays the same part in determining wages as the cost of producing a commodity plays in determining its price.

It is obvious, to begin with, that standards of living, as thus technically conceived, have a profound influence upon the economic well being of nations and of classes within a nation. If the standard of living of every individual of a group, either territorial or occupational, is high, it insures against territorial over-population or occupational congestion. If no one would undertake to support a family until he was reasonably certain of being able to educate his children, to house them comfortably, and provide them with a motor car, it is reasonably certain that no children would be legitimately born except in families which could afford these things. Besides, such a country, in the absence of immigration, would never have any more people than could afford these things. Disasters and bankruptcies might reduce some to want, but normally there would be no want. On the other hand, if every one would marry and undertake the support of children as soon as he was able to provide a bare physical subsistence, it is certain that a great many children would be born in families which could only afford bare physical subsistence. In other words, wide-spread poverty would be the normal state of large masses of people. In the above characterization we have coupled both sex and domesticity as factors in a low standard of living. In a rather strict and narrow sense however, it is a relatively strong sexual desire rather than a high development of domesticity which characterizes a low standard of living. A highly developed domesticity would lead an intelligent person to desire not merely children, but the welfare of his future children. This would lead to some postponement of marriage until one could provide for their welfare.

The items which go to make up a high standard of living include other things than material articles of consumption. Those who will not marry until, as suggested above, they are reasonably

certain of being able to educate their children, have a high standard of living. Such a desire to safeguard the welfare of their future children has the same effect on marriage rates and marriage ages as the desire for beefsteak and race track tickets. Even a high degree of thrift may be a mark of a high standard of living. He who will not marry until he can afford a sizeable insurance policy or bank account may be called a thrifty individual, but he also has a high standard of living. In such a case the desire for an insurance policy or a bank account has the same effect on the postponement of marriage as the desire for a motor car or an eight-room house and must be accounted as a part of a high standard of living. Certain it is that if no one would marry until he had an insurance policy or a bank account, no children would be legitimately born except in families which, at one time at least, had insurance policies or bank accounts. There would generally be no poverty except as the result of unforeseen disasters which dissipated savings and cut off incomes out of which savings were made. It is well to remember that this balancing of sex against other desires is conditioned upon an economic system which imposes parental responsibility. If one did not have to pay the expenses of one's own family, no other desires would have to be sacrificed when the procreative desires were gratified.

Different nations, and different classes within each nation may have different standards of living in the strict as well as in the general sense of the term. There are, however, no statistics available which throw any very direct light on these differences in the stricter sense. Some indirect light is thrown on the subject by an exceedingly valuable study by Baber and Ross on "Changes in the Size of American Families in One Generation" (University of Wisconsin Studies in the Social Sciences and History, No. 10, Madison, 1924). Tables are included which show that farmers and labourers tend to marry earlier than business and professional men; other tables show that on the average, more children are born of early than of late marriages.

Most of the statistical studies of standards of living have to do with the loose, general and semi-popular meaning of the term. Family budgets as evidences of the spending habits of people with different incomes, were the first records to be studied statistically with a view to determining standards of living. The most famous of these is that of Dr. Ernst Engel. The following table summarizes the general results of that study.

| Items of expenditure | Percentage of expenditure of family income | | | | | |
|---|---|---|---|---|---|---|
| | $225–$300 | | $450–$600 | | $700–$1,000 | |
| Subsistence | 62·0 | 95·0 | 55·0 | 90·0 | 50·0 | 85·0 |
| Clothing | 16·0 | | 18·0 | | 18·0 | |
| Lodging | 12·0 | | 12·0 | | 12·0 | |
| Heat and light | 5·0 | | 5·0 | | 5·0 | |
| Education, public worship, etc. | 2·0 | | 3·5 | | 5·5 | |
| Legal protection | 1·0 | 5·0 | 2·0 | 10·0 | 3·0 | 15·0 |
| Care of health | 1·0 | | 2·0 | | 3·0 | |
| Comfort and recreation | 1·0 | | 2·5 | | 3·5 | |
| | 100·0 | | 100·0 | | 100·0 | |

From Ernst Engel, *Prussian Statistical Bureau Report No. 1857*, p. 145, Table I.

The only striking thing about this table is that it shows that as incomes increase the percentage spent for the basic necessaries decreases while the percentage spent for education, health, comfort, etc., increases.

A fairly clear idea of the comparative standard of living of different countries and at different times may be gained from a study of the relative cost of living.

*Cost of Living in Different Countries, 1926–36 (1929=100)*

| Year | Germany | Canada | France | United Kingdom | United States | Switzerland |
|---|---|---|---|---|---|---|
| 1926 | 99·6 | 100·1 | 90·8 | 104·9 | 103·0 | 100·6 |
| 1927 | 100·2 | 98·5 | 92·4 | 102·4 | 101·8 | 99·4 |
| 1928 | 100·3 | 99·0 | 93·3 | 101·2 | 99·9 | 100·0 |
| 1929 | 100·0 | 100·0 | 100·0 | 100·0 | 100·0 | 100·0 |
| 1930 | 97·6 | 99·3 | 104·5 | 96·3 | 96·4 | 98·1 |
| 1931 | 94·0 | 89·7 | 102·3 | 89·6 | 87·2 | 93·2 |
| 1932 | 89·9 | 81·5 | 94·6 | 87·8 | 78·7 | 85·7 |
| 1933 | 87·5 | 77·9 | 93·5 | 85·4 | 76·4 | 81·4 |
| 1934 | 88·6 | 78·3 | 92·8 | 86·0 | 79·2 | 80·1 |
| 1935 | 88·1 | 79·7 | 85·3 | 87·7 | 81·0 | 79·8 |
| 1936 | 88·3 | 80·8 | 91·1 | 89·8 | 82·1 | 81·2 |

From the "Monthly Bulletin of Statistics," (League of Nations), Vol. XVIII, 1937.

A comparison of the changes in the cost of living in different countries is contained in the preceding table. These, together with the statistics of wages, furnish the best information available as to the standards of living of wage workers in those countries.

The changes in the cost of living have been compared with the changes in money wages in order to give the trend of real wages in various countries.

A somewhat more elaborate study was made in 1909 by Robert Coit Chapin in his *Standard of Living in New York City*, page 70. The following is a brief summary of his more elaborate table:

*Expenditures of Families in New York City*

| Income group | Rent, per cent | Carfare, per cent | Fuel and light, per cent | Food, per cent | Clothing, per cent | Insurance, per cent | Health, per cent | Sundries, per cent |
|---|---|---|---|---|---|---|---|---|
| $ 400–$ 499 | 26·8 | 2·6 | 5·6 | 40·8 | 13·0 | 1·2 | 3·1 | 6·9 |
| 500– 599 | 25·9 | 1·8 | 5·9 | 44·4 | 12·4 | 1·3 | 1·9 | 6·4 |
| 600– 699 | 23·6 | 1·7 | 5·8 | 44·6 | 12·9 | 2·0 | 2·1 | 7·3 |
| 700– 799 | 21·9 | 1·5 | 5·0 | 45·6 | 13·4 | 2·5 | 1·9 | 8·2 |
| 800– 899 | 20·7 | 2·0 | 5·0 | 44·3 | 14·0 | 2·2 | 2·7 | 9·1 |
| 900– 999 | 19·0 | 1·5 | 5·1 | 44·7 | 14·6 | 2·6 | 2·6 | 9·9 |
| 1,000– 1,099 | 18·1 | 1·8 | 4·5 | 44·7 | 15·5 | 2·5 | 1·5 | 11·4 |
| 1,100– 1,199 | 16·2 | 1·9 | 3·8 | 45·6 | 14·9 | 2·5 | 3·6 | 11·5 |
| 1,200– 1,299 | 19·8 | 2·2 | 3·8 | 45·0 | 15·2 | 2·2 | 1·3 | 10·5 |
| 1,300– 1,499 | 16·8 | 1·1 | 3·6 | 43·6 | 13·7 | 4·9 | 1·1 | 15·2 |
| 1,500– 1,599 | 16·3 | 1·2 | 4·1 | 36·8 | 16·8 | 2·3 | 7·4 | 15·1 |

On the basis of these studies of actual budgets, various estimates have been made as to the money income necessary at existing prices to enable an average family to maintain a satisfactory standard of living. Of course something depends upon what the estimator considers a satisfactory standard. One of the best of these estimates was made by Robert Coit Chapin in 1909. His estimate was that in New York City in that year $900.00[1] was necessary. Various other estimates, based on different price levels and costs of living are tabulated by Paul Douglas in his *Wages and the Family*[2]. A summary of this tabulation follows:

*Total Amounts Required to Support the Standard Family of Five According to Various Budgets*

| Year | City | Investigator | Amount of budget | |
|---|---|---|---|---|
| | | | Subsistence plus health and decency | Comfort |
| 1913–15 | Philadelphia | Cotton and Little | $1,070 | .. |
| 1917 | San Francisco | Peixotto | 1,476 | .. |
| 1918 | Philadelphia | Beyer | 1,637 | .. |
| 1919 | Washington | U.S. Bureau of Labor Statistics | .. | $2,262 |
| 1919 | Lawrence, Massachusetts | Nat. Ind. Conf. Board | 1,658 | .. |
| 1920 | Cincinnati, Ohio | Nat. Ind. Conf. Board | 1,692 | .. |
| 1920 | Chicago, Illinois | Council of Social Agencies | 1,666 | 2,322 |
| 1920 | San Francisco, Los Angeles, and Sacramento | Blum and Peixotto | .. | 2,292 |
| 1921 | Philadelphia, Pa. | Beyer | 1,847 | .. |
| 1922 | Anthracite region of Pennsylvania | Nat. Ind. Conf. Board | 1,322 | .. |

It is frequently asserted that because the well-to-do classes have a low and the poor a high birth rate, the difference in wealth is the cause of the difference in the birth rate. On the mere ground of probability it would be at least as likely that the causal connection is the exact reverse, or that the difference in the birth rate is the cause of the difference in prosperity. There are some rather strong reasons for believing that, *in the same economic class*, an increase of prosperity increases rather than decreases the birth rate. If, without first raising the standard of living, in the strictly technical sense, a given economic class is provided with larger incomes, the larger incomes are used as a means of

[1]Cf. *The Standard of Living Among Workingmen's Families in New York City*, p. 246. [2]Chicago, 1925, pp. 7 and 8.

earlier marriages and larger families.

From Malthus to the present day, it has been recognized that a low standard of living among the working classes was the chief hindrance to the success of schemes of social betterment. Efforts to improve the condition of backward peoples are clearly frustrated by their enormous fecundity. During 40 years of British rule in Egypt, 1882–1922, the population doubled. This was made possible by irrigation and other economic improvements. Had the population not doubled, the lot of the masses might have been greatly improved. But with a low standard of living, the increased food supply merely resulted in a greater excess of births over deaths with no great improvement in the average well being. Similar results followed British rule in India, the French control of Algeria, the American occupation of the Philippines and Puerto Rico. In every case, there has been a phenomenal increase in population, with no apparent change in the standard of living. The net result is, as Ross so expressively states, *"The white race is today serving as a midwife to the blacks and the browns."*

If the standards of living of the blacks and the browns could have been raised while the productivity of their countries was being increased, the results would have been different. Instead of merely increasing the number of people living a miserable existence, white control would have lifted those people to a higher state of comfort. Similar results seem to follow most so-called humane movements for the improvement of the condition of the lower classes of labourers within advanced countries. So long as the standard of living remains low, men will marry as soon as they are assured of sufficient income to satisfy the basic necessaries of life. Any improvement in wages or employment is likely to result merely in earlier marriages and larger families with a consequent increase in the supply of labourers followed by a reduction of wages to the old level. On the other hand, if the reform can start with, or be accompanied by, a rise in the standard of living, this train of evil consequences will not follow. The real question, therefore, upon which the success of most schemes of social amelioration depends, is, Can the standard of living of the mass of the labourers be raised? For the more intelligent portion of the labouring classes the raising of the standard of living is not only feasible but offers the most effective means of social amelioration. For the less intelligent classes, those bordering on feeblemindedness, some more drastic method will have to be employed to prevent the overstocking of the labour market. The most significant discussion of the standard of living is found in Malthus's *Essay on Population*. Ricardo recognized it as an important factor in determining rates of wages. Most recent statistical studies of standards of living could have been called studies in costs of living. Probably the best of these is the "Report on The Standard of Living of Workers in Various Countries" to the International Economic Conference, Geneva (1927). Next in importance are a series of annual studies published by the National Industrial Conference Board, New York.

Among the many volumes printed, the following are especially to be commended: *Real Wages in The United States* by Paul A. Douglas (Boston, 1930); *Cost and Standards of Living* by Thomas D. Elliot (Boston, 1931).

Numerous other studies have been made, notable among which are those of Henry Higgs, "Workingmen's Budget," *Journal of the Royal Statistical Society* (1893); Louise Bolard More on *Wage Earner Budgets* (N.Y., 1907); Frank Hatch Streightoff on *The Standard of Living among the Industrial People of America* (Boston, 1911); William C. Beyer, Rebekah P. Davis and Myra Thwing on *Workingmen's Standard of Living in Philadelphia* (N.Y., 1919), and a symposium by various writers on *Standards of Living; a Compilation of Budgetary Studies*, published by the Bureau of Applied Economics (Washington, 1920). (T. N. C.)

**STANDARD OIL COMPANIES,** American petroleum corporations which were formerly a single group operating throughout the world under the stock ownership of Standard Oil Company of New Jersey. In 1911 the United States Supreme Court ordered the dissolution of the N.J. company and shares of 33 subsidiaries were distributed to stockholders of the N.J. company.

Since that time there has been a gradually decreasing community of interest among the different units and the ownership of the shares has become widely diversified. There is now active competition between certain large former Standard Oil companies in every branch of petroleum activity, in domestic marketing territory and in foreign trade.

As is the case with certain large independent companies, tremendous growth of certain Standard Oil companies has been notable since the petroleum industry became a gasoline industry. Standard Oil companies, as the large independent companies, tended toward integration of their operations in the four major fields of production, transportation, refining and marketing. Moreover, always active in foreign development and marketing, certain Standard Oil companies, notably the N.J. company, Socony-Vacuum and the Standard Oil Company of California have held their important place in this respect. The Socony-Vacuum Oil Company was a merger in 1931 of two former Standard Oil corporations, the Vacuum Oil Company and the Standard Oil Company of New York, a merger officially approved on the grounds that the companies were not competitive and the only such corporate merger of former Standard Oil companies made since 1911. In the case of all the large Standard Oil companies, growth has been by plowing earnings back into expansion and by purchase and absorption or affiliation with existing independent companies.

It is estimated that former Standard Oil companies own and operate about 30% of U.S. refining capacity, whereas at the time of dissolution and before the advent of the motor car, they probably accounted for 70%. In 1911 Standard Oil companies purchased the bulk of their domestic crude oil requirements from independent producers, themselves engaging but little in producing. But this was quickly changed as large independent crude oil producing companies built their own transportation systems and refineries and enlarged their markets. Former Standard Oil companies, it is estimated, produce about 20% of U.S. crude oil production.

The Standard Oil Company of New Jersey is the largest American oil company and one of the greatest American industrial corporations. A tabulation showing the assets and net income of 32 leading oil companies in the United States for 1938 showed Standard Oil of N.J. the largest member of the group with total assets of $2,044,635,000 and earnings of $76,000,000. Socony-Vacuum ranked second with assets of $923,439,000 and profits of $40,107,000. Standard Oil Company (Indiana), third largest in point of size with assets of $724,663,000, ranked fourth in earnings with $27,772,000. Standard Oil Company of California, with fourth largest assets totalling $605,138,000, was third in earnings with $28,876,000. Texas Corporation, fifth largest of the group with assets of $605,361,000, ranked fifth in earnings with $23,139,000.

Of the total net earnings of the 32 companies, 51% was earned by the four leading Standard Oil companies. The four leading independent oil companies—Texas Corporation, Gulf Oil Corporation (assets $546,871,000), Shell-Union Oil Corporation (assets $399,399,000) and Consolidated Oil Corporation (assets $362,145,000)—accounted for 16% of the group's total earnings.

Principal companies formerly in the Standard Oil group are:

| | Total Assets as of 12/31/38 |
|---|---|
| Standard Oil Company (New Jersey) | $2,044,635,000 |
| Socony-Vacuum Oil Corporation | 923,439,000 |
| Standard Oil Company (Indiana) | 724,663,000 |
| Standard Oil Company of California | 605,138,000 |
| Atlantic Refining Company | 199,058,000 |
| Ohio Oil Company | 138,670,000 |
| Standard Oil Company (Ohio) | 70,548,000 |
| Standard Oil Company (Kentucky) | 41,057,000 |
| South Penn Oil Company | 38,986,000 |
| Standard Oil Company (Kansas) | 4,991,000 |
| Standard Oil Company (Nebraska) | 4,910,000 |

(L. M. F.)

**STANDARD PRICE:** *see* PRICE MAINTENANCE.

**STANDARDS, NATIONAL BUREAU OF.** This United States body was established by act of Congress on March 3, 1901, and has for its functions the development, construction, custody

and maintenance of reference and working standards, and their intercomparison, improvement and application in science, engineering, industry and commerce. The bureau is a part of the Department of Commerce. Its services are available without charge to the national and State Governments, and under certain conditions, tests and investigations are conducted for the public. In the case of tests for other than the national and State Governments, fees are charged which are paid in to the U.S. Treasury. The original staff of the National Bureau of Standards numbered 14 persons. In 1939 there were about 950, of whom two-thirds were technically trained. The plant comprised 19 permanent buildings on a site of 56 ac. in the north-west suburbs of Washington.

The bureau serves as a clearing house for scientific and technical information and to this end co-operates with similar institutions abroad and with the research laboratories of American industries. Large industrial groups send research associates to work in the bureau's laboratories on problems of mutual interest, the results of which are published for the public benefit. The laboratory equipment is unusually complete and includes several small-scale manufacturing plants in which mill processes can be studied.

**Scope.**—The bureau's work falls into two major classes, the first comprising scientific and technical research and testing, and the second the establishment of commercial standards. Each of these major groups includes several divisions which in turn are made up of sections, the section being the working unit dealing with some specific class of problems. The research and testing group consists of the following divisions: electricity, weights and measures, heat and power, optics, chemistry, mechanics and sound, organic and fibrous materials, metallurgy, and ceramics. The commercial standardization group is composed of the following divisions: simplified practice, trade standards, and codes and specifications. Members of the staff co-operate with such organizations as the Federal Specifications Executive Committee and the American Standards Association. In addition to these two groups there are divisions concerned with the administrative work of the central office, the operation of the bureau's plant, and the construction of apparatus.

**Achievements.**—Through conferences held, practical uniformity in weights and measures has been secured throughout the country. In this connection it should be remembered that the National Bureau of Standards has no police power. The bureau, with other national laboratories, is engaged in a determination of the values of the electrical units in terms of the mechanical units, and has published its results on the ampere and ohm. Many contributions have been made to the art of radio communication, particularly as regards the fundamental data underlying the propagation of radio waves, and the measurement and control of frequency. The bureau developed a radio beacon by which aircraft are guided in fog and by which the pilot can tell when he is following the desired course. Contributions have been made to the art of manufacturing railroad rails, car wheels, and to the development of the light alloys used for aircraft. A means for retarding the corrosion of duralumin has been developed, and the plating of metals with chromium has been made a commercial success.

The bureau's polarimetry section has made many fundamental discoveries in the field of carbohydrates. A commercial method was developed for the production of corn-sugar (dextrose) and this is a most important industry. Similar work was started years ago on levulose (sugar obtained from a weed, the Jerusalem artichoke) and it has been demonstrated that the recovery of this sugar on a commercial scale is practicable.

In 1914 experiments were started on the making of optical glass, and in three years the bureau was able to turn out good grades of glass in all the usual varieties. This work has been continued and the bureau regularly supplies the Navy Department with glass for range finders, periscopes and other optical instruments.

In the experimental paper-mill, a paper on which to print American currency has been developed which shows a strength twice as great as the paper formerly used. Optimum conditions for the storage of books and documents have been worked out for libraries, and special attention is (1940) being paid to the durability of motion picture film used for micro-reproduction of records.

During the past few years special attention has been paid to the properties of building materials, including prefabricated units, with special reference to low-cost housing. Heating appliances, ventilating equipment, and thermal and acoustical insulating materials have likewise been studied. The results of this work are made available through a new series of publications called "Building Materials and Structures Reports."

The bureau is active in the automotive field and has equipment for studying the performance of internal-combustion engines and auxiliary equipment under service conditions. It also has a well equipped hydraulics laboratory where large-scale models of dams and other structures can be built. These facilities are utilized by the Engineer Corps of the Army, Reclamation Service and many other agencies.

The bureau's publications comprise the *Journal of Research of the National Bureau of Standards,* reprints from the *Journal* known as Research Papers, Circulars, Handbooks, Simplified Practice Recommendations, Commercial Standards, Building and Housing, Building Materials and Structures Reports, Miscellaneous, and the Technical News Bulletin. They are obtained from the Superintendent of Documents, Government Printing Office, Washington, D.C. (*See* STANDARDIZATION.) (L. J. BR.)

**STANDERTON,** a town in South Africa at the Vaal river bridges, pop. (1936) 5,595 (2,350 whites), 114 mi. S.E. of Johannesburg; altitude 5,022 ft. It is chief town of a district of the same name and the centre of an agricultural and coal-mining region.

**STANDISH, MYLES** or **MILES** (*c.* 1584–1656), American colonist, was born, according to Nathanael Morton, in Lancashire, England; but became a soldier in the Netherlands, where he met the Pilgrim Fathers. He sailed with them in the Mayflower in 1620, and became the Captain or military defender of New Plymouth. As soldier and linguist he was invaluable in dealing with the natives. He rescued Weymouth colony from the Indians in 1623; returned to England on behalf of Plymouth colony in 1625–26, and later helped to buy out the Merchant Adventurers. He was treasurer of the colony 1644–49, and for a time assistant governor; but was never elected governor, perhaps because not a member of the Pilgrim Church. He removed to Duxbury, 1632, where he died, 1656, and a monument was erected to him in 1872. Longfellow's well known poem, *Courtship of Myles Standish,* is based on a late tradition, published in Alden's work on Epitaphs in 1812–14.

The story that Chorley Church Register was defaced to defeat his title to local lands is proved to be unfounded. Myles Standish was one of the Ormskirk branch of the Standish family.

*See* the histories of Plymouth colony by William Bradford and by Nathanael Morton. Also Porteus: *Captain Myles Standish* (1920) and *History of Standish* (1927). (T. C. P.)

**STAND PAT,** a term used in American politics, signifying opposition to progressive policies. It originated in Theodore Roosevelt's administration when certain progressive members of the Republican Party, mostly from western States, called the conservative members of the party "standpatters."

**STAND-PIPE** is a vertical pipe coupled to a ground hydrant, to lead off water suitably for filling buckets, street-watering hose, fire-hose, watering-carts, etc. The pipe is either permanent or detachable, and the top may be of fixed or swivel type, with one or more outlets. A tall bent pipe is sometimes attached for filling watering-carts or small locomotives. A stand-post is often combined with a drinking fountain or with a lamp column. In the United States a stand-pipe is a vertical pipe or high tank to which water is forced in order to obtain a better head-pressure than is afforded by the mains. (*See* HYDRANT.)

**STANFIELD, WILLIAM CLARKSON** (1794–1867), English marine painter, was born of Irish parentage at Sunderland in 1794. As a youth he went to sea, but he practised sketching to such good effect that, on being incapacitated by an accident, he was able to paint scenery at the "Old Royalty," a sailors' theatre in Wellclose Square, London, the Coburg theatre, Lambeth and at Drury Lane. His first easel exhibit was "Wreckers off Fort Rouge" at the British Institution in 1827, and in 1832 he was

made A.R.A. and in 1835 R.A. He died on May 18, 1867. His art was influenced by his early scene painting and tends to be spectacular and dry and hard in colour; on the other hand the treatment is broad and effective.

His principal works are: "Mount St. Michael", "The Opening of London Bridge" and "Portsmouth Harbour" (1832), "The Battle of Trafalgar" (1836) for the United Service Club, "Isola Bella" (1841), "The 'Victory' bearing the Body of Nelson towed into Gibraltar" (1853) and "The Abandoned" (1856). *Stanfield's Coast Scenery* contains 40 of his works engraved in line.

**STANFORD, SIR CHARLES VILLIERS** (1852–1924), Irish composer, was born in Dublin on Sept. 30, 1852. After studying in London under Ernst Pauer he won (1870) a scholarship at Queen's College, Cambridge, whence he migrated to Trinity College in 1873, and succeeded J. L. Hopkins as college organist, a post he held till 1892. His appointment as conductor of the Cambridge University Musical Society gave him great opportunities. In 1874 to 1877 he visited Germany each year, studying under Reinecke and Kiel. His first important composition was incidental music to Tennyson's *Queen Mary* (Lyceum, 1876). In 1881 his opera, *The Veiled Prophet,* was given at Hanover; followed by *Savonarola* (Hamburg and Covent Garden, 1884), and *The Canterbury Pilgrims* (Drury Lane, 1884). A long interval separates these from his later operas, *Shamus O'Brien,* the least pretending but most successful of his dramatic works (Opéra Comique, 1896) and *Much Ado About Nothing* (Covent Garden, 1901). Meanwhile he had been appointed professor of composition at the Royal College of Music, 1883; conductor of the Bach choir, 1885; professor of music in the university of Cambridge, succeeding Sir G. A. Macfarren, 1887; conductor of the Leeds Philharmonic Society, 1897, and of the Leeds Festival from 1901 on. He was knighted in 1902 and died in London March 29, 1924. His instrumental works include six symphonies, many chamber compositions, among them two string quartets; besides many songs, part-songs, madrigals, etc., and incidental music to the *Eumenides* and *Oedipus Rex* (as performed at Cambridge), and Tennyson's *Becket.* His last operatic work was *The Travelling Companion,* posthumously produced in 1926. His church music and editions of Irish and other songs are well known. *See* his *Studies and Memories* (1908), and *Pages from an Unwritten Diary* (1914).

**STANFORD UNIVERSITY:** *see* LELAND STANFORD JR. UNIVERSITY.

**STANHOPE, CHARLES STANHOPE,** 3RD EARL (1753–1816), English statesman and scientist, was born on Aug. 3, 1753, and educated at Eton and Geneva, where he studied mathematics. In politics he was democratic; he represented High Wycombe from 1780 until his accession to the peerage in 1786, giving his support (1783–84) to the administration of Pitt, whose sister, Lady Hester Pitt, he married in 1774; but when Pitt forsook his Liberal principles, Stanhope severed their political connection. He was the chairman of the "Revolution Society," which expressed its sympathy, in 1790, with the aims of the French Republicans, and in 1795 he introduced into the Lords a motion deprecating any interference with the internal affairs of France, on which point he was in a "minority of one." He thereupon retired from politics for five years. He spent much money on experiments in science and philosophy. His inventions include the printing press and the lens which bear his name, a monochord for tuning musical instruments, and two calculating machines. He projected a canal through Devonshire and took the levels himself. His writings include *Principles of Electricity* (1779); a reply to Burke's *Reflections on the French Revolution* (1790); and an *Essay* on the rights of juries (1792). The lean and awkward figure of Lord Stanhope figured in a host of caricatures. His first wife died in 1780, and in 1781 he married Louisa, daughter and heiress of the Hon. Henry Grenville, who survived him, and died in 1829. Lady Hester Stanhope (*q.v.*) and Lady Lucy Rachael Stanhope, who eloped with the family apothecary and was never reconciled with her father, were daughters by his first wife. Lord Stanhope died at Chevening, Kent, on Dec. 15, 1816.

*See* G. P. Gooch, *Life of Charles, 3rd Earl Stanhope* (1914).

**STANHOPE, LADY HESTER LUCY** (1776–1839), the eldest child of the 3rd Earl Stanhope by his first wife, Lady Hester Pitt, was born on March 12, 1776, and lived at her father's seat of Chevening in Kent until early in 1800, when his excitable and wayward disposition drove her to her grandmother's house at Burton Pynsent. In 1803 she became the chief of the household of her uncle, William Pitt. Although her wit and beauty cheered his declining days, her satire created enemies. Lady Hester Stanhope possessed great business talents, and when Pitt was out of office she acted as his private secretary. On his death she was granted a pension of £1,200 a year, dating from Jan. 30, 1806. On Pitt's death she lived in Montagu Square, London, but in 1810, she left England for ever. After many wanderings she settled among the Druses on Mt. Lebanon, and from the lonely villa of Djoun, 8 m. from Sidon, she wielded an almost absolute authority over the surrounding districts, maintained by her commanding character and by the belief that she possessed the gift of divination. Ibrahim Pasha, when about to invade Syria in 1832, solicited her neutrality. She died on June 23, 1839. Her disappointments and her dictatorship intensified a temper naturally imperious. In appearance as in voice she resembled her grandfather, the first Lord Chatham.

Some years after her death there appeared three volumes of *Memoirs of the Lady Hester Stanhope as related by herself in Conversations with her Physician* (Dr. Meryon, 1845), and these were followed in the succeeding year by three volumes of *Travels of Lady Hester Stanhope, forming the Completion of her Memoirs narrated by her Physician.* They presented a lively picture of this strange woman's life and character, and contained many anecdotes of Pitt and his colleagues in political life for a quarter of a century before his death. *See* also Mrs. Charles Roundell, *Lady Hester Stanhope* (1910); the Duchess of Cleveland, *Life and Letters of Lady Hester Stanhope* (1914); and F. Hamel, *Lady Hester L. Stanhope* (1913).

**STANHOPE, JAMES STANHOPE,** 1ST EARL (*c.* 1673–1721), English statesman and soldier, the eldest son of Alexander Stanhope (d. 1707), a son of Philip Stanhope, 1st earl of Chesterfield, was educated at Eton and Trinity college, Oxford. He served in Italy and Flanders as a volunteer against France, and in 1695 obtained a commission in the British army. Entering the House of Commons in 1701 he still continued his career as a soldier. In 1706 he was appointed British minister in Spain, and in 1708 commander-in-chief there. He captured Port Mahon, assisted at the battles of Almenara and Saragossa in 1710, but was forced to capitulate to the French at Brihuega on Dec. 9, 1710, and was imprisoned in Spain for a year.

Returning to England in 1712 he became one of the leaders of the Whig opposition in the House of Commons, and, in 1714, he became secretary of State for the southern department, sharing with Walpole the leadership of the House. In 1716, as George I.'s foreign minister he only just failed to conclude a treaty with France. He was made first lord of the Treasury in 1717, but in 1718 returned to his former office of secretary of State. In 1717 he was created Viscount Stanhope of Mahon, and in 1718 Earl Stanhope. He helped to conclude the quadruple alliance between England, France, Austria and Holland (1718). He died in London on Feb. 5, 1721, just after the collapse of the South Sea scheme, for which he was partly responsible, though he did not profit.

**STANHOPE, PHILIP HENRY STANHOPE,** 5TH EARL (1805–1875), English historian, better known as Lord Mahon, son of the 4th earl, was born on Jan. 30, 1805, was educated at Christ Church college, Oxford, and entered parliament in 1830. His chief interest was in literature. He was a trustee of the British Museum, and in 1856 proposed the foundation of the National Portrait Gallery, whose subsequent creation was due to his executors. He also assisted in the establishment of the Historical Manuscripts Commission, and was president of the Society of Antiquaries from 1846 onwards. In 1855 he founded the Stanhope Essay prize at Oxford. His works include: *Life of Belisarius* (1829); *History of the War of Succession in Spain* (1832); *History of England from the Peace of Utrecht to the Peace of Versailles* (1836–53); *Life of William Pitt* (1861–62); and *History of England, comprising the reign of Queen Anne until the Peace of Utrecht* (1870, new ed. 1908), the last two of which remain standard works. Stanhope had unique access to ms. authorities, a clear style, and a general impartiality in criti-

cism. He died on Dec. 24, 1875, and was succeeded by his son, Arthur Philip (1838–1905).

**STANIMAKA,** a town of south Bulgaria, at the foot of the Rhodope mountains. Pop. (1934), 17,817. It is a very old Greek colony; its inhabitants speak a dialect containing otherwise obsolete classical terms. On the hill above the town is "Tsar Asen's tower" (*see* ASEN). This was a very strong fortress, and here Renier of Trit, the Latin Count of Philippopolis, was besieged for nine months, until relieved by Villehardouin (*q.v.*). A few miles up the valley of the Čepelare is the monastery of Bačkovo, the second in Bulgaria, with a famous library.

**STANISLAUS I.** [LESZCZYNSKI] (1677–1766), king of Poland, born at Lemberg in 1677, was the son of Rafael Leszczynski, palatine of Posen, and Anne Catherine Jablonowska. He married Catherine Opalinska by whom he had one daughter. In 1697, as cupbearer of Poland, he signed the confirmation of the articles of election of Augustus II. In 1703 he joined the Lithuanian Confederacy against Augustus, and in the following year Charles XII. selected him to supersede Augustus, and by bribery and intimidation secured his election (July 2, 1704). A few months later Stanislaus was forced by a sudden inroad of Augustus to seek refuge in the Swedish camp, but finally on Sept. 24, 1705, was crowned king with great splendour. Stanislaus at once concluded an alliance with Charles, and rendered him some small assistance against the tsar; but he depended entirely on the success of his ally's arms, and after Poltava (1709) the vast majority of the Poles hastened to repudiate him and make their peace with Augustus, and Leszczynski, henceforth a mere pensioner of Charles XII., retreated to Swedish Pomerania. On the restoration of Augustus, Stanislaus resigned the Polish Crown (though he retained the royal title) in exchange for the little principality of Zweibrücken, residing at Weissembourg in Lorraine.

In 1725 Louis XV. of France married Stanislaus' daughter Mary, and supported his claims to the Polish throne after the death of Augustus II. in 1733, which led to the war of the Polish Succession. On Sept. 9 1733 Stanislaus himself arrived at Warsaw, having travelled through central Europe disguised as a coachman, and on the 10th was once more elected king of Poland. Russia, however, protested, proclaimed the Saxon candidate king as Augustus III. (June 30, 1734), and in October besieged Stanislaus with his partisans in Danzig. The expected French help did not arrive until May 20, 1735, when a fleet disembarked a small force, which, however, could do little. On June 30 Danzig capitulated unconditionally after a stubborn resistance of 135 days. Stanislaus, disguised as a peasant, had contrived to escape two days before. He attempted to rally his partisans from Königsberg, and to secure fresh help from France and from Count Potocki in the Ukraine, but without avail.

In 1736 Stanislaus again abdicated the throne, but received by way of compensation the dukedom of Lorraine and Bar, which was to revert to France on his death. He settled at Lunéville, founded there the *Academia Stanislai,* and devoted himself for the rest of his life to science and philanthropy. He died in 1766 at the age of 89. Among his works may be mentioned: *Oeuvres du philosophe bienfaisant* (Paris, 1763; 1866).

*See* Robert Nisbet Bain, *Charles XII.* (1895); Louis Lacroix, *Les Opuscules inédites de S. L.* (Nancy, 1866); *Lettres inédites de S. L.,* ed. P. Boyé (1901); Marchioness Des Reaulx, *Le Roi Stanislas et Marie Leszczynski* (1895).

**STANISLAUS II. AUGUSTUS** [PONIATOWSKI] (1732–1798), king of Poland, the son of Stanislaw Poniatowski, palatine of Cracow, the friend of Charles XII. of Sweden. Through the influence of his uncles the powerful Czartoryski, he was sent to St. Petersburg in the suite of the English ambassador Hanbury Williams. Subsequently, through the influence of the Russian chancellor, Bestuzhev-Ryumin, he was accredited to the Russian court as the ambassador of Saxony. Through Williams he was introduced to the grand duchess Catherine, who was irresistibly attracted to the brilliant young nobleman, for whom she abandoned her other lovers. Poniatowski was concerned in the conspiracy to set aside the succession of the grand duke Peter and his son Paul in favour of Catherine, a conspiracy frustrated by the unexpected recovery of the empress Elizabeth and the consequent arrest of the conspirators.

Stanislaus returned to Warsaw much discredited, but nevertheless was (Sept. 7, 1764) elected king of Poland through the overwhelming influence of Catherine, and crowned on November 25 to the impotent disgust of his uncles. He was hated by the nobility, yet he tried to do his best. He inaugurated some economical reforms. After the first partition he sought to restore the power of their country, while his eloquent oration before the Diet on taking the oath on May 3, 1791, moved the deputies to tears. But when the confederation of Targowica was formed against the constitution, he was one of the first to accede to it, in this way completely paralysing the action of the army which, under his nephew Prince Joseph and Thaddeus Kosciuszko, was performing prodigies. On the outbreak of the insurrection of 1794 he was obliged to sue for his very life to Kosciuszko, and saw his effigy expunged from the coinage a year before he was obliged to abdicate his throne. The last years of his life were employed in his sumptuous prison at St. Petersburg (where he died in 1798) in writing his memoirs. He contracted a secret marriage with the countess Grabowska. He was capable of the most romantic friendships, as witness his correspondence with Mme. Geoffrin.

*See* Lars von Engeström, *Minnen och Anteckningar,* vol. i. (Stockholm, 1876); *Correspondance inédite de Stanislas Poniatowski avec Madame Geoffrin* (Paris, 1875); Jan Kibinski, *Recollections of the Times of Stanislaw Augustus* (Pol. Cracow, 1899); *Mémoires secrets et inédits de Stanislas Auguste* (Leipzig, 1862); *Stanislaw and Prince Joseph Poniatowski in the Light of their Private Correspondence,* in French, edited in Polish by Bronislaw Dembinski (Lemberg, 1904). Stanislaus's diaries and letters, which were for many years in the Russian foreign office, have been published in the *Vestnik Evropy* for January 1908. *See* also R. N. Bain's *The Last King of Poland and his Contemporaries* (1909).

**STANISLAVSKY,** stage name of Constantine Sergeevich Alexeev (1863–1938), Russian theatrical producer, was born in Moscow. His father was a rich mill owner and his grandmother a French actress; he studied at the imperial school of dramatic art and in 1888 began work as an actor and producer in the Society of Art and Literature and after ten years of training founded in 1898 together with the playwright V. Nemirovitch-Dantchenko (1858?–1943) the Moscow Art Theatre. His productions were varied, ranging from the historical *Czar Fedor* to the extreme naturalism of Chekhov's plays. He was also an actor of great force and subtlety, taking the leading parts in Chekhov's and Gorky's plays. Stanislavsky revolutionized the art of producing and was the father of the modern Russian theatre.

*See* Stanislavsky, *My Life in Art* (Eng. trans., 1924).

**STANISLAWÓW,** a province of Poland. Area 7,090 sq.mi. Pop. (1931) 1,477,000. In 1931 68.9% were Ruthenians, 22.4% Poles; the rest mostly Jews. The Ruthenians speak a different dialect from that of the Ukrainians and the Polesian groups, those in the Carpathian area maintaining their Highland customs, especially the interesting tribes of Hucules, who seem to be of Rumanian admixture. They are members of the Greek Catholic or Uniat Church. The province consists of a fertile belt drained by the tributaries of the Dniester, which forms its northeast boundary, of the Carpathian slopes and the mountains themselves, which rise in height to the east and form the lofty Czarna Hora, with dense forests of beech, fir, etc. The province produces large quantities of timber. Stanislawów is famous for its horses and dairy cattle. The salt of Kolomyja has been worked since the earliest times, forming part of the salt belt which extends all along the mountains to Cracow. Potash is found at Kalusz and Turka. The Stanislawów district also has oilfields. Other districts, such as Kolomyja, produce oil and there is mineral gas at Kalusz.

The mountain scenery of the province is very beautiful, particularly in the valley of the Stryj. There are a number of health resorts, such as Kosów, in Pokucie. The chief towns are Stanislawów (pop. 1931, 60,000), Stryj (30,682), Kolomyja (33,385), Kalusz and Sniatyn. Halicz (Russian *Galich*), the ancient capital of the three provinces of Stanislawów, Tarnopol and Lwow, is a small town near the Dniester. It was the capital of a line of Russian princes, which became extinct in 1340 when Casimir the

Great occupied the principality. The province was occupied by soviet troops in 1939 and was conquered by axis troops in 1941.

**STANLEY** (FAMILY), derived its name from Stanley in Leek (in the Staffordshire "moorlands"). Its first known ancestor is Adam de Stanley, brother of Liulf de Audley, who lived in the time of King Stephen. His descendant, William de Stanley, acquired the forestership of Wirral, with an heiress, in 1284, and was ancestor of two brothers, Sir William and Sir John Stanley. The former married the heiress of Hooton in Wirral and was ancestor of the Stanleys of Hooton, whose baronetcy, created in 1661, became extinct in 1893. The younger brother, lieutenant of Ireland under Richard II. and Henry IV., obtained from the latter the Isle of Man in fee. His grandson Thomas was father of the first earl of Derby and of Sir William Stanley of Holt, whose great wealth led to his execution for treason in 1495, and also of Sir John Stanley, ancestor of the Stanleys of Alderley, who obtained a baronetcy in 1660 and a barony in 1839. The earls of Derby are noticed under DERBY.

The barony of STANLEY OF ALDERLEY was created in 1839 for Sir John Thomas Stanley, Bart. (1766–1850), of Alderley Park. EDWARD JOHN STANLEY, 2ND BARON (1802–1869), entered the House of Commons in 1831 and became under-secretary to the home department in 1841, patronage secretary to the treasury from 1835 to 1841, paymaster-general in 1841, and under-secretary for foreign affairs from 1846 to 1852. In 1848, two years before he succeeded to the barony of Stanley, he was created Baron Eddisbury of Winnington. He was president of the board of trade from 1855 to 1858, and postmaster-general from 1860 to 1866. His wife, Henrietta Maria (1807–1895), a daughter of Henry Augustus Dillon-Lee, 13th Viscount Dillon, was a remarkable woman. Before her marriage in 1826 she had lived in Florence, and had attended the receptions of the countess of Albany, the widow of Charles Edward, the Young Pretender; and in London she had great influence in social and political circles. When he was patronage secretary her husband was described by Lord Palmerston as "joint-whip with Mrs. Stanley." Later in life Lady Stanley of Alderley helped to found the Women's Liberal Unionist Association, and she was a strenuous worker for the higher education of women, helping to establish Girton College, Cambridge, the Girls' Public Day School Company, and the Medical College for Women. She died in 1895.

**STANLEY, ARTHUR PENRHYN** (1815–1881), English divine, dean of Westminster, was born on Dec. 13, 1815, at Alderley, Cheshire, the son of Edward Stanley (1779–1849), afterwards bishop of Norwich. He was educated at Rugby under Arnold, and at Balliol college, Oxford. In 1839 he was elected fellow of University college, also taking orders. In 1840 he travelled in Greece and Italy, and for ten years he was tutor of his college. In 1845 he was select preacher, and published in 1847 *Sermons and Essays on the Apostolic Age.* He was a strong advocate of toleration and used his influence to protect from formal condemnation the "Tractarian" party. In 1847 he resisted the movement set on foot at Oxford against R. D. Hampden's appointment to the bishopric of Hereford. Finally, in 1850, in an article in the *Edinburgh Review,* in defense of the "Gorham judgment" he asserted two principles which he maintained to the end of his life—first, "that the so-called supremacy of the Crown in religious matters was in reality nothing else than the supremacy of law," and, secondly, "that the Church of England by the very condition of its being, was not High or Low, but Broad, and had always included and been meant to include, opposite and contradictory opinions."

He was greatly interested in university reform and acted as secretary to the royal commission reporting in 1852. Stanley was also appointed to a canonry at Canterbury. During his residence there he published his *Memoir* of his father (1851), and completed his *Commentary on the Epistles to the Corinthians* (1855). In the winter of 1852–53 he made a tour in Egypt and the Holy Land, the result of which was his well-known volume on *Sinai and Palestine* (1856). In 1857 he travelled in Russia, and collected much material for his *Lectures on the Eastern Church* (1861).

At the close of 1856 Stanley was appointed regius professor of ecclesiastical history at Oxford, a post which, with the attached canonry at Christ Church, he held till 1863. He published the first two volumes of his *History of the Jewish Church* in 1863 and 1865. In the storm which followed the publication of *Essays and Reviews* Stanley opposed the High Church Party. In 1836 he published a *Letter to the Bishop of London,* advocating a relaxation of the terms of clerical subscription to the Thirty-nine Articles and the Prayer Book. An act amending the Act of Uniformity, and carrying out in some degree Stanley's proposals, was passed in the year 1865. In 1862, Stanley accompanied the prince of Wales in Egypt and Palestine.

In 1863 he was appointed dean of Westminster. In December he married Lady Augusta Bruce, sister of Lord Elgin, then governor-general of India. He wrote a third volume of his *History of the Jewish Church,* a volume on the *Church of Scotland,* another of *Addresses and Sermons* preached in America, and another on *Christian Institutions* (1881). He was constantly fighting for the interests of the poor. He gave offence by defending Bishop Colenso, although he disapproved of Colenso's views, and, still more, by his invitation to the Holy Communion of all the revisers of the translation of the Bible, including a Unitarian among other Nonconformists. He desired that the Athanasian Creed be optional instead of imperative in the Church of England. In 1874 Stanley, who was much esteemed by Queen Victoria, conducted the Anglican ceremony at the marriage of the duke of Edinburgh and the grand duchess Marie. He died on July 18, 1881, and was buried in Henry VII.'s chapel.

Stanley's other works include: *Life of Dr. Arnold* (1844); *Essays on Church and State* (1870); *Memorials of Westminster Abbey* (1865). *See* G. G. Bradley *Recollections of A. P. Stanley* (1883); R. E. Prothero and G. G. Bradley, *Life and Correspondence of Dean Stanley* (2 vols., 1893).

**STANLEY, SIR HENRY MORTON** (1841–1904), British explorer of Africa, discoverer of the course of the Congo, was born at Denbigh, Wales, on June 10, 1841, of a family named Rowlands or Rollant. John Rowlands, by which name Stanley was baptized, was brought up first by his maternal grandfather, and after his death was boarded out by his mother's brothers at half a crown a week. In 1847 he was taken to the St. Asaph Union workhouse, where the schoolmaster, James Francis (who eventually died in a madhouse), was a tyrant of the Squeers type, and in May 1856, Rowlands, after giving Francis a thrashing, ran away from school. His paternal grandfather having refused to help him, he became a pupil teacher at Brynford, where his cousin was master. But within a year he was sent to Liverpool, where he lived in poverty with an uncle, and after working at various trades, he sailed as a cabin boy to New Orleans, where he landed in 1859. There he obtained a situation through the good offices of Henry Morton Stanley, who subsequently adopted the lad as his son, but died without making provision for him.

When the Civil War broke out in 1861 Stanley enlisted in the Confederate army; he was captured at the battle of Shiloh (April 1862), and after two months' imprisonment at Camp Douglas, Chicago, he obtained release by enrolling in the Federal artillery. In less than a month he was discharged as unfit. In November 1862 he returned to Liverpool "very poor, in bad health and in shabby clothes," and made his way to Denbigh, but was turned away from his mother's door. For a livelihood he took to the sea—was wrecked off Barcelona—and in August 1864 enlisted in the United States navy. After the war he crossed the plains to Salt Lake City, Denver, and other parts, and became a vivid descriptive writer.

Thus began a series of adventures in search of "copy," which led him through Asia Minor, Tiflis and Tibet. In 1866 Stanley revisited Denbigh and St. Asaph, returning thence to America, where he joined General Hancock's expedition against the Red Indians, acting as correspondent for the *Missouri Democrat* and other papers. His reports induced the *New York Herald* to send him to accompany the British expedition of 1867–68 against the emperor Theodore of Abyssinia. Succeeding in sending through the first news of the fall of Magdala, Stanley received a roving commission from the proprietor of the *Herald,* James Gordon Bennett. He went to Crete and Spain, but in 1869 was recalled to Paris by Mr. Gordon Bennett, Jr.

Convinced that David Livingstone was alive Bennett commissioned Stanley to go in search of him. But he cumbered Stanley with a large number of commissions in Egypt, Syria and Persia before the quest for Livingstone could be begun. Eventually he sailed from Bombay for Africa, reaching Zanzibar on Jan 6, 1871.

The journey to the interior was begun on March 21; on Nov. 10, having overcome innumerable difficulties, Stanley arrived at Ujiji, where he found Livingstone. With Livingstone Stanley navigated the northern shores of Tanganyika, settled the question as to whether the Rusizi was an effluent or an affluent—a point then much debated in connection with the hydrography of the Nile basin, and regained Zanzibar on May 7, 1872. His story, made public in a picturesque narrative, *How I Found Livingstone* (1872), was received in London with some incredulity; but the journals of Livingstone, which he brought home, silenced the critics, and from Queen Victoria Stanley received a gold snuff-box set with brilliants and her thanks for his services.

A series of public lectures in England and America followed. In 1873, as war correspondent of the *Herald,* he accompanied Wolseley's expedition to Ashanti, which he described, together with his Abyssinian experiences, in a volume entitled *Coomassie and Magdala: Two British Campaigns* (London, 1874). On reaching the island of St. Vincent from Ashanti in 1874 he first heard that Livingstone was dead.

**Second African Journey.**—Stanley now desired to return to Africa to determine geographical problems left unsolved by the deaths of Livingstone and Speke, and the discovery by Sir Samuel Baker of Albert Nyanza, a lake then reputed to extend illimitably in a southerly direction. A fund was raised by Lord Burnham, Gordon Bennett and others for an Anglo-American expedition under Stanley's command. This expedition lasted from October 1874 to August 1877 and accomplished more than any other single exploring expedition in Africa. Politically the journey led to the foundation of the Congo State and to the partition of the hitherto unappropriated regions of Africa between the states of western Europe. Stanley started from the east coast and reached the ocean again at the mouth of the Congo, having demonstrated the identity of that river with Livingstone's Lualaba by navigating its course from Nyangwe—the point at which both Livingstone and Lovett Cameron had turned aside.

Of the three white men who accompanied him all died during the journey; Stanley himself was prematurely aged. The discovery of the course of the Congo, though the greatest, was but one of many geographical problems solved during this memorable expedition. The part played by the Kagera in the Nile system, the unity and approximate area of Victoria Nyanza, the true length and area of Tanganyika and the whereabouts of its outlet, and the discovery of a new lake, Dweru, which at the time Stanley believed to be a branch of Albert Nyanza, are some of the other discoveries made by Stanley at this time. The story of the expedition was given at length in *Through the Dark Continent* (London, 1878). Stanley's letters from Uganda and his call for missionaries to go to the court of Mtesa met with an immediate response and proved the first step in bringing the region of the Nile sources under the protection of Great Britain. Commercially the discovery of a navigable waterway penetrating the heart of Africa, was of paramount importance, a fact which was grasped by Leopold II., king of the Belgians, who sent commissioners to intercept Stanley at Marseilles, when he was on his way back to England, with proposals to return to the Congo, proposals which Stanley, much needing rest, put aside for the time. In November, 1878, Stanley went to Brussels and entered into the schemes of the Belgian king.

**Congo Free State.**—A *Comité d'études du Haut Congo* was formed and Stanley was entrusted with the leadership of the new expedition. Stanley reached the Congo in August 1879, and the work he accomplished there in the ensuing five years enabled the comité, which had meantime changed its name to that of *Association internationale du Congo,* to obtain the recognition of America and Europe to its transformation into an independent state ("The Congo Free State") under the sovereignty of King Leopold. Stanley described his labours in *The Congo and the Founding of its Free State* (London, 1885). For the political aspects of the question *see* AFRICA: *Partition Among European Powers;* CONGO FREE STATE. He was restricted by the enterprise of the French traveller de Brazza, who, reaching Stanley Pool by a more northern route, placed the neighbouring districts on the north bank of the Congo under French protection (1880). Stanley returned to Europe in the middle of 1884 and attended the Berlin Conference of 1884–1885, which dealt with African affairs, acting as technical adviser of the American plenipotentiaries.

**Third African Journey.**—Stanley now became interested in the schemes of Mr. (afterwards Sir) William Mackinnon for establishing a British protectorate in East Equatorial Africa, and it was believed that this object could be furthered at the same time that relief was afforded to Emin Pasha (*q.v.*), governor of the Equatorial Province of Egypt, who had been isolated by the Mahdist rising of 1881–1885. Stanley agreed to conduct an expedition, nominally in the service of the khedive of Egypt, for the relief of Emin. He decided to go by way of Zanzibar and the Congo State. He left Europe in January 1887 and at Zanzibar entered into an agreement with Tippoo Tib, the chief of the Congo Arabs, appointing him governor of Stanley Falls station on behalf of the Congo State, and making another arrangement with him to supply carriers for the expedition. On June 15, Yambuya, on the lower Aruwimi, was reached, and here Stanley left his rearguard under command of Major E. M. Barttelot and Mr. J. S. Jameson. On the 28th Stanley and the advance-guard started for Albert Nyanza, "and until Dec. 5, for 160 days, we marched through the forest, bush and jungle, without ever having seen a bit of greensward of the size of a cottage chamber floor. Nothing but miles and miles, endless miles of forest." Starvation, fever, the hostility of the tribes, were daily incidents of this terrible march, during which Stanley lost nearly 50% of his men. On Dec. 13, Albert Nyanza was reached, and after some delay communication was opened with Emin, who came up the lake from the Nile in a steamer. Disquieted by the non-arrival of his rearguard, Stanley retraced his steps, and on Aug. 17, 1888, a short distance above Yambuya, found that Tippoo Tib had broken faith, that Barttelot had been murdered, that Jameson (who soon afterwards died of fever) was absent at Stanley Falls, and that only one European, William Bonny, was left in the camp.

Collecting those who survived of the rearguard Stanley for the third time traversed the primeval forest, and in January 1889 all that was left of the expedition was assembled at Albert Nyanza. Of 646 men with whom he entered the Congo, but 246 remained. In April the return journey to Zanzibar by way of Uganda was begun, Emin reluctantly accompanying Stanley. On this homeward journey Stanley discovered Ruwenzori (the Mountains of the Moon), traced the course of the Semliki River, discovered Albert Edward Nyanza and the great south-western gulf of Victoria Nyanza. During his stay in the Congo forests he had also obtained much information concerning the pygmy tribes. As to the political results of the expedition, Stanley's proposals to Emin to hold the Equatorial Province for the Congo State or to move nearer Victoria Nyanza and enter the service of Mackinnon's British East Africa Company had not been accepted, but he concluded agreements with various chiefs in the lake regions in favour of Great Britain, agreements which were handed over to the East Africa Company. Zanzibar was reached on Dec. 6, 1889, and the expedition was at an end. *In Darkest Africa,* was published (in six languages) in 1890.

Returning to England, Stanley was received with much honour, and received many distinctions. There was, nevertheless, bitter controversy over the fate of the rearguard of the expedition. On July 12, 1890, he married Miss Dorothy Tennant, second daughter of Mr. Charles Tennant, sometime M.P. for St. Albans. Later in the year he visited the United States, and in 1891–1892 went to Australia and New Zealand on lecturing tours. On his return he was renaturalized as a British subject, and after an unsuccessful attempt in 1892, he was elected member of parliament in 1895. He did not seek re-election in 1900. In 1895 Stanley published *My Early Travels and Adventures in America and Asia,* in

which he retold the story of his experiences with the Red Indians and of his eastern journey of 1869–1870. In 1897 Stanley paid his last visit to Africa. He went to the Cape as the guest of the British South Africa Company, spoke at the opening of the railway from the Cape to Bulawayo, visited the Victoria Falls of the Zambezi and had an interview with President Kruger, of whom he gives a characteristic pen-picture. One result of this journey was *Through South Africa* (1898), the last of his published works. In 1899 in recognition of his services in Africa he was made a K.C.B. The last few years of his life were spent mainly in retirement on a small estate he had purchased, Furze Hill, near Pirbright. He died at his London residence in Richmond Terrace, Whitehall, on May 10, 1904, and was buried at Pirbright. The monolith over his grave bears the inscription: "Henry Morton Stanley 1841–1904" with his African name "Bula Matari" and the one word "Africa."

In geographical discoveries Stanley accomplished more than any other explorer of Africa. Notwithstanding his frequent conflicts with Arabs and negroes, he possessed in extraordinary degree the power of managing native races; he was absolutely fearless and ever ready to sacrifice either himself or others to achieve his object. His books differ widely from the ordinary books of travel. Stanley had a gift of dramatic narrative, and his power of portraiture was remarkable. Curiously, the least successful of his works was the only one which he cast in the form of fiction, *My Kalulu, Prince, King and Slave. My Dark Companions and their Strange Stories* (1893) is a valuable contribution to folklore.

*The Autobiography of Sir Henry Morton Stanley,* ed. by his wife, Dorothy Stanley, appeared in 1909. *Henry M. Stanley, the Story of his Life . . .* (London, n.d. [1872]), by C. Rowlands, contains, notwithstanding many inaccuracies, valuable information concerning his family and early career. The following books may also be consulted: Mrs. J. S. Jameson, *Story of the Rear Column of the Emin Pasha Relief Expedition* (1890); W. G. Barttelot, *The Life of Edmund Musgrave Barttelot . . .* (1890); H. Brode, *Tippoo Tib, the Story of his Career in Central Africa* (1907). (F. R. C.)

**STANLEY, THOMAS** (1625–1678), English poet and philosopher, son of Sir Thomas Stanley of Cumberlow, in Herts, was born in 1625. His mother, Mary Hammond, was the cousin of Richard Lovelace, and Stanley was educated in company with the son of Edward Fairfax, the translator of Tasso. He studied both at Cambridge and Oxford, and travelled widely in Europe. Stanley was the friend and companion, and at need the helper, of many poets, and was himself both a writer and a translator of verse. His *Poems* appeared in 1647; his *Europa, Cupid Crucified, Venus Vigils,* in 1649; his *Aurora and the Prince,* from the Spanish of J. Perez de Montalvan, in 1647; *Oronta, the Cyprian Virgin,* from the Italian of G. Preti (1650); and *Anacreon; Bion; Moschus; Kisses by Secundus . . .* a volume of translations, in 1651. Stanley's most serious work in life, however, was his *History of Philosophy* (3 vols., 1655–61). A fourth volume (1662), bearing the title of *History of Chaldaick Philosophy,* was translated into Latin by J. Le Clerc (Amsterdam, 1690). The three earlier volumes were published in an enlarged Latin version by Godfrey Olearius (Leipzig, 1711). In 1664 Stanley published in folio a monumental edition of the text of Aeschylus. He died at his lodgings in Suffolk Street, Strand, London, on April 12, 1678.

The English metaphysical school closes with Stanley, who went on weaving his fantastic conceits in elaborately artificial measures far into the days of Dryden and Butler. His *History of Philosophy* was long the principal authority on the progress of thought in ancient Greece.

Stanley's original poems were imperfectly reprinted in Sir S. Egerton Brydges's edition of 150 copies in 1814. His "Anacreon" was issued, with the Greek text, by Mr. Bullen in 1892.

**STANNARIES,** tin mines (late Lat. *stannum,* Cornish, *stéan,* tin). Stannary courts exercised a jurisdiction peculiar to Cornwall and Devon. By ancient charters, the tinners of Cornwall were exempt from all other jurisdiction than that of the stannary courts, except in cases affecting land, life and limb. Tin-mining in Cornwall, from the very earliest times was always prosecuted in accordance with a particular code of customs; the earliest charter which embodies them is that of Edmund, earl of Cornwall, but it is impossible to say how far these customs go back.

Twenty-four stannators were returned for the whole of Cornwall. Their meeting was termed a parliament, and when they assembled they chose a speaker. In earlier times the combined tinners of Devon and Cornwall assembled on Hingston down, a tract of highland on the Cornish side of the Tamar. After the charter of Earl Edmund, the Cornish stannators met (apparently) at Truro; those of Devon at Crockern Tor on Dartmoor. An officer was appointed by the duke of Cornwall or the Crown, who was lord warden of the stannaries. The last Cornish stannary parliament was held at Truro in 1752. A committee was appointed to report on the subject, and an act of parliament was (1836) passed, suppressing the law courts of the stewards of the different stannaries and giving to the vice-warden their jurisdiction. By the Stannaries Act 1855 the respective parliaments or stannaries courts of Cornwall and Devon were consolidated. By the Stannaries Courts Abolition Act 1896 the jurisdiction was transferred to the county courts. The most important customs were: (*a*) "free tinners" had the right to work upon rendering the "toll-tin," usually one-fifteenth of the produce, to the owner or lord of the soil; (*b*) the right of "tin-bounding," that is, the right of bounding waste lands, subject to tin-toll.

*See* G. R. Lewis, *The Stannaries* (Boston and New York, 1908); W. S. Lewis, *West of England Tin Mining,* with bibliography (Exeter, 1923); A. K. Hamilton Jenkin, *The Cornish Miner* (1927).

**STANNITE,** a rare mineral consisting of tin, copper and iron sulphide (a sulpho-stannate, $Cu_2FeSnS_4$), containing, when pure, tin 27·5, copper 29·5%. It has a metallic lustre, and, when pure, is iron-black in colour; more often, however, it is bronze-yellow, owing to tarnish or to the presence of intimately admixed chalcopyrite: for this reason it is known to miners as "bell-metal-ore" or as "tin pyrites." The hardness is 3·5 and the specific gravity 4·45. It usually occurs as granular to compact masses, rarely as crystals. Minute crystals from Bolivia have been shown to be tetragonal and hemihedral, like chalcopyrite; and to be invariably twinned, giving rise to pseudocubic forms. The mineral has been found in a number of Cornish tin mines, and was formerly worked to a limited extent as an ore. At Zinnwald in Bohemia it occurs with blende and galena, and in Bolivia with silver ores. (L. J. S.)

**STANTHORPE,** a town in the S.E. of Queensland, Australia, 198 mi. by rail southwest of Brisbane. Altitude 2,650 ft.; av. ann. temp.: 80°–35° F., with winter frosts; av. ann. rainfall 30.5 in. It is on the main interstate line (Brisbane-Sydney), and is a summer resort. It lies at the north end of one of the largest masses of granite in eastern Australia, and was a producer of tin (119 tons in 1938). Gold and copper are mined nearby. (Pop. [1933] 2,158).

**STANTON, EDWIN McMASTERS** (1814–1869), American statesman, was born at Steubenville, O., on Dec. 19, 1814. He attended Kenyon college at Gambier, O., and was admitted to the bar in 1836. In 1847 he removed to Pittsburgh, Pa. As counsel for the State, he invoked successfully the aid of the Federal Government in preventing the construction of a bridge over the Ohio river at Wheeling, Va., (now West Virginia)—on the ground that the structure would interfere with the navigation of that stream by citizens of Pennsylvania. He removed to Washington in 1856. In 1858 he was sent to California by the United States attorney general as special Federal agent for the settlement of land claims. Before the Civil War, Stanton was a Democrat, opposed to slavery, but a firm defender of the constitutional rights of the slaveholders, and was a bitter opponent of Lincoln, whose party he then hated and distrusted. In the reorganization of President Buchanan's cabinet in 1860 Stanton became attorney general, and he did what he could to strengthen the weak policy of the President. Although he had often violently denounced President Lincoln, the latter thought he saw in Stanton a good war minister, and in January, 1862, invited him into his cabinet. Stanton was often harsh, and his peremptory manner was the cause of friction with the generals, an instance being his controversy with Gen. Sherman over the terms of surrender granted to J. E. Johnston's army. But he removed a horde of

fraudulent contractors, kept the armies in the field well equipped and infused energy into procrastinating generals. Not the least of his achievements was the peaceable disbandment of 800,000 soldiers at the end of the war.

Remaining in the cabinet of President Andrew Johnson, Stanton exerted all his energies toward thwarting the policies of that executive, especially those related to the reconstruction of the Southern States. He expressed disapproval of the Tenure of Office Act, making the consent of the Senate necessary for the removal of civil officers, and drafted the supplementary act on reconstruction, passed over the President's veto on July 19, 1867. Stanton was finally asked to resign, and on his refusal to do so the President suspended him (Aug. 12) from office and appointed Gen. Grant (who had disapproved of the secretary's removal) secretary *ad interim*. When the Senate, however, under the terms of the Tenure of Office Act, refused (Jan. 13, 1868) to concur in the suspension, Grant left the office and Stanton returned to his duties. On Feb. 21, 1868, Johnson appointed Gen. Lorenzo Thomas secretary of war *ad interim*, and ordered Stanton to vacate, but on the same day the Senate upheld Stanton, and by way of reply the secretary made oath to a complaint against Thomas for violating the Tenure of Office Act, and invoked military protection from Gen. Grant, while Congress came to Stanton's rescue by impeaching the President, the principal article of impeachment being that based on the removal of Stanton (*see* JOHNSON, ANDREW). When the impeachment proceedings failed (May 26) Stanton resigned and returned to the practice of law. Stanton had a violent temper and a sharp tongue, but he was courageous, energetic, thoroughly honest and a genuine patriot. He died in Washington on Dec. 24, 1869.

**STANTON, ELIZABETH CADY** (1815–1902), American leader in the woman's rights movement, was born in Johnstown, N.Y., on Nov. 12, 1815, the daughter of Judge Daniel Cady. In her father's law office she learned of the discriminating laws under which women lived, and many tragic cases observed there determined her in the ambition to equalize the rights of her sex. She did much by the circulation of petitions to secure the passage in New York in 1848 of a law giving a married woman property rights. In the same year, on June 19 and 20, in Seneca Falls, was held, chiefly under the leadership of Mrs. Stanton and Mrs. Lucretia Mott, the first woman's rights convention in the United States. For this convention Mrs. Stanton had drawn up her famous woman's bill of rights setting forth the inferior and unjust position of women in State, church, law and society, and resolutions demanding redress, which were adopted. All of these demands have since been extensively granted. One of them, introduced without Mrs. Mott's approval, was a resolution in favour of equal suffrage for women, which, when approved, became the first organized demand in the United States by women for the ballot. In 1850 she became associated with Susan B. Anthony and for 40 years the two worked together, each admirably supplementing the other, Mrs. Stanton writing, Miss Anthony managing affairs. In 1867–70 they co-operated in editing *The Revolution*, a women's rights newspaper. She was president of the National Woman Suffrage Association from 1865 to 1893. With Miss Anthony and Mathilda Gage she wrote *The History of Woman Suffrage* (4 vol., 1887–1902). She died in New York city on Oct. 2, 1902.

*See* T. Stanton and H. S. Blatch, ed., *Elizabeth Cady Stanton as Revealed in Her Letters, Diary and Reminiscences* (1922).

**STANYHURST, RICHARD** (1547–1618), English translator of Virgil, was born in Dublin in 1547. At University College, Oxford, he met Edmund Campion. After studying law, he went to Spain, ostensibly as a physician, but really to keep Philip II. in touch with the Catholic interest in England. In 1602 he took holy orders, and died at Brussels in 1618. He translated *The First Foure Bookes of Virgil his Aeneis* (Leiden, 1582), to prove Gabriel Harvey's theory that classical prosody could be applied to English poetry. The translation is a jargon arranged in so-called hexameters.

A reprint in 1583 by Henry Bynneman forms the basis of J. Maidment's edition (Edinburgh, 1836), and of Professor E. Arber's reprint (1880), which contains an excellent introduction. Stanyhurst's Latin works include *De rebus in Hibernia gestis* (Antwerp, 1584) and a life of St. Patrick (1587).

**STAPLE,** originally a prop or support; in current usage a U-shaped piece of metal, generally galvanized or wrought iron, in wire form with sharpened points, and used as a fastener by driving into wood; also the chief or ordinary bulk articles of trade. In England the term was applied to towns which were appointed by the king to be the merchants of the staple. These merchants had a monopoly in the staple commodities, viz., wool, wool fells, leather, tin and lead, and were the origin of all English trading companies. (*See* also NAIL MANUFACTURE.)

*See* C. Gross, *Gild Merchants;* W. Cunningham, *Growth of English Industry and Commerce.*

**STAR,** the general term for the luminous bodies seen in the sky, but more especially applied to the "fixed stars," which maintain practically the same relative positions in the sky and form constant patterns or constellations. The planets or "wandering stars" are accordingly excluded (*see* ASTRONOMY).

Unlike the planets which shine by reflected light from the sun, the stars are self-luminous. They are bodies of the same nature as the sun; and the only reason why the sun appears so much more brilliant is that it is comparatively close to us. The following figures speak for themselves: Distance of sun—93,000,000 miles; distance of nearest star—25,500,000,000,000 miles. Each star is a fiery globe and most stars are enormously larger than the earth, though a small proportion are comparable in size with the major planets. Some stars may have planets, but it is not possible to detect these by direct observation; if sufficiently massive, they might be detected by the disturbance of the motion of the parent star caused by their gravitational attraction. In this way a few of the nearer stars have been proved to have companions which, though considerably more massive than Jupiter, are much less massive than any known star. It can be inferred that these companions are not self-luminous, and they are therefore to be regarded as planets.

Although we have been able to learn indirectly the actual dimensions of many of the stars, their size is not revealed by telescopic observation. In the largest telescope a star remains a point of light, and there is no possibility of observing surface markings such as we see on the sun. One unexpected feature, however, is seen directly a telescope is used; a considerable number of the stars which appear single to the naked eye, are seen in the telescope to consist of two stars. The occurrence of close pairs of stars is far too frequent to be due to chance; and, indeed, in some cases the two components have been observed to be revolving round one another. We have to recognize that although single stars like the sun are in the majority, evolution has very frequently taken another course and furnished pairs of luminous globes.

It can be recognized with the naked eye that the stars differ in colour. The colour is not very vivid; but, for example, if the reader is familiar with the constellation Orion, he will easily see that the brighter of the two shoulder stars (Betelgeuse) has a reddish tinge in contrast to all the other bright stars in the constellation, which are white. The quality of the light (crudely indicated by the colour, and in a more detailed way by examination with a spectroscope) is a clue to the surface temperature of the star. As we should expect, the "white-hot" stars are the hottest, and the "red-hot" stars the coolest. Another fact which can be verified with the naked eye, though it requires patient and systematic watching, is that some of the stars give an inconstant light. There are several different kinds of variable stars described below; in one class the variation is a genuine physical change, the star swelling and contracting with regular pulsations.

**The Stellar Universe.**—Thus the statement that the stars are "suns," while giving a correct general idea of their nature, must be amplified to cover a wide variety of objects with many individual characters. They differ greatly in physical condition. Betelgeuse (above-mentioned) is an example of one extreme; it is a gigantic globe so large that the whole orbit of the earth

could be put inside it, but so tenuous that its density is less than $\frac{1}{1000}$ that of air—many a so-called vacuum is not more exhausted than this. An example of the other extreme is the companion of Sirius (*see* SIRIUS), which is compressed to a density far exceeding anything known on earth, and is in size not so large as the planet Uranus. Besides the study of the stars as individual units we have to consider their organization as a system. The principal indication of this organization is found in their motions. Although we often call them *fixed stars,* they are moving rapidly with speeds of the order 10 to 100 mi. a second. Notwithstanding their great distance, the resulting changes of position in the sky can be determined by refined measurement; it is the exception for a bright star to have a motion too small to be detected in, say, 20 years. Further evidence of organization is afforded by the distribution of the stars in the sky. They are crowded toward one special plane, viz., that marked out by the Milky Way, or Galaxy, a band of diffuse light stretching all round the sky which, under telescopic examination, is resolved into millions of faint stars. In general, in speaking of the stars we refer to this galactic system or universe; but it is known that the spiral nebulae, of which there are a great number, are island universes coequal with our galactic system. In some of these other galaxies individual stars can be detected by aid of the largest telescopes.

We find ourselves then in a galaxy which is just one amid many millions. This galaxy has two dwarfish satellites—the Star Clouds of Magellan, which are at a distance of about 80,000 light-years. Beyond these, the nearest of the other systems is so remote that light takes 750,000 years to traverse the void which separates us from it. The number of stars in our own galaxy is of the order of 100,000 millions. To one of the less distinguished stars of this host is attached the earth, which is our home. The evolutionary process which has swept across this system, condensing stars out of the primitive mist, has occupied a time which must be reckoned in thousands of millions of years. From this orgy of inconceivable numbers we may, perhaps, glean an impression of man's place in the material universe. The space and the time which belong to him are as nothing in the far extent and the untold ages of inorganic nature. Is terrestrial man the one and final purpose of it all? Nothing in astronomy has appealed more to the imagination than the conception that each of the myriad points of light in the sky may be giving warmth and light to planets like our earth. It would seem a presumption to deny to them inhabitants of the same order of creation as ourselves. Nevertheless, we must not forget the prodigality of nature. If indeed she has no grander aim than to bring forth her favoured child, man, it would be just like her methods to scatter a million stars whereof but two or three might haply achieve her purpose. Strong reasons have been given by J. H. Jeans for regarding our solar system as a very unusual development. Although probably not unique, the formation of a system of planets is not the normal course of evolution of a star. It only happens when, at a critical stage of development, disruption is caused by the accidental approach of another star—a fortune which, perhaps, not one star in a hundred millions would be likely to undergo. This theory is subject to much uncertainty; but it is at least a useful corrective to the view, often too facilely accepted, which assumes an almost infinite plurality of living worlds.

**History of the Study of Stars.**—In the older books on astronomy most of the space is devoted to the bodies of the solar system (sun, moon, planets, comets); the little that was known of the stars could be compressed into two or three chapters at the end. It is natural that our first acquired knowledge should relate chiefly to the bodies that are nearest to us. Much labour was devoted to observing the stars, but that was largely because they had to serve as graduation marks in the sky against which the movements of the planets and comets could be recorded. Of late the *centrifugal* march of astronomical knowledge has been very remarkable, and the study of the stars is now the largest field of astronomical research. The following may be selected as the chief landmarks in this progress:

1. The first new star or nova was discovered by Tycho Brahe in 1572.

2. The first variable star (Mira Ceti) was discovered by Fabricius in 1596.

3. The first double star (Mizar) was discovered by Jean Baptiste Riccioli in 1650.

4. Edmund Halley first detected the proper motions of stars (Arcturus, Aldebaran, Sirius) in 1718.

5. Sir William Herschel may be regarded as the pioneer of studies of the sidereal system. He discovered the solar motion (motion of the sun through the system of the stars) in 1783. By his famous counts of stars (star-gauges) he established the flattened form of the stellar universe. In 1803 he was able to announce, from his measures of double stars made during the previous 25 years, the confirmation of the theory (urged by Christian Mayer in 1779) that the components revolve round one another.

6. In 1839 distances of the three stars 61 Cygni, $\alpha$ Centauri and Vega were found by measurement of parallax by F. W. Bessel, T. Henderson and F. G. W. Struve respectively. This gave the first definite idea of the scale of the stellar system.

7. In 1862 William Huggins applied the spectroscope to the stars and identified many familiar terrestrial elements as present in their atmospheres. The classification of stars according to their spectra was instituted by Angelo Secchi shortly afterwards.

8. Photography of the stars was developed between 1882 and 1887, the international photographic chart of the heavens and catalogue (not yet completed) being planned in the latter year.

9. Measurement of the velocities of stars in the line of sight by means of the spectroscope was developed very slowly in the latter part of the 19th century. The early measurements were entirely untrustworthy, and it is difficult to say when this powerful aid to stellar research properly started. Good results were obtained by H. C. Vogel and J. Scheiner in 1888–91. A great development of this branch of work was brought about by W. W. Campbell from 1897 onward. The first spectroscopic binary star (Mizar) was found by E. C. Pickering in 1889.

10. J. C. Kapteyn discovered, in 1904, that, at least in our local system, the stars are moving in two main streams. This gave great stimulation to statistical studies of the sidereal universe.

11. The distinction between giant and dwarf stars made manifest by the researches of E. Hertzsprung and H. N. Russell began to be generally accepted about 1913.

12. The study of the internal constitution of the stars, on the basis of the theory of radiative equilibrium, was begun by A. S. Eddington in 1916.

13. The first direct determination of the angular diameter of a star, *i.e.,* the apparent size of its disk, was made by F. G. Pease and J. A. Anderson in 1920, using an interferometer designed by A. A. Michelson.

14. The physical theory of ionization was applied by M. N. Saha to the interpretation of spectral features of the stars in 1920. This led to a branch of research which has had most extensive developments.

**The Twinkling of Stars.**—Before entering on a fuller account of this progress we must refer to a question which is often put. Why do the stars twinkle? If we trace the beam of light, roughly $\frac{1}{10}$ in. in diameter, which fills the eye-pupil back toward the star, it has passed through some miles of terrestrial atmosphere. Differences of density due to slight inequalities of temperature will cause continual changes of refraction at one point or another on the path, giving rise to a general unsteadiness. More important still is the "interference of light." The irregularity of density may be such that the light at opposite edges of the narrow beam has traversed different effective thicknesses of air, so that the corresponding waves are delayed by different amounts. If the delay amounts to half a wave length the waves will arrive crest-on-trough, and, instead of summing up to give a bright star-image, they will cancel one another. Thus the image pops in and out as the changes of atmospheric density succeed one another. The condition for cancelling is different for light of different colours (corresponding to different wave lengths), consequently the star sparkles with different colours. To understand why this does not happen to the light of the planets we must recall that the disk of the planet, unlike the star-disk, subtends a consider-

able angle at the eye. The diameter of Saturn, for example, is normally about 20 seconds of arc, which means that at the height of a mile the rays which reach the eye fill an area 6 in. in diameter. This gives plenty of scope for the variations of the individual beams ($\frac{1}{10}$ in. in diameter) to average out, and consequently they combine to give a fairly steady brightness. Interference or cancelling of waves occurs between waves reaching different parts of the pupil, but not between waves starting from different parts of the disk of the planet or star; thus twinkling depends on the ratio between the angular sizes of the celestial object and of the eye-pupil as viewed from an average height in the earth's atmosphere.

## NUMBER AND MAGNITUDE OF THE STARS

On a clear dark night the stars seem to be innumerable in multitude, but in reality the number in the whole sky visible to the unaided eye is about 6,000. A small telescope greatly multiplies the number, and the largest instruments (aided by long photographic exposures) would reveal some hundreds of millions. The brightness is expressed by "magnitudes," the progressively fainter stars being of progressively greater magnitude. A star is defined to be one magnitude higher than another if its light is fainter in the ratio 2.512; this ratio is adopted so that a difference of five magnitudes may correspond to a light-ratio of 1:100. The faintest stars visible to the naked eye on clear nights are about the 6th magnitude. The brightest star, Sirius, has magnitude −1.6 *i.e.*, 7.6 magnitudes brighter, or just over 1,000 times more luminous, than the faintest naked-eye stars. Classified on the same scale, the sun's magnitude is −26.7. It is possible with the largest instruments to reach stars of about the 21st magnitude. It gives some idea of the light-grasp which has been attained if we notice that the interval from the sun to Sirius (25 magnitudes) is comparable with the interval from Sirius to the faintest stars observed (23 magnitudes).

If the stars were distributed uniformly through infinite space and their light suffered no absorption, each magnitude would comprise 3.98 times as many stars as the preceding magnitude (the number 3.98 is the $\frac{3}{2}$ power of the light-ratio 2.512). This theoretical star-ratio is not realized in the actual distribution. It may be taken as a rough rule that an increase of one magnitude multiplies the number of stars about threefold for the brighter stars, but the factor falls off rapidly for the faintest stars. This is an indication that the density of distribution of the stars in space falls off at great distances—that we are in the middle of a limited cluster or star-cloud. The following table gives the results of F. H. Seares and P. J. van Rhijn (1925) for the number of stars in the sky brighter than the indicated visual magnitude:

| Magnitude | Number of stars | Magnitude | Number of stars | Magnitude | Number of stars |
|---|---|---|---|---|---|
| 4.0 | 530 | 9.0 | 117,000 | 14.0 | 13,800,000 |
| 5.0 | 1,620 | 10.0 | 324,000 | 15.0 | 32,000,000 |
| 6.0 | 4,850 | 11.0 | 870,000 | 16.0 | 71,000,000 |
| 7.0 | 14,300 | 12.0 | 2,270,000 | 17.0 | 150,000,000 |
| 8.0 | 41,000 | 13.0 | 5,700,000 | 18.0 | 296,000,000 |
| | | | | 19.0 | 560,000,000 |

Up to a certain point each magnitude contributes more star light than the preceding, the increased number of stars in the magnitude-interval more than counterbalancing their individual faintness. The maximum is reached between the 11th and 12th magnitudes, the 1,500,000 stars in this interval giving a combined light equivalent to 84 stars of magnitude 1.0. Beyond this the contribution falls off. All the stars together give as much light as 1,100 stars of magnitude 1.0—a result which has been checked closely by direct measurement of the general light of the sky. By extrapolating to fainter magnitudes, Seares and van Rhijn estimated the total number of stars to be about 30,000,000,000. In 1925 the dimming of distant stars by the diffuse matter in interstellar space was not realized. This dimming must result in counts of stars giving an underestimate of the total number of the stars.

The above figures relate to the whole sky. Interesting results are found when we compare the density of distribution of the stars in different parts of the sky, particularly when we compare regions in the plane of the Milky Way with those near its poles. The galactic concentration (ratio of the number of stars in equal areas in the galactic plane and at the galactic pole) increases from 3.4:1 for mag. 4 to 4.3:1 for mag. 10, and to 21:1 for mag. 18. These results refer to photographic magnitude, no sufficiently extensive counts for visual magnitude being available. The great excess of stars in the galactic regions is not wholly or even mainly due to the star-clouds of the Milky Way itself; the star-density increases steadily from the poles to the galactic plane, and the concentration is conspicuous before any part of the Milky Way is reached. This phenomenon was discovered by William Herschel and the modern results are in good agreement with the star-counts made by him and by his son, John Herschel.

The density of the stars in the vicinity of the sun (the "local system") was found by Jacobus Kapteyn to diminish in all directions outward from the sun. They were therefore believed to form one of many star-clouds lying in the galactic plane, the whole being coiled into a spiral nebula. But the effect of dimming by obscuring matter has to be taken into account. The average effect is an obscuration of about 0.8 magnitudes in a distance of a kiloparsec. The obscuring matter is not uniformly distributed and the amount of the obscuration is different in different directions and does not increase uniformly with distance. It is at present doubtful whether there is an increase or decrease of star-density outward from the sun and the existence of a local system remains uncertain. From other considerations it is known that we are very far (about 8,000 parsecs or 26,000 light-years) from the centre of the galaxy, which is found to be in the direction of the constellation Sagittarius. The sun cannot be said to occupy a privileged position among the stars: it is an outlier in the galaxy, which in turn is only one among many millions of its kind.

**Nomenclature of the Stars.**—The brighter stars are designated by a Greek letter followed by the name of the constellation, according to a system introduced by J. Bayer in his star maps in 1603. The letters are assigned roughly in order of brightness, but for stars of nearly equal brightness the order is that of position in the constellation usually beginning at the head of the object figured. Alternatively, a system of numbers (followed by the constellation name) introduced by John Flamsteed can be employed; this covers many stars which have no Bayer letter. Flamsteed's numbers were assigned in order of right ascension. For example, 27 Geminorum = $\epsilon$ Geminorum; 32 Leonis = $\alpha$ Leo-

| Name | Bayer equivalent | Visual magnitude |
|---|---|---|
| Achernar | $\alpha$ Eridani | 0.60 |
| Alcor | 80 Ursae Majoris | 4.0 |
| Alcyone | $\eta$ Tauri | 2.96 |
| Aldebaran | $\alpha$ Tauri | 1.06 |
| Algenib | $\alpha$ Pegasi | 2.87 |
| Algol | $\beta$ Persei | Var. |
| Altair | $\alpha$ Aquilae | 0.89 |
| Antares | $\alpha$ Scorpii | 1.22 |
| Arcturus | $\alpha$ Boötis | 0.24 |
| Bellatrix | $\gamma$ Orionis | 1.70 |
| Betelgeuse | $\alpha$ Orionis | Var. |
| Canopus | $\alpha$ Carinae | −0.86 |
| Capella | $\alpha$ Aurigae | 0.21 |
| Castor | $\alpha$ Geminorum | 1.58 |
| Cor Caroli | $\alpha$ Can. Venaticorum | 2.90 |
| Deneb | $\alpha$ Cygni | 1.33 |
| Denebola | $\beta$ Leonis | 2.23 |
| Fomalhaut | $\alpha$ Piscis Australis | 1.29 |
| Markab | $\alpha$ Pegasi | 2.57 |
| Mira | $o$ Ceti | Var. |
| Mizar | $\zeta$ Ursae Majoris | 2.40 |
| Polaris | $\alpha$ Ursae Minoris | 2.12 |
| Pollux | $\beta$ Geminorum | 1.21 |
| Procyon | $\alpha$ Canis Minoris | 0.48 |
| Regulus | $\alpha$ Leonis | 1.34 |
| Rigel | $\beta$ Orionis | 0.34 |
| Sirius | $\alpha$ Canis Majoris | −1.58 |
| Spica | $\alpha$ Virginis | 1.21 |
| Vega | $\alpha$ Lyrae | 0.14 |

nis = Regulus. A number of ancient names of conspicuous stars survive; many of these are of Arabic origin. The list on page 319 gives those which are familiar to the modern astronomer, together with their Bayer equivalents and their visual magnitudes.

The Arabic names of many additional stars are in common use in sea and air navigation, where a proper name is preferred to a Greek letter followed by the name of the constellation: the Arabic names of these additional stars are rarely used by astronomers. Only 20 stars are ranked as brighter than mag. 1.5. Of these 17 (including the variable Betelgeuse) are named in the above list. The other three are the southern stars, $\alpha$ Centauri (mag. 0.06), $\beta$ Centauri (0.86), $\beta$ Crucis (1.50).

Stars not bright enough to have a constellation letter or number are designated by their reference number in some catalogue. Thus we have names like Bradley 1,940, Groombridge 2,230, Boss 3,932, the last reference (Lewis Boss, *Preliminary General Catalogue*), being especially preferred. The most comprehensive source of reference is the *Bonn Durchmusterung* made by Argelander. This work, completed in 1862, lists the places of 324,000 stars between the north pole and 2° S. An extension to 23° S. by Schönfeld adds 133,000 stars. Star charts to be used with the catalogue are published, and there is no difficulty in identifying in the sky a star referred to, for example, as B.D.+13°, 2,966. The *Cordoba Durchmusterung* (C.D.M.) and *Cape Photographic Durchmusterung* (C.P.D.) fulfil a similar function for the rest of the southern sky. For stars fainter than the limits of these surveys an author must describe the identity as best he can.

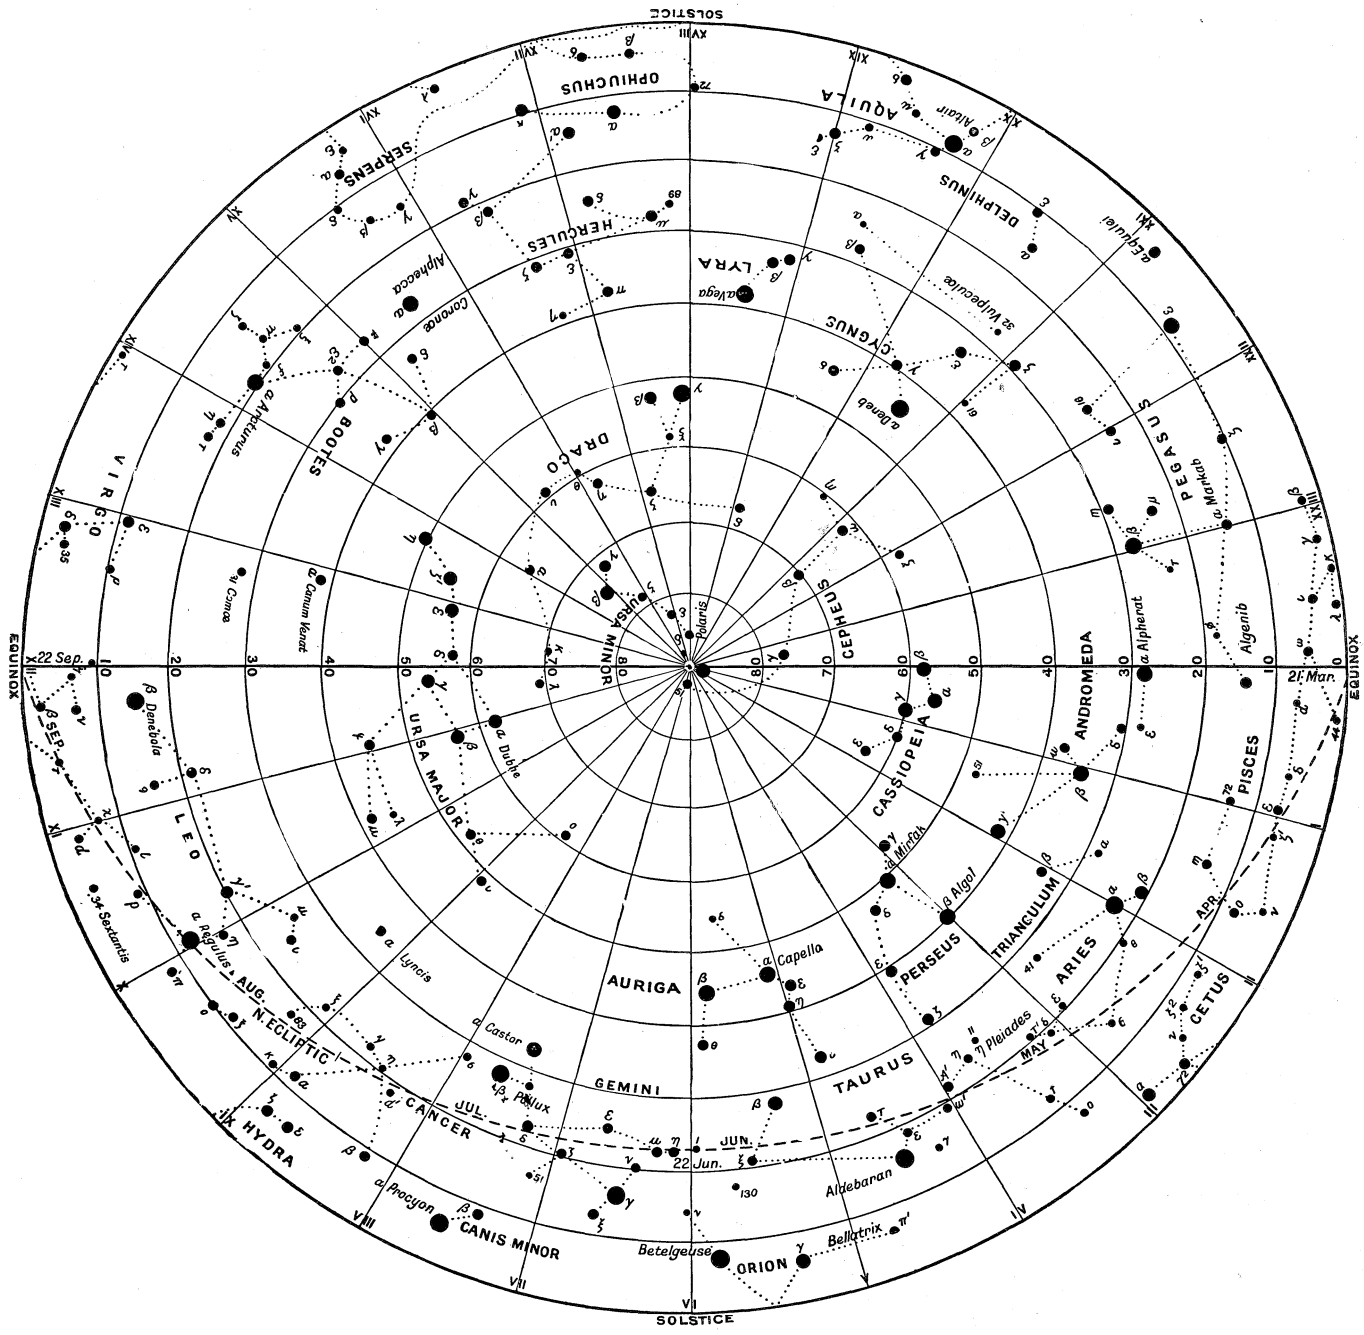
Double stars are generally designated by the name of the discoverer, with the ordinal number of his discovery, or the number in Burnham's *General Catalogue* may be given. Variable stars are assigned (in order of discovery in the constellation) Roman capital letters from R to Z, or a pair of these letters, *e.g.*, X Cygni, RT Aurigae.

**Colour of Stars.**—In stellar observation the photographic plate is used quite as commonly as the eye. Alongside the visual scale of magnitudes measuring the brightness of the stars as judged by the eye, we have a photographic scale of magnitudes giving the brightness as judged by the effect on ordinary photographic plates. It is well known that blue light has proportionately greater actinic power than red light; consequently a comparison of the magnitudes of a star on the two scales gives a measure of its colour. The difference, photographic minus visual magnitude, is called the *colour-index*. (*See* PHOTOMETRY: *Celestial.*) The visual estimation of magnitudes for stars differing in colour is complicated by the Purkinje effect, the relative sensitivity of the eye to differing colours varying with the intensity of the light. Photovisual magnitudes, determined photographically with isochromatic plates and a suitable colour filter, agree closely with the visual scale and are free from the Purkinje effect, and have accordingly in large measure superseded the visual magnitudes.

A classification which runs nearly parallel with classification by colour is afforded by examination of the spectrum of the light. In the Draper classification, now universally adopted, a continuous sequence of types is recognized denoted by the letters O, B, A, F, G, K, M. Intermediate types are indicated by decimal division, *e.g.*, A2 is a type two-tenths of the way between Ao and Fo. A cursory examination of the spectrum is sufficient to determine the type, and 225,000 stars have been classified in this way by Miss A. J. Cannon (*Harvard Annals*, vols. 91–99). The sequence O to M corresponds to progression in colour from blue to red, and progression in temperature from the hottest to the coolest stars. The sun is of type Go. The percentages of stars catalogued in these classes are: B, 2; A, 29; F, 9; G, 21; K, 33; M, 6. Type O is rare, not more than 20 stars brighter than mag. 6.25 being known. The letters R, N, S denote other rare types whose relation to the recognized sequence is still uncertain. The properties of the stars (distribution, mass, luminosity, motion, variability, etc.) are all closely correlated to the spectral type; so that in nearly all investigations it is necessary to study the different types separately. The terms "early type" and "late type" are still commonly used in accordance with the order in this series, *i.e.*, for the bluer and redder stars respectively. The terms originally had reference to a theory of the progress of stellar evolution which is now entirely discarded.

Some progress has been made with the direct measurement of the heat received from the stars, and the corresponding bolometric magnitudes (related to heat intensity in the same way that visual magnitudes are related to light intensity) have been determined. The star-image is focussed on a small disk in which a thermoelectric junction is embedded, and many hundreds of stars are found to give sufficient heat to be measured in this way. The main trouble in these investigations is that the radiant heat over a certain band of wave lengths is largely absorbed by the water-vapour in our atmosphere, and rather large corrections must be applied on this account. The bolometric magnitude may also be inferred from the visual magnitude by applying a correction depending on the spectral type of the star. This correction, called the *heat-index,* is analogous to the colour-index, and varies in correspondence with it. Naturally, the red stars are "brighter" bolometrically than visually, because their radiation is of low luminous efficiency. The greatest luminous efficiency is for stars of types F and G, perhaps because the human eye has been developed so as to make the most of sunlight. In still hotter stars there is a falling off of luminous efficiency, the radiation being too far in the violet and ultra-violet to suit the eye.

**Absolute Magnitude.**—We turn now to consider the real brightness of the stars. How would they compare with the sun in splendour if we could see them at the same distance? To infer the true brightness from the apparent brightness we must first know the distance (for the methods of measuring the distance *see* PARALLAX). An idea of the variety of brightness may be given by considering the seven most conspicuous stars. Sirius gives 28 times the sun's light, but it has a companion only $\frac{1}{360}$ as bright as the sun. Canopus is so remote that its distance cannot be found accurately, but it can scarcely be less than 10,000 times as luminous as the sun. $\alpha$ Centauri consists of two stars, one almost a replica of the sun and the other considerably fainter. Then follow Vega and Arcturus with luminosities 50 and 100 in terms of the sun. Capella consists of two stars, with luminosities 110 and 70, having a faint distant companion of luminosity about 0.01. Rigel is remote, but its distance is more certain than that of Canopus; its luminosity is greater than 10,000.



This shows that there are stars far surpassing the sun in brilliancy; but, naturally, if we pay attention only to the most conspicuous stars we shall form an exaggerated idea of the general order of brilliance. There would be the same difficulty if we extended our survey to all the naked-eye stars; these would include the most luminous stars contained in a very wide region and the feebler stars in a much smaller region. It is only by rather elaborate investigations that we can get together a fair sample of the stellar population, in which the luminous stars are not over-represented by forcing themselves on our attention. According to the latest discussions the following table gives the relative proportions of stars of different degrees of intrinsic brightness in any volume of space:

| Light power | Number | Light power | Number |
|---|---|---|---|
| 10,000 × sun | 1 | 1 × sun | 200,000 |
| 1,000 " | 90 | 0.1 " | 350,000 |
| 100 " | 3,300 | 0.01 " | 500,000 |
| 10 " | 42,000 | 0.001 " | 600,000 |

Stars fainter than the sun far outnumber those which are brighter.

At present the faintest known star is one to which attention was drawn by G. van Biesbroeck. It is a distant companion to the star BD+4°4048 and has an absolute photovisual magnitude of 18.1 and an absolute photographic magnitude of 19.5. It has only 1/200,000 of the brightness of the sun, but it is still seven magnitudes brighter than Jupiter at full phase. It is intrinsically fainter by about three magnitudes than the next faintest known star, Wolf 359. The faintest known stars are all cool red stars.

At the other end of the scale it is difficult to assign an upper limit to the brightness because the objects suspected of great brilliancy are generally too remote for parallax measurement. In

## STAR CHART OF NORTH POLAR HEMISPHERE

Most stars visible to the naked eye and north of the celestial equator are shown in this chart. The North Star, Polaris, is shown slightly to the right of the north celestial pole. This star is not exactly true north. At the bottom of the chart is the first magnitude star Betelgeuse in the constellation of Orion. This was the first of the large stars to have its diameter measured. At the left of the north celestial pole is the "Great Bear" with its pointer stars in line with the North Star. In the upper part of the chart is the constellation Hercules toward which the entire solar system is moving at the rate of about 12 miles per second. Owing to the rotation of the earth on its axis, all stars shown in this chart appear to rotate around the north celestial pole in a counter clockwise direction

## STAR CHART OF THE SOUTH POLAR HEMISPHERE

Showing all of the principal stars visible to the naked eye found south of the celestial equator. To the left of the south celestial pole in the chart is the Southern Cross (Crux). Below the south celestial pole and slightly to the left is Scorpio which contains the giant red star Antares, which has the greatest diameter of any star that has been measured up to the present time. It is visible from practically every point in the inhabited world. To the right of the south celestial pole is Fomalhaut, a first magnitude star in the constellation "The Southern Fish." Sirius, of the constellation "The Big Dog" and the brightest star in the sky, is near the top of the chart. All stars shown in chart appear to revolve around the south celestial pole in a clockwise direction due to the rotation of the earth on its axis

the star clusters, however, we see a group of stars all at practically the same distance, and can therefore measure at once the relative brightness of different classes of objects. The variable star S. Doradus in the Greater Magellanic Cloud has a mean absolute magnitude $-9.4$(500,000×sun); and other stars in the same cloud are not far short of this. The range in real brightness of the stars is at least 24 magnitudes—very much the same as the range in apparent brightness so far as it is possible to observe it.

**Size of Stars.**—The radius of a star may be calculated from the absolute luminosity (which requires a knowledge of the star's distance) and the observed surface-temperature. Other things being equal, the luminosity is proportional to the area of the surface, *i.e.*, to $R^2$, but allowance must be made for the different radiating power of surfaces of different temperatures: this allowance can be calculated from the laws of radiation (Planck's law). In this way it is found that the stars differ greatly in size. Some have diameters some hundreds of times greater than that of the sun; others have diameters less than one-hundredth that of the sun. If the sun were placed at the centre of Antares, the entire orbit of Mars would be well within the star. Van Maanen's star, on the other hand, is smaller than the planet Neptune. For a few stars, the sizes deduced from the star's luminosity and surface temperature have been confined by direct measurement of the apparent angular diameter of the disk with Michelson's interferometer.

**Interferometer Measurements.**—The measurement of the angular diameters of a few favourable stars has been made by means of Michelson's interferometer (*q.v.*). As adapted to astronomical work this consisted of a 20 ft. beam carrying two inclined mirrors which could slide along it, and carried on the 100 in. telescope at Mt. Wilson observatory; the light from the movable mirrors fell on two fixed mirrors, and was directed by them on to the great telescope mirror. Virtually the observer was looking simultaneously through two apertures whose separation could be varied up to 20 ft., very much as in a gigantic range finder. (*See* BINOCULAR INSTRUMENT: *Stereoscope.*) The effect of using two apertures is that the spurious (diffraction) disk of the stellar image is crossed by fine diffraction lines, and the lines become closer as the separation of the apertures is increased. If the object looked at is not a mere point of light, its finite size blurs the diffraction pattern, and the object of using widely separated apertures is to obtain a diffraction pattern so fine that even the invisible disk of a star is sufficient to blur it out and make it disappear. Seven stars have been found to have angular diameters exceeding 0.″02 which is about the limit attainable with this instrument; a 50 ft. interferometer has been constructed at Mt. Wilson, with which some further measures have been made, but the great majority must remain beyond the scope of this method. In some ways this application of the interferometer is to be regarded rather as a *tour de force* than an important advance of knowledge, serving merely to confirm the angular diameters inferred from the diameters, computed as described above, and measured distances. Of special interest, however, are the observations of the variable stars, Mira Ceti and Betelgeuse; here the interferometer measurements indicate variations in the diameter, and seem to confirm the theory, put forward on other grounds, that this type of variability is due to pulsation.

Another application of the interferometer is to measure the separation of double stars in which the components are so close that ordinary visual measurements are impossible. In particular Capella, which is known to be a double by spectroscopic observation, cannot be resolved by any telescope. Nevertheless, by interferometer measurement the orbit has been found just as though it were a visual double. We have the rare opportunity of combining visual and spectroscopic orbital data, and the result is that Capella is one of the best known stars as regards mass, absolute luminosity, etc.

## DOUBLE STARS

About the year 1650 Jean Baptiste Riccioli made the first discovery of a double star, viz., Mizar or $\zeta$ Ursae Majoris, the middle star in the tail of the Great Bear. Looking at Mizar with the naked eye, we see a fainter star, Alcor, very close to it; it is a fair test of eyesight to separate them. Their separation is however, 11′, and although there is no doubt that Mizar and Alcor have a physical association, since they are found to be moving at just the same rate across the sky, the term double star is only applied in case of much closer proximity. Riccioli's discovery was that Mizar itself consists of two stars separated by 15″ or about $\frac{1}{40}$ of the distance between Mizar and Alcor. This would now be regarded as a wide pair, and many of the most interesting double stars have a separation under 1″. The actual distance between the two components of Mizar is not less than 11 times the distance of Neptune from the sun. The two stars must be attracting one another, but the gravitational control across such a distance is so feeble that they will take more than 3,000 years to complete their orbital revolution. It is, therefore, not surprising that the measures made during the last 150 years fail to indicate definitely any orbital motion; and the only evidence of genuine connection (apart from the improbability of two independent bright stars lying so closely in the same line of sight) is afforded by their common motion across the sky, and common radial velocity.

Similar discoveries followed rapidly. $\theta$ Orionis (in the midst of the great nebula) was resolved by Huyghens in 1656; $\gamma$ Arietis by Hooke in 1664. In the southern hemisphere the duplicity of $\alpha$ Crucis and $\alpha$ Centauri was discovered by Jesuit missionaries in 1685–89. The foundation of systematic measurement and study of double stars is due principally to William Herschel and Wilhelm Struve. The latter, working at Dorpat between 1813 and 1835, formed a catalogue of 3,110 pairs as the result of surveying about 120,000 stars.

The number of recognized visual double stars is now about 20,000, but the number is necessarily somewhat arbitrary since, if too wide limits of separation are admitted, stars which are only in accidental proximity may be included. Among the naked-eye stars, one in nine is a telescopic double. It is certain that the true proportion of binary systems is much greater than this, many being too close to be resolved with the telescope. Thus, taking the nearest known stars (which give the best chance of observing duplicity), eight out of 20 are double.

Catalogues of double stars no doubt contain a number of spurious pairs, *i.e.*, stars which are not actually near one another in space and merely happen to lie in the same line of sight, but considerations of probability show that there will not be many of these. The physical connection is generally shown, as in the case of Mizar, by common proper motion. If spectroscopic determinations of radial velocity have been made these will provide an additional check. The connection implied is evidently the connection of a common origin. The two stars were born from the same nebula; they originally shared in common the velocity of the parent nebula, and they have gone on moving together because they have been subjected to the same influences ever since. In most of them the gravitational tie is too weak to resist any differential disturbance, *e.g.*, another star passing between the pair. The fact that so many of these wide doubles survive teaches us that chance approaches of stars to one another must be very rare.

Of greater interest are those double stars close enough together to show the effects of their mutual gravitation. There are about 170 double stars for which it has been possible to work out definite orbits. In about 2,000 more there is a rough indication of orbital motion, but the arc described since observation commenced is too short to determine the orbit satisfactorily. The shortest periods are 5.7 years ($\delta$ Equulei) and 6.9 years (13 Ceti); about 60 pairs have periods of under 100 years. It is natural to enquire whether the planes of the orbits tend to lie in any particular direction—parallel to the galactic plane, for example. A curious difficulty arises in this investigation. If the reader has watched the revolution of a cup-anemometer (or of a garden sprinkler) he will probably recall that the direction of revolution appears obvious and unmistakable, but after blinking the eyes the revolution seems just as unmistakably in the opposite direction and in a different plane. For the same reason we always find two planes of rotation of the double star, either of which may be the true

one. We can only adopt both planes, and investigate as best we can the resulting mass of data, half of which is correct and half spurious. So far as can be ascertained the planes of double star orbits are quite at random.

The two dog-stars, Sirius and Procyon, are double stars of exceptional historic interest. Being conspicuous stars they were well observed a hundred years ago and used as fundamental reference stars for determining time, etc. It was found that they were moving irregularly—not with uniform proper motion like other stars. It was evident that each was being disturbed by the gravitation of a massive body in its neighbourhood, although the companions were invisible. The theory was given by Bessel in 1844, and orbits were computed from the observations, the periods of revolution being 50 and 39 years respectively. The disturbing stars, whose existence was thus convincingly demonstrated, have since been seen. The companion of Sirius was observed by Alvan Clarke in 1862, and is a comparatively easy object for modern telescopes; the companion of Procyon, which is more difficult, was observed by Schaeberle in 1896. They are faint stars, respectively 10 and 13 magnitudes fainter than their primaries. Nevertheless, they must be massive bodies to exert so large a pull on their brilliant neighbours.

Another star of special interest is the double star, 61 Cygni. In 1942 Strand found that one of the visual components was perturbed by an unseen faint companion, which proved to have a mass of only $\frac{1}{60}$ that of the sun. This is considerably more massive than Jupiter, but much less massive than any star of known mass. It is inferred that this faint companion cannot be self-luminous and it must therefore be regarded as a massive planet and not as a star.

**Masses of Stars.**—The orbital motion of double stars conforms to the law of gravitation. It gives evidence that gravitation is universal in the stellar system. The study of binary systems performs a unique service in the general advance of our knowledge of the stars since it is through it that we arrive at knowledge of the masses of the stars. By the law of gravitation the extent to which a body disturbs the motion of other bodies is proportional to its mass. It is when we find bodies in close proximity that we obtain a chance to observe the disturbance, and so obtain a measure of the mass. It is good fortune for the astronomer that the course of evolution has been such as to provide pairs of stars close enough together; otherwise we should probably still be in total ignorance as to the masses of stars, except in so far as the sun's known mass might be assumed to be typical.

If $M_1$, $M_2$ are the masses of the two components, $a$ the mean distance between them (strictly the semiaxis major of their relative orbit), and $P$ the period of revolution, Kepler's laws give

$$k(M_1+M_2)=a^3/P^2$$

where $k$ is a universal constant. Let us measure the mass in terms of the sun's mass as unit, the period in years, and $a$ in astronomical units, *i.e.*, in terms of the earth's distance from the sun. Applying the equation to the earth's motion round the sun (the earth's mass $M_2$ being negligible) we see that for these units $k=1$. Now apply the equation to Sirius. The mean distance of the two components is 7.55 seconds of arc. To convert this into linear measure we must know the parallax of Sirius, 0.37 second. This means that one astronomical unit seen at the distance of Sirius would appear to extend 0.37 second; hence 7.55 seconds corresponds to 20.4 astronomical units, determining $a$. The period $P$ is 49 years. Hence

$$a^3/P^2=(20.4)^3/(49)^2=3.5=M_1+M_2$$

We learn, therefore, that the combined mass of the two components is three and one-half times that of the sun. If it is preferred to express the mass in tons, this can be done since the sun's mass is 1,980,000,000,000,000,000,000,000,000 tons.

To find the masses of the two stars separately we must determine their absolute orbits about their common centre of gravity instead of the relative orbit considered above. This means measuring the motions of the components with respect to surrounding stars instead of with respect to one another. It is found that the bright star has the greater share of the mass, nearly in the ratio 3:1.

From the visual double stars, together with the spectroscopic binaries (described below), an idea of the masses of stars in general has been obtained. Comparatively few determinations reach high accuracy, because a rather accurate parallax is required which is not generally forthcoming. The first thing that strikes us is the wonderful uniformity of mass. By far the majority of the determinations give between one-third and three times the sun's mass, which seems a very small range when compared with the great differences of luminosity. Another result brought out is the close relation of mass to luminosity, the brighter stars being the more massive. It is probable that (excluding a peculiar class of stars known as *white dwarfs*) the luminosity depends almost entirely on the mass; it makes little difference whether the star is in a dense or in a diffuse state. The theory of this relation will be explained later. Having checked it by the masses determined for double stars, we can use it to find the masses of other stars whose absolute brightness is known.

We naturally select the most conspicuous stars for special investigation, and as a result we tend to pick out exceptionally high masses. Among the spectroscopic binaries some very high masses have been found, which, however, are believed to be exceptional. For one binary of Type O discovered by J. S. Plaskett the components have masses greater than 87 and 73 in terms of the sun. (Only a lower limit can be stated.) Another O type binary has masses 36 and 34. The eclipsing variable V Puppis has two components each of mass 19.2. There is at present no evidence of any stellar masses below one-sixth of the sun's mass.

From the close uniformity of stellar masses it follows that the stars of gigantic volume like Betelgeuse must be of extremely low density. Assuming that the mass of Betelgeuse is something less than 100 times the sun's mass, in order to fill a volume 50,000,000 times greater than the sun, the density must be less than $\frac{1}{100}$ that of air. The small compact stars, like the companions of Sirius and Procyon, which are of planetary dimensions, must be of extremely high density, many thousands of times that of water. The large, diffuse, highly luminous stars are called *giant stars;* the stars of low luminosity, which are smaller and of higher density, are called *dwarf stars.*

**Spectroscopic Binaries.**—When a source of light is approaching us, the lines in its spectrum appear displaced towards the violent end; when receding, the displacement is toward the red end. By means of this "Doppler effect" (*see* LIGHT) the velocity of a star in the line of sight can be measured. In examining the stars with a spectroscope we sometimes turn the instrument on to what is telescopically a single point of light, but is actually a double star with components too close to be separated. Since the two components have different velocities toward or away from us their spectra will not be exactly superposed and every spectral line will appear double. The first example of this was found by E. C. Pickering in 1889. This was the star Mizar already mentioned as the first visual double star to be discovered. The two components seen in the telescope take at least 3,000 years to perform their revolution; but the doubling of the spectral lines of the brighter component shows that it is itself a double star with a revolution period of 104 days. If a star showing a doubled spectrum is watched for some time it is seen that the doubled lines close up and then cross one another. This is in accordance with the theory of orbital motion, for the two components must approach us and recede from us alternately in the course of a revolution.

It is only when the two components are of nearly equal brightness that this doubling of the spectral lines can be observed. A difference of about two magnitudes is sufficient to render the fainter spectrum invisible. In the majority of spectroscopic binaries only the brighter spectrum is observed, and the binary character is inferred from the periodic approach and recession of the source emitting it. The argument is that the changing displacement of the spectral lines shows that the source of light is describing an orbit; there must be some mass for it to revolve around; and therefore a fainter component must exist although

invisible. About 1,500 spectroscopic binaries have been discovered, and definite orbits have been computed for about 400 of these. The spectroscope can only measure velocity in the line of sight, and many binaries must escape detection through having their orbits nearly perpendicular to the line of sight.

Spectroscopic binaries afford valuable additional information as to the masses of stars, but of a statistical rather than of an individual kind. When one component only is observed, all that can be deduced is a rather complicated function of the masses and the unknown inclination of the orbit; but when both spectra are observed, a minimum mass of each component can be found. This minimum mass has to be multiplied by $\operatorname{cosec}^3 i$ ($i$=inclination of orbit plane to the sky plane) which is unknown unless the star can also be observed visually or is an eclipsing variable, but in researches on the average mass of any class of stars a suitable mean value of this factor may be used.

In rare cases the same system may be observed as a visual and a spectroscopic binary; but in general only the close pairs with periods less than a year are detected spectroscopically, and wide pairs with periods of many years or centuries are detected visually. Many intermediate pairs must escape both methods of discovery. The first star to be observed by both methods was $\alpha$ Centauri. The results have a special interest because they afford a determination of the star's distance entirely independent of the ordinary method of parallax measurement. The visual observations determine the angular size of the orbit; the spectroscopic observations determine the same quantity in kilometres; so that we have only to compute the distance at which the given length subtends the given angle. The result for $\alpha$ Centauri satisfactorily checked the ordinary trigonometric determination of its distance.

Multiple systems containing more than two components are not uncommon. We have already noticed the system of Mizar. The star Castor is an easy visual double, both components of which are spectroscopic binaries. These systems all appear to be built by successive subdivisions of one mass into two, and it is clear that after such a fission a long period of evolution and condensation must elapse before either of the resulting masses is ready to divide again. An important question is whether the widely-separated pairs were originally formed with their present separation or whether the distance has increased in the course of time. It is difficult to resist the impression that the components gradually recede from one another, especially as the statistics show markedly that the stars supposed to be oldest in evolution form the widest pairs. Two causes are acting which will tend to increase the initial separation to some extent, viz., the mutual tidal forces and the loss of mass of the stars by radiation; but neither can produce a large effect. The cumulative effect of perturbations by casual approaches of other stars would in the long run, drive the components further apart; this process, however, is too slow to produce much effect, even in the long periods of stellar evolution. The general problem of the formation of double stars is discussed in the article COSMOGONY.

## VARIABLE STARS

There are three main classes of variable stars: (1) eclipsing variables, (2) Cepheid variables, (3) long period variables. In a sense the sun is a variable star, since the changes of its surface condition which follow the sunspot cycle of $11\frac{1}{2}$ years must involve some small variation in the rate of emission of light and heat (*see* SUN); but this is not analogous to any of the recognized forms of stellar variability. Novae or "new stars" might also be counted technically as variables; it is, however, no longer believed that they have anything in common with the ordinary types of variables, and we shall not include them here. (*See* NOVA.)

**Eclipsing Variables.**—In this type of variation there is no physical change in the star. It emits light steadily all the time, but it is occulted at times by another body passing in front of it. The present explanation dates from 1782, when John Goodricke, having discovered the regular period of fluctuation ($2^d\ 20^h\ 49^m$) of the variable star Algol, suggested that the periodic dimming was caused by a dark body revolving round it and eclipsing it once a revolution. Knowing, as we now do, that there are multitudes of close binary systems, it is only to be expected that we should sometimes observe an eclipse of one component by the other. Each system will provide regularly recurring eclipses for observers situated sufficiently near the plane of the orbit; the eclipsing variables are therefore ordinary binaries whose orbits we happen to be viewing nearly edge on. For Algol and many other variables of this class it has been verified that the object is a binary system, and that the decline of light occurs when the principal star is in the part of its orbit most remote from us, which is the time when the second component would intervene.

It is not necessary to assume that the intervening object is a dark body. Even if the system consisted of two equal stars a total eclipse of one by the other would halve the light received. In most systems that have been studied, one component is considerably brighter than the other, but the light of the second component is quite recognizable. Half a period after the main eclipse, when the faint star occults the brighter, a secondary eclipse is observed owing to the bright star occulting the fainter. There is, of course, a considerable period when no eclipse is occurring and the system shines steadily with its maximum light. (By this feature eclipsing variables are easily distinguished from all other types.) The steadiness in these intervals is, however, only approximate, and is complicated by two phenomena of singular interest:

(1) *Reflection Effect.*—Systems in which the two stars are very close together have the best chance of showing eclipses, since the orbit does not then need to be so accurately orientated with respect to our terrestrial post of observation. The closeness of some of the best-known eclipsing variables is remarkable, the components being separated by no more than their own diameter. Each is therefore strongly illuminated by the other, and the hemisphere turned toward the companion becomes heated and shines more brightly than the other hemisphere. For the fainter star in particular, the disparity in brightness of the two hemispheres is considerable, and as it moves round its orbit it exhibits variations of brightness analogous to the phases of the moon. Owing to this reflection effect, the end of the principal eclipse is followed by a gradual brightening, which continues until the dip representing the secondary eclipse begins.

(2) *Ellipsoidal Effect.*—Owing to their close proximity the two stars are distorted, being elongated toward one another. Thus, in addition to the variation due to eclipses and reflection, there will be a variation depending on the aspect of these elongated objects. Their apparent sections will be smallest when we see them end-on near the time of the eclipses; halfway between eclipses we see the prolate spheroids broadside-on and correspondingly brighter.

We may hope ultimately to learn much as to the physical state of the stars from these two effects; but, unfortunately, they are only just within our range of detection, and it is difficult to obtain accurate measurements of their amount. Meanwhile, an examination of the light-curve during the eclipses teaches us much about the dimensions of the system. The method of analysing the light-curves was developed by H. N. Russell and H. Shapley; for an example of the results obtainable *see* ALGOL. As a rule the fainter component is found to have the larger diameter although it has the smaller mass; *i.e.*, the companion is one of the giant diffuse stars of fairly low density and surface temperature. The eclipses are usually partial, but are in a few stars total or annular. The number of eclipsing variables known at present is about 200.

**Cepheid Variables.**—Like the preceding class the Cepheid variables have short periods seldom exceeding 20 days, but the cause of the variation is entirely different. A very significant fact is that the colour of the light (or the spectrum) is different at maximum and minimum light, showing that the star undergoes an actual physical change. The surface temperature is much higher at maximum than at minimum, and, in fact, the changes of brightness may be ascribed to the changes of temperature. It is probable that the Cepheid variable is a pulsating star—a globe which swells and contracts with a regular period. Leaving aside the question as to how the star comes to be in this oscillating state, the pulsation theory agrees with the main phenomena. The alternate compression and rarefaction naturally produces the

changes of temperature; moreover, the approach and recession, as the part of the surface presented toward us heaves up and down, is observed and measured spectroscopically. The most striking confirmation is the agreement of the theoretical period of such a pulsation with the observed period. The natural free period of a pulsation of a spherical mass of gas should vary approximately as the inverse square root of the density, and the observations show that the Cepheids closely follow this law; moreover, the absolute value of the period can be calculated (with a small margin of uncertainty due to our ignorance of the chemical constitution of the star's interior) and the observed period is found to agree. On the other hand, no satisfactory theoretical explanation has yet been given of the phase-relation between the velocity-curve and light-curve. The mathematical theory of a pulsating star seems to show that maximum brightness must occur at the moment of greatest compression, whereas in all the more typical Cepheids it is found to occur a quarter-period later.

The study of Cepheid variables is likely to lead to results of the greatest importance, since they give the opportunity of observing stellar matter in motion, thereby extending the information obtainable from the ordinary static stars. They are important also for another reason. In 1912 it was noted by Miss Leavitt that, when the periods and apparent magnitudes of the variables in the Lesser Magellanic Cloud were plotted as abscissae and ordinates, the points lay on a smooth curve. Since the stars in the Cloud must all be at approximately the same distance from us, this indicates that the absolute brightness is a definite function of the period. H. Shapley subsequently found the same uniformity in a number of globular clusters. The same period-magnitude curve is repeated in each cluster, except that the curve is displaced as a whole towards fainter or brighter (apparent) magnitude, according as the cluster is remote or near. It follows that Cepheids of the same period have the same absolute luminosity, and presumably are alike in all respects. The absolute brightness being identical, the apparent brightness indicates the distance; *e.g.*, if the apparent magnitude of the Cepheids of 5-day period in a particular globular cluster is 13 we know at once that the cluster is 100 times as distant as a Cepheid of apparent magnitude 3; if the 5-day Cepheids observed in a spiral nebula have apparent magnitude 18, the nebula is ten times more remote than the cluster. Thus the general structure of the universe can be plotted out to scale. The scale is made absolute by a study of the brighter and nearer Cepheids which are not beyond the range of ordinary methods of distance determination. The Cepheids are stars of high intrinsic luminosity, which are visible at great distances; practically all our knowledge of the distances of the more remote objects of the sidereal universes has grown up from the study of these stars. The only caution required in using these variables as standard lights for gauging distance is that we must have evidence whether their light has been dimmed by passing through absorbing matter. It is known that the interstellar spaces contain extremely diffuse matter in the form of atoms, molecules and particles of dust, which causes both a dimming and a reddening of the light from distant objects. This matter is concentrated near the plane of the Milky Way, but is not uniformly distributed. Allowance can be made for the average effect of the dimming produced by it, but there is necessarily some uncertainty in the individual distances derived for remote objects in the Milky Way regions.

No theoretical basis for the period-magnitude relation has yet been found. Since the period (as already explained) depends on the density and the absolute magnitude depends mainly on the mass, it would seem that for a star of given mass there is just one stage in the course of its contraction when it becomes unstable and is thrown into pulsation; at other times it burns steadily. The theoretical conditions for starting and maintaining a pulsation are bound up with the laws of liberation of sub-atomic energy in the interior of the star (*see* STELLAR CONSTITUTION AND EVOLUTION; COSMOGONY). It seems likely that ordinary stars may be near the border line between stability and pulsation, and that some small change in the physical constants of the material occurring when a particular temperature or density is reached puts the star over the borderline.

The typical Cepheid variable which has given its name to the class is $\delta$ Cephei. Its period is 5.366 days. It is seven magnitudes brighter than the sun, and is believed to have about nine times the sun's mass. It is a giant diffuse star having a radius of 20 million kilometres, which changes by $\pm 1\frac{1}{4}$ million kilometres in the course of the pulsation. The light-range is 0.6 mag. visual and 1.0 mag. photographic, the difference being due to the fact that the light becomes much bluer at maximum brightness. The "cluster variables" are a subclass of the Cepheids; they have very short periods usually about 12 hours. The shortest period known is 3.22 hours.

**Long Period Variables.**—There are very few variable stars with periods between 30 and 100 days, but beyond 100 days and especially near 300 days they become numerous again. The numbers within given limits of period are:

| Days . . | 100–200 | 200–300 | 300–400 | 400–500 | 500 |
|---|---|---|---|---|---|
| Stars . . | 64 | 194 | 182 | 54 | 12 |

The leading characteristics of these long-period variables are: (1) their light-range is very great averaging 5.5 magnitudes, and in a few stars exceeding 8 magnitudes; (2) the variations do not repeat themselves with the clocklike precision of the other classes of variables, and both the amplitude and period fluctuate irregularly; (3) they are red stars, chiefly of type M, but sometimes of the rarer spectral types R, N, S; during the great outburst of light at maximum, bright emission lines of hydrogen appear in the spectrum.

The enormous variation of light is rather misleading to us, because there is no such large variation in the output of heat. The surface-temperature is varying through a range which happens to be especially critical for the sensitiveness of the human eye. The following results relate to Mira Ceti which is the most famous star of this type (discovered by Fabricius about 1596). To the eye at minimum it appears as a faint star of magnitude 9, difficult to distinguish from the numerous other ninth magnitude stars in the field; but the more impartial bolometer, which measures the total radiant energy or heat received, singles it out as a very conspicuous object of bolometric magnitude 1.5. At maximum the surface temperature has risen a little, causing a moderate increase of radiation and bringing it up to bolometric magnitude 0.2; at the same time the character of the radiation becomes more suited to the sensitiveness of the eye, so that an enormous increase of visual brightness occurs. At maximum Mira is generally between mag. 3 and 4 (visual), and occasionally it reaches mag. 2. Accordingly the variation of heat output is not much more than one magnitude, and is much the same as in the Cepheid variables. It is now generally believed that the long-period variables are pulsating stars not essentially different from the Cepheids. They are very diffuse stars of great bulk, and this extreme physical condition is probably responsible for the differences of behaviour between them and the typical Cepheids. Pease has measured the angular diameter of Mira, obtaining the result 0″.056. It is probable that the star has a radius of at least 1.5 astronomical units or 300 times the radius of the sun.

A number of minor classes of variables are recognized, which differ in material respects from the three chief classes here described. The whole subject of variable stars is now one of the most active branches of stellar research.

## STELLAR MOTIONS

We learn about the motion of a star in two ways. Firstly, the change of position in the sky can be observed directly by making from time to time accurate measurements of the position with respect to surrounding stars. The motion thus detected is called *proper motion*. It is measured in seconds of arc per year; if the distance of the star has also been measured, the result can be converted into miles per second. Secondly, by measurements of the positions of lines in the star's spectrum, the speed of approach or of recession can be found; this radial velocity is given immediately in miles per second, whether the distance of the star is known or not. The two methods supplement one another, the

first giving the motion transverse to the line of sight, and the second the motion in the line of sight; combining them we obtain the direction and speed of the whole motion.

**Proper Motions.**—The stars differ greatly in proper motion. For a naked-eye star a motion of about 3″ per century may be taken as typical. The corresponding change of position would be measurable without difficulty in an interval of ten years. For some stars the displacement is less, either because their actual speeds are small, or because their motion is mainly in our line of sight, or because they are very distant. Other things being equal, the stars which are especially near to us will have large proper motions. Just as great apparent brightness may be due to nearness or to high intrinsic luminosity, so great proper motion may be due to nearness or to high actual speed; but, in general, great proper motion is a much more dependable indication of nearness than great apparent brightness, and it is used as a criterion to pick out stars likely to have measurable parallaxes from the great majority which are too far away to be measured. Proper motions have been measured in tens of thousands; and, moreover, there are methods of quickly detecting stars of large proper motion on a pair of plates of the same region taken at a suitable interval of time (*see* BLINK MICROSCOPE).

The star of greatest proper motion known up to the present is a ninth magnitude star discovered by Barnard, which travels 10¼″ per year (more than 300 times the typical speed mentioned above). Even at this speed it would take about 900 years to go from end to end of Orion's belt. The following table gives particulars of the stars of largest proper motion:

| Star | Mag. | Ann. P.M. | Dist. (L.Y.) | Speed | | Lum. |
|---|---|---|---|---|---|---|
| | | | | Trans. | Rad. | |
| Barnard star | 9.7 | 10″.25 | 6.0 | 90 | −117 | .0004 |
| Kapteyn star | 9.2 | 8.76 | 10.3 | 131 | +242 | .002 |
| Groombridge 1830 | 6.5 | 7.05 | 32.0 | 330 | − 97 | .23 |
| Lacaille 9352 | 7.4 | 6.90 | 11.2 | 112 | + 12 | .011 |
| Cord. 32416 | 8.3 | 6.11 | 14.8 | 132 | + 26 | .009 |
| 61 Cygni | 5.6 | 5.20 | 10.9 | 82 | − 64 | .058 |

The distance in light-years is given in the fourth column; the transverse and radial speeds are given in km. per sec. in the fifth and sixth columns; the last column gives the intrinsic luminosity, the sun's luminosity being the unit. It will be noticed that these are all inconspicuous stars, faint both apparently and actually. Well-known stars which come further down the list are $\alpha$ Centauri and Arcturus, with annual proper motions 3″.66 and 2″.29 respectively. The motions cannot have caused any noticeable change in the appearance of the sky within historic times; but the change in, say, 250,000 years would be considerable, and it is doubtful if any of the familiar constellations except Orion would be recognizable. When the parallax is known, proper motion is converted into linear measure by the formula:

$$\text{speed} = \frac{\text{annual P.M.}}{\text{parallax}} \times 4.74 \text{ km. per second.}$$

**The Solar Motion.**—If we examine the proper motions in any small region of the sky, it is at once evident that they are not directed at random; an average motion in a certain direction is plainly shown. Comparing different regions of the sky and allowing for the different aspects of projection, it is found that the stars in the mean are moving in a direction toward the southern constellation Columba, not far from the south part of Canis Major. The same average motion is also shown by the spectroscopic radial velocities; *i.e.*, the stars in the Columba region have an average motion away from us, whilst those in the opposite part of the sky have an average motion towards us. The effect is so pronounced that a dozen stars taken at random will be sufficient to show the prevailing direction roughly (the first determination by Sir William Herschel was made from seven stars only); but in attempts to fix this important direction as accurately as possible many thousands of stars have been used.

In measuring proper motion, or radial velocity, our standard of reference is the sun; and the foregoing result shows that the stars in the mean are travelling past the sun in the direction toward Columba. This, however, is rather an egocentric way of expressing the facts. It is more natural to say that the sun is travelling relatively to the mean of the stars in the opposite direction—toward a point in Hercules or Lyra not far from the bright star Vega. This point is called the *solar apex,* and the relative velocity that is found is the *solar motion.* Attempts to determine an accurate position of the solar apex are not very closely accordant. In particular, radial velocity determinations seem to give systematically a lower declination than the proper motions, and bright stars give a lower declination than the faint stars. It is now generally agreed that systematic errors in the proper motions are mainly responsible for these differences. We could scarcely expect the apex to be definite, because the "mean of the stars" is an indefinite conception. The stellar background appears to consist of interpenetrating clusters with different motions, and the relative solar motion will depend on what part of this background is sampled by our observational data. In round figures the general result is: Solar apex, R.A. 270°, dec.+30°; speed 20 km. per sec.

In measuring the parallaxes of stars we use the diameter of the earth's orbit as base line—a length of two astronomical units. The solar motion of 20 km. per sec. transports the observer through 4.2 astronomical units per year, so that observations taken now and 50 years ago give us a base line of 210 astronomical units. With the longer base line it is possible to survey the stellar system to a distance far exceeding that attainable by parallax measurement. The method cannot be applied to individual stars because the parallactic displacement cannot be discriminated from the star's own motion; but when we are dealing with a class of stars (*e.g.*, stars of 9th magnitude, bright stars of type K, long-period variables, etc.) which are not likely to have any important common tendency of motion as compared with the general mean of the stars, the method will give the average parallax of the class. Fortunately, results obtained in this way can be checked by an independent determination based on similar principles. The *cross* proper motion, or component at right angles to the line towards the solar apex, is a component of the individual motion of the star; the radial velocity (after correcting for the known solar motion) is also a component of individual velocity. Hence, for a class of stars we can find the average value of a component of individual velocity both in arc and in linear measure; comparing the two results we deduce the mean distance. These methods have proved extremely useful in supplementing the meagre knowledge of the distances and absolute luminosities of the stars furnished by direct parallax determinations. For still greater distances the method described under *Cepheid Variables* and analogous methods are employed.

**Moving Clusters.**—A number of groups of stars have been recognized which share a common proper motion, and evidently form a connected system. We must assume that they have a common origin, *i.e.*, are evolved from the same nebulous condensation. Apparently, having started to move together, they continue to move together simply because encounters which might deflect them are extremely rare. One of the arguments against the existence of great numbers of dark stars in space, is that their passage between the stars of the moving cluster would break it up too rapidly. There is a typical moving cluster in Taurus, studied by L. Boss, which includes many of the stars in the Hyades. The true motions of these stars must be very nearly equal and parallel, otherwise the cluster would rapidly disperse, but as projected on the sky they appear to converge toward one point. As the cluster covers a reasonably large area the convergent point can be found with considerable accuracy. By geometrical construction it becomes possible (without parallax measurement) to determine the distance of each star of the group and to find the precise arrangement of the stars in three dimensions. Another cluster consists of five stars of the Plough together with Sirius and some other bright stars; the sun is in the middle of this moving cluster, so that its members appear in different parts of the sky. The stars of type B seem to have a special tendency to form associations of this kind; one of the best marked groups consists of about 16 stars in Perseus and neighbouring constellations. Perhaps the most im-

portant conclusion to be drawn from these clusters is that the stars are not born individually and independently, *e.g.*, by accidental collisions of extinct stars, but that the evolutionary process of star formation is capable of generating a number of stars simultaneously.

**The Two Star Streams.**—Eliminating the recognized moving clusters, we are left with the general body of the stars whose motions have no obvious association with one another. It is found on examination, however, that their motions are not at random. In 1904 J. C. Kapteyn showed that the proper motions show a decided preference for two favoured directions, apparently implying that the stars around us do not constitute a single system but a dual one. The observed motion of the stars in the mean towards the solar antapex is due to the intermingling of two systems moving in very different directions. These two streams are found to prevail in every part of the sky examined; they are shown both in the proper motions and in the radial velocities. It is not likely that the same stream motion extends throughout the galactic system, but up to the present no limit has been found. Originally discovered in the motions of the bright stars, the phenomenon is found to be essentially the same in stars as faint as mag. 11.5, and there is evidence of its occurrence in much fainter stars. The following determinations of the apices and relative speeds of the two streams refer respectively to the bright stars of Boss's catalogue (Eddington) and the Cambridge photographic proper motions of faint stars (Smart). The speed is expressed in terms of a theoretical unit which is probably about 22 km. per second.

| | Bright stars | | | Faint stars | | |
|---|---|---|---|---|---|---|
| | R.A. | Dec. | Speed | R.A. | Dec. | Speed |
| Apex of stream I . . | 91° | −14° | 1.52 | 88° | −12° | 1.50 |
| " " " II . . | 288° | −64° | 0.86 | 289° | −73° | 0.97 |
| Vertex . . . . | 94° | +12° | 1.87 | 92° | +20° | 1.84 |
| Solar apex . . . | 267° | +36° | 0.91 | 273° | +44° | 0.88 |

The first two lines give the motions of the streams relative to the sun, but greater cosmical importance must be attached to the motion of one stream relative to the other, which is given in the third line of the table. The principal difference between bright stars and faint stars lies in their distribution between the two streams. For the bright stars the numbers belonging to stream I and stream II are as 3:2, for the faint stars the numbers in the two streams are practically equal. It is partly for this reason that the declination of the solar apex increases progressively with the faintness of the stars considered; stream II is receiving more and more weight in the "mean of the stars."

If two interpenetrating streams of stars exist, moving relatively to one another in space, all that can be learned about their motions is the direction and magnitude of their *relative* motion. Schwarzschild pointed out that the observed phenomena can be explained by supposing that the stars have a greater freedom of movement in a certain direction than in other directions or, in other words, that there is a preferential direction of motion of the stars, instead of the motions being at random. The direction of preferential motion lies in the plane of the galaxy and nearly, but not exactly, in the directions toward and away from the galactic centre.

Stars of type B are aloof from the two star-streams. Their motions (relative to the mean of the stars) are smaller than those of other types, and show little systematic tendency of any kind. A number of stars of other types are associated with them and form a third stream, known as stream O. In most parts of the sky it is difficult to disentangle stream O from stream I, but in regions where the circumstances of projection are favourable the third stream always appears clearly.

**Rotation of the Galaxy.**—If the galactic system is analogous to a spiral nebula it is presumably rotating in its own plane; in any case its flattened form would lead us to suspect rotation. If the rotation were like that of a rigid body the radial velocities, as viewed from any point, would be unaffected; but it is more reasonable to suppose that the angular velocity diminishes outwards from the centre of the system, as with the planets in the solar system. Then, if we take a group of stars surrounding the sun, those between us and the centre will be gaining on us and those outside us will be lagging behind. This shearing motion distorts a square into a parallelogram, that is to say one diagonal is lengthening and the other diagonal is shortening; so if we observe stars in two opposite regions of the sky, corresponding to the direction of one diagonal, these should be receding from us, and along the other diagonal, 90° away, the stars should be approaching us, on the average. J. H. Oort has found that this effect is quite prominently shown in the observed radial velocities, and that the direction of the galactic centre deduced from it accords well with the direction generally accepted (deduced from the distribution of globular clusters and other classes of distant objects). Moreover, taking different classes of stars, the positions found for the centre are very accordant, and the effect increases, as it should do, proportionately to the mean distance of the class. Oort's results have been fully confirmed by J. S. Plaskett, from the analysis of his measures of the radial velocities of stars of types O and B, which are particularly suitable for the purpose, because of their high intrinsic luminosities. The rotation of the galaxy has also been investigated by using the proper motions of the stars, though this method suffers from the drawback that the greater the distance of the star, the smaller is its proper-motion.

The analysis of the radial velocities of stars at different distances gives the change of velocity throughout the region covered by the survey, but does not give the actual velocity at any point. The velocity in the neighbourhood of the sun can be found from the radial velocities of the globular clusters, which extend well beyond the centre of the galaxy. The velocity is found to be about 300 km. per sec., but is subject to a somewhat large probable error. The distance to the centre of the galaxy and the mass of the system whose gravitational attraction controls the orbital motion can be determined when reasonable assumptions about the distribution of the mass in the system are made. The distance to the centre is some 30,000 light-years, the period of rotation at this distance is about 200,000,000 years and the total mass of the system is about 160 thousand million times the mass of the sun.

It was suggested by H. H. Turner that the preferential direction of star-streaming was toward the centre of the galaxy: he pointed out that the comets of the solar system, because of the elongated shape of their orbits, have a preponderatingly radial direction of motion. Situated, as the sun is, at some distance from the centre, the directions to and from the centre appear as the favoured direction of motion. The direction of preferential motion deviates by about 22° from the direction to the galactic centre; it is doubtful to what extent this deviation is significant. B. Lindblad has suggested that a satisfactory agreement can be obtained by taking into account not merely the general gravitational effect of the system as a whole but also the local gravitational fields due to star clouds and local aggregations of stars.

**Individual Motions.**—After eliminating all systematic motion there remains the individual motion of the star itself. An interesting field of study arises from the correlation between individual speed and other characteristics, such as mass, spectral type, brightness. The earliest result of this kind was found by W. W. Campbell and J. C. Kapteyn in 1910; viz., a progressive change of mean speed with spectral type. Campbell's results for bright stars were: Type B, 6.5 km. per sec.; A, 11; F and G, 15; M, 17 km. per second. The figures refer to the radial component only, and must be doubled to give the mean speed in three dimensions. At the time it was thought that this sequence of types represented the order of evolution, so that the progression implied that the speed of the stars increases with their age; with the recognition of giant and dwarf stars this interpretation has become inadmissible. Actually type M consists of two distinct classes, viz., very diffuse stars supposed to be in an early stage of condensation from a nebula, and very dense stars supposed to be at a later stage of the evolutionary sequence; both classes have high speeds, the latter being particularly large. Generally speaking, faint stars have greater speeds than bright stars; owing to the

mass-luminosity relation this means that stars of small mass have greater speeds than massive stars. It has been suggested that there is a law of equipartion of energy so that the average value of $\frac{1}{2}mv^2$ is the same for all classes of stars; this might have a dynamical explanation, since the speeds of the molecules of a gas distribute themselves according to the same law. Up to a certain point observations agree with the equipartion law, but there are noteworthy exceptions; the massive B stars have low average speed as the law requires, but the most massive stars of all, type O, have rather large speeds. The present position is that our knowledge of the factors determining the mean speed of different kinds of stars is made up of fragmentary correlations, and has not yet led to any generally comprehensive theory.

One complicating factor is the asymmetry of high velocity stars, which was discovered by J. H. Oort and G. Strömberg. Stars with speed greater than about 80 km. per sec. are moving almost exclusively toward one hemisphere of the sky. The group as a whole is moving nearly in the galactic plane and at right angles to the direction to the centre of the system, so that it lags behind the average of the stars at the same distance from the centre by about 80 km. per sec. No stars with velocities in excess of the average by a similar amount are observed. Any such stars originally present in our local star-cloud have been lost to it because their velocities have exceeded the "velocity of escape." Stars with velocity below the velocity of escape are permanent members of the system, and describe orbits within it under its gravitational attraction; on the average, therefore, they move as much in one direction as in the opposite. Stars with velocity above that of escape cannot be permanent members; they pass once through the system and do not return; accordingly they may well show an asymmetry of motion, dropping into our local star-cloud from a cluster or clusters on one side of it, passing through it, and not returning. The value of the velocity of escape is more or less what we should expect from our general knowledge of the extent of the star-cloud and the number of stars per unit volume.

About 25 stars are known within a sphere of 4 parsecs radius surrounding the sun, *i.e.*, having parallaxes greater than 0.″25; there may be a few additional faint stars yet to be detected. Many of these near neighbours are red dwarfs with masses one-quarter or one-fifth that of the sun; on the other hand a considerable proportion are double stars (here counted as one). The total mass within the 4 parsecs sphere may be estimated at about 11 times the sun's mass. In addition to the mass of the lucid stars there may be other masses in the sphere, *e.g.*, dark stars, in addition to scattered nebulous matter of great tenuity. There is direct observational evidence, referred to at the end of this article, for the existence of a cloud of diffuse matter in interstellar space. It is extremely rarefied: one atom per cubic centimetre is the most we can possibly allow consistently with the dynamics of stellar motions. Even so, the total mass of this rarefied matter in the galactic system is comparable to the total mass of the lucid stars.

## CONSTITUTION OF THE STARS

**Density.**—When the mass and radius of a star are known, the mean density of the material can be calculated immediately. Direct determinations of the *mass* are only available for double stars; but for other stars the mass may with some confidence be inferred from the absolute magnitude by means of the mass-luminosity relation described later in this section. In any case the range of stellar masses is so restricted that errors are not likely to affect the general order of magnitude of the densities deduced. The *radius* $R$ may be calculated from the absolute luminosity and the observed surface-temperature. In this way we find that some of the red giant stars, such as Betelgeuse, Antares, Mira, have densities less than $\frac{1}{100}$ that of air; Capella has a mean density nearly equal to air; the sun, we already know, has a density 1.4× water; the faint red dwarfs have density about 10× water. For the class of stars called *white dwarfs,* which includes the companion of Sirius (*see* SIRIUS), the method gave an enormous density 60,000 times that of water; this result was at first regarded as incredible, but it is now clear that it is to be accepted literally.

For the more diffuse stars it is evidently legitimate to treat the stellar material as perfect gas. The study of stellar equilibrium thus reduces to the study of the equilibrium of a globe of perfect gas held together by its own gravitational attraction. It was thought that the simple theory must break down for stars of higher density (such as the sun) owing to the deviations from the laws of a perfect gas; but in 1924 it was found by Arthur S. Eddington that the dense stars agreed observationally with laws which had been deduced theoretically for gaseous stars. The fact is, that at the temperatures of the order of 10,000,000 degrees occurring in the stellar interior, the atoms are stripped of all their outer electrons and reduced to ions of very small dimensions; consequently the jamming of atoms against one another, which causes the breakdown of the gas laws, does not occur in the stars until far higher densities are reached. The high density found for the white dwarfs confirms this conclusion; close packing is possible because the atoms have lost their balloonlike envelopes. In all stars other than white dwarfs the material may be treated as perfect gas, except that in the stars of least mass (red dwarfs) there is a small correction arising from the electrostatic forces between the ions which makes the gas *superperfect, i.e.*, makes it deviate in the opposite direction to the deviations of *imperfect* terrestrial gases.

**Internal Temperature and Pressure.**—The distribution of temperature and density in a sphere of gas in equilibrium under its own gravitational attraction is a classical problem studied by Lane, Ritter, Emden and others. The mathematical analysis developed in these earlier researches is used in the modern theory, but three new features have been introduced. (1) It used to be supposed that the heat radiated from the star's surface into space was brought up from the interior by convection currents, but it has now become evident that it is transferred by radiation. Accordingly the stars are now assumed to be in *radiative* equilibrium instead of in *convective* equilibrium. The condition of radiative equilibrium is that each region must have settled down to a temperature at which it radiates an amount of heat equal to that which it absorbs from the radiation passing through it. One simplification resulting from this change is that we no longer need to know the ratio of specific heats of stellar material—a physical constant difficult to estimate. (2) Radiation-pressure is sufficiently great to play an important part in the equilibrium, especially of the massive stars, and it is now taken into account. (3) Formerly the average molecular weight of the stellar gas was taken to be the weight of the atoms likely to preponderate, *e.g.*, iron (at. wt. 56). It is now recognized that the atoms in the interior will be highly ionized; most of the electrons which circulate round the nucleus will have broken loose, and must be counted as independent "molecules." Taking this into account the molecular weight will be slightly over two, a result nearly independent of the chemical constitution of the star provided only that there is not an excessive proportion of hydrogen. Owing to this decrease in the adopted molecular weight, the internal temperatures are considerably lower than those calculated on the older theories.

Since it is believed that a star's heat is maintained by liberation of subatomic energy, another unknown condition enters into the problem, viz., the distribution of subatomic sources in the interior. This, however, has no very important effect on the main results of the investigation, and, by considering the extreme cases of a source wholly concentrated at the centre and a source evenly distributed through the mass, we can set limits to the uncertainty.

For the sun the central temperature is found to be of the order 20,000,000° C. The mean temperature (averaged for equal mass) is about 12,000,000°, and is less subject to uncertainty arising from ignorance of the distribution of the source of energy and other data. Moreover, all stars of the Main Series (*see* STELLAR CONSTITUTION AND EVOLUTION) have nearly the same internal temperature. The Main Series, which comprises the great majority of the stars, includes B type stars several hundred times more luminous than the sun, and red dwarfs, giving a hundredth or a thousandth of its light. It is remarkable that stars differing so widely in mass, in output of heat and light, and in surface

temperature, should be so uniform in internal temperature. The giant stars have lower internal temperature, *e.g.*, Capella, which is of the same spectral type as the sun but has only $\frac{1}{600}$ of its density, has a central temperature 6,000,000°.

The temperature gradient from the centre to the surface causes a flow of heat outwards, which is hindered by the opacity of the stellar material; hence, knowing the temperature distribution in the interior, and having observed the total outflow of heat from the star (*i.e.*, its luminosity reduced to heat units) we can compute the opacity. This astronomical opacity may be compared with the theoretical opacity for material of the density and temperature concerned, as calculated from the modern theory of the atom. The astronomical opacity is very sensitive to the assumed proportion of hydrogen in the star but, when this is given, the composition of the rest of the material makes very little difference. The luminosity of a star with the mass of the sun can range over seven magnitudes according to the proportion of hydrogen which it contains. Comparison between the astronomical opacity and the theoretical opacity consequently enables the proportion of hydrogen in the star to be estimated. For several stars for which first-class observational data are available, it is found that about one-third part by weight of each star consists of hydrogen. There is some evidence that the most massive stars contain a larger proportion of hydrogen.

**The Mass-luminosity Relation.**—Having calculated the temperature distribution in the star by the condition of radiative equilibrium, we find the following formula for the total outflow of heat $L$ (in ergs per second):

$$L=4\pi cGM(1-\beta)/k,$$

where $c$ is the velocity of light, $G$ the constant of gravitation, $M$ the mass of the star (in grams); $k$ the coefficient of opacity, and $1-\beta$ the ratio of radiation pressure to the whole pressure, obtained by solving the quartic equation,

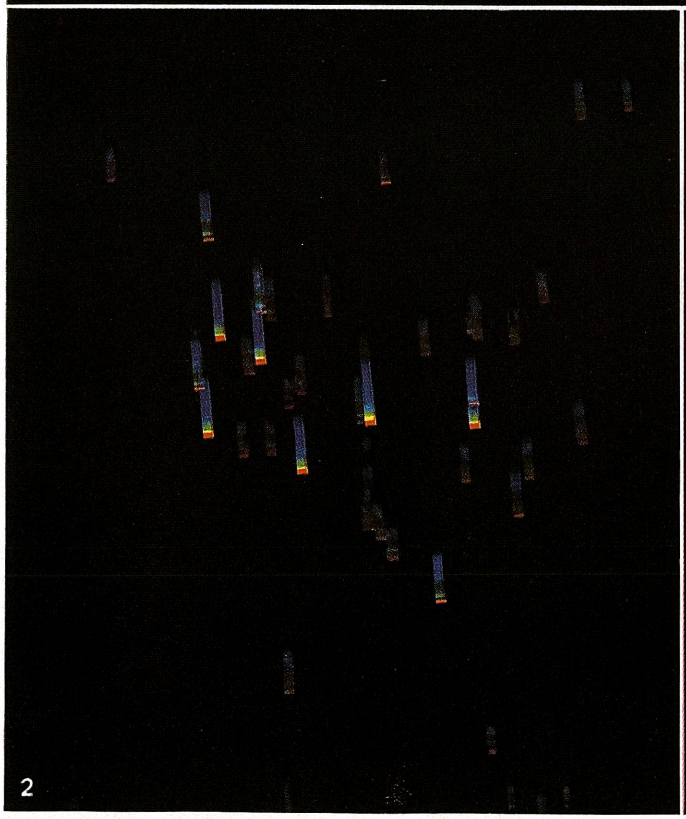
$$1-\beta=0.0031M^2\mu^4\beta^4,$$

where $M$ is now expressed in terms of the sun's mass, and $\mu$ is the average molecular weight in terms of the hydrogen atomic weight. Knowing $L$ and $M$ for any star we can calculate $k$; for example in Capella we find $k=120$ C.G.S. units. This means that a screen containing $\frac{1}{120}$ gram. per sq.cm. (equivalent to about 6 cm. of air) would stop about two-thirds of the radiation passing through it. At first sight this is a surprisingly high opacity. The old problem as to how the heat is brought up from the interior of a star to replace that radiated from the surface, has completely changed; we see rather that the star has to be constructed of highly opaque material in order to hold back the internal heat and permit it to come to the surface no faster than it does. The high opacity is, however, not so surprising when we realize that at 10,000,000 degrees the radiation in the interior consists of X-rays chiefly of wave length 2 to 6 Ångstroms, which are highly absorbed in a few millimetres of air. In fact the stellar opacity is less than the observed opacity in the laboratory—a fact explained by the high ionization of the stellar atoms, which throws a great part of their absorbing mechanism out of order.

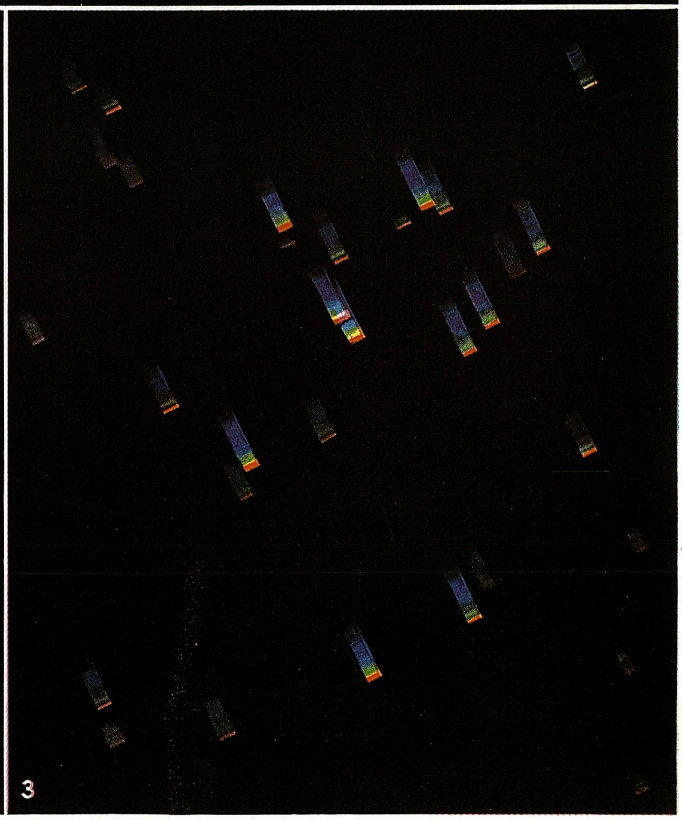
According to modern theories of X-ray absorption, the coefficient of opacity should (approximately) be proportional to the density and inversely proportional to the $\frac{7}{2}$ power of the temperature ($k\propto\rho/T^{\frac{7}{2}}$). By the use of this law we can eliminate $k$ from the equation given above and obtain the relation between $L$ and $M$. The density of the star nearly disappears from this relation, so that the total radiation or absolute bolometric magnitude of a star is a function of the mass and molecular weight only, apart from a trivial correction dependent on the density, which can be calculated and applied when the spectral type is known. This predicted relation between $L$ and $M$ can be plotted as a graph; it is called the mass-luminosity relation. It appears to be well confirmed by all the observational data available; but it must be remembered that accurately determined masses are rare, so that the test is not so complete as we should desire. The mass-luminosity relation cannot conveniently be expressed by an algebraic formula, but as a rough guide it may be stated that the heat outflow from a star varies as the third or fourth power of the mass in the most important part of the range.

These results are mainly independent of the assumed chemical constitution of the stars, owing to the fact that the average molecular weight for all elements except the lightest turns out to be nearly 2 when account is taken of ionization; but for stars composed mainly of hydrogen the mass-luminosity relation would be greatly altered. It may be inferred, therefore, that stars of the same mass do not differ widely in their hydrogen content.

It is interesting that we should be able to learn anything at all about the chemical composition of the inaccessible interior; but the fact has also a definite bearing on theories of the source of a star's heat. It is probable that the store of energy needed to maintain the star for thousands of millions of years is provided by the evolution of higher elements from hydrogen. (Hydrogen, which consists merely of protons and electrons, is perhaps best regarded as *unformed matter*.) By cutting down the admissible proportion of hydrogen to, say, 10%, we reduce the supply from this source to one-tenth, and it becomes very doubtful whether it will suffice. Secondly, if we admit that 90% of the star must consist of "formed" matter, we must suppose that the main process of formation of matter occurs in a prestellar stage. Evolution of the elements is, therefore, in the main a low temperature process and, perhaps still more surprisingly, a low density process.



**Radiation-pressure.**—At any point in a star, gas-pressure and radiation-pressure together support the weight of the layers above. The proportion supported by radiation-pressure ($1-\beta$) is found by a quartic equation already given. To a first approximation it is the same in all parts of the interior, and is independent of the star's density; the molecular weight being given, it depends only on the star's mass. It is remarkable that for stellar masses there is no great disparity between radiation-pressure and gas-pressure, whereas for masses of a different order $1-\beta$ would begin .00.... or .99.... It seems clear that the condition of rough equality of the two pressures has in some way determined the size of the aggregations of the primitive matter of the universe. The simplest view is to suppose that, when radiation pressure amounts to say one-tenth of the whole pressure, it renders the aggregation of further material more difficult or makes the mass more liable to break up. Hence larger masses are more and more rare. Gravitation by drawing together the primitive nebulous material will, in general, build up masses to a size at which radiation pressure first begins to offer serious opposition to further increase.



## STELLAR SPECTRA

We deal rather briefly with this branch of the subject since some of the more interesting developments are treated under ASTROPHYSICS; STELLAR CONSTITUTION AND EVOLUTION; SUN. By the appearance of their spectra (*see* SPECTROSCOPY) stars are arranged in a sequence of types O, B, A, F, G, K, M. This turns out to be the order of decreasing surface temperature. The "effective" surface temperatures of stars are calculated by Planck's law of radiation (for theory, *see* RADIATION, RAYS) from the relative intensity of the continuous spectrum for different wave-lengths; the higher the temperature the more the region of maximum intensity is displaced to the violet. For the sun this method of finding the equivalent black-body temperature is checked by calculating also the temperature corresponding to the absolute intensity of its radiation; so presumably it will apply to other stars, although we have not usually any direct check. Good indirect confirmation of these temperatures has been afforded by studying the spectral indications of ionization of the elements. (*See* below.) The following temperature scale is a combination from various sources; the results are in degrees absolute.

| Type | Temperature | Type | Temperature |
|---|---|---|---|
| | ° | | ° |
| Bo | 20,000 | Go | 5,500 |
| B5 | 15,000 | G5 | 4,700 |
| Ao | 11,000 | Ko | 4,000 |
| A5 | 8,500 | K5 | 3,300 |
| Fo | 7,500 | Mo | 3,000 |
| F5 | 6,500 | | |

PHOTOGRAPHS BY J. J. NASSAU AND C. K. SEYFERT

## KODACHROME PHOTOGRAPHS OF THE HEAVENS

1. Shows the great nebula in Orion, a cloud of dust and gas at least 10 light years in diameter and at a distance of 600 light years. The ultra violet radiation from several very hot (blue) stars embedded in the gas causes the nebula to shine. Most of the stars in this region of the sky are blue (exposure 1 hour)
2. Objective prism spectra of the bright stars in the Pleiades cluster (exposure 15 minutes)
3. Spectra of the brighter stars in the Hyades cluster (exposure 1 hour).

These photographs were obtained with the 24-in. Schmidt-type telescope at the Warner and Swasey observatory of the Case School of Applied Science, Cleveland, Ohio. (2) and (3) were made by placing a 4° prism, 24 in. in diameter, in front of the objective lens of the telescope. The light of each star is dispersed into its component colours, producing a spectrum. The hottest stars have a greater percentage of their light in the violet part of the spectrum whereas the cooler stars have most of their light in the red region

This refers to giant stars; dwarf stars of the same type are about 500° hotter. The radiating power of the surface in heat units is proportional to the fourth power of the temperature.

In all the later types the stars fall into two groups, the *giant* or diffuse stars, and the *dwarf* or dense stars. They are most widely distinct in type M, and converge to coalescence in types A and B. If, instead of arranging the stars in order of surface temperature, we put them in order of increasing density, we must start with the giants of type M, follow the giant branch through K, G, F until it coalesces with the dwarf branch in types A and B, and then continue along the dwarf branch in the reverse order A, F, G, K, M. It seemed natural to suppose that the order of increasing density is that of evolution.

Following this supposed order of evolution, the temperature of the surface starts very low, increases to a maximum, and then decreases again, the giant stage being one of ascending temperature, and the dwarf stage of descending temperature. This fact has probably no great significance, since the surface temperature does not correspond at all closely to the internal temperature. It is more important to note that the mass (corresponding closely with the luminosity) is nearly steady in the giant sequence, perhaps decreasing slightly, and then diminishes rapidly as we pass down the dwarf sequence. It seems impossible to retain this idea of stellar evolution without admitting that the mass of a star must decrease substantially during its lifetime. Radiation is the principal cause of loss of mass by a star, and hence it would follow that a large part of the mass of a star is convertible into radiation—in short, matter must disappear, its energy of constitution being released as aether waves. Admitting this source of energy, the age of the stars is of the order of a billion ($10^{12}$) years or more. But there is strong evidence against so long a life and in support of a much shorter age of several thousand million years. A large part of the mass of the star could be converted into radiation only if the actual annihilation of matter, by the combination of protons with electrons to produce radiation, were to occur within the star. This would require, however, a temperature very much higher than is found within any star. According to views current in 1945, the main source of stellar energy is provided by the building up of atoms of helium from atoms of hydrogen. In this process, not more than 1% of the mass of the star would be lost. Up to 1945 no plausible theory of the course of stellar evolution had been expounded.

After the first use of spectroscopy to identify chemical elements in the atmosphere of a star, the most important advance was the discrimination of "enhanced lines," *i.e.*, lines strengthened in the spark spectrum as compared with the arc. Much of the early progress in this direction was due to J. N. Lockyer and A. Fowler. In general, enhanced lines are those due to the atom with one electron missing (singly ionized atoms), the arc lines being due to neutral atoms. The spectra of all the important elements have now been unravelled, and we can say at once which lines belong to neutral atoms, which to singly ionized, which to doubly ionized atoms, etc. Thus it is found that in some stars the atoms of calcium in a position to form an absorption spectrum are neutral, in others they are singly ionized, in others doubly ionized. Clearly this is a clue to the physical conditions in the outer layers of a star. The modern thermodynamical theory of ionization was brought to bear on the astronomical observations by M. N. Saha in 1920, and has dominated all later progress. The degree of ionization depends on both the temperature and pressure, the former representing the factor which causes the breaking away of electrons and the latter the factor which determines their opportunity of recombining. By connecting together the data for different elements and controlling the results by reference to other methods of determining stellar temperatures, much information has been obtained as to the temperature and pressure in the reversing layer. In particular it is found that the pressure is generally between $10^{-3}$ and $10^{-4}$ atmospheres—much lower than used to be supposed.

**Spectroscopic Parallaxes.**—Since the nature of the spectrum shown by a star is conditioned both by the temperature and pressure of the reversing layer, a complete classification of spectra should be two-dimensional. Ordinarily we recognize only a linear series—the Draper sequence of types considered above; but by attention to detail we can recognize also a classification transverse to this. Taking the Draper sequence to correspond roughly to temperature, the transverse classification will correspond to pressure. Since low pressure favours ionization, it will be marked in the spectrum by great strength of the enhanced lines relatively to the arc lines. The giant and dwarf stars of the same spectral type can easily be distinguished from one another by this method; the reversing-layer pressure is low in the giant stars owing to the small value of gravity at the surface.

It was early recognized by E. Hertzsprung that those spectra marked by Miss Maury as having the "*c*-characteristic" belong exclusively to the giant stars. This characteristic is an unusual fineness of the lines—a feature which also results from low pressure. More precise criteria were found by Adams and Kohlschütter in 1914; and the method has been developed by Adams into a means, not only of distinguishing giant and dwarf stars, but of determining quantitatively the absolute luminosities of stars. At present the procedure is empirical; the curve connecting absolute magnitude with differential intensity of certain selected pairs of spectral lines is deduced from and tested by stars of known trigonometrical parallax; it is then applied to find the absolute magnitudes and hence the distances of other stars. Parallaxes of some thousands of stars determined in this way have been announced, and are known as spectroscopic parallaxes. The underlying principle of the method may be summarized as follows: Stars may differ in mass, and stars of the same mass may differ in density; but, when the mass and density are given, no other important difference can occur, and the luminosity, surface temperature and pressure in the reversing layer should be uniquely determined; hence the spectrum should be determinate. Conversely, a sufficiently close examination of the spectrum (its position both in the Draper sequence and in the classification transverse to it) should fix the mass and density of the star, and hence its other physical properties, including luminosity. Ideally the deduction of luminosity might be made theoretically, but in any case the connection between luminosity and spectrum can be observed experimentally and formulated as an empirical law.

**The Interstellar Gas.**—In certain spectroscopic double stars the phenomenon of "stationary calcium lines" is observed. Whereas the other spectral lines shift to and fro as the star approaches and recedes in its orbit, the H and K lines of ionized calcium remain stationary. It is clear that somewhere between us and the star's photosphere there must be an absorbing cloud of calcium vapour which does not follow the star in its orbit. The phenomenon was first pointed out by Hartmann in 1904 for the star $\delta$ Orionis. Later Miss Heger discovered that the D lines containing sodium also remain fixed in $\delta$ Orionis. The same behaviour has now been observed in a large number of stars. In recent years, T. H. Dunham and W. S. Adams have found stationary lines of potassium, titanium, iron and neutral calcium, as well as of the molecules of CH and CN, in the spectra of a number of stars. The important question to decide is whether the cloud belongs to the double star or whether it is a continuous cloud filling interstellar space. J. S. Plaskett has shown that the latter alternative is correct; the motion of the calcium cloud is often different from that of the centre of mass of the star. After removing the solar motion the velocity of the cloud relative to the mean of the stars is found to be small. Just as there are lines in the solar spectrum which do not share in the sun's rotation and are accordingly to be attributed to absorption during the passage of the light through the earth's atmosphere, so we have stationary lines of elements which do not share in the orbital or individual motion of the star and are to be attributed to absorption in an interstellar "atmosphere." In the spectra of some stars the stationary lines are double or consist of three or four components, giving evidence of the absorption of the starlight by two or more interstellar clouds, which are in motion relatively to one another. The stationary lines are extremely sharp, which often enables them to be distinguished from the ordinary lines in the spectrum: this sharpness is the consequence of the extremely low density of the

interstellar gas, which is so tenuous that the starlight must pass through a very great length of it to produce an absorption line of sufficient strength to be detected. The fixed lines appear most conspicuously in the spectra of the hottest stars because these stars are highly luminous and are consequently observed at a great distance; the cooler stars, moreover, have strong calcium and other metallic lines of their own, which mask the lines of the cloud. The absorption occurs along the whole track of the light, and though the absorption is not necessarily uniform along the track (as evidenced by double or multiple components) there is a strong correlation between the strength of the lines and the distance of the star.

It is probable that many common elements, in addition to those which have been detected, are present in the interstellar gas; but the gas is so extremely rarefied that only the most abundant elements and compounds can be detected. Many elements must also evade discovery, even though they may be very abundant, because their atoms, when in their state of lowest energy as they must be in the interstellar gas, are indifferent to visible light. Thus, for instance, hydrogen has never been detected in interstellar space by its spectral lines; the detection of molecules of CH prove it to be present, and for other reasons it is known to outstrip by far all other elements in abundance.

In order to avoid a huge mass of the stellar system inconsistent with the observed velocities of the stars, it must be postulated that this interstellar cloud is of very low density. About one atom per cubic centimetre is the maximum that can be allowed. It is calculated that matter so diffuse as this would take up a high temperature not much lower than the photospheric temperatures of the stars, although a black-body in interstellar space would sink to a temperature of 3° absolute. The density is too small to give any appreciable scattering or absorption of light in space other than the special line-absorption of calcium and sodium light. The dimming and reddening of distant objects is caused by interstellar dust; a small quantity of dust can cause appreciable obscuration and the interstellar dust forms but a small fraction of the total mass of the interstellar matter.

**STAR APPLE** (*Chrysophyllum cainito*), an evergreen tree of the family Sapotaceae (*q.v.*), called also cainito, native to tropical America and cultivated for its edible fruit. The pleasantly flavoured fruit, 2 to 4 in. across, is apple-shaped. In a cross-section of the unripe fruit the seed-bearing cells form a star.

**STARAYA RUSSA,** a town of the Russian S.F.S.R. in the Leningrad region, in 58° N., 31° 22′ E., on the river Polista, by means of which and Lake Ilmen it is brought into steamer communication with Leningrad. Pop. 21,511. Brine springs on the east of the town were used as a source for the supply of salt as late as 1865; afterward they were used only as mineral waters (temperature 51°–54° F.), having a great resemblance to those of Kreuznach in Germany. Some thousands of visitors were accustomed to resort to them every summer, and owing to this circumstance Staraya Russa was better built and better kept than any other town in the government of Novgorod. The inhabitants are supported chiefly by the summer visitors. There is a trade in rye, oats and flax. Staraya Russa belonged to the republic of Novgorod, and suffered in the wars between Russia, Lithuania and Livonia. It was afterwards annexed to Moscow.

**STARA ZAGORA,** the capital of a department of southern Bulgaria lying on the southern slope of the Karaja Dagh, 70 mi. N.W. of Adrianople, with which it is connected by railway. Population (1934), 29,857. The city is surrounded by vineyards, and has flour mills, breweries, brandy distilleries, copper foundries and tanneries. The production of silk and attar of roses is carried on in the district, which contains numerous mineral springs, and there is a trade in corn and wine. It is the junction of the trans-Balkan and Burgas-Philippopolis railway lines. It was destroyed during the Russo-Turkish War (1877–78) and rebuilt on modern lines. During the rebuilding, important Thracian, Roman, Byzantine and Turkish antiquities were discovered.

Stara Zagora, founded probably by the Thracians, was known to the Romans as Augusta Traiana, but afterward, to distinguish it from a Macedonian town of this name, it was named Beroe or Berrhoea. By the Turks the name was changed in the 17th century to Eski-Zagra or Eski-Zaara, whence its Bulgarian name.

**STARCH.** This is perhaps the most widely distributed substance in the vegetable kingdom and occurs, often in great abundance, in almost every plant. Pure starch has the appearance of a white, glistening, friable powder, and possesses a harsh feel when rubbed between the fingers; it is tasteless, has no smell, is not soluble in cold water and undergoes no change when exposed to the air. When examined under the microscope it is found to consist of granules of definite shape, size and appearance. These show very wide variations, some being minute while others attain a comparatively large size; they are, nevertheless, quite characteristic of the plant from whence they are obtained, and the identification of any particular starch by comparison with those of known origin is a more or less simple matter. Granules or cells which are usually oval in shape are found to be composed of a series of concentric layers arranged around a nucleus or hilum which appears as a dark spot, the outer layers being the oldest in point of growth.

Starch belongs to the group of carbohydrates in which are included the sugars, gums and cellulose, and is composed of the elements carbon, hydrogen and oxygen. Its constitution is very complex, but it is built up in the plant from two simple compounds, water and the carbon dioxide gas present in the atmosphere, through the agency of the green colouring matter, chlorophyll, under the activating influence of sunlight. The rôle of starch in plant economy is that of a reserve material, and as such it must be transferred from the leaves and other green parts of the plant, where it is formed, to more permanent quarters. To facilitate this migration it is broken down into sugars which dissolve in the cell juice, in this way passing through the cell walls of the plant finally to become reconverted into starch, either in the fruit or seeds, or in the bulbs and tubers as the case may be. It is thus rendered available as a source of sustenance for the young plant until it is sufficiently advanced to carry on the process of starch formation itself. Starch as it occurs in the granular packages visible under the microscope, is not present as simple molecules of the empirical formula $(C_6H_{10}O_5)_n$, but probably *as sheaves or groups of molecules of varying density of packing,* the individual molecules being associated together by secondary valence forces. Starch is a highly organized or "associated" substance. When heated with water it forms a paste, the physical characteristics of the resulting paste being different for each type of starch. Aside from the differences in these pastes due to the variety of starch grains, the properties are further modified by mechanical and chemical action. When starch is heated in plain water, it takes on water and hydrates. The granular packages first swell and then rupture to form a paste. The body and consistency of the pastes will vary greatly, depending on the severity and intensity of the cooking and agitating treatments. These modifications are due mainly to mechanical means—that is, merely tearing the granules without materially altering the chemical structure. In the presence of chemicals, however, particularly acids and enzymes, the molecule itself is degenerated, the products formed representing a breakdown of the original molecule. The type of starch degeneration product formed in the presence of these chemicals and the extent to which the original molecules are degenerated will depend on the nature of the chemical substance, concentration, temperature, etc. In this manner are made the thin boiling (low viscosity) starches, dextrins, syrups and sugars. This process is employed in the manufacture of corn or glucose syrups, used extensively in confectionery, and of glucose sugar used in

brewing. Hydrolytic degeneration is also effected by certain natural ferments or "enzymes" such as those in saliva, pancreatic juice, malted grain (diastase)—all germinated seeds, and it is the latter agent which is employed in the fermentation industries—brewing, distilling, etc.—converting starch in the materials used into material capable of fermentation by yeast.

Development of starch in the growing plant already referred to, and the rebuilding of the soluble products into the cellulose which constitutes the tissues, is carried out by ferments or enzymes elaborated by the plant itself, while a similar process goes on in the human system when starchy foods are eaten and converted into soluble sugars capable of assimilation.

Dry starch heated to upwards of 320° F. is transformed into dextrin, a pale, yellowish powder soluble in water, known as British gum. Dextrins of lighter colour are also made by spraying with aqueous acids and heating to lower temperatures.

A very sensitive reaction of starch is the production of an intense blue coloration with a solution of aqueous iodine, a characteristic much used in its identification. The average starch content of the principal starch yielding plants, together with the temperatures at which the purified starch gelatinizes when heated with water, are, according to Lippmann, as in the following table:

| | *Average Starch content %* | *Gelatinizing temp.° F* | | *Average Starch content %* | *Gelatinizing temp.° F* |
|---|---|---|---|---|---|
| Potato | 18–20 | 145 | Millet | 53–55 | .. |
| Wheat | 54–58 | 152 | Peas | 39–40 | .. |
| Barley | 40–46 | 145 | Lentils | 39–40 | .. |
| Oats | 35–38 | .. | Arrowroot | 26–39 | 158 |
| Rye | 44–46 | 131 | Tapioca | 25–40 | 156 |
| Maize | 55–65 | 145 | Yams | 25–35 | .. |
| Rice | 70–79 | 142 | Sago | .. | 158 |

The storehouse, or starch-containing part of the plant, consists of a network of cells, within the walls of which the starch granules are closely packed together. The process of manufacture involves the rupturing of the enveloping cell walls and separation of the starch from the associated material by levigation.

**Manufacture.**—The manufacture of starch from roots and tubers is usually carried on in the locality in which they are grown; that from potatoes on the continent of Europe, principally in Germany, France and the Netherlands; arrowroot, cassava and tapioca are prepared from the roots and tubers of the maranta and manioc plants in the West Indies and South America; sago is manufactured from the pith of the sago palm and also from the yams or sweet potatoes in the East Indies and Borneo. Cereals can be more readily transported and stored, so locality is a matter of convenience; thus rice is used as a raw material in England, France, Germany and Italy and other parts of Europe, while maize is used very extensively in North America, and in England, France and Germany. Wheat is not largely employed.

The purposes for which starch is manufactured can be classified under three heads: (*a*) *Industrial.* These include sizing yarn and cloth in the textile industries; dressing cloth; thickening mordants and colours in calico printing; the preparation of British gums and dextrin, confectioners' glucose or corn syrups, and sugars for use in the fermentation industries. (*b*) *Food.* Used alone in the form of cornflour, arrowroot, tapioca, sago, etc., or in conjunction with other substances in the preparation of custard and blanc mange powders, sauces, cocoa, confectionery, etc. (*c*) *Laundry.* In pipe or crystal form and powders, both "thick" and "thin boiling" preparations.

The suitability of starches from various sources for these purposes depends on their cost, purity, the stiffness or viscosity of the paste they make with hot water and the size of the granules. Potato, maize, rice and wheat starches are those chiefly used for industrial purposes; rice, maize, arrowroot, cassava and sago for foodstuffs; and the small granuled starches, rice and maize, are used extensively in the laundry owing to the fact that the granules are required to enter the texture of the linen or cloth before becoming gelatinized by the hot iron.

The general principles for dealing with all types of roots and tubers are substantially the same, but of course vary in their elaboration and efficiency in different parts of the world, and they also only differ to some extent in detail when cereals are being treated. They are briefly as follows:—The tubers first go through washing machines where earth, stones, sand and grit are removed; they then pass to a rasping machine where all the cells are completely ruptured. The resulting pulp is washed in a fine stream of water on fine-mesh brass sieves, which separate the starch from vegetable fibre, etc.; the resulting milky starch liquor is run into vats to separate fine sand and grit by settlement, through fine silk sieves for further purification, and is finally allowed to run very slowly over long, shallow, wood troughs, runs or tables, where the pure starch settles out and the impurities pass off at the ends with the water. The pure white starch is washed from the runs by a jet of water and is pumped to either filter presses or hydro extractors, which remove all except about 40–45% of the water, leaving the starch in the form of a damp cake.

The cereals contain varying proportions of protein or gluten material associated with the starch, and special methods have to be employed in their preliminary treatment. The protein contained in rice is found to be rendered soluble by very weak caustic soda solution, and advantage is taken of this in the production of starch from the raw material. Maize in addition to protein contains an oil-containing germ which it is necessary to remove. In this case the grain is first steeped for 2 to 4 days in warm water containing 1% of sulphur dioxide, ground in burr stone mills, and the resulting diffluent mass diluted with water is passed through a long V-shaped tank where the germ floats and is skimmed off.

Wheat contains gluten which forms an elastic paste with water and cannot be removed by levigation. The procedure carried out in this case is to reduce the grain to flour which is then made into a dough with water, divided into small pieces and placed in a semicircular silk or fine brass sieve where a travelling roller presses out the starch which is removed by a fine spray of water. The starch liquor goes through a very similar purification process to that employed for maize, often being treated with dilute caustic soda solution to swell the gluten and assist its removal between the sieving processes. It is necessary to carry out the final drying process at very low temperatures to prevent the gelatinization of the starch granules. Several methods, similar in principle for starches from all sources, are in use in the large factories, and consist of either bringing the starch lumps or blocks in contact with a continuous current of warm air, or evaporating off the excess of moisture in a vacuum chamber. For producing the starch in the form of powder or flour the moist lumps are either placed on an endless band running backwards and forwards in an enclosed chamber through which warm air is drawn, or they are placed on trays mounted on a trolley and passed through a tunnel in contact with warm air. In the tropics drying is usually carried out in the open air.

Prism or crystal starch is prepared from maize or rice starch for laundry purposes, and is produced by forming the damp starch into blocks by draining off the water from the starch liquor in boxes with perforated bottoms covered with filtering cloths; the blocks are cut into two or more sections which are partly dried in a warm chamber; the yellowish brown crust which forms on the outside is scraped off, and the blocks wrapped in paper, returned to the drying chamber and dried very slowly. Under this treatment the blocks break up into irregularly shaped prisms technically termed "crystals." Pearl tapioca is made by heating the slightly moist starch from manioc in a steam-heated copper pan with constant stirring, some of the cells becoming gelatinized and adhering together in small, irregular masses. Further drying follows and the crude lumps are passed through rollers and graded.

Granulated or pearl sago is prepared by drying the starch in such a way that it forms a plastic dough in which a portion of the granules have become gelatinized, forcing this through sieves, and drying the resulting granules in the air.

**STAR CHAMBER,** the name of an apartment in the royal palace of Westminster, a meeting place of the king's councillors, derived from stars fashioned on the roof, perhaps, of the hall. By derivation, later on, the name of councillors and judges sitting there as a court.

In 1398 repairs of the "Sterred Chambre" are mentioned. In 1453 a meeting "in concilio nostro" (in our council) was held "in the Sterred Chambre." In 1542 a law provided punishment for those convicted "in the Starr Chamber at Westmynster before the Kinges most honorable Counsell."

In the middle ages judicial functions were exercised by the king of England and his council. The crown never parted with supreme jurisdiction. The council shared it, and also did judicial work not specially delegated to the particular courts which had evolved from the *curia regis*. The king's council, in star chamber and elsewhere, was reinforced by judges of the royal courts and by various others. From time to time parliament defined and approved this judicial work. In 1487 a statute (3 Henry VII, c. 1)—for a long time mistakenly supposed to have established the court of star chamber—named a commission of seven principal councillors and two of the judges, to try offenders too great to be dealt with by ordinary courts.

In the 16th century councillors, judges, persons specially summoned, additional "counsel," and great lords sometimes attending, acted either as a council or a court in star chamber, records being kept by clerks.

Councillors and judges sitting in star chamber were more and more thought of as the court of star chamber. They dispensed much justice and heard many cases often by desire of the parties concerned. Hearings were public; there was no jury; torture was sometimes used to get confession. Generally speaking, it was a court of criminal jurisdiction, particularly in respect of violation of royal proclamations; but "all offences may be here examined and punished if the king will." Sentence of death was never pronounced. The court punished with imprisonment and with fine, even with mutilation.

Under Elizabeth attendance at star chamber approximated to that at privy council, with reinforcement of judges, so that the two bodies were differentiated in function rather than in personnel. Under James I and Charles I star chamber continued as an active, important court, largely respected and liked. As Puritan and parliamentary opposition developed, however, it incurred odium from severe penalties, and the reputation then affixed by enemies has since persisted. In 1641 it was abolished by an act of the long parliament (16 Charles I, c. 10) and the judicial power of the councillors in privy council was abridged. (E. R. T.)

**STAR CLUSTER.** There are regions here and there in the sky where the stars are much more richly strewn than usual. Some of these are clusters, where hundreds or thousands of stars are seen concentrated together in a small field of view, providing show-objects—beauty spots of the celestial landscape. Not only are they impressive to observe, but they have led to remarkable advances in our knowledge. The measurement of the extent of the visible universe and an indication of its organization, information on the existence and distribution of dark diffuse matter in interstellar space are among the contributions to astronomy that have been made chiefly through the study of star clusters. The researches have been descriptive, astrometric, photometric, spectroscopic, statistical, mathematical and speculative—often complicated, and more often very tedious.

**Discovery and Catalogues of Star Clusters.**—Among the few clusters observable with the naked eye the Pleiades group is undoubtedly the best known. It attracted the attention of primitive men and became the subject of numerous myths and legends. The Hyades group surrounding the bright star Aldebaran and the dim star group in the constellation of Coma Berenices were also noticed in ancient times. About a score of the brighter clusters such as the double cluster in Perseus are visible to a keen eye as diffuse unresolved nebulous spots of light.

The true nature of star clusters as a class of celestial objects was, however, not recognized until after the invention of the telescope and many of the most striking clusters were discovered by the early telescopic observers during the 17th and 18th centuries. A catalogue of nebulae and clusters published in 1784 by the French astronomer Charles Messier listed 57 star clusters. A systematic search of the whole heavens undertaken by William Herschel at that period and continued by his son John Herschel led to many new discoveries of clusters to which relatively few have been added.

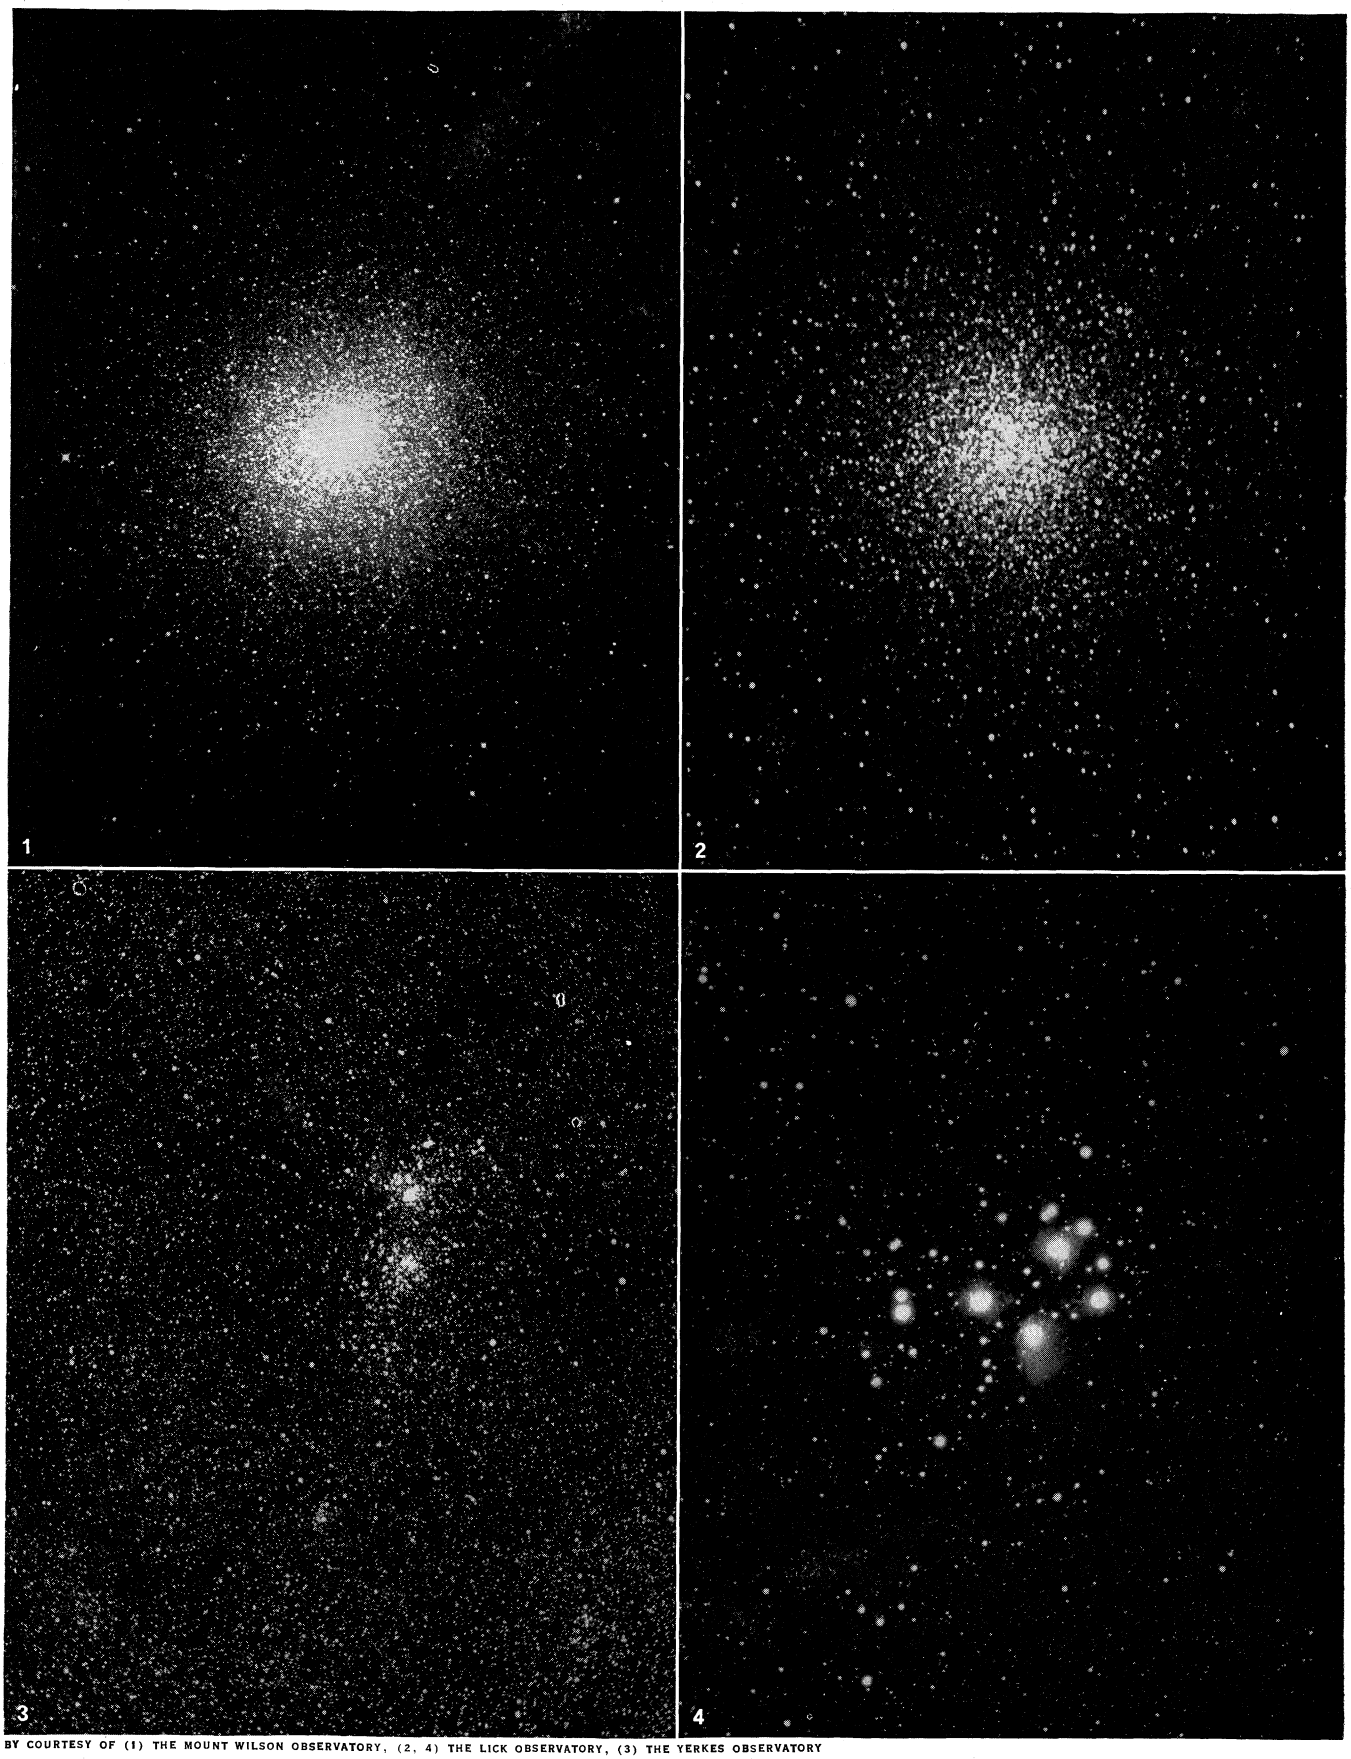
Star clusters are in general designated by their number in the catalogue of Messier or in the *New General Catalogue* (N.G.C.) of John L. E. Dreyer.

**Galactic Star Clusters and Globular Star Clusters.**—The amazing variety in appearance of star clusterings led Herschel to divide them into classes. The principal division into loose or open clusters and densely crowded globular clusters was later recognized to be fundamental, mainly through the researches of Harlow Shapley. The two kinds of clusters differ not only in constitution but also in their cosmic relation to our stellar system.

The open clusters are easily resolvable, varied in shape and richness and the star population ranges from a few dozen to a few thousand. They are scattered all along the Milky Way, often appearing like nuclei of condensation in the rich star clouds. On account of their close relation to the Milky Way they are now more commonly designated as galactic star clusters. About 350 objects of this class are known.

The globular clusters, about 100 in number, are characterized by their uncommon richness in stars (several thousand to several hundred thousand), by the remarkable regularity of structure and nearly globular symmetry. Their stars are faint and generally show a high degree of concentration toward the centre where they often appear so closely crowded that the photographic plate is unable to resolve them.

## GALACTIC STAR CLUSTERS



**Definition.**—In the scientific sense of the term, a cluster is a local group of astronomical bodies held together by their mutual gravitational attraction. Its members must have had a common origin and are thus physically related to each other. Wide binary stars, multiple stars, typical star clusters and star clouds are examples of such gravitational organization. Galactic clusters are generally distinguished from star clouds by their subordinate size and greater unity of structure. Between multiple stars and the poorer star clusters, however, there seems to be no real division. The line drawn by the astronomer is merely one of convenience dictated by methods of observation and description. Among star clusters those systems are to be included which contain a sufficient number of stars (not less than about 20) to be described statistically. A star cluster can then be characterized by such data as angular diameter, degree of concentration toward its centre, symmetry, distribution of stars according to brightness, richness in stars, etc. Some of the poorer clusters like N.G.C. 957 consist of a mere sprinkling of faint stars and it is often difficult to decide which of these should be included in a cluster catalogue.

**Constitution.**—To obtain a true idea of a cluster as a system of stars in space three difficulties have to be overcome:

1. When a cluster is examined in a telescope or on a photograph, it appears superposed on the general star field of the sky, and it must be expected that some of the stars seen within the outline of the cluster are in reality located far behind it or in front of it. To study the constitution of the system it is necessary to identify its individual members by their motion, spectral class or colour or to allow for the probable number of background and foreground stars statistically.

2. The observation of a cluster furnishes a two-dimensional picture, the arrangement of stars in depth escapes our scrutiny. For systems with spherical symmetry the statistical star distribution in space can be calculated from the apparent distribution in the projection.

3. The most difficult problem is to measure the distance of a

## EXAMPLES OF GLOBULAR AND GALACTIC STAR CLUSTERS

1. Messier 13 in Hercules, a rich globular cluster with considerable central concentration
2. Messier 55 in Sagittarius, a loose globular cluster
3. Double cluster in Perseus, a pair of rich galactic star clusters; also below centre N.G.C. 957, a small, poor Milky Way clustering
4. The Pleiades, a galactic cluster with nebulosity

cluster from the observer. This knowledge is needed to find the linear dimensions from the observed angular diameter, to gain an idea of the distances separating the individual stars from each other, of the gravitational forces acting between them and to calculate from the apparent brightness of its stars their true luminosity as compared with the sun.

A rich galactic star cluster like the Pleiades consists of 300 to 500 stars spread through a sphere about 50 light-years in diameter. The stars, particularly the brighter ones tend to congregate near the centre and thin out very gradually toward the periphery, so gradually that the extreme limit of the system is difficult to ascertain. On mere examination of a photograph only the central core of the cluster (about one-third of the limiting diameter) attracts the attention of the observer; the thinly scattered members of the outer parts are lost among the background stars.

Even in the concentrated central part of a cluster each star is on the average separated from its nearest neighbour by the enormous distance of $1\frac{1}{2}$ light years. If we attempted to make a model of a galactic cluster with pinheads as stars, the pinheads would have to be placed 4 to 5 mi. apart; a few hundred pinheads scattered through a sphere 150 mi. in diameter. Nevertheless, the space density of stars, at the centre of a rich cluster, is more than 100 times greater than in the vicinity of the solar system.

The limiting diameters of galactic clusters vary between 15 and 75 light years. The richer systems are larger than the poorer ones; their average star density therefore shows little variation, but in some the stars are more concentrated toward the centre than in others.

**Spectral Classes and Luminosities of Cluster Stars.**—Most clusters of the galactic class are so well resolved that spectroscopic and photometric observations of its individual stars can be made. The distribution of stars according to spectral class and magnitude or luminosity reveals significant differences between clusters. In some, like the Pleiades, all members belong to the Main Sequence: the brightest stars are of spectral classes O, B, or A (high temperature); with decreasing brightness the spectral class advances gradually through F and G to the K dwarfs. In other clusters, like the Hyades, we find in addition to Main Sequence stars also some giant stars of great luminosity and low temperature, and in a few the low temperature giant stars are very numerous. The latter clusters seem to form a transition toward globular clusters. A system for classifying galactic star clusters according to the magnitude-spectral class distribution of its members has been developed by Robert J. Trumpler.

Compared with the star population in the vicinity of the sun, galactic clusters are relatively rich in stars of high luminosity or candle power. Often the brightest stars in a cluster are several thousand times more luminous than our sun, in fact some of the most luminous stars known are involved in star clusters. Since high luminosity is associated with great mass the presence of such stars is important for the stability of the group. The gravitational attraction of these massive stars which are usually near the centre contributes much toward keeping the cluster together and preventing its stars from escaping into space. According to Bart J. Bok, a cluster must have an average mass density of more than 2.7 solar masses per 1,000 cubic light-years to resist disruption by the rotational motion of the stellar system.

It is not unusual to find that a member of a star cluster is itself a visual double star and spectroscopic binaries are quite numerous among cluster stars. Variable stars with periodic change of brightness, on the other hand, are very rare. It should also be mentioned that many clusters of the galactic class are involved in faintly luminous nebulosity.

**Common Motion of Cluster Stars.**—That the individual stars in a cluster share the same motion through space has been ascertained by studies of the proper motions (changes of position on the celestial sphere) as well as of the radial velocities (motions in the line of sight measured spectroscopically). For large and near clusters, like the Hyades, the paths of the stars appear to converge to a common point (or diverge from one). This convergence is obviously a matter of perspective. When the convergent point is accurately determined and the radial velocities of some stars are measured, the distance of the cluster and the velocity of its motion through space can be deduced.

For the smaller and more distant clusters the motions of the stars appear practically parallel and equal. If the proper motions are sufficiently accurate, however, their study makes it possible to distinguish the physical members from the background and foreground stars.

This phenomenon of common motion should be interpreted in the sense that the velocity with which the whole cluster travels through the stellar system is much larger than the internal motions of its stars with respect to each other. Under the gravitational attraction of all the other cluster stars each member will describe some kind of orbit around the common centre of gravity, but the velocities of these orbital motions are quite small and for their successful study several centuries will be required.

Common space motion is sometimes found among stars widely spread over the celestial sphere without any noticeable clustering. The Ursa Major group is an example of such a case. Five of the seven conspicuous stars of the Big Dipper as well as Sirius and other bright stars are alike in spectral class and move in parallel paths through space. Such groups are called moving clusters. They are probably remnants of star clusters in the stage of dissolution.

**Distances.**—Most of the galactic star clusters are so far away that their distances cannot be found by measurement of parallax or by the convergence of the proper motions; more or less indirect methods must be resorted to.

The spectroscopic-photometric method takes advantage of the fact that for stars of the Main Sequence (or the Giant Branch) the luminosity is closely related to the spectral class, a relation which has been well established by studies of the nearer stars. For any cluster stars whose spectra have been classified this relation will furnish a fair estimate of their luminosity. A comparison of the luminosity with the observed apparent brightness leads to the distance on the assumption that the apparent brightness of a star decreases with the square of the distance. This assumption, however, holds true only if the space through which the light travels is perfectly transparent. In the Milky Way, where most galactic clusters are situated, there is evidence of the presence of dark matter, cosmic dust scattered through interstellar space and the absorption of light caused by this matter must be taken into account for the more distant clusters.

Another method of distance determination is based on the assumption that star clusters of similar constitution have the same linear dimensions. For each homogeneous group of clusters the distances are then inversely proportional to the measured angular diameters. The diameter method must be calibrated by means of distances determined by the other method; it is then applicable to those objects which are too faint for spectroscopic observations. This method has also been valuable for testing the distance scale of the photometric method and for determining the effect of absorption of light in space.

The distances of the known galactic clusters as determined by Trumpler range from 120 to 20,000 light-years and 80% of these are between 2,000 and 12,000 light-years.

**Space Distribution and Motion.**—When the arrangement in space is considered (*see* fig. 1), the galactic clusters are found to nestle close to the plane of the Galaxy and to scatter through a disk about 35,000 light-years in diameter. This disk has the sun near its centre but has a very eccentric position compared with the outline of the stellar system. The whole situation suggests that the observed extent of these clusters is conditioned by the observer's location and his range of vision. Our list of galactic clusters is evidently incomplete. The light absorbing interstellar material forming a layer along the galactic plane spreads like a haze throughout the region occupied by galactic star clusters and is responsible for dimming or obscuring the more distant ones. Even a rich brilliant star group like the Pleiades when seen at a distance of 20,000 light-years would be so dim that it would hardly be noticed among the innumerable faint Milky Way stars and would have escaped discovery by the survey methods of the

past. Photographs utilizing red light which has a greater penetrating power, however, may reveal many additional star clusters of this class at greater distances.

Radial velocity measures are available for many galactic clusters, distant as well as near ones. Their analysis shows these star groups to follow closely the rotational motion of our galaxy as represented by the Oort-Lindblad theory. Each cluster revolves

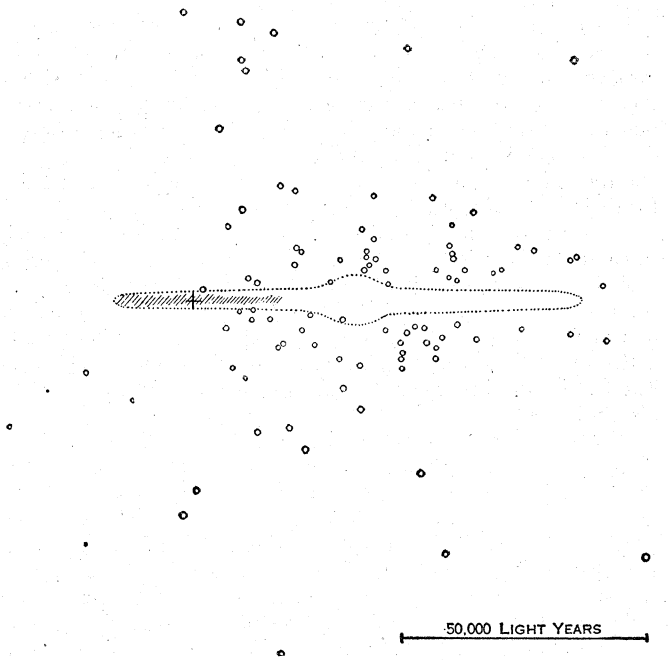

FIG. 1.—SPACE DISTRIBUTION OF GALACTIC AND GLOBULAR STAR CLUSTERS

The figure illustrates how our stellar system would appear to an outside observer. The dotted line indicates the probable outline of the flattened lens-shaped system formed by the stars, pictured as seen edgewise. The eccentric position of our sun is shown by a cross. The 350 known galactic star clusters are scattered among the stars through the region marked by shading. Absorption of light by cosmic dust spreading between the stars prevents the visibility of galactic clusters at greater distances from the sun. The small circles represent the hundred globular clusters which surround the star system like satellites

around the centre of the galaxy in an orbit which is nearly circular and parallel to the galactic plane.

By the kind of stars they contain, by their space distribution and motion galactic star clusters are intimately related to the Milky Way star clouds. Like these they probably had their origin and evolution in the highly flattened outer part of our stellar system which by analogy with other galaxies is assumed to have a spiral structure.

## GLOBULAR STAR CLUSTERS

**Distribution and Classification.**—In their distribution over the sky the globular clusters are most peculiar; they are nearly all found in one hemisphere which is centred in the rich Milky Way region of Sagittarius. On both sides of the Milky Way they extend to high galactic latitudes. As we approach the low galactic latitudes, however, they become more numerous, up to the very edges of the stream of Milky Way star clouds. But their number suddenly falls off near the central line of the Milky Way, so that only two or three are found along a central belt seven or eight degrees in width. It is just within this region devoid of globular clusters that the galactic clusters and rich star clouds are most numerous.

There is a general similarity among globular clusters except for considerable variations in star content and marked differences in compactness. The latter has been made the basis of a classification by Shapley and Miss H. B. Sawyer. The 100 globular clusters are divided into 12 approximately equal classes, Class I representing the highest concentration of stars toward the centre, and Class XII the least.

Messier 13 is a rich cluster with considerable central concentration (Class V), while Messier 55 is an example of a loose globular cluster (Class XI).

Many of the objects with little concentration are also relatively poor in stars. They are called giant-poor and are by some considered as a special subdivision of globular clusters.

**Size and Structure.**—The angular diameters of globular clusters are difficult to measure because of the ill-defined limits. Moreover, these clusters appear to grow in size when the exposure time of the photograph is increased. If the distances are known, the linear diameters can be calculated; they vary from about 50 to 300 light-years, not counting the most outlying members. Clusters of the globular class are thus on the average 3 to 4 times larger in diameter than those of the galactic class. Systems very rich in stars are generally larger in size and it has been suggested that the average space density of stars tends to be the same in all globular clusters, but is considerably higher than in galactic clusters.

A typical globular cluster is slightly flattened as though by rotation. This flattening reveals itself through the elliptical form of the projected image and the latter has been established in many cases by detailed counting of stars. It is not possible, however, to evaluate separately both the true flattening of a cluster and the inclination of its equatorial plane to the line of sight. The most we can say is that some globular clusters have equatorial diameters at least 40% greater than their polar diameters. In no cases do they appear to attain the high degree of flattening observed in spiral nebulae (*see* NEBULA) or in the Milky Way system itself.

Much work has been devoted to studies of the statistical laws governing the star distribution in globular systems. Assuming radial symmetry the number of stars per unit volume, $N$, at distance $\rho$, from the cluster centre can be calculated from star counts in the projected image, which gives the number of stars per unit area, $n$, at the projected distance, $r$, from the centre. The formula (Edward C. Pickering, H. von Zeipel) is

$$N(\rho) = \frac{1}{\pi}\int_{\rho}^{R} \sqrt{(r^2-\rho^2)}\,\frac{d}{dr}\left(\frac{1}{r}\frac{dn}{dr}\right) dr$$

Analogies with the kinetic theory of gases have encouraged some of these researches; but no completely satisfactory representation of the observations has been found. It must, however, be realized that the available star counts deal only with the few hundreds or few thousands of the most luminous stars and that they are affected by errors caused by photographic and instrumental effects.

In general, the frequency of giant stars, except near the centre, is (roughly) inversely proportional to the fourth power of the distance from the centre for most of the typical globular clusters.

**Colours and Variable Stars.**—Spectroscopic observations of individual stars in globular clusters are very difficult; but colour indices have been determined in several systems. The star distribution according to colour and brightness in globular clusters is undoubtedly different from that predominating in galactic clusters, but its interpretation is still somewhat uncertain. The most luminous stars seem to be red supergiant stars, the fainter ones appear to belong to the normal giants. Remarkable is the absence of Main Sequence stars of high luminosity which are an outstanding feature of most galactic clusters. Dwarf stars of the sun's light and diameter are unattainable with our present telescopic power when at the distance of even the nearer globular clusters.

The presence of great numbers of variable stars in globular clusters was first brought to attention by the work of Solomon I. Bailey at the Harvard observatory. In some systems one star out of six among the giant stars proves to have a periodic variation in brightness, whereas in other clusters of practically the same appearance no variable stars are found.

The overwhelming majority of the several hundred variable stars discovered in globular clusters have periods of less than a day and belong to the class now designated as cluster type variables. They form a subdivision of the Cepheid variables and their light variation is thought to be due to pulsation—that is, periodic

expansion and contraction of the stars.

A few Cepheid variables of periods longer than one day, and a few irregular variables have also been found among the stars of these clusters.

**Distances.**—The relation between apparent brightness and period for Cepheids in the Small Magellanic Cloud, found by Miss Henrietta Leavitt, was generalized by Shapley with the aid of galactic Cepheids and the variables of the globular clusters. The period-luminosity curve, which relates the absolute magnitude (intrinsic luminosity) of the Cepheid variable to the logarithm of its period, was thus derived. The zero point of the curve was fixed with the aid of the nearer galactic Cepheid variables, for which the distances and absolute magnitudes were determined from studies of their motions.

The period-luminosity curve permits the determination of the intrinsic luminosity and therefore of the distance of any Cepheid variable when the period of its variation and its apparent brightness are measured. With its use the distances of all the globular clusters, or other stellar systems, which contain Cepheid variables are simply derived. When the distances of clusters containing Cepheids have been obtained, the distances can be inferred also for the clusters devoid of variables, because of the apparently inherent similarity of all globular systems in linear size, total luminosity and in the real brightness of their most luminous stars. The observed angular sizes and apparent magnitudes thus become indicators of distance.

The effect of interstellar light absorption which must be allowed for in the distance determination is relatively small for most globular clusters because they are situated far from the galactic plane, outside of the absorbing layer. Our list of 100 globular clusters should thus be nearly complete except for those in the central belt of the Milky Way which are heavily obscured.

Though subject to considerable uncertainties, the distances of the globular clusters range from 12,000 to more than 100,000 light-years. The evaluation of these tremendous distances with a reasonable degree of reliability constitutes one of the triumphs of modern astronomical investigation.

**Cosmic Role of Globular Clusters.**—As shown in fig. 1, the globular star clusters are arranged in a fairly symmetrical group surrounding our stellar system. The centre of this group is at a distance of 35,000 light-years from the sun and in 1918 Shapley suggested that it represents also the centre of the stellar system. This hypothesis has now been generally accepted. The study of globular clusters has thus given the first important clue to the eccentric location of the sun and the extent of our galaxy of which large parts are hidden from our view by absorption of light.

The proper motions of globular clusters are as yet practically unattainable because of their great distances. The radial velocities of many of these systems, however, have been measured by feeding the total light of the numerous crowded stars near the centre of each object into the spectrograph. The results obtained by Vesto M. Slipher at the Lowell observatory and more recently by Nicholas U. Mayall at the Lick observatory show that globular clusters move through space with velocities of 100 to 400 km.p.sec., velocities much larger than those of most classes of stars. If the centre of gravity of the globular clusters is taken to be at rest with respect to our stellar system, the sun appears to be moving at the rate of 300 km.p.sec. and this probably represents the speed of the sun's orbital motion around the centre of our galaxy.

The observed radial velocities as well as the spherical grouping of the globular clusters seems to indicate that they do not take part in the rapid rotational motion of the stellar system. Their orbits with respect to the centre of the galaxy are probably much elongated and in planes of varying orientations.

The globular clusters must have separated from the main body of our galaxy at an early period of its evolution and now surround it as satellite systems.

(R. J. TR.)

**STARFISH.** This name covers three classes of the echinoderms, sea stars or Asteroidea, brittle stars or Ophiuroidea, and feather stars or unstalked Crinoidea. (*See* ECHINODERMA, figs. 1, 2 and 4.) The Asteroidea and Ophiuroidea are free-moving and live mouth downward; the feather stars, though they can swim or crawl, live most of the time attached to some object by their dorsal cirri, mouth upward or outward. (*See* ECHINODERMA.)

**The Sea Stars,** to which the name "starfish" is usually restricted, include many different forms of which the most familiar are *Asterias* of the North Atlantic coasts and its relatives in the North Pacific. These animals consist of a central body radiating out into five tapering arms. The flattened upper surface is covered with a leathery skin in which are small lobed plates of carbonate of lime, many bearing prickles, together forming a jointed reticulate skeleton. Multitudes of small pincerlike pedicellariae are present. (*Cf.* SEA-URCHIN.) For further details of structure *see* ECHINODERMA. A sea star of this type can crawl over any surface and can squeeze its supple body through incredibly narrow crevices. The rate of progress is about 6 in. a minute. The common sea star of the Atlantic coast of North America south of Cape Cod (*Asterias forbesi*) is very destructive to mussels and oysters, which form its favourite food. No less than 42,000 bu. have been removed from the oyster beds of Connecticut in a single year. They had damaged the beds to the extent of $631,500. In attacking oysters and similar bivalves the sea star fixes the suckers of one or two arms to one valve, and those of the opposite arms to the other. It then begins to straighten out its rays. The oyster can withstand a strong sudden pull, but not a continued pull, and eventually it opens its shell. The sea star then extrudes its stomach through its mouth, digests the oyster, and after the meal is finished withdraws its stomach. Sea stars begin to eat voraciously when very young. One less than $\frac{3}{8}$ in. across ate over 50 young clams of half that length in six days. A sea star may become sexually mature in less than a year, then producing many thousands of young.

These familiar sea stars, however, are scarcely representative of the group as a whole. Sea stars vary in shape from sharply stellate with long tapering rays, or pentagonal with the angles of the pentagon produced into slender spikelike arms, to pentagonal or almost circular; but most of them are stellate. The great majority have normally five rays, but some have six and a number have more, in one type (*Heliaster*) from 20 to 44. In size they vary from $\frac{1}{2}$ in. to more than 3 ft. across. There are about 1,500 known kinds distributed in 300 genera. Most of them are predacious, feeding on molluscs, barnacles, worms, crustaceans and other smaller creatures which they take into their stomachs, but many are scavengers feeding on detritus or swallowing mud and digesting out of it the organic matter. Most commonly seen of the exotic sea stars is a large one more than a foot across, common in tropical American waters, in shape a low pyramid with a stellate base (*Oreaster*), which is widely sold as a curio. Related species, smaller, more solid and with large bony tubercles, are also popular with curio dealers; these are from the Pacific and Indian oceans. The cushion stars, also from the Indo-Pacific region, are pentagonal to circular, 6 to 8 in. across, greatly swollen with broadly rounded edges, and look like small cushions. When young they are pentagonal and flat with a border of large plates. Along the sandy or muddy coasts of all warmer seas live two types of sea stars which, though common, are usually unfamiliar. One of these (*Astropecten*) is regularly star-shaped with stiff arms bordered with large plates. It usually lives just beneath the surface of the sand. The other (*Luidia*) has five or more broad, flat and brittle sharp-edged arms. It is said sometimes to swim by means of the podia. In these, as in many other kinds, the podia have no

suckers, ending in a conical point. Sea stars are eaten by gulls, crows, ravens, foxes and various fishes. Their chief parasites are crustaceans.

**The Brittle Stars or Ophiuroidea** ("snake-tails") differ from sea stars in having long and slender arms which are quite distinct from the usually pentagonal or circular body. The digestive and genital organs are wholly within the body, except in a few cases where the latter extend into the arm bases. There is no vent and pedicellariae are never present. (*See* ECHINODERMA, fig. 2.) There are about 1,500 known kinds arranged in 200 genera. In most of them the arms are moved chiefly sideways, though they may coil vertically at the tip. The body varies between 3 and 57 mm. in diameter. The arms are usually long, flexible and brittle, but may be rigid and tough. The common shore-living forms all belong to this section. They are the most active of all echinoderms. They live among seaweeds or eelgrass, in chinks and crevices of rocks or corals, buried in mud, or lying on the sea bottom in deep water. Some are symbiotic or semiparasitic in sponges or on various coelenterates, feather stars or sea-urchins. In the tropics many are brilliantly coloured. In another type the arms, which may be more than 2 ft. long, coil vertically. These are all semiparasitic on coelenterates and live in deep water. To these are related the basket stars or "sea spiders" with their many-branched arms, most of which live clinging to coelenterates. Several brittle stars are hermaphroditic, some live in pairs, male and female, and some brood their young. Many brittle stars are important as food for fishes, in the North Atlantic particularly cod and haddock.

**The Feather Stars (unstalked Crinoidea)** are distinguished as Comatulida ("hair stars") from various other crinoids that at earlier periods of the world's history have lost the stem. (*See* ECHINODERMA, fig. 4.) The stem is not really absent, but is reduced to a knob from which arise numerous jointed appendages (cirri) by which the animal clings to some support. From the small body extend five arms (in two genera ten) which may remain undivided, but most commonly fork near the base or branch several or many times. The arms are fringed with slender branches (pinnules) giving a feathery appearance. Though usually sedentary, feather-stars can crawl about and some can swim. There are about 600 kinds arranged in 140 genera. They occur from the shore line down to about 18,045 ft. and are most diversified in the Indo-Pacific region, most abundant in the north.

**STARGARD,** a town in the Prussian province of Pomerania, Germany, on the left bank of the navigable Ihna, 20 mi. E. of Stettin on the railway to Danzig and at the junction of lines to Posen, Schneidemühl and Cüstrin. Pop. (1939) 40,334. Stargard, mentioned as having been destroyed by the Poles in 1120, received civic rights in 1229, and became the capital of eastern Pomerania. As a Hanseatic town it enjoyed considerable commercial prosperity, but it had also to undergo siege and capture in the middle ages and during the Thirty Years' War.

**STARK, JAMES** (1794–1859), British painter, was born in Norwich on Nov. 19, 1794, and at the age of seventeen was articled to John Crome for three years. He died in London on March 24, 1859. Between 1831 and 1859 most of his pictures were shown at the Royal academy. He undertook in 1827 the publication of a work on *The Scenery of the Rivers of Norfolk,* which was completed seven years later; the illustrations he prepared for it have much topographical and artistic interest. His painting "The Valley of the Yare," is in the National Gallery of British Art.

**STARK, JOHANNES** (1874– ), German physicist, was born April 15, 1874 at Schickenhof in Bavaria and studied at the University of Munich. In 1900 he became an assistant at the University of Göttingen. He went as professor in 1907 to the Technische Hochschule at Aix-la-Chapelle, in 1917 to Greifswald and in 1920 to Würzburg; he retired in 1922. Stark devoted himself principally to the study of the modern theory of radiation and the atomic theory. He discovered the Doppler effect in parallel rays, for which the Vienna Academy awarded him the Baumgartner Prize. Later he discovered the Stark effect, named after him, and in 1919 was awarded the Nobel Prize for Physics. He wrote numerous essays on physical problems, including the *Prinzipien der Atomdynamik,* in 3 parts (1910–15); *Die elektrischen Quanten, Die elektrische Strahlung, Die Elektrizität in Gasen* (1902) and *Die Dissociierung und Umwandlung chemischer Atome* (1903).

Stark was the founder of the *Jahrbuch der Radioaktivität und Elektronik* (1904), which he edited until 1919.

**STARK, JOHN** (1728–1822), U.S. soldier, was born at Nutfield, now Londonderry, N.H., on Aug. 28, 1728. During the Seven Years' War he served under Robert Rogers, first as a lieutenant and later as a captain. At the beginning of the Revolutionary War he raised a regiment and as colonel did good service in the Battle of Bunker Hill, the Canadian expedition, and Washington's New Jersey campaign in the winter of 1776–77. In March 1777 he resigned his commission. Later in the year, he was placed in command, with the rank of brigadier general of militia, of a force of militiamen, with whom, on Aug. 16, near Bennington, Vt., he defeated two detachments of Burgoyne's army. For this victory, which did much to bring about the capitulation of Gen. Burgoyne, Stark received a commission as brigadier general in the Continental army (Oct. 4, 1777). He took part in the operations about Saratoga, and for a short time was commander of the northern department. In Sept. 1783 he was breveted major general. He died at Manchester, N.H., on May 8, 1822.

See *Memoir and Official Correspondence of General John Stark* (1860) by his grandson Caleb Stark.

**STARK EFFECT:** *see* QUANTUM MECHANICS; LIGHT.

**STARLEY, JAMES** (1830–1881), British inventor, the son of a farmer, was baptized at Albourne, Sussex, on June 13, 1830. At 18 he ran away from home and started on foot for London, but on the way obtained work as a gardener at Lewisham, Kent, where he lived for a number of years. He had always been an ingenious mechanic, inventing trifling novelties and repairing watches and clocks in the neighbourhood, and when sewing machines began to be much used they attracted his practical attention, and aroused his inventive genius. Leaving his garden he went up to London and became working mechanic for a firm of sewing-machine makers. Here he was in his element, and in several particulars improved his principal's machines, and invented a new one with an arm attachment that permitted circular as well as straightforward work. With a fellow workman he moved in 1857 to Coventry, and started the manufacture of the "European" and other sewing machines from his patents. This was the beginning of the Coventry Machinists' company, a pioneer among bicycle and tricycle works which later made that city a centre of the industry. Former acquaintances of Starley at Lewisham and elsewhere migrated to Coventry to become skilled mechanics for this company. In 1868 they began the manufacture, after a Paris model and at first for French use, of bicycles, several of the earliest suggested improvements being Starley's. A number of firms were soon devoting themselves exclusively to the manufacture of bicycles, and for one of these Starley designed the Coventry tricycle. As it was harder to propel than the bicycle, he invented the balance gear, and applied it in the Salvo tricycle. Starley died on June 17, 1881 and a public monument was erected to his memory in Coventry. His nephew, J. K. Starley, patented the tangent wheel in 1874.

**STARLING, ERNEST HENRY,** F.R.S. (1866–1927), English physiologist, eldest son of H. H. Starling, clerk of the crown at Bombay, was born in London, 1866. Educated at King's College school; entered Guy's hospital in 1882 and graduated M.D. in 1890. He never practised as a physician and in the same year he was appointed lecturer in physiology at Guy's. In 1900 he became Jodrell professor of physiology at University college, London, where he continued to work throughout his life, although, in 1922, he retired from the Jodrell chair and was appointed Foulerton research professor of the Royal society.

Starling was one of the foremost physiologists of his age. The subjects for investigation which particularly attracted him were those physiological processes which seemed capable of interpretation in terms of chemistry and physics. The conditions determining transudation from the vessels and lymph flow occupied his attention for some years and he showed that the hydrostatic and osmotic pressures within the vessels supplied the balance of force necessary to explain the hitherto perplexing experimental facts. His researches on the movements of the intestines, undertaken in conjunction with Bayliss (*q.v.*) demonstrated the neuromuscular mechanisms involved and reduced the previous chaos to order. Their discovery of "secretin" not only laid bare the way in which the secretion of the pancreas was called forth and adjusted, but stimulated further research on the chemical integration of the body functions, since so profitable. By ingenious methods of experimentation he was successful in maintaining the mammalian kidney, isolated from all connection with the body, in a state of functional activity and thereby to bring to light new and fundamental facts concerning renal secretion. Starling's most important researches were, however, those dealing with the heart and circulation. Together with many other important discoveries on the physiology of the circulation, he demonstrated the mechanism by which the heart is able to automatically increase the energy of each contraction in proportion to the mechanical demand made upon it and, apart from the nervous system, to adapt its work in accordance with the needs of the body. No one physiologist has so greatly advanced knowledge of the heart's action since the discovery of the circulation by Harvey 300 years ago.

During World War I, he became director of research at the R.A.M.C. College and engaged in devising defensive methods against poison gas. Subsequently, 1917–19, Starling rendered valuable national service as chairman of the Royal Society Food committee, scientific adviser to the Ministry of Food and British scientific delegate on the Inter-Allied Food commission.

**STARLING** (*Sturnus vulgaris*), a bird common throughout northern Europe and Asia and also found in India. About the size of the thrush, the starling has a plumage of black, beautifully glossed with purple, green and steel-blue and having each feather tipped with buff. The starling is an omnivorous feeder, but, where numerous (as in Britain), it must undoubtedly be numbered among the injurious species. It gathers in enormous flocks in the autumn to roost in reed-beds, and such a flock on the wing is a memorable sight, their simultaneous turns in the air being very remarkable. Of late years, it has taken to roosting in increasing numbers on large buildings in London and other towns. The song of the male is cheerful and varied, if not very beautiful, and the bird's disposition is bustling and lively. It nests in holes in trees, which it frequently appropriates from a woodpecker, or in buildings. The eggs, four to seven in number, are a pale blue-green. As the young grow, they become extremely noisy. The starling was introduced into New York city in 1890. It spread rapidly in New York and adjoining states.

It has caused a decrease in many native hole-breeding birds by usurping the available nest sites. Allied species occur in the Mediterranean, Kashmir, Persia and Armenia.

The related genus *Pastor* includes the beautiful rose-coloured starling (*P. roseus*), a bird of irregular and erratic habits, arriving in incredible numbers in unexpected places to breed—usually in a district where locusts are becoming or have become excessively abundant. The plumage is rose-pink and black.

**STARNBERG,** a village and climatic health resort of Germany, situated in Upper Bavaria, on the Starnberger See, 16 mi. S. from Munich by rail. Pop. (1933) 4,879. It has an old castle (now government offices). The Starnberger See (or Würmsee) is a lake with a length of 12 mi., a breadth of 3 mi., and covering 23 sq.mi. Its greatest depth is about 400 ft. On the Roseninsel, an island in the lake, remains of lake dwellings were found.

*See* Ule, *Der Würmsel in Oberbayern* (Leipzig, 1901).

**STAR-NOSED MOLE** (*Condylura cristata*), a North American species. In habits it resembles the other moles, but is distinguished by the presence of a ring of tentacles, probably tactile, round the nostrils. (*See* INSECTIVORA.)

**STARODUB,** a town of the Russian S.F.S.R., in the Orel region, in 52° 35′ N., 32° 45′ E. It is the terminus of a branch railway, and three telegraph lines radiate from it. Population 10,919. Russian princes contended with one another for it in the 11th and 12th centuries. It was destroyed by the Mongols in the 13th century. In the 15th and 16th centuries the Russians and Lithuanians struggled for it; it became a Polish stronghold in the 17th century, but was handed over to Russia in 1686.

**STARVATION,** the state of being deprived of the essentials of nutrition, particularly of food (*see* HUNGER AND THIRST).

In starvation those tissues which are of the greatest importance to the economy are nourished at the expense of less important tissues. Thus the brain and spinal cord lose only 3% of their weight in a hunger period during which fat loses 96%. From the behaviour of the respiratory quotient in starvation it is clear that the wastage of muscle and other proteins is due to endeavours to keep up the body temperature at its normal level. Experimental starvation, even though food be entirely withheld, is not accompanied by any great alteration in body temperature until starvation has been going on for perhaps three weeks.

**STAS, JEAN SERVAIS** (1813–1891), Belgian chemist, was born at Louvain on Aug. 21, 1813. He studied for a medical career and took his doctor's degree, but soon turned to chemistry. In 1835 after much trouble he gained admission to J. B. A. Dumas' (*q.v.*) laboratory in Paris in order to continue a research on phloridzin which he had begun in an attic in his father's house, and he was associated with that chemist in several researches, including his redetermination of the atomic weight of carbon. In 1840, he left Paris on his appointment to the chair of chemistry at the École Royale Militaire in Brussels. There he remained for more than a quarter of a century, but before he had served the thirty years necessary to secure a pension he was obliged to resign because of a malady which affected his speech. He was then appointed to a post in connection with the Mint, but gave it up in 1872, and spent the rest of his life in retirement in Brussels, where he died on Dec. 13, 1891. Stas' name is best known for his determination of the atomic weights (*q.v.*) of a number of the more important elements, for which he was awarded a Davy medal by the Royal Society in 1885. His work in this field was marked by extreme care, and he adopted the most minute precautions to avoid error, with such success that the greatest variation between his numerous determinations for each element was represented by from 0.005 to 0.01. In connection with a poisoning case in 1850, Stas worked out a method for the detection of the vegetable alkaloids, which, modified by Friedrich Julius Otto (1809–1870), professor of chemistry at Brunswick, has been widely used by toxicologists as the Stas-Otto process.

Stas' papers on atomic weights were collected in *Recherches sur les Rapports réciproques des Prids Atomiques* and in *Nouvelles Recherches sur les Lois des Proportions Chemiques.*

**STASINUS,** of Cyprus, according to some ancient authorities the author of the *Cypria* (in 11 books), one of the poems belonging to the epic cycle. Others ascribed it to Hegesias of Salamis or even to Homer himself. The *Cypria* contains an account of the events leading up to the Trojan war, such as the judgment of Paris and the rape of Helen. It is probable that the list of the Trojans and their allies (*Iliad,* ii, 816–876), which formed an appendix to the catalogue of the Greek ships, is abridged from that in the *Cypria.* Proclus, in his *Chrestomathia* gave an outline of the poem (preserved in Photius, *cod.* 239).

*See* D. B. Monro, Appendix to his edition of *Odyssey,* xiii–xxiv (1901); T. W. Allen, "The Epic Cycle," in *Classical Quarterly* (Jan. 1908, *sqq.*); and HOMERIC POEMS.

**STASSFURT,** a town in the Prussian province of Saxony, Germany, and one of the chief seats of German salt producing; on the river Bode, 20 mi. S.W. of Magdeburg by rail to Aschersleben. Pop. (1939) 15,783. The systematic exploitation of the salt beds to which the town owes its prosperity, dates from 1856 only. Besides the rock salt, the saline deposits yield deliquescent salts and other saline products, which have encouraged the foundation of numerous chemical factories. For about 50 years prior to World War I the bulk of the potash used throughout the world

originated in the Stassfurt mines. The deposit underlies an area of about 100 sq.mi. and is the largest body of soluble potash known. Production continues to be heavy, although Germany's monopoly after 1918 was no longer complete.

**STATE:** *see* SOVEREIGNTY.

**STATE, ACT OF,** the plea of "act of state" in English law means primarily a defense raised by the crown on behalf of a servant of the crown, who is sued in the English courts for some wrongful act ratified by the crown. In this sense the plea is not recognized by the English courts who, in rejecting it, have uniformly held that, as the king cannot do a wrong so also "it follows that the king cannot authorize a wrong." The only exception to this rule is in the case of a wrongful act done to an alien who, in such a case cannot sue (*Buron* v. *Denman* [1848] 2 Ex. 167) if the act was done outside British territory and was ratified by the crown, but it has recently been held in *Johnstone* v. *Pedlar* 90 L.J.P.C. 181 that if the act complained of was done to him in British territory he has the same right to sue as a British subject and the defense of "act of state" is, in that case, equally inapplicable. But the term is also used in another and less questionable sense. It will be entertained by English courts where the acts in respect of which an action is brought are "transactions of independent states between each other," such as those arising out of the execution, or nonexecution, of a treaty, the succession of the crown to a foreign territory by cession or conquest, and the like. For example, a concession granted by the chief of native territory is not enforceable whether by Petition of Right or otherwise in British courts by the grantees against the crown, on succeeding to the territory by annexation (*Cook* v. *Sprigg* [1897] A.C. 572). So too the contractual obligations incurred, whether toward a British subject or an alien, by a foreign state are not binding on the crown, after its conquest and annexation by the crown, unless the crown expressly elects to adopt them (*West Rand Gold Mining Co.* v. *the King* [1905] 74 L.J.K.B. 753); for annexation is an "act of state" of an international character. In such cases the title of the subject has originated with a foreign government, not with the crown. If the contract or concession in question had originally been made by the crown itself, it would be another matter. Even in the case of a British protectorate the crown may plead "act of state" as a defense to claims in respect of expropriation of native territory because the crown in such a case is acting in territory which is not British (*see* the recent case of *Sobhuza II,* v. *Miller* [1926] A.C. 518). So too claims arising under a treaty are not enforceable against the crown unless and until the treaty, which is an international act, becomes part of English municipal law by being incorporated in a statute. The negotiation of the treaty is an "act of state" into which, and its meaning, the courts cannot enquire. In this sense the declaration of war and the making of peace by the sovereign is also an act of state. As Lord Somer put it in *Johnstone* v. *Pedlar* (Op. cit. at p. 794) "Municipal Courts do not take it upon themselves to review the dealings of State with State and Sovereign with Sovereign." On the other hand the mere fact that some act, wrongful *per se* in English law, was done in execution, or alleged execution, of a treaty made by the crown against the person or property of a British subject is a defense that would never be entertained by the courts in action against a servant of the crown, for, while a treaty cannot confer new rights, enforceable at law, upon a British subject, neither can it deprive him of any of his existing rights under English law. This was specifically laid down in *Walker* v. *Baird* [1892] A.C. 491 where in an action for trespass an officer of the crown put in the plea of "act of state" in that he was acting in the execution of a convention with the French government.

**STATE, DEPARTMENT OF:** *see* GOVERNMENT DEPARTMENTS.

**STATE GOVERNMENT (U.S.).** At the close of the Revolutionary War in 1783 the 13 British colonies in America became 13 independent sovereign states. Presumably they could at once have begun to function in international relations on an equal legal basis with all other sovereign states. But they had already created a confederation under a document known as the Articles of Confederation. However, this document, and membership in the confederation, did not impair their status as free and independent sovereign states. Each had joined voluntarily, and each one was free to withdraw. Their sovereign powers as separate states were not affected.

This confederation existed until the constitution of the United States was adopted by the 13 states in 1789. By that action they ceased to be free, independent, sovereign states. They were not free to withdraw from the newly created union, they had irrevocably surrendered certain very important powers to the new national government, and they had no status whatever as sovereign states in international relations. Some confusion grows out of the fact that they continued to be called states, for in the terminology of political science the very word state had generally been supposed to imply sovereignty and independence. Certainly by the close of the 19th century this was no longer true, if indeed it ever was, for states like France and Sweden are independent and sovereign while states in the American Union are not.

The constitution brought into being a federal system of government. It created a national government usually called the federal government, and it also preserved the integrity of each of the states and their separate governments. An effort was made clearly to divide powers between the federal government and the states. The powers of the federal government are enumerated and delegated, *i.e.,* the federal government can do only those things which the constitution says it can do. The powers of the states are inherent and residual, *i.e.,* each of them can exercise within its borders all governmental powers which are not delegated to the federal government, or not specifically forbidden to the states, or reserved to the people. Thus it is impossible to enumerate the powers of the states. One can enumerate the powers of the federal government and the things the states are forbidden to do. The states possess all remaining powers.

It is to be observed that under this federal system the national government has no power to coerce states, to use force upon them, or to compel a state to do or not to do any particular thing. The national, or federal government has abundant power to compel people, as individuals, anywhere within its jurisdiction, to obey its laws, passed in accordance with the constitution. That is all the power the federal government needs—power to enforce its laws upon people who try to resist, however numerous they may be, or in whatever state they dwell. Such power is wholly adequate; and the need for coercing a state cannot arise. If unhappily the people of a given state were to endeavour to resist the enforcement of a federal law, the federal government would proceed to enforce it upon those people, as people, and not upon the state as a state.

This fact is immensely important. It is perhaps the most significant feature of the United States federal system. It is in this way that the authors of the constitution sought to avoid war as between the United States, and one or more of the states composing the union. Armed force applied to a state is war. The federal government has no power to make war upon a state and does not need such power. This feature of the federal system is often misunderstood by people who advocate federalism on the international level and propose to give the international federal government power to police international society and compel states to obey. That is precisely what the authors of the U.S. constitution sought to avoid. They came close to performing a miracle in the realm of political science. Only once has the system failed to work and that was at the time of the Civil War.

The constitution guarantees the boundaries of each state and provides for the admission of new states to the union. There were 48 in 1946. Whether or not the outlying dependencies can be admitted as states is a question which had not been settled. Each of the states has exactly the same power. Once admitted to the union the powers of a state are determined by the provisions of the constitution, and they apply to all in exactly the same way. There is some confusion about this point because the

legislatures of various states do not have the same powers, and governors of some states have much more power than governors of other states. These variations grow out of the fact that each state provides for its own agencies of government in its own constitution. The states as states have equal and identical powers.

The federal government cannot deprive a state of powers reserved to it by the constitution. Thus it is improper to say that the federal government has power superior to that of the states. The federal government can do only what the constitution says it can do; but within these limits the federal law prevails, and provisions of state constitutions and state laws which interfere with the enforcement of federal laws are null and void. Beyond these limits the state prevails, and the federal government cannot interfere. This basic theory of the constitution is easily stated. The practical application of it has produced a multitude of hairsplitting interpretations which would fill many volumes. Suffice it to say, the supreme court of the United States is the ultimate authority in the matter of determining the dividing line between state and federal power.

Each state may provide for its own government subject only to the few limitations in the federal constitution. Each state has a written constitution, in essential features similar to the federal constitution. They all contain bills of rights limiting their own governments. They all provide for the tripartite division of powers into separate branches: legislative, executive and judicial. They all apply the doctrine of judicial review under which the courts interpret and apply the provisions of the state constitution. They all provide for popularly elected governors. In every state except Nebraska there is a bicameral legislature—a senate and a so-called lower chamber, usually at least twice as large as the senate. Members of both houses are popularly elected from districts, in many states the counties. No state has provided for a cabinet truly comparable to the cabinet in the federal government, although some states have experimented with the idea. In a great majority of the states the high administrative officers, such as the secretary of state, treasurer, auditor, attorney general and secretary of agriculture, are elected and not subject to the administrative control of the governor.

It is not possible to go much further in describing state government in the United States without qualifying each statement with such words as "usually," "generally," "in most states," or "in a majority of cases." The reason is that although the institutions of state government are very similar, they do differ somewhat. To the casual observer and to the ordinary citizen who travels from one state to another the systems of government are so nearly alike that he is scarcely conscious of the fact that he has moved from one jurisdiction to another. He takes it for granted that the political and legal system which prevails in his own state also prevails in another; and in general he is right.

Thus each state has its own complete system of civil and criminal law. There are variations but they are not particularly significant to the ordinary citizen.

Each state has power to determine who may vote, subject only to the provisions of the federal constitution which say that the right to vote shall not be denied on account of race, colour or sex. The federal constitution does not guarantee the right to vote to anyone—to citizens over 21 years of age, to women, to soldiers or to Negroes. It does not forbid poll tax requirements or property qualifications. One gains a right to vote under state law. But the all-important fact is that the right of all citizens over 21 years of age to vote has been established in all states, with some qualifications in some states, usually involving term of residence and literacy.

The structure of courts is much the same in all the states, and follows rather closely the model of the federal judiciary. The most notable difference between the federal judiciary and that of the states is that in most of the latter the judges are elected instead of being appointed and hold office for fixed terms.

Administrative departments, offices and agencies to be found in all the states are quite similar but not identical either in organization or as respects relationship to each other and to the governor. A marked tendency in the 20th century has been to reduce greatly the number of independent administrative agencies, to merge them into large departments of administration and to strengthen the power of the governor over them. Further generalization would serve little purpose. The facts with respect to each of the states can be found in their constitutions and laws and in the textbooks.

The same observations can be made with respect to the structures of local government and the public school systems. They are very similar but not identical.

Throughout the entire history of the United States there has been an apparent tendency for the national government to increase its powers and to extend its scope of operations, often, it is said, "at the expense of the states." From 1932 this tendency has been greatly accelerated and some observers have been prompted to predict the ultimate subordination, if not the virtual extinction of the states. Political theorists have often commented upon the instability of a federal system, saying that one of two things is likely to happen: either the national government will acquire such power as to lead to the extinction of the component units—the states; or, the states will be so jealous of their own powers as to lead to the paralysis of the national government and the ultimate collapse of the union.

After a century and a half of experience there seems to be no remote possibility that either prediction will be fulfilled in the United States. The powers of the national government have indeed been expanded. This has come about largely because of the application of the idea of loose or broad construction to the grants of power to congress, chiefly the power to regulate commerce among the states, and the power to tax for the general welfare; while the states have been held in check by the strict application of that provision of the fourteenth amendment to the constitution which says, "No state shall make or enforce any law which shall abridge the privileges or immunities of citizens of the United States, nor shall any state deprive any person of life, liberty or property, without due process of law; nor deny to any person within its jurisdiction the equal protection of the laws."

But on the other hand the powers of the states have expanded also and seem destined to continue to expand. The states have vast power in the realm of civil and criminal law, domestic relations, property rights, taxation, the regulation of business, agriculture, the professions and commercial relationships. The states have almost unlimited power in such matters as public education, social betterment, public health and welfare, the building of highways and public works and the control of public utilities and intrastate commerce. Thus the opportunities for the expansion of state powers would seem to be enormous. This is sometimes overlooked by those who are more impressed by what seem to them to be the encroachments of the federal government upon the states.

Many other countries, chiefly in the western hemisphere, have established federal systems of government similar to that of the United States. Serious difficulties frequently have arisen, leading sometimes to a complete breakdown of the system. Although many factors have contributed to these failures the weak spot in the system seems to be the supreme court. It is that agency which passes finally upon questions involving the powers of the states and of the national government. If the court becomes corrupt or incompetent, or if the people are unwilling to accept its decisions, the entire system is in danger of collapse. Both the national government and the states must rely on the court to protect them against encroachments.

**STATEN ISLAND,** or the borough of Richmond, one of the 5 counties of New York city, is in New York harbour, S. of Manhattan, between New Jersey and Brooklyn. Triangular in shape, the island is 13.9 mi. long, 7.3 mi. across at its widest part, has 35 mi. of water front, and a land area of 57 sq.mi. In the northeast quarter are two ranges of wooded hills. Todt hill, with an elevation of 413 ft., is the highest point along the Atlantic coast between Maine and Florida. The island

population was 174,441 by the 1940 federal census. The larger communities are Port Richmond, West New Brighton, New Brighton, St. George, Tompkinsville, Stapleton, New Dorp, Great Kills and Tottenville.

The county seat, formerly at Richmondtown, was moved in 1920 to St. George, the northeastern tip of the island and central point of communication with the rest of the city. Transportation to Manhattan is provided from St. George by municipal ferries and to Brooklyn by both municipal and privately operated ferries.

Three vehicular bridges connect Staten island with the state of New Jersey: the Outerbridge crossing, extending from Tottenville to Perth Amboy, N. J.; Goethals bridge, from Holland Hook to Elizabeth, N. J.; and the Bayonne bridge, from Port Richmond to Bayonne, N. J.

Transportation facilities on Staten island itself consist of surface electric trains, steam freight service and an extensive bus system.

The Staten island chamber of commerce in 1941 listed approximately 250 industries, the largest being shipbuilding, oil refining metal working, smelting and refining, and the manufacturing of soap, dental supplies, fireworks, colours and dyes and building supplies.

Other products are dresses, hats, ice cream, silk labels, bricks, glass flowers, printing, baking, paints, sirens, varnish, barrels and bookbinding. Numerous truck farms and a certified goat-milk farm are also located on the island.

The major shipyards are on the north shore; the east shore is the site of shipping terminals including the New York foreign trade zone No. 1, or free port, a municipal area used for shipping, storing and packing commodities, now privately operated.

About 70% of Staten island's 48,000 families own their homes. There are 726 mi. of streets, 124 churches, 83 private and public schools, five hospitals, seven public libraries and 47 city parks and golf courses, with a total area of 2,800 ac. There are three liberal arts colleges, the largest being Wagner Memorial Lutheran college, a coeducational institution with a 53-ac. campus on Grymes hill; Notre Dame college for women, a four-year institution also on Grymes hill, and the Staten island branch of Manhattan college, New Brighton, a two-year institution for men. Wagner houses the Edwin Markham Memorial library, left to the college in his will by the poet, who lived in Westerleigh, S.I., until his death in 1940.

Points of interest are the Barrett park zoo, the museum of the Staten Island Institute of Arts and Sciences, the Richmond Historical museum, U.S. marine hospital, Seaview hospital, Silver Lake park and reservoir, Sailors' Snug Harbor, U.S. coast guard base and lighthouse service and the U.S. quarantine station. Among the 45 historic houses standing is the Voorlezer's house (1696), Richmondtown, the earliest known elementary schoolhouse in the country.

When discovered by Europeans, Staten island was inhabited by a few Aquehonga Indians, a branch of the Raritans. The first land grant was made by the Dutch West India company in 1630. After several settlements by white men, unsuccessful because of Indian attacks, the first permanent settlement was established in 1661 at Oude Dorp (Old Town) at South Beach. The island was named "Staaten Eylandt" during the period of Dutch control, in honour of the states general, the governing body of Holland. The name "Richmond" was derived from the town and dukedom of Richmond in Yorkshire, England.

In 1668, according to legend, in order to prove that Staten island was part of New York rather than New Jersey, the duke of York commissioned Captain Christopher Billopp to sail around the island in 24 hr. Billopp, according to the story, made the trip within the time limit and was rewarded for this and other services with a grant of 1,163 ac. at the southern end of the island, now Tottenville.

In the Billopp or "Conference" house, Lord Howe on Sept. 11, 1776 met with Benjamin Franklin, John Adams and Edward Rutledge, three representatives of the Continental congress, to discuss reconciliation with England. The house has been preserved as a historic landmark.

Staten island did not become part of New York state by law until 1892. In 1896 it became one of New York city's five boroughs.

**STATE RIGHTS,** a term used generally in political science to denote those Governmental rights which belong to the individual States of a Federal union, there being a certain sphere of authority in which these individual States may act without interference from the central Government. Thus in the United States there were certain rights reserved to themselves by the States when forming the union under the Constitution of 1787. These rights the central Government is by fundamental law bound to respect, and they can be reduced only by amendment to the Constitution. For 1,000 years the various German States were so jealous of any curtailment of their individual rights as to prevent the formation of an efficient Federal Government. In Federal unions, such as Mexico and Brazil, where a central authority existed first and created the States, the belief in State rights is much weaker than it is in unions composed of originally independent States. The rights of a State are said to be delegated when, as in Mexico, Brazil and Colombia, the Constitution is created by a central national authority which also makes the States; State rights are residuary when independent States unite to delegate by a constitution certain powers to a central Government, as in the case of the United States, Switzerland and, until 1905, Sweden-Norway. History shows that States forming unions of the second class are certain in aftertime to deny or assert that the sovereignty of the State is one of the rights reserved, according as the State belongs to a stronger or weaker section or faction; State sovereignty being the defence of the weaker State or faction, and being denied by the stronger group of States which controls the Government and which asserts that a new sovereign State was created by a union of the former independent ones. This dispute is usually ended by civil war and the destruction of State sovereignty. The evolution of State rights as shown in the history of the United States is typical. Thirteen independent States formed a Union in 1787 under a Constitution reserving certain rights to the States. The sphere of the State authority embraced most of the powers of government, except, for instance, those relating to foreign affairs, army and navy, interstate commerce, coinage and the tariff; the powers of the central Government were specified in the fundamental law. Most of the States claimed at one time or another that sovereignty was one of the reserved rights of the States and on this theory the Southern States acted in the secession in 1861. The war that resulted destroyed all claims of State sovereignty. The other rights of the States consisted of those not delegated to the central Government or forbidden to the States by the Constitution. In case of doubt the presumption was in favour of the State. Since the beginning, however, the central Government has gained strength at the expense of the States, seldom by direct usurpation (except during the Civil War and Reconstruction, 1861–76), but indirectly through use and custom, as the country and people developed and new conditions of government arose. The field of State rights has not increased, while centralization has slowly but surely taken place. The central authority in the United States, formerly affecting the average citizen but little, now touches him in many of the activities of life and sometimes intrudes even into the domain of local self-government. The history of the decay of State rights makes it seem doubtful if the Federal form of government is a permanent one, or is only a transient form between independent State Governments or loose confederacies and a centralized national Government.

H. Stephens, *Constitutional View of the War Between the States* (Philadelphia, 1868–70); A. L. Lowell, *Governments and Parties in Continental Europe* (Boston, 1896); and H. P. Judson, *Our Federal Republic* (1925).

**STATE'S EVIDENCE,** the term used in the United States for evidence given by an accomplice upon promise of pardon.

**STATES-GENERAL,** the English translation of (1) the *états-généraux* of France and (2) the *staten-generaal* of the Dutch Netherlands. The name in both cases signifies the assembly of the estates of the realm, as distinct from provincial assemblies of estates; it is thus the equivalent of the English parliament, of the Cortes in Spain, or the diet of the Holy Roman empire, which the states-general resembled in their original constitution.

In France the states-general were first summoned in 1302 by Philip IV for the purpose of giving him moral support in his quarrel with Pope Boniface VIII. They consisted of representatives of the three orders of clergy, nobles and commons (*tiers état,* third estate), an arrangement which survived to the end, though their composition, as well as their effective powers varied greatly at different times. For various reasons (notably the disorganization occasioned by the Hundred Years' War and the religious wars of the 16th century) they never secured the power over taxation and legislation early obtained by the English parliament, and after 1615 they were never summoned until 1789, when they transformed themselves into the National Constituent assembly. This assembly consisted of the representatives of the three orders sitting together, but the states-general had ceased to exist (*see* FRANCE: *History*).

In the Netherlands the convocation of the states-general, consisting of delegates from the provincial estates, dates from about the middle of the 15th century, under the rule of the dukes of Burgundy. The name was transferred, after the separation of the northern Netherlands from the Spanish dominions, to the representatives elected by the seven sovereign provincial estates for the general government of the United Provinces. The states-general, in which the voting was by provinces (each province having one vote) was established from 1593 at The Hague. The states-general came to an end after the revolution in 1795, with the convocation of the National assembly (March 1, 1796); but modern Holland continues to use their name for its national legislature, which consists of the first chamber and the second chamber. (*See* HOLLAND: *History.*)

**STATES OF THE CHURCH** or **PAPAL STATES,** that portion of central Italy which, previous to the unification of the kingdom, was under the direct government of the see of Rome. Area in 1859 was 16,000.8 sq.mi.; pop. in 1853, 3,124,758.

With the exception of Benevento, surrounded by the Neapolitan province of Principato Ulteriore, and the small State of Pontecorvo, enclosed within the Terra di Lavoro, the States of the Church formed a compact territory, bounded on the N.W. by the Lombardo-Venetian kingdom, N.E. by the Adriatic, S.E. by the kingdom of Naples, S.W. by the Mediterranean, and W. by the grand-duchy of Tuscany and the duchy of Modena. On the Adriatic the coast extended 140 mi. from the mouth of the Tronto (Truentus) to the southern mouth of the Po, and on the Tyrrhenian Sea 130 mi. from 41° 20′ to 42° 22′ N. latitude. The former papal territories are now comprised within the Italian provinces of Bologna, Ferrara, Forlì, Ravenna, Pesaro and Urbino, Ancona, Macerata, Ascoli-Piceno, Perugia, Rome and Benevento. For the origin of the territorial jurisdiction of the pope *see* PAPACY. With the moral and ecclesiastical decay of the papacy in the 9th and 10th centuries much of its territorial authority slipped from its grasp; and by the middle of the 11th century its rule was not recognized beyond Rome and the immediate vicinity. By the Treaty of Sutri (Feb. 1111) Paschal II was compelled by Emperor Henry V to surrender all the possessions and royalties of the church; but this treaty was soon repudiated, and by the will of Matilda, Countess of Tuscany, the papal see was enabled to lay claim to new territories of great value. By the capitulation of Neuss (1201) Emperor Otto IV recognized the papal authority over the whole tract from Radicofani in Tuscany to the pass of Ceperano on the Neapolitan frontier—the exarchate of Ravenna, the Pentapolis, the March of Ancona, the bishopric of Spoleto, Matilda's personal estates, and the countship of Brittenoro; but much of the territory described remained for centuries an object of ambition only by the popes. The actual annexation of Ravenna, Ancona, Bologna, Ferrara, etc., dates from the 16th century. The States of the Church were submerged for a time by the ground-swell of the French Revolution, but they reappeared in 1814. In 1849 they received a constitution. On the formation of the kingdom of Italy in 1860 they were reduced to the Comarca of Rome, the legation of Velletri, and the three delegations of Viterbo, Cività Vecchia and Frosinone; in 1870 they disappeared from the political map of Europe. From that time, the popes retired within the Vatican as self-constituted prisoners. This situation was changed by the Lateran treaty between the Holy See and the kingdom of Italy (signed Feb. 11, 1929), which recognized Pope Pius XI as sovereign of a clearly defined territory, entitled "the city of the Vatican." Therein the Holy See has full and exclusive dominion and sovereign jurisdiction. (*See* VATICAN; PIUS XI.)

**STATE SUCCESSION.** The extent to which a succession State is bound by the obligations of its predecessor constitutes one of the most difficult problems in international law. The clearest statement is probably that contained in the report of the Transvaal Concessions Commission; *see* Parl. Pap. South Africa, 1901 [Cd. 623]. The principles which the commissioners regarded as applicable to the determination of questions relating to various concessions granted by the Transvaal Government in view of the conquest and annexation of the Transvaal by Great Britain are as follows:—(1) "It is clear that a State which has annexed another State is not legally bound by any contract made by a State which has ceased to exist, and that no court of law has jurisdiction to enforce such contracts if the annexing State refuses to recognize them, see *Cook* v. *Sprigg* (1899) A. C. 572. But the modern usage of nations has tended in the direction of the acknowledgment of such contracts. After annexation, it has been said the people change their allegiance, but their relations to each other and their rights of property remain undisturbed, *U.S.* v. *Pencheman,* 7 Pet. 51; and property includes rights which lie in contract, *Soulard* v. *U.S.,* 4 Pet. 54." Concessions of a mixed public and private character probably continue to exist after annexation until abrogated by the succession State. There would not appear to be any distinction between cession and annexation. Private rights should be respected, but this is based rather on ethics than law. (2) "Though we doubt whether the duties of an annexing State towards those claiming under concessions or contracts . . . have been defined with such precision in authoritative statement or acted upon with such uniformity in civilized practice, we are convinced that the best modern opinion favours the view that as a general rule the obligations of the annexed State towards private persons should be respected. Manifestly the general rule must be subject to qualification, as that an insolvent State could not by aggression which practically left to a solvent no other course than to annex it, convert its worthless into valuable obligations; again an annexing State would be justified in refusing to recognize obligations incurred by the annexed State for the immediate purposes of the war against itself; and that probably no State would acknowledge private rights the existence of which caused or contributed to cause the war which resulted in annexation." (3) The principle to be adopted was that proclaimed by the Prussians upon the annexation of Hanover "we will protect every one in the possession and enjoyment of his duly acquired rights." (4) "The acceptance of this principle clearly renders it necessary that the annexing Government should in each case examine whether the rights which it is asked to recognize have, in fact, been duly acquired. (5) Thus a concession may properly be cancelled when "(*a*) the grant of the concession was not within the legal powers of the late Government, or (*b*) was in breach of a treaty with the annexing State, or (*c*) when the person seeking to maintain the concession acquired it unlawfully or by fraud, or (*d*) has failed to fulfil its essential conditions without lawful excuse." (6) A concession may be cancelled when its maintenance would be injurious to the public interest.

**STATESVILLE,** a city of North Carolina, U.S.A., county seat of Iredell county; 130 mi. W. of Raleigh, on federal highways 21, 64 and 70, and served by the Southern railway. Pop. 7,895 in 1920 (18% Negroes); 11,440 in 1940 by federal census.

The city is in the upper Piedmont section of the State, at an altitude of 960 feet. Statesville was laid out in 1790 as the capital of Iredell county (organized 1788), near old Ft. Dobbs, which was twice defended against the Indians by Daniel Boone, the most famous of American backwoodsmen. During the Civil War Governor Zebulon Vance took refuge in Statesville when Sherman entered Raleigh (April 13, 1865).

**STATIC,** a term in radio denoting conduction or charging current in an antenna (*q.v.*) resulting from physical contact between the antenna and charged bodies or masses of gas. In America this term is synonymous with atmospherics.

**STATICS,** the branch of mechanics which discusses the conditions of rest or equilibrium of forces (from Gr. root στα, stand) (*see* MECHANICS).

**STATIONARY MACHINERY:** *see* PROCESSING MACHINERY.

**STATIONERY.** The word now covers all writing materials and implements, together with the numerous appliances of the desk and of mercantile and commercial offices. The principal articles and operations of the stationery trade are dealt with under such headings as BOOKBINDING; OFFICE APPLIANCES; INK; LITHOGRAPHY; PAPER; PEN and PENCIL.

**STATIONS OF THE CROSS,** a series of 14 pictures or images representing the closing scenes in the Passion of Christ, viz., (1) the condemnation by Pilate, (2) the reception of the cross, (3) Christ's first fall, (4) the meeting with His mother, (5) Simon of Cyrene carrying the cross, (6) Veronica wiping the face of Jesus, (7) the second fall, (8) the exhortation to the women of Jerusalem, (9) the third fall, (10) the stripping of the clothes, (11) the crucifixion, (12) the death, (13) the descent from the cross, (14) the burial. Sometimes a 15th—the finding of the cross by Helena—is added; on the other hand in the diocese of Vienna, the stations were at the end of the 18th century reduced to eleven. The representations are usually ranged round the church; sometimes they are found in the open air, especially on the ascent to some elevated church or shrine. The normal form of the devotion, which began among the Franciscans, is to visit the stations of the cross wherever represented, and exercise a devout meditation on passing from station to station.

*See* article "Stations of the Cross" in the *Catholic Encyclopaedia.*

**STATISTICS.** The name *statistics* was first applied to collections of data relating to matters important to the State, such as the numbers of the population, the yield of taxation, the value of trade carried on within the territory of the State or between that territory and other parts of the world, the mortality from particular diseases and from all causes together, etc., and to the study and interpretation of such data. The data were not at first numerical and later not exclusively numerical, but the precision and convenience of data expressed in numbers, as compared with other forms of statement, have led to the more general cultivation of arithmetical data and to the common use of the term "statistics" as if it related exclusively to data expressed in numerical form. At the same time, the numerical data to which the name "statistics" is generally applied are not limited to such as have some connection with the organization or administration of the State, the methods appropriate to the study of statistics being, broadly speaking, the same whether the data under consideration relate to human communities or are concerned with any other branch of knowledge or investigation.

**Statistical Tables.**—The simplest way of arranging numerical records is to set them out in tabular form. We may, for example, ascertain the amount of sugar consumed in a given country in each year of a given period. A table may be drawn up in which each line contains the figures for the year the date of which is shown at the beginning of the line. If each line relates to the year next following that dealt with in the preceding line, the sequence of figures of consumption will enable us to determine whether, and at what rate, the yearly consumption of sugar increased in successive intervals of years. The increase of population from year to year observed in most countries is an obvious influence tending to increased use of any popular article of consumption, and it will be advantageous to add, to the figures showing the total consumption of sugar in the country, another series of figures showing the number of persons living in that country in each of the years covered by the table. To the columns containing (1) the dates of the years to which the information relates, and (2) the total amounts of sugar consumed in the respective years, there will thus be added (3) a column showing the numbers of persons concerned in the consumption of these quantities of sugar. The significance of this last column in relation to the preceding may be made clearer by the addition of a fourth column (4) deduced from the two preceding by dividing the quantity of sugar shown in any line of the table by the number of the population shown in the same line, thus obtaining the average amount of sugar consumed per head of the specified population. The form of the table is sufficiently indicated by means of the lines relating to the United Kingdom in ten years, 1903 and 1913, given below:

*Consumption of Sugar in the United Kingdom*

| (1) Year | (2) Total consumption thousand cwt. | (3) Population thousands | (4) Consumption per head, lb. |
|---|---|---|---|
| 1903 . . . | 28·847 | 42·247 | 76·5 |
| 1913 . . . | 36·734 | 45·713 | 90·0 |

If to this table further columns are added or a new table is drawn up, in which data relating to the consumption of tea in the same country and in the same years is set out, we obtain two sets of facts the comparison of which may prove of interest and importance. We can ascertain whether the variations in the consumption of sugar and of tea were related.

**Graphs.**—It is frequently of advantage to set out in diagrammatic form such tabulated results as those referred to, as at least the broader features of the comparison of two or more series of

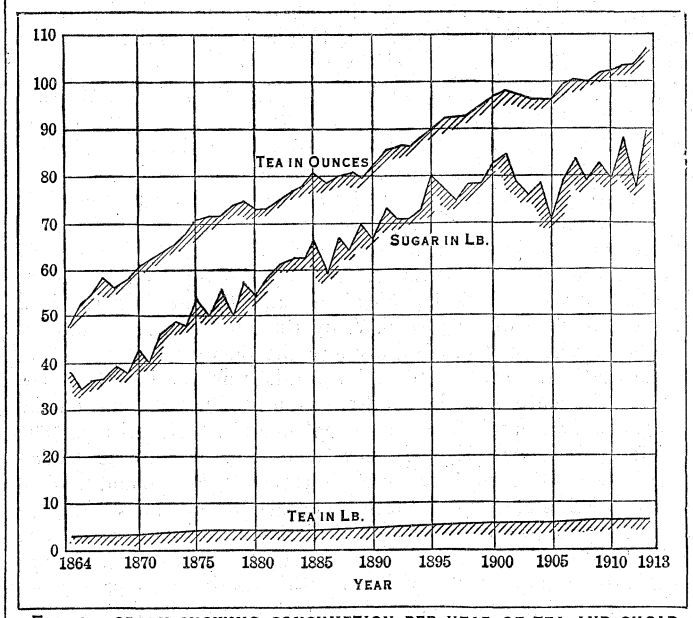

FIG. 1.—GRAPH SHOWING CONSUMPTION PER HEAD OF TEA AND SUGAR IN THE UNITED KINGDOM IN EACH YEAR, 1864–1913
Quantities in stock at the end of each year are not taken into account

figures can often be seen more clearly in this form. Such simple graphical comparisons are familiar through their use in meteorological reports where readings are shown by the upward and downward movements of a line crossing from left to right a series of vertical lines marking the hours of the day or the days of the week. The particulars of the consumption, per head of the population of the United Kingdom, of sugar and of tea in each of the 50 years from 1864 to 1913, are thus shown in Fig. (1). A necessary precaution in planning such graphical comparisons is also illustrated in the same diagram. The figures which are plotted relating to sugar show the average consumption year by year in lb. per head. The consumption of tea in lb. per head yields the

line at the foot of the diagram, the variations of which are so slight as to suggest no similarity with those of the line showing sugar consumed. If, however, the consumption of tea per head is expressed in ounces, it becomes clear that, though in individual years the variations shown are by no means similar for sugar and for tea, over the whole period the increase was in approximately the same proportion for these two commodities[1]. The fluctuations were more considerable in the case of sugar, and the diagram suggests that, up to 1901, the quantities of sugar increased somewhat more rapidly than, and thereafter failed to maintain as great an increase as, those of tea.

Even though graphs fall short, in the matter of precision of statement, of the numerical tables, they have the great advantage of enabling a large mass of figures to be grasped as a whole much more readily than is possible when those figures are presented in one or more tables.

**Averages and Dispersion.**—A second illustration of statistical series is seen in the following summary of the heights of a number of men:—

| Height in inches. | 61 | 62 | 63 | 64 | 65 | 66 | 67 |
|---|---|---|---|---|---|---|---|
| Number recorded | 2 | 10 | 11 | 38 | 57 | 73 | 106 |
| Height in inches. | 68 | 69 | 70 | 71 | 72 | 73 | 74 |
| Number recorded | 126 | 109 | 87 | 75 | 23 | 9 | 4 |

The table may be interpreted as meaning that 126 were found between 5 ft. $7\frac{1}{2}$ in. and 5 ft. $8\frac{1}{2}$ in. and similarly for other heights. In tables such as this some method of dealing with cases falling exactly on the dividing line between two adjacent groups must be laid down, and a common method is to assign half the number found on the dividing line to each of the classes of which it forms the limit. This procedure may, of course, result in numbers in some of the groups which are not integers. The true average height of the 730 men covered by the table can be ascertained only by reference to a more detailed statement showing the height of each man exactly, instead of in a number of groups. It will be observed that 297 were not taller than 5 ft. $7\frac{1}{2}$ in., while 307 were 5 ft. $8\frac{1}{2}$ in. or more, the distribution being not quite symmetrical on both sides of the numerically largest group. The approximate average height was about $\frac{1}{20}$in. less than 5 ft. 8 in.

A table of this kind tells us, however, something more than the average height of the individuals represented. We note that 191 were not more than 5 ft. $6\frac{1}{2}$ in. in height and 198 were not less than 5 ft. $9\frac{1}{2}$ in. in height. By calculation from the figures shown, assuming that the individual heights were distributed with approximate regularity along the intervals from inch to inch, the points representing 5 ft. 6·3 in. and 5 ft. 9·7 in. would divide the series of heights so that one-quarter of the whole number fell below the former, and one-quarter of the whole number above the latter. A similar calculation gives, as the point dividing the series into two equally numerous groups, 5 ft. 8·04 in. This last point is called the *median* of the series, and the two others are the *lower* and *upper quartiles*, the three points serving to divide the whole number examined into four groups of equal numbers of cases. The distance between the upper and lower quartiles, in the case in question 3·4 in., gives the range within which the middle half of the instances recorded lay. This distance expresses much more definitely the degree of concentration of the individuals in the neighbourhood of the median height than, for example, the whole range (14 in.) within which all the measurements lie. If a more exact description of the nature of the distribution than is afforded by the specification of the median and quartiles, but of the same general character, is desired, the group may be divided into a number of parts, *e.g.*, into ten equally numerous parts, the points of division being then known as *deciles*.

In many varieties of statistical problems it is found that the observations are distributed in a manner similar to that shown in the above illustration, and the question arises whether the form of the distribution is of a recognizably definite character, the determination of which can be of use in the interpretation of the results obtained. It is found that, in numerous cases, the manner in which the individual observations are distributed is in close accordance with that of events dependent on pure chance. Such a case is presented by the following. A number of balls, indistinguishable in size, weight or form, are placed in a bag, half of the balls being white and half black. If one ball be drawn from the bag, its colour, whether white or black, may be noted. The ball being replaced and the bag shaken, another drawing will give a result wholly independent of the first. The repetition of such drawings will furnish a record of runs of white and of black balls, some short, some long. The numbers of cases (a) of a change of colour in consecutive drawings (b) of sequences of the same colour of two, three, four, etc., in number, being noted, the material for a table is furnished, and this table would have a general similarity with that of the men's heights used above for illustration. It is possible to determine theoretically the relative frequency with which the various sequences would recur in a series of trials indefinitely extended.

If, in a large number of drawings, sequences of $x_r$ white (or of $x_r$ black) balls are recorded on $Y_r$ occasions, the total number $n$ of drawings will be expressed by $n=x_1Y_1+x_2Y_2+x_3Y_3+\ldots+x_rY_r+\ldots$. The relative frequencies of the different series are $y_1$, $y_2$, etc., where $n\cdot y_1=Y_1$, $n\cdot y_2=Y_2$, etc., and, when $n$ is indefinitely increased, the relation between the $x$'s and the $y$'s is expressed by the formula $y=a\cdot e^{-mx^2}$, which represents a curve of the shape shown below in fig. (2), known as the probability curve.

It is not proposed to enter into discussion of the character of the probability curve, or the interpretation of the variations. It will be sufficient here to point out that the equation given relates to a curve symmetrical in form to right and left of the position represented by $x=0$. The part to the right may be supposed to show the record of white sequences, and that to the left the

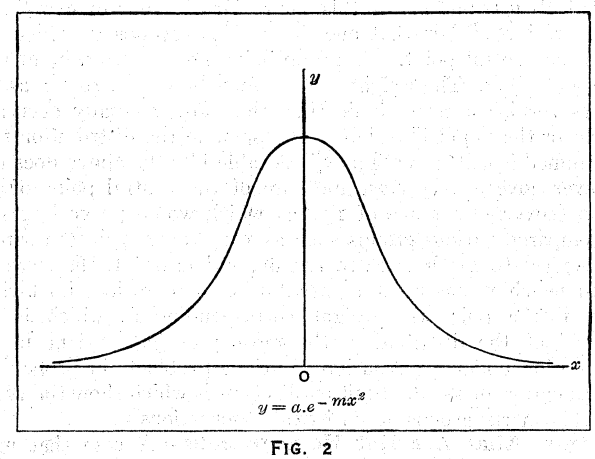

FIG. 2

exactly similar record of black sequences, *i.e.*, of sequences in which white balls failed to appear.

In any actual series of observations (*e.g.*, of the colours of balls drawn from, and returned to, a bag) the observed numbers expressing the frequency of different events will be found to differ more or less from those expressed by the curve, of the form given by the above equation, which is appropriate to the circumstances of the experiment. Prolonged trials would give results approximating to those derived from theoretical calculations and expressed in the shape of the probability curve. Thus, in the case of the heights of 730 men, it is probable that records covering larger numbers of men, of the same race and social condition and within the same limits of age as those from which the 730 were selected, would give a distribution of heights more closely corresponding to that shown by a typical probability curve than the numbers cited. If, for example, for every one actually covered by our table, 10 or 20 or 50 or 100 had been measured, closer correspondence with a suitably selected theoretical series would have been probable.

In considering the meaning of changes in the observed frequency of events, it is generally of considerable importance to ascertain what is the extent of variation that is as likely to happen as not, since the significance of actual variations can only be

[1] *Cf.* Jubilee Vol. of the Royal Statistical Society, p. 257, where the late Professor Marshall used this illustration. The figures are based on imports less exports of sugar, excluding sugared goods.

judged in relation to those which may have no significance at all in reference to the problem under consideration.

**Skew Distributions.**—The normal probability curve, referred to above, is not the only form resulting from the theoretic consideration of chance events, and presenting close correspondence with statistical records of various kinds. The study of these forms, and of their theoretical bases, has been particularly active since the last decade of the 19th century. It will suffice here to mention that particular statistical problems are found to yield distributions of observations, not only symmetrical on either side of their mean, as with the normal probability curve, but also grouped more closely on one side of the mean than on the other. The illustration from men's heights showed some small tendency to a skew shape, though it appears possible that the apparent deformation would, on extending the field of observation, be found to disappear and be shown to result from the fact that, in so small a number of cases as 730, the even representation of men of all heights in the population from which these cases were drawn had not been exactly secured. The following records of weights of men of 25 and less than 30 years of age and within half an inch of 5 ft. 6 in. in height, shows a more marked skewness.

| Weight in lb. | 105 | 120 | 135 | 150 | 165 | 180 | 195 | 210 |
|---|---|---|---|---|---|---|---|---|
| Number of cases | 17 | 722 | 2,175 | 1,346 | 485 | 155 | 33 | 3 |

In this case the average (or arithmetic mean) of the weights of the 4,936 men is, on the assumption of continuous distribution, approximately 141·6 lb. The median is at about 1 lb. less, viz., 140·5 lb. In the previous illustration of heights, the median was greater than the mean, so that the skewness shown is of opposite direction in the two cases.

This illustration serves also to show a third characteristic of statistical distributions of this kind. Nearly four of every nine cases are included in that one of the eight groups of which 135 lb. is the central point, this group being notably more numerous than any other. The weight 135 lb. may be called, so far as the figures furnish a ready indication, the most generally occurring weight or the "modal" weight. The point in the distribution thus determined is called the "mode." A table like the above does not, however, give a very close measure of the central point of the group (covering a range of 15 lb.) which would prove largest if we compared various groups such as 127½ to 142½ lb. (the group shown) 127 to 142 lb., 128 to 143 lb., and so on. If the curve be found which represents the distribution in question, its highest point is the point the weight corresponding to which is the "mode" of the distribution, the most prevalent weight in the distribution under examination. Various problems in probability lead to curves of the distribution of chances which show the skewness that marks groups of statistical observations.

**Groups That Are Not Homogeneous.**—A case that may, however, be mentioned is that in which the measurements obtained relate, not to a homogeneous group, but to a mixture of two or more groups. The manner in which such a mixture might affect the characteristics of a distribution may be illustrated from the figures given below for the heights of a particular group of men. Suppose two such groups were found differing in the heights of the individuals composing them, but in such a way that the numbers in one of them whose heights were between any two specified limits were exactly twice those for limits an inch higher in the other group. We might have, for example:—

| Height in inches. | 60–61 | 61–62 | 62–63 | 63–64 | 64–65 | 65–66 | 66–67 | 67–68 | 68–69 | 69–70 | 70–71 | 71–72 | 72–73 | 73–74 | 74–75 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Numbers in Group I. | 4 | 20 | 22 | 76 | 114 | 146 | 212 | 252 | 218 | 174 | 150 | 46 | 18 | 8 | .. |
| Numbers in Group II. | .. | 2 | 10 | 11 | 38 | 57 | 73 | 106 | 126 | 109 | 87 | 75 | 23 | 9 | 4 |
| Numbers in the two groups | 4 | 22 | 32 | 87 | 152 | 203 | 285 | 358 | 344 | 283 | 237 | 121 | 41 | 17 | 4 |

The numbers in the last row represent a compound of two groups as numerous as the original group, the individuals of each of which were half an inch shorter than those of the original group, and another group, equal in number to the original group, the individuals of which were half an inch taller than those of the original group. If the distribution of the original group were such as could be precisely represented by an appropriate theoretical formula, the compound group would not be, in general, represented by the same formula. In some instances, it has been found possible to show that an observed group was so distributed as to be consistent with the assumption that it was made up of two groups of different characteristics, the members of which were included within one and the same series of observations. Such an analysis can clearly be of considerable importance with reference to the deductions to be drawn from the examination of the observed data.

**Three Variable Elements.**—In what precedes, the statistical material considered has consisted of series of pairs of quantities, the values of the two quantities in each pair being related; for example, where one of the quantities is the height of a man, the other the relative frequency with which men of that height were observed. We pass now to the consideration of series of three quantities, for example, where two of the quantities express the measures of different phenomena (which may be connected in some way, or may be independent) and the third expresses the relative frequency with which any combination of the other two occurs. Such a series is represented in the table given below, which shows the proportions in which, over a period of years, in a particular country, marriages in which both bride and bridegroom had been married previously were distributed according to the ages of the brides and of the bridegrooms. The particulars might advantageously be set out in fuller detail, but the condensed table will serve quite well to illustrate the nature of the problems connected with the analysis of data of this kind.

| Ages of wives at date of marriage | Ages of husbands at date of marriage | | | | | | Total wives |
|---|---|---|---|---|---|---|---|
| | Under 25 | 25–34 | 35–44 | 45–54 | 55–64 | 65 and over | |
| Under 25 | 10 | 75 | 46 | 13 | 3 | .. | 147 |
| 25–34 | 20 | 175 | 167 | 65 | 17 | 3 | 447 |
| 35–44 | 5 | 54 | 104 | 79 | 29 | 7 | 278 |
| 45–54 | .. | 5 | 18 | 36 | 33 | 9 | 101 |
| 55–64 | .. | .. | 1 | 5 | 13 | 5 | 24 |
| 65 and over | .. | .. | .. | .. | 1 | 2 | 3 |
| Total husbands | 35 | 309 | 336 | 198 | 96 | 26 | 1,000 |

The table is to be read as follows: Of each thousand women married for the second (or later) time to men who had been married before, 447 were between 25 and 35 years old, and of these 20 married men under 25 years of age, 175 married men between 25 and 35, 167 married men between 35 and 45 and 17 men between 45 and 55. The other rows of figures will be read similarly, and the columns are to be read in corresponding manner, with the words "husband" and "wife" interchanged.

The columns, and also the rows, representing the age distributions of particular sections of the wives and of the husbands, are examples of skew distribution of numbers. It is clear, from the clustering of numbers in the neighbourhood of a band crossing the table from its upper left side towards its lower right side, that there is some association between the ages of the wives and the husbands, which are more often relatively high together, or relatively low together, than in other relations. The average age of the husbands is near 41 years and that of the wives somewhat in excess of 34 years.

**Correlation.**—If the average ages of the husbands shown in each row of the table be computed, and also those of the wives shown in each column, the two series of figures thus obtained show

the variation of the average ages of corresponding groups of husbands and wives. They furnish the measures of what are known as the regression of the ages of husbands on those of wives, and the regression of the ages of wives on those of husbands. The two regressions would be complementary if the distribution represented complete linear correlation of husbands' ages and wives' ages. When this complete correlation is not shown, a measure of the degree in which the distribution diverges from that corresponding to complete correlation is afforded by the so-called coefficient of correlation. Between two series of quantities

$$x_1, x_2, x_3 \ldots\ldots$$

and

$$y_1, y_2, y_3 \ldots\ldots$$

if the sums of the squares of each series, $S(x^2)$ and $S(y^2)$ be calculated, and the sum of the pairs of products $x_1y_1$, $x_2y_2$, $x_3y_3$ . . . , *i.e.*, $S(x{\cdot}y)$ be also calculated, the fraction $S(x{\cdot}y)/\sqrt{[S(x^2){\cdot}S(y^2)]}$ gives the coefficient of correlation.

In the case represented by the final row and the final column of the last table, the calculation gives a fraction exceeding ·9. The highest possible value for the coefficient is 1. The coefficient is a measure of the divergence between the two lines of regression in cases like that illustrated, those two lines coalescing when the correlation is complete. If the series compared are such that decreases in the one correspond to increases in the other, the calculated coefficient is negative. The range of values for the coefficient lies between 0 and 1 for positive correlations and between 0 and —1 for negative correlations. Small values of the coefficient mean that the connection between the series is slight, and, in view of the extent to which, in actual observations, the records obtained are affected by disturbances having no relation to the matter under examination, no great significance can generally be attached to the occurrence of correlation coefficients of small magnitude.

The class of problem of which the figures given in the last table furnish an illustration is one of great importance in statistical work. Thus the variation of the height and weight of men with their age, the questions relating to the transmission of characteristics from parents to children, the association of different diseases or defects and the results of combinations of treatment of diseases or defects, the interpretation of the results of variation in different features of the weather, for example rainfall and temperature, on crop yields and many other problems give rise to such distributions, while the limitation of the illustration to the case of three kinds of variation should not be taken to imply that larger numbers of elements may not be considered.

The practical application of the procedure of calculating coefficients of correlation is not confined to cases such as that in connection with which the nature of correlation was illustrated. It may also be applied to determine, in cases such as that of the consumption of sugar and of tea, illustrated earlier, the closeness with which the variations in the two series of figures coincide. In some cases it is of importance to compare, not two series the trends of which are, on the whole, similar, but two series of which the trends are different, though the variations from the general trend may prove to be similar in the two cases. Whether for diagrammatic representation, or for preliminary arrangement of material for testing by the calculation of coefficients of correlation, it is desirable to isolate the important features as far as possible. The relation between economic prosperity and the marriage rate is a problem that has attracted much attention, and in using as a measure of economic prosperity the value of the exports year by year, or of imports and exports together, the connection which appears in some periods may be obscured in later periods by other conditions which cause one or other, or both, of the curves compared to diverge from the trend previously shown. To a considerable extent the effect of these disturbing elements in obscuring the significant relation may be evaded by using for comparison, not the absolute measures, *e.g.*, of the value of trade and of the marriage rate, but the proportion in which the figures for a given year are in excess or defect in comparison with those of the average of a series of several years of which the year under consideration is the middle year, or the final year.

It may be noted that when two series of quantities, showing the variations in time of phenomena under examination, are tested for closeness of fit by the calculation of correlation coefficients, it is possible to test whether one of the two series differs from the other mainly in respect of the time at which variations are greatest or smallest. In comparing two series such as

$$x_1\ x_2\ x_3\ x_4 \ldots\ldots$$
$$y_1\ y_2\ y_3\ y_4 \ldots\ldots$$

the sum of products used in calculating the correlation coefficient was conceived of as

$$x_1\ y_1 + x_2\ y_2 + x_3\ y_3 + \ldots\ldots$$

It may be found that such product-sums as

$$x_1\ y_2 + x_2\ y_3 + x_3\ y_4 + \ldots\ldots$$

or

$$x_2y_1 + x_3y_2 + x_4y_3 + \ldots\ldots$$

show significantly larger resulting coefficients than the product-sum first named. If so, it may be taken as meaning that of the two phenomena the variations of which are compared, those variations are not contemporaneous, but the members of one series follow, or precede, those of the other by a roughly constant interval. The repetition of the calculations for several different intervals may furnish a measure of the lag of one of the two phenomena on the other.

It has been stated that the lowest value of the correlation coefficient is zero. It may be added that when, in practice, a calculation of such a coefficient gives a result practically equal to zero, it is not to be concluded that there is no correlation between the quantities. The form given for the correlation coefficient was based on the assumption that the lines of regression were sufficiently nearly straight lines to render it unnecessary to call attention to their divergence from that form. In some cases in which a high correlation with non-linear regression exists, the coefficient calculated by the formula given will be small. On the other hand, there are cases in which large correlation coefficients result from the formula of calculation, though the phenomena compared are, in fact, not related to each other. The principal cause of such apparently strange results is found in the fact that actual series of observations may be but small samples of the universe of phenomena of which they are taken as representative, and in small samples the securing of really representative results is not easily achieved. We turn, therefore, to the consideration of some questions relative to sampling.

**Sampling.**—Two principal reasons lead to the use of statistics of samples in place of complete statistics of an exhaustive character covering the whole of the so-called universe of instances. One is that only portions of that universe may be accessible as sources of data, the other that the labour and expense involved in handling very large masses of statistics render it expedient to seek representative selections of moderate extent as the basis of the data to be submitted to detailed examination. In the latter case, it is to be supposed that the selection of instances is at the discretion of the investigator, and the practical question involved is the devising of a means that will ensure that the instances selected should give, as far as is possible, a picture *in petto* of the whole field of enquiry.

The most common method is to choose the instances in a manner that shall ensure that there is no concentration on those possessing any particular characteristic in preference to those lacking that characteristic. All cases are to be given an equal chance of selection; the sample is to be a *random* selection. It is only necessary to illustrate the kind of procedure that will secure that result. Suppose we have to select 200 cases from a total of (say) 20,000. We may, if the 20,000 are arranged in any kind of sequence, take the first, pass over 99 and take the case then next following, again pass over 99 and take the case then next following, and so on. Another method would be to place in a bag cards bearing the series of numbers from 1 to 20,000 and to draw from the bag 200 cards in succession, shaking the bag between each pair of drawings. The numbers of the cards drawn would show what choice of cases from the complete series should be made, and any effect produced by the arrangement of the cases in a particular order, which might influence the result of the method of selection first named, would tend to be avoided by the second procedure.

Random sampling has, as its object, as already stated, the securing of a comparatively small group possessing the same general characteristics, *i.e.*, showing the same proportions in which each special feature is present or absent, as the complete series of cases. This may, in some conditions, be secured more effectively by deliberate selection of instances in which a number of characteristics are distributed in a manner similar to that in which the same characteristics are distributed in the mass from which the sample is taken. This involves, of course, that, in respect of the characteristics used as guides, available records exist covering the mass.

Another mode of testing a sample in respect of its representative character is to divide it into two or more parts at random, and compare the characteristics of the separate parts. Agreement between the parts is commonly taken as an indication that the sample is representative in character, though such agreement, or its absence, is not a final test. To illustrate, suppose the special case of random samples of men of specified age from a defined race and locality. Suppose a sample of 1,000 such men taken, and their characteristics examined: for example, their average height, median height, the dispersion of these heights and other features of the distribution of heights may be determined. The process may be repeated for a second, third, etc., sample of 1,000 until we have (say) 1,000 sets of results derived from 1,000 samples each consisting of 1,000 units. Taking one of the characteristics, say the average height, we may examine 1,000 results from the separate samples. It will almost certainly happen that these differ from one another but slightly as compared with the differences between the heights of the individuals in any one sample. But these averages would themselves generally possess a degree of variation, and their grouping according to their order of magnitude would furnish a frequency distribution having its own mean, median, dispersion, etc. This latter distribution would, in fact, indicate the degree of variability of the results obtained by sampling.

The study of the mathematical theory relating to the problems thus illustrated furnishes estimates of the answers to such questions as: what is the probability that the divergence of the mean value of a specified feature of the sample from the (unknown) mean value of the same feature of the universe from which the sample is drawn shall not be greater than a specified amount? The answers may be a guide to a decision on the questions of whether procedure by sample is satisfactory, and what size of sample may be desirable to justify the use of the sampling method.

When procedure by sample is adopted because only data derived from samples are procurable, the investigation of the entire mass of cases being excluded, the use of methods aimed at securing that the samples are *random* or are *representative* is, generally if not universally, not a matter for consideration. It is, therefore, of the greatest importance to examine the conditions affecting the selection of the sample. It may be found that some bias in the selection is unavoidable, while the extent to which that bias affects the results may not be capable of estimation. To apply to the results of biassed sampling the tests and limitations determinable by theory for the case of random sampling may lead to error.

The relative stability of the relations between different groups of statistics relating to human communities and their organization was a feature that attracted attention at a very early stage of statistical enquiry. Changes in habits of masses of men are generally of slow development. The consequence is that any well ascertained sequence of phenomena in economics may be expected to be repeated, that is, the repetition of certain conditions may be expected to be followed by consequences of a definite character. The underlying assumption is the permanence of the essential determining features of the organism with whose manifestations we are concerned. The introduction of new conditions, not all of which may be obvious or ascertainable, may destroy that stability of relations on the faith of which future changes might be expected when observed conditions show particular mutual relations. Not only new conditions, but also the deviations from uniformity recognizable in the comparison of different samples of one and the same universe of phenomena, must be kept in mind in forming any judgment of the probable future based on observations of the course of events in the recent past.

**Sources of Statistical Data.**—In the work of administration, the governments of most civilized countries are able to make exhaustive enumerations of various classes of events occurring within their territory. A few examples are:—the number of births in successive weeks, months or years, the deaths in the same periods, the causes of deaths and the sexes and ages of the persons dying, the amount of property or income serving as the basis of assessment to taxation of individual citizens, the value and quantity of each of various kinds of merchandise imported from or exported to other countries during any determined interval of time, the numbers of various kinds of animals existing in the country at selected dates, the length of the roads maintained at the public expense and of the railway tracks existing from time to time, the numbers of various kinds of vehicles for the use of which licences are required, the quantities of certain dutiable articles of food and drink on which duties are paid in successive months or years.

From time to time, generally at intervals of ten years, the total number of persons of each sex, the age of each being also recorded, is ascertained for each administrative subdivision of the country, and either simultaneously or on other, and possibly less frequent, occasions the number of persons engaged in each principal class of occupation is also generally ascertained.

Organizations of a private character, including corporate bodies, obtain, like the public administrative bodies, much information for their own guidance, some of which is made public. In some cases there results an exhaustive enumeration of events of certain kinds occurring within the country, in other cases a series of more or less representative illustrations of what has happened is furnished. Thus the total weight of goods carried by railway may be available, while the quantities of gas, water or electricity supplied may only be made public by some of the undertakings supplying them, and the extent to which the ascertained aggregates fall short of the actual aggregates supplied may be variable in a degree that cannot be determined and may be of importance.

In addition to the data arising out of the general administration of a country, and those published by business organizations, statistical data may be obtained as the outcome of special enquiries by either of these classes of bodies or by private bodies or persons. The latter class of data generally presents the characteristic just referred to as affecting some of the data obtained by business organizations, namely, that an exhaustive enumeration covering the whole country is not secured. What is obtained is a record relating to a part, more or less typical of the whole so far as the matter under examination is concerned. The principles to which attention was directed in the paragraphs relating to sampling apply to the statistics thus secured. (A. W. F.)

**STATIUS, PUBLIUS PAPINIUS** (*c.* A.D. 45–96), Latin poet, was born at Naples. His father was also a poet, and Statius seems to have been trained as one from the start. Of events in the life of Statius we know little. From his boyhood he was victorious in poetic contests—many times at his native city Naples, thrice at Alba, where he received the golden crown from the hand of the emperor Domitian. But at the great Capitoline competition (probably on its third celebration in A.D. 94) Statius failed to win the coveted chaplet of oak leaves. Perhaps the emperor's favour had failed him; in any case, he withdrew to Naples (*Silv.* iii. 5).

The rôle of court poet seems to have suited Statius. His flattery is as far removed from the gentle propitiatory tone of Quintilian as it is from the coarse and crawling humiliation of Martial. It is in the large extravagant style of a nature in itself healthy and generous, which has accepted the theme and left scruples

behind. In one of his prefatory epistles Statius declares that he never allowed any work of his to go forth without invoking the godhead of the divine emperor. Statius had taken the full measure of Domitian's gross taste, and, presenting him with the rodomontade which he loved, puts conscience and sincerity out of view, lest some uneasy twinge should mar his master's enjoyment.

As a poet, Statius unquestionably shines in many respects when compared with most other post-Augustans. He was born with exceptional talent, and his poetic expression is, with all its faults, richer on the whole and less forced, more buoyant and more felicitous, than is to be found generally in the Silver Age of Latin poetry. Statius is at his best in his occasional verses, the *Silvae,* which have a character of their own, and in their best parts a charm of their own. The subjects of the *Silvae* are very various. Five poems are devoted to flattery of the emperor and his favourites; but of these enough has already been said. Six are lamentations for deaths, or consolations to survivors. Another group of the *Silvae* give picturesque descriptions of the villas and gardens of the poet's friends. In the "Kalendae decembres" we have a striking description of the gifts and amusements provided by the emperor for the Roman population on the occasion of the Saturnalia. In his attempt at an epithalamium (*Silv.* i. 2) Statius is forced and unhappy. But his birthday ode in Lucan's honour (*Silv.* ii. 7) has, along with the accustomed exaggeration, many powerful lines, and shows high appreciation of preceding Latin poets. Some phrases, such as "the untaught muse of high-souled Ennius" and "the lofty passion of sage Lucretius," are familiar words with all scholars.

The epic poems of Statius are less interesting because cast in a commoner mould, but they deserve study in many respects. They are the product of long elaboration. The *Thebais,* which the poet says took 12 years to compose, is in 12 books, and has for its theme the old "tale of Thebes"—the deadly strife of the Theban brothers. There is also preserved a fragment of an *Achilleis,* consisting of one book and part of another. In the weary length of these epics there are many flowers of pathos and many little finished gem-pictures, but the trammels of tradition, the fashionable taste and the narrow bars of education check continually the poet's flight.

The *editio princeps* of the epics is dated 1470, of the *Silvae* 1472. Notable editions since have been those of Bernartius (Antwerp, 1595), Gronovius (1653) and Barth (1664). Recent texts are the Teubner (the *Achilleis* and *Thebais* by Kohlmann, the *Silvae* by Baehrens) and that contained in the new edition of the *Corpus poetarum latinorum;* and of the *Silvae* only, texts by Klotz (1899), and Vollmer (1898), the last with an explanatory commentary. Among editions of portions of Statius's works, that of the *Silvae* by Markland (1728) deserves special attention. A translation of the *Silvae* with introduction and notes was published by D. A. Slater in 1908 (Oxford Library of Translations). A critical edition of the *Thebais* and *Achilleis* was begun by O. Müller (*Thebaid* i.–vi., Leipzig, 1870) but not completed.

For the poet's life *see* Lehanneus, *De P. P. Statii Vita et Operibus* (La Rochelle, 1878); *Riv. Fil.* 35 (1907) 3. (J. S. R.; X.)

**STATUE OF LIBERTY.** *See* LIBERTY, STATUE OF.

**STATUTE,** in English law, is a law made by the "sovereign power" in the State. (*See* ACT OF PARLIAMENT.) It forms a part of the *lex scripta,* which by English legal authorities is used solely for statutory law, a sense much narrower than it bore in Roman law. To make a statute the concurrence of the Crown and the three estates of the realm is necessary. Thus a so-called statute of 5 Ric. II. c. 5, directed against the Lollards, was afterwards repudiated by the Commons as passed without their assent. The validity of a statute was indeed at times claimed for ordinances such as that just mentioned, not framed in accordance with constitutional rule, and was actually given to royal proclamations by 31 Hen. VIII. c. 8 (1539). But this Act was repealed by 1 Edw. VI. c. 12, and since that time nothing but a statute has possessed the force of a statute, except perhaps certain subordinate legislation ("Statutory Rules and Orders"), the making of which has been delegated by parliament to departments and other authorities (*see* also PROVISIONAL ORDER), and except Church Assembly Measures passed under the Church of England Assembly (Powers) Act of 1919 and presented for the royal assent after a favourable resolution of both houses of parliament.

The list of English statutes as at present existing begins with the Statute of Merton, 1235. The earliest existing statute roll is 6 Edw. I. (the Statute of Gloucester). After 4 Hen. VII. the statute roll ceased to be made up, and enrolments in chancery (first made in 1485) take its place.

All statutes were originally public, irrespective of their subject-matter. The division into public and private dates from the reign of Richard III. At present statutes are of four kinds, public general Acts, public local and personal Acts, private Acts printed by the king's printers and private Acts not so printed. The division into public general and public local and personal rests upon a resolution of both houses of parliament in 1798. In 1815 a resolution was passed in accordance with which private Acts are printed, with the exception of name, estate, naturalization and divorce Acts. The last two are now practically superseded by changes in the law of divorce and nationality. Each Act is strictly but a chapter of the legislation of the session, which is regarded as composing a single Act divided into chapters for convenience, the chapters themselves being also called Acts. The citation of previous Acts is provided for by the Interpretation Act 1889 (s. 35). Every Act now contains a short title by which it may be cited, *e.g.,* the Housing Act 1925. The Short Titles Act 1896 creates short titles for numerous single Acts and groups of Acts, and it is now usual to cite Acts and groups by their short and collective titles rather than by the year of the reign. At common law judicial notice is taken of all public Acts of parliament; the king's printers' copies of private and local and personal Acts are admitted as evidence without further proof under the Evidence Act 1845; private Acts not printed by the king's printers are proved by an examined copy of the parliament roll.

A public Act binds all subjects of the realm, and need not be pleaded (except where the law from motives of policy specially provides for pleading certain Acts, as in the defences of not guilty by statute, the Statute of Frauds and the Statute of Limitations). A private Act must generally be pleaded, and does not as a rule bind strangers to its provisions. Formerly an Act took effect from the first day of the session in which it was passed. The hardship caused by this technical rule was obviated by statute in 1793, since when an Act takes effect from the day on which it receives the royal assent, where no other date is named. This has been held to mean the beginning of the day, so as to govern all matters occurring on that day. An Act cannot in the strict theory of English law become obsolete by disuse. Nothing short of repeal can limit its operation. The law has, however, been interpreted in many cases with somewhat less rigour. In the case of a prosecution for blasphemy in 1883 (*R.* v. *Ramsay*) Lord Coleridge said, "though the principles of law remain unchanged, yet (and it is one of the advantages of the common law) their application is to be changed with the changing circumstances of the times." This would be applicable as much to the interpretation of statutes as to other parts of the common law. The title, preamble and marginal notes are strictly no part of a statute, though they may at times aid its interpretation; the same is true of punctuation and brackets.

Besides the fourfold division above mentioned, statutes are often classed according to their subject-matter, as perpetual and temporary, penal and beneficial, imperative and directory, enabling and disabling. Temporary Acts expire at a date fixed in the Act itself. Thus the Army Act is passed annually and continues for a year, and the London Traffic Act 1924 was to expire at the end of 1928. By such provision experimental legislation is rendered possible where the success of a new departure in legislation is doubtful. An annual Expiring Laws Continuance Act is passed for the purpose of continuing (generally for a year) various temporary Acts; the list is periodically revised and those of proved value are then made permanent. Penal Acts are those which impose a new disability; beneficial, those which confer a new favour. An imperative statute (often negative or prohibitory in its terms) makes a certain Act or omission absolutely necessary, and subjects a contravention of its provisions to a penalty. A directory statute (generally affirmative in its terms) recommends a certain Act or omission, but imposes no penalty on non-

observance of its provisions. To determine whether an Act is imperative or directory the Act itself must be looked at, and many nice questions have arisen on the application of the rule of law to a particular case. Enabling statutes are those which enlarge the common law, while disabling statutes restrict it. Declaratory statutes, or those simply affirming the common law, once not uncommon, are at the present time practically unknown; the Treason Act is an example. Statutes are sometimes passed in order to overrule specific decisions of the courts. Examples are the Territorial Waters Jurisdiction Act 1878, the Married Women's Property Act 1893, the Trade Disputes Act 1906.

**Interpretation of Statutes.**—The construction or interpretation of statutes depends partly on the common law, partly on statute. The main rules of the common law, as gathered from the best authorities, are these: (1) Statutes are to be construed, not according to their mere letter, but according to the intent and object with which they were made. (2) The relation of the statute to the common law is to be considered. In the words of the resolution of the court of exchequer in *Heydon's case,* 3 Coke's Rep. 7, the points for consideration are: "(*a*) What was the common law before the making of the Act? (*b*) What was the mischief and defect against which the common law did not provide? (*c*) What remedy the parliament hath resolved and appointed to cure the disease of the Commonwealth? (*d*) The true reason of the remedy." (3) Beneficial or remedial statutes are to be liberally, penal more strictly, construed. (4) Other statutes *in pari materia* are to be taken into consideration. (5) A statute which treats of persons of inferior rank cannot by general words be extended to those of superior rank. (6) A statute does not bind the Crown, unless it be named therein. (7) Where the provision of a statute is general, everything necessary to make such provision effectual is implied. (8) A later statute repeals an earlier, as far as the two are repugnant, but if they may stand together repeal will not be presumed. (9) There is a presumption against creation of new or ousting of existing jurisdictions, against impairing obligations, against retrospective effect, against violation of international law, against monopolies, and in general against what is inconvenient or unreasonable. (10) If a statute inflicts a penalty, the penalty implies a prohibition of the Act or omission to which the penalty is imposed. Whether the remedy given by statute is the only one depends on the words of the particular Act. In some cases an action or an indictment will lie; in others the statutory remedy, generally summary, takes the place of the common law remedy. In some instances the courts have construed the imposition of a penalty as operating not to invalidate a contract but to create a tax upon non-compliance with the terms of the statute. The Interpretation Act 1889 provides an authentic interpretation for numerous words and phrases of frequent occurrence in statutes.

The earlier Acts are generally simple in character and language, and comparatively few in number. At present the number passed every session is substantial; for the session of 1925 there were 91 general Acts (occupying over 1,800 pages in the official volumes) and 132 local and personal Acts. Without going as far as to concede with an eminent legal authority that of such legislation three-fourths is unnecessary and the other fourth mischievous, it may be admitted that the immense library of the statutes would be but a trackless desert without trustworthy guides. Revision of the statutes was evidently regarded by the legislature as desirable as early as 1563 (*see* the preamble to 5 Eliz. c. 4.). It was demanded by a petition of the Commons in 1610. Both Coke and Bacon were employed for some time on a commission for revision. In 1861 was passed the first of a long series of Statute Law Revision Acts. The most important action, however, was the nomination of a Statute Law Committee by Lord Chancellor Cairns in 1868, a body of experts in drafting and public administration, which continues to supervise the official publication of revised statutes and indexes to statutes and to statutory rules. *A Chronological Table and Index of the Statutes* which are still law is annually published under the Committee's direction; the Table shows how far any enactment has been repealed or amended. The first edition of *Revised Statutes,* begun in 1870, substituted 18 volumes for 118; a second edition, begun in 1886, contains the Acts from 1235 to 1900 in 20 volumes, extended further by the Statute Law Revision Act of 1927.

The chief editions of the British statutes are the *Statutes of the Realm* printed by the king's printers, Ruffhead's and the fine folio edition issued from 1810 to 1824 in pursuance of an address from the House of Commons to George III. The safest authority is the *Revised Statutes.* Chitty's selection of *Statutes of Practical Utility* is useful. Earlier works on statute law include the readings and commentaries on statutes by great lawyers, such as the second volume of Coke's *Institutes,* Bacon's *Reading on the Statute of Uses,* Barrington's *Observations on the more ancient Statutes from Magna Carta to the 21 Jac. I. c. 27* (5th ed., 1796), and the Introduction to Blackstone's *Commentaries.* Among the later works are the treatises of Dwarris (2nd ed., 1848) and Maxwell (6th ed., 1920) and Craies (founded on Hardcastle) (3rd ed., 1923). On the interpretation of statutes, *see* Sir C. P. Ilbert, *Legislative Methods and Forms* (1901) and *Mechanics of Law-Making* (1914); Sir H. Thring, *Practical Legislation* (1902). An official *Index to Statutory Definitions* (1923) is valuable for draftsmen. For bibliography of English Statutes *see* P. H. Winfield, *Chief Sources of English History* (1925). For Revised Statutes see *Law Quarterly Review* (1929, p. 168). Statutory rules and orders are officially published by H.M. Stationery Office both singly and in annual volumes.

**Scotland.**—The statutes of the Scottish parliament before the union differed from the English statutes in two important respects: they were passed by the estates of the kingdom sitting together and not in separate houses, and from 1367 to 1690 they were discussed only after preliminary consideration by the lords of the articles, a legislative committee. An Act of the Scottish parliament may in certain cases cease to be binding by desuetude.

Acts of the imperial parliament which have been passed since the union extend in general to Scotland, unless that country be excluded from their operation by express terms or necessary implication. Scottish Acts are cited thus, 1678, c. 10. An edition was issued by order of the Treasury, 1844–75. *Scots Statutes Revised* (*1707 to 1900*) in 10 volumes is a useful publication. Obsolete Acts from 1424 to 1707 were repealed by the Statute Law Revision (Scotland) Act 1906.

**Ireland.**—Originally the lord deputy appears to have held parliaments at his option, and their Acts were the only statutory law which applied to Ireland, except as far as judicial decisions had from motives of policy extended to that country the obligation of English statutes. In 1495 the Act of the Irish parliament known as Poynings' Law or the Statute of Drogheda enacted that all statutes lately made in England be deemed good and effectual in Ireland. This was construed to mean that all statutes made in England prior to the 18 Hen. VII. were valid in Ireland, but none of later date were to have any operation unless Ireland were specially named therein or unless adopted by the Irish parliament, as was done, for instance, by Yelverton's Act, 21 and 22 Geo. III. c. 48 (I.). Another article of Poynings' Law secured an initiative of legislation to the English privy council, the Irish parliament having simply a power of acceptance or rejection of proposed legislation. The power of the parliament of Great Britain to make laws to bind the people of Ireland was declared by 6 Geo. I. c. 5. This Act and the article of Poynings' Law were repealed in 1782, and the short-lived independence of the parliament of Ireland was recognized by 23 Geo. III. c. 28. The application of Acts passed since the union is the same as in the case of Scotland. Irish Acts are cited thus, 26 Geo. III. c. 15 (I.) or (Ir.). The best edition is that issued in 20 volumes pursuant to an order of the earl of Halifax, lord-lieutenant in 1762. A volume of revised statutes was published in 1885. The earliest that is still law is one of 1459. Since the constitutional changes in the Government of Ireland, the Irish Free State passes Acts printed bilingually and cited by year and number. The Northern Ireland legislation in form and citation resembles that of Westminster.

**British Colonies, Dominions and Dependencies.**—Acts of the imperial parliament do not extend to the Isle of Man, the Channel islands or the colonies, unless they are specially named therein. By the Colonial Laws Validity Act 1865 ("the charter of colonial legislative independence") any colonial law repugnant to the provisions of any Act of parliament extending to the colony is void to the extent of such repugnancy, and no colonial law is to be void by repugnancy to the law of England unless it be re-

pugnant to such an Act of parliament. The 1865 Act is discussed in the Summary of Proceedings of the Imperial Conference of 1926 in its application to the self-governing dominions, for which the imperial parliament does not legislate without their consent. For colonies without representative legislatures the Crown usually legislates, subject to the consent of parliament in particular cases. Examples of imperial legislation for the colonies in general are the Colonial Stock Act 1877, and the Colonial Courts of Admiralty Act 1890. Imperial Acts dealing with particular dominions include the New Zealand Constitution Act 1852, the British North America Act 1867, the Commonwealth of Australia Constitution Act 1900, and the South Africa Act 1909: these statutes, like the Irish Free State Constitution Act 1922, deal with the competence of the dominion legislature. A colony is defined for the purposes of imperial legislation by the Interpretation Act 1889, s. 18. In certain dominions like Canada, the constitutionality of an Act of the colonial legislature is, as in the United States, a matter for the determination of the local court or of the judicial committee of the privy council on appeal.

**Other Countries.**—In most European countries there is a code, the existence of which makes the system of legislation hardly comparable to that of Great Britain. The assent of two chambers and of the president or other head of the State, is generally necessary.

The term "statute" is used by international jurists and civilians mostly on the continent of Europe to denote the whole body of the municipal law of the State. In this sense statutes are either real, personal or mixed. A real statute is that part of the law which deals directly with property, whether movable or immovable. A personal statute has for its object a person, and deals with questions of status, such as marriage, legitimacy or infancy. A mixed statute affects both property and person; or, according to some authorities, it deals with Acts and obligations. Personal statutes are of universal validity; real statutes have no extra-territorial authority. The determination of the class under which a particular law ought to fall is one of great difficulty, and one in which there is often a conflict of legal opinion.

*See* J. Story, *Conflict of Laws* (Boston, 1834; 8th ed. by H. M. Bigelow, 1883) ss. 12–16; von Bar, *Private International Law* (2nd ed., Eng. trans. by Gillespie, 1892); A. Pillet, *Traité Practique de droit international privé* (1924). (J. WIL.; C. T. C.)

## UNITED STATES

Statute in American law is generally confined to an act of the legislature, though the term is occasionally used to apply to municipal ordinances and the rules and regulations of administrative agencies passed in the exercise of delegated legislative functions. The concurrence of the executive is demanded for the efficacy of the legislative act. The executive is accorded a veto over legislative action which can, however, be overridden by concurrence of a sufficient majority in the houses of the legislature.

Any consideration of statute-making in the United States must bear in mind the Federal character of the nation. Not only does each of the 48 States possess statute-making powers for that State, but the national Government within the ambit of its delegated powers may pass statutes effective throughout the nation. The device of judicial review over legislation is the scheme by which conflict between the various statutes is resolved. As the supreme law of the land stand the Constitution, treaties and laws of the United States, and State statutes passed in contravention of them are unenforceable. Not only are State and the lower Federal courts obliged to refuse to enforce a State statute contravening Federal constitutional or statutory law, but by providing for an appeal to the U.S. Supreme Court, the validity of State statutes can be brought for judgment to that ultimate tribunal. The Supreme Court thus occupies the position of arbiter in the eternal conflict between States and nation. State statutes must also comply with the provisions of the State Constitution but the final arbiter of their compliance is the State supreme court and not the U.S. Supreme Court. (*See* CONSTITUTION AND CONSTITUTIONAL LAW.) State statutes in violation of the State or Federal Constitution are void, but State statutes contravening Federal statutes are suspended during the operation of the latter.

The fact that there are 49 different statute-making bodies in the United States makes for an immense mass of legislation. Despite the fact that most State legislatures have only biennial sessions, their legislative activity produces a vast number of statutes. The first thorough attempt to keep in touch with their activity by the mechanism of an index to State legislation was originated in 1928 by the Library of Congress. Periodic revisions of their statutes are made by each State but upon plans that lack any uniformity. No revision of the statutes of the Federal Government was made until 1874. A second revision was accomplished in 1925.

Statutes commonly take effect from the date that they receive the executive assent. In some States constitutional provisions prescribe that they shall not be effective until after the expiration of a certain time after their passage, unless the legislature shall designate that the matter is one of such public urgency as to require their immediate operation. The result of these restrictions has been simply to induce the legislature to append an urgency clause to each statute irrespective of its subject-matter and thus override the constitutional restriction. Two other common constitutional provisions relative to statute-making in the State legislatures deserve notice. To avert the process of "log-rolling" or the inclusion of particular legislation in a general statute, the Constitutions provide that no statute shall deal with more than one subject, to be plainly and specifically expressed in the title to the act.

The legislation of the United States and its constituent States is generally conceded to be in an unhappy state. Several significant reform movements are (1929) in progress. A movement for the creation of legislative reference bureaux, organizations with the double purpose of offering expert help in the draughting of statutes and of affording to legislators information upon the subject matter of specific statutory proposals, was begun in Wisconsin and has gained wide acceptance during the last 15 years. Expert legislative draughtsmen are now attached to the Senate and House of the U.S. Congress and to a number of State legislatures. A movement for introducing uniformity in the statutory laws of the several States was initiated by the organization of the Commissioners on Uniform State Laws in 1892. They consist of commissioners appointed by each State who meet annually to frame legislation on subjects upon which uniformity is believed essential and recommend its enactment by the various State legislatures. Their most successful achievements have been in the field of commercial law, though their endeavours have embraced subjects of wide variety. Similar efforts to promote uniformity have been made by groups representing private interests and public welfare organizations. Interpretation statutes upon the British model have also been enacted in some States and the work of expert draughtsmen has brought some order and method in the process of statute-making.

Another peculiar American problem relates to the extent to which courts take cognizance of statute law. All courts are bound to take judicial notice of the Federal laws and the statutes of the State in which suit is brought. But different doctrines are in force as to the extent to which they will take notice of the statute law of other States. Some State courts have boldly asserted their willingness to take notice of such laws; others refuse to recognize them unless they are specially pleaded or proved, in default thereof assuming that the law of the other State is identical either with their decisional or statutory law.

Statutes have different forms, being either acts of the legislature or joint or concurrent resolutions of both houses of the legislature. In each instance they must secure the approval of the executive. In many cases the same subject-matter is alternately dealt with by both forms of statutes. Treaties of the national Government have the force of statutes and stand on a parity with them. Like statutes they are the "supreme law of the land" and supersede conflicting State legislation. Just as a subsequent statute may repeal an earlier one, a later statute repeals an earlier treaty. States are forbidden to conclude treaties but may make compacts with one another with the assent of Congress. Such compacts also have the effect of statutes. They have been used as an instrument of statecraft to deal effectively with problems that demand a

regional treatment greater than a single State can give and yet less than is desirable for nation-wide control.

Codification on an analogy to the European systems began as a movement in 1848, the date of the adoption of the Field Code in New York. That code was limited to an attempt to recognize and simplify procedural law. A similar programme for the codification of the substantive law was initiated by the same sponsor, David Dudley Field, but failed of adoption. Procedural and substantive codes on the model of the Field Code were, however, adopted in numerous States. The merits and demerits of a codification in statutory form of the procedural and substantive law became a heated matter of professional controversy during the latter part of the 19th century. The controversy has not yet abated. The hopes of the codifiers of remodelling the common law on lines akin to the civil law systems have not been realized. Judges imbued with the common law training and technique have continued to handle codifications as mere statutes and not as ultimate sources of the law in the manner of the civilians. The "code States" are thus common law jurisdictions to the same extent as the other States.

(J. M. La.)

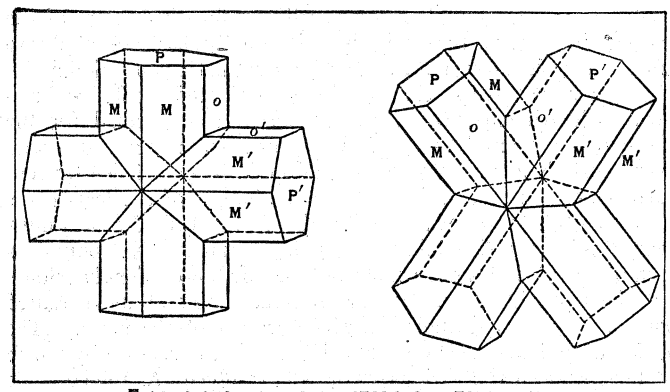
**STATUTORY RULES AND ORDERS.** The British parliament being a sovereign body, its acts cannot be challenged as *ultra vires*. "Statutory rules and orders," not passed directly by parliament but made under delegated powers, have no such immunity. Occasionally a statute, when authorizing such delegations, directs that the resultant rules, regulations or orders shall "have effect as if enacted in this Act." These words, formerly used by draftsmen when annexing schedules to statutes, may place the rules and orders beyond challenge (*Patent Agents Institute* v. *Lockwood,* 1894, A.C. 347), but normally the law courts will vigilantly examine the departmental exercise of legislative power. Law-making by statutory rules and orders was immensely extended during World War I, under the Defence of the Realm Acts, and is authorized by the Emergency Powers Act of 1920, when the community requires special protection. The pressure upon parliamentary time is developing a system by which Acts contain bare principles of law, and the clothing of the skeleton is left to subordinate rule-making. The making of rules of procedure in various courts or Orders in Council (*see* Privy Council) to bring Acts into effect on appointed days are well-known instances of such delegated legislation. Special provisions exist for the publication of draft rules (*see* especially the limited effect of s. 1 of the Rules Publication Act, 1893), for consultation with interests concerned, for control by parliament, and for the promulgation of all subordinate legislation when finally made. The extremely limited and unsatisfactory character of parliamentary control over this delegation of its powers, and the fact that the enabling statute itself often excludes control by the courts, has given rise to repeated demands, both in and out of parliament, that some means shall be devised of restoring the control alike of parliament and the courts over the exercise of this legislative power by government departments. As a result of this agitation, a Committee was appointed by the Lord Chancellor in the autumn of 1929 to explore and report upon the situation.

*See* C. T. Carr, *Delegated Legislation* (1921); J. H. Morgan, *Remedies against the Crown* (1926); Lord Justice Sankey, *Principles and Practice of the Law To-day* (1928). (C. T. C.)



**STAUNTON, HOWARD** (1810–1874), English Shakespearian scholar and writer on chess, supposed to have been a natural son of Frederic Howard, fifth earl of Carlisle, was born in 1810. As a Shakespearian commentator he showed the qualities of acuteness and caution which made him excel in chess. In 1864 he published a facsimile of the Shakespeare folio of 1623, and a facsimile edition of *Much Ado about Nothing,* photolithographed from the quarto of 1600. He died on June 22, 1874.

**STAUNTON,** a city of Macoupin county, Illinois, U.S.A., 42 mi. N.E. of Saint Louis. It is served by the Wabash, the Litchfield and Madison, and the Illinois Terminal (electric) railways. The population of Staunton was 4,618 in 1930, and it was 4,212 in 1940 by the federal census.

**STAUNTON** (stăn'ton), a city of Virginia, U.S.A., 1,385 ft. above sea level, in the heart of the beautiful and fertile Shenandoah valley, 135 mi. N.W. of Richmond; the county seat of Augusta county, but administratively independent of it. It is at the intersection of federal highways 11 and 250, and is served by the Baltimore and Ohio and the Chesapeake and Ohio railways. Pop. 13,337 in 1940 (17% Negroes) by federal census. It is a city of beautiful residences and numerous schools and institutions. The manse of the First Presbyterian church was the birthplace and childhood home of Woodrow Wilson. About 20 mi. S. of the city is the homestead of Cyrus McCormick, where he invented the reaper. Within 50 mi. are five great caverns, Natural Bridge, and other points of interest. Just east of the city is a national cemetery, and west of it a Confederate cemetery. Staunton was the first city in America to adopt a city-manager form of government (1908). There are large hosiery, silk, woollen and flour mills.

The first settlement in the vicinity was made in 1731, 2 m. E. of the present city. A county court-house was built in 1745, and the name Staunton (the family name of the wife of Sir William Gooch) was adopted about 1748. In 1781, when Col. Tarleton drove the general assembly of Virginia across the Blue Ridge, they took refuge here, holding their sessions for a time in the old Trinity Episcopal church. During the Civil War Staunton was an important supply-base for the army of northern Virginia and for Jackson's Valley campaign, and it was twice occupied by Federal troops. It was chartered as a city in 1870.

**STAUROLITE,** a mineral consisting of basic aluminium and ferrous iron silicate with the formula $HFeAl_5Si_2O_{13}$. The material is, however, usually very impure, the crystals enclosing sometimes as much as 30 or 40% of quartz and other minerals as well as carbonaceous matter. Crystals are orthorhombic and have the form of six-sided prisms. Interpenetrating cruciform twinned crystals are very common and characteristic; they were early known as *pierres de croix* or *lapis crucifer,* and the name staurolite has the same meaning (Greek, *σταυρός*, a cross, and *λίθος*, a stone). In fig. 1 the twin-plane is (032) and the two prisms intercross

FIGS. 1 & 2.—TWIN CRYSTALS OF STAUROLITE

at an angle of 91° 22′; in fig. 2 the twin-plane is (232) and the prisms intercross at nearly 60°. The mineral is translucent to opaque and dark reddish-brown in colour. Waterworn pebbles of material sufficiently transparent for cutting as gem-stones are occasionally found in the diamantiferous sands of Brazil. The hardness is 7·5, specific gravity 3·75. Staurolite is a characteristic mineral of crystalline schists, and it is also a product of contact-metamorphism. (L. J. S.)

**STAVANGER,** a seaport of Norway, capital of Stavanger *amt* (county), on the west coast on the Bukken fjord. Pop. (1930) 46,780. The town is one of the oldest in Norway, founded in the 8th or 9th century, but the greater part of the present town is modern and built of stone. It became the seat of a bishopric in the 13th century, and though the see was removed to Christian-

sand in 1685, it was restored in 1925. The cathedral church of St. Swithun, founded by the English bishop Reinald at the end of the 11th century, and rebuilt after being burned in 1272, is, next to the cathedral of Trondheim, the most interesting stone church in Norway. The old episcopal palace of Kongsgaard is now a Latin school. The fisheries are important—for herring, mackerel, sprats, cod, salmon, lobsters and anchovies. The extraordinary growth of Stavanger was mainly due to its fish-canning industry. Other industries are the making of iodine from seaweed, and shipbuilding. It was occupied by Germany in April 1940.

**STAVELEY,** town and urban district of Derbyshire, England, 12 mi. S.E. of Sheffield, on the L.M.S. and L.N.E. railways. Pop. (est. 1938) 16,960. Area, 10.2 sq.mi. The ancient church of St. John the Baptist contains a 12th century font. Staveley hall, formerly the home of the Frechevilles, was built in 1604 and is now the rectory. Coal mining is the dominant industry, though there is also an old established brush manufactory.

**STAVELOT,** town on the Amblève, province of Liége, Belgium. Pop. (1939) 4,792. Here Charles Martel gained a signal victory over Neustria in 719. The prince-abbot of the monastery of Stavelot (established 7th century) exercised secular authority over many towns in the Amblève and Warche valleys, including Malmédy, and had a seat in the old German Diet.

**STAVROPOL,** a former province of Russia, now in the Caucasian Area, North (*q.v.*).

**STAVROPOL,** a town of Russia: *see* VOROSHILOVSK.

**STAWELL,** a municipality of Borung county, Victoria, Australia, 179 mi. by rail W.N.W. of Melbourne. Pop. (1933) 4,747. The quartz reefs of the Pleasant Creek goldfields near by are worked at very deep levels and there are cyanide plants. It lies near the Wimmera river just north of the Grampian and Pyrenees plateaus, in an important sheep and fruit district.

**STEAD, WILLIAM THOMAS** (1849–1912), English journalist, was born at Embleton, Northumberland, on July 5, 1849, the son of a Congregational minister. He was early apprenticed in a merchant's office at Newcastle-on-Tyne; he soon gravitated, however, into journalism, and in 1871 became editor of the Darlington *Northern Echo*. In 1880 he went to London to be assistant editor of the *Pall Mall Gazette* under John Morley, and when the latter retired he became editor (1883–1889). Up to 1885 he had distinguished himself for his handling of public affairs, and his brilliant modernity in the presentation of news. He introduced the "interview," made a feature of the *Pall Mall Gazette* "extras" (*see* also NEWSPAPERS: *The London Press*), and his enterprise and originality exercised a potent influence on contemporary journalism and politics. In 1885 he entered upon a crusade against vice by publishing a series of articles on the "Maiden Tribute of Modern Babylon." Though his action undoubtedly furthered the passing of the Criminal Law Amendment act, it made his position on the paper impossible; and he was imprisoned in Holloway jail for three months on a charge arising out of his crusade. On leaving the *Pall Mall Gazette* he founded the monthly *Review of Reviews* (1890).

He started cheap reprints (*Penny Poets* and *Prose Classics*, etc.), conducted a spiritualistic organ, called *Borderland* (1893–1897), in which he gave full play to his interest in psychical research; and became an enthusiastic supporter of the peace movement, and of many other movements, popular and unpopular. He wrote with facility and sensational fervour on all sorts of subjects, from *The Truth about Russia* (1888) to *If Christ Came to Chicago* (1893), and from *Mrs. Booth* (1900) to *The Americanization of the World* (1902). In private life his keen sense of merit and kindly interest influenced many aspirants to journalism and literature.

Stead went down in the "Titanic" on April 15, 1912.

See *Life of W. T. Stead* (1913), by his daughter; and F. Whyte, *Life of W. T. Stead* (1925).

**STEAM,** the vapour of water. In the pure state it is a dry invisible gas. Often, however, as in a jet escaping from the spout of a kettle or the funnel of a locomotive, it is mixed with minute particles of water which are produced by condensation of portions of the gas. In such a mixture the suspended particles of water constitute a visible cloud. Any mixture of steam with water, whether in such a cloud or in the working chamber of an engine or turbine, is often spoken of as wet steam.

Its properties are most conveniently described by imagining an experiment in which steam is formed by applying heat to a small quantity of water contained at the bottom of a large upright cylindrical vessel. Suppose that the vessel is fitted with a piston which rests on the water to begin with and can rise when the fluid below it is made to change from water into steam by applying heat. Imagine further that the piston is frictionless and carries a definite weight so that, as the piston rises, the fluid continues to be subjected to a constant pressure, say, $p$ lb. per square inch.

**Saturated Steam.**—When heat is applied, no steam is formed until the temperature of the water is raised to a value $T$ which depends on $p$. Steam then forms, raising the piston, and this goes on without further rise of temperature until all the water is converted into steam, when it occupies a certain volume $V$. During this stage the steam is said to be *saturated*. $T$ is the temperature of saturation corresponding to the pressure $p$, and is the lowest temperature at which steam can exist in stable equilibrium at that pressure.

**Superheated Steam.**—Suppose now, after all the water has turned into steam, that we go on applying heat. The temperature will rise and the volume will increase beyond $V$ if we keep $p$ constant, or the pressure will increase beyond $p$ if we then fix the piston so as to keep $V$ constant. In either case the steam is said to be *superheated*.

Steam is superheated when its temperature is raised in any manner to a value which exceeds the temperature of saturation corresponding to the actual pressure. Thus for example steam may change from the saturated to the superheated condition by being compressed (without loss of heat), or by passing (without loss of heat) through a throttle valve into a region of lower pressure. When steam is so "throttled" its temperature falls to some extent, but remains higher than the temperature of saturation corresponding to the reduced pressure.

**Properties of Steam: Callendar's Tables.**—The physical properties of steam have been the subject of systematic experimental enquiry by Regnault and many later observers. Our modern knowledge of them is largely due to H. L. Callendar who, with the help of formulas the basis of which is partly theoretical and partly empirical, has rationalized the experimental data and has compiled comprehensive tables for the use of engineers. Callendar's tables, published in 1915 and in an enlarged form in 1924, set forth all the important properties throughout a suitable range of pressures and temperatures. From the principles of thermodynamics (*q.v.*) it is known that certain relations hold between various properties, in steam or any other vapour; the values stated by Callendar, besides being founded on the best available data, are consistent with these relations. They apply to the superheated as well as to the saturated state; saturation is to be regarded as only a limiting case.

So long as steam is saturated the relation of temperature to pressure is definite. But steam may be superheated to any temperature above the saturation temperature at which it is formed in the boiling of water, and the temperature then becomes an independent variable. This affects certain other properties with which the steam engineer is concerned, namely:—

The volume $V$,
The internal energy $E$,
The total heat $I$,
The entropy $\phi$,

all of which are to be reckoned per lb. of the substance. Each of these quantities has a definite value for steam or for water in any assigned state of pressure and temperature. Steam tables usually follow a convention, according to which quantities such as the energy or the entropy are treated as zero for water at 0° C; the tabulated numerical value accordingly expresses the amount by which the quantity in question has changed when the substance passes from that zero condition to the actual state.

**Internal Energy.**—When steam is formed (starting, say, from

the state of water at 0° C) heat is taken in, and some external work is done by the expansion of the substance. The difference, which depends simply on the final state and not on the manner of formation, is called the *internal energy E.*

**Total Heat.**—The total heat $I$ is conveniently defined by the equation

$$I=E+APV,$$

where $P$ and $V$ are respectively the pressure and volume of the substance, and $A$ is a factor which converts units of work into units of heat. Hence when the substance is heated under constant pressure the change of $I$ is measured by the quantity of heat that is taken in, for it is then equal to the gain of internal energy plus the work done. In a process of throttling it is easy to show that $I$ does not change, provided there is no loss of heat to other bodies.

**Entropy.**—To define entropy, it may be said that when the substance takes in heat in a reversible manner (namely a manner which excludes the existence of any turbulent movement) its entropy changes by the amount $\frac{Q}{T}$ where $Q$ is the heat taken in and $T$ is the temperature (on the absolute scale) at which it is taken in. If $T$ is itself changing while the heat is being taken in, we must write this change of entropy as $\int\frac{dQ}{T}$. Thus when steam is formed in a quietly steaming boiler, at a constant temperature $T$, from water at the same temperature, the entropy $\phi$ changes by the quantity $\frac{L}{T}$, where $L$ is the "latent heat." Like the other quantities, the entropy of water at 0° C is reckoned as zero for convenience in tabulation. Both the entropy of steam and the total heat are quantities of great importance in the theory of the steam-engine (*q.v.*).

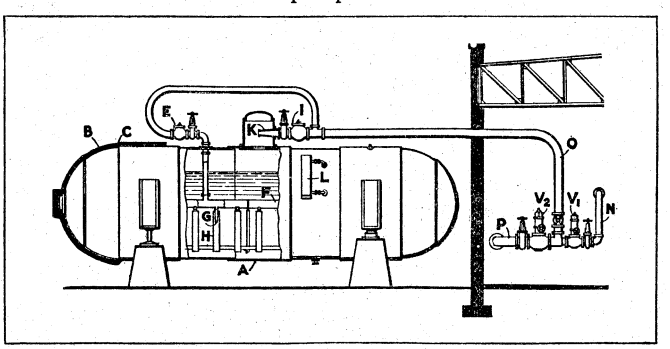
**Critical Temperature.**—Imagine a quantity of superheated steam at any usual temperature to be compressed while the temperature is kept constant. When the pressure reaches a certain value condensation begins, and we are then dealing with a substance which is partly water and partly saturated steam. The pressure in question is that which corresponds to saturation at the assumed constant temperature. This pressure will not rise further until all is condensed: after that the pressure on the water may of course be increased to any extent. The process is discontinuous, with three distinct stages. Suppose this experiment to be repeated at various temperatures: it will be found that when the temperature is sufficiently high there is no stage during which both water and steam are present together. When this temperature is reached or exceeded, the substance passes, as its pressure is increased, from the condition of steam to that of water—from vapour to liquid—in a continuous manner without ever being a mixture of the two. The lowest temperature at which this can happen is called the *critical Temperature,* and the limit of pressure above which the substance cannot exist as a non-homogeneous mixture of liquid and vapour is called the *critical Pressure.* These conditions of pressure and temperature constitute the "critical point." The critical temperature of steam is about 374° C and the critical pressure about 3,158 lb. per square inch.

The properties of steam in the neighbourhood of the critical point are less exactly known than at lower and more usual pressures. The "characteristic equation" on which Callendar founds many of his tabulated values applies with sufficient exactness within the lower range of pressures commonly met with in engineering practice. It takes the form

$$V=\frac{RT}{P}-c+b,$$

where $V$ is the volume (per lb.), $T$ is the absolute temperature, $P$ is the pressure, $R$ is a constant relating to the ideal volume of a "perfect" gas, $b$ is a constant which expresses the additional volume of the molecules, and $c$ is a term, depending on the temperature, which expresses the loss of volume through "coaggregation" or temporary association of molecules. The equation is applicable to the superheated as well as the saturated state.

**Super-saturation.**—When steam is cooled to a temperature at which condensation should occur, it is found, when no nuclei are present about which water droplets may form, that the temperature may fall some way below the temperature of saturation before condensation begins. A temporary and unstable state may accordingly be produced, called *super-saturation.* The vapour in this condition may be described as supercooled: its state is analogous to that of a liquid cooled below its melting point without crystallization.



**Water-vapour in Air.**—Water vapour is one of the constituents of the atmosphere, the proportion depending not only on the temperature but on other causes which affect local dryness. At any given temperature air is said to be saturated with water vapour when the proportion present is such as to exert a partial pressure equal to the pressure of saturation corresponding to the given temperature. Any excess tends to be thrown out as mist or rain: any less quantity than that required for saturation is held as an invisible constituent, namely, in the state of superheated steam. The quantity of water-vapour present in air may be expressed as a fraction of the quantity which would cause saturation: this fraction is called the "relative humidity" of the air. The "dew-point" is the temperature to which air must be cooled to allow a deposit of water to take place.

Air is often dried for industrial uses by cooling it to a very low temperature. This causes it to deposit nearly all its contained moisture, which is then drained away, leaving only the trifling quantity that suffices to produce saturation at the low temperature. When the air returns to normal temperature without taking up more water its relative humidity is very small.

**STEAM ACCUMULATORS** are devices for equalizing steam flow and steam demand. They are inserted between the source of steam supply and the point where it is used for the purpose of absorbing steam at times of low demand and releasing it when needed; several types have been developed. One of the earliest was the Rateau accumulator or regenerator. Its primary purpose was to utilize the intermittent exhaust from prime movers—such as steel rolling-mill engines—for driving low-pressure turbines carrying a fairly constant load; installed in the steam line between these two units, it served to equalize supply and demand, the turbine governor being designed to admit live steam when necessary. Another type is the Smoot accumulator, designed primarily for use in gas manufacturing plants. It collects, or accumulates, in a steel tank the exhaust from pumps and auxiliaries and from the

FIG. 1.—MECHANICAL DRAWING OF A COMPLETE ACCUMULATOR INSTALLATION

hot-water drips; by decreasing the pressure in this tank steam is made available for the intermittent operation of the water-gas apparatus, and deficiency in supply is taken care of by a live steam "make-up" valve. The latest development is known as the Ruths steam accumulator, and while it operates on the same general principle as the others, it has been applied over a wider field of usefulness. Specially designed governor valves make its operation entirely automatic up to 200 lb. per sq.in. and through greater pressure ranges (fig. 1). The tank $A$ is filled with water to 90% of its capacity, and the regulating valves $V$-1 and $V$-2 automatically control the charging and discharging of the accumu-

lator. The accumulator must be placed between the high and the low pressure steam line, and its pressure varies between these limits; accumulated steam is made available by the regulating valves in such a way as to maintain uniform steam pressures in the low pressure steam lines. Any steam generated by the boilers and not used by the high pressure consumers overflows through valve *V-1* into the accumulator. *V-2* maintains a uniform pressure in the line *P* carrying the low pressure steam, so that if the valve *V-1* is passing more steam than is required in the low pressure line, the excess is stored in the accumulator. Charging nozzles *G* are equipped with circulating pipes *H* which permit a uniform and noiseless heating of the water. Should a sudden demand for high pressure steam arise the boiler pressure would drop slightly, *V-1* would close and a certain amount of steam would become available at or near this higher pressure. This diversion to the high pressure line of steam intended for the lower pressures would cause a deficit in the low pressure line. *V-2* would then open and the heat energy previously stored in the accumulator would instantly flash into steam to meet this deficit. Should the sudden increase in demand be caused by low pressure consumption and the flow through *V-1* not sufficient, the accumulator would supply it. (R. A. L.)

**STEAM-CHEST** is a box cast on or attached to the side of a steam cylinder, and containing the slide-valve which slides over the steam and exhaust ports, and uncovers these in turn. A stuffing-box maintains the valve-rod steam-tight. Some engines have two valves, one sliding upon the top of the other, for the purpose of giving expansive working of the steam. Cylindrical or piston valves are used extensively in marine and locomotive cylinders, as they give a balanced effect all around. In locomotive practice these valves have to be placed above the cylinders in many cases for reasons of design.

**STEAM COAL:** *see* COAL AND COAL MINING.

**STEAM ENGINE.** A steam engine is a heat engine in which the working substance is steam. By a heat engine is meant a machine for doing mechanical work through the agency of heat: it does this by taking in heat at comparatively high temperature, converting part of the heat into another form of energy, and rejecting the remainder of the heat at a lower temperature. The working substance is the vehicle by which heat is taken in and rejected. In a steam engine, the substance takes in heat mainly in a separate vessel—the boiler—in the process of being vaporized; it does work by expanding under pressure and thereby converts part of the heat that is taken in; finally the remainder of the heat is rejected, either by allowing the steam to escape into the atmosphere, as in locomotives, or by condensing it at a comparatively low temperature and pressure, as in marine and many other engines. This gives a broad distinction between non-condensing and condensing steam engines. The latter have the great advantage that they allow the effective expansion of the steam to be carried much farther; the substance rejects heat at a lower limit of temperature, and this enables the engine to convert into work a larger fraction of the heat which it has received. That fraction expresses what is called the *efficiency* of the engine as a contrivance for converting heat into work. The addition of a condenser, while it increases the efficiency, of course complicates the mechanism: it requires a supply of cooling water or some equivalent means of keeping down the temperature by absorbing the heat which the steam gives up in the act of being condensed, and also a pump or other means of removing the condensed substance together with any air that may be present. But the advantage which it brings about in respect of efficiency is so great that all engines of large power, where economy of fuel is an important factor, and where the use of a condenser is practicable, are of the condensing kind.

Given the upper limit of temperature, at which heat is taken in, the efficiency which the engine may attain is determined by the lowness of the temperature at which heat is rejected. Similarly, when the lower limit of temperature, at which heat is rejected, is assigned, the efficiency which the engine may attain is increased by raising the temperature at which the working substance takes in heat. To secure high efficiency there must be a wide range through which the temperature of the working substance falls, as a consequence of expansion within the engine, from the level of temperature at which heat is received to the level at which heat is rejected. Thus in the steam engine the most efficient performance, that is to say the greatest output of work in relation to the heat supplied, is secured by keeping the condenser as cold as the available cooling water will allow, and at the same time using a high boiler pressure, so that the working substance is very hot while it receives heat in the act of changing from water into steam. For this reason, modern practice tends towards higher and higher boiler pressures, as the mechanical difficulties of boiler construction and high pressure working are overcome.

After conversion into steam the working substance may take in a supplementary supply of heat on its way from the boiler to the engine, by passing through a *superheater,* in which its temperature is raised above that of the boiler. A common form of superheater is a group of parallel pipes with their surfaces exposed to hot gases of the boiler furnace.

Steam engines are classified into two general types according to the manner in which the steam does work during its expansion. In the first, or piston-and-cylinder type, the steam, in a confined space, namely the part of the cylinder behind the piston, enlarges the volume of that space by pushing the piston forward. It does work by exerting a static pressure on the moving piston: the movement of the steam itself is of no significance. In the second class, to which belong all kinds of steam turbines, the action is less direct. The pressure of the steam is first employed to set the steam itself into motion, forming a jet or group of jets, the momentum of which causes work to be done on a moving part of the machine, either by the impulsive action of the jet or jets on revolving vanes, or by the reaction on revolving guide-blades during the formation of the jets, or, as in Parsons' turbine, by a combination of impulse and reaction. In any turbine the action of the steam is kinetic, in contrast with its static action in an engine of the piston type. In both types there is progressive expansion of the steam from the high pressure and relatively small volume at which it is admitted, to the low pressure and relatively very great volume at which it is discharged. The principle already stated, that a large range of temperature and pressure, between admission and exhaust, is essential to efficiency applies equally to both types. In practice, the turbine has a notable advantage over the piston-and-cylinder engine in this respect, that it allows the last stages of the expansion, when the volume of the steam has become very great, to be effectively utilised, to a degree which is impracticable in the other type, because of the enormous size which the cylinder would have to assume and the waste of work that would be caused by piston friction, if the steam were expanded down to a very low pressure by the piston method. The turbine method escapes these difficulties; mainly for that reason it has become the most efficient way of converting heat into work, on a large scale, through the agency of steam. It has further advantages in compactness, in simplicity of working, and in the facility with which it can be adapted to take steam of exceptionally high initial pressure and high superheat.

### HISTORICAL

In any historical sketch of the steam-engine, stress must be laid on the work of James Watt. But a process of evolution had been going on before his time which prepared a crude and primitive device for the immense improvements it received at his hands. The labours of Watt stand in natural sequence to those of Newcomen, and Newcomen's to those of Papin and Savery. Savery's engine, in its turn, was the reduction to practical form of an ancient scientific toy. Along another line of development, the modern steam turbine, which we owe to the genius of Charles Parsons, can be traced back to an early prototype.

In the *Pneumatica* of Hero of Alexandria (*c.* 130 B.C.) there is described the aeolipile, which may be called a primitive steam reaction turbine. It consists of a hollow globe pivoted so that it can turn on a pair of central trunnions, and supplied with steam through one of them, which is hollow. The steam escapes from the globe to the outside air through two bent pipes facing tan-

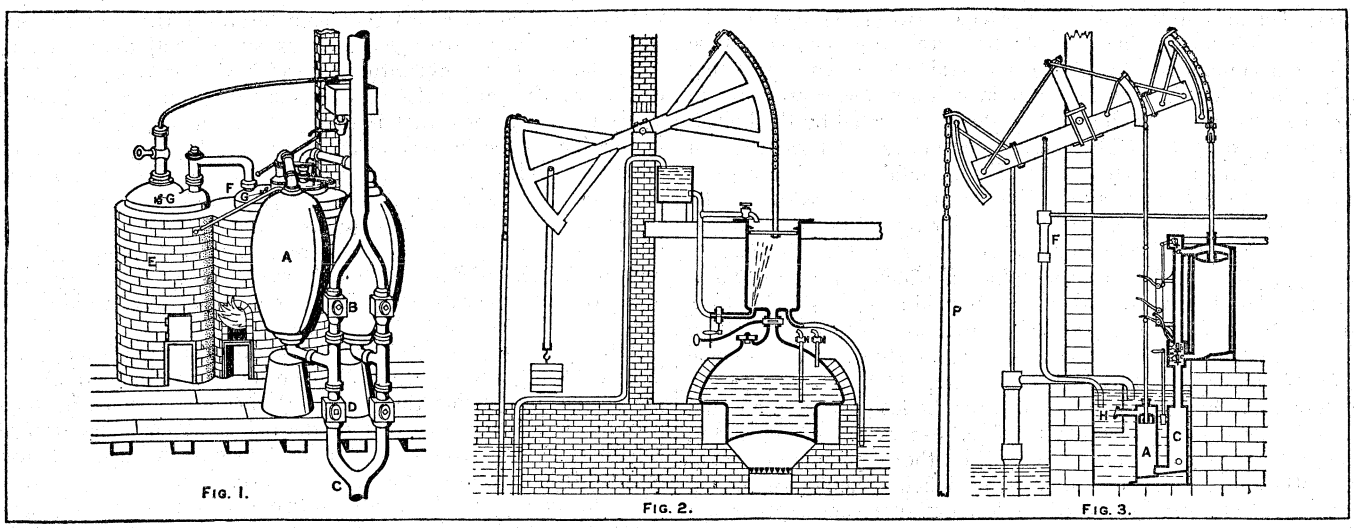

FIG. 1. FIG. 2. FIG. 3.

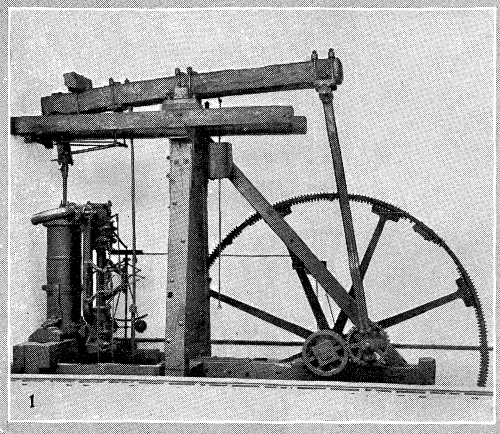
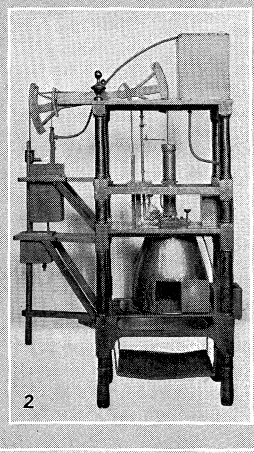
gentially in opposite directions at the ends of a diameter perpendicular to the axis. The globe revolves by reaction from the escaping steam. Hero's volume also mentions (Greenwood's translation of Hero's *Pneumatica*) another device which may be described as the prototype of the pressure engine. A hollow altar containing air is heated by kindling a fire on it; the air expands and by its pressure drives some of the water in a vessel below into a hanging bucket, which then descends, opening the doors of a shrine. When the fire is extinguished the air contracts, the bucket empties, and the doors close.

In a treatise on pneumatics (1601) by Giovanni Battista della Porta there is shown a somewhat similar apparatus, but with steam for working substance. Its pressure forces up water from a separate vessel. He also points out that the condensation of the steam may be used to produce a vacuum and thereby suck up water from a lower vessel. His suggestions go far to anticipate the engine which, a century later, in the hands of Savery, became the first commercially successful steam engine.

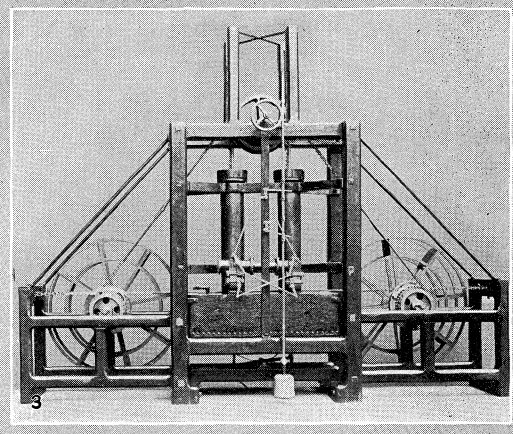
Meanwhile Edward Somerset, second Marquis of Worcester, described in his *Century of Inventions* (1663) a method of raising water by the agency of steam. His description is obscure, and no drawings of the device are extant. It appears to have consisted of a pair of displacement chambers, from each of which alternately water was forced, probably by admitting steam from an independent boiler, while the other vessel was allowed to refill.



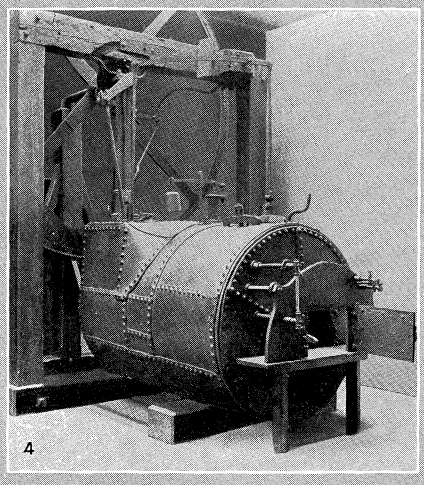
**Savery, 1698.**—The earliest steam-engine to take a practical form and find employment in industry was that of Thomas Savery, who, in 1698, obtained a patent for a water-raising engine, shown in fig. 1. Steam is admitted to one of the oval vessels *A*, displacing water, which it drives up through the check-valve *B*. When the vessel *A* is emptied of water the supply of steam is stopped, and the steam already there is condensed by allowing a jet of cold water from a cistern above to stream over the outer surface of the vessel. This produces a vacuum and causes water to be sucked up through the pipe *C* and the valve *D*. Meanwhile steam has been displacing water from the other vessel, and is ready to be condensed there. The valves *B* and *D* open only upwards. The supplementary boiler and furnace *E* are for feeding water to the main boiler; *E* is filled while cold and a fire is lighted under it; it then forces a supply of feeding-water into the main boiler *F*. The gauge cocks *G, G* are an interesting detail. Another form of Savery's engine had only one displacement-chamber and worked intermittently. In the use of artificial means to condense the steam, and in the application of the vacuum so formed to raise water by suction from a level lower than that of the engine, as well as in practical features, Savery's engine marked an inventive advance. It found considerable employment in pumping mines and in raising water to supply houses and towns, and even to drive water-wheels. A serious difficulty which prevented its general use in mines was the fact that the height through which it would lift water was limited by the pressure the boiler and vessels could bear. Pressures as high as 8 or 10 atmospheres were employed—and that, too, without a safety-valve—but Savery found it no easy matter to deal with high-pressure steam. Apart from this drawback, the waste of fuel was enormous, from the condensation of steam which took place on the surface of the water and on the sides of the displacement-chamber at each operation; the consumption of coal was, in proportion to the work done, some twenty times greater than in a modern engine.



Before Savery's engine was displaced by its successor, Newcomen's, it was improved by J. T. Desaguliers who applied to the safety valve (invented by Papin), and substituted condensation by a jet of cold water within the vessel for the surface condensation used by Savery. To Savery is ascribed the first use of the term "horse-power" as a measure of performance.



In 1690 Denis Papin suggested that the condensation of steam should be employed to make a vacuum under a piston previously raised by the expansion of the steam. Papin's was the earliest cylinder and piston steam engine, and his plan of using steam was that which afterwards took practical shape in the atmospheric engine of Newcomen. But his scheme was made unworkable by the fact that he proposed to use but one vessel as both boiler and cylinder. A small quantity of water was placed at the bottom of a cylinder and heat was applied. When the piston had risen the fire was removed, the steam was allowed to cool, and the piston did work in its down-stroke under the pressure of the atmosphere. After hearing of Savery's engine in 1705 Papin turned his attention to improving it, and devised a modified form, with a floating diaphragm or piston on the top of the water to keep the water and steam from direct contact with one another. Papin's engine may be described as a non-condensing single-acting steam pump, with steam cylinder and pump cylinder in one.



**Newcomen's Atmospheric Engine, 1705.**—While Papin was thus going back from his first notion of a piston engine to Savery's cruder type, a new inventor had appeared who made the piston engine a practical success by separating the boiler from the cylinder and by using (as Savery had done) artificial means to condense the steam. This was Thomas Newcomen, who in 1705, with his assistant, John Cawley, gave the steam engine the form shown in fig. 2. Steam admitted from the boiler to the cylinder by the opening of a valve allowed the piston to be raised by a heavy counterpoise on the other side of the beam. Then the steam valve was shut and a jet of cold water entered the cylinder and condensed the steam. The piston was consequently forced down by the pressure of the atmosphere and did work on the pump. The next entry of steam expelled the condensed water from the cylinder through an escape valve. The piston was kept tight by a layer of water on its upper surface. Condensation was at first effected by cooling the outside of the cylinder, but an accidental leakage of the packing water past the piston showed the advantage of condensing by a jet of injection water, and this plan took the place of surface condensation. The engine used

## THE PROGRESS OF THE STEAM ENGINE

1. One of Boulton and Watt's early (1789) rotative steam engines, among the first to utilize the double-acting principle
2. Model of Newcomen's steam engine (1719), the precursor of Watt's engine, and successfully used in pumping and mine drainage. Newcomen created a vacuum within the cylinder by the condensation of steam
3. Symington's original marine steam engine (1788), first used to propel a paddle-boat on Dalswinton Loch, Scotland, at a speed of about 4 m. per hour
4. Trevithick's high-pressure, or non-condensing engine (1811)
5. Quadruple piston-rod steeple paddle engine (1842)
6. Grasshopper engine (1862), so-called because of the obvious resemblance of its upper and right-hand portions to that insect
7. Model of single-cylinder horizontal engine (1898), with Corliss valve gear. A sectional view at the right end of cylinder reveals the piston and valve construction
8. Parsons' turbo-generator (1902), with upper turbine casing lifted to show rotor

steam whose pressure was little if at all greater than that of the atmosphere.

About 1711 Newcomen's engine began to be introduced for pumping mines. It is doubtful whether the action was originally automatic, or depended on the periodical turning of taps by an attendant. The common story is that in 1713 a boy named Humphrey Potter, whose duty it was to open and shut the valves of an engine he attended, made the engine self-acting by causing the beam itself to open and close the valves by suitable cords and catches. This device was simplified in 1718 by Henry Beighton, who suspended from the beam a rod called the plug-tree, which worked the valves by means of tappets. By 1725 the engine was in common use in collieries, and it held its place without material change for about three-quarters of a century in all. Near the close of its career Newcomen's engine was much improved in its mechanical details by John Smeaton, who built many large engines of this type about the year 1770, just after the great step which was to make Newcomen's engine obsolete had been taken by James Watt.

Compared with Savery's engine, Newcomen's had (as a pumping engine) the great advantage that the intensity of pressure in the pumps was not in any way limited by the pressure of the steam. It shared with Savery's, in a scarcely less degree, the defect already pointed out, that steam was wasted by the alternate heating and cooling of the vessel into which it was led. Though obviously capable of more extended uses, it was in fact almost exclusively employed to raise water—in some instances for the purpose of turning water-wheels to drive other machinery. Even contemporary writers complain of its great consumption of fuel.

**James Watt, 1763, 1769, 1781, etc.**—In 1763 James Watt, an instrument maker in Glasgow, while engaged by the University in repairing a model of Newcomen's engine, was struck with the waste of steam to which the alternate chilling and heating of the cylinder gave rise. He saw that the remedy, in his own words, would lie in keeping the cylinder as hot as the steam that entered it. With this view he added to the engine a new organ—namely the "separate condenser"—an empty vessel separate from the cylinder, into which the steam should be allowed to escape from the cylinder, to be condensed there by the application of cold water either outside or as a jet. To preserve the vacuum in his condenser he added a pump called the air pump, whose function was to extract from it the condensed steam and water of condensation, as well as any air which might come in by leakage or by solution in the steam or the injection water. Then, as the cylinder was no longer used as a condenser, he was able to keep it hot by clothing it with non-conducting bodies, and in particular by the use of what is called a steam-jacket—a layer of hot steam between the cylinder and an external casing. Further and still with the same object, he covered in the top of the cylinder, taking the piston-rod out through a steam-tight gland or stuffing-box, and allowed steam instead of air to press upon the piston's upper surface. After much experiment Watt patented his improvements in 1769; they are described in a specification from which the following extracts are taken:—

"My method of lessening the consumption of steam, and consequently fuel, in fire-engines, consists of the following principles:—

"*First,* That vessel in which the powers of steam are to be employed to work the engine, which is called the cylinder in common fire-engines, and which I call the steam vessel, must, during the whole time the engine is at work, be kept as hot as the steam that enters it; first by inclosing it in a case of wood, or any other materials that transmit heat slowly; secondly, by surrounding it with steam or other heated bodies; and, thirdly, by suffering neither water nor any other substance colder than the steam to enter or touch it during that time.

"*Secondly,* In engines that are to be worked wholly or partially by condensation of steam, the steam is to be condensed in vessels distinct from the steam-vessels or cylinders, although occasionally communicating with them; these vessels I call condensers; and, whilst the engines are working, these condensers ought at least to be kept as cold as the air in the neighbourhood of the engines, by application of water or other cold bodies.

"*Thirdly,* Whatever air or other elastic vapour is not condensed by the cold of the condenser, and may impede the working of the engine, is to be drawn out of the steam-vessels or condensers by means of pumps, wrought by the engines themselves, or otherwise.

"*Fourthly,* I intend in many cases to employ the expansive force of steam to press on the pistons, or whatever may be used instead of them, in the same manner in which the pressure of the atmosphere is now employed in common fire-engines. In cases where cold water cannot be had in plenty, the engines may be wrought by this force of steam only, by discharging the steam into the air after it has done its office."

The "common fire-engine" alluded to was the steam engine of Newcomen. Highly important as Watt's first inventions were, they resulted for a time in the production of nothing more than a greatly improved engine of the Newcomen type, much less wasteful of fuel, able to make faster strokes, but still only suitable for pumping, still single-acting, with steam admitted during the whole stroke, the piston, as before, pulling the beam by a chain working on a circular arc. The condenser was generally worked by injection, but Watt has left a model of a surface condenser made up of small tubes, in every essential respect like the condensers now used.

Fig. 3 is an example of the Watt pumping engine of this period. It should be noticed that, although the top of the cylinder is closed, and steam has access to the upper side of the piston, this is done only to keep the cylinder and piston warm. The engine is still single-acting; the steam on the upper side merely plays the part which was played in Newcomen's engine by the atmosphere; and it is the lower end of the cylinder alone that is ever put in communication with the condenser. There are three valves: the "steam" valve *a*, the "equilibrium" valve *b*, and the "exhaust" valve *c*. At the beginning of the down-stroke *c* is opened to produce a vacuum below the piston and *a* is opened to admit steam above it. At the end of the down-stroke *a* and *c* are shut and *b* is opened. This puts the two sides in equilibrium and allows the piston to be pulled up by the pump-rod P, which is heavy enough to serve as a counterpoise. C is the condenser, and A is the air-pump, which discharges into the hot well H, whence the supply of the feed-pump F is drawn.

In a second patent (1781) Watt describes the "sun-and-planet" wheels and other methods of making the engine give continuous revolving motion to a shaft provided with a flywheel. The crank and connecting-rod—already a familiar mechanical device from its use on the treadle of a lathe—would have been the natural means of doing this, but its application to the steam engine in a particular manner had been made the subject of a patent by James Pickard, and Watt, rather than make terms with Pickard, whom he regarded as a plagiarist of his own ideas, made use of his sun-and-planet motion until the patent on the crank expired. The reciprocating motion of earlier forms had served only for pumping; by making the steam engine drive a revolving shaft Watt opened up for it many other channels of usefulness. The engine was still single-acting; the connecting-rod was attached to the far end of the beam, and that carried a counterpoise which served to raise the piston when steam was admitted below it.

In 1782 Watt patented two further improvements of the first importance, both of which he had invented some years before. One was the use of double action, that is to say, the application of steam and vacuum to each side of the piston alternately. The other (invented as early as 1769) was the use of steam expansively, in other words the plan, essential to economy of fuel, of stopping the admission of steam when the piston had made only a part of its stroke, and allowing the rest of the stroke to be performed by the expansion of the steam already in the cylinder. To let the piston push as well as pull the end of the beam Watt devised his so-called parallel motion, an arrangement of links connecting the piston-rod head with the beam in such a way as to guide the rod to move in a very nearly straight line. He further added a throttle valve, for regulating the rate of admission of steam, and a centrifugal governor, in the form of a double conical pendulum, which controlled the speed by a throttle-valve.

Among other important devices associated with Watt was the "indicator," by which diagrams showing the relation of the steam pressure in the cylinder to the movement of the piston are automatically drawn: its invention seems to have been mainly due to his assistant John Southern.

In partnership with Matthew Boulton, Watt carried on in Birmingham the manufacture and sale of his engines with great success, and held the field against all rivals in spite of severe assaults

on the validity of his patents. Notwithstanding his knowledge of the advantage to be gained by using steam expansively, he continued to employ only low pressures—seldom more than 7 lb. per square inch over that of the atmosphere. His boilers were fed, as Newcomen's had been, through an open pipe which rose high enough to let the column of water in it balance the pressure of the steam. He gave a definite numerical significance to the term "horse-power," defining it as the rate at which work is done when 33,000 lb. are raised one foot in one minute.

In the fourth claim of Watt's first patent, quoted above, the second sentence describes a non-condensing engine, which would have required steam of a higher pressure. This, however, was a line of invention which Watt did not follow up, perhaps because so early as 1725 a non-condensing engine had been described by Jacob Leupold in his *Theatrum machinarum.*

It was not till much later that the thermodynamic principles underlying the action of the steam engine came to be understood. Engineers were consequently slow to appreciate the fact that to obtain economy of fuel it was advantageous to employ a high initial pressure, in combination with much expansion in the cylinder and with the separate condenser of Watt.

**Trevithick, Bull and Evans.**—The introduction of the non-condensing and, at that time, relatively high-pressure engine was effected in England by Richard Trevithick and in America by Oliver Evans about 1800. Both Evans and Trevithick applied their engines to propel carriages on roads, and both used for boiler a cylindrical vessel with a cylindrical flue inside containing the fire—the construction now known as the Cornish boiler. In association with Edward Bull, Trevithick had previously made direct acting pumping-engines, with an inverted cylinder set over and in line with the pump-rod, thus dispensing with the beam that had been a feature in all earlier forms. But in these "Bull" engines, as they were called, the steam was condensed by a jet of cold water in the exhaust-pipe, and Boulton and Watt successfully opposed them as infringing Watt's patent. To Trevithick belongs the honour of being the first to use a steam carriage on a railway; in 1804 he built a locomotive in the modern sense, to run on what had formerly been a horse-tramway, in Wales. In this connection it may be added that as early as 1769 a steam carriage for roads had been built in France by Nicolas Joseph Cugnot, who used a pair of single-acting high-pressure cylinders to turn a driving axle step by step by means of pawls and ratchet-wheels. To the initiative of Evans may be ascribed the early general use of high-pressure steam in the United States, a feature which for many years distinguished American from English practice. (*See* LOCOMOTIVE.)

**Compound Engine and Cornish Engine.**—Among contemporaries of Watt the name of Jonathan Hornblower deserves special mention. In 1781 he constructed and patented what would now be called a compound engine, with two cylinders of different sizes. Steam was first admitted into the smaller cylinder, and then passed over into the larger, doing work against a piston in each. In Hornblower's engine the two cylinders were placed side by side, and both pistons worked on the same end of a beam overhead. This was an instance of the use of steam expansively, and as such was earlier than the patent, though not earlier than the invention, of expansive working by Watt. Hornblower was crushed by the Birmingham firm for infringing their patent in the use of a separate condenser and air-pump. The compound engine was revived in 1804 by Arthur Woolf, with whose name it is often associated. Using steam of fairly high pressure, and cutting off the supply before the end of the stroke in the small cylinder, Woolf expanded the steam to several times its original volume. Mechanically the two-cylinder compound engine has some advantage over a one-cylinder engine with the same amount of expansion, in exerting a more uniform driving effort. But another and more important merit of the system lies in the fact that by dividing the whole range of expansion into two parts the cylinders in which these are separately performed are subject to a reduced range of fluctuation in their temperature. This helps to limit a source of waste which is present in all piston engines, namely the waste which results from the heating and cooling of the metal by its alternate contact with hot and cooler steam. The introduction of compound expansion forms the most outstanding improvement which steam engines of the piston and cylinder type have undergone since the time of Watt.

Woolf introduced the compound engine somewhat widely about 1814 as a pumping engine in the mines of Cornwall. But here it met a strong competitor in the high-pressure single-cylinder engine of Trevithick, which had the advantage of greater simplicity in construction. Woolf's engine fell into comparative disuse, and the single-cylinder type took a form which, under the name of the Cornish pumping-engine, was for many years famous for its great economy of fuel. In this engine the cylinder was set under one end of a beam, from the other end of which hung a heavy rod which operated a pump at the foot of the shaft. Steam was admitted above the piston for a short portion of the stroke, thereby raising the pump-rod, and was allowed to expand for the remainder. Then an equilibrium valve, connecting the space above and below the piston, as in fig. 3, was opened, and the pump-rod descended, doing work in the pump and raising the engine piston. The large mass which had to be started and stopped at each stroke served by its inertia to counterbalance the unequal pressure of the steam, for the ascending rods stored up energy of motion in the early part of the stroke, when the steam pressure was greatest, and gave out energy in the later part, when the pressure was much lowered by expansion. The frequency of the stroke was controlled by a device called a cataract, consisting of a small plunger pump, in which the plunger, raised at each stroke by the engine, was allowed to descend more or less slowly by the escape of fluid below it through an adjustable orifice, and in its descent liberated catches which held the steam and exhaust valves from opening. A similar device controlled the equilibrium valve, and could be set to give a pause at the end of the piston's down-stroke, so that the pump-cylinder might have time to become filled.

The final revival of the compound engine did not occur until about the middle of the 19th century, and then several agencies combined to effect it. In 1845 John M'Naught introduced a plan of improving beam engines of the original Watt type, by adding a high-pressure cylinder whose piston acted on the beam between the centre and the fly-wheel end. Steam of higher pressure than had formerly been used, after doing work in the new cylinder, passed into the old or low-pressure cylinder, where it was further expanded. Many engines whose power was proving insufficient for the extended machinery they had to drive were "M'Naughted" in this way, and after conversion were found not only to yield more power but to show a marked economy of fuel. The compound form was selected by William Pole for the pumping engines of Lambeth and other waterworks about 1850; in 1854 John Elder began to use it in marine engines; in 1857 E. A. Cowper added a steam-jacketed intermediate reservoir for steam between the high- and low-pressure cylinders, which made it unnecessary for the stroke of the low-pressure piston to be just beginning when that of the other piston was just ending. As facilities increased for the use of high-pressure steam, compound expansion came into more general use, its advantage becoming more conspicuous with every increase in boiler pressure. In marine practice, where economy of fuel was from the first an obviously important factor in design, the principle of compound expansion was extended by the introduction of triple and even quadruple expansion engines.

**Application to Locomotives and Steamboats.**—The adaptation of the steam engine to railways, begun by Trevithick, became a success in the hands of George Stephenson, whose engine, the "Rocket," when tried along with others in 1829, distanced its competitors. The principal features of the "Rocket" were an improved steam-blast for urging the combustion of coal and a boiler (suggested by Henry Booth) in which a large heating surface was given by the use of many small tubes through which the hot gases passed. Further, the cylinders, instead of being vertical as in earlier locomotives, were set at a slope, which was afterwards altered to a position more nearly horizontal. To these features there was added later the "link motion," a contrivance which enabled the engine to be easily reversed, and the amount of expansion to be readily varied. In the hands of George Stephenson

and his son Robert the locomotive took a form which in the main is retained by the far heavier locomotives (*q.v.*) now in use.

The first practical steamboat was the tug "Charlotte Dundas," built by William Symington, and tried in the Forth and Clyde canal in 1802. A Watt double-acting condensing engine, placed horizontally, acted directly by a connecting-rod on the crank of a shaft at the stern, which carried a revolving paddle-wheel. The trial was successful, but steam towing was abandoned for fear of injuring the banks of the canal. Ten years later Henry Bell built the "Comet," with side paddle-wheels, which ran as a passenger steamer on the Clyde; but an earlier inventor to follow up Symington's success was the American, Robert Fulton, who, after unsuccessful experiments on the Seine, fitted a steamer on the Hudson in 1807 with engines made to his designs by Boulton and Watt, and brought steam navigation for the first time to commercial success.

**Rise in Steam Pressure and in Piston Speed.**—With improvements in the details of design and construction it gradually became practicable to use higher steam pressures and higher piston speeds, and consequently to obtain not only greater efficiency, but also a greater amount of power from engines of given bulk. The triple expansion engine, introduced by A. C. Kirk in 1874, did not come into general use until after 1881. It became the normal type of marine engine, with pressures ranging, as a rule, from 150 to 200 lb. per sq. inch, piston speeds generally of 500 or 600 ft. per minute, but sometimes as high as 900 or 1,000, and coal consumption of about $1\frac{1}{2}$ lb. per hour per indicated horse-power. It continues to be very largely used in steamships which are not driven by turbines. In some instances quadruple expansion has been preferred, with somewhat higher pressures, but when the pressure is much raised the tendency is to abandon the piston type in favour of the steam turbine. This is true both in marine and in land practice. The gigantic concentration of steam power that is found in a great steamship or in a power station has been made practicable by the turbine. The selection of Parsons turbines in 1907 as the motive engines of the Cunarders "Lusitania" and "Mauretania" constituted a new departure in steam engineering. It was then a novelty to develop some 70,000 horse-power in the engine room of a single ship. Many of the turbines in power stations now exceed this figure.

**Introduction of the Steam Turbine.**—The invention of the steam turbine has revolutionized marine engine practice, in respect especially of the largest and fastest vessels. For the generation of electricity the turbine has a notable advantage in directly developing the high speed of rotation which a dynamo requires, and, when designed on a large scale, its efficiency is unrivalled by steam engines of other kinds. To Sir Charles Parsons we owe not only the main idea of the modern steam turbine, but also the invention of many mechanical features and details essential to its practical success and general adaptation.

In the steam turbine, as we have seen, pressure, instead of being exerted on a piston, is employed in the first instance to set the fluid itself in motion. There is a conversion of pressure-energy into velocity-energy as a preliminary step towards obtaining the effective work of the machine. If this were done in a single step it would involve immensely high velocities in the steam jet and in the vanes on which the jet acts. Attempts to design a steam turbine were made by numerous inventors, but fell short of practical success mainly because of the difficulty of arranging for high enough velocity in the working parts to utilize a reasonably large fraction of the kinetic energy of the steam. There was a further difficulty in getting the energy of the steam into a suitable kinetic form, namely, to get the stream of issuing particles to take a single direction, without undue dispersion, when steam was allowed to expand through an orifice from a chamber at high pressure into a space where the pressure was greatly less.

In 1889 Dr. Gustaf de Laval introduced a form of steam turbine in which both of these difficulties were, to a considerable degree, overcome, partly by the special form of the nozzle used to produce the steam jet and partly by features of design which allowed an exceptionally high speed to be reached in the wheel carrying the vanes against which the steam impinged.

Parsons attacked the problem at an earlier date and in a different way, by his invention of the "compound" turbine. He divided the whole expansion of the steam into a great number of successive and separate steps and thereby limited the velocity acquired at each step to such an extent as to make it comparatively easy to extract the greater part of the kinetic energy as work done upon the moving blades, without making the velocity of these blades inconveniently high. Moreover, in Parsons's compound turbine the range of pressure through which the steam expands in each separate step is too small to cause any difficulty in the formation of the jets. The guide blades, which form the jets, are distributed round the whole circumference of the revolving wheel, and all the revolving blades are consequently in action at once. The steam streams from end to end of the turbine through an annular space between a revolving drum and the casing which surrounds it. Parallel rings of fixed guide blades project inwards from the casing at suitable distances, and between these are rings of moving blades which project outwards from the drum and revolve with it. At each step in the expansion the steam streams through a ring of fixed guide blades, and the streams so formed impinge on the next ring of moving blades, and so on. The construction, which is of great simplicity, is described, along with others, in the article TURBINE: STEAM. It lends itself well to the generation of power on a large scale, especially where a fairly high speed of rotation is wanted.

Parsons introduced his compound steam turbine in 1884. For some years it was made in small sizes only, and the steam was discharged to the atmosphere without condensation. So long, however, as this was done the steam turbine was sacrificing one of its most important advantages, namely, its exceptional capacity for utilizing the energy of low-pressure steam down to the lowest vacuum obtainable in a condenser. In 1891 it was first fitted with a condenser, and it then began to be used in electric supply stations. The first application to marine propulsion was in the "Turbinia," in 1897. The success of this little experimental vessel of 100 tons, which, with its horse-power of 2,100, made what was then a record in speed for any ship, was soon followed by the application of the turbine to war-ships and other steamers. In merchant vessels its use was at first limited to those of the highest speed, for the turbine shaft was directly coupled to the shaft of the screw propeller; but in 1910 Parsons introduced a mechanical reducing gear between the two, which allowed the turbine shaft to run much faster than the propeller shaft, to the great advantage in efficiency of both turbine and propeller. Later he followed this up by a "double-reduction" gearing which admitted of a still greater difference in speed of rotation between the propeller and the turbine. In most ships the single reduction system is sufficient for the purpose: its introduction greatly extended the range within which the turbine could be advantageously substituted for the three-cylinder or four-cylinder compound engine of the piston type in ocean-going steamships.

Enough has been said to show that the invention of the steam turbine is by far the most important step in steam engineering since the time of Watt. It solved the problem of using steam efficiently in an engine without reciprocating parts.

**Early Theory.**—In the early development of the steam engine inventors had little in the way of theory to guide them. Watt had the advantage of a knowledge of Joseph Black's doctrine of latent heat; but there was no philosophy of the relation of work to heat until long after the inventions of Watt were complete. The theory of the steam engine as a heat engine may be said to date from 1824, when N. L. Sadi Carnot published his *Réflexions sur la puissance motrice du feu*, a remarkable essay in which he showed that heat does work only by being let down from a higher to a lower temperature. But Carnot was not then aware that any of the heat disappears in the process, and it was not until the doctrine of the conservation of energy was established in 1843 by the experiments of James Prescott Joule that the theory of heat engines began a vigorous growth. From 1849 onwards the science of thermodynamics was developed with extraordinary rapidity by Rudolf Clausius, W. J. Macquorn Rankine and William Thomson (Lord Kelvin) and was applied, especially by Rankine, to prac-

tical problems in the use of steam. Rankine's *Manual of the Steam Engine,* published in 1859, was the first attempt at a systematic treatment of steam-engine theory. It involved the simplifying assumption that the cylinder and piston might be treated as behaving to the steam like non-conducting bodies, in other words, that the transfer of heat between the steam and the metal might generally be disregarded. One effect of this was to treat the volume of steam consumed per stroke as corresponding to the volume of the cylinder up to the point of cut-off. When steam enters the engine cylinder it finds the metal chilled by the previous exhaust, and a portion of it is at once condensed. This has the effect of increasing, often very largely, the volume of boiler steam required per stroke. As expansion goes on, the water that was condensed during admission begins to be re-evaporated, and this action is often prolonged into the exhaust. It is now recognized that exchanges of heat between the steam and its metal envelope cannot be ignored. They cause the actual performance to fall short, in some cases very much short, of the ideal limit. They may be reduced by suitable design.

## ACTION OF RECIPROCATING ENGINES

Most, though not all, reciprocating engines are double-acting: that is to say, steam from the boiler is alternately admitted to each side of the piston. In each double stroke, or revolution, there are four events for each end of the cylinder:—(1) *Admission,* which begins by the opening of a steam-valve when the piston is at or very near the limit of its travel; (2) *Cut-off,* at which the steam-valve is closed and admission ceases. This may take place early in the stroke. The steam which is enclosed behind the piston then expands, with falling pressure, while the stroke continues, until (3) *Release* occurs; that is to say, an exhaust-valve opens, allowing the steam to escape from the cylinder. Its discharge generally continues for a large part of the back-stroke, until event (4), at which the exhaust-valve closes, and *Compression* begins: from there to the end of the back-stroke, the steam remaining in the cylinder is compressed into the clearance space behind the piston. This compression of the residue of steam, which is called cushioning, assists smoothness of working as the piston passes what is called the dead-point, at the limit of its stroke; and the cushioning effect is often augmented by giving the steam-valve what is called "lead,"—that is, causing it to open a little before the piston reaches the dead point.

**Distribution of the Steam: Indicator Diagram.**—Together, these various events of the stroke constitute what is termed the distribution of the steam. They are conveniently exhibited by drawing an indicator diagram of the action, such as that illustrated in fig. 4. There, on a base $PQ$ which represents the stroke, lines are drawn to show the continuous changes of pressure that go on within the cylinder during the whole action. Starting from the beginning of the stroke at *a,* for one side of the piston, steam is admitted up to the point *b* which shows the cut-off. At (or near) the end of the forward stroke, at *c,* the steam is allowed to escape. Compression, in the return stroke, begins at *d.* From *b* to *c* the steam confined in the cylinder is expanding, with falling pressure, doing work on the piston. The whole work done in the revolution, namely the integral of the force acting on the piston and the distance through which it moves, is represented by the enclosed area of the indicator diagram, *a b c d.*

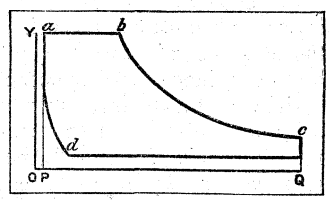

FIG. 4.—INDICATOR DIAGRAM SHOWING DISTRIBUTION OF STEAM

The diagram is idealised in the sense that the events are shown as if they happened suddenly, giving sharply defined changes from admission to expansion and so on. In any real engine the events are necessarily gradual, for no valve—whatever its type—can close or open quite instantaneously. A real indicator diagram accordingly has a smoother outline with rounded corners to mark the places of cut-off, release, compression and admission. In practice release always occurs before the piston has quite completed its stroke.

The distance $PQ$ which represents the stroke may (by the use of an appropriate scale) be interpreted as a volume, namely the volume swept through by the piston, and a point $O$ behind $P$ may be so taken that $OP$ represents, on the same scale, the volume of the clearance. The distance measured horizontally from the line $OY$ to any point of the curve represents the whole volume of steam behind the piston at that point, and the curve between admission and release exhibits the relation of the pressure to the total volume of the steam enclosed behind the piston throughout its process of expansion.

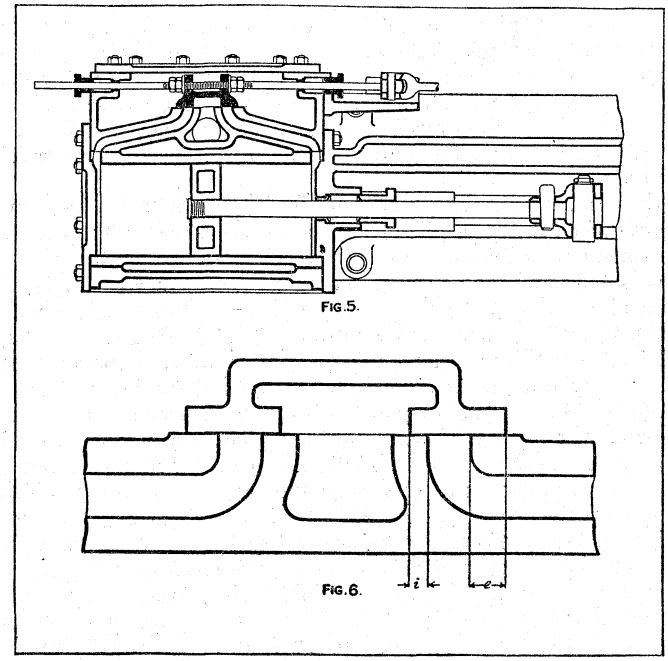

FIG. 5.—CROSS SECTION DIAGRAM OF A SLIDE-VALVE SHOWING THE EXHAUST AND INLET PORTS BELOW IT, AND CYLINDER AND PISTON
FIG. 6.—CROSS SECTION OF SLIDE-VALVE IN MIDDLE POSITION: (I) INTERNAL LAP, (E) EXTERNAL LAP

Actual indicator diagrams may be automatically drawn by attaching to the cylinder of the engine a device in which a pencil is made to rise or fall proportionally to the variations of steam pressure, while a paper, on which it inscribes a record, moves back and forth horizontally through distances proportional to the movement of the engine piston. Many forms of indicator have been designed to give, in some such way, a diagram in which the co-ordinates represent respectively the displacement of the piston and the pressure of the steam against it. From such diagrams it is easy to infer the mean effective pressure throughout the stroke, and also to observe how the valves are working. By connecting the instrument successively to each of the two ends of the cylinder, in a double-acting engine, a complete record is obtained for the two strokes which make up a revolution. The "indicated horse-power" is determined by the formula

$$\text{I.H.P.} = \frac{nL(p_1A_1 + p_2A_2)}{33{,}000}$$

where $A_1$ and $A_2$ are the areas of the two sides of the piston, in square inches; $p_1$ and $p_2$ are the mean effective pressures on the two sides, in lb. per sq. inch, as determined from the diagrams; $n$ is the number of revolutions per minute, and $L$ is the stroke in feet. In trials of a steam engine such diagrams are taken during a considerable period. The amount and condition of the steam passing through the engine is observed, by measuring either the quantity of water discharged from the condenser (if of the surface type), or the quantity of feed-water required to be supplied to the boiler to keep the water level constant. From these data it becomes possible to compare the power developed with the heat supplied. Measurements of the heat rejected may also be made by observing the quantity of condensing water used and its rise in temperature; and together these figures give material for drawing up a balance sheet of the disposal of thermal energy.

**The Slide-valve.**—The admission and exhaust of steam, for each end of the cylinder, may be controlled by separate valves, but very commonly a single moving piece, called a slide-valve, serves to control the events for both ends. The slide-valve was invented by William Murdock, an assistant of Watt. A common form of it is illustrated in section in fig. 5, which also shows the cylinder, with the piston, and the steam ports and passages leading to each end of the cylinder. The face on which the valve slides is a plane surface on one side of the cylinder with three ports or openings which extend across the greater part of the cylinder's width. The central opening is the exhaust port, through which the steam escapes after doing its duty in the cylinder. The others, which are narrower, lead to the two ends. The valve itself is a box-shaped cover, sliding on the face, and contained in the valve-chest, or chamber to which steam is admitted from the boiler. When the valve moves a sufficient distance to either side of the middle position steam is admitted to one end of the cylinder, past the outer edge. Similarly steam escapes from the other end of the cylinder, through the cavity of the valve, to the exhaust port. The valve takes its motion from an eccentric on the engine shaft, which is set more than 90° ahead of the crank, so that the valve has already begun to uncover the port on one side when the piston is at the corresponding dead point, with the result that steam passes from the steam chest above the valve into the space behind the piston. Figure 6 shows a slide-valve in its middle position, and illustrates the internal lap *i* and the external lap *e* which the valve must have to make expansive working possible. At the beginning of the stroke it has already passed its middle position by an amount at least equal to *e*, so that steam may enter. It continues to move further, opening the port more widely, and then begins to return, while the piston is still advancing in the cylinder. At a particular point in its return the outer edge of the valve closes the port; this determines the instant of cut-off. The piston continues to advance, with expansion of the steam confined in the cylinder, while the valve continues to move back, until the inner edge of the valve begins to uncover the port, allowing steam from the cylinder to escape to the exhaust channel. This point, which depends on the internal lap *i*, determines the instant of release. The port then opens more widely to exhaust, and remains open during most of the back stroke of the piston, until the valve, again moving in the original direction, brings its inner edge again over the port and compression begins. Similar events for the other end of the cylinder are determined by the other side of the valve. The positions of the piston when the several events occur depend on the amounts of the laps *e* and *i*, and of the "angular advance" which is the excess over 90° in the angle by which the eccentric stands ahead of the crank. If there were no laps and no angular advance steam would be admitted during the whole forward stroke and exhausted during the whole backward stroke. By giving the valve laps and angular advance expansive working becomes possible. But the slide-valve is not well adapted to effect a cut-off early in the stroke, and when much expansion is desired, a device called a separate expansion valve is added, or valves of a different type are used to control the distribution of the steam.

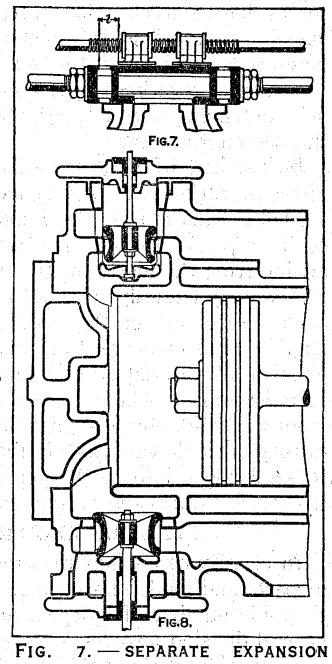

FIG. 7.—SEPARATE EXPANSION VALVE

FIG. 8.—CROSS SECTION OF ONE END OF A CYLINDER SHOWING DROP VALVES

**Separate Expansion Valves.**—Fig. 7 shows Meyer's expansion valve, which consists of two blocks sliding on the back of a slide-valve. It is caused to reciprocate by an eccentric, generally set directly opposite the crank, so that it moves to the left while the piston moves to the right, and *vice versa*. The admission of steam ceases when the relative displacement of the expansion blocks over the slide-valve amounts to the distance *l*, and this can be arranged to happen early in the piston's stroke without affecting the release or the compression.

In this example the rod which carries the two blocks is fitted with right- and left-handed screws, so that by turning the rod the distance between the blocks may be adjusted, and the distance *l* consequently altered. This allows the valve to be set to give an earlier or later cut-off: when *l* is increased by bringing the blocks nearer together, the cut-off comes later in the stroke. The adjustment may be made while the engine is running. Another way to change the cut-off with a valve of the Meyer type is to alter its travel. Increasing the travel of the expansion valve, while *l* remains constant, makes the cut-off come later.

In many engines the events are controlled by using, at each end of the cylinder, separate valves for admission and exhaust (fig. 8). Sometimes these are drop valves which are "double-beat" in the sense that the valve when it drops into its seat closes simultaneously two passages. These are so arranged that the steam pressure tending to close or open the valve remains balanced, and no large force has to be exerted. Such valves are often worked by cams and levers from a lay shaft alongside the cylinder, driven from the main shaft so as to turn in unison. In many examples the valves giving admission are caused to close by a tripping device; that is to say they spring suddenly into the closed position, at the instant when cut-off is desired, through the action of a trigger which brings a closing spring into play; and the tripping device is connected with the governor of the engine in such a manner that the cut-off comes earlier or later when the speed exceeds or falls short of the normal. In this way the engine automatically adjusts the amount of power it develops to suit changes in the demand made upon it by the mechanism which it drives.

**Balanced Valves.**—Fig. 5 shows a slide-valve form usual in locomotives and small engines but in large sizes the objection is that the unbalanced pressure of steam on the back of the valve would cause much friction and wear in the movement of the valve over the working face on which it slides. In large engines, such as those of steamships, it is usual to relieve the pressure of the valve on the working face by fitting the back of the valve with what is called a relief frame, extending between the valve and the steam-chest cover, the effect of which is to prevent the steam of the steam-chest from having access to the whole back surface of the valve. Another device, often resorted to, is to substitute for the flat form of slide-valve a piston form in which the effective sliding portions of the valve extend all round the surface of a cylinder and slide over cylindrical fixtures in the valve chest, round which the steam-ports extend.

**Reversing Gears.**—The slide-valve is a particularly convenient means of controlling the admission of steam when, as in locomotives or marine engines, etc., the engine's direction of motion has frequently to be reversed. It is only necessary to provide means by which the valve may be actuated by either of two eccentrics, one set at the angle suitable for forward running and the other set at the angle suitable for backward running.

In Stephenson's link motion which is an early and familiar device for this purpose, the engine shaft carries two eccentrics, one of which is set ahead of the crank at a suitable angle for one direction of running, and the other at a suitable angle for the other direction. Their rods are connected to the ends of a link which gives its name to the contrivance. The link is a slotted bar curved to a circular arc, and capable of being moved up or down, being suspended from a rod which can be raised or lowered by means of the hand lever above. The valve rod ends in a block which slides within the link. This device allows either the forward eccentric or the backward eccentric to determine the motion of the valve, and so allows the engine to be reversed. But it does more, for if the link be set to an intermediate position, in which it takes its motion chiefly from one eccentric but partly from the other, the valve receives a motion virtually the same as that which it would get from a single eccentric of shorter travel and greater

angular advance. The effect is to give a distribution of steam in which the cut-off is hastened and the expansion and compression are increased. Thus besides allowing of "full forward" and "full backward gear" the link may be "notched up" to give a much shorter admission of steam along with more compression, a matter of practical value in the running of a locomotive, where frequent large variations in the demand for driving effort have to be met.

Various other forms of link-motion have been devised which

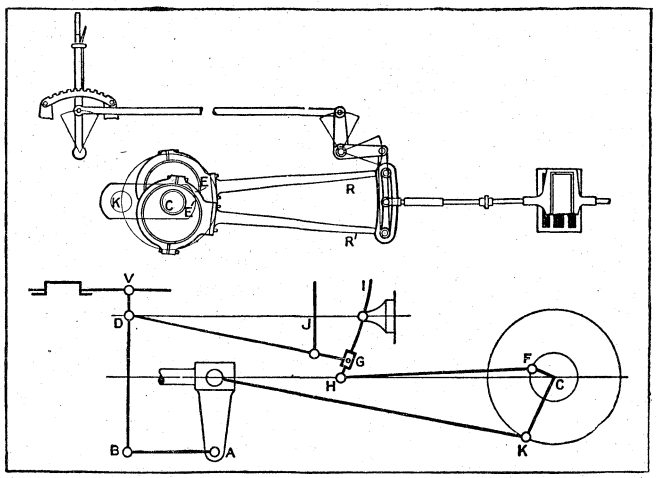

FIG. 9.—(ABOVE) STEPHENSON'S LINK-MOTION; (E, E') ECCENTRICS, (R, R') RODS CONNECTED TO ECCENTRICS: (BELOW) WALSCHAERT'S GEAR

share this advantage. It is also shared by a group of equivalent mechanical devices, called by the general name of "radial valve gears," in which only one eccentric is employed but the valve is caused to take a motion capable of being varied in the same way. Of these the most widely used is the Walschaert's gear, very common in locomotives, a skeleton diagram of which is shown in fig. 9. There *A* is a projection moving with the engine piston. The valve *V* takes motion partly from it, through the rods *AB* and *BV;* but *BV* has a fulcrum at *D,* the position of which varies through the movement of the rod *DG.* That rod is supported by a suspension rod *J,* and its end at *G* can slide in a link *HI* rocking about a fixed fulcrum at *O.* There is one eccentric, *CF,* set at right angles to the crank *CK,* and giving motion to the rocking link *HI* by the rod *FH.* The block *G* can be shifted from near *H* to *I* by raising the suspension rod *J.* This reverses the motion, and allows also of notching up to any intermediate position.

**Governing.**—To keep a steam engine running at a uniform speed, notwithstanding variations in the demand for power, hand regulation may to some extent serve, but in very many cases an automatic regulator called a governor is provided. Regulation, whether by hand or by automatic governor, may be effected in two ways: the steam may be throttled more or less on its way from the boiler to the engine, so that the pressure of admission is reduced when the speed tends to rise, and increased when the speed tends to fall: or the point of cut-off may be varied, with the result of admitting a greater or less volume of steam in each stroke. In small engines the governor often acts on a throttle valve, but at engines which aim at efficiency it is preferable to govern by altering the cut-off. In such engines, to secure in any case a proper amount of expansion, there is an early cut-off, and a small change in its position largely affects the amount of steam admitted and consequently the amount of work done.

Watt's original governor was a pair of balls revolving about a vertical spindle as conical pendulums under the combined effect of their own weight and the "centrifugal force" due to their speed of revolution. Any increase of speed sufficient to overcome the slight friction of the attached gearing made them take up a higher position, and in so doing they partially closed a throttle valve. This went on till, at a slightly greater speed than before, equilibrium was established between the supply of steam and the demand for power. Here, as in all governors, the effect is not to maintain a strictly constant speed, but to prevent the variation, either way, from exceeding narrow limits.

In modern governors the "centrifugal force" of the balls generally acts not simply against their own weight, but against an extra load or against the force of a spring.

In many factory and other engines the governor determines the position of cut-off by means of a trigger action of the type already mentioned: the admission valve, which has been opened and held open by a cam turning with the engine shaft, is suddenly disconnected by the release of a trigger, at a point depending on the exact height of the governor balls.

**Function of the Fly Wheel.**—The function of the governor is, generally, to keep the engine running at a nearly uniform rate, measured in turns per minute: the function of the flywheel is to keep the rate nearly uniform within the limits of any one revolution. For this purpose it must act as a reservoir of energy, alternately storing and restoring the excess amounts which result from periodic variations of turning moment in the operation of the piston on the crank. At the dead points the piston's rate of doing work is zero, and it rises to a maximum at an intermediate point the position of which may be much affected by an early cut-off. The flywheel is drawn upon for energy during those parts of the revolution in which the work done by the piston (or pistons) on the engine shaft is less than the work done by the shaft on the mechanism which the engine drives; and it takes up the surplus during the other parts of the revolution. To effect this alternate give and take of energy the flywheel must undergo small variations of speed, the magnitude of which may be kept down to any assigned amount by giving the rim a sufficient mass and speed.

**Inertia of Reciprocating Parts.**—The effective effort on the crank is greatly influenced, especially in high-speed engines, by the inertia of the piston, piston-rod and connecting rod. At the beginning of the stroke, when the piston is coming towards the crank-shaft, these reciprocating masses are acquiring motion; from a point near the middle to the end of the stroke they are losing motion. Hence in the early part the effort on the crank is reduced below what is due to the steam-pressure on the piston and in the later part it is increased. In a high-speed engine the forces due to acceleration become so large as seriously to affect questions of design. In direct-acting steam pumps the inertia of pump rods and buckets forms an additional item in the consideration of reciprocating mass: its effect there is on the whole beneficial in tending to equalize the force which is exerted on the pump throughout the stroke.

**Balancing of Engines.**—Another aspect of the acceleration of reciprocating parts is its effect on the balance of the engine as a whole. This is specially important in locomotives and marine engines (*q.v.*). In a locomotive the forces on the engine frame arising from the inertia of the pistons and rods tend to make the engine sway laterally: this is to some extent prevented by placing "balance masses" on the wheels. But such masses, although they may be adjusted nearly to balance the horizontal forces, introduce unbalanced vertical forces, causing what is called hammerblow. In extreme cases these vertical forces might even lift the wheels from the rails: short of that, however, they are objectionable in causing periodic variations in the pressure on the rails, which tend to set bridges into oscillation and may add substantially to the stresses for which the railway engineer must provide.

## TYPES OF RECIPROCATING ENGINES

In classifying engines with regard to their general arrangement of parts and mode of working, account has to be taken of a considerable number of independent characteristics. We have first a general division into *condensing* and *non-condensing* engines, with a subdivision of the condensing class into those which act by surface condensation and those which use injection. Next there is the division into *compound* and *non-compound,* with a further classification of the former as double-, triple-, or quadruple-expansion engines. Again, engines may be classed as *single* or *double-acting,* according as the steam acts on one or alternately on both sides of the piston. Again, a few engines—such as steam hammers and certain kinds of steam pumps—are *non-rotative,* that is to say, the reciprocating motion of the piston does work simply on a reciprocating piece; but generally an engine does work on a continuously revolving shaft. In most cases the crank-pin of the

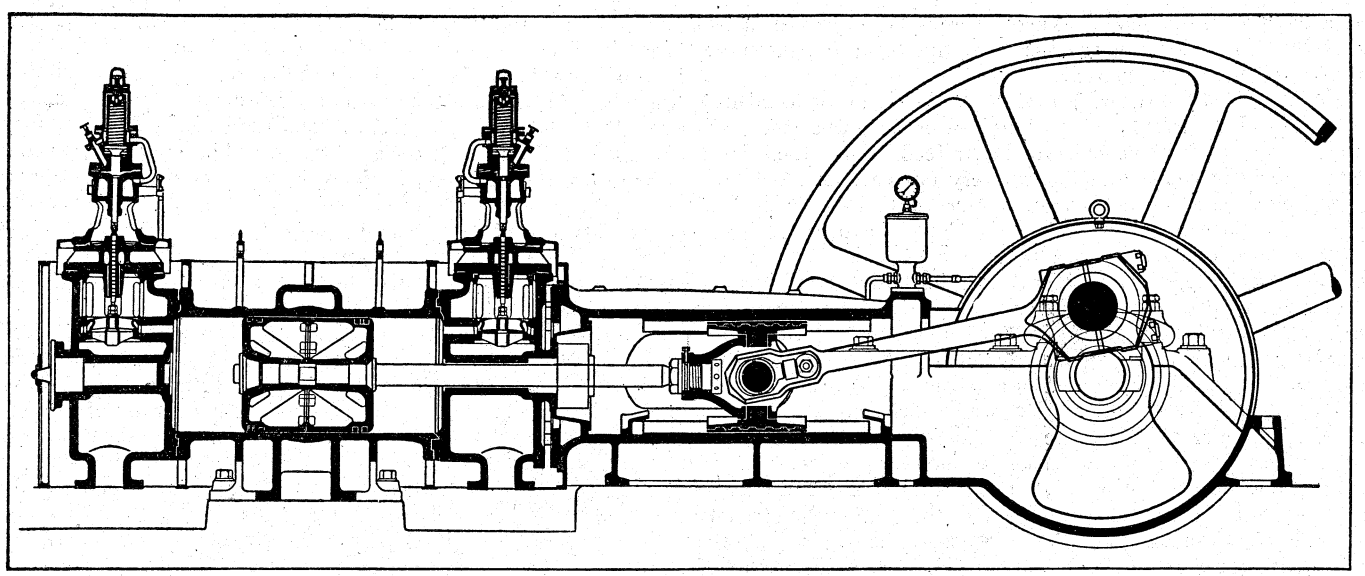

FIG. 10.—UNIFLOW ENGINE IN WHICH THE PISTON ACTS AS EXHAUST VALVE AND THE ADMISSION VALVES ARE IN THE CYLINDER ENDS

revolving shaft is connected directly with the piston-rod by a connecting-rod, and the engine is then said to be *direct-acting;* in other cases, of which the beam engine is an historical example, a lever is interposed between the piston and the connecting-rod. The same distinction applies to non-rotative pumping engines, in some of which the piston acts directly on the pump-rod, while in others it acts through a beam. The position of the cylinder is another element of classification, giving *horizontal, vertical* and *inclined cylinder* engines. In most vertical engines the cylinder is above the connecting-rod and crank. In *oscillating cylinder* engines (a type still found in some river boats) the connecting-rod is dispensed with; the piston-rod works on the crank-pin, and the cylinder oscillates on trunnions to allow the piston-rod to follow the crank-pin round its circular path. In *rotary* engines there is no piston in the ordinary sense; the steam does work on a revolving piece, and the necessity is thus avoided of afterwards converting reciprocating into rotary motion.

**Beam Engines.**—In the single-acting atmospheric engine of Newcomen the beam was a necessary feature; the use of water-packing for the piston required that the piston should move down in the working stroke, and a beam was needed to let the counterpoise pull the piston up. Watt's improvements made the beam no longer necessary; and in one of the forms he designed it was discarded—namely, in the form of pumping engine known as the Bull engine, in which a vertical inverted cylinder stands over and acts directly on the pump-rod. However, the beam formed a convenient driver for pump-rods and valve-rods; and the parallel motion invented by Watt as a means of guiding the piston-rod, which could easily be applied to a beam engine, was, in the early days of engine-building, an easier thing to construct than the plane surfaces which are the natural guides of the piston-rod in a direct-acting engine. In modern practice the direct-acting type has almost wholly displaced the beam engine.

**Direct-acting Engines.**—Of direct-acting engines the horizontal arrangement has in general the advantage of greater accessibility, but the vertical economises floor space. In small forms the engine is generally self-contained, that is to say, a single frame or bedplate carries all the parts including the main bearings in which the crank-shaft with its flywheel turns. The frame often takes what is called a girder shape, which brings a portion of it into a favourable position for taking the thrust between the cylinder and the crank-shaft bearings and allows two surfaces to be formed on the frame to serve as guides for the cross-head. When a condenser is used with a horizontal engine it is often placed behind the cylinder, and the air-pump, which may be within the condenser, has a horizontal plunger or piston on a "tail-rod" or continuation of the main piston-rod through the back cover of the cylinder. In large horizontal engines the condenser generally is in a well below, and its pump is driven by a mechanism linked with the crosshead.

**Coupled Engines.**—When uniformity of driving effort or the absence of dead points is important, two independent cylinders often work on the same shaft by cranks at right angles to each other. Such engines, which are called "coupled," can start readily from any position; the ordinary locomotive engine is an example. In some engines three cylinders, set to work on cranks 120° apart, co-operate in giving a still more uniform drive. Winding engines for mines and collieries, in which ease of starting, stopping and reversing is essential, are very generally made by coupling a pair of cylinders on opposite sides of the winding drum.

**Compound Engines, Coupled or Tandem.**—Large direct-acting engines are usually compounded either by having a high- and a low-pressure cylinder side by side, with cranks at right angles, or by putting one cylinder behind the other with a common centre line. The latter is called a *tandem* arrangement. In a tandem engine, since the pistons agree in phase, the steam may expand directly from the small into the large cylinder. But the connecting-pipe and steam chest form a receiver of considerable size, and it is preferable to cut off the supply of steam to the large cylinder at an earlier stage of the stroke. For mill engines the compound tandem and compound coupled types of engine are very usual. The high-pressure cylinder is often fitted with some form of trip-gear.

The chief advantage of compounding, as was pointed out in the historical section, is that it reduces the condensation which hot steam undergoes in the cylinder through contact with metal which has been chilled by the exhaust of the previous stroke. Compound working acts beneficially by narrowing the range through which the temperature periodically fluctuates in the metallic surfaces exposed to contact with the operative steam. The amount of steam that is at once condensed on admission depends on the extent to which the surface with which it comes in contact has been chilled during the previous exhaust. For this reason there is less loss through initial condensation in a compound engine giving the same total ratio of expansion.

**Uniflow Engine.**—The periodic give and take of heat between the steam and the metallic surfaces, which is a serious source of loss in any reciprocating engine, can be reduced by having separate valves for admission and exhaust, so that the same port-surfaces and valve-surfaces are not brought into contact with hot and comparatively cold steam. This idea is carried further in what is called the "uniflow" engine, by an ingenious arrangement which secures that the ends of the cylinder, where the steam is admitted, shall always be kept hot, the exhaust taking place at the middle of the cylinder through ports in the circumference which are uncovered by the motion of the piston.

The uniflow design is a recent but conspicuously successful departure from earlier practice. It allows high pressure steam to be expanded in a single cylinder without the drawbacks ordinarily

entailed in non-compound working. There is, however, still enough exchange of heat between the metal and the steam to make superheating highly advantageous.

**Condensation.**—In land engines a jet form of condenser is common, but surface condensation is resorted to when the available water-supply is unsuited for boiler feed. When there is no large supply of condensing water a very fair vacuum can be obtained by using an *evaporative condenser,* consisting of a stack of pipes into which the exhaust steam is admitted and over which a small amount of cooling water is allowed to drip. This water is evaporated by the heat which the condensing steam gives up. Such a condenser is placed in the open, generally on a roof where the air has free access. The amount of water it uses need not exceed the amount of steam that is condensed, and is a small fraction of the amount that would be required in a jet or surface condenser.

**High-speed Direct-acting Engines.**—Prior to the development of the steam turbine the demand for engines suitable for driving electric generators without the intervention of a belt led to the introduction of various forms of direct-acting engine adapted to run at a high speed. Some of these were *single-acting,* steam being admitted to one side of the piston only, generally the back, with the result that the rods could be kept in a state of thrust throughout the revolution, and alternations of stress in them and at the joints thereby avoided, together with the knocking and wear of the bearing brasses which it is apt to cause. To secure, however, that the connecting-rod should always push and never pull against the crank-pin there had to be much cushioning during the out stroke on account of the fact that from about the middle of that stroke to the end the reciprocating mass was being retarded. In engines of this class designed by P. W. Willans, which were at one time much used, but are now displaced by turbines, the cushioning was provided by means of a supplementary piston which compressed air during the out stroke; the energy which the reciprocating masses had to part with in losing their motion during the second half of the out stroke was stored in this air and was restored in the succeeding down stroke. The engine was entirely enclosed in a casing the bottom of which formed an oil bath in which the cranks splashed to ensure ample lubrication. This feature is retained in many modern high-speed engines.

**Pumping Engines.**—In engines for pumping or for blowing air it is not essential to drive a revolving shaft, and in many forms the reciprocating motion of the steam piston is applied directly to produce the reciprocating motion of the pump-piston or plunger. Often an inverted vertical triple expansion engine is used, resembling the usual marine form, with a pump-plunger under each of the three cylinders. Most of the power is directly transmitted from the piston to the pump, but there is an auxiliary crank for each cylinder, driving a shaft with a flywheel to equalize the effort on the pump.

A familiar example of direct-acting pump is the small donkey pump used for feeding boilers, in which the steam-piston and pump-plunger are on one and the same rod. In some of these pumps a rotative element is introduced, partly to secure steadiness of running and partly for convenience in working the valves. But many pumps of this class are entirely non-rotative, and in such cases the steam is generally admitted throughout the stroke without expansion. The valve may be actuated by tappets from the piston-rod. In some cases a tappet worked by the piston as it reaches each end of its stroke throws over an auxiliary steam-valve, which admits steam to one or other side of an auxiliary piston carrying the main slide-valve.

**Pulsometer.**—Hall's "pulsometer" is a peculiar pumping engine without cylinder or piston, which may be regarded as the modern representative of the engine of Savery. The sectional view, fig. 11, shows its principal parts. There are two chambers, *A, A′,* narrowing towards the top, where the steam-pipe *B* enters. A ball-valve *C* allows steam to pass into one of the chambers and closes the other. Steam entering (say) the right-hand chamber forces water out of it past the clack-valve *V* into a delivery passage *D,* which is connected with an air-vessel. When the water level in *A* sinks so far that steam begins to blow through the delivery passage, the water and steam are disturbed and so brought into intimate contact, the steam in *A* condenses, and a partial vacuum is formed. This causes the ball-valve *C* to rock over and close the top of *A,* while water rises from the suction-pipe *E* to fill that chamber. At the same time steam begins to enter the other chamber *A′,* discharging water from it, and the same series of actions is repeated in each chamber alternately. While the water is being driven out there is comparatively little condensation of steam, partly because the shape of the vessel does not promote the formation of eddies, and partly because there is a cushion of air between the steam and the water. Near the top of each chamber is a small air-valve opening inwards, which allows a little air to enter each time a vacuum is formed. When any steam is condensed, the air mixed with it remains on the cold surface and forms a non-conducting layer. The pulsometer is, of course, far from efficient as a thermodynamic engine, but its adaptability to situations where other steam-pumps cannot easily be applied, and the simplicity of its working parts, sometimes make it practically useful.

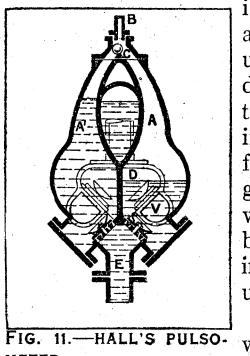

FIG. 11.—HALL'S PULSOMETER

**Marine Engines.**—The early steamers were fitted with paddle-wheels, and the engines used to drive them were for the most part modified beam engines. Bell's "Comet" was driven by a species of inverted beam engine, and another form of inverted beam, known as the *side-lever* engine, was for long a favourite with marine engineers. An old form of direct-acting paddle-engine was the *steeple* engine, in which the cylinder was set vertically below the crank. Two piston-rods projected through the top of the cylinder, one on each side of the shaft and of the crank. They were united by a cross-head sliding in vertical guides, and from this a return-connecting-rod led to the crank. Most modern paddle-wheel engines are direct-acting engines of the ordinary connecting-rod type, with the cylinders fixed on an inclined bed and the guides sloping up towards the shaft.

When the screw-propeller began to take the place of paddle-wheels in ocean steamers, the increased speed which it required was at first obtained by using spur-wheel gearing in conjunction with one of the forms of engines then usual in paddle steamers. Types of engine better suited to the screw were introduced later, and were driven fast enough to be connected directly to the screw-shaft. After passing through various forms, now obsolete, the marine engine settled into one which is now universal in all screw steamships that are not driven by steam turbine.

This is the inverted vertical direct-acting engine, with two or more cylinders placed side by side directly over the shaft. It has the great advantage that the shaft can readily be put at the low level necessary for screw propulsion. Two, three and four cranks are employed, the arrangement with four cranks being specially suitable, as has already been pointed out, when a balance of the engine at high speeds has to be secured. In vessels of high speed and power the engines are often arranged in twin sets, on two shafts with twin screw propellers.

The marine engine is always furnished with a surface condenser, consisting of a multitude of brass tubes about $\frac{3}{4}$ inch in diameter cooled by sea-water which is caused to circulate through the condenser by means of a circulating pump. This pump and the air pump are often driven independently of the main engine.

It is in marine practice that the most powerful reciprocating engines are still to be found, although in the largest and fastest vessels the turbine has taken their place. Another and more recent rival is the internal combustion engine, using the Diesel cycle of action, which by 1928 had found favour in many new liners. The reciprocating engine continues, however, to be much used for sea-going vessels, especially those of the "tramp" class, most commonly in the triple expansion form. Often the third stage of the expansion is performed in two cylinders, making four in all. This avoids the use of a very large cylinder, and secures an advantage in the better balance which can be obtained with four cranks.

**Locomotive Engines.**—The ordinary locomotive consists of a

pair of direct-acting horizontal or nearly horizontal engines, fixed in a rigid frame under the front end of the boiler, and coupled to the same shaft by cranks at right angles, each with a single slide-valve worked by a link-motion, or by a form of radial gear. The engine is non-condensing, except in a very few special cases, and the exhaust steam, delivered at the base of the funnel through a blast-pipe, serves to produce a draught of air through the furnace. In some instances a portion of the exhaust steam, amounting to about one-fifth of the whole, is diverted to heat the feed-water.

On the shaft are a pair of driving-wheels, whose frictional adhesion to the rails furnishes the necessary tractive force. Nearly always a greater tractive force is secured by having two or more driving-wheels on each side, connected by a coupling-rod between pins on the outside of the wheels.

It is general to have under the front of the engine a group of smaller wheels which do not form part of the driving system. These are carried in a *bogie*, that is, a small truck upon which the front end of the boiler rests by a swivel-pin or plate which allows the bogie to turn, so as to adapt itself to curves in the line, and thus obviate the grinding of tyres and danger of derailment which would be caused by using a long rigid wheel base.

In *inside-cylinder* engines the cylinders are placed side by side within the frame of the engine, and their connecting-rods work on cranks in the driving shaft. In *outside-cylinder* engines the cylinders are spread apart far enough to lie outside the frame of the engine, and work on crank-pins on the outsides of the driving wheels. Many modern locomotives combine the outside and inside arrangement, in order to get greater power, placing one or in some cases two cylinders within the frame, as well as two outside.

The principle of compounding has often been applied to locomotive engines, but without much advantage. (*See* LOCOMOTIVES.)

## THEORY OF THE STEAM ENGINE AS A HEAT ENGINE

**Properties of Steam.**—Steam-engine theory is an application of the principles of thermodynamics (*q.v.*) to a machine using steam as its working substance. The relevant properties of the substance have been briefly described in the article STEAM. They include the pressure, temperature, and density (or volume per unit of mass); also (per unit of mass) the entropy $\phi$ and the total heat I. For definitions of these quantities reference should be made to that article. Numerical values will be found in Callendar's or other steam tables, over a sufficiently wide range of conditions to meet the purposes of the engineer.

Given steam in any initial state, we have to consider what happens when it expands, doing work, as in the cylinder of a steam engine. It is easy to imagine steam expanding without turbulence in an ideal cylinder which is a perfect non-conductor of heat. Under these conditions no heat is being taken in, and there is no change of entropy: such expansion is said to be *adiabatic*. Adiabatic expansion, and adiabatic compression, although never strictly realized owing to the influence of the conducting cylinder walls, are ideal actions important in the theory of the steam engine.

During adiabatic expansion the substance is doing work at the expense of its stock of internal energy, and its temperature falls. Steam expanding adiabatically becomes partly condensed: the substance then becomes a mixture of saturated steam with water at the same temperature, and the energy or the total heat of one pound is to be found by considering what fraction is present as water and what fraction is steam. Such a mixture is often called wet steam. The degree of wetness reached at any stage of adiabatic expansion is readily calculated by taking account of the fact that the expanding mixture keeps its entropy unchanged.

From the general principles of thermodynamics it is easy to assign an upper limit to the efficiency of a steam engine, when the temperatures are known at which the working substance takes in and rejects heat. By "efficiency" is here meant the ratio of the work done to the quantity of heat supplied. Suppose, to simplify the problem, that there is no superheating, that is to say no supplementary taking in of heat after the steam has been formed at the constant temperature $T_1$ of the boiler. Suppose also that the only rejection of heat is at the constant temperature $T_2$ of the condenser. Then the principle of Carnot (*see* THERMODYNAMICS) shows that under ideally favourable conditions of working the fraction of the heat supplied which is converted into work cannot exceed $1-T_2/T_1$, when the temperatures are expressed on the absolute scale.

**Carnot Cycle.**—This result would be attained in an engine working in a strictly reversible manner, where the whole change from $T_1$ to $T_2$ occurs as a result of adiabatic expansion, and the whole change from $T_2$ to $T_1$ as a result of adiabatic compression. The indicator diagram of an ideal engine working in this manner is shown in fig. 12. The engine there imagined is one whose cylinder also serves as boiler and condenser. It is supposed to have perfectly non-conducting sides, but a conducting bottom to which any one of three bodies A, B, or C may be applied. B is a non-conducting cover, to be applied during the two adiabatic stages. A is a hot "source," maintained at a high temperature $T_1$, and C is a cold "sink" or receiver of heat, maintained at a low temperature $T_2$. Imagine the cylinder to contain one lb. of water at $T_1$ and A to be applied, while the piston begins to move towards the right. The "isothermal" (constant temperature) line *ab* is traced out during the evaporation of the water. At *b* the substance is all steam. A is then removed, B is applied, and the adiabatic expansion *bc* takes place, until the temperature of the working substance falls to $T_2$. C is then applied and the piston is pressed back, giving an isothermal line *cd* during which most of the steam is condensed. At *d* there is a mixture, chiefly water, which is adiabatically compressed. If this point *d* has been properly chosen, the operation *da* completes the cycle, bringing the substance back to the condition *a* in which it is all water at temperature $T_1$. The whole process is called Carnot's cycle.

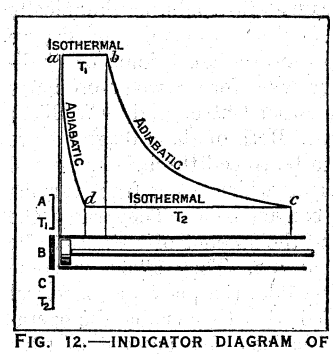

FIG. 12.—INDICATOR DIAGRAM OF CARNOT'S CYCLE

The formula $1-T_2/T_1$ which expresses the efficiency in this ideal operation shows the importance of making $T_1$ high and $T_2$ low. No real engine attains this limit of efficiency, for no engine completely expands the steam down to the condenser temperature in a strictly adiabatic manner. Further, no engine has an adiabatic compression stage corresponding to *da*: the use of a separate condenser makes that impracticable.

The action in an engine cylinder may be more appropriately idealized as in fig. 13 where *AB* represents the admission of the steam at $T_1$, *BC* its adiabatic and complete expansion to $T_2$, and *CD* its rejection to the condenser. Under these conditions it is easy to show that the work done, which corresponds to the area of this ideal diagram, is equal to

$$I_1-I_2$$

for each lb. of steam admitted to the engine, where $I_1$ is the total heat (per lb.) on admission, and $I_2$ is the total heat (per lb. of mixture) in the condition *C*, when expansion is complete. This applies whatever be the state of the steam on admission, whether superheated or not. The quantity $I_1-I_2$ is called the *adiabatic heat-drop*, and measures the greatest amount of work theoretically obtainable from each lb. of steam. In practice about 70 per cent. of the adiabatic heat-drop may be realized in favourable cases. Tables of the adiabatic heat-drop, for steam in various assumed initial states as to pressure and temperature, expanding to various assumed condenser pressures, have been compiled, and are of great service in problems of engine design.

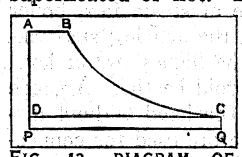

FIG. 13.—DIAGRAM OF THE ACTION OF AN AVERAGE ENGINE

**Rankine Cycle.**—The process exhibited in fig. 13 becomes a complete cycle when, in addition, account is taken of the action by which the feed-pump restores the condensed steam to the boiler. Thus completed the process is called the Rankine cycle. Its efficiency is necessarily somewhat less than that of the Carnot cycle of fig. 12. Superheating, which is not in practice carried

beyond a temperature of 400° C, and rarely so far, adds to the heat-drop by increasing $I_1$. But its chief effect on the efficiency of the process is indirect. By tending to keep the steam in a drier state it greatly reduces the losses that arise through exchange of heat between the working substances and the cylinder walls: in effect superheating makes the expansion more nearly adiabatic than it would otherwise be, and therefore gives a better approach to the ideal conditions of fig. 12. In a turbine superheating is beneficial by reducing the friction of wet steam on the blades.

**Entropy-temperature Diagrams.**—In exhibiting graphically the action of an engine under assumed conditions of working we may adopt various alternatives to the pressure-volume or "indicator" diagram. One interesting form takes for its two co-ordinates the temperature and the entropy: another (introduced by Mollier) takes the entropy and the total heat. Both of these diagrams are instructive in allowing the action to be traced through its several stages and in exhibiting the differences which result from varying the conditions of supply and of condensation. They show the direct influence of superheating, and the amount of wetness to be expected at any stage in the expansion. They allow, in some cases, measurement from a chart to take the place of numerical calculation; but their greatest merit is that they enable the operation of the working fluid to be visualized. No account of such diagrams can, however, be attempted within the limits of this article.

**Modern High-efficiency Steam Plants.**—In modern steam engines, especially of the turbine class where a very large range of expansion may be effectively carried out, efficiency is aimed at by using the best possible vacuum, to make $T_2$ low, and by raising the pressure of supply to make $T_1$ high. Pressures approaching 1000 lb. per square inch are not uncommon; occasionally that figure is exceeded, and even at the highest pressures some additional high-temperature heat is taken in by superheating. Reheating at one or more stages during expansion is resorted to, in order to prevent the expanding steam from becoming unduly wet. Another device, which is also applied in the most economical large-scale turbine plants, is to remove a portion of the expanding steam at each of two or three stages, and apply it in heating the feedwater on its way back from the condenser to the boiler. This progressive heating of the feedwater, by "bleeding" the turbine of steam which has already done more or less work, is called "cascade" feed-heating. Its effect is to make the whole cycle approach more nearly to the ideal cycle of Carnot, for the progressive feed-heating is nearly reversible and serves as a substitute, in this respect, for the adiabatic compression which makes that cycle differ from the cycle of Rankine. (*See* also TURBINE: STEAM; LOCOMOTIVES; MARINE ENGINEERING.)

A. E.)

**STEAM-GAUGE** is an instrument which by utilizing the elasticity of a metal indicates the pressure of steam in a boiler or other vessel. The action is explained in the article PRESSURE-GAUGE. The gauge must be fixed above the highest water level of the boiler, and stand away from it to avoid heating. A gauge is unduly hot if it cannot be touched by the hand without discomfort, and the U-tube or syphon is therefore used for connection to the boiler. In order to avoid straining the action, a gauge is generally graduated to twice the working pressure. Then the pointer stands vertically at the normal working pressure. High-pressure steam-gauges are those graduated for pressures between 200 lb. and 1,000 lb.

**STEAM GENERATION.** In a modern plant the course of operation can be traced broadly as follows: The water operates in a closed system and circulates in the form of steam or vapour and returns to its original state in the form of condensation. The water is first heated in feed water heaters, then goes through the tubes in the boilers and is changed to steam, then through a superheater that adds heat to it and from there to the utilizing equipment, a turbine for example. Finally it reaches the condenser from which it is returned to the starting point. The fuel usually starts through some preparation process such as crushing. From there it is usually conveyed to bunkers that provide a continuous feed to the stokers under the boilers. It is burnt on the stoker grates in the furnaces with natural or forced draft and the gases are used as they leave the boiler in superheaters, economizers and air preheaters. From there they finally escape through the stack. The economizers, superheaters and air preheaters are means by which some of the waste heat in the gases is reclaimed. In steam generating plants is found all or some of this equipment and much other auxiliary equipment.

Subjects dealing with the generation of steam and with the equipment used in that process will be found in the articles: BOILERS; STEAM; COMBUSTION; ECONOMIZER; ELECTRICAL POWER GENERATION; FUEL; HEAT; HEATING AND VENTILATION; PULVERIZED FUEL; STEAM ACCUMULATORS; STEAM CHEST; STEAM ENGINE; STEAM TURBINE, etc. The present article attempts to co-ordinate the above references under the following headings: *Fuel; Combustion; Boilers; Mechanical Stokers; Other Equipment;* and *Selection of Steam Generating Equipment.*

### DEVELOPMENT OF STEAM GENERATORS

When steam units were first used industrially the boiler was purchased, a brickmason employed to set the boiler in place and a labourer indiscriminately secured to shovel fuel under the boiler to generate enough steam for the process in question. Fuel, labour and material were cheap. It was not then economical to seek refinements in equipment or labour-saving devices; steam demands and pressures were low and in many cases, return tubular boilers answered the necessary requirements. The industrial development of the 20th century caused rapidly increasing demands for power. These were first met by the improvement in the design of steam turbines, and the application of mechanical stokers to the existing boilers. This met the needs for a few years but about 1916 steam turbine units began to increase rapidly in size and in 1939 single turbines of 60,000 kw. were in operation and compound units of 200,000 kw. turbines in course of construction. In 1939 power houses containing 770,000 kw. were in operation and power houses designed for 1,000,000 kw. output have been projected. In 1920 there were a few stations operating above 250 lb. pressure. In 1939 there were several score of stations operating at over 1,200-1,400 lb. pressure and a few are now in operation at higher pressures.

With these changes steam boilermakers discarded rule of thumb methods and employed research engineers, metallurgists and various specialists, installed machine tools, and adopted scientific methods of manufacture. It was found at this time that the kind of water introduced into the boiler was of considerable importance; that the superheater should be located in a position that would give a wide range of load with very little change of temperature; that an evaporation of from 13 to 21 lb. of steam per square foot of heating surface per hour should be the minimum; that the use of pulverized coal to secure these high ratings was desirable. Air-cooled refractory furnaces to burn pulverized coal at high ratings were tried but it was seen that, with water-cooled furnaces, a unit could be designed that would combine economy and efficiency with low maintenance cost and maximum continuous hours of service. With new and larger plants, the question of the best cycle to be used became of paramount importance affecting the boiler, superheater, feed water heater and economizer design. Means were needed to remove free oxygen from water to prevent corrosion. The water entering the economizer was of higher temperature than when exhaust steam alone was used and the temperature of the gases leaving the economizer were too high for the best efficiency. Consequently air preheaters were developed to recover heat from the escaping gases, to provide hot air for drying the coal in the course of pulverization and to preheat the air for combustion before being introduced into the furnace. This cut down the time required for complete com-

bustion and raised the temperature of the furnace.

A 400,000 kw. plant will burn 200 tons of coal per hour and roughly one-tenth of this will be ash which must be removed. Ash, in a dry state, is removed by conveyors or by sluicing with water. A newer development is to melt the ash and to remove as slag. Safety consideration, abatement of smoke and noise, consideration of the design of the plant to fit in with surrounding buildings and landscape, were additional problems to be solved. It will be seen then that the problem of generation of steam to meet the requirements of modern industrial civilization has become extremely complex. (J. B. C.)

## FUELS

The principal fuels for the generation of steam are coal and oil (*see* FUEL; PULVERIZED FUEL; PETROLEUM; COAL AND COAL MINING). There are, however, many localities where there is a limited supply of certain other materials which are sometimes used for fuel. *Coke breeze* is the small size coke and dust which is burned successfully on chain grate stokers. *Lignites* (*q.v.*) are burned on chain grate stokers and in pulverized form. *Wood* is usually put through a hogger to reduce it to small sizes for greater ease in handling and better burning in the furnace. The furnace must be large to provide sufficient time for complete combustion. *Bagasse* is the residual sugar cane, left after the juice has been extracted. The furnace is especially constructed for admitting air around its sides. The silica in the bagasse runs on to the grate and prevents air coming in from underneath. *Bonecoal* is the name given to coal taken off the top of coal seams and contains a large amount of impurities. Formerly discarded, it is now being burned on stokers and in pulverized form. *Anthracite coal* is used for household use in the districts adjacent to the anthracite fields. There is, however, a large amount of small sizes and dust that is now being burnt on travelling grate stokers, especially built for this purpose. *Natural gas* (*q.v.*), *blast furnace gas* (*q.v.*), *coke oven gas* (*q.v.*) and *producer gas* (*see* GAS MANUFACTURE) are also frequent boiler fuels.

Boilers are used to generate steam from the otherwise waste heat of cement kilns, metallurgical furnaces, coke ovens, gas generators and other such processes where high exit temperatures of the products of combustion prevail. In the McEwen-Runge process of coal carbonization, the coke in pulverized form served as a fuel for boilers as did also the screened coke residue from the K.S.G. process which was burnt on forced draft chain grate stokers.

## COMBUSTION

Combustion within the furnace of a steam generator consists in the chemical combination of the elements of the fuel with oxygen from atmospheric air supplied for that purpose. Corresponding to the weights of carbon (C), hydrogen (H), oxygen (O) and sulphur (S) in the fuel fired, the weight of air theoretically required for combustion is given by

$$A = \frac{2{\cdot}67\,C + 8\,(H - o/8) + S}{0{\cdot}232}$$

since atmospheric air contains 23·2% of oxygen by weight.

It is necessary to supply "excess air" above this theoretical minimum, however, and "free oxygen" always occurs in the products of combustion. Even with excess air, some combustible will escape unburnt from the furnace and a small amount of carbon monoxide may simultaneously be found in the products of combustion. The unburnt combustible is generally carbon with a corresponding combustion loss of 14,600 B.T.U. per pound. The formation of carbon monoxide (CO) instead of carbon dioxide ($CO_2$) is named "incomplete combustion." One pound of carbon burned completely to $CO_2$ liberates 14,600 B.T.U. One pound of carbon burned incompletely to CO liberates only 4,400 B.T.U., hence the loss is the difference between these values or 10,160 B.T.U. per pound of carbon burnt to carbon monoxide. While these losses are reduced by increasing the percentage of excess air, the gain in combustion efficiency is more or less counteracted by the increase in another loss, namely, the heat content of the excess air at the temperature of the products of combustion escaping to the stack. Leakage of air through the walls of the furnace and boiler setting increases the excess air loss to the stack without effecting, in general, any corresponding gain in combustion efficiency. Considerable saving in fuel may often be made simply by reducing leakage through cracks or openings in boiler settings.

For each kind of fuel, type of furnace and method of firing, there is a certain percentage of excess air which results in a minimum loss. The most economical percentage of excess air is determined for any given installation from analyses of the products of combustion, and it corresponds to that percentage of carbon dioxide at which the carbon monoxide amounts to only a few tenths of 1%. For hand-fired coal furnaces and older stoker installations with restricted furnace volume, the best carbon dioxide percentage is around 12% which represents about 50% excess air. Larger combustion chambers were later employed because it was thereby possible to reduce the excess air below 50% without producing much carbon monoxide. At high operating capacities, however, furnace temperatures became so high that slagging of refractory walls and formation of clinkers in fuel beds became excessive. Water-cooled walls have eliminated refractory troubles and permitted the most economical percentage of excess air to be used without reaching excessively high temperatures, so that in some of the most modern steam generator furnaces as high as 15 to 16% of carbon dioxide is attained in daily operation.

With gases and oils, the most economical percentage of carbon dioxide will, in general, be less than mentioned above for coal, although the excess air percentage may be lower by reason of the more intimate mixture of fuel and air that can be obtained with proper burners and furnaces. This is due to the larger percentage of hydrogen in these fuels which combines with oxygen-forming water that is not ordinarily included in analyses of products of combustion.

When burning pulverized coal, thorough mixing in the furnace of the fuel particles with the air is conducive to complete combustion with low excess air. This may be secured by means of turbulent firing where the coal and air streams impinge upon one another in the furnace; but while the volatile matter may be burnt within a small volume, a much larger furnace must be provided to give time for the fixed carbon particles to burn before they escape from the furnace. Finer pulverization will reduce the unburnt combustible loss at the expense of the use of more power for grinding the coal. For solid fuels burned on grates and stokers, the furnace shape as well as its size is important in securing thorough mixture.

Smoke is often taken as an indication of poor combustion, and so it may be. However, smoke is often due to the presence of fine particles of soot resulting from breaking down volatile matter by heating with insufficient air rather than to larger particles of unburnt fixed carbon. Hence a smoking furnace may be working at fairly high efficiency, while one with a clear stack may have a large excess air loss. Smoke may be prevented by using a low volatile fuel such as anthracite coal and coke, or by mixing air with the volatile matter more thoroughly and thereby insuring its complete combustion in the furnace.

Combustion losses are reduced by preheating the air. The maximum permissible preheat temperature is determined by the durability of grates or stoker parts. In pulverized coal firing, the preheat temperature is limited only by the durability of the preheater elements. There is an economic relation, however, between the cost of air preheater surface, economizer surface and boiler tube surface, which results in a minimum cost for the complete steam generating unit corresponding to a moderate air preheat temperature between 400° and 500° F.

If all the heat liberated by combustion and carried into the furnace in the preheated air were imparted to the products of combustion, very high furnace temperatures would be reached. Much lower temperatures actually obtain in boiler furnaces due to radiation. Radiation from the incandescent fuel and flames varies approximately as the fourth power of their absolute tem-

perature. With water-cooled walls, over one-half the heat of combustion is absorbed in the furnace by radiation from the incandescent fuel and flames. This radiant heat will fuse any particles of ash which cannot be kept cool by adjacent water-cooled surfaces. Hence refractory baffles must be protected by two or more rows of boiler tubes on the furnace side or particles of ash adhering to them will fuse and form large slag masses. With pulverized coal firing, ash will melt on the furnace bottom unless cooled below its fusing temperature and protected from radiation by "screen tubes." While the melted ash may be run out of the furnace as molten slag, there is an additional furnace loss in the latent heat of fusion of this slag.

Boiler test codes adopted by engineering societies in various countries, define boiler efficiency as the ratio of the heat absorbed by the steam produced per unit weight of fuel burned, to the gross, or upper, heating value of the fuel as determined in a calorimeter where the moisture present in the fuel and formed from the hydrogen therein is condensed to water. In England, efficiencies are often guaranteed as based on the lower heating value, which is equal to the upper heating value minus $1{,}050\times(M+9H)$, where M = lb. of moisture and H = lb. of hydrogen per lb. of fuel burned and 1,050 = latent heat of steam at atmospheric temperatures. (W. L. De B.)

## BOILERS AND STEAM GENERATORS

Boilers are of the following designs: return tubular, water tube, electric, steam generator.

**Return Tubular** boilers consist of a shell 60 in. to 108 in. in diameter. The shells are made of several plates riveted together with the tubes acting as stay bolts for the heads. The gases pass through the tubes. The boilers are limited in size to about 3,000 square feet. This type of boiler is used where small quantities of steam are required, at pressures not exceeding 250 lb. per square inch. It is also used extensively for waste heat in the manufacture of open hearth steel and other processes, in marine work and for locomotives.

**Water Tube Boilers** are boilers in which the water passes through the tubes and the gases are on the outside of the tubes. One of the main advantages of this type of boiler is safety. The latent heat in hot water under pressure has a particularly destructive effect in case the pressure in the vessel is suddenly released.

By confining the water to tubes, the quantity of water in any particular part of the boiler is kept to a minimum and if a tube bursts, the resulting damage will be small. Another advantage is that the size of the unit is limited only by the size of plates available.

This boiler is made in several different classes; *straight tubes with box headers* and both longitudinal and horizontal drums, *straight tubes with sectional headers,* and both longitudinal and horizontal drums, *bent tubes with vertical and semi-vertical tubes* and drums.

For box header boilers the headers are formed by riveting together two plates, spaced apart to form a boxlike structure. This construction is usually limited to 10,000 sq.ft. on account of the difficulty of shipping larger plates and to pressures of about 400 lb. per square inch.

The straight tube sectional header boiler is substantially of the same general cross-section as the box header except that in some cases there is a greater inclination of the tubes. The headers are made of forged steel and contain one or more vertical rows of tubes. This type of boiler has been built in sizes up to 35,000 sq.ft. and can be built larger and for pressures up to 1,800 lb. per square inch.

**Electric Boilers.**—The electric boiler is used to generate steam or hot water where a small quantity of steam is required or in larger sizes where electricity can be secured at reasonable rates to improve the load factor of plants.

**Steam Generators.**—The advent of pulverized coal (*see* Pulverized Fuel) crystallized the design of complete steam generating units giving consideration to the proper furnace volume and co-ordination of radiant and convection heating surface, superheater, economizer and air preheater. Such construction can be fired by oil, gas or pulverized fuel. It can readily be built for pressures up to 2,000 lb. per square inch. The fuel may be introduced at several points and sometimes the burners are located at the top of the furnace with the gases passing downward. In other designs the fuel is introduced at the front wall or at the four corners with the gases passing upward through the furnace. The economizer and fan may be placed directly back of the convection surface and the fans directly above the air preheater so that the duct work, with its chances for radiation and leakage, is reduced to a minimum. Some steam generator units give efficiencies of 89%.

**Drums.**—When built for pressure of 100 to 350 lb. all boiler drums were constructed of rolled plates formed on bending machines and riveted together. As the pressure increases the plate is necessarily thicker, making it more difficult to form plates and drive the rivets. It is generally accepted in 1939 that riveted drums should be limited to not more than $1\frac{1}{2}$ inches. Up to 1928 a few boiler drums less than 2 in. thick have been constructed by forge welding. In Europe, but not in the United States up to 1929, drums have been constructed of drawn seamless tubes. In 1931 the A.S.M.E. boiler code made permissible the use of autogenous or electric welding for the construction of boiler drums. Prior to 1931 it was customary to construct drums $2\frac{1}{2}$ in. thick and over of forgings but welded drums are now made up to five inches in thickness.

The joints to be welded are carefully machined before welding and submitted to X-ray examination after welding under rigid inspection. The drums are then annealed to remove stresses.

In the United States the steel for riveted and forge-welded boiler drums must conform with the chemical and physical characteristics given in the A.S.M.E. boiler code. Alloy steels with varying percentages of chrome, titanium, molybdenum, and other elements are used to take care of the higher temperatures and to keep plate thicknesses within reasonable limits for high pressure.

**Large Units.**—For large capacity units, the bent tube boiler has been found to give the most economical results. At low ratings, below 300%, the straight tube boiler has been found to give lower exit temperature but above these ratings the bent tube boiler gives approximately the same and in some cases lower exit temperatures.

At high ratings the draft loss of the bent tube boiler is much less. It is customary in designing large boilers to place two bent tube boilers in the same setting and facing each other. With this method of construction, firing is usually done from two sides or from the four corners. The radiation losses are low, the gases are most thoroughly mixed before entering the boiler surface, the unit is compact and the drums are practically one-half the length that would be required for a single unit with firing from one side. Single units to deliver 750,000 lb. of steam per hour and double units to deliver over 1,000,000 lb. of steam per hour at 1,400 lb. per square inch pressure, and over 900° F. steam temperature, were in operation in 1939.

(*See* Boiler-making; Boilers.) (J. B. C.)

## MECHANICAL STOKERS

A mechanical stoker is a device for stoking or firing a furnace by mechanical means. In its broadest interpretation mechanical stoking would include the mechanical feeding of any kind of fuel to a furnace, but in common usage the term is limited to the firing of solid fuels such as coal and coke. The earliest form of mechanical stoker was an endless conveyor with two endless chains situated near the sides of the furnace and engaging sprockets mounted on shafts situated at the front and rear. Transverse grate bars were attached to these chains to form the fuel-supporting surface, one shaft was provided with means for driving the chains and grate so that the top surface moved through the furnace from front to rear. A hopper fixed at the stoker front supplied fuel to the grate and natural or chimney draft provided air for combustion which was admitted through the grate and fuel bed. The speed of the grate was regulated so that the fuel

was burnt out during its travel through the furnace and the resultant ash and refuse was discharged into a pit as the grate made the return bend around the sprockets on the rear shaft. A natural draft chain stoker is applicable to non-coking or free burning bituminous coals.

A modification of this type of stoker provides for the use of forced draft supplied by a fan or blower for admitting the air for combustion. With this provision, higher rates of combustion are made possible, and a wide variety of fuels may be burned successfully including anthracite fines, coke fines, lignite, and free burning bituminous coal.

The overfeed, inclined grate natural draft stoker is used to a limited extent for burning bituminous coals at moderate ratings under small boilers. The fuel is fed from the hopper usually at the front, to stepped grates which are rocked by mechanical means to impart a downward travel of the fuel during combustion and to deposit the ash and refuse at the rear, on dump trays which are lowered by hand at intervals to discharge the ash into a pit below.

In overfeed stokers of the spreader type the coal is fed from a hopper into the path of rapidly revolving paddles which throw the coal into the furnace where the fines are burnt in suspension and the coarser particles on a grate using forced draft.

Underfeed stokers, as the name suggests, introduce the fuel below the surface of the fuel bed. The volatile constituents of the coal are distilled off and pass up through the incandescent fire where they are rapidly ignited and burned without producing smoke. Forced draft is used with this type of stoker. This method of firing finds its greatest field for use with those bituminous coals which during combustion tend to form coke masses that must be broken up to insure uniform fuel bed conditions. Underfeed stokers may be broadly subdivided into two general classes—single retort stokers and multiple retort stokers.

In single retort stokers the coal is commonly fed from a hopper at the stoker front into a centrally situated trough or retort by means of a pusher driven by a steam actuated piston or by an electric motor. In small underfeed stokers a slowly revolving screw or worm is commonly used to feed the coal from the hopper to the retort. Each new charge of coal introduced serves to push an equal volume of fuel out of the top of the retort and onto the grate bars which extend transversely from the sides of the retort. Alternate grate bars are movable and are connected to the stoker drive so as to impart a slight slicing motion which serves to maintain a porous fuel bed, to distribute the burning fuel across the stoker and to carry the ash and refuse to dump trays placed along each furnace side wall. Air for combustion is supplied under pressure by a fan or blower and is admitted to the fuel bed through openings along the sides of the retort and between the grate bars.

The multiple retort underfeed stoker comprises a series of retorts (usually inclined) mounted side by side across the furnace width. Coal is fed from a hopper, fixed at the stoker front, by rams connected to a crank shaft and driven through proper reducing gearing by an electric motor or other means. Secondary rams, situated in the bottom of the retorts, serve to break up the coke masses, to distribute the fuel over the stoker and to deposit the ash and refuse either on dump grates or into a pit at the rear where grinder rolls crush the refuse and discharge it into a pit below. Air for combustion is supplied under pressure by a fan, through nozzles or tuyeres arranged in longitudinal rows between adjacent retorts.

Mechanical stokers are usually controlled by regulators which are set to maintain a predetermined steam pressure and which are actuated by changes in this pressure. A drop in steam pressure causes an increase in stoker and fan speed so that more coal and air are admitted to correct the falling steam pressure. An increase in steam pressure causes a decrease in the amount of coal and air admitted. Stokers so equipped maintain constant steam pressure automatically and are called "automatic mechanical stokers." Mechanical stokers are principally used for firing stationary steam boilers and metallurgical furnaces. However, types have been developed and satisfactorily applied to locomotives and marine boilers. (C. STR.)

## OTHER EQUIPMENT

*Superheaters* are used to increase the temperature of steam without increasing its pressure. The furnace gases furnish the heat, either in the furnace, among the boiler tubes or in the exhaust to the stack where some lost heat can be recovered. For a discussion of superheaters and superheat *see* BOILERS; STEAM.

*Reheaters* are used to prevent loss of superheat and the formation of moisture when steam is used in turbines. (*See* BOILERS.)

*Air Preheaters.*—The exhaust gases coming directly from the furnace or from the economizers are used in air heaters or preheaters to heat the air that is to be used for combustion in the furnace, thus making use of otherwise lost heat. (*See* BOILERS.)

*Feed Water Heaters.*—Before water fed to a boiler can be converted into steam it must first be heated to the temperature corresponding to the pressure in the boiler. This feed water is heated in open heaters, closed heaters or economizers, either to that or to a lesser temperature, depending on the plant. The first two types of feed water heaters use live or exhaust steam to obtain heat, the last uses the exhaust gases from the furnaces. (*See* ECONOMIZER; BOILERS; ELECTRICAL POWER GENERATION.)

*Evaporators and De-aerators* are used to supply loss in feed water and to remove the air dissolved in the water in the condenser. (*See* ELECTRICAL POWER GENERATION.)

## SELECTION OF STEAM GENERATING EQUIPMENT

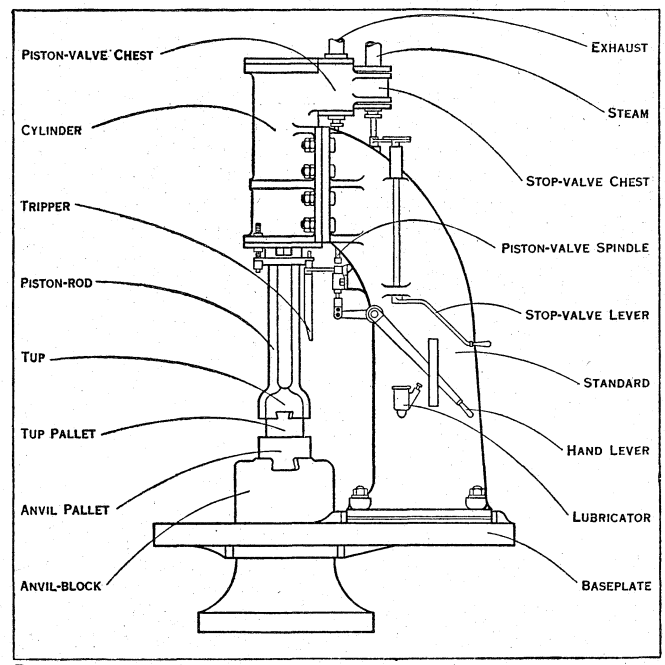
Steam generating equipment may be considered as comprising not only the boiler and furnace but all auxiliaries necessary or desirable from the point of delivery of the coal to the stop valve on the boiler. A proper evaluation of factors which determine the correct selection of the necessary or desired equipment can only be made by an engineer thoroughly familiar with all the factors, their relations and a knowledge of costs, values and economics.

In a modern utility plant the steam end may and frequently does include in addition to the boiler a water-cooled furnace—steam superheaters and re-heaters—mechanical stokers of various types; burners for pulverized coal or oil; economizers and air preheaters; induced and forced draft fans or blowers and their necessary motor or turbine drive; ducts and flues for conducting the air and flue gas to desired points; chimney and dampers; cinder or dust catchers; boiler feed pumps and feed water regulators; soot blowers for the boilers; economizers and air-heaters; condensers; blow down valves; heat inter-changers to abstract heat from boiler blow down; open or closed feed water heaters; deaerators; a feed water treating plant or evaporators.

The complete coal and ash handling system from the railroad siding to the coal bunkers may include a car dumper, track hopper, screens, crushers, magnetic separators, conveyors, skip hoists, locomotive-crane and all equipment necessary for storing and reclaiming coal. If coal is pulverized there will be dryers, pulverizing mills with piping collectors, conveyors, feeders, burners and necessary motors. Ash may be handled by cars, conveyors or by water in sluices or grab buckets. Other auxiliary equipment may include a combustion control system with elaborate inter-locking of the electrical equipment. Pressure and draft gauges, thermometers, steam flow meters and gas analysers, all of the indicating or recording type, will also be found.

The problem of the selection of proper equipment may be very simply stated. Equipment should be selected that will produce steam at the lowest total cost for the expected life of the plant, with the required reliability. The weight given to various factors will differ in various types of plants. In public utility plants where the fuel cost is about half the total cost of operation greater weight is given to economy, this factor being modified by the cost of fuel. In some industrial plants operating only ten hours per day with cheap coal, first cost may be a major factor. There are certain processes requiring continuity of steam pressure or power in which a failure of either or both for a few minutes may ruin material valued at thousands of dollars. In such cases reliability usually secured by duplication or excess spare capacity should be one of the major factors considered. The total cost of

steam generation is made up of fixed or capital costs and operating costs. The fixed charges or costs are made up of interest on first cost, taxes, insurance, depreciation or obsolescence. The operating costs include fuel; water; maintenance material-repairs; supplies of oil, tools and chemicals; operating labour; maintenance labour; clerical salaries and operating supervision. Generally, by increasing the capital cost, the operating cost may be reduced. High efficiency can be obtained by high capital expenditure. However, depending on the fuel cost and many other factors, a point is reached where the fixed charges of additional equipment equal the saving obtained by that equipment and any additions beyond that point result in fixed charges in excess of savings.



One of the important factors having a major bearing on economy and in capital costs is the plant capacity factor, sometimes named load factor. The capacity factor is the total load per year expressed in any suitable units divided by the rated or normal capacity of the units times 8,760 hours per year or the relation of the actual annual load carried to the annual load if units were operated at normal capacity every hour of the year.

In view of the complexity of the many factors affecting the selection of steam generating equipment and their interrelation it is only possible to list them in their major relations and group these relations as logically as possible. The considerations listed below are the most usual. There may be others peculiar to certain specific problems.

*The size, type and operating rate of boilers may be limited by quality of water. (J. Van Br.)

**STEAM-HAMMER.** Steam-hammers are made in sizes ranging from ½ cwt. to about 12 tons. The size is merely a nominal rating, being the weight of the falling parts—piston, rod, tup, pallet—and takes no account of the pressure of steam which drives the piston down for the blow. As an approximate guide, however, it may be stated that the steam pressure in a 5-cwt. hammer gives a crushing effect on hot iron equal to a load of about 30 tons. Types of hammers are classified in three principal forms, the overhanging with slide, the arch and the Rigby (*see* drawing). In the last-named there is plenty of clearance space for the smith to manipulate work above and around the anvil-block, and the piston has a longer stroke and gives more power than corresponding hammers of other types. The overhanging type hammer has slides reaching down to guide the tup accurately, an advantage in many cases of forging, including that done in dies. The arch form has two standards between which the tup is also run in guides, and it is much used for forgework of heavy description, being a very rigid construction. The frame is often built of rolled steel plates and angles instead of cast-iron or cast-steel. The operating mechanism of the B. and S. Massey hammer shown comprises the stop-valve lever which regulates the quantity of steam admitted to the hammer, and the hand-lever that is moved to strike light or heavy blows, or to hold work between the pallets as in a vice, for bending purposes, etc. The steam is used expansively, with resulting economy, by the action of the tripper, which begins to close the piston-valve after the tup has moved a certain distance. A self-acting valve-gear can be applied to any type of hammer, so as to cause the hammer to work automatically. Many special shapes of hammer framings and anvils are built for specific purposes. Control is in some cases effected by a treadle, so that one man can use the hammer. Compressed air may be utilized instead of steam, should it not be convenient to furnish a supply of the latter. The lubricator attached to the side of the frame consists of a hand pump with which

B AND S MASSEY STEAM HAMMER WHICH DELIVERS BLOWS IN ACCORDANCE WITH THE MOVEMENTS OF THE HAND LEVER

the cylinder and valves can be oiled without stopping the hammer. To secure efficient results the anvil-block must be of great weight, and supported on a mass of timbering resting on deep concrete or rock. The base also rests on timbers and concrete. (*See* Presses and Presswork and Drop Forging.) (F. H.)

**STEAM PLOUGH:** *see* Agricultural Power and Machinery.

**STEAM-ROLLER:** *see* Road Roller.

**STEAMSHIP:** *see* Shipbuilding.

**STEAMSHIP LINES:** *see* Shipping Lines and Groups.

**STEAM SHOVEL** or **NAVVY.** A form of excavator which drags a bucket or shovel, at the end of a pivoted arm, from a surface position up to the top of a cutting or other place to be excavated, filling the bucket meanwhile. The mouth has steel cutting teeth or tines for easy penetration. When the bucket is filled, discharge is made into wagons or elsewhere by opening a door at the bottom. The machine is a very powerful modified type of jib crane, specially constructed for fast and severe duty, with a great amount of steel construction, and extra hard parts of manganese steel for those subjected to excessive friction and exposure to grit. The pivoted arm either has a fixed swing from its pivotal point about half-way up the jib, or the swing may be varied by racking the arm to or fro. As the crane stands still during a succession of cuts the depth of penetration has to be regu-

lated to suit the capacity of the bucket. With the fixed arm design this is done by varying the radius of the jib, and with the racking arm by the movement of the latter alone. Bucket capacity varies from ½ cubic yard to about 15 cubic yards. The drive is by steam (the oldest system) but alternatively may be by petrol or paraffin motor, by electric motors, or Diesel-electric. The last-mentioned possesses the advantage of flexibility similar to the steam drive, *e.g.*, it will give a sudden access of power (not possible with a direct Diesel drive) due to the high torque characteristic of an electric motor. Shovels are either mounted on plain wheels, or on railway wheels; or caterpillar tracks are fitted, to transfer the machine as required on any ground. Some of the largest shovels are built for "stripping" or removing a deep overburden of earth covering ironstone or coal. The biggest machine yet built, a Marion, for this duty weighs 1,400 tons, and carries a 15 cubic yard bucket at the end of an arm 120 feet long. Eight caterpillar tracks sustain the shovel, with hydraulic devices to compensate for uneven ground. The three motions, hoisting the bucket, crowding or thrusting it into the cut, and rotating, are performed by separate electric motors. This is similar to the practice in steam shovels, which carry separate engines for the three functions.

Shovels can be adapted to work grabs when this provision is necessary for handling piles of material and loose excavation. The *dragline* excavator is either a machine solely used for this special kind of excavating, or is a modified shovel, the change being made rapidly. Instead of thrusting a bucket, it drags it towards the machine, being suitable for reclamation, canalization, drainage, foundation work, etc. The *skimmer scoop* acts in a horizontal direction, the jib of the navvy being set parallel with the ground, and the bucket dragged along under it, so that the surface of a road can be torn up. Also the loose debris may be scooped up and loaded into a lorry. A *back-acting trencher* has the bucket arm pivoted at the top end of the jib, the latter being lowered to a suitable distance above the ground. As the bucket is reversed to the normal direction for a steam navvy it is dragged towards the machine excavating a trench, and the machine retreats as the work progresses. Narrow and deep trenches can be cut rapidly with this adaptation of the navvy. *See* EXCAVATION. (F. H.)

**STEAM TURBINE:** *see* TURBINE, STEAM.

**STEARIC ACID:** *see* FATTY ACIDS.

**STEARIN:** *see* CANDLE.

**STEATOPYGIA,** the term used of the accumulation of fat on the buttocks, thighs and knees, specially observed among Bushman, Hottentot and Pygmy women. It is less common among these men but is recorded fairly often among males of the Bastaards. Statuettes found in Southern France which exhibit these features point to the former existence in Europe of such a race.

**STEDMAN, EDMUND CLARENCE** (1833–1908), an American poet and critic, was born of Puritan stock at Hartford (Conn.), Oct. 8, 1833. He was rusticated after two years at Yale, and was not allowed to return. In 1871, however, the college conferred on him the B.A. and M.A. degrees, and in 1895 the degree of LL.D. Clarence Stedman became connected with the New York *Tribune,* and in 1860 went to the *World* as editor, later becoming its war correspondent. A clerkship in Washington formed an interlude, but much of his life was spent in trading on the New York Stock Exchange, of which he edited a history (1905). He edited a volume of *Cameos* from Landor (with T. B. Aldrich, 1873), *A Library of American Literature* (11 vol. 1887–90), *The Works of Edgar Allan Poe* (with G. E. Woodberry, 10 vol. 1894–95), *A Victorian Anthology* (1895) and an *American Anthology* (1900). In addition to a large number of ephemeral reviews, he published *Victorian Poets* (1875), *Poets of America* (1885), and *The Nature and Elements of Poetry* (1892), books which show the poet's critical insight, technical knowledge, and high standards of workmanship. His most enduring place in literature, however, is due to his poetry—the deep serious note of his war lyrics or the whimsical fantasy of "Pan in Wall Street." The title of his rather conventional first book, *Poems, Lyrical and Idyllic* (1860), sounds the keynote of his work. Always a lover of beauty, he refused to be swayed from his ideals by the contemporary popularity of such *jeux d'esprit* as "The Diamond Wedding." As a result he has to his credit a group of fine and true lyrics such as the "Creole Lover's Song" and some commendable longer poems—*Alice of Monmouth; An Idyl of the Great War* (1863), *The Blameless Prince* (1869), and the elaborate commemorative ode on Hawthorne (read before the Harvard Phi Beta Kappa Society, 1877). He died in New York on Jan. 18, 1908.

**STEED, HENRY WICKHAM** (1871– ), British journalist, was born on Oct. 10, 1871, at Long Melford, Suffolk. He studied economics, philosophy and history at Jena, Berlin and Paris universities, and in 1896 joined the staff of *The Times* as acting correspondent in Berlin, and was appointed correspondent in Rome in 1897. Transferred thence to Vienna in 1902 as correspondent for Austria-Hungary, he remained there until 1913 when he returned to London, and was appointed foreign editor of *The Times,* in Jan. 1914. In 1913 he published *The Habsburg Monarchy,* in which the internal condition of Austria-Hungary was critically examined and the possibility of a European war discussed. During the World War, Steed was mainly responsible for the foreign policy of *The Times* and, in 1918, was chosen to frame the policy of Lord Northcliffe's Department for Propaganda in Enemy Countries. He was sent on an official mission to the Italian front where he was authorized by the Allied Governments to promise independence to the subject Habsburg peoples. He helped also to arrange, in April 1918, the Rome congress of the oppressed Austro-Hungarian races. In Feb. 1919 he was appointed editor of *The Times,* and held this post until Nov. 1922. From 1923 to 1930 he was editor of *The Review of Reviews.* His publications include *Through Thirty Years* (1924); *Hitler: Whence and Whither?* (1934; 5th ed. 1937); *Vital Peace, a Study of Risks* (1936); and *The Press* (1938).

**STEEL:** *see* IRON AND STEEL; WIRE ROPE; BESSEMER STEEL; STRUCTURAL ENGINEERING; OPEN HEARTH STEEL; HIGH SPEED STEEL; MANGANESE STEEL; MOLYBDENUM STEEL; MUSHET STEEL; NICKEL STEEL; NICKEL CHROMIUM STEEL; TOOL STEEL; TUNGSTEN STEEL; VANADIUM STEEL; NITROGEN HARDENING; STAINLESS STEEL; STEELS, ALLOY; ALLOYS; PRESSED METAL; SHEETS, IRON AND STEEL; and other specific headings.

**STEELE, SIR RICHARD** (1672–1729), Irish man of letters in the reign of Queen Anne, is inseparably associated in the history of literature with his personal friend Addison. The two were born in the same year. Steele, the senior by less than two months, was baptized on March 12, 1672 in Dublin. His father, also Richard Steele, was an attorney. He died before his son had reached his sixth year, but the boy found a protector in his maternal uncle, Henry Gascoigne, secretary and confidential agent to two successive dukes of Ormonde. Through his influence he was nominated to the Charterhouse in 1684, and there first met with Addison. Five years afterwards he proceeded to Christ Church, Oxford, and was a postmaster at Merton when Addison was a demy at Magdalen. Their schoolboy friendship was continued at the university, and probably helped to give a more serious turn to Steele's mind than his natural temperament would have taken under different companionship. Without waiting for a degree he volunteered into the army, and served for some time as a cadet "under the command of the unfortunate duke of Ormond" (*i.e.,* the first duke's grandson, who was attainted in 1715). This escapade was made without his uncle's consent, and cost him, according to his own account, "the succession to a very good estate in the county of Wexford in Ireland." He found a patron in Lord Cutts, to whom he dedicated a poem on the funeral of Queen Mary (1695). Cutts took the gentleman trooper into his household as secretary, made him an officer in his own regiment, and ultimately procured for him a captaincy in Lord Lucas's regiment of foot. A duel which he fought with Captain Kelly in Hyde Park in 1700, and in which he wounded his antagonist dangerously, inspired him with the dislike of duelling that he showed to the end of his life. Steele won William III.'s favour (too late to be of practical use) by a timely reference to him in *The Christian Hero,* his first prose treatise, published in April 1701. Steele complained that the reception of *The Christian*

*Hero* by his comrades was not so respectful; they persisted in trying him by his own standard, and would not pass "the least levity in his words and actions" without protest. He therefore determined to clear his character of the charge of undue solemnity by writing a comedy, *The Funeral* (1701). With this play he began his work of reconciling wit, good humour and good breeding with virtuous conduct which he was afterwards to accomplish in the famous essays in the *Tatler* and the *Spectator*. In his next comedy, *The Lying Lover; or, the Ladies' Friendship* (1703), based on Corneille's *Menteur*, Steele's moral purpose was directly avowed, and the play, according to his own statement, was "damned for its piety." *The Tender Husband,* an imitation of Molière's *Sicilien* (in April 1705), was more successful. It was seventeen years before Steele again tried his fortune on the stage with *The Conscious Lovers,* the best and most successful of his comedies, produced in December 1722.

**The Tatler and the Spectator.**—In 1707 Steele was given the office of gazetteer. The *Gazette* gave little opening for the play of Steele's lively pen, his main duty, as he says, having been to "keep the paper very innocent and very insipid"; but the position gave him insight into journalism. The *Tatler* made its first appearance on April 12, 1709. It was partly a newspaper, a journal of politics and society, published three times a week. Steele's position as gazetteer furnished him with special advantages for political news, and as a popular frequenter of coffee-houses he was at no loss for social gossip. He gradually introduced into the *Tatler* as a special feature essays on general questions of manners and morality.

Steele was always in want of money. He had £300 a year from his gazetteership (paying a tax of £45), £100 as gentleman waiter to Prince George, £850 from the Barbadoes estates of his first wife, a widow named Margaret Stretch, and some fortune by his second wife—Mrs. Mary Scurlock, the "dear Prue" of his charming letters. But he lived in considerable state after his second marriage, and before he started the *Tatler* was borrowing money. The assumed name of the editor was Isaac Bickerstaff, but Addison discovered the real author in the sixth number, and began to contribute in the eighteenth. The success of the *Tatler* was established before Addison joined him, and Addison contributed to only forty-two of the two hundred and seventy-one numbers that had appeared when the paper was stopped, obscurely, in January 1711.

Only two months elapsed between the stoppage of the *Tatler* and the appearance of the *Spectator,* which was the organ of the two friends from March 1, 1711 to Dec. 6, 1712. Addison was the chief contributor to the new venture, and the history of it belongs more to his life. Nevertheless, it is to be remarked as characteristic of the two writers that in this as in the *Tatler* Addison generally follows Steele's lead in the choice of subjects. The first suggestion of Sir Roger de Coverley was Steele's although it was Addison that filled in the outline.

Steele projected various journals in the next years, most of them, such as the *Englishman* (1733), and the *Reader* (1714), *Town Talk, Tea Table* and *Chit Chat,* very short lived; though the *Guardian* (1713) had 176 numbers. Steele's most famous political paper, the *Plebeian* (1718) embroiled him in a controversy with Addison. A pamphlet, *An Apology for Himself and his Writings* (1714) is important biographically.

**Later Life.**—The fortunes of Steele as a zealous Whig varied with the fortunes of his party. Over the Dunkirk question he waxed so hot that he threw up a pension and a commissionership of stamps, and went into parliament as member for Stockbridge to attack the ministry with voice and vote as well as with pen. But he had not sat many weeks when he was expelled from the house for the language of his pamphlet on the *Crisis,* which was stigmatized as seditious. The *Apology* already mentioned was his vindication. With the accession of the House of Hanover his fortunes changed. Honours and substantial rewards were showered upon him. He was made a justice of the peace, deputy-lieutenant of Middlesex, surveyor of the royal stables, governor of the royal company of comedians—the last a lucrative post—and was also knighted (1715). After the suppression of the Jacobite rebellion he was appointed one of the commissioners of forfeited estates, and spent some two years in Scotland in that capacity. In 1718 he obtained a patent for a plan for bringing salmon alive from Ireland. Differing from his friends in power on the question of the Peerage Bill he was deprived of some of his offices, but when Walpole became chancellor of the exchequer in 1721 he was reinstated. With all his emoluments however the imprudent, impulsive, ostentatious and generous Steele could never get clear of financial difficulties, and he was obliged to retire from London in 1724 and live in the country. He spent his last years on his wife's estate of Llangunnor in Wales, and, his health broken down by a paralytic seizure, died at Carmarthen, Sept. 1, 1729.

A selection from Steele's essays, with a prefatory memoir, has been edited by Austin Dobson (1885; revised 1896). *See* also *Selected Essays* (1907) ed. L. E. Steele; and *Letters of Richard Steele* (1928), ed. R. B. Johnson. Dobson contributed a biography to Andrew Lang's series of *English Worthies,* in 1886. In 1889 an exhaustive life was published by G. A. Aitken, who also edited Steele's plays (1898) and the *Tatler* (1898).

**STEELS, ALLOY.** It is almost as hard to draw a clear line of demarcation between "alloy steels" and "steels," as it is between "steel" and "iron." Diverse definitions have been set up legally for customs purposes, and commercially for statistical but more especially for pricing purposes. As may be seen in the article IRON AND STEEL, iron is produced from its ores by commercial processes that leave a number of impurities, either alloyed with it or included as insoluble non-metallic particles. (A brief definition of an alloying element or compound is one that is more or less soluble in the major metal and which participates in physical or chemical reactions with changing temperatures and thus modifies the properties.) Carbon (in the chemical compound iron carbide, "cementite," $Fe_3C$) is the principal alloying element in iron, proportionately increasing its strength and hardness, especially after a correct heat treatment. Only a little iron carbide (carbon) is needed to convert iron into a hardenable steel, so a metallographer's definition of carbon steel might well be "a malleable alloy of iron and iron carbide" ("malleable" being inserted to distinguish plain carbon steel from cast iron, which is a non-malleable alloy of the same substances). The article IRON AND STEEL also explains the necessity for the presence of fractional percentages of the alloying metals manganese and silicon in commercial plain carbon steels, and it is difficult to say, as these incidental elements increase, just where a carbon steel stops and a manganese alloy steel (or more briefly, a "manganese steel") and a silicon steel start. Likewise "alloy steel practice" consists of far more than adding alloying metals to the liquid steel. The raw material is selected for a low content of deleterious impurities, the furnace practice is extended to include a careful refining period, additions are made to control the grain size (which, in turn, controls the toughness), all surface defects are cut out of ingots or billets—to mention some of the major differences. It may be said, then, that an "alloy steel is a carefully made steel with sufficient alloying metals added to it to modify usefully the properties of a plain carbon steel." The *amount* of alloy added is no distinction, it may range from very low (0·10% vanadium) to very high (18% chromium or more).

The earliest alloy steels used those alloys then available; since the World War very useful steels have been developed with alloying metals that were formerly unavailable, even rarities. *Chromium* alloy steels were made commercially into hard grinding equipment by the American, Baur, in 1865. They made their debut into structures in the main arch members of the Eads bridge (1874) across the Mississippi river at St. Louis (U.S.A.); they now enter many steels for machine parts, and the high chromium steels are corrosion and oxidation resistant (*see* RUSTLESS STEEL). *Nickel,* now the other most common constituent of alloy steels, was first incorporated in steels by the Frenchman, Marabeau; the properties were described in 1889 by the Scot, James Riley. Nickel steel was adopted by the American Navy for armour-plate in 1891; it is said that the first application in the mass production industries was some armour-plate rolled into small bars for bicycle chains. *Tungsten* is the essential element in the air-hardening tool steel of the Englishman, Mushet (1871), the precursor of modern high

speed tools. It is also used in magnets and in steels for high temperature, high pressure service. (*Molybdenum,* its chemical cousin, was unavailable until large American deposits began producing in Colorado about 1918. In addition to being a substitute for tungsten, it is now a most important element, in fractional percentages, in engineering alloy steels.) *Manganese* formed the first high alloy steel, 10% being added by the Englishman, Hadfield, in 1882 to form a very tough steel of unique properties, largely used in places like steam-shovel dipper teeth that must resist tremendous battering. Low manganese steels are the product of 1920–30, and are being substituted in many uses for the more expensive chromium and nickel steels. *Silicon* steels, especially useful for electrical transformers and other equipment, were devised in 1889 by Hadfield. *Vanadium* and chromium-vanadium steels were investigated in England by Arnold and J. Kent-Smith at the turn of the century; the latter, at Canton, Ohio, U.S.A., in 1907 made the first alloy steel by the open-hearth process for the Ford Motor Co., and this company pioneered the use of alloy steels in mass production. *Copper,* used in fractional percentage for atmospheric corrosion resistance, is a pre-World War product.

These eight common elements in various percentages and combinations, to say nothing of an equal number of less commonly used alloying metals, may formulate an infinite variety of steels. In the last half-century literature about them has accumulated at an accelerated rate until its mass is now formidable. A group of metallurgists led by the American, Edgar C. Bain, has systematized much of the existing information. Commercial requirements of both producers and consumers have also demanded a limitation of types. The American Society of Automotive Engineers led the way in 1911 by adopting chemical specifications for 7 carbon and 11 alloy steels, a list extended in 1935 to 102. Many large transportation companies and Governments have their own lists, and the total (exclusive of tool steels and high alloy steels) was somewhere in the neighbourhood of 300 in 1939. The scientific classification above mentioned has given logic to the practical conclusion that many of the varieties are interchangeable. However, users are slow to discard a steel that has served well in the past, fits into an existing heat treatment schedule, and is approved by the staff, but economics slowly forces the adoption of the cheapest suitable raw material. This generally means steels of lower and lower alloy content.

**General Influence of Alloys.**—A statement frequently heard is that alloy steels are chiefly valuable because they may be hardened and strengthened by heat treatment without incurring the brittleness associated with hardened plain carbon steel. Further it is frequently said that to be economically justified, the alloy steels should be used in the quenched and tempered state. It will be shown below that the true function of alloys in the engineering or machine steels is to get high strength and toughness, or hardness and toughness, simultaneously, either more easily than they can be had in carbon steels, or in sizes and shapes in which they *cannot* be had in carbon steels. Certain alloys also impart unique properties to carbon steels (such as high chromium for corrosion resistance or high manganese for battering abrasion) but in defence of the plain carbon steel it may be said that high strength, hardness and toughness are not the sole property of alloys. Thus, the intensity of hardening primarily depends on carbon content, and no alloy steel has yet been discovered which can be made harder than properly quenched carbon steel containing 0·75% or more carbon (measured as C-67 by the Rockwell instrument, wherein hardness number is inversely proportional to size of indentation by a loaded diamond point). There are also very strong, tough steel wires for steel cable; these are of high carbon steels, properly cold drawn to high strength; they withstand 225,000lb. per sq.in. before fracture, at which time they have extended 4% in 10in. of their original length. Since steel is an alloy of iron and iron carbide, the alloys present in it can be located in one or more of three possible phases or micro-constituents: (*a*) in solid solution in the iron—the alpha iron or "ferrite"; (*b*) combined with carbon, either replacing some iron in the iron carbide, or forming a special carbide of its own; (*c*) combined with oxygen or nitrogen in non-metallic, insoluble inclusions. Rarely does one alloy act in one way alone; their partition between (*a*), (*b*), and (*c*) depends upon the amount of alloying element or elements, amount of carbon, and the temperature. However, some alloys, such as nickel and manganese, act notably to form solid solutions and strengthen the ferrite. Others act notably to enter and form carbides, as vanadium and molybdenum. Aluminium is the outstanding example of the elements in category (*c*).

**Strong Structural Steels.**—Alloys falling in category (*a*) are particularly useful in improving the mild steels used for plates and structural shapes. These steels are fabricated by the user as they are delivered to him from the rolling mill, without heat treatment. In fact, they must be rather insensitive to heat treatment, else bending, flanging, and especially welding will produce hard regions ruinous to the tools that punch or cut them, or regions lacking in required ductility. Extra strength and correspondingly lighter sections, such as are desirable for a long-span bridge or for railway car bodies can, of course, be had by increasing the carbon content, but this aggravates the above troubles of hardness. The alternative is to add alloys that enter into solid solution with the iron and so strengthen the ferrite, which, by the way, is the bulkiest constituent of these low carbon steels. E. C. Bain lists, in the order of their influence as ferrite strengtheners, from strongest to weakest, these alloying elements as phosphorus, silicon, manganese, nickel, and that portion of the chromium which is not combined with carbon. Each of them is used and in various combinations in commercial tonnage steels. Nickel steel was undoubtedly the first, used for long-span bridges, 3½% of that element greatly improving the tensile properties and doubling the impact strength. A cheaper alloy, known as "structural silicon steel," is now favoured in America and much used by structural engineers. An early type of such steel, used by constructors of the pre-World War "Mauretania" is also shown in the table, although the British admiralty now prefers the "D-steel." These strong steels, when weldability is important, have very low carbon content. Reductions in section thickness also demand a better degree of corrosion resistance than is afforded by the normal addition of 0·20% copper, and phosphorus and chromium have been added to low carbon steels (<0·10% C) for their combination strengthening and ennobling effect. American steels much used for railway rolling stock and bus and truck bodies are shown in the last three lines of Table I.

**Hardenability of Alloy Steels.**—Alloys are, of course, of most importance to heat treatable steels. To understand their action it is necessary to know that when steels are heated above their "critical points"—a characteristic range of about 725° to 825° C.—the crystal structure of alpha ferrite is transformed into a new one called "gamma iron" which has far greater solubility for carbide. This high temperature solid solution of the carbides in gamma iron is called "austenite." On slow cooling the reverse action takes place at about the same critical range, and the annealed, fairly soft and ductile steel is reconstituted, except that the process may have refined the grain. On more rapid cooling the precipitation of carbide from austenite is delayed—a little time is necessary for the action to incubate and then to proceed to completion—and occurs at a somewhat lower temperature. On rapid cooling, as when quenching a small piece in cold water, austenite is trapped unchanged down to below 150° C. but then changes completely in a second or two to a very hard structure called "martensite," which seems to be alpha iron (ferrite) in which the iron carbide is dispersed in almost molecular particles. This is the essence of the hardening action. (For a fuller account of the metallographic changes *see* IRON AND STEEL.) Plain carbon steels have a low hardenability, in the sense that if a 1½in. round bar is quenched in cold water only the outer layers of the steel are cooled rapidly enough to transform at low temperature into martensite; the inner core, cooling more slowly, is transformed at high temperatures near the critical into a much softer entity, a coarser mixture of laminated ferrite and carbide. The outer surface may be intensely hard, even the maximum possible for the carbon content of the steel, but the "penetration" of that hardness is low. To harden more deeply the cooling rate at the surface must be faster, so the deeper regions of the steel may cool rapidly

TABLE I.—*Low Alloy, High Yield Steels for Riveted and Welded Structures*

| Steel | Composition | | | | Tensile strength | Yield point | Elongation in 8 in. |
|---|---|---|---|---|---|---|---|
| | C | Si | Mn | Others | | | |
| Good structural | 0·20 | 0·15 | 0·50 | .. | 60,000–68,000 | 40,000–47,500 | 30%–25% |
| Nickel | 0·33 | 0·06 | 0·60 | 3·25%Ni | 105,000 | 63,000 | 20% |
| Structural silicon | 0·30 | 0·25 | 0·80 | .. | 85,000–90,000 | 50,000 | >20% |
| Mauretania | 0·25 | 1·10 | 0·75 | .. | 92,000–105,000 | 65,000 | 30%–25% |
| D-steel | 0·33 | 0·12 | 1·25 | .. | 83,000–96,000 | 56,000 | 17% |
| "Cor-ten" | <0·10 | 0·75 | <0·40 | 0·15%P, 1·0% Cr, 0·40% Cu | 65,000–75,000 | 50,000–60,000 | 25% in 2in. |
| "Man-ten" | <0·30 | <0·30 | 1·50 | .. | 80,000–90,000 | 55,000–60,000 | 30%–20%in2in. |
| "Double Strength" | <0·12 | .. | 0.75 | 1·0% Cu, 0·60% Ni, 0·20% Mo | 75,000 | 65,000 | 30% |

enough to escape the high temperature transformation; even the most drastic quenching, as in brines or water sprays, may be insufficient for complete hardening. Fortunately, the presence of all the alloying metals except cobalt slows up both the solution of carbides in the austenite on heating, and their precipitation on cooling. This means that alloy steels do not need to be cooled nearly so fast in order for the austenite to be "trapped" and transformed at about 150° C. into hard martensite. Alloy steels therefore have a higher hardenability. Given an equal quench and an equal sized bar, the alloy bar will harden much more deeply than the carbon steel bar of the same carbon content; or it may be satisfactorily hardened in a much milder quenching bath, as in oil or even in still air, with correspondingly less warpage and danger of cracking. As an example, the presence of 1¼% nickel and 0·60% chromium doubles the hardenability of a 0·45% carbon steel. Bain's list of the relative potency of alloys in this respect follows: Very strong, vanadium; strong, molybdenum and tungsten; moderate, chromium, manganese, silicon; mild, copper, nickel, phosphorus.

**Toughness of Alloy Steels.**—Certain of the alloys have still another beneficial effect—that of refining the grain. According to the laws of crystallography, certain favoured austenite grains should grow at the expense of their neighbours, with the result that the hot steel should become coarser grained with longer and longer stay at higher and higher temperature. But first a considerable time is necessary to dissolve complex and sluggish carbides in the austenite, and many seem to have a central particle that resists dissolution, and these refractory particles disseminated through the metal effectually prevent the natural grain growth of the solid solution. The advantage is that a fine-grained austenite, when quenched and tempered, has a very desirable degree of toughness. Bain's list of grain refining elements, arranged according to their effectiveness is: Titanium (very strong), vanadium, molybdenum, tungsten, chromium, and manganese (mild).

Aluminium, added to the metal in proper small quantity in a properly deoxidized steel, apparently reacts with traces of oxygen and nitrogen dissolved in the steel, and precipitates out as a cloud of insoluble particles in the solidifying steel. These inclusions are even more effective obstructions to austenite grain growth. Such fine-grained steels are popular in America. They are especially useful in low carbon, carburizing steels. In the carburizing operation, machined steel parts can acquire a high carbon skin or case, say 0·05in. deep in 5hr. exposure to a highly carbonaceous gas at 1,700° F. Even after such a long and high heating the austenite remains so fine in grain size that the parts can be quenched direct from the carburizing heat to harden the high carbon case, secure in the fact that the inner portions remain fine grained and tough.

The toughness of alloy steels, or the ability to absorb rapid blows, is also improved by the circumstance that those containing the carbide-forming elements listed two paragraphs above may be tempered or reheated after quenching to considerably higher temperatures than carbon steels of the same carbon content and still retain the hardness of the plain carbon steel, quenched and tempered at a lower temperature. Evidently the sluggish diffusion of alloying elements, trapped in solution in the freshly quenched martensite, requires a higher temperature and a longer time before the complex carbides can re-form, in comparison with the formation of simple iron carbide ($Fe_3C$) by diffusion of trapped carbon. Since the toughening due to tempering is largely a matter of relieving the high internal stresses in freshly quenched steels, and since this stress-relief is greater at higher temperature, it can be seen why alloy steels may give, after proper heat treatments, metal that is strong, hard and unusually tough.

These sluggish changes in the complex alloy carbides are utilized in steels for high temperature, high pressure equipment. Stable carbides enable the hot metal to resist "creep" at high temperature. The American Society of Mechanical Engineers' Boiler Code has tentatively proposed a working stress of 5,750lb. per sq.in. for plain carbon steels at 900° F. and 10,000lb. per sq.in. (nearly double) for the same steels plus 0·50% molybdenum.

**Interchangeability of Alloy Steels.**—From what has gone before one might properly conclude that a definite combination of strength, hardness, and toughness might be secured from any one of a large number of alloy steels, provided the size was not too large and the heat treatment properly adjusted. How true this is may be proved by transmission drive shafts in six leading American automobile plants. One firm uses 0·60% carbon steel, oil quenched; another 1·75% nickel, 0·25% molybdenum, 0·20% carbon steel, carburized; two others use 1% nickel, 0·60% chromium, 0·75% manganese, 0·40% carbon steel, oil quenched; another uses 0·25% carbon, 0·80% manganese, 0·20% molybdenum steel, carburized; and the last one uses 1% chromium, 0·75% manganese, 0·35% carbon steel, oil quenched.

It will also be noted that the above alloys are all *low* alloys, and this represents an undoubted trend in alloy practice, both in England and America, especially in the smaller sizes of forgings or machined gears where adequate penetration of hardness may be secured by not too drastic quenches. For the massive forgings, steels with higher content of alloys, and long continued heat treatments to permit the sluggish reactions, are still necessary.

**Gear Steels.**—As a specific application of the above general principles, the problems of gear manufacture may be considered, for the choice of steel and its treatment depends very intimately on the design of the part and its intended duty. Large gears for rough service are frequently cast direct in gray iron or low carbon steel, but the irregularities in dimensions of wheel and gear teeth are such that speed and power transmitted must be relatively small, life is short and noise is great. An improvement as to accuracy and wear resistance consists in welding together a gear "blank" of appropriate shapes, the rim into which the teeth are to be cut being of medium carbon steel; after machining, the teeth surfaces are individually hardened by passage of an enveloping flame from oxy-acetylene torches, followed closely by quenching jets. In comparison with these, the high duty herringbone gear sets used on turbine-driven propeller shafts are marvels of precision; they are of cast alloy steels heat treated to relieve internal stresses and insure dimensional stability as well as induce as much hardness for wear resistance as is consistent with machinability. This hardness limit is somewhere about C-40 (Rockwell scale). The steels contain 0·50 to 0·60% carbon, but alloys are necessary to give proper depth of hardening and fine grain size. Examples are 1·25% manganese plus one or more of the elements molybdenum (0·30%), nickel (1%), chromium (0·5%) and vanadium (0·15%). In large sections a quenched and tempered chromium-nickel-molybdenum cast steel will have the following physical properties indicating medium strength and hardness with great toughness: Yield point 105,000lb. per sq.in.; tensile strength 135,000lb. per sq.in.; elongation 20% in 2in.; reduction of area 64%; Rockwell hardness C-32.

In the smaller gears utilized for automobile transmissions and rear axle drives the mass effect or deep hardening effect is not so necessary. Requirements are very diverse and exacting, and these, together with the desire to save weight, and therefore to have gears as small as possible, have preserved this field to alloy steels. The original conception of a gear tooth was that it should have a hard surface to resist wear and a tough centre or core to

resist impact. Following this idea, gears were cut from annealed blanks, forged from low carbon alloy steels (less than 0·20% carbon); the machined gears were then carburized by heating in contact with carbonaceous solids or gases until their surfaces had come up to 0·90 or 1·00% carbon for a depth of 0·030 to 0·050in. (about ⅛ the thickness of the tooth at the base). The subsequent heat treatment was at times rather intricate, consisting of a high temperature quench to refine the low carbon core, a lower temperature quench to harden properly the high carbon surface, and a tempering to improve the toughness. Steels widely used in this way included those shown in Table II. Representative properties of the core after an oil quench suitable to harden the carburized case are as shown. Evidently here is a variety of steels suitable for any designer's requirements, where he balances cost (alloy content, machinability, and heat treatment schedule) against strength desired to carry the loads on the gear tooth, and toughness against impact loadings. Probably the ultimate in properties, disregarding cost, is a so-called "armour plate" analysis with carbon 0·10%, nickel 4%, and chromium 1·5%, used for aircraft, heavy duty truck, and bus gears. Its heat treatment is quite complicated, including an oil quench from 850° C. and draw at 650° to make the forgings machinable, 24hr. carburizing of machined gears at 940° F., annealing at 730° F. and cooling slowly (80hr.) to soften the case so the teeth can be finish-machined a few thousandths to remove distortion. The gears are then hardened by oil quenching from 760° C. and tempering at 150° C.

Carburizing all these analyses gives an outer surface containing 0·90 to 1·0% carbon, and since surface hardness of the quenched gear depends on carbon, rather than alloy, content, all of these teeth can be made "file hard"—that is, too hard to be bitten by a testing file whose hardness is Rockwell C-65. Experience has also proven that maximum resistance to abrasion is secured from such high carbon cases on steel containing chromium or molybdenum carbides. One serious objection to the practice outlined above is the cost of heat treatment after carburization, and this has been attacked by the use of the fine-grained steels which may be quenched direct from the carburizing heat and still possess a fine structure and considerable toughness. This practice was fairly common with the 1% chromium, 0·15% vanadium steels, which are inherently fine-grained, before the special fine-grained steels were regularly produced by the steel mills. One much used type is the nickel-molybdenum steel shown in the last line of Table II.

TABLE II.—*Properties of Low-Carbon Cores of Gear Teeth*
Carburized and oil quenched from temperature shown

| Steel | Quenching temperature | Tensile strength lb.persq.in. | Rockwell hardness | Izod impact ft.-lb. |
|---|---|---|---|---|
| 0·20% carbon (no alloy) . . | 780° C.* | 80,000 | C–0 | 70 |
| 3·5% nickel . . . . . | 800° C. | 160,000 | C–35 | 35 |
| 5% nickel . . . . . | 815° and 735° C. | 110,000 | C–20 | 75 |
| 1·25% nickel, 0·50% chromium | 800° C. | 155,000 | C–34 | 30 |
| 1% chromium, 0·15% vanadium | 890° C. | 125,000 | C–25 | 80 |
| 1·75% nickel, 0·25% molybdenum | 930° C. | 140,000 | C–32 | 35 |

*Water quench.

High speed transmission gears in automobiles must operate without much noise, and this requires a degree of accuracy of shape on the order of 0·0005 inch. Warpage increases with the depth of carburization, so shallow cases were tried to give quieter gears. This was successful, but the hard case now tended to flake off, due to fatigue failure of the weaker low carbon metal at junction of case and core. To strengthen this metal it has been necessary to increase carbon content, and the result is that in 1940 American automobiles the great majority of transmission gears are of steels that used to be called "oil quenching gear steels," high enough in carbon and alloy to quench to a file hard surface without carburization. An upper carbon limit is set by the demands of reasonable machinability. Whereas the old oil quenched gears were heated in molten lead for quenching (in order to avoid any trace of decarburized soft skin), the more modern practice is to hold them in a cyanide bath at 815° C. for about 25min. which is enough to induce a 0·002-in. case of carbides and nitrides, exceedingly hard and wear resistant, or to heat them in a controlled gas of carburizing nature. A representative steel would contain 0·45% carbon, 1·25% nickel, 0·60% chromium. After the above quenching from cyanide and a 2-hr. draw at 235° C. the core would have a tensile strength of 275,000lb. per sq.in., and a correspondingly high fatigue strength. After such treatment the involute errors seldom would amount to 0·0004 inch. It is seen that the result is a gear with high surface hardness to resist wear, high core strength just under the case to resist fatigue failure (flaking or pitting of the surface), high strength to carry the normal loads, moderate cost of the steel with its moderate alloy content, cheap heat treatment, and a quiet running gear. "A soft, tough core to resist impact," once a prime requisite of a successful gear, is not contained within these specifications, as it has become amply evident that if design and shape are correct, a transmission gear set will operate normally without much impact. Toughness is achieved by fine grain size rather than high tempering after quench; indeed, tempering is done at the minimum temperature to avoid letting down the hardness at the surface. Other 0·40 to 0·50% carbon fine-grained steels widely used in this improved practice contain 1·75% nickel and 0·25% molybdenum; 1% chromium; 1% chromium with 0·18% vanadium. Here is a good example of that interchangeability of alloy steels mentioned in the preceding section; choice may depend more on personal preference than on demonstrated advantages.

**Austenitic Steels.**—Hadfield's cast 10% manganese steel, discovered in 1882, was remarkable in that it did not harden on quenching. It is, in fact, an austenitic alloy, in the sense that the expected change from austenite solid solution to hard martensite does not occur at 200° C. but the quenched austenite is very stable at room temperature. Cobalt, but especially nickel, has similar effects. One result of this is that the most useful of the stainless steels, known as 18-8 and containing 18% chromium and 8% nickel, is unhardenable by quenching.

One characteristic of these commercial austenitic steels is that the austenite is not entirely stable. The small plastic movements in high manganese steel, associated with battering or attempted cutting, permit the martensitic reaction to occur in those restricted regions, causing intense hardness—hence their wear resistance in rough service. This is a favourable reaction, but many of the 18-8 steels are put into petroleum stills operating between about 450° and 850° C., and this temperature gives enough thermal agitation to the atoms so that chromium carbides form from the austenite solid solution, unfortunately not in a cloud throughout the mass to "key" and strengthen the metal, but localized at the grain boundaries, seriously depleting the surrounding matrix of its chromium necessary for corrosion resistance. This deterioration of 18-8 (even by the heat of welding) is prevented by introducing minor amounts of strong carbide-forming elements, like molybdenum, titanium or columbium. The latter two, especially, form carbides that are so insoluble in austenite that they act as inert non-metallic inclusions. (*See* also IRON AND STEEL; ALLOYS; and the various types of steels under their own headings.)

BIBLIOGRAPHY.—Edgar C. Bain, *The Alloying Elements in Steel* (1939); Sir Harold Carpenter and J. M. Robertson, *Metals* (vol. II, 1939). Comprehensive monographs critically appraising the literature on the various alloys are being issued by Alloys of Iron Research, New York. (E. E. T.)

**STEELTON,** a borough of Dauphin county, Pennsylvania, U.S.A., 3 m. S.E. of Harrisburg, on the Susquehanna river; served by the Pennsylvania, the Reading and the Steelton and Highspire railways. Pop. (1920) 13,428 (21·6% foreign-born white), and 13,115 in 1940. It has vast steel works and various smaller manufacturing industries, and there is a large limestone quarry within its limits. A town called Baldwin was laid out here in 1866, and the present name was adopted for the borough in 1880.

**STEEL WOOL,** a mild abrasive commonly used to clean or polish metals and metallic objects. It is of great practical use in the japanning, plating and moulding rooms of factories. In rubbing down metallic articles to attain a fine finish, steel wool achieves much the same results as pumice. Steel wool is also used to clean rusty and tarnished hollow-ware.

**STEELYARD, MERCHANTS OF THE,** Hansa merchants who settled in London in 1250 at the steelyard on the riverside, near Cosin lane, now Ironbridge Wharf. Henry III in 1259, at the request of his brother Richard of Cornwall, king of the Romans, conferred on them important privileges, which were confirmed by Edward I. It was chiefly through their enterprise that the early trade of London was developed, and they continued to flourish till, on the complaint of the Merchant Adventurers in the reign of Edward VI, they were deprived of their privileges. They succeeded in maintaining a footing in London till 1597.

**STEEN, JAN HAVICKSZ** (1626–1679), Dutch subject-painter, was born at Leyden in 1626, the son of a brewer. According to Houbraken he studied under Nicolas Knupfer, a German artist, at Utrecht, and under Jan van Goyen, whose daughter he married in 1649. In November 1646 he enrolled himself as a student of the university at Leyden and in 1648 he was one of the founders of the Guild of St. Luke in that city. He settled at The Hague in 1649, and at Delft in 1654. In 1657 he is said to have been a brewer at Delft. He is repeatedly mentioned in documents in the Delft archives during 1656–57. He was a resident of Haarlem during the years 1661–69. He then moved to Leyden, where he received permission to open a tavern in 1672. In 1673 he took a second wife, Maria van Egmont, the widow of a Leyden bookseller. He died at Leyden Feb. 3, 1679.

The works of Jan Steen are distinguished by correctness of drawing, admirable freedom and spirit of touch, and clearness and transparency of colouring. But their true greatness is due to their intellectual qualities. In the wide range of his subjects, and their dramatic character, he surpasses all the Dutch figure-painters, with the single exception of Rembrandt. His productions range from the stately interiors of grave and wealthy citizens to tavern scenes of jollity and debauch. He painted chemists in their laboratories, doctors at the bedside of their patients, card-parties, marriage feasts—even religious subjects, though in these he was least successful. His rendering of children is especially delightful. Portraits from his brush are comparatively rare.

The National gallery contains three pictures by Jan Steen, of which the "Music Master" is the most important, and other excellent examples of his art in England are preserved in the Royal, the Bute, and the Northbrook collections, at Apsley House and Bridgewater House, and in the galleries of The Hague, Amsterdam, and the Hermitage, St. Petersburg (Leningrad). A remarkably fine example of his work is the "Grace Before Meat" in the collection of Charles Morrison, London.

**STEENKIRK** or **STEENKERKE,** a village in Belgian province of Hainaut, on the river Senne, pop. (1939) 494; battle of Steenkirk (Steinkirk, Estinkerke) fought here July 23–Aug. 3, 1692 between Allies (*see* GRAND ALLIANCE, WAR OF THE) under William III of England and the French commanded by the duke of Luxemburg. Previous to the battle the French army lay facing north-west, with its right on the Senne at Steenkirk and its left towards Enghien, while the army of William III was encamped about Hal. William, seeing the opportunity of surprising a part of the enemy's forces and having forced a detected spy to give Luxemburg misleading news, set his army in motion before dawn on Aug. 3 to surprise the French right about Steenkirk. The advanced guard, mainly English and Danish infantry, under the duke of Württemberg, deployed close to the French camps ere Luxemburg became aware of the impending blow; at this moment the main body of the army farther back was forming up after the passage of some woods. When the fight opened, Luxemburg was completely surprised, and could do no more than hurry the nearest foot and dragoons into action as each regiment came on the scene. But the march of the Allies' main body had been mismanaged; while Württemberg methodically cannonaded the enemy, waiting for support and for the order to advance, the Allies' main body, which had marched in the usual order, one wing of cavalry leading, the infantry following, and the other wing of cavalry at the tail of the column, was being hastily rearranged in rear. A few battalions only had come up to support the advanced guard when the real attack opened (12.30). The advanced guard had already been under arms for nine hours, and the march had been over bad ground, but its attack swept the first French line before it. The English and Danes stubbornly advanced, the second and third lines of the French infantry giving ground before them, but Luxemburg was rapidly massing his whole force to crush them, and meanwhile the confusion in the allied main body had reached its height. Count Solms, who commanded it, ordered the cavalry forward, but the mounted men, scarcely able to move over the bad roads and heavy ground, only blocked the way for the infantry. Some of the English foot, with curses upon Solms and the Dutch generals, broke out to the front, and Solms, angry and excited, thereupon refused to listen to all appeals for aid from the front. No attempt was made to engage and hold the centre and left of the French army, which hurried, regiment after regiment, to take part in the fighting at Steenkirk. William's counter-order that the infantry was to go forward, the cavalry to halt, only made matters worse, and by now the advanced guard had at last been brought to a standstill. At the crisis Luxemburg had not hesitated to throw the whole of the French and Swiss guards into the fight, and as, during and after this supreme effort, more and more French troops came up, the Allies were driven back, contesting every step against weight of numbers. Those troops of the main body, foot and dragoons, which succeeded in reaching the front, served only to cover and to steady the retreat of Württemberg's force, and, the *coup* having manifestly failed, William ordered the retreat. The Allies retired as they had come, their rear-guard—of grenadiers from the British regiments—showing too stubborn a front for the French to attack. The latter were indeed in no state to pursue. Over eight thousand men out of only about fifteen thousand engaged on the side of the Allies were killed and wounded, and the losses of the French out of a much larger force were at least equal. Contemporary soldiers affirmed that Steenkirk was the hardest battle ever fought by infantry.

**STEEPLECHASING:** *see* HORSE RACING AND BREEDING.

**STEER, PHILIP WILSON,** O.M. (1860–1942), English painter, born at Birkenhead. He was trained at the Gloucester school of art and afterwards in Paris at the Académie Julian, and in the École des Beaux Arts under Cabanel. After 1886, before which date he had shown three pictures at the Royal academy, practically the whole of his work was seen in the exhibitions of the New English Art club. In his early work he appears as an adherent of the French Impressionist movement, and as a teacher at the Slade school he exercised an important influence on the development of English art. His figure subjects and landscapes show great technical skill. He died March 21, 1942.

**STEEVENS, GEORGE** (1736–1800), English Shakespearian commentator, was born at Poplar on May 10, 1736, the son of an East India captain, afterwards a director of the company. He was educated at Eton and at King's college, Cambridge. Leaving the university (1756) without a degree, he settled in chambers in the Temple, removing later to a house on Hampstead Heath, where he collected a valuable library, rich in Elizabethan literature. He walked from Hampstead to London every morning before seven o'clock, discussed Shakespearian questions with his friend, Isaac Reed, and, after making his daily round of the booksellers' shops, returned to Hampstead. He published in 1766 reprints of the quarto editions of Shakespeare's plays, entitled *Twenty of the Plays of Shakespeare.* . . . Dr. Johnson suggested to him the preparation of a complete edition of Shakespeare. The result, known as Johnson's and Steevens's edition, was *The Works of Shakespeare with the Corrections and Illustrations of Various Commentators* (10 vols., 1773), Johnson's contributions to which were very slight. This early attempt at a variorum edition was revised and reprinted in 1778, and further edited in 1785 by Isaac Reed; but in 1793 Steevens, who had asserted that he was now a "dowager-editor," was persuaded by his jealousy of Edmund Malone to prepare an edition of 15 volumes. He made

somewhat reckless emendations, but the edition showed a wide knowledge of Elizabethan literature. Steevens was one of the foremost in exposing the Chatterton-Rowley and the Ireland forgeries. He wrote an entirely fictitious account of the Java upas tree, derived from an imaginary Dutch traveller, which imposed on Erasmus Darwin, and he hoaxed the Society of Antiquaries with the tombstone of Hardicanute, supposed to have been dug up in Kennington, but really engraved with an Anglo-Saxon inscription of his own invention. He died at Hampstead on Jan. 22, 1800. A monument to his memory is in Poplar chapel.

Steevens's Shakespeare was re-issued by Isaac Reed in 1803, in 21 volumes, with additional notes left by Steevens. This, which is known as the "first variorum" edition, was reprinted in 1813. Steevens's notes are also incorporated in the edition of 1821, begun by Edmund Malone and completed by James Boswell the younger.

**STEEVENS, GEORGE WARRINGTON** (1869–1900), English journalist, was born at Sydenham, near London, on Dec. 10, 1869, and was educated at the City of London school and Balliol college, Oxford, of which he was a scholar. In 1893 he was elected a fellow of Pembroke college, Oxford. In September 1899 he went to South Africa and joined Sir George White's force in Natal as war correspondent, being subsequently besieged in Ladysmith. He died during the siege, of enteric fever, on Jan. 15, 1900. The articles he had sent home from South Africa were published posthumously in a volume called *From Capetown to Ladysmith* (1900). Another of his most interesting books was *With Kitchener to Khartoum*. Steevens had a remarkable gift of seizing the salient facts and principal characteristics in anything he wished to describe and putting them in a vivid way.

**STEFANIE, BASSO NAEBOR** or **CHUWAHA,** a lake of East Africa, lying in 37° E., between 4° 25′ and 5° N., and measuring some 40 mi. by 15. It is the southernmost and lowest (1,880 ft.) of a series of lakes which lie in the northeasterly continuation of the great East African rift valley (*see* ABYSSINIA: *Physical Features*). The character of the lake, which has no outlet, varies greatly according to the amount of water brought down by its principal feeder, the Dulei, which enters at its north end, being there a rapid stream 50 yd. wide and 3½ ft. deep.

Lake Stefanie was discovered by Count Samuel Teleki in 1881, and has since, with others of the series, been explored by Donaldson Smith, V. Bottego, M. S. Welby, Oscar Neumann, Arnold Hodson and others. An agreement of 1907 with Great Britain recognized the lake as within the Abyssinian empire.

See *Geographical Journal* (Sept. 1896, Sept. and Dec. 1900, Sept. 1901, Oct. 1902, July 1922); L. von Höhnel, *Discovery of Lakes Rudolf and Stefanie* (1894); L. Vannutelli and C. Citerni, *L'Omo* (Milan, 1899); British War Office map, Africa, 1.2,000,000 (1924).

**STEFANSSON, VILHJALMUR** (1879– ), Arctic explorer, was born on Nov. 3, 1879, at Arnes, Manitoba, Canada, of Icelandic parents. He graduated from the University of Iowa and later studied theology and anthropology for three years at Harvard university. After two archaeological voyages to Iceland in 1904 and 1905 he turned to arctic research and had by 1928 spent altogether 10 winters and 13 summers in scientific work north of the polar circle. In 1906–07 he was ethnologist of the Leffingwell-Mikkelsen expedition on the north coast of Alaska and at the mouth of Mackenzie river; in 1908–12 he commanded an expedition on which he discovered certain Eskimo groups and visited others who had not seen a white man for half a century. From 1913 to 1918 he commanded an arctic expedition under the auspices of the Canadian government. During more than five years continuously north of the Arctic Circle (the longest arctic expedition on record) he explored vast regions north of Canada and Alaska, sometimes sledging for months over moving ice, accompanied by two or three companions and living exclusively by hunting. He discovered between 1915 and 1917 the islands now known as Borden, Brock, Meighen and Lougheed, and several smaller islands. In 1918 his then second in command, Storker Storkerson, taking charge while Stefansson was ill with typhoid fever, explored by sledge, with four companions, the Beaufort sea north of Alaska. They were absent from shore about eight months, during six of which they were encamped, and lived by hunting, on a floe more than five miles in diameter while it drifted with them 450 mi. over a previously unexplored ocean from 1 mi. to 3 mi. deep. They found an abundance of seals everywhere, had therefore plenty of food and fuel, suffered no hardships, and reported on their return that they felt sure they could have spent several years on this floe safely. This confirmed the conclusions of all the previous sledge journeys of the expedition over the moving ocean ice: that seal life, and therefore probably other water life, does not necessarily decrease, as was previously believed, farther north in the arctic. Stefansson laid stress on the economic value of the arctic regions, chiefly as meat-supplying countries through cultivation of the domestic reindeer and domestication of the ovibos or musk ox. In 1932 he became adviser on northern operations for Pan American Airways. During World War II he served the U.S. government in an advisory capacity, surveyed defense conditions in Alaska and prepared reports and manuals for the armed forces.

His principal publications are: *My Life with the Eskimo* (1913); *The Friendly Arctic* (1921); *The Northward Course of Empire* (1922); *Hunters of the Great North* (1922); *The Adventure of Wrangel Island* (1926); *The Standardization of Error* (1927); *Unsolved Mysteries of the Arctic* (1938); *Greenland* (1942); *Arctic Manual* (1944).

**STEFFANI, AGOSTINO** (1653–1728), Italian ecclesiastic, diplomatist and musical composer, was born at Castelfranco on July 25, 1653. At a very early age he was admitted as a chorister at St. Mark's, Venice. Count Tattenbach took him in 1667 to Munich, where his education was completed at the expense of Ferdinand Maria, elector of Bavaria, who gave him a court appointment. He was sent in 1673 to study in Rome, where Ercole Bernabei was his master, and among other works he composed six motets, the original manuscripts of which are now in the Fitzwilliam Museum at Cambridge. On his return to Munich in 1674 he published his first work, *Psalmodia vespertina,* a part of which was reprinted in Martini's *Saggio di contrappunto* in 1674. In 1675 he was appointed court organist. The date when he was ordained priest, with the title of Abbate of Lepsing, is not precisely known. Steffani's first opera, *Marco Aurelio,* which was written for the carnival and produced at Munich in 1681, was followed by other works now lost. In 1688 he became Kapellmeister at the court of Hanover, where he made many friends. He wrote for the opening of the new opera house in 1689, an opera called *Enrico il Leone,* which was produced with extraordinary splendour. For the same theatre he composed *La Lotta d'Ercole con Achilleo* in 1689, *La Superbia d'Alessandro* in 1690, *Orlando generoso* in 1691, *Le Rivali concordi* in 1692, *La Libertà contenta* in 1693, *I Trionfi del fato* and *I Baccanali* in 1695, and *Briseide* in 1696. Elevation of Ernest Augustus to the electorate in 1692 led to difficulties with the various German courts; Steffani was sent round as an envoy in 1696 and as a result received from Innocent XI the bishopric of Spiga for his services in securing privileges for Hanoverian Catholics. In 1698 he was sent as ambassador to Brussels, and after the death of Ernest Augustus in the same year he entered the service of the elector palatine, John William, at Düsseldorf, where he held the offices of privy councillor and protonotary of the Holy See.

Steffani did not accompany the elector George to England; but in 1724 the Academy of Ancient Musick in London elected him its honorary president for life; and in return for the compliment he sent the association a magnificent *Stabat Mater,* for six voices and orchestra, and three fine madrigals. The manuscripts of these are still in existence, and the British museum possesses a very fine *Confitebor,* for three voices and orchestra, of about the same period. All these compositions are very much in advance of the age in which they were written; and in his operas Steffani shows a remarkable appreciation of the demands of the stage. Notable too are his beautiful chamber-duets, which, like those of his contemporary Carlo Maria Clari (1669–1745), are chiefly written in the form of cantatas for two voices, accompanied by a figured bass. The British museum (Add. MSS. 5,055 *seq.*) possesses more than a hundred of these compositions, some of which were published at Munich in 1679. Steffani visited Italy for the last

time in 1727. He died at Frankfurt on Feb. 12, 1728.

Steffani stands somewhat apart from contemporary Italian composers (*e.g.*, Alessandro Scarlatti) in his mastery of instrumental forms. His opera overtures show a combination of Italian suavity with a logical conciseness of construction which is due to French influence. His vocal music and his famous duets are inferior to those of Scarlatti, but his instrumental music is historically important as a factor in the artistic development of Handel.

**STEFFEN, ALBERT,** Swiss novelist and dramatist, was born at Murgental (Canton Aargau) on Dec. 10, 1884. He is an imaginative, spiritual, mystical and idealistic writer, showing little of the concrete and disciplined methods that are so characteristically Swiss. His nearest spiritual kinsman is, perhaps, Dostoievski (*q.v.*); he has also something in common with Carl Spitteler (*q.v.*). His special quality reveals itself in his novels, such as *Ott, Alois, und Werelsche* (1907), *Die Bestimmung der Roheit* (1912), *Der Rechte Liebhaber des Schicksals* (1916), *Sibylla Mariana* (1917) and *Die Erneuerung des Bundes* (new ed., 1925); in his shorter stories, such as *Die Heilige mit dem Fische* (1919) and *Verhängnisse* (1927); in his plays, such as *Das Viergetier* (1924) and *Der Chef des Generalstabs* (1927); and in his essays, such as *Die Krisis im Leben des Künstlers* (1922), *Der Künstler zwischen Westen and Osten* (1925) and *Begegnungen mit Rudolf Steiner* (1926).

**STEFFENS, HENRIK** (1773–1845), German philosopher, of Norwegian extraction, was born on May 2, 1773, at Stavanger. He studied in Germany, and began to lecture at Copenhagen in 1802. His lectures were appreciated by Grundtvig and Oehlenschläger, but the authorities regarded them with disfavour, and Steffens removed to Germany, where he fought in the Napoleonic wars on the German side. He was professor of physics at Breslau (1811–32) and at Berlin (1832–45). He died in Berlin on Feb. 13, 1845. Steffens was the friend and adherent of Schelling and Schleiermacher. His profound knowledge of physics modified the speculations of Schelling. His chief works were *Beiträge zur innern Naturgeschichte der Erde* (1801); *Grundzüge der philos. Naturwissenschaft* (1806); *Anthropologie* (1824). He also wrote novels and poetry and an autobiography, *Was ich erlebte,* and after his death there was published *Nachgelassene Schriften* (1846).

*See* M. Tietzen, *Zur Erinnerung an Steffens* (1871); Petersen, *Henrik Steffens* (1884); W. Dilthey, *Leben Schleiermachers* (1870).

**STEFFENS, LINCOLN** (1866–1936), American journalist and political philosopher. In 1901, after graduate study in Germany and newspaper experience in New York, Steffens became managing editor of *McClure's Magazine.* Here he published the influential articles later collected as *The Shame of the Cities.* For ten years he was the leading figure among the writers whom Theodore Roosevelt called muckrakers, but he was more concerned with the causes of corruption than with specific reforms, and he became a student of revolution, first in Mexico and then in Russia. Barred from many American magazines by his unorthodoxy during and after World War I, he lived quietly and obscurely in Europe during the 1920s, pondering his experiences and observations. His conclusions finally found expression in his autobiography, which had a great success when it appeared in 1931. Although he supported many communist activities in the depression years of the early 1930s, he remained essentially a pragmatist, preferring to ask questions rather than to answer them. His characteristic achievement, both as muckraker and as autobiographer, was in persuading readers to examine for themselves the character of contemporary civilization.

See: *The Autobiography of Lincoln Steffens* (1931); *The Letters of Lincoln Steffens* (1938). (G. Hs.)

**STEGANOPODES** or **PELICANIFORMES,** an order of birds characterized by the fact that the hind toe is united to the second toe by a web. Most species are gregarious and live on fishes. The order includes the pelicans, cormorants, gannets, snake-birds, frigate-birds and tropic-birds (*qq.v.*).

**STEGOCEPHALIA,** a term often applied to Palaeozoic and Triassic amphibians with solidly roofed skulls, mainly members of the Labyrinthodontia. (*See* AMPHIBIA.)

**STEGOSAURUS,** the name given to a type of dinosaur found in the late Jurassic of North America. The name (plated lizard) refers to the armament of the reptile in the shape of a paired row of bony plates extending upward along the length of the back; the tail bore two pairs of bony spikes. *Stegosaurus* was an inoffensive, small-headed vegetarian with a maximum length of 30 ft. The hind legs are much longer than the fore, suggesting a descent from bipedal ancestors. (*See* REPTILES; DINOSAURS.)

(A. S. Rr.)

**STEIBELT, DANIEL** (*c.* 1764–1823), German pianist and composer, was born at the earliest in 1764 or 1765 in Berlin. He was indebted to the crown prince Frederick William for his musical education. Very little is known of his artistic life before 1790, when he settled in Paris and attained great popularity as a virtuoso by means of a pianoforte sonata called *La Coquette,* which he composed for Queen Marie Antoinette; his dramatic opera entitled *Roméo et Juliette,* produced at the Théâtre Feydeau in 1793, was equally successful. In 1796 Steibelt moved to London, where his pianoforte playing attracted great attention. In 1798 he produced his concerto (No. 3, in E flat) containing the famous "Storm Rondo"—a work that ensured his popularity. In the following year Steibelt started on a professional tour in Germany; and, after playing in Hamburg, Dresden, Prague and Berlin, he arrived in May 1800 in Vienna, where he challenged Beethoven to a trial of skill. His discomfiture was complete and he retired to Paris, living alternately in that city and London during the next eight years. In 1808 he was invited by the emperor Alexander to St. Petersburg, succeeding Boieldieu as director of the royal opera in 1811. Here he resided in the enjoyment of a lucrative appointment until his death on Sept. 20, 1823.

Besides his dramatic music, Steibelt left behind him an enormous number of compositions for the pianoforte. His playing, though brilliant, was wanting in the higher qualities which characterized that of his contemporaries, John Cramer and Muzio Clementi; but he was gifted with talents of a high order, and the reputation he enjoyed was fully deserved.

**STEIN, SIR AUREL** (1862–1943), British archaeologist, was born at Budapest on Nov. 26, 1862. Educated at Budapest and Dresden and at the Universities of Vienna and Tübingen, he went to England for further study and then to India, where he became principal of the Oriental college, Lahore, and registrar of the Punjab university in 1888. He was appointed in 1899 to the Indian Education service, and for the next two years carried out archaeological explorations for the Indian government in Chinese Turkestan. In 1906–08 he made further explorations in central Asia and western China. From 1910 he was superintendent of the Indian Archaeological survey, and in 1913–16 carried out explorations in Iran and central Asia, described by him in *The Geographical Journal* (1916). He was created K.C.I.E. in 1912. In 1926 he continued his explorations on the northwest frontier and identified the site of Aornus, thus correcting Abbott's view, and between 1926 and his death explored Iran, Iraq and Trans-Jordan. He died in Kabul, Afghanistan, Oct. 28, 1943.

His writings include: *Chronicle of Kings of Kashmir* (1900); *Ancient Khotan* (1907); *Ruins of Desert Cathay* (1912); *Serindia* (5 vols., 1921); *The Thousand Buddhas* (1921); *On Alexander's Track to the Indus* (1929); *A Catalogue of Paintings Recovered from Tun-Huang* (1931); *An Archaeological Tour in Gedrosia* (1931); *Archaeological Reconnaissances in S.E. Iran* (1937); *On Old Routes of Western Iran* (1940).

**STEIN, CHARLOTTE VON** (1742–1827), the friend of Goethe, was born at Weimar on Dec. 25, 1742, the eldest daughter of the Hofmarschall (master of the ceremonies) von Schardt. She became in her 16th year lady-in-waiting to the duchess Anna Amalia, the accomplished mother of Duke Karl August of Saxe-Weimar. In 1764 she married Freiherr Friedrich von Stein, master of the horse to the duke, and seven children were the issue of the union. Goethe, who arrived in Weimar in 1775, was soon captivated by the charm of this lady, his senior by seven years, and the *Seelenbund* (union of souls) they formed exercised a furthering and ennobling influence upon Goethe's life and work. For more than ten years Charlotte von Stein was his constant companion, and by her bright and genial nature and friendship she stimulated his efforts and assuaged his cares. On Goethe's return from Italy

in 1788 the previous close relationship between them came to an end although their friendship was later renewed. Goethe's letters to Frau von Stein form one of the most interesting volumes of the poet's correspondence. She was also a close friend of Schiller and his wife, and numerous interesting letters from her are to be found in *Charlotte von Schiller und ihre Freunde* (vol. ii, 1862). She became a widow in 1793 and continued to live at Weimar until her death there on Jan. 6, 1827.

Goethe's *Briefe an Frau von Stein aus den Jahren 1776–1820* was edited by A. Schöll (3 vols., 1848–1851; 2nd ed. by W. Fielitz, 1883–1885; 3rd ed. by J. Wahle, 1900). *See* H. Düntzer, *Charlotte von Stein* (2 vols., 1874); id., *Charlotte von Stein und Corona Schröter* (1876); G. H. Calvert, *Charlotte von Stein* (Boston and New York, 1877); and A. Sauer, *Frauenbilder aus der Blütezeit der deutschen Literatur* (1885); W. Bode, *Charlotte von Stein* (1910).

**STEIN, GERTRUDE** (1874–1946), expatriate U.S. author, was born in Allegheny, Pa., Feb. 3, 1874, spent her infancy in Vienna and Paris, her girlhood in Oakland, Calif. She read Shakespeare at eight years. At Radcliffe college, 1893–97, she specialized in psychology. William James is said to have considered her the most brilliant woman pupil he ever had. She studied at Johns Hopkins Medical school, 1897–1902. Of independent means, she went abroad to live in 1903. Her home in Paris, 27 rue de Fleurus, was a centre for artists and writers for more than a generation. After 31 years, she returned to the U.S. for a lecture tour in 1934. Notwithstanding her German-Jewish origin, she continued living in Paris under nazi occupation.

A literary "cubist," Gertrude Stein carried to extremes her weird, repetitious, and seemingly nonsensical manipulation of words and of words and of words. "Widely ridiculed and seldom enjoyed," comments Edmund Wilson in a chapter about her in *Axel's Castle,* "she has yet played an important role in connection with other writers who have become popular." Sherwood Anderson and Ernest Hemingway were two such. In *The Autobiography of Alice B. Toklas* (1933), simply written and easily readable, Miss Stein, while ostensibly writing the life of her secretary and close companion since 1907, actually wrote her own. In this book she appeared as one of her protégés, Bravig Ihms, called her in his *Confessions of Another Young Man,* a "vital, headstrong and cordial personality," with "an insatiable appetite for people." They came and went in an unending procession, year after year, some famous, some unknown, some to become famous later: Matisse, Cézanne, Pablo Picasso, Juan Gris, Mildred Aldrich, Clive Bell, Wyndham Lewis, Carl Van Vechten, Avery Hopwood, Ezra Pound, Ford Madox Ford, Bernard Faÿ, André Gide, John Reed, Elliot Paul, Jo Davidson, Paul Robeson, and scores of others.

"Flowing," said Carl Van Vechten, "is the one word that best describes Gertrude Stein." Sherwood Anderson likened her to "an American woman of the old school," plain and strong, who worked hard in her "kitchen" to make good things—out of words. She was a substantial person, with a striking head and close-cropped hair. She dressed plainly. She laughed infectiously. When angry, she swore. Her favourite song was *On the Trail of the Lonesome Pine.* Alice Toklas, so the *Autobiography* recounts, knew personally three geniuses in her lifetime: Picasso, Alfred North Whitehead and Gertrude Stein. She died on July 27, 1946, in Paris.

The principal works of Gertrude Stein are: *Three Lives* (1908); *Tender Buttons* (1915); *Geography and Plays* (1923); *The Making of Americans* (1925); *Useful Knowledge* (1928); *Acquaintance with Description* (1929); *Ten Portraits* (1930); *Lucy Church Amiably* (1930); *Before the Flowers of Friendship Faded Friendship Faded* (1931); *How to Write* (1931); *Operas and Plays* (1932); *Matisse, Picasso and Gertrude Stein* (1932); *The Autobiography of Alice B. Toklas* (1933); *Four Saints in Three Acts;* an opera (1934); *Portraits and Prayers* (1934); *Lectures in America* (1935); *Narration* (1936); *Everybody's Autobiography* (1937); *Picasso* (1938); *The World is Round* (1939); *Paris France* (1940); *Ida* (1941); *Wars I Have Seen* (1945); *Yes Is for a Very Young Man;* a play (1946); *Brewsie and Willie* (1946).

**STEIN, HEINRICH FRIEDRICH KARL,** BARON VOM UND ZUM (1757–1831), German statesman, was born at the family estate near Nassau, on Oct. 26, 1757. He studied law at Göttingen, Wetzlar, Regensburg and Vienna, and settled in Berlin in 1780. There he entered the Prussian service.

After holding various diplomatic and other appointments he became (1787) Kammerdirektor, *i.e.,* director of the board of war and domains for the king's possessions west of the river Weser; and in 1796 he was appointed supreme president of all the Westphalian chambers dealing with the commerce and mines of those Prussian lands. Among the benefits of his administration was the canalization of the river Ruhr, which became an important outlet for the coal of that region. He also improved the navigation of the Weser, and kept up well the main roads committed to his care. On June 8, 1793 he married the countess Wilhelmine von Wallmoden-Gimborn, daughter of a natural son of King George II of Great Britain.

Stein's early training, together with the sternly practical bent of his own nature, made him completely impervious to the enthusiasm which the French Revolution had aroused in many minds in Germany. He disliked its methods as an interruption to the orderly development of peoples. Nevertheless he carefully noted the new sources of national strength which its reforms called forth in France. Under the untoward circumstances which followed the Peace of Basel Stein in 1804 took office at Berlin as minister of state for trade. He protested against the effects of the Gallophil policy of the chief minister, Haugwitz, and the evil influences which clogged the administration. Little, however, came of Stein's protests, though they were urged with his usual incisiveness and energy. Prussian policy continued to progress on the path which led to the disaster at Jena (Oct. 14, 1806).

The king then offered to Stein the portfolio for foreign affairs, which he declined, because he desired to see Hardenberg take that office and effect, with his own help, the necessary administrative changes. The king refused to accept Hardenberg, and, greatly irritated by Stein's unusually outspoken letters, dismissed him altogether, adding that he was "a refractory, insolent, obstinate and disobedient official." Stein now spent in retirement the months during which Napoleon completed the ruin of Prussia; but he saw Hardenberg called to office in April 1807 and important reforms effected in the cabinet system. During the negotiations at Tilsit, Napoleon refused to act with Hardenberg, who thereupon retired. Strange to say, the French emperor at that time suggested Stein as a possible successor, and on Oct. 4, 1807, Frederick William called Stein to office with very wide powers.

Stein's strong convictions led him to press on drastic reforms in a way which could not otherwise have been followed. First came the Edict of Emancipation, issued at Memel on Oct. 9, 1807, which abolished the institution of serfdom throughout Prussia from Oct. 8, 1810. All distinctions affecting the tenure of land (noble land, peasants' land, etc.) were also swept away, and the principle of free trade in land was established forthwith. The same famous edict also abrogated all class distinctions respecting occupations and callings of any and every kind, thus striking another blow at the caste system which had been so rigorous in Prussia. Stein's next step was to strengthen the cabinet by wise changes and he also furthered the progress of the military reorganization which is connected more especially with the name of Scharnhorst (*q.v.*). Stein's efforts were directed more towards civil affairs; and in this sphere he was able to issue a measure of municipal reform (Nov. 19, 1808) which granted local self-government on enlightened and practical lines to all Prussian towns.

In August 1808 the French agents, who swarmed throughout the land, had seized one of his letters, in which he spoke of his hope that Germany would soon be ready for a national rising like that of Spain. On Sept. 10 Napoleon gave orders that Stein's property in the new kingdom of Westphalia should be confiscated, and he likewise put pressure on Frederick William to dismiss him. The king evaded compliance; but the French emperor, on entering Madrid in triumph, declared (December 16) *le nommé Stein* to be an enemy of France and the Confederation of the Rhine; and ordered the confiscation of all his property in the Confederation. Stein saw that his life was in danger and fled from Berlin (Jan. 5, 1809) to Bohemia.

For three years he lived in the Austrian empire, generally at Brünn; but in May 1812 he received an invitation from the emperor Alexander I to visit St. Petersburg, seeing that Austria was certain to range herself on the side of France in the forthcoming Franco-Russian War. At the crisis of that struggle Stein may have been one of the influences which kept the tsar determined never to treat with Napoleon. When the miserable remains of the Grand Army reeled back into Prussia at the close of the year, Stein urged the Russian emperor to liberate Europe.

Events now brought Stein rapidly to the front. On Dec. 30, 1812, the Prussian general Yorck signed at Tauroggen a convention with the Russian general Diebitsch for neutralization of the Prussian corps at and near Tilsit, and for the free passage of the Russians through that part of the king's dominions. The tsar thereupon requested Stein to act as provisional administrator of the provinces of East and West Prussia. In that capacity he convened an assembly of representatives of the local estates, which Feb. 5, 1813, ordered the establishment of a militia (*Landwehr*), a militia reserve and a final levy (*Landsturm*). He took part in the drafting of a Russo-Prussian convention (March 19, 1813) respecting the administration of the districts which should be delivered from French occupation. During the varying phases of the campaign of 1813 Stein continued to urge the need of war *à outrance* against Napoleon. The Allies conferred on Stein the important duties of superintending the administration of the liberated territories. After the battle of Leipzig (Oct. 16–19, 1813) Stein entered the city.

He now desired to see Germany reconstituted as a nation, in a union which should be at once strong for purposes of defense and founded on constitutional principles. His statesmanlike projects were foiled, partly by the short-sightedness of German rulers and statesmen, but also by the craft with which Metternich gained the alliance of the rulers of south and central Germany for the Austrian empire. During the Congress of Vienna Stein pressed in vain for an effective union of the German people. Austria and the secondary German states resisted all proposals in this direction; and Stein blamed the Prussian chancellor Hardenberg for an indefiniteness of purpose which probably resulted from the same defect in Frederick William of Prussia. Stein shared in the desire of all Prussian statesmen at that time to have Saxony wholly absorbed in their kingdom. In that, as in other matters, he was disappointed.

Stein passed into retirement after the Congress of Vienna, and saw with pain and disgust the postponement of the representative system of government which Frederick William had promised to Prussia in May 1815. His chief interest was in the study of history, and in 1818–1820 he worked hard to establish the society for the encouragement of historical research and the publication of the *Monumenta Germaniae historica,* of which his biographer, Pertz, became director. Stein died on June 29, 1831.

Possibly there has been a tendency to magnify the achievements of Stein. Research has shown that the credit for originating his reforms must be shared with Heinrich Theodor von Schön and many others.[1] The king himself rendered large services to this cause, but Stein's enlightenment, insight and almost superhuman energy ensured the triumph of these principles.

[1]Thus Schön's memorandum on the abolition of serfdom was the basis of the law of emancipation; and Stein's *Politisches Testament* was also based on a draft by Schön. Schön was born in 1773, entered the Prussian civil service in 1793, and subsequently held various high ministerial appointments. He was made castellan (*Burggraf*) of Marienburg on his retirement in 1842, and died in 1856. The share claimed by him in Stein's reforms has been the subject of some controversy.

**STEINER, JAKOB** (1796–1863), Swiss mathematician, was born on March 18, 1796, at the village of Utzendorf (Berne). At eighteen he became a pupil of Heinrich Pestalozzi, and afterwards studied at Heidelberg. Thence he went to Berlin and became one of the chief contributors to Crelle's *Journal* founded in 1826. In 1834 a new chair of geometry was founded for him. This he occupied till his death on April 1, 1863.

Steiner was one of the great developers of synthetic geometry. In his *Systematische Entwickelung der Abhängigkeit geometrischer Gestalten von einander* he introduces the geometrical forms (the row, flat pencil, etc.), and establishes between their elements a one-one correspondence, or, as he calls it, makes them projective.

*See* C. F. Geiser's pamphlet, *Zur Erinnerung an J. Steiner* (Zürich, 1874).

**STEINER, RUDOLF** (1861–1925), German philosopher, was born on Feb. 27, 1861, at Kraljevic, Austria, the son of a minor railway employee. From 1890 to 1897 he worked in Weimar at the "Goethe-Schiller Archive," editing Goethe's works on natural history. In 1902 the German section of the theosophic association was founded and Steiner was called upon to become its spiritual leader. As such he developed for some years an astonishing activity as regards lectures and writings, but then became opposed to theosophy altogether, and was therefore excluded from the theosophical centre under English leadership. Steiner now developed his own teaching in a series of writings. He called this "anthroposophy," *i.e.,* wisdom of humanity: mankind is regarded as the centre of all perceptions of this "spiritual science," and an attempt is made to deduce the nature of the world from the nature of humanity. In 1913 the Anthroposophical society was formed to further spiritual research on Steiner's principles. In order to try his educational and political views in practice, Steiner founded the Waldorf school, near Stuttgart, and the "free high school for spiritual science" known as the "Goetheanum" at Dornach near Basle, which was burned a few years later. All Steiner's works are published by the *Philosophisch-anthroposophischer-Verlag,* Berlin, and *Der kommende Tag,* Stuttgart. He died at Dornach on March 30, 1925.

His chief works include: *Goethe, als Vater einer neuen Aesthetik* (1888), Eng. ed. in preparation; *Die Philosophie der Freiheit* (1894), Eng. trans. ed. H. Collinson, *The Philosophy of Freedom* (1916); *Friedrich Nietzsche* (1895); *Goethes Weltanschauung* (1897); *Theosophie* (1904), Eng. trans. by E. D. S., *Theosophy* (1910); *Haeckel, die Welträtsel und die Theosophie* (1905), Eng. trans. *Haeckel, The Riddles of the Universe;* and *Theosophy in Three Essays on Haeckel, and Karma* (1914); *Wie erlangt man Erkenntnisse der höhern Welten* (1909); Eng. ed. trans. Clifford Bax, 2 vol., *The Way of Initiation* and *Initiation and its Results* (1909–10); *Die Aufgabe der Geisteswissenschaft und deren Bau in Dornach* (1916); Eng. ed. trans. A. M. Wilson, *The Mission of Spiritual Science and of its Building at Dornach, Switzerland* (1917); *Die Kernpunkte der sozialen Frage* (1919); Eng. ed *The Threefold State—The True Aspect of the Social Question* (1920); *In Ausführung der Dreigliederung des Sozialen Organismus* (1920), Eng. trans. in *The Threefold Commonwealth* (1921 *seq.*).

*See* E. Boldt, *Von Luther bis Steiner* (1921), Eng. trans. (1923); F. Rittelmeyer, *Von Lebenswerk R. Steiners* (1921); G. Kaufmann, *Fruits of Anthroposophy; an Introduction to the Work of Dr. R. Steiner* (1922).

**STEINLE, EDUARD** (1810–1886), Austrian painter, was born in Vienna on July 2, 1810. In 1828 he joined the "Nazarene" groups, started by Overbeck and Cornelius in Rome. It was not, however, a congenial atmosphere for one of his romantic temperament, and in 1833 he returned to Vienna, moving in 1838 to Frankfurt, where he was professor of historical painting at the

Staedel institute from 1850, and where he died on Sept. 19, 1886. He had the freshness and poetical fancy of the Viennese, and his best work is found in such legendary subjects as "Loreley" (Shack gallery, Munich), "The Violinist," and the illustrations to fairy-tales by Brentano and others.

*See* O. Berggruen, *Die Galerie Shack* (*Graphische Künste*, iv, 3, 4); C. v. Wurzbach, *E. Steinle, ein Madonnenmaler unserer Zeit* (Vienna, 1879).

**STEINMETZ, CHARLES PROTEUS** (1865–1923), American electrical engineer, born at Breslau, Germany, April 9, 1865. He was educated at Breslau, Zürich and Berlin, specializing in mathematics, electrical engineering and chemistry. His activities as a Socialist led him into difficulties with the authorities, and, after a short sojourn in other countries, he emigrated in 1889 to the United States and found work with the Osterheid and Eickemeyer factory at Yonkers. In 1893 when that factory was absorbed by the General Electric Co., Schenectady, he was given an appointment as consulting engineer. His knowledge won him speedy promotion and he soon became recognized as one of the outstanding electrical geniuses of America. After 1902 he served also as professor of electrical engineering at Union college. Steinmetz regarded his three greatest contributions to electrical science to be: (1) his investigations on magnetism resulting in his discovery of the law of hysteresis, which enabled losses of electric power due to magnetism to be accurately forecast before starting the construction of motors, generators, transformers, and other electrical apparatus employing iron; (2) the development of his symbolic method of calculating alternating-current phenomena which simplified an extremely complicated field, understood by few, so that the average engineer could work with alternating-current, an accomplishment which was largely responsible for the rapid progress made in the commercial introduction of alternating-current apparatus; (3) his investigation of lightning phenomena which resulted in his theory of electrical transients, and opened the way for his development of lightning arresters to protect high-power transmission lines. Though primarily a mathematical genius and a student of theory, he had some 200 patents to his credit, including improvements on generators, motors, transformers, in electro-chemical operations, and the invention of the induction regulator, the method of phase transformation and the metallic electrode arc lamp. Besides a large number of scientific papers he was the author of a number of standard text-books. He died at Schenectady, N.Y., Oct. 26, 1923.

*See* J. W. Hammond, *Charles Proteus Steinmetz, a Biography* (1924), and J. N. Leonard, "Steinmetz, Jove of Science," in *World's Work*, vol. 53, nos. 2, 3 and 4 (1929).

**STEINMETZ, KARL FRIEDRICH VON** (1796–1877), Prussian general field-marshal, was born at Eisenach on Dec. 27, 1796. At the outbreak of the War of Liberation he and his elder brother made their way through the French posts to Breslau, where they at once received commissions. The brothers took part in the hardest fighting of the campaign of 1813, the elder being killed at Leipzig and the younger being more than once wounded. After the peace he entered Paris but once, fearing to infringe upon the ten ducats that he saved monthly from his pay to send to his mother. His character and physique were strengthened by his Spartan way of life, but his temper suffered. From 1820 to 1824 he studied at the General War academy.

Steinmetz was promoted general of infantry in 1864, and led the V Corps to the war against Austria in 1866. This was the chance of his lifetime. His skilful and resolute leadership was displayed in his three battles, won on three successive days, of Nachod, Skalitz and Schweinschädel (*see* SEVEN WEEKS' WAR).

At the outbreak of the war of 1870 Steinmetz was appointed to command one of the three armies assembled on the Rhine, the others being led by Prince Frederick Charles and the crown prince. Serious differences arose between Steinmetz and Prince Frederick Charles. After the battle of Gravelotte he was relieved of the command of the I Army and was sent home as governor-general of the V and VI Army Corps districts. In April 1871 he was retired at his own request, but his great services were not forgotten, and he was promoted to general field-marshal. He died at Bad Landeck on Aug. 2, 1877.

**STELE,** a nonstructural pillar or vertical slab of stone, metal or marble, usually set up for votive or commemorative purposes, sometimes decorated with bas-reliefs and bearing inscriptions, and generally terminated with a cresting enriched in classic examples with the anthemion plant with a small pediment. Stelae are common in Chinese tombs and temples, and usually these consist of an inscribed panel crowned by the dragon, and supported on the back of a great turtle.

**STELLAR CONSTITUTION AND EVOLUTION.** Mere observation of the stars cannot tell us which are young and which are old, for all their changes are far too slow to detect. The only safe guide is a physical theory, which starts from knowledge of the general properties of matter and deduces the behaviour of great masses isolated in space through long intervals of time. Such knowledge first became available with the advance of atomic physics shortly after 1920. By 1945 the general constitution of the stars appeared to be fairly well understood—though only a beginning can be made toward deducing their history throughout the ages.

**Constitution of the Stars.**—An isolated mass of matter will settle down into a spherical form unless it is distorted by rotation (a complication which need not be considered in this sketch). The gravitational attraction of the body will produce a pressure, increasing toward the centre, which may be calculated for any assumed "model" defining the increase of density toward the centre. The temperature at any point follows from the pressure and density, if the composition of the material is known, and the familiar gas laws may be assumed.

For bodies comparable in size and mass with the stars, the calculated temperatures come out in millions of degrees.

The properties of matter under these conditions are now fully understood, and are considerably simpler than at ordinary temperatures. All substances are volatilized, all compounds decomposed, and all but a few of the innermost electrons are stripped from the nuclei of the atoms. The simple gas laws may safely be applied unless the density exceeds a thousand times that of water. The calculated temperature for a given pressure and density depends very little upon the composition, except that the presence of hydrogen lowers it considerably, and of helium to a smaller degree. At the centre of a body of the size and mass of the sun, the temperature is of the order of 20,000,000° C.—varying with the density model and hydrogen abundance. At corresponding points in stars of the same composition, and built on the same model, the temperature is directly proportional to the mass, and inversely to the radius (Lane's law).

This theory is due mainly to Sir Arthur Stanley Eddington, who applied it with marked success to the study of the escape of heat from a star.

**Stellar Luminosity.**—Inside a star radiation is flying from atom to atom in all directions but going only a short distance before it is absorbed and re-emitted. On the average this results in a flow of energy from the hotter to the cooler parts, at a rate which is greater the more rapid the fall in temperature per mile; and less, the greater the opacity of the gas to radiation. The laws which govern the emission and absorption of radiation in a very hot gas are now well established, and the rate of escape of heat from the interior to the surface of a star can be calculated. The surface will automatically adjust its temperature so that it loses into space as much as it receives from below, so that this calculation gives us the total heat radiation, or luminosity, of the star.

It is found (again following Eddington) that the luminosity of a star depends primarily upon its mass—increasing somewhat faster than the cube of the latter. This conclusion is fully confirmed by observations of hundreds of stars, which afford strong evidence of the essential soundness of the theory and the postulates on which it is based.

Changes in the size of a star have but a small effect on its calculated luminosity, which varies inversely as the square root of the radius.

The effect of changes in the density model is rather small—

rarely exceeding a factor of three. Stars containing no hydrogen should be much brighter (in some cases 100 times) than those containing 50% hydrogen. (For stars composed almost entirely of hydrogen, the calculated brightness increases again: but no such cases appear to be known.) A body of the sun's size and mass would shine as brightly as the sun if it contained 35% by weight of hydrogen, no helium and 65% of heavier atoms; also with 51% hydrogen, 42% helium and 7% heavy atoms; and for a series of intermediate compositions.

**The Contraction Theory.**—The energy which a star radiates must be provided from some internal source. Before the rise of atomic physics, the greatest known supply was the gravitational potential energy, arising from the mutual attraction of its parts. These attractive forces tend to compress the star. If they were not balanced by the internal pressure of the gases of the interior the star would contract, the gravitational forces would do work, and a corresponding amount of potential energy would be liberated, appearing as heat of compression in the gas. If, at a given instant, the internal pressures just balanced those due to gravity, nevertheless, as the star lost heat by radiation from its surface, the interior would tend to cool and the gas pressure to diminish. Contraction would then begin and continue till enough heat had been produced to raise the pressure and restore the balance. The evolution of a star, on this conception, would be a gradual shrinkage—part of the heat liberated by transformation of the gravitational potential energy maintaining the internal equilibrium and the rest keeping up the radiation.

This first rational theory of stellar evolution owes its origin to Hermann von Helmholtz. What proportion of the liberated energy is stored inside the star, and how much remains available to keep it shining, can be calculated from the known laws of gases. Much of the internal energy is the *kinetic energy* of motion of the atoms of the gas, to which it owes its high temperature. Part is energy of *ionization*. The collisions between the atoms are so violent that the outer electrons which normally belong to their structure are detached and fly about independently. To remove them against the electrical attraction of the residue of the atoms demands a large expenditure of energy which would be released again if the gas should cool and the collisions become less violent. Finally, the *radiation* imprisoned within the star, flying from atom to atom and gradually working its way out to the surface, carries an amount of energy which, especially in the stars of greatest mass, is a considerable fraction of the whole.

All told, it appears that more than half of the energy liberated by contraction, and sometimes a good deal more, must be stored inside the star in these three forms; but that, under actual conditions, a surplus will be available to meet the loss by radiation.

**Age of a Star.**—When the length of a star's life comes to be considered, the contraction theory meets with grave difficulties. The amount of gravitational energy which would have been released by the contraction of the sun, for example, from an indefinitely great size to its present dimensions is readily calculable, and is found to amount to as much as would supply the present rate of radiation from the surface for 46,000,000 years. More than half this must still be stored inside the sun, and 20,000,000 years' supply at most can be counted available for radiation. This was pointed out long ago by Lord Kelvin.

But there is now abundant evidence from radioactive data that the oldest sedimentary rocks recognized by geologists are more than 1,000,000,000 years old (probably somewhat more), and that, during all this interval, the temperature of the earth's surface has been closely the same as at present. The sun has therefore, during geological time, dissipated in radiation more than 50 times as much energy as it could have derived from gravitational sources, and yet has remained of about the same brightness all the time. For the giant red stars of low density the case is even stronger. The gravitational energy available for a star's past radiation is proportional to $M^2/R$ (M being the star's mass and R its radius). For Antares, for example, for which R is 480 times as great as for the sun, and M probably only 30 or 40 times as great, the available energy is some three times as great as for the sun. Antares radiates heat at 10,000 times the sun's rate, so that its whole past history, if gravitational energy only were available, would occupy only 6,000 years.

**Subatomic Energy.**—Such arguments have convinced practically all workers in the field that the sun, and the stars in general, must draw to maintain their radiation upon some vast supply of energy whose very existence was previously unsuspected. The only storehouses in the known universe *small* enough to hold so much energy are the tiny nuclei of the atoms, or perhaps the still smaller protons and electrons of which they are composed. For particles at greater distances, such as those at the periphery of an atom, the forces are not great enough to do so much work. The main source of stellar energy appears therefore to be of "subatomic" nature.

**Loss of Mass.**—A second conclusion follows from the theory of relativity. According to this all energy possesses mass, and mass and energy are, to some degree at least, interconvertible, in a definitely known ratio. To m grams of matter correspond $mc^2$ ergs of energy (where c is the velocity of light). Translated into more familiar units, this means that it is as legitimate to speak of a pound of heat as of a pound of iron. But a pound of heat is a very large amount, measured by ordinary standards; it would suffice to raise 20,000,000 tons of rock to a temperature of 1,500° C. and melt it into incandescent lava. The amounts of heat involved in all ordinary thermal changes are therefore of such small mass that it is still usually permissible to treat heat as "imponderable"; but when it comes to the radiation of the stars the case is different. The sun radiates energy into space at the rate of $3.8\times10^{33}$ ergs per second—a number too great to be directly appreciable even by the physicist. Expressed as mass, this means that the sun is getting rid of 4,200,000 *tons of heat every second.* No other mode of statement comes so near to conveying to human apprehension the tremendous activity of a star.

The sun's mass must actually be diminishing at this portentous rate, which might raise fears of its disappearance. But its present mass is so great ($1.98\times10^{33}$ grams) that the existing radiation would use up only a millionth part of it in 15,000,000 years, and the consumption of a moderate fraction would give a life long enough to meet the wildest demands of geology.

The process of transformation by which mass disappears and energy is liberated within the stars must satisfy these conditions: (1) it must be a nuclear reaction; (2) it must be capable of furnishing energy at the observed rate (usually a few ergs per gram per second) in the stellar gas at a temperature of the order of 20,000,000° C.; (3) it must *be self-regulating,* so that stars of different masses can have different rates of supply, and *stable*—free from danger of catastrophe. The last requirement may be considered first, since it depends upon the properties of a star as a whole.

**Stability.**—The rate at which heat can escape from a star changes but little with its size. If, in a given configuration, the rate of income of heat from subatomic sources is less than the rate of escape, the star will have to draw on its gravitational store, and contract; if the income exceeds the outgo, the process will be reversed, and the star will expand, storing up the excess energy by means of the work done against gravitation.

As a star contracts, the rate of expenditure of heat by radiation from its surface will slowly increase, and the temperature and pressure in its interior will also rise. If these changes increase the rate of liberation of subatomic energy fast enough, a star of deficient income, as it contracts, will find its income gaining upon expenditure, and will approach a state of equilibrium. Should it overshoot this and contract too far, the income would exceed the outgo, and expansion would be forced, tending again to restore equilibrium. In this case the equilibrium is stable; but if, after contraction, the outgo gained upon the income, it would be unstable, and even a small unbalance would tend to increase indefinitely.

Eddington has pointed out that if this increase is too rapid the star will tend to pulsate (alternately expanding and contracting) to an increasing extent; but Cowling has shown that this pulsatory instability will not arise unless the rate of liberation of energy increases faster than the 20th power of the temperature,

so that the margin of safety is wide.

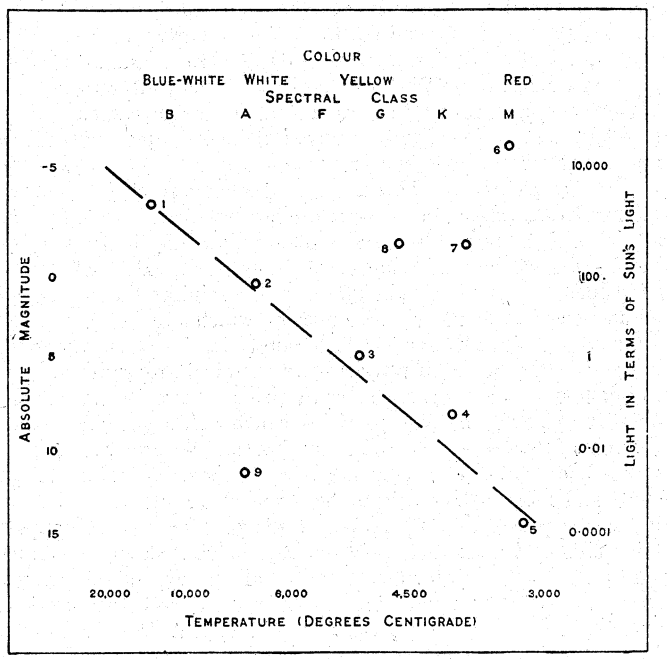
**Nuclear Reactions.**—Further progress depends upon a knowledge of actual reactions between nuclei. Fortunately, it is possible, with the aid of the cyclotron and similar devices, to accelerate nuclei of hydrogen (protons), of deuterium (deuterons), and of helium (alpha particles) so that their collisions with other atoms are extremely violent, and a great variety of nuclear reactions, involving practically all the elements, have been observed. In many of these, changes in the total mass of the reacting particles occur, with corresponding liberation of energy; but these all involve transformations in which but a small fraction of the whole mass disappears. Annihilation, with the complete disappearance of the particles and liberation of all the corresponding energy, has been observed for positive and negative electrons, but never for particles of greater mass. It is to transformation, therefore, and not to annihilation of atoms, that the source of stellar energy is to be ascribed.

For example, the mass of a hydrogen atom is 1.00813 of the chemist's ordinary units, and that of a helium atom 4.00386. A process, or set of processes, which resulted in the transformation of four hydrogen atoms into a helium atom would diminish the mass by 1/141 of the original amount. To liberate the 4,200,000 tons of energy which the sun radiates every second would require the transformation of 590,000,000 tons of hydrogen into helium every second. At this rate, the hydrogen which is present in the sun would last for at least 35,000,000,000 years.

Reactions between protons and many heavier nuclei have been studied in the laboratory. The helium nucleus alone is inert—too stable to disturb. For the others, the probability of a successful hit by a proton of given energy can be measured, and from this it is possible to calculate how rapidly each reaction would occur in a hot dense gas containing given proportions of hydrogen and the atoms concerned.

The most valuable nucleus is the deuteron (heavy hydrogen) which, in a body of the sun's mass would supply heat enough to supply the sun's radiation at a gas temperature of about 400,000° C. Lithium, the next lightest element, would be affected at about 2,000,000° C.; and boron and beryllium at from 4,000,000° to 9,000,000° for different isotopes. In all these cases the reaction products break down, either at once or after a few intermediate stages, into helium nuclei, and no trace is left of the nuclei which originally reacted.

**The Carbon Cycle.**—Carbon behaves quite differently—taking part in a very remarkable cycle of reactions, discovered by Hans A. Bethe, which are so important that it is worth while writing down the equations which express them.



$$C^{12}+H=N^{13}+\gamma \qquad N^{14}+H=O^{15}+\gamma$$
$$N^{13}=C^{13}+e^{+} \qquad O^{15}=N^{15}+e^{+}$$
$$C^{13}+H=N^{14}+\gamma \qquad N^{15}+H=C^{12}+He^{4}$$

A proton H, entering an ordinary carbon nucleus $C^{12}$ (of mass 12), forms a peculiar kind of nitrogen $N^{13}$, while excess energy is liberated as a gamma-ray, $\gamma$. This nucleus is radioactive, and breaks down in a few minutes, emitting a positive electron $e^{+}$, and turning into the heavier isotope of carbon $C^{13}$. Two more proton penetrations follow, producing first ordinary nitrogen $N^{14}$, and then a radioactive oxygen, $O^{15}$, which decays into the rare isotope of nitrogen $N^{15}$. When a proton hits this nucleus, the combined mass breaks up into two pieces, a helium nucleus, $He^{4}$, and one of carbon like the original one. Every one of these six reactions has been produced and studied in the laboratory, and there is no guesswork at any point. Energy is liberated at each step as radiation or by rapidly moving particles—and is speedily transformed to heat in the gas.

The distinctive feature of this process is that the carbon is regenerated ready to work again. The lighter nuclei play their part in consuming hydrogen but are consumed themselves at the same time, while carbon and its associated nitrogen work again and again and can catalyze the transformation of many times their own weight of hydrogen without being exhausted.

In a star like the sun, this cycle would furnish the needful energy supply at a temperature of about 20,000,000° C. (depending on the amounts of carbon and of hydrogen). For example, in the model already described, containing 51% of hydrogen, the presence of ⅔% carbon and nitrogen together would be sufficient. It is now generally agreed that this is the process by which the sun's radiation is actually maintained.

Reactions between protons and heavier nuclei, such as oxygen and fluorine, are known, but they demand a higher temperature,

**RELATIONS BETWEEN THE COLOUR AND BRIGHTNESS OF STARS**
(1) Stars of Orion's Belt, (2) Sirius, (3) The Sun, (4) 61 Cygni, (5) Barnard's Star, (6) Antares, (7) Arcturus, (8) Capella, (9) Companion of Sirius

and so would not have a chance to occur in a star containing carbon or nitrogen, which would get rid of its hydrogen before they came into play. Another process involving formation of deuterons by collision of two protons, and ultimately converting hydrogen with helium, is theoretically possible, and may occur in some stars of high density and low temperature, but its rate cannot yet be calculated with any accuracy.

**Theoretical History of a Star.**—We may now sketch a scheme of stellar evolution, based entirely on the known properties of atoms. Start with a large mass of low density, containing atoms of all sorts. It will come rapidly into a spherical form, under its own gravitation. If its mass is as much as 100,000 times that of the earth, it will be very hot inside, and enough heat will escape to the surface to keep this incandescent. It will be a *star*.

So long as the central temperature is low, no nuclear energy will be liberated and the star will draw on its gravitational energy and contract. With rising internal temperature, the reactions involving the lighter nuclei will successively be "turned on." Contraction will practically cease when enough heat is liberated from the nuclear process—to be gradually resumed as the active constituent becomes exhausted. In this way all the light nuclei will be consumed in successive or overlapping stages until the carbon cycle comes into play. If, as seems probable, hydrogen was originally very abundant, there will be a prolonged halt in contraction, while the hydrogen itself is being consumed.

So much is clear; but further details depend upon a question which has not yet been theoretically settled. If the gases inside the star are kept mixed by currents, turbulence, or the like, practically all the hydrogen will in time be transported to the hot centre and consumed. But, if there is little or no mixing of concentric layers, a core of exhausted material (helium and heavy nuclei) will form, surrounded by a working layer in which nuclear reactions are occurring and this again by an outer part too cool to permit them. The theory of this model is complicated, and by 1945 had not been fully worked out.

Lithium, beryllium and boron are present in the sun's atmosphere, though in very small quantities, and must long ago have been completely consumed in its interior. Hence mixing has not been complete, but it may have been extensive.

Assuming thorough mixing, which is theoretically easier to work with, the temperature inside our hypothetical star would tend to rise as the percentage of hydrogen diminished. Its radiation would also increase, and calculation shows that a slight increase of diameter would at first be required to prevent too great a liberation of energy. Finally, when the hydrogen was almost exhausted, contraction would begin. With the hydrogen gone, contraction would have to supply almost all the radiation, since the reactions which might happen between heavier nuclei at high temperatures would liberate relatively little energy.

*Limiting Density.*—The question whether any limit would be set by nature to such a contraction can be answered only by an appeal to fundamental principles of quantum physics. Sir Ralph Fowler showed in 1926 that such a limit would exist. There is a fundamental "exclusion principle" which prohibits the occurrence of any two electrons within an atom which are in exactly the same state, and accounts for the ground plan in which atoms are built, and on which their physical and chemical properties depend. Applied to a mass of gas, this same principle fixes a limit to the number of *slowly moving* particles which can occupy any given volume of space—say a cubic centimetre. Where this limit is reached, only faster moving particles can get in, and to crowd more and more of them into the same space requires an ever-increasing pressure. So long as all the particles are shut up in this volume, their motions will not slow down below the average value set by this principle. Additional energy, if supplied to them, would set them moving faster, and increase the pressure. This excess could escape again as heat, but the "zero-point energy" cannot so escape, nor the corresponding pressure be reduced.

In a mass of ionized gas, the electrons, which are the fastest moving particles, would be the first to suffer from this restriction, and become degenerate. The properties of a degenerate gas can be precisely calculated and then those of a body composed of it. It is found that a mass equal to the sun's and containing no hydrogen would, if completely degenerate, have a diameter of about 13,000 mi., and a mean density somewhat more than 1,000,000 times that of water.

In this condition, it would have lost all the heat which it might have contained when larger and all that which would be liberated by contraction, except for the irremovable zero-point energy, and could contract no further. At the limit it would be cold and dark, and "fixed in an eternal state" apart from the chance of collision with another body. A very thin surface layer would still consist of ordinary nondegenerate matter, but would form a negligible fraction of the whole body.

For smaller masses, the calculated limiting diameter is larger, and the limiting density smaller. For larger masses the calculated velocities of the electrons approach those of light, and relativistic theory must be applied. S. Chandrasekhar, after a thorough study, has concluded that for masses more than 1.5 times the sun's, and containing no hydrogen, the velocity which the electrons must have to support their share of the gravitational pressure will always be greater than the zero-point velocity, so that the gas can never become completely degenerate, and no limit can be set to its contraction.

Present theory, therefore, presents this picture of the later history of a star. After the hydrogen has been exhausted by the carbon cycle, the body contracts, growing very much hotter inside and considerably hotter on the surface, and increasing in luminosity. This stage probably occupies but a small portion of the star's history. For smaller masses, maximum internal and external temperatures will be reached at a diameter probably about five times the limit just discussed. After this the star cools and grows fainter, still shrinking slowly until it settles down toward the dense degenerate state and, at long last, becomes an inert dark body. Stars of larger mass continue to contract beyond the power of present theory to follow them.

It should be especially noticed that this long account has been derived entirely from general physical theory. No use has been made of actual observations of the stars except to define in a general way the masses, sizes, and composition of the type of bodies with which we are dealing, and to calculate illustrative examples for a body comparable with the sun (except for a few incidental notes, unimportant to the course of the argument).

**Comparison with Observation.**—In comparing these predictions with the actual properties of the stars, we must evidently use those which can be found by observation for large numbers of them. The most suitable characteristics are the luminosity (or the absolute magnitude, which is another way of describing the same thing) and the surface temperature (for which the colour of the light or the type of spectrum may be substituted), since all these are very closely correlated.

Plotting the absolute magnitude vertically and the spectral type horizontally, diagrams have been prepared showing the relations for thousands of stars. It is found that the points on the diagram are very far from being distributed at random.

*The Main Sequence.*—The majority of the points are concentrated into a rather narrow band, running downward to the right across the diagram, as illustrated schematically by the heavy broken line in the figure. The corresponding stars form a great group called the *main sequence,* including all colours and all degrees of brightness, but with all the faint stars red, all those of medium brightness yellow (the sun belongs here) and all the bright ones white. The extreme range of brightness is much more than a millionfold. That in the diameters (which may be readily calculated) is thirty or fortyfold, and in the masses a hundredfold (agreeing with Eddington's relation).

With the density model indicated by the laws of radiative equilibrium, the central temperature comes out about 25,000,000° C. for the sun, 35,000,000° or 40,000,000° for the great white stars at the top of the sequence, and 15,000,000° or 20,000,000° for the faint red ones at the bottom. There must be a reason for this similarity.

It has already been mentioned that Bethe's carbon cycle suffices to account for the source of the sun's energy. When similar calculations are made, it is found that it will account for all the main sequence stars—the higher internal temperatures in the hotter stars being just enough higher to provide the much greater amounts of energy per unit mass which they radiate. The agreement is so striking that it is now generally agreed that the main sequence consists of stars whose energy is supplied by the operation of the carbon cycle. If all these stars contained exactly the same percentages of hydrogen and carbon, the points representing them would be on a definite line in the colour-brightness diagram; but, if the percentages were different, the points would be scattered on each side of this line, and form a strip extending diagonally across the diagram, as they actually do, even after allowance for the effect of errors in the observed data.

The existence of this great sequence of luminaries could have been predicted, and the place which the points representing them have on the diagram pretty closely defined, by applying general principles of physics, without ever having seen a star.

*The White Dwarfs.*—The point numbered 9 in the figure represents a star of a very different sort—the faint companion of the bright star Sirius (which itself belongs to the main sequence). This star, though less than 1/300 as bright as the sun, is much hotter on the surface, and its diameter has been estimated as 1/50 of the sun's. Its mass is very nearly equal to the sun's, and its calculated mean density 175,000 times that of water. When these values were first calculated, they appeared unbelievable, but they are just what might be expected for a star which was almost completely in the degenerate state, though enough energy above the zero point still remained to keep it shining feebly.

About 40 "white dwarf" stars of this sort are now known. They differ considerably among themselves in brightness and colour, as is again to be anticipated theoretically. Such stars must be very numerous in space, but they are so faint that we can detect only the nearer ones.

*The Giants and Super-Giants.*—Many of the stars most con-

spicuous to the eye are yellow and red, but lie at great distances and are of high luminosity. These bodies are of large diameter—a few of them as big as the earth's orbit—but there is evidence that their masses agree fairly well with Eddington's relation.

Their internal densities must then be very low, and their temperatures probably only a few million degrees, even at the centre. This is much too low to "turn on" the carbon cycle, but high enough to activate nuclear reactions involving the light elements.

If this were the whole story, we should find them represented on the diagram by groups of points lying along several lines above the main sequence but parallel to it, and corresponding to reactions involving different elements. The points actually congregate in a rather wide strip extending upward to the right, as indicated by points 6, 7 and 8 in the figure. There are also "super-giants" of very high luminosity, among which all varieties of colour and spectral type may be found.

At the time of writing (1945) the physical processes which supply these stars with energy were not fully understood. It could hardly be expected that the whole problem of the inner economy of the stars should be solved at one blow by the first advances in the physical field.

**Stellar Evolution.**—With all this advance in knowledge of the physics of the stars, the problem of their evolution remains full of difficulties. The chief complication arises from the very different rates at which stars of different masses should lead their lives.

The sun, according to the best present estimate of its composition, has reserves of hydrogen sufficient to keep it shining at its present rate for more than 30,000,000,000 years in the future, and helium enough to have required almost as long to accumulate. For a faint red star of the main sequence, the calculated life would be 15 or 20 times as long. Now there is much concordant evidence from different sources—ranging from radioactive production of lead in terrestrial minerals to the recession of the extra-galactic nebulae—which indicates strongly that the stellar universe has been in its existing state for not more than 3,000,000,000 years.

During this interval, stars of small mass and luminosity should have passed through only a very small fraction of their whole career. If the white dwarfs have passed through earlier stages of normal density (as sketched above) their whole careers should have been even longer.

The stars of great luminosity, however, are spendthrifts. For example, each component of the eclipsing pair Y Cygni (at the very top of the main sequence) has 17 times the sun's mass and about 30,000 times the sun's luminosity. The transformation of its whole mass from hydrogen into helium would keep it shining at its present rate for only about 60,000,000 years. For the super-giants in general, the situation is similar, though not so acute.

The chief difficulties of a theory of stellar evolution, therefore, appear to be to explain why there are any super-giants still and any white dwarfs yet.

The most promising suggestion in the first case comes from work by L. Spitzer and F. L. Whipple, who have independently shown that dust and other small bodies, situated in a rotating system like the Galaxy, would tend to accumulate close to its equatorial plane. It is conceivable, though far from being proved, that such matter might have concentrated into great masses, and so started huge stars upon their lives as luminaries, at a relatively recent date in cosmic history—in which case those stars—as stars—are really young. No process for accelerating the development of a white dwarf has yet even been suggested, and we are left to the belief that they—and the faint stars in general—have been very much as they are now back to the remotest time to which we dare at present to extrapolate the past history of the universe.

(H. N. R.)

**STELLAR DISTRIBUTION:** *see* STAR.

**STELLENBOSCH,** a town 31 mi. E. of Capetown by rail, and, next to the latter, the oldest town in the province; 33° 54′ S., 18° 48′ E.; altitude 364 feet. It was founded in 1681, and named after the governor, Simon van der Stel, and his wife, whose maiden name was Bosch. The town is built in a valley, and its streets are lined with oak trees and open channels of water. Many of the houses with heavy, thatched gables date from the 17th century. The Dutch church in the market square is also thatched. Stellenbosch is the centre of a rich fruit and wine producing area, and the headquarters of the Cape branch of the Dutch Reformed church, with a Dutch theological seminary. There are several high schools in the town, a normal training college and a self-contained university, in which the study of the Afrikaans language and literature is emphasized. The population in 1936 was 8,782, of whom 4,995 were Europeans, 3,558 "coloured," 52 Asiatics and 177 Bantu natives.

**STEM,** in popular language the stalk of a plant or trunk of a tree. In botany a stem may be defined as an axis bearing leaves. The stem with its leaves is known as the shoot. Structurally it differs from a root in having no cap (*rootcap*) over the growing point, in terminating in a bud and in having nodes and internodes. Even when the stem has a superficial resemblance to a root, as in some subterranean forms, it can be distinguished from one on the basis of its internal structure. The chief difference is the spatial relationship of the primary vascular tissues (xylem and phloem) which is usually *collateral* or *bicollateral* in stems of gymnosperms and angiosperms and *radial* in roots. There are also differences in the manner in which the primary xylem is differentiated in the two organs (*e.g., mesarch* or *endarch* in many stems, *exarch* in roots). (*See* also PLANTS AND PLANT SCIENCE: *Anatomy of Plants.*) In general, the habit of the stem is *erect* or *ascending,* but it may lie prostrate on the ground, thus becoming *procumbent* as in the sweet potato and strawberry. The *scandent* stem may climb on rocks or plants by means of rootlets as in ivy; other vines have *twining* stems which twist around a supporting plant in a spiral manner like morning glory. Twining plants turn either anticlockwise, as in Convolvulus, dodder and gourd; or clockwise, as in honeysuckle, twining polygonum and hop. In other cases climbing plants are supported by tendrils which may be specialized stems as in the grape and passion flower, tendril-like leafstalks, as in clematis, or specialized leaflets, as in the pea. In warm climates twining plants (*lianas*) often form thick woody stems, while in temperate regions they are generally herbaceous. In some plants the stem does not elongate during its early development but forms a short conical structure from which a crown of leaves arises. These may form a *bulb* (onion, lily), a *head* (cabbage, lettuce) or a *rosette* as in dandelion and plantain. Later this type of stem may grow rapidly into an elongated axis. *Subterranean* stems include *rhizomes, corms* and *tubers.* These are described in a later section.

The character of the stem may be related to the longevity of the plant. Thus many *herbaceous* plants or *herbs* are *annuals* and complete their life cycle in one growing season, after which the entire plant dies. In *biennial* herbs the whole plant dies after two years, the lower part of the stem or *crown* persists after the first growing season and bears buds from which an erect stem arises the second season. In *perennial* herbs the short crown stem may produce new shoots for many years. Plants producing permanent woody stems are called *trees* and *shrubs.* The latter produce branches from or near the ground, while the former have conspicuous trunks. Shrubby plants of small stature are called *undershrubs* or *bushes.* The limits between these different kinds of stem are not always well defined; and there are some plants occupying an intermediate position between shrubs and trees, sometimes called *arborescent shrubs.*

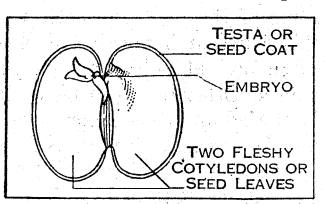


FIG. 1.—EMBRYO OF BEAN WITH COTYLEDONS SEPARATED

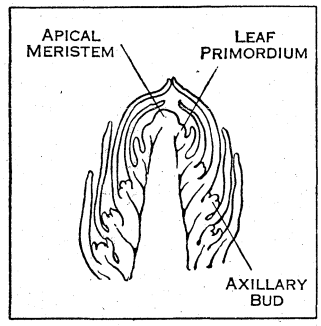
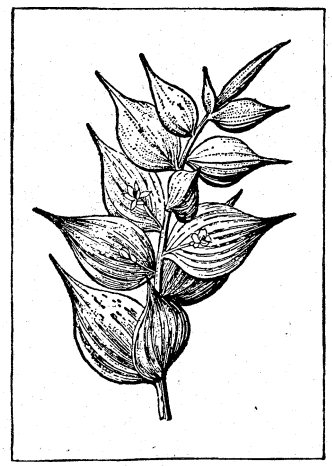
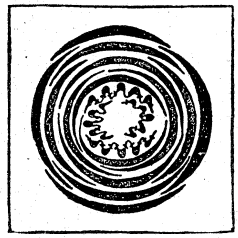
The stem is not always conspicuous. Plants with a distinct stem are *caulescent;* those in which it is inconspicuous are *acaulescent,* as the primrose, cowslip and dandelion. A similar term is given in ordinary language to plants whose stems are buried in the soil such as cyclamen and *Primula.* Some plants are truly stemless. These may be

thallophytes or bryophytes. (*See* ALGAE; FUNGI.)

**Development of Stem.**—The first rudiment of the young shoot of the embryo appears from the seed after the radicle (young root) has protruded. It is termed the *plumule,* and differs from the radicle in the absence of a rootcap and in its tendency to ascend. (*See* SEED.) The apical growing portion constitutes the terminal bud of the plant, and by continued development the stem increases in height; projections appear at intervals, which are the rudimentary leaves. Lateral buds are produced which develop into lateral shoots more or less resembling the parent stem, and by these the branching of the plant is determined. A bud may be found in the *axil* of a previously formed leaf; or, in other words, in the angle formed between the stem and leaf. Such buds are called *axillary* and are produced like the leaves from the tissues of the stem. During their development vascular bundles are formed which are continuous with those of the stem. Ultimately branches are produced that in every respect resemble the axis from which the bud was differentiated. The place of origin of the leaf is called a *node;* the intervals between nodes are called *internodes.*







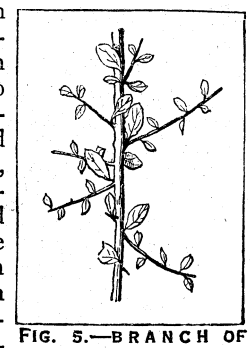


FIG. 2.—APEX OF SHOOT OF PHANEROGAMIC PLANT STEM

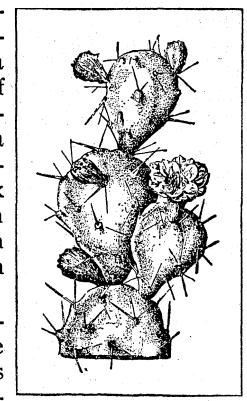
FIG. 3.—TWIG OF BUTCHER'S BROOM (RUSCUS)



**Functions of the Stem.**—The primary functions of the stem are support of the leaves, conduction of water and nutrient substances to the leaves and movement of elaborated foods from them. Other functions which may be performed by stems are storage of reserve food, photosynthesis and vegetative reproduction. The regular arrangement of leaves on the stem distributes them in such a manner that they are equally exposed to the light, as is necessary for photosynthesis. (*See* LEAF: *Phyllotaxis.*) The stem also supports the flowers in a position for pollination and the subsequent dissemination of seeds. Conduction of water and nutrient salts from regions of absorption in the roots to the leaves takes place through certain vascular elements of the xylem (*tracheae* and *tracheids*) while the movement of synthesized foods from the leaves to other organs of the plant occurs chiefly through the phloem. Radial movement of food within the stem may take place through ray and other parenchymatous cells. Storage of food and water frequently occurs in stems. Examples of food-storing stems are specialized forms such as tubers, corms and rhizomes, and the woody stems of trees and shrubs. Water storage in stems is developed to a high degree in the Cactaceae. All green stems carry on some of the photosynthetic work of the plant, but in most cacti this function is performed chiefly by the stem, the leaves being often present only for brief periods or as spines. Other plants in which food making is carried on in large measure by the stem are *Asparagus* and various species of *Euphorbia.* Where the stem is specialized so that it is flattened and leaf-like it is termed a *cladophyll* as in butcher's broom or asparagus. Vegetative reproduction is accomplished by many underground stems and is especially common among the grasses and many members of the lily family.

FIG. 4.—TRANSVERSE SECTION OF SYCAMORE LEAF BUD

**Growth and Bud Formation.**—Growth in length of the stem is due to the activity of the apical meristem and to elongation of the internodes; the zone of most rapid growth is at some distance below the apex; below this the rate of growth gradually diminishes until the portion is reached where growth in length no longer takes place. In some cases, as in the stems of grasses, growth in length persists for a longer time in a small region at the base of the internodes; this is known as *intercalary* growth. In shoots of limited growth, such as those of the larch, the internodes elongate only slightly and the leaves remain close together. Lateral buds give rise to *branches,* from which others, called *branchlets* or *twigs,* arise. The terminal bud sometimes dies at the end of one season, and the whole plant, as in annuals, perishes; or part of the axis is persistent, and remains for two or more years, each of the leaves before its decay producing a bud in its axil which continues the growth in spring. In ordinary trees, in which numerous lateral buds are formed, any injury done to a few branches is easily repaired; but in palms, which form mainly terminal buds, and have no other provision for a lateral formation of them, destruction of the terminal bud results in no further growth of the tree. In the trees of temperate and cold climates the buds which are developed during one season lie dormant during the winter, ready to open in the spring. They are generally protected by specialized leaves in the form of *scales,* which frequently exhibit a firmer and coarser texture than the foliage leaves. They serve a temporary purpose, and usually fall off sooner or later, after the leaves are expanded. The bud is often protected by a coating of resinous matter, as in the horse-chestnut and balsam poplar, or by a thick downy covering, as in the willow. In plants of warm climates the buds are often devoid of any protecting appendages; such buds are called *naked.*

FIG. 5.—BRANCH OF SLOE (PRUNUS)

When the terminal bud is injured or arrested in its growth the elongation of the main axis stops, and the lateral branches often acquire increased activity. By continually cutting off the terminal buds or branches, a woody plant is made to assume a bushy appearance, and thus *pollard* trees are produced. The peculiar bird-nest appearance often presented by the branches of the common birch depends on an arrestment in the terminal buds, a shortening of the internodes, and a consequent clustering or fasciculation of the twigs. (*See* GALLS.)

FROM STRASBURGER, "LEHRBUCH DER BOTANIK" (FISCHER)
FIG. 6.—OPUNTIA MONACANTHIA

**Branching.**—The mode in which branches come off from the stems gives rise to various forms of trees, as pyramidal, spreading or weeping—the angles being more or less acute or obtuse. In the Italian poplar and cypress the branches are erect, forming acute angles with the upper part of the stem; in the oak and cedar they are spreading, forming nearly a right angle; in the weeping ash and elm they develop at an obtuse angle; while in the weeping willow and birch they are pendulous, owing to their flexibility. The comparative length of the upper and under branches also gives rise to differences in the contour of trees, as seen in the conical form of spruce, and the umbrella-like form of the Italian or stone pine (*Pinus pinea*).

Branches are sometimes long and slender, and run along the ground, producing buds and adventitious roots at their extremity. This is seen in the *runner* of the strawberry. In the houseleek (*Sempervivum*) there is a similar prostrate branch of a shorter and thicker nature, known as an *offset,* producing a bud at its extremity capable of independent existence. In many instances the branch decays, and the young plant is separated from the parent plant.

Gardeners propagate plants by the process of *layering,* which

consists in bending a twig, fixing the central part of it into the ground, and, after the production of roots, cutting off its connection with the parent. A *stolon* is a branch which curves towards the ground, and, on reaching a moist spot, takes root and forms an upright stem, and ultimately a separate plant. This is a sort of natural layering, and the plant producing such branches is called *stoloniferous*. In the rose and mint a subterranean branch arises from the stem, which runs horizontally to a certain extent, and ultimately sends up an aerial stem, which may become an independent plant. Such branches are denominated rhizomes or *suckers*, and the gardener cuts the connection between the sucker and the parent stem, to propagate these plants.

In asparagus and other plants which have a perennial stem below ground, subterranean buds are annually produced which appear above ground as shoots or branches covered with scales at first, and ultimately with cladophylls resembling true leaves. These branches are herbaceous and perish annually, while the main stem remains below ground to send up fresh shoots next season.

In bananas and plantains the aerial stem is a shoot sent up by an underground stem, and perishes after fruiting. Branches are sometimes arrested in their development, and, in place of forming leaves, develop as *spines* or *thorns*, as in the hawthorn. Plants which have spines in a wild state, as the apple and pear, often are less spiny when cultivated; in some cases, as in the sloe (*Prunus spinosa*), a branch bears leaves at its lower portion, and terminates in a spine.

**Rhizomes, Corms, Tubers and Bulbs.**—Stems are sometimes compressed or flattened laterally, while at other times they are angular. Various terms are applied to the forms of stems, as *cylindrical* or *terete*, *quadrangular* or *square*, *jointed* or *articulated*, etc. The following are some of the more important modifications of stems. A *rhizome* or *rootstock* is a horizontal stem usually sending out numerous adventitious roots and leaf buds from its upper surface. It occurs in ferns, iris, *Acorus* or sweet flag, ginger, waterlily, many species of *Carex*, rushes, grasses, anemone, etc. The leaves develop as scales and by their presence, the absence of a root-cap and the presence of a bud at the apex, a rhizome can be distinguished from a root.

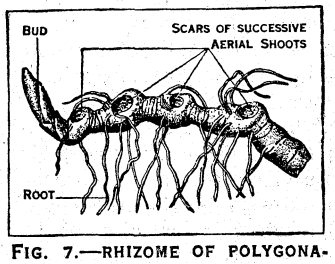


FIG. 7.—RHIZOME OF POLYGONATUM MULTIFLORUM

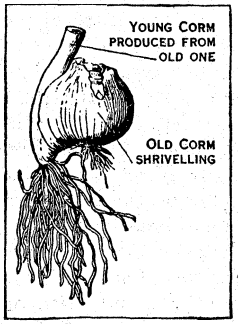
A rhizome such as occurs in Solomon's seal is not the product of a single bud, but is composed of portions of successive axes, the aerial parts of which have died off, leaving their scars. A rhizome sometimes assumes an erect form, as in *Scabiosa succisa*, in which the so-called *praemorse* root is in reality a rhizome, with the lower end decaying. The erect rhizome of *Cicuta virosa* (water hemlock) has hollow internodes, separated by partitions. In the coral-root orchid *Corallorhiza*, which grows in soil rich in humus, no roots at all are developed, the coral-like branching rhizome acting as the absorbing organ. A *tuber* is a short thickened stem or branch in which there is little internodal elongation, as in the potato. The eyes of the potato are leaf buds. Tubers are sometimes aerial, occupying the place of branches. The ordinary herbaceous stem of the potato, when cut into slips and planted, sends off branches from its base, which assume the form of tubers. Tubers frequently store up a quantity of starch, as in *Maranta arundinacea*, whence West Indian arrowroot is derived.



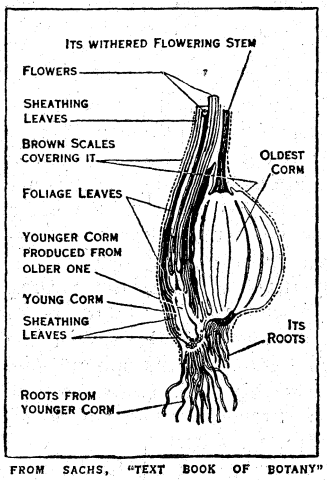


FIG. 8.—CORM OF MEADOW SAFFRON

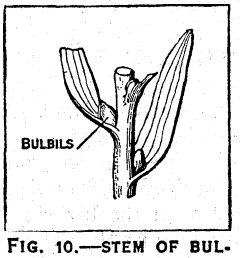
Another form of thickened underground stem is the *corm*, as seen in the autumn crocus (*Colchicum*), gladiolus, etc. Structurally it is composed of a solid more or less rounded axis covered by thin membranous scales. A corm is often only of one year's duration, giving off buds annually in the form of young corms. In the axil of the uppermost leaves the flowering stem develops and bears the flowers. The flowering stem dies down, and the young corm from which it arose enlarges greatly at the expense of its parent corm, which thus becomes shrivelled. In spring the leaves produced on it, which were merely rudiments in autumn, appear above ground as conspicuous large leaves. At the end of spring these leaves die down, the bases of the lower ones alone remaining as thin brown scales around the corm. Meanwhile, the young bud corm in the axil of the middle leaf grows rapidly at the expense of its parent corm, but it does not attain a great size. In autumn it produces new leaves, which remain small, but from the axil of the upper the flowering stem rises up and bears flowers; while in the axil of one of its middle leaves a new bud corm appears, which will the following autumn produce young leaves, flowering stem, and a new bud corm, and thus the cycle goes on.

FROM SACHS, "TEXT BOOK OF BOTANY" (CLARENDON PRESS)
FIG. 9.—CORMS OF COLCHICUM AUTUMNALE

The *bulb* is a bud which is often subterranean. The axis in this case is much shortened, and the internodes are unelongated. The bases of the leaves rising from the stem are close together, and become succulent and enclose the axis. In the lily the thick and narrow scales are arranged separately in rows, and the bulb is called *scaly;* while in the leek, onion and tulip the scales are broad, and enclose one another in a concentric manner, the outer ones being thin and membranous, and the bulb is *tunicated*. In the axils of these fleshy scales new lateral shoots arise, forming new bulbs. The lateral buds sometimes remain attached to the axis, and produce flowering stems, so that apparently the same bulb continues to flower for many years, as in the hyacinth and tulip; at other times the young bulbs form separate plants.



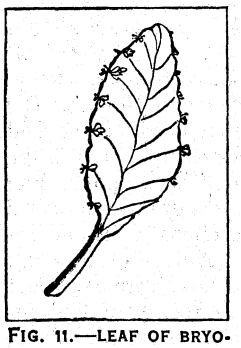


FIG. 10.—STEM OF BULBIFEROUS LILY

In the axil of the leaves of *Lilium bulbiferum*, *Dentaria bulbifera*, and some other plants, small conical or rounded bodies are produced, called *bulbils* or *bulblets*. They resemble bulbs and consist of a small number of thickened scales enclosing a growing point. These scales are frequently united closely together, so as to form a solid mass. The scales in bulbs vary in number. In *Gagea* there is only one scale; in the tulip and *Fritillaria imperialis* they vary from two to five; while in lilies and hyacinths there are a great number of them.

FIG. 11.—LEAF OF BRYOPHYLLUM CALYCINUM

**Adventitious Shoots.**—Adventitious shoots are those which arise elsewhere than in the normal place, as from old stems or roots. Such shoots are frequent on the roots of elm, poplar, plum and other fruit trees. Occasionally adventitious buds are produced on the edges of leaves, as in *Bryophyllum calycinum*, *Malaxis paludosa*, and various species of *Asplenium*, and on the surface of leaves, as in *Ornithogalum thyrsoideum*. These are capable of forming independent plants. Similar buds develop on the leaves of *Begonia*, *Gesnera*, *Gloxinia* and *Achimenes*, by wounding various parts of them, and placing them in moist soil; a method pursued by gardeners in their propagation.

(H. E. Hd.)

**STENCIL,** a thin plate or sheet of metal, leather, paper or other material cut or pierced with a pattern or design; this is laid upon a surface and colour or ink is brushed or rubbed over it, thus leaving the ground colour of the surface imprinted with the design or pattern cut out. In ceramics the stencil is produced by coating the biscuit with a preparation which prevents the transfer-paper or enamelling from adhering to the surface at those parts where the original colour of the biscuit is to be preserved.

**STENDAL,** a town in the province of Prussian Saxony, Germany, on the Uchte, 70 mi. W. of Berlin on the main line of railway to Hanover and at the junction of lines to Bremen, Magdeburg and Wittenberge. Pop. (1939) 35,691. Stendal was founded in 1151 by Albert the Bear, on the site of a Wendish settlement, and soon afterwards acquired a municipal charter. Becoming capital of the Altmark, it rose to a considerable degree of prosperity, in part recently restored to it by its railway connections. The original Wends were gradually fused with the later Saxons.

**STENDHAL** (1783–1842) the pseudonym of MARIE HENRI BEYLE, who borrowed the name from a small German town, the birthplace of Winckelmann, and who chose for his epitaph, *Quì giace, Arrigo Beyle Milanese; visse, scrisse, amò.* He was one of the most original and distinguished of French essayists and novelists. He was born at Grenoble on Jan. 23, 1783.

From Nov. 1796 to 1799, he attended the Ecole Centrale at Grenoble, where he was brilliantly successful. Here he was initiated into mathematics and accurate thinking. He arrived in Paris soon after the 18th Brumaire to study for the Ecole Polytechnique, but he soon gave up this scheme. Pierre Daru, the future *grand administrateur* of the empire, was a relation and his patron, and obtained a post for him in the War Office; later, in 1799, he sent him to Italy which became the chosen country of this cosmopolitan. He lived at Novara and Milan, in the autumn of 1800 became a sub-lieutenant, but resigned in 1802 and lived in Paris, where he frequented the *salons* and the theatres. After attempting business in Marseilles, in Aug. 1805, out of infatuation for an actress, he became a deputy to the *commissaire des guerres* (1806). He then lived for two years beyond the Rhine in Brunswick. He asked vainly for a post in Spain, was appointed auditor to the *Conseil d'Etat* in 1810, took part in the Russian campaign and became *intendant* at Sagan in 1813. He had received his baptism of fire in the Alps; he had heard the cannon at Marengo, and seen close at hand the horrors of war at the burning of Ebersberg, Smolensk and Moscow. During the tragic hours at the Beresina, he presented himself, freshly shaved, to Daru, who by this recognized in him an *homme de coeur.* After the empire fell, having lost all hope of being appointed a prefect, he went to live in Italy (1814–21); he spent six years in Milan, where he became acquainted with Byron, Madame de Staël, Silvio Pellico, Manzoni and Monti, whom he calls "the greatest living poet."

In 1814, he published in Paris *les Lettres écrites de Vienne en Autriche sur le célèbre compositeur, Joseph Haydn, suivies d'une vie de Mozart et de considérations sur Métastase et l'état présent de la musique en France et en Italie, par L. C. A. Bombet.* Herein he pillaged Carpani, Schlichtegroll, Winckler and Cramer. His plagiarisms would have brought him less reproach if he had acknowledged them more generously. *L'histoire de la peinture en Italie, par M.B.A.A.* (Beyle, *ancien auditeur*), appeared in 1817. Stendhal explains and animates the works of the abbé Lanzi and Vasari; he adds trivial or profound reflections to his borrowings from Lavater and Bossi. In *Rome, Naples et Florence* (1817), Stendhal supplemented his recollections with abundant documentary research; the work contains a wealth of fine, ingenious and vivid impressions on life, music, Italian patriotism, and on the charm of the delicious life he was enjoying. In this respect, this work seems to contain the matter of and to be a commentary on *La Chartreuse de Parme.*

In 1821 Stendhal was suspected of *carbonarisme* and espionage, and had to return to Paris. Exiled from his terrestrial paradise in Italy, he visited the houses of La Pasta, de Tracy and Delécluze, and made friends of Mérimée and Jacquemont. A brilliant and paradoxical talker, he both pleased and scandalized. He attempted to reconcile his dandyism with his poverty. He travelled in England in 1821 and 1826 and sent regular accounts and articles to the various English reviews, and to French journals.

He continued to publish literary hack-work: the amusing and anecdotal *Vie de Rossini* (1823) in which his dilettante spirit demanded from music a sentimental pleasure and poetic reverie. *Les Promenades dans Rome* (1829) was a partial success. The "cicerone of intelligence and taste" was not content with anecdotes; he described manners, customs and the art of the *"chasse au bonheur"* in Italy; and the guide may again be seen in the account of the landscapes and monuments which enchanted the author. In 1838 appeared *Les Mémoires d'un Touriste.* Stendhal had travelled extensively through France, either alone or in company with Mérimée, who instructed him in the Gothic. In addition to *choses vues,* the description of his native province, the Dauphiné, and the fair of Beaucaire, the work contains many stories clipped from journals or taken from the impressions of others. But it is saved by its vivid and feeling style, and by its "precious nothings." Stendhal also wrote some more original works. *De l'amour* (1822) constitutes under the guise of a psychological and documented analysis, a study and a preface for his novels; physiology is mingled with psychology. In it is also found a curious and original theory of "crystallization," a symbolic picture of the birth and growth of love.

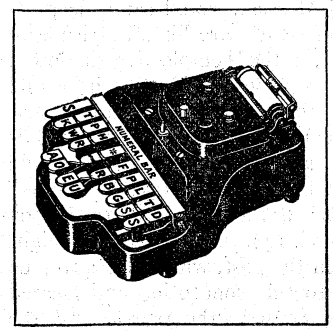
Stendhal's first novel was an interesting study of this "crystallization," *Armance ou quelques scènes d'un salon de Paris en 1827* (1827). This was followed by a novel dealing with love and ambition—*Le Rouge et le Noir* (1830). In reading the *Gazette des Tribunaux,* which he cynically called "the golden book of French energy in the 19th century," Stendhal had noticed a tragic incident. The son of a farrier of the Dauphiné, a former seminarist, had been guillotined at Grenoble on Feb. 23, 1828, for having shot and wounded a lady whom he loved. On this scandalous material the novelist constructed his story and even wove in some personal confessions, for his Julien Sorel sometimes resembles the author. The interest of this novel is found in the energetic spirit of his characters, full of intense and unscrupulous life, in the dramatic adventures, traits of character and passion noted with precision and clearness, and in its psychological analysis.

Stendhal had already shown himself to be a pamphleteer. It was by a real pamphlet that he took his position in the Romantic battle, when he published in 1823 *Racine et Shakespeare,* which was re-published in 1825 with more vigour and more mordancy than ever. This work was impregnated with the Italian Romanticism of Manzoni, Visconti and Berchet. Stendhal attempted to free the theatre from the "unities" of place and time. He condemned Alexandrine verse and recommended a national tragedy which would be modern, even topical, and by preference liberal. These ideas were not all new, but the tone and the accent were completely personal. Stendhal had protested against the industrialism of Saint Simon in his witty work *D'un nouveau complot contre les industriels* (1825).

Shortly after the revolution of July 1830 Stendhal was appointed consul at Trieste, but since Metternich refused him his *exequatur,* he was sent in April 1831 to Civita-Vecchia. There he longed for Paris, the city of conversation. He wandered about Naples, made excavations in the papal territory, continually visited Rome and took holidays in Paris between 1836 and 1839. He had not yet had any true success when he was hailed as a great novelist by Balzac in an article published on Sept. 25, 1840, in the *Revue Parisienne,* on the *Chartreuse de Parme.* He had just completed an advantageous contract with the *Revue des deux Mondes* for "nouvelles" when he was overcome on the boulevard by an attack of apoplexy on March 22, 1842. Three friends, including Mérimée, followed his funeral to the cemetery of Montmartre. He counted on obtaining a little glory about 1880 or even later: "I take a ticket in the lottery, the grand prize of which may be summed up as—to be read in 1935."

He was read long before this, and *La Chartreuse de Parme* is one of the great romances of the 19th century. The hypothesis which saw in it only an ingenious reproduction of ancient Italian chronicles which Stendhal had dug out of the libraries bas been exploded. The value of the novel lies in the analysis of the *grandes*

*passions* and in his pictures of contemporary manners. It differs widely from the rude and simple stories which he liked to take as his inspiration. Stendhal has put in this book his experiences and intimate feelings, his impressions of Italy revived by nostalgia. This book was seven years in contemplation and it was finally written in Paris in seven weeks, appearing in April 1839. The first part of the book consists of memories rearranged by the author—of Milan on the morrow of Lodi, of the adventures of Fabrice, present at a great battle without seeing much of it, of France after Waterloo, of the intrigues of a little Italian court in 1820. The book is full of Stendhal's reading on Italy of former days which gives rise to certain discrepancies. The actors are original characters, even if one sees the prototype of Count Mosca in Metternich or in Count Sauron, the governor of Lombardy. The Duchess of Sanseverina differs greatly from la Vannoza, the mistress of the future Pope Alexander VI., and Fabrice del Dongo, the Napoleonic marquis who became a priest after taking part in a conspiracy, has more resemblance to Julien Sorel than to Alexander Farnese. Stendhal excels in the delineation of souls and of exceptional and complex characters, scheming and energetic. Portraits, landscapes and Italian life play a large part in this crowded and disconcerting romance. The style is always natural, clear and limpid. The "little precise phrases, worthy of a code or of algebra" raised the enthusiasm of Taine who regarded Stendhal as a "superior spirit."



From his "Italian chronicles" he repeatedly drew dark and bloody stories and horrible and romantic novels. He was amused by these stories which he published between 1829 and 1838 in the *Revue de Paris: Vanina Vanini, Le coffre et le revenant, Le Philtre. Vittoria Accoramboni, Les Cenci, La duchesse de Palliano, L'Abbesse de Castro, San Francesco a Ripa,* appeared in the *Revue des deux Mondes* (1837–53).

Stendhal's admirers have published his unpublished works and even some illegible fragments preserved in the library at Grenoble. With audacious disquieting sincerity, sometimes bordering on cynicism, Stendhal wrote autobiographies entitled *La Vie d'Henri Brulard* (1890), *Souvenirs d'Egotisme* (1892), *Lucien Leuwen* (1894), *Journal d'Italie* (1911), in order to enjoy his past and to rescue from oblivion his "so different" personality. *Lamiel* (1889) is a romance in the style of Balzac and Sue of a foundling child of a seduced peasant woman. In his correspondence, vivid, primitive, amusing, passing from irony to tenderness, he paints himself with somewhat crude freedom. It is a feast for lovers of human documents. A place apart must be given to the *Lettres à Pauline,* his younger sister, whom Stendhal adored and whom he made his confidante. *La Vie de Napoléon* (1876) is less original than might have been expected. History is mingled with legend and gossip.

Stendhal, the "hussar of romanticism," independent of all schools, was at once behind the times and a pioneer. Disciple of the ideologues and even of the philosophers of the 18th century, he nevertheless seems to have been in advance of our own generation. Almost unknown during his lifetime, Stendhal the psychologist, an expert in unravelling and analyzing the sentiments of the human heart, curious about the "little true facts," careful to "write philosophically" for a fastidious *élite,* for the "happy few," was one of the introducers of romanticism and of the psychological novel. It was all very well for him to write that "a novel is a mirror taking a walk along the high road"; his mirrors possessed a strange magic. Of him more than anyone else it may be said that he was original. There are "Stendhaliens" and "anti-Stendhaliens." Henri Beyle lives to-day more than 100 years ago.

BIBLIOGRAPHY.—Stendhal's works have been published in 17 vols. by Michel Levy (1853–55). They were republished from 1913 under the direction of Paul Arbelet and Edouard Champion (35 vols.). His correspondence has been collected and re-arranged by A. Paupe and P. Cheramy (1908). The following works are important: *Notice sur M. Beyle,* by his friend Romain Colomb (1845); Mérimée, *Henri Beyle* (1850); the articles by Sainte-Beuve, in tome IX. of the *Causeries du lundi,* and by Taine in *Nouveaux essais de critique et d'histoire;* the books of E. Rod (1892), A. Chuquet (1902), P. Martino (1914) and P. Arbelet, *La jeunesse de Stendhal* (1914). H. Cordier, *Bibliographie Stendhalienne,* gives a list of articles before 1914. *See* also Paul Hazard, *La vie de Stendhal* (1927), trans. Eleanor Hard (1929); Lytton Strachey in *Books and Characters* (1922). (J. GIR.)

**STENOTYPY** is the substitution of a printed character for the usual shorthand phonogram. This is accomplished by means of a machine called the stenotype. The machine is equipped with 23 keys and a numeral bar and prints 16 letters of the alphabet, plus 11 combinations of these letters to form the complete alphabet, also with the numerals from zero to nine and an asterisk. The mechanism is such that any one or any combination of the 16 letters or numbers can be printed at one time on one line of a strip of paper which is fed automatically through the back of the machine. This permits the printing of several short words, a complete word or the contraction of a word at a single stroke. The keys are so arranged that the initial consonants are under the fingers of the left hand, the vowels under the thumbs, and the final consonants under the fingers of the right hand. Duplication of consonants accounts for the five additional keys. The machine weighs only about 5¼lb. and is correspondingly small.

MASTER MODEL FOUR OF A STENOTYPE MACHINE

**STENTOR,** one of the Greeks before Troy (*Iliad* v. 783), whose "stentorian" voice was as loud as that of 50 men.

**STEPHAN, HEINRICH VON** (1831–1897), German statesman, was born at Stolp, Pomerania, on Jan. 7, 1831. He entered the Prussian postal service, in which he rose rapidly. He was the first postmaster-general of the German Empire and was the chief promoter of the International Postal Union, presiding at the first conference, at Bern, in 1874. He died on April 8, 1897. *See* E. Knickeberg, *H. v. Stephan* (1897).

**STEPHANITE,** a mineral consisting of silver sulphantimonite, $Ag_5SbS_4$; containing 68·5% of silver, and sometimes of importance as an ore of this metal. Under the name *Schwarzerz* (black ore) it was mentioned by G. Agricola in 1546. The stephanite mineral has a hardness of 2·5 and is very brittle; the specific gravity is 6·3. It occurs with other ores of silver in metalliferous veins, as in the Comstock lode in Nevada.

**STEPHANUS BYZANTINUS** (STEPHEN OF BYZANTIUM), the author of a geographical dictionary entitled *Ἐθνιάκ,* of which, apart from some fragments, we possess only the meagre epitome of one Hermolaus, dedicated to Justinian; whether to the first or second emperor of that name is disputed. Stephanus probably flourished in the earlier part of the 6th century, under Justinian I. The chief fragments remaining of the original work (which contained quotations from classical authors and topographical and historical details) are preserved by Constantine Porphyrogennetos, *De administrando imperio,* ch. 23 (the article *Ἰβηρίαι δύο*) and *De thematibus,* ii. 10 (an account of Sicily); the latter includes a passage from the comic poet Alexis on the Seven Largest Islands. Another fragment, from the article *Δύμη* to the end of Δ, exists in a ms. of the Seguerian library.

*See* E. H. Bunbury *History of Ancient Geography,* i. 102, 135, 169; ii. 669–671 (1883); Riese, *De Stephani Byzant. auctoribus* (Kiel, 1873); J. Geffcken, *De Stephano Byzantio* (Göttingen, 1886).

**STEPHEN,** in some senses the greatest figure in primitive Christianity prior to Paul's conversion, was one of "the Seven" (Acts xxi. 8, nowhere called "deacons") set over the "daily ministration" towards the needy members of the Jerusalem community. Like Philip and perhaps others of his colleagues (vi. 3), he had higher gifts than his office would suggest. He was "full of faith and of holy Spirit"; and as his spiritual power showed itself in mighty deeds as well as words (vi. 5, 8), he became a marked man in Jerusalem. Himself a Jew of Greek culture, he naturally tried to win over his fellow Hellenists (vi. 9).

It is here that Stephen's advance upon prior Apostolic teaching becomes apparent. His special "wisdom" lay in greater insight into the merely relative nature and value of the externals of Israel's religion, particularly those connected with the Temple. His fellow Hellenists, as a body, were eager to disprove the feel-

ing of the native "Hebrews" that they were only half Jews. Hence teaching which minimized the value of the sacred "customs which Moses had delivered" (vi. 14), by making "salvation" depend simply on faith in Jesus as Messiah, would cause deep resentment in such circles, in spite of their more liberal attitude to things non-Jewish. For in Jerusalem the Temple overshadowed men's thoughts touching the Divine presence. To this he would reply in the spirit of the prophets, that the heart is the true seat of the Shekinah; and that if they refused God manifest in His Messiah, no holy "customs"—no, not the Temple itself—could save from the displeasure of the living God. Nay, he argued, quoting words of Jesus (Matt. xxvi. 61, Mk. xiv. 58, Jo. ii. 10) which were easy to misquote (Acts vi. 14), that the Temple might even be destroyed, as it had been in the past, without loss to true religion. But they could not rise to this conception and treated his words as "blasphemous," and roused "the people and the elders and the scribes" against him.

He was seized and brought before the Sanhedrin on the charge of speaking "against the Temple and the Law" (vi. 11–14). His defence took the form of a survey of Israel's religious past, with a view to show: (1) that "the God of Glory" had covenant relations with their forefathers before they had either Holy Place (Land or Temple) or Law (vii. 1–17); (2) that the first visible meeting place between God and His people was far other than that for which absolute sanctity was now claimed. Indeed, the form of "the tabernacle of testimony in the wilderness" (no Holy Land) had more divine sanction than any later Temple (44–47); (3) that, after all, the presence of "the Most High" was not bound up with any structure of human hands, as Isaiah witnessed (48–50). The moral of all this was plain: Israel's *forms* of fellowship with the Most High had all along been relative and subject to change. Hence there was no "blasphemy" in suggesting that in the Messianic age yet another change might come about, and that observance of Temple services could prove little as to acceptance with God. But there is another and more urgent line of pleading. This is found in the elaborate section dealing with the person and work of Moses, the great lawgiver (17–38)—a section full of extra-biblical touches—followed by one on Israel's hardness of heart towards him, together with its result, the Exile (39–43). Pure and original Mosaism is represented as something which in its full spiritual intention had been frustrated by Israel's stiff-neckedness (39, 42 *seq.*). The figure of Moses is made to stand forth in ideal outlines, the thinly-veiled Christian application shining through. "This is that Moses who said unto the children of Israel, 'A prophet shall God raise up unto you . . . like unto me:' who received living oracles to give unto us: to whom our fathers would not be obedient, but thrust him from them, and turned back in their hearts. . . ." (38 *seq.*). Here we have the very situation as between Stephen and his hearers; and it is made unmistakable by the speaker's closing words (51–53). Had they kept the Law dutifully, they would have believed on Him in whom true Mosaism was fulfilled and transcended. The author of Acts probably owed his report of Stephen's speech (as of his whole story) to Philip the "evangelist," who had been one of the Seven (xxi. 8). Possibly also Paul had spoken in Luke's hearing of Stephen's death and his own part in it (vii. 58, 60, *cf.* vi. 9).

Stephen's martyrdom is described as tumultuary in character, though the legal forms of stoning for blasphemy were observed (vii. 58); nor is it inconceivable that an act exceeding Jewish rights under the Romans should have taken place at the sudden impulse of religious fanaticism.

*See* articles in the *Ency. Bib.* vol. iv., and Hauck's *Realencykl. f. protestant. Theol. u. Kirche,* vol. xix. (J. V. B.)

**STEPHEN,** the name of nine popes.

STEPHEN I., bishop of Rome from about 254 to 257, followed Lucius I. He withdrew from church fellowship with Cyprian and certain Asiatic bishops on account of their views as to the necessity of rebaptizing heretics (Euseb. *H. E.* vii. 5; Cypr. *Epp.* 75). He is also mentioned as having insisted on the restoration of the bishops of Merida and Astorga, who had been deposed for unfaithfulness during persecution but afterwards had repented. He is commemorated on August 2. His successor was Sixtus II.

STEPHEN II., pope from March 752 to April 757, was in deacon's orders when chosen to the vacant see within twelve days after the death of Zacharias.[1] The main difficulty of his pontificate was in connection with the aggressive attitude of Aistulf, king of the Lombards. The death of Stephen took place not long after that of Aistulf. He was succeeded by Paul I.

STEPHEN III., pope from Aug. 7, 768 to Feb. 3, 772, was a native of Sicily, and, having come to Rome during the pontificate of Gregory III., gradually rose to high office in the service of successive popes. On the deposition of Constantine II. Stephen was chosen to succeed him. He was succeeded by Adrian I.

STEPHEN IV., pope from June 816 to Jan. 817, succeeded Leo III. He did not continue Leo's policy, which was more favourable to the clergy than to the lay aristocracy. Immediately after his consecration he ordered the Roman people to swear fidelity to Louis the Pious, to whom he found it prudent to betake himself personally in the following August. After the coronation of Louis at Reims in October he returned to Rome, where he died in the beginning of the following year. His successor was Paschal I.

STEPHEN V., pope from 885 to 891, succeeded Adrian III., and was in turn succeeded by Formosus. In his dealings with Constantinople in the matter of Photius, as also in his relations with the young Slavonic Church, he pursued the policy of Nicholas I.

STEPHEN VI., pope from May 896 to July–August 897, succeeded Boniface VI., and was in turn followed by Romanus. His conduct towards the remains of Formosus, his last predecessor but one (*see* FORMOSUS) excited a tumult, which ended in his imprisonment and death by strangling.

STEPHEN VII. (January 929 to February 931) and STEPHEN VIII. (July 939 to October 949) were virtually nonentities, who held the pontificate while the real direction of the pontifical state was in the hands of Marozia and, afterwards, of her son Alberic, senator of the Romans.

STEPHEN IX., pope from August 1057 to March 1058, succeeded Victor II. (Gebhard of Eichstädt). His baptismal name was Frederick, and he was a younger brother of Godfrey, duke of Upper Lorraine, marquis of Tuscany (by his marriage with Beatrice, widow of Boniface, marquis of Tuscany). Frederick, who had been raised to the cardinalate by Leo IX., acted for some time as papal legate at Constantinople, and was with Leo in his unlucky expedition against the Normans. He shared his brother's fortunes, and at one time had to take refuge from Henry III. in Monte Cassino. Five days after the death of Victor II. he was chosen to succeed him. He showed great zeal in enforcing the Hildebrandine policy as to clerical celibacy. He died at Florence on March 29, 1058.

**STEPHEN** (1097?–1154), king of England, was the third son of Stephen Henry, count of Blois and Chartres, and, through his mother Adela, a grandson of William the Conqueror. Born some time before 1101, he was still a boy when he was taken into favour by his uncle, Henry I. of England, and received the honour of knighthood and the county of Mortain. In 1118 he severed his connection with Blois and Chartres, renouncing his hereditary claims in favour of his elder brother Theobald. But he acquired the county of Boulogne by marrying Matilda (*c.* 1103–1152), the heiress of Count Eustace III. and a niece of Henry's first wife. The old king arranged this match after the untimely loss of his son, William Atheling, in the tragedy of the White Ship; until 1125 Stephen was regarded as the probable heir to the English throne. But on the return of the widowed empress Matilda (*q.v.*) to her father's court, Henry compelled Stephen and the rest of his barons to acknowledge her as their future ruler (1126). Seven years later these oaths were renewed; and in addition the ultimate claims of Matilda's infant son, Henry of Anjou, were recognized (1133). But the death of Henry I. found the empress absent from England. Stephen hurried across the Channel and began to canvass for supporters, arguing that his oaths to Matilda were taken under coercion, and that she, as the daughter of a professed nun, was illegitimate.

He was raised to the throne by the Londoners, the official

[1] A priest named Stephen, elected before him, died three days after, without having received the episcopal consecration.

baronage and the clergy; his most influential supporters were the old justiciar, Robert, bishop of Salisbury, and his own brother Henry, bishop of Winchester. Innocent II. was induced by Bishop Henry to ratify the election, and Stephen thus cleared himself from the stain of perjury. Two charters of liberties, issued in rapid succession, confirmed the King's alliance with the Church and earned the good will of the nation. But his supporters traded upon his notorious facility and the unstable nature of his power. Extortionate concessions were demanded by the great barons, and particularly by Earl Robert of Gloucester, the half-brother of the empress. The clergy insisted that neither their goods nor their persons should be subject to secular jurisdiction. Stephen's attempt to create a mercenary army and a royalist party led at once to a rupture between himself and Earl Robert (1138), which was the signal for sporadic rebellions. Soon afterwards the king attacked the bishops of Salisbury, Ely and Lincoln—a powerful family clique who stood at the head of the official baronage—and, not content with seizing their castles, subjected them to personal outrage and detention. The result was that the clergy, headed by his brother, the bishop of Winchester, declared against him (1139).

Stephen was thoroughly discredited when the empress at length appeared in England (Sept. 30, 1139). Through a misplaced sense of chivalry he declined to take an opportunity of seizing her person. She was therefore able to join her half-brother at Gloucester, to obtain recognition in the western and south-western shires, and to contest the royal title for eight years. Stephen's initial errors were aggravated by bad generalship. He showed remarkable energy in hurrying from one centre of rebellion to another, but he never ventured to attack the headquarters of the empress. In 1141 he was surprised and captured while besieging Lincoln castle. The empress in consequence reigned for six months as "Lady (*Domina*) of the English"; save for her faults of temper, the cause of Stephen would never have been retrieved. But, later in the year, his supporters were able to procure his release in exchange for the earl of Gloucester. After an obstinate siege he expelled Matilda from Oxford (Dec. 1142) and compelled her to fall back upon the west.

The next five years witnessed anarchy such as England had never before experienced. England north of the Ribble and the Tyne had passed into the hands of David of Scotland and his son, Prince Henry; Ranulf earl of Chester was constructing an independent principality; on the west the raids of the Angevin party, in the east and midlands the excesses of such rebels as Geoffrey de Mandeville, earl of Essex, turned considerable districts into wildernesses. Meanwhile Geoffrey of Anjou, the husband of the empress, completed the conquest of Normandy (1144). In 1147 the situation improved for Stephen; Robert of Gloucester, the ablest of the Angevin partisans, died, and the empress left England in despair. But her son soon appeared in England to renew the struggle (1149) and conciliate new supporters. Soon after his return to Normandy Henry was invested by his father with the duchy (1150). He succeeded to Anjou in 1151; next year he acquired Aquitaine by marriage.

Stephen struggled hard to secure the succession for Eustace, his elder son. But he had quarrelled with Rome respecting a vacancy in the see of York; the pope forbade the English bishops to consecrate Eustace (1151); and there was a general unwillingness to prolong the civil war. Worn out by incessant conflicts, the king bowed to the inevitable when Henry next appeared in England (1153). Negotiations were opened; and Stephen's last hesitations disappeared when Eustace was carried off by a sudden illness. Late in 1153 the king acknowledged Henry as his heir, only stipulating that the earldom of Surrey and his private estates should be guaranteed to his surviving son, William. The king and the duke agreed to co-operate for the repression of anarchy; but Stephen died soon thereafter (Oct. 1154).

On his great seal Stephen is represented as tall and robust, bearded, and of an open countenance. He was frank and generous; his occasional acts of duplicity were planned reluctantly and never carried to their logical conclusion. In warfare he showed courage, but little generalship; as a statesman he failed in his dealings with the Church, which he alternately humoured and thwarted. He was a generous patron of religious foundations; and some pleasing anecdotes suggest that his personal character deserves more commendation than his record as a king.

Round's *Geoffrey de Mandeville* (London, 1892); H. W. C. Davis's "The Anarchy of Stephen's Reign" in *Eng. Hist. Review* for 1903. (H. W. C. D.)

**STEPHEN I.** [ST. STEPHEN] (977–1038), king of Hungary, was the son of Geza, duke of Hungary, and of Sarolta, one of the few Magyar Christian ladies. His tutors included the German priest Bruno, the Czech priest Radla, and an Italian knight, Theodate of San Severino, who taught him arms and letters. In 996 Stephen married Gisela, the daughter of Duke Henry II. of Bavaria. In the following year his father died and the young prince was confronted by a formidable pagan reaction between the Drave and Lake Balaton. Stephen hastened against the rebels, bearing before him the banner of St. Martin of Tours, whom he now chose to be his patron saint, and routed the rebels at Veszprem (998), assuming the royal title immediately afterwards.

The rest of Stephen's life was spent largely in a struggle against the pagan nobles, which engrossed his energies, and compelled him to adopt a pacific policy towards the emperors of the East and West; but when attacked by the emperor Conrad in 1030 Stephen repelled the invasion successfully. He died at Esztergom in 1038 and was canonized in 1083. For an account of his reforms *see* HUNGARY: *History*.

*See* Antal Pór, *Life of St. Stephen* (Hung.; Pest, 1871); Lajos Balics, *History of the Roman Catholic Church in Hungary*, vol. i. (Hung.; Pest, 1885); János Karácsonyi, *Documents issued by Stephen I.* (Hung.; Pest, 1892), idem, *Life of St. Gellert* (Hung.; Pest, 1887); W. J. Winkler de Kétrszynski, *Vita sancti Stephani* (Cracow, 1897); E. Horn, *St. Etienne, roi apostolique de Hongrie* (1899).

**STEPHEN V.** (1239–1272), king of Hungary, was the eldest son of Béla IV., whom he succeeded in 1270. In 1262, as crown prince, he had compelled his father, whom he had assisted in the Bohemian War, to surrender 29 counties to him, virtually dividing Hungary into two kingdoms; while afterwards he seized the southern banate of Macso, which led to a fresh war between father and son in which the latter triumphed. In 1268 he invaded Bulgaria and assumed the title of king of Bulgaria. During his father's lifetime Stephen had a double matrimonial alliance with the Neapolitan princes of the House of Anjou, the chief partisans of the pope. He certainly needed exterior support; for on his accession to the Hungarian throne he encountered almost universal hostility owing to his alleged pagan leanings, due largely to the influence of his Cuman wife Elizabeth, to whom his father had married him for political reasons in 1255. The malcontents combined with Ottakar II. of Bohemia, and invaded western Hungary; but Stephen routed Ottakar at Mosony (1271) and was preparing to recover his infant son Ladislaus whom the rebels had kidnapped, when he died suddenly on Aug. 6, 1272.

**STEPHEN, SIR JAMES FITZJAMES,** BART. (1829–1894), English lawyer, judge and publicist, was born in London on March 3, 1829, the third child and second son of Sir James Stephen. He was educated at Eton, London university, and Trinity, Cambridge. He was already acquainted with Sir Henry Maine (*q.v.*), six years his senior, and then newly appointed to the chair of civil law. This acquaintance now ripened into a perfect friendship, which ended only with Maine's death in 1888.

Stephen was called to the bar in 1854, and in 1859 he was appointed recorder of Newark. In 1863 he published his *General View of the Criminal Law of England* (2nd recast ed. 1890). This was the first attempt that had been made since Blackstone to explain the principles of English law and justice in a literary form, and it had a thoroughly deserved success. All this time Stephen kept up a great deal of miscellaneous writing, and the foundation of the *Pall Mall Gazette* in 1865 gave him a new

field. The decisive point of his work was in the summer of 1869, when he accepted the post of legal member of council in India. Fitzjames Stephen's friend Maine was his immediate predecessor in this office. Guided by Maine's comprehensive genius, the government of India had entered on a period of systematic legislation which was to last about twenty years. The materials for considerable parts of this plan had been left by Maine.

Stephen had the task of working them into their definite shape and conducting the bills through the Legislative Council. This he did with wonderful energy, with efficiency and workmanship adequate to the purpose, if sometimes rough according to English notions, and so as to leave his own individual mark in many places. The Native Marriages Act of 1872 was the result of deep consideration on both Maine's and Stephen's part. The draft of the Contract Act was materially altered in Stephen's hands before, also in 1872, it became law. The Evidence Act of the same year was entirely Stephen's own. He came home in 1872.

Indian experience had supplied Stephen with the motive for his next piece of work, which historians of the common law may well regard as his greatest title to remembrance. The materials which Stephen had long been collecting took permanent shape in the *History of the Criminal Law of England* (1883), which, though not free from inequalities and traces of haste, must long remain the standard work on the subject. The Bills of Exchange Act (1882), the Partnership Act (1890), the Sale of Goods Act (1893) and the Marine Insurance Act (passed 1906) are indirectly due to his efforts. In 1879 Stephen became judge of the queen's bench division. He resigned that office in April 1891, after a breakdown, and died on March 11, 1894, having filled a not very long life with a surprising amount of work, of which a large proportion was of permanent value. He married Mary Cunningham in 1855.

*See* Sir Leslie Stephen, *Life of Sir James Fitzjames Stephen* (London, 1895), with bibliographical appendix, a model biography; same author's article in the *Dict. Nat. Biog.; Letters with biographical Notes,* by his daughter, Caroline Emelia Stephen (1907). *See* also Sir C. P. Ilbert, "Sir James Stephen as a Legislator," *Law Quart. Rev.* x. 222.

**STEPHEN, SIR LESLIE** (1832–1904), English philosopher and man of letters, son of Sir James Stephen, was born in London on Nov. 28, 1832. He was educated at Eton, at King's college, London, and Trinity Hall, Cambridge. In 1854 Stephen obtained a Goodbehere fellowship, and was ordained deacon on Dec. 21, 1855, becoming a priest in 1859. In 1856 he was admitted to a junior tutorship at Trinity Hall. He was a good athlete and a mountaineer. His first ascent was in 1857 (Col du Géant), and he made many others in the following years, until his first marriage in 1867. He was president of the Alpine club from 1865 to 1868, and editor of the *Alpine Journal* from 1868 to 1871. His accounts of his mountaineering feats were published in various journals, and collected in *The Playground of Europe* (1871). In the meantime, during his residence at Trinity Hall, his philosophical studies led him to abandon the orthodox theological position, and in 1875 he relinquished his orders. He interested himself in university politics, and advocated the need for examination reforms. During the American Civil War he was greatly in sympathy with the North, and in 1863 visited America to investigate the situation. On his return he published *The Times and the American War by L. S.* (1865), in answer to English arguments in support of the South. Stephen came to London in 1864, with useful recommendations from his brother Sir J. Fitzjames Stephen. He contributed for many years to the *Saturday Review,* and from 1865 co-operated with George Smith in the foundation of the *Pall Mall Gazette.* From Oct. 1866 to Aug. 1873 he contributed political articles to the *Nation.* His literary criticisms for the *Cornhill Magazine* (from 1866) were collected from time to time in separate volumes, as *Hours in a Library* (1874, 1876 and 1879). In 1871 he became editor of the *Cornhill,* and during the 11 years of his editorship the magazine made a reputation by its literary excellence. R. L. Stevenson, Thomas Hardy, Henry James and Edmund Gosse were among his contributors. In his *Essays on Free Thinking and Plain Speaking* (1873) Stephen challenged the dogmas of popular religion. His *History of English Thought in the Eighteenth Century* (2 vols., 1876), later extended into *The English Utilitarians* (1900), remains a standard work on the subject. He married in 1867 the younger daughter of W. M. Thackeray, and in 1868 visited America with her, where he met Emerson and Oliver Wendell Holmes the younger.

In Nov. 1882 George Smith made Stephen editor of the *Dictionary of National Biography,* which he conducted until April 1891, continuing to contribute until 1901. His first wife died in 1875, and in 1878 he married again. In his later years he was greatly affected by the death first of his brother James (1894), and shortly afterwards (1895) of his wife. One of his daughters, Mrs. Virginia Woolf, is separately noticed in this book. Stephen received many marks of distinction, and in 1902 was made K.C.B. He continued his literary work almost to the end of his life, and his last books were a monograph on Hobbes (1904), and his Ford lectures, *English Literature and Society in the Eighteenth Century,* published on the day of his death, Feb. 22, 1904. His work, both philosophical and literary, is remarkable for the sincerity of the author's outlook, and for his unprejudiced judgments. He wrote also *Social Rights and Duties* (1896); *Science and Ethics* (1882); *An Agnostic's Apology* (1893); *Studies of a Biographer* (2 vols., two series, 1899 and 1902), and monographs for the "English Men of Letters" series.

*See* F. W. Maitland, *Life and Letters of Leslie Stephen* (1906); Sir Sidney Lee, *Principles of Biography* (the Leslie Stephen lecture, 1911).

**STEPHEN (ISTVÁN) BÁTHORY** (1533–1586), king of Poland and prince of Transylvania. Báthory spent his early years at the court of the emperor Ferdinand, subsequently attached himself to Janos Zapolya, and won equal renown as a soldier and diplomatist. Zapolya rewarded him with the voivodeship of Transylvania, where his defence of the rights of his patron's son, John Sigismund, incurred the animosity of the emperor Maximilian, who kept him in prison for two years. On May 25, 1571, on the death of John Sigismund, Báthory was elected prince of Transylvania by the Hungarian estates, in spite of the opposition of Vienna. He expelled the rival candidate, Gaspar Békesy, from Transylvania (1572). In 1579 the Polish nobility, at the instigation of Zamoyski (*q.v.*) elected Báthory king of Poland, in opposition to the emperor Maximilian, the candidate of the senate. Báthory persuaded the Transylvanian estates to elect his brother Christopher in his stead, hurried to Cracow, espoused the princess Anne, the sister of the last Jagiello, and was crowned on May 1.

The leading events of Stephen Báthory's reign can here only be briefly indicated. All armed opposition collapsed with the surrender of Danzig, after a six months' siege, on Dec. 16, 1577. Stephen was now able to devote himself to foreign affairs. The difficulties with the sultan were temporarily adjusted by a truce signed on Nov. 5, 1577; and the Diet of Warsaw having voted supplies, Stephen embarked on war with Muscovy. Penetrating to the heart of the country, he besieged Pskov (Aug.–Dec. 1581), and forced Ivan the Terrible to cede him Polotsk and Livonia (peace of Zapoli, Jan. 15, 1582). The chief domestic event of Stephen's reign was the establishment in Poland of the Jesuits, in furtherance of his designs of uniting Poland, Muscovy and Transylvania into one great state. The project was dissipated by his sudden death, of apoplexy, Dec. 12, 1586.

*See* I. Polkowski, *The Martial Exploits of Stephen Báthory* (Pol.; Cracow, 1887); Paul Pierling, *Un Arbitrage pontifical au xvime siècle* (Brussels, 1890); Lajos Szadeczky, *Stephen Báthory's Election to the Crown of Poland* (Hung.; Budapest, 1887).

**STEPHENS, ALEXANDER HAMILTON** (1812–1883), American statesman, vice president of the Confederate States during the Civil War, was born in Wilkes (now Taliaferro) county, Georgia, on Feb. 11, 1812. He was a weak and sickly child of poor parents, and from his sixth to his 15th year, when he was left an orphan, he worked on a farm. After his father's death he went to live with an uncle in Warren county. The superintendent of the local Sunday school sent him to an academy at Washington, Wilkes county, for one year and in the following year (1828) he was sent by the Georgia Educational society to Franklin college (University of Georgia), where he graduated in 1832. Deciding

not to enter the ministry, he paid back the money advanced by the society. He was a schoolmaster for about two years, and then was admitted to the bar in 1834.

In 1836 he was elected to the Georgia house of representatives after a campaign in which he was vigorously opposed because he had attacked the doctrine of nullification, and because he had opposed all extra-legal steps against the abolitionists. He was annually re-elected until 1841; in 1842 he was elected to the State senate, and in the following year, on the Whig ticket, to the national House of Representatives. In this last body he urged the annexation of Texas, chiefly as a means of achieving more power for the South in Congress. He was denounced as a traitor to his party because of his support of annexation, but he later became the leader of the Whig opposition to the war with Mexico. He vigorously supported the Compromise Measures in 1850, and continued to act with the Whigs of the North until they, in 1852, nominated Gen. Winfield Scott for the presidency without Scott's endorsement of the Compromise. Stephens and other Whigs of the South then chose Daniel Webster, but a little later they joined the Democrats. In 1854 Stephens helped to secure the passage of the Kansas-Nebraska Bill. Before the Georgia legislature in Nov. 1860, and again in that State's secession convention in Jan. 1861, he strongly opposed secession, but when Georgia seceded he "followed his state," assisted in forming the new government, and was elected vice president of the Confederacy. Throughout the war, he was so concerned about States' rights and civil liberty that he opposed the exercise of extra-constitutional war powers by President Jefferson Davis lest the freedom for which the South was fighting should be destroyed. His policy was to preserve constitutional government in the South and strengthen the anti-war party in the North by convincing it that the Lincoln administration had abandoned such government; to the same end he urged, in 1864, the unconditional discharge of Federal prisoners in the South. Stephens headed the Confederate commission to the peace conference at Hampton Roads in Feb. 1865. In the following May, after the fall of the Confederacy, he was arrested at his home and taken to Fort Warren, in Boston harbour, where he was confined until Oct. 12. In 1866 he was elected to the United States Senate, but was not permitted to take his seat. He was a representative in Congress, however, from 1873 to 1882, and was governor of Georgia in 1882–83, dying in office, at Atlanta, on March 4, 1883.

From 1871 to 1873 he edited the *Atlanta Daily Sun*, and he published *A Constitutional View of the Late War between the States* (1868–70), perhaps the best statement of the Southern position with reference to state sovereignty and secession; *The Reviewers Reviewed* (1872), a supplement to the preceding work; and *A Compendium of the History of the United States* (1875; new ed., 1883).

*See* Louis Pendleton, *Alexander H. Stephens* (Philadelphia, 1908); R. M. Johnston and W. H. Browne, *Life of Alexander H. Stephens* (Philadelphia, 1878; new ed., 1883); Henry Cleveland, *Alexander H. Stephens in Public and Private, with Letters and Speeches* (Philadelphia, 1866); M. L. Avary (ed.), *Recollections of A. H. Stephens*, with a biographical study (1910); U. B. Phillips (ed.), "The Correspondence of Robert Toombs, Alexander H. Stephens and Howell Cobb," in *American History Association, Annual Report*, vol. ii. (1911); and Gamaliel Bradford, *Confederate Portraits* (1914).

**STEPHENS, JAMES** (1882– ), Irish poet, was born in Dublin. He was earning his living as a clerk in Dublin when he made his name by the exquisite prose of the delightful fairy stories published as *The Crock of Gold* (1912). He shows a sense of fantasy and a delicate poetic talent in all his works. The later ones include *Reincarnation* (1918); *Deirdre* (1923); *In the Land of Youth* (1924); *Collected Poems* (1926) and *Etched in Moonlight* (1928). Stephens was an ardent Nationalist, and worked hard for the creation of the Irish Free State.

**STEPHENS, JOHN LLOYD** (1805–1852), American traveller, was born Nov. 28, 1805, at Shrewsbury, N.J. Having been admitted to the bar, he practised for about eight years in New York city. In 1834–36 he made extensive travels in Europe, Egypt and Syria. In 1839 Stephens arranged with Frederick Catherwood to make an exploration in central America, with a view to discovering and examining the antiquities said to exist there. Stephens, meantime, was appointed to a mission to central America. Stephens published in 1841 *Incidents of Travels in Central America, Chiapas and Yucatan.* A second visit (1841) to Yucatan is described in *Incidents of Travel in Yucatan* (1843). Stephens died at New York on Oct. 10, 1852.

**STEPHENSON, GEORGE** (1781–1848), English engineer, was the second son of Robert Stephenson, fireman of a colliery engine at Wylam, near Newcastle, where he was born on June 9, 1781. In boyhood he was employed as a cowherd, and afterwards he drove the "gin-horse" at a colliery. At 14 he became assistant fireman to his father at a shilling a day, and at 17 he was appointed plugman, his duty being to attend to the pumping-engine. As yet he was unable to read, but stimulated by a desire to study the inventions of Boulton and Watt, he attended a night school and made rapid progress. In 1801 he became brakesman, in 1802 engineman at Willington Quay, where he took up watch and clock cleaning in his spare time. In 1804 he moved to Killingworth, where in 1812 he was appointed engine-wright of the High Pit at a salary of £100 a year. It was here in 1815 that he devised his miner's safety lamp, at the time when Sir Humphry Davy was also producing his lamp, a coincidence which led to much controversy.

In 1813 Stephenson was authorised to build a "travelling engine" for the tramroads between the Killingworth colliery and the port 9 mi. away on the plan of one already running at Wylam. The engine, which was named "Blucher," ran a successful trial on July 25, 1814, and in 1822 he persuaded the directors of the Stockton and Darlington railway (then in construction) to use steam instead of animal traction. At the opening of this railway on Sept. 27, 1825, therefore, the first public passenger train in the world was drawn by Stephenson's locomotive "Active," which was subsequently renamed "Locomotion." His connection with the Stockton and Darlington led to his employment on the Liverpool and Manchester railway, whose track he carried successfully over Chat Moss. When the line was nearing completion he persuaded the directors, who favoured haulage by fixed engines, to give the locomotive a trial. They offered a prize of £500 for a suitable machine, and in the Rainhill trials in October, 1829, Stephenson's engine, "The Rocket," was chosen. (For a description see *Steam Engine.*) On September 15, 1830, the railway was formally opened, the eight engines employed having been built at the works started at Newcastle in 1823 by Stephenson, his cousin Thomas Richardson, and Edward Pease. Stephenson was engineer of the Grand Junction, London & Birmingham (with his son Robert), Manchester to Leeds, Derby to Leeds, Derby to Birmingham, and Birmingham to York railways; but he strongly disapproved of the "railway mania" of 1844. He was also consulted about the construction of railways in Belgium and Spain. The last years of his life were spent in retirement at Tapton House, Chesterfield, in farming and horticulture, and there he died on Aug. 12, 1848.

See *Life of George Stephenson*, by Samuel Smiles (1857, new ed., 1881); and Smiles's *Lives of the Engineers*, vol. v. (1873).

**STEPHENSON, GEORGE ROBERT** (1819–1905), British civil engineer, was born at Newcastle-on-Tyne on Oct. 20, 1819, and was the nephew of George Stephenson (1781–1848) (*q.v.*). After working in colliery workshops near Manchester, he was sent to King William's School, Isle of Man. After his father's death in 1837, he worked for his uncle in the drawing-office of the Manchester and Leeds railway. In 1860, when he was consulting engineer to the provincial government of Canterbury, New Zealand, the Lyttelton-Christchurch line was built under his direction. He returned to England, and with Sir John Hawkshaw in 1864 built the East London railway. He was partly responsible for the construction of the Victoria tubular bridge across the St. Lawrence, and designed many bridges in England and abroad. In 1859 he succeeded his cousin Robert Stephenson (*q.v.*) at the locomotive works at Newcastle-on-Tyne, and at the Snibston and Tapton collieries. He died at Cheltenham on Oct. 26, 1905.

**STEPHENSON, ROBERT** (1803–1859), English engineer, only son of George Stephenson (*q.v.*), was born at Willington Quay on Oct. 16, 1803. He spent four years at school in New-

castle, and was then (1819) apprenticed to Nicholas Wood, a coal-viewer at Killingworth, after which he was sent in 1822 to attend science classes at the university of Edinburgh. He assisted his father in surveying the Stockton and Darlington and Liverpool and Manchester railways, and in 1824 he took charge of the engineering operations in South America of the Colombian Mining Association of London. He resigned in 1827, and returned to England via New York in company with Richard Trevithick, whom he had met in a penniless condition at Cartagena. Stephenson then undertook the management of his father's factory in Newcastle, and assisted in the improvement of the locomotive. His work extended to Sweden, Denmark, Belgium, Switzerland and Egypt. He specialised in the construction of railway bridges, especially those of the tubular girder type, and among his more notable examples are the Royal Border bridge at Berwick-on-Tweed, the High Level bridge at Newcastle-on-Tyne, the Britannia tubular bridge over the Menai Straits, the Conway tubular bridge, and the Victoria tubular bridge over the St. Lawrence at Montreal. In 1847 he entered the House of Commons as member for Whitby, retaining the seat till his death in London on Oct. 12, 1859. He was buried in Westminster Abbey.

See *The Story of the Life of George Stephenson, including a Memoir of his Son Robert Stephenson,* by Samuel Smiles (1857; new ed. 1881); Jeaffreson, *Life of Robert Stephenson* (2 vols., 1864); and Smiles's *Lives of the Engineers,* vol. v. (1873).

**STEPNEY,** an eastern metropolitan borough of London, England, bounded north by Bethnal Green, east by Poplar, south by the river Thames, and west by the City of London and Shoreditch. Pop. (est. 1938) 200,500; area, 2.75 sq.mi. The thoroughfares of Mile End Road and Whitechapel Road and that of Commercial Road East traverse the borough from the east and converge near the City boundary, where stood the ancient Aldgate. In the north Stepney includes the districts of Spitalfields, Whitechapel and Mile End (where William Booth commenced the work of the Salvation Army, July 1868); and in the south Wapping, Shadwell, Ratcliff and Limehouse. The name appears in Domesday and later as *Stevenhethe.* The suffix is thus the common form *hythe,* a haven; but for the prefix no certain derivation is offered. At Mile End, so called from its distance from the City (Aldgate), Wat Tyler and Richard II met in 1381. The district of Spitalfields has an old association with the silk-weaving industry; a trade in singing birds is also characteristic of this district. Wharves and factories line the river bank. In the extreme west the borough includes within its bounds the historic Tower of London (*q.v.*), the Royal Mint and the Tower Bridge over the Thames. Stepney is a bishopric suffragan in the diocese of London. The metropolitan borough of Stepney returns three members to Parliament, one each for the Limehouse, Mile End and Whitechapel and St. George's divisions.

**STEPNIAK, SERGIUS** (1852–1895), Russian revolutionist, whose real name was Sergius Michaelovich Kravchinski, was born in South Russia, of noble parents. He became an officer in the artillery; but his sympathy with the peasants, among whom he had lived during his boyhood in the country, developed in him at first democratic and, later, revolutionary opinions. He began secretly to sow the sentiments of democracy among the peasants. His teaching did not long remain a secret, and in 1874 he was arrested. He succeeded in making his escape—possibly he was permitted to escape on account of his youth—and immediately began a more vigorous campaign against autocracy. His sympathetic nature was revolted by the brutal methods adopted towards prisoners, especially political prisoners, and by the stern measures of repression of revolutionary sentiment. For a time he supported a terrorist policy, and in 1880 he was obliged to leave the country. He settled for a short time in Switzerland, and after a few years came to London. He was already known in England by his book *Underground Russia,* which had been published in London in 1882. He followed it up with other works on the condition of the Russian peasantry, on Nihilism, and on the conditions of life in Russia. Stepniak was killed by a railway engine at a level crossing at Bedford Park, Chiswick, on Dec. 23, 1895.

**STEPPE,** the level treeless Russian plains and thence sometimes extended as a type-name for similar plains elsewhere; specifically it is usually applied to the plains in the south and south-east of European Russia and in the south-west of Asiatic Russia, and in this connection the term connotes level grassy areas on which the slight summer rainfall with a winter deficiency produces patches with semi-desert conditions.

**STERCORARIIDAE:** *see* SKUA.

**STEREOBATE,** in architecture, the rough masonry substructure, or foundation, of a Greek temple.

**STEREOCHEMISTRY** is a branch of chemistry which is concerned with the arrangement in space of the atoms in the molecules of which substances are composed. (Gr. στερεός, solid). Knowledge regarding the spatial configuration of molecules has been acquired chiefly through the investigation of examples of *stereoisomerism,* a type of isomerism in which the isomers exhibit the same chemical reactions (and therefore possess the same chemical structure) and yet differ in certain physical properties; for differences between compounds of the same structure can only be due to differences in the arrangement of the atoms in their molecules in space.

The fundamental principles of stereochemistry were established by Louis Pasteur in a series of investigations on tartaric acid, carried out chiefly during the years 1849–53. Tartaric acid is obtained as a by-product in the manufacture of wine, being deposited from the fermented must in the form of potassium hydrogen tartrate. The crude salt contains, however, a small proportion of the potassium hydrogen salt of another acid of the same composition named racemic acid. Now tartaric and racemic acid not only have identical chemical compositions but they also possess the same chemical structure. Yet they show certain marked differences in properties. For example, racemic acid is much less soluble in water than tartaric acid and crystallizes with water of crystallization, whereas tartaric acid separates in anhydrous crystals; but the most remarkable difference between the two substances is in their effect on plane-polarized light. Many naturally occurring substances of organic origin, such as sugar, camphor and oil of turpentine, possess, even in the liquid or dissolved state, the curious property of rotating the plane of polarization of a beam of plane-polarized light through an angle proportional to the thickness traversed. Tartaric acid and the tartrates have this property, being *dextrorotatory* (*i.e.,* they rotate the plane of polarization to the right, or in the sense which is clockwise when regarded in the direction contrary to that in which the light is travelling), while racemic acid and the racemates are optically inactive.

Pasteur's discoveries arose out of a crystallographic investigation of tartaric acid. He observed that there was a certain lack of symmetry in the crystalline form of this substance of such a kind that the crystal was non-superposable on its mirror-image. The crystal and its image thus differ in the same kind of way as the right hand from the left hand. He prepared and examined 19 different salts of tartaric acid and found that each of these showed a similar lack of symmetry in its crystalline form. Thus fig. 1*a* represents the crystalline form of one of these salts, sodium ammonium tartrate. If the crystal possessed the full symmetry of the system to which it belongs, two faces, corresponding with the two shaded, should be found in the positions indicated by dotted lines. These faces, instead of occurring 8 times in the crystal, occur only 4 times (there are of course two corresponding faces on the back of the crystal not shown in the figures) and such faces, occurring only half as frequently as the full symmetry of the crystal demands, are termed *hemihedral faces.* The sodium ammonium tartrate crystal, on account of the presence of these hemihedral faces, is evidently non-superposable on its mirror-image represented in fig. 1*b.* In contrast to tartaric acid and the tartrates, racemic acid and such of its salts as Pasteur examined (with one exception, which will be considered below) crystallize in symmetrical forms superposable on their mirror-images. The optically active tartrates thus crystallize in dissymmetric forms, whilst the optically inactive racemates yield symmetrical crystals.

Pasteur's chief discovery was made through investigating the exceptional racemate referred to above, which was sodium am-

monium racemate. Crystallized under certain conditions this salt yielded crystals which unlike those of the other racemates exhibited hemihedral faces, but the crystals were of two kinds. Some were identical in form with dextrorotatory sodium ammonium tartrate (fig. 1*a*) and were in fact crystals of that salt. The other crystals differed from these only in that their hemihedrism was in the opposite sense; they were the realization of the mirror-

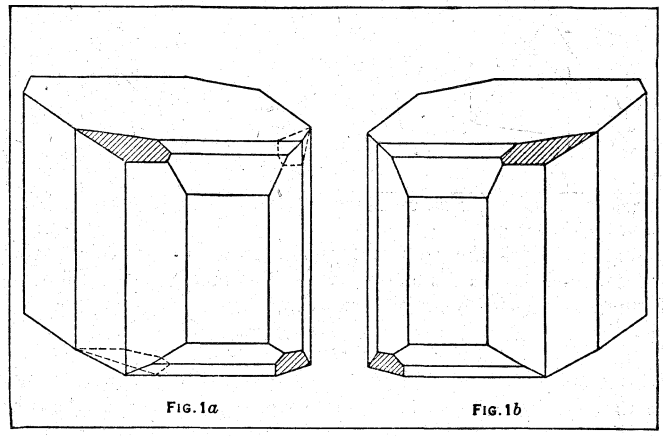

FIG. 1*a* FIG. 1*b*

FROM STEWART, "STEREO-CHEMISTRY" (LONGMANS GREEN & CO.)

FIG. 1.—(A & B) ENANTIOMORPHOUS CRYSTALS OF SODIUM AMMONIUM TARTRATE

image of sodium ammonium tartrate: they had thus the form represented in fig. 1*b*. When picked out from the mixture and dissolved in water they gave a laevorotatory solution; and the acid extracted from them had a crystalline form which was the mirror-image of that of tartaric acid, and its solutions were laevorotatory.

This new acid has exactly the same solubility, melting point, specific gravity, etc., as tartaric acid; in all such properties the two acids are identical. They differ in that, (1) solutions of the new *laevorotatory* acid rotate the plane of polarization exactly as much to the left as equivalent solutions of tartaric acid rotate it to the right, and (2) their crystals cannot be superposed; their hemihedrism is in opposite senses. In the two compounds, therefore, all properties are identical except those which have direction, and these are equal and opposite. The only relationship between their molecules that can give this relationship in properties is evident; the molecules must be related as object to mirror-image. The reason why tartaric acid exists in two forms is thus that its molecule has a lack of symmetry that renders it non-superposable on its mirror-image, so that right- and left-handed forms of the molecule are possible. The dextrorotatory tartaric acid obtained directly from grape-juice is termed *dextro*-tartaric (or *d*-tartaric) acid, and the laevorotatory modification extracted from sodium ammonium racemate is known as *laevo*-tartaric (or *l*-tartaric) acid.

When concentrated solutions of *d*-tartaric and *l*-tartaric acids are mixed, the less soluble racemic acid crystallizes at once from the mixture. Racemic acid is evidently composed of molecules of *d*- and *l*-tartaric acids in equal proportions, and its optical inactivity is the result of the summation of the equal and opposite activities of its components. In the crystal of racemic acid the *d*- and *l*-molecules are packed together in pairs; such a crystal may therefore be compared with a large package of pairs of gloves. The salts of racemic acid similarly crystallize almost invariably in uniform crystals composed of pairs of the *d*- and *l*-molecules. Under exceedingly special conditions, however—in the case of a particular salt, the sodium ammonium double salt, and provided that crystallization takes place below 27° C—the constituent *d*- and *l*-tartrates crystallize in separate crystals, just as under exceptional circumstances gloves might be packed with right-hand and left-hand gloves in separate packages.

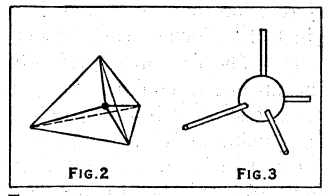
The discovery of *l*-tartaric acid thus revealed the significance of optical activity in liquid and dissolved substances. All natural objects can be divided into two classes: (i.) those which are superposable, and (ii.) those which are non-superposable on their mirror-images. It is evident that a substance of which the molecules belong to the first class can only exist in one form and cannot be optically active in the liquid or dissolved state, for in view of the symmetry of its molecules there can be nothing in them to cause the rotation of the plane of polarization in one direction rather than in the other. The molecules of substances that are optically active in the liquid or dissolved state must therefore belong to the second class, and such molecules are necessarily capable of existence in enantiomorphous (opposite-shaped) forms, and the optical activities of these forms must be equal and opposite; these complementary forms are termed *enantiomorphs antimers* or *optical antipodes*. Optically active substances must therefore occur in pairs. To every naturally occurring optically active compound there should be an optical antipode. Many of these are known as, for example, the laevorotatory antipodes of glucose and camphor, whilst others still await discovery.

To express the fact that a substance is composed of molecules which are non-superposable on their mirror-images, Pasteur introduced a new term. He described such substances as possessing *molecular dissymmetry*. The fundamental principle established by his investigations may thus be stated as follows: *If any substance exhibits optical activity in the liquid or dissolved state it possesses molecular dissymmetry.* The converse principle is also to be regarded as well established (for it now rests on a very broad experimental basis), namely, *Every molecularly dissymmetric substance is capable of showing optical activity in the liquid or dissolved state.* It would appear also that the *d*- and *l*-modifications of a molecularly dissymmetric substance crystallize in enantiomorphous forms, though the enantiomorphism may be difficult to detect.

**Separation of the Antimeric Forms.**—When a molecularly dissymmetric substance is prepared in the laboratory from inactive materials, an optically inactive mixture composed of equal parts of its dextro- and laevo-modifications must be formed, since there will be no asymmetric influence to favour the formation of one antimer rather than the other. The experimental demonstration of the molecular dissymmetry of a synthetic compound therefore always involves the resolution of the initially formed inactive mixture into its active antimeric components. The separation of antimeric substances requires, however, the use of special methods, since the processes of fractional crystallization and distillation usually employed for the isolation of individual substances are inapplicable, for antimers have equal solubilities in all solvents and equal vapour pressures at all temperatures. The special processes by which the resolution of molecularly dissymmetric substances can be effected are of three types which may be entitled: (i.) The method of manual separation of the enantiomorphous crystals of the antimers, (ii.) the method of conversion of the mirror-image isomers into diastereoisomers, (iii.) the biochemical method.

(i.) The first method is illustrated by Pasteur's separation of the antimeric sodium ammonium tartrates. Whilst it is thus of great historical interest, it has been of comparatively little practical value in the subsequent development of stereochemistry on account of its exceedingly limited applicability, for when an equimolecular mixture of the *d*- and *l*-forms of a molecularly dissymmetric substance crystallizes, it almost always happens that uniform crystals, built up of pairs of enantiomorphous molecules, are formed. Such crystals, being analogously constituted to those of racemic acid, are termed *racemic crystals,* and the association of *d*- and *l*-molecules of which they are formed is termed a *racemic compound,* though there is no evidence that the molecules constituting each pair are linked by forces different from the cohesive forces binding together the molecules in a crystal.

(ii.) The second method of resolution may be illustrated by considering the salt of an inactive molecularly dissymmetric acid with an active base. If the symbols + and − are used to denote enantiomorphous configurations, the antimeric forms of the acid may be represented as (+A) and (−A), and the base, *e.g.*, a laevorotatory alkaloid, as (−B). Combination of the acid and the base will then yield the two salts (+A) (−B) and (−A) (−B). It is clear then that two compounds which can be thus repre-



sented are not antimeric; they are said to be *diastereoisomeric*. Similarly an inactive dissymmetric base (+B), (−B) will give rise with a dextrorotatory acid (+A) to the diastereoisomeric salts (+A) (+B), (+A) (−B). Diastereoisomeric compounds, being different and not antimeric, must differ to a greater or less degree in all their properties, and a pair of diastereoisomeric salts may in fact differ very considerably in solubility so that they can be easily separated by fractional crystallization. Each then yields on decomposition one of the pure antimeric forms of the acid or base as the case may be. This is the most important of the methods of resolution, and most of the very large number of optically active substances that have been prepared artificially have been obtained by its means.

(iii.) The biochemical method depends on the different effects of living organisms on antimeric compounds. Thus moulds grown in a solution of ammonium racemate destroy the *d*-tartrate and leave the *l*-tartrate; yeasts added to solutions of inactive glucose ferment the naturally occurring *d*-glucose and leave the *l*-antimer; similarly, rabbits fed with the inactive forms of common α-amino-acids assimilate or destroy the active modification occurring in nature and excrete the other. Since digestive chemical changes are mainly effected through enzymes, the biochemical method of resolution evidently depends on the well-known high specificity of enzyme action. Enzymes act very unequally on antimers, and must therefore themselves be dissymmetric; Emil Fischer used the simile that the enzyme fits the substrate as the key fits the lock.

## THE STEREOCHEMISTRY OF CARBON

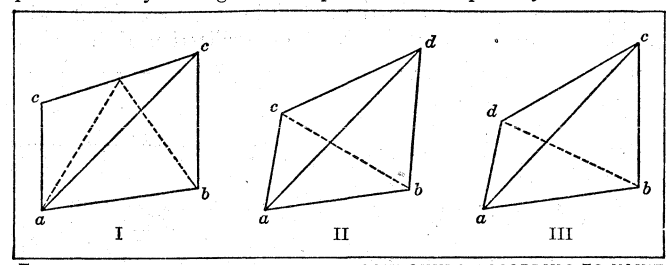
The most symmetrical arrangement possible for the valencies of a quadrivalent element is that in which their relative directions correspond with those of the four axes of a regular tetrahedron (fig. 2).

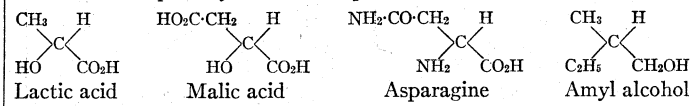
This view of the spatial distribution of the carbon valencies was adopted by F. A. Kekulé as early as 1867, and he had models constructed to represent the carbon atom, somewhat of the form shown in fig. 3, consisting of a sphere with four rods attached in the directions of the axes of a circumscribed regular tetrahedron. It was, however, a few years later (1873) that the attention of chemists was first directed seriously to the need for considering the spatial configuration of molecules. In that year J. Wislicenus showed that the lactic acid of sour milk and the sarcolactic acid of muscle juice (which differed in the hydration and solubility of their salts and in their optical properties, the latter being optically active) had the same chemical structure, and hence concluded that their difference could only be due to the different position of their atoms in space. In the following year J. H. van't Hoff published a pamphlet entitled "A Proposal respecting the Extension of Chemical Structural Formulae into Space," in which he showed that the "tetrahedral" theory of the arrangement of the carbon valencies supplied an interpretation of the molecular dissymmetry of organic compounds which was in accordance with the experimental facts. Similar views were put forward almost simultaneously by Le Bel.

FIGS. 2, 3.—TETRAHEDRAL DISTRIBUTION OF VALENCIES IN A SINGLE CARBON ATOM

On van't Hoff's theory the molecule of a carbon compound of the type C *a b c c* has the configuration I., as shown in fig. 4, and this has a plane of symmetry, namely, the plane passing through the edge *a b* and the middle point of *c c* cutting the tetrahedron in half as indicated by the dotted line; the molecule is therefore superposable upon its mirror-image, and a compound of this type should exist in one modification only. Replacement in this compound of one of the two radicals *c* by a fourth radical *d* will give, however, two enantiomorphous configurations, II. and III., according as the one or the other of these two radicals is replaced, for this substitution destroys the plane of symmetry and leaves a completely asymmetric molecule. A compound of the type C *a b c d* containing a carbon atom linked to four different radicals should therefore be molecularly dissymmetric and should exist, according to the principles established by Pasteur, in two antimeric optically active forms. A carbon atom thus linked is termed an *asymmetric carbon atom*.

This conclusion accorded well with the observed distribution of optical activity in organic compounds. All optically active com-





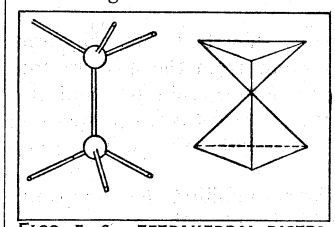


FIG. 4.—CONFIGURATION OF CARBON COMPOUNDS ACCORDING TO VAN'T HOFF'S THEORY

pounds of which the constitution was known contained a carbon atom linked in this manner. This is illustrated by the following formulae of optically active compounds:

When we come to consider the configuration of compounds containing more than one carbon atom, a further question arises.

FIGS. 5, 6.—TETRAHEDRAL DISTRIBUTION OF VALENCIES OF TWO CARBON ATOMS

In addition to knowing the relative positions of the valency bonds of the individual atoms we should have some idea of the orientation of the different atoms relatively to one another in the molecule. Evidently the valencies linking two carbon atoms together will lie in a straight line as illustrated by the models shown in fig. 5 (tetrahedral axes) and fig. 6 (solid tetrahedra), and the experimental facts indicate that the two atoms can rotate freely about this line as an axis, for compounds like $CH_2Br$–$CH_2Br$, ethylene bromide, or $HO_2C{\cdot}CH_2$–$CH_2{\cdot}CO_2H$, succinic acid, exist in one modification only. The two halves of such molecules must therefore be capable of rotating about the linking by which they are united so as to assume the relative position of maximum stability. These two simple assumptions of the *tetrahedral distribution of the carbon valencies* and *free rotation about a single linking* provide so complete an explanation of practically the whole of the stereochem-

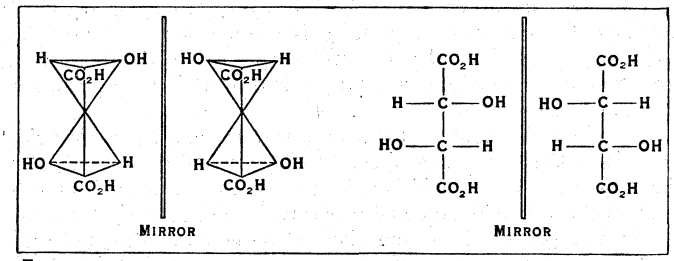

FIG. 7.—ENANTIOMORPHOUS CONFIGURATIONS AND PROJECTION FORMULAE OF THE TRANS-D- AND L-TARTARIC ACIDS

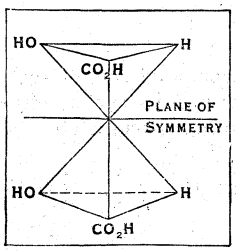
istry of carbon that there can be little doubt of their essential correctness.

## THE STEREOCHEMISTRY OF OPEN-CHAIN COMPOUNDS

**Mirror-image Isomerism.**—As regards their mirror-image isomerism, open-chain compounds may be considered according to the number of carbon atoms that their molecules contain. Dissymmetric compounds with *one* or *two carbon atoms* in the molecule suitable for resolution are not easy to obtain, and it was not until 1913 that a one-carbon compound—bromo-iodomethanesulphonic acid, $CHBrI{\cdot}SO_3H$—was satisfactorily resolved (Pope and Read). It proved to be optically stable. Among the compounds with *three carbon atoms* in the molecule are the

biochemically important substances, lactic acid and the $\alpha$-amino-acids, alanine, serine and cystine. The configuration of the group $-H_2C-HCX-CO_2H$(X = OH or $NH_2$) seems to be the same in the naturally occurring optically active forms of these substances. The compounds containing *four carbon atoms* in the molecule include the tartaric acids which played so important a part in the establishment of the fundamental principles of stereochemistry. Their structure having been fixed as dihydroxy-succinic acids, the tetrahedral theory enabled a precise form to be given to their molecular dissymmetry envisaged by Pasteur; *d*- and *l*-tartaric acids will have the enantiomorphous configurations shown in fig. 7 which can also be conveniently indicated by the projection formulae shown on the right. It will probably only be possible to determine which of these configurations corresponds with which antimer when a method has been discovered of calculating the optical rotation of a dissymmetric compound from some measurable property, such as the refractivity, of the radicals *a, b, c, d,* associated with the asymmetric carbon atom.



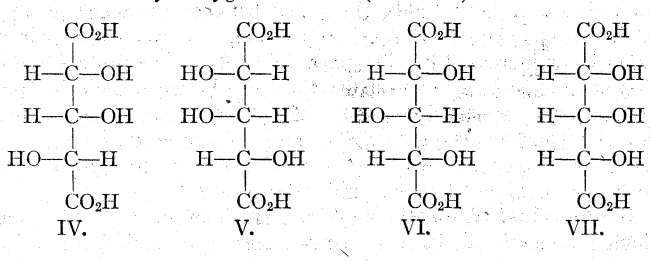


FIG. 8.—THIRD POSSIBLE, OR CIS-, CONFIGURATION OF TARTARIC ACID MOLECULE PLANE OF SYMMETRY

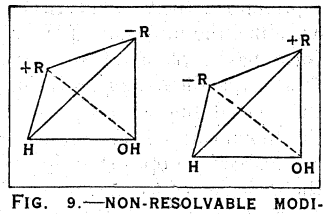
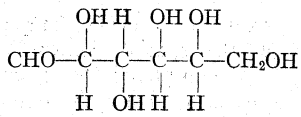
Besides the two configurations of the tartaric acid molecule shown above, a third, represented in fig. 8, is also possible. This configuration has a *plane of symmetry,* as indicated, and is therefore superposable upon its mirror-image and is incapable of optical activity. This inactive, non-resolvable form of tartaric acid was discovered by Pasteur, who obtained it by the action of heat on salts of tartaric acid, and is known as *mesotartaric acid.* The existence of this form is determined by the structural identity of the two halves of the tartaric acid molecule. The acid contains two equivalent asymmetric carbon atoms, and the relation between its *d-, l-,* and *meso*-modification can be represented by the symbols +A+A, −A−A, and +A−A. Every compound containing two equivalent asymmetric carbon atoms must be capable of existence in three such forms and generally in a racemic form.

In the *five-carbon series* a new stereochemical feature is exhibited in trihydroxyglutaric acid (IV.–VII.).

This compound contains two equivalent asymmetric carbon atoms and thus occurs in two optically active antimeric forms, IV. and V., but instead of having only one meso-form like tartaric, it possesses two such inactive non-resolvable modifications as shown by the projection formulae VI. and VII. If the enantiomorphous configurations of the group $CH(OH)\cdot CO_2H$ are indicated by +R and −R, the relation between these two non-resolvable forms of the acid can also be represented as in fig. 9.





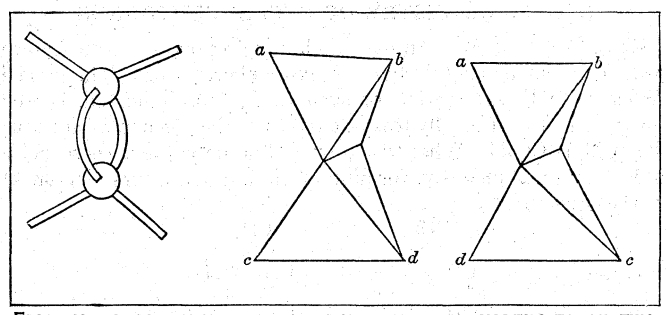


FIG. 9.—NON-RESOLVABLE MODIFICATIONS OF TRIHYDROXYGLUTARIC ACID

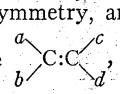
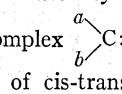
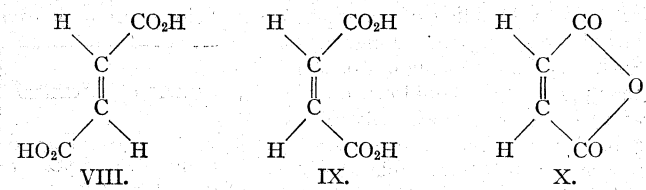
The *six-carbon series* contains the sugars glucose and fructose and their stereoisomers, and it is in this group of compounds that the usefulness of the conception of the asymmetric carbon atoms has been most strikingly demonstrated. The hydroxy-aldehydic formula for glucose

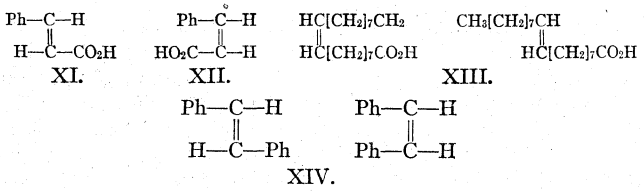


contains four non-equivalent asymmetric carbon atoms. Since the introduction of a new asymmetric carbon atom into a compound doubles the number of stereoisomerides previously possible, a compound containing *n* non-equivalent asymmetric carbon atoms should exist in $2^n$ forms. The number of possible stereoisomers of the same structure as glucose is therefore sixteen; in other words, there should be eight stereoisomeric aldohexoses,





FIGS. 10, 11, 12.—TETRAHEDRAL DISTRIBUTION OF VALENCIES OF TWO DOUBLY LINKED CARBON ATOMS

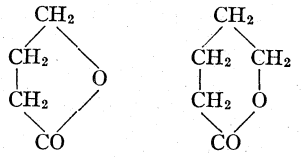


each existing in two antimeric forms. All the eight are known, many of them in both antimeric forms, and their configurations have all been determined. (*See* CARBOHYDRATES.) It is unnecessary to proceed further with the consideration of open-chain compounds as the study of the more complex series has not brought new principles to light.

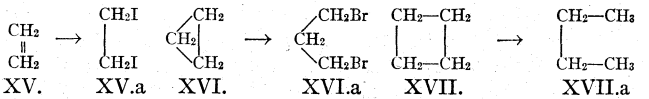
**Geometrical Isomerism.**—On the tetrahedral hypothesis two doubly linked carbon atoms will be represented by models such as those shown in fig. 10 or figs. 11 and 12.

Van't Hoff pointed out in his original brochure that this view of the ethylenic linking leads to two conclusions: (1) That there should be no free rotation about an ethylenic linking; the molecule should possess two equilibrium configurations as indicated by figs. 11 and 12. Ethylenic compounds should therefore exist in stereoisomeric forms, except when the radicals *a* and *b* (or *c* and *d*) are identical; (2) That the doubly linked carbon atoms and the four radicals *a, b, c, d* all lie in one plane. This plane is then a plane of symmetry, and thus ethylenic compounds, even when of the type , should be incapable of exhibiting optical activity.

These conclusions are fully confirmed by experiment. A large number of ethylenic compounds of the requisite structural type have been found to exist in two isomeric forms, and no adequate explanation has been found for this isomerism except the *cis-trans isomerism* determined by this conception of the ethylenic linking; also no case of optical activity determined by the non-planar configuration of the complex  has been established. The best known example of cis-trans isomerism is that presented by fumaric and maleic acids. These acids are structurally identical; each of them is an ethylenedicarboxylic acid of the structure $HO_2C\cdot CH{:}CH\cdot CO_2H$. The great difference in properties which they exhibit can only be due to difference in configuration. Maleic acid, which readily forms a cyclic anhydride X., and is regenerated from it by addition of water, must have the cis-configuration IX. Fumaric acid consequently has the trans-configuration VIII. Other examples of cis-trans isomers are cinnamic, XI., and allocinnamic acids, XII., oleic and elaidic acids, XIII., and stilbene and isostilbene, XIV.



XI. XII. XIII. XIV.



## STEREOCHEMISTRY OF CYCLIC COMPOUNDS

**Ring Formation.**—An overwhelming proportion of the known cyclic compounds contain five- or six-numbered rings. The special tendency to the formation of such rings, thus indicated, is well illustrated by the hydroxy-acids of the general formula $HO\cdot(CH_2)_n\cdot CO_2H$. When $n=3$ or 4, but only then, these acids lose water spontaneously, forming cyclic internal esters (lactones) of the structure

Such ring formation can thus only occur when a 5- or 6-membered compound will be formed.

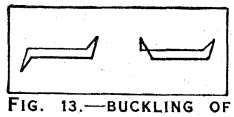
It is possible to form three- and four-membered rings, but they tend to spring open under the influence of reagents, the tendency being more marked in the 3- than in the 4-rings. Thus ethylene, XV., which we can regard as a 2-ring, cyclopropane, XVI., and cyclobutane, XVII., form a series of diminishing unsaturation.

XV. XV.a XVI. XVI.a XVII. XVII.a

For ethylene combines with all the halogens, even with iodine, when ethylene di-iodide XV.a is formed; cyclopropane, XVI., is stable towards iodine but reacts with bromine in the cold, forming trimethylene dibromide; cyclobutane, XVII., is not opened by bromine, but is converted by catalytic reduction with hydrogen (under conditions under which cyclopentane and cyclohexane are perfectly stable) into *n*-butane, XVII.a.

These facts constitute a striking confirmation of the tetrahedral theory, for the angle at which the axes of a regular tetrahedron are inclined to one another is 109° 28′, and this is very nearly the same as the angle between adjacent sides of the regular pentagon (108°). Thus we have an immediate explanation of the ready formation of 5-membered carbon rings; in them the valencies linking each carbon atom to its neighbour on either side are inclined at an angle which hardly differs from the natural angle between carbon valencies. In cyclobutane, however, the angle of deflection of the valencies from their natural inclination, $\frac{1}{2}$ (109° 28′−90°)=9° 44′, is considerable; in cyclopropane it is larger, $\frac{1}{2}$(109° 28′−60°)=24° 44′; whilst in ethylene it amounts to 54° 44′.

This theory correlating the relative instability of 3- and 4-rings with the strain due to deflection of the valencies from their natural directions is known as *Baeyer's Strain Theory* (1885). In six- and higher-membered rings there is apparently no strain; the strain is relieved by buckling of the ring. Thus cyclohexane may have either of the strain free arrangements.



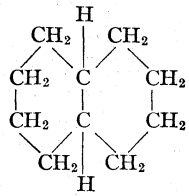


FIG. 13.—BUCKLING OF SIX-MEMBER RINGS TO RELIEVE STRAIN

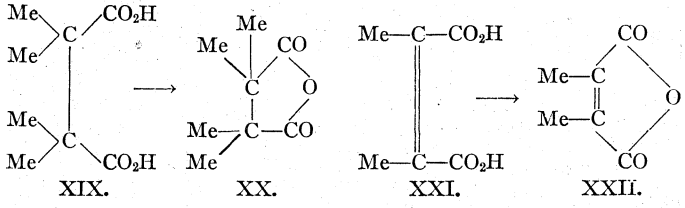
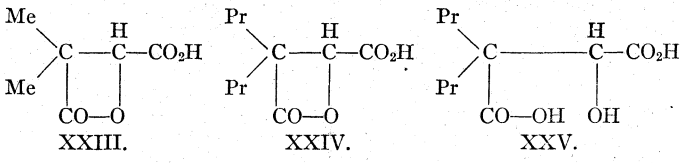


Such non-planar configurations, if sufficiently permanent, should cause molecular dissymmetry in appropriate derivatives. It has been impossible to demonstrate this dissymmetry; hence the molecules of these buckled rings are probably in a state of flux between their various possible configurations on account of their thermal agitation. Convincing evidence of the non-planar configuration of the cyclohexane ring is however supplied by the discovery (Hückel, *Annalen*, 1925, 441, 1) that decahydronaphthalene, XVIII., can exist in a trans- as well as in a cis-modification, for if the two cyclohexane rings in this compound were plane

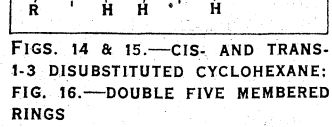
XVIII.



the cis-form would alone be possible.

Substitution has a remarkable effect in promoting ring closure. Thus tetramethylsuccinic acid, XIX., passes into its cyclic anhydride, XX., with far greater readiness than succinic acid itself,

XIX. XX. XXI. XXII.



and dimethylmaleic acid, XXI., shows so great a tendency to ring-closure that when liberated from its salts it passes spontaneously into its anhydride, XXII. The larger the substituent the greater seems to be its effect. Thus the dimethyl-lactone, XXIII., can only be produced indirectly, and once opened it cannot be re-formed, but the analogous dipropyl-lactone, XXIV., is formed spontaneously from the corresponding hydroxy-acid, XXV.:—

XXIII. XXIV. XXV.

It has long been held probable that the regular tetrahedral configuration obtains only in a carbon atom attached to four like radicals, as in methane or carbon tetrachloride, and that when the radicals are not all alike the angles between the valencies may be rendered unequal. Further, if the angle between one pair of valencies is increased by the space demands or the mutual repulsion of the two attached radicals, the angle between the other pair may suffer a correlated decrease. Many facts have been accumulated by Thorpe and Ingold which can be interpreted as supporting the view that enhanced tendency to ring closure may arise from such modifications of the natural valency angle.

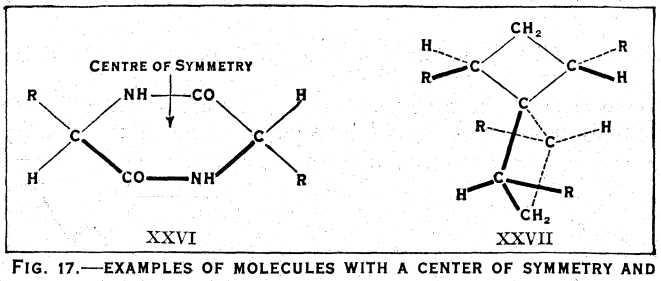
**Geometrical Isomerism.**—Since freedom of rotation about single linkings is abolished by ring-closure, geometrical isomerism is of frequent occurrence among cyclic compounds. Thus any disubstituted polymethylene (in which the substituents are on different carbon atoms) may exist in a *cis*- and a *trans*-form as the accompanying diagrams of a *cis*- and *trans*-1-3-disubstituted cyclohexane show.

FIGS. 14 & 15.—CIS- AND TRANS-1-3 DISUBSTITUTED CYCLOHEXANE: FIG. 16.—DOUBLE FIVE MEMBERED RINGS

Where, as in the compound represented, the two substituents are alike, the molecule of the *cis*-form has a plane of symmetry (the perpendicular plane through the dotted line in fig. 15) and this modification is therefore non-resolvable into optical antipodes; the molecule of the *trans*-form has, however, only an axis of symmetry (the dotted line in fig. 14); it is therefore dissymmetric, and this modification can thus exist in optically active forms. This difference between cis- and trans-modifications provides a very reliable method for determining configuration in those cases (as in many cyclo-paraffin carboxylic acids) where it is applicable.

The phenomena presented by cyclic compounds have a most important bearing on the spatial distribution of the carbon valencies. For whilst *any* non-planar configuration would account for the observed relationship between molecular dissymmetry

and structure, and for the isomerism due to the combinations of centres of asymmetry, the relative stability and readiness of formation of 5-membered rings proves that the natural angle between two of the carbon valencies must be close to 108° (the angle of the regular pentagon). Since, further, spirocyclic compounds of the double 5-ring type are formed with great readiness it would appear that the angle between the other two valencies



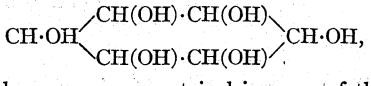


FIG. 17.—EXAMPLES OF MOLECULES WITH A CENTER OF SYMMETRY AND WITH AN ALTERNATING AXIS OF SYMMETRY

also approximates to 108°. The chemistry of cyclic carbon compounds thus strongly indicates the regular tetrahedral arrangement in which the intervalency angle is 109·5°.

**Mirror-image Isomerism.**—The conception of the asymmetric carbon atom, which in the open-chain series provides such a ready means of recognising molecular dissymmetry, is much less useful when applied to cyclic compounds. In cyclic compounds molecular dissymmetry is most easily recognised by noting the absence of centre, alternating axis and planes of symmetry from the tridimensional formula, for a molecule must possess at least one such element of symmetry to have the property of superposability upon the mirror-image. Examples of molecules with a *plane of symmetry* have already been given. Well known examples of molecules with a *centre of symmetry* are those of the trans-forms of the cyclic anhydrides of the $\alpha$-amino-acids, XXVI. (fig. 17). The *alternating axis of symmetry* has not yet acquired practical importance in stereochemistry, since no compounds with a molecule having an alternating axis but no plane or centre of symmetry are known; one of the simplest examples would be a compound of the type XXVII.

Among the cyclic compounds possessing special stereochemical interest are methylcyclohexylideneacetic acid, XXVIII. (fig. 18), resolved by Perkin, Pope and Wallach (*J. Chem. Soc.*, 1909, *95*, 1789) and the naturally occurring *d*- and *l*-inositols. The latter are cyclic hexahydric alcohols of the structure

and although there are 7 geometrical isomers of this formula, the configuration of the active forms can be deduced because only

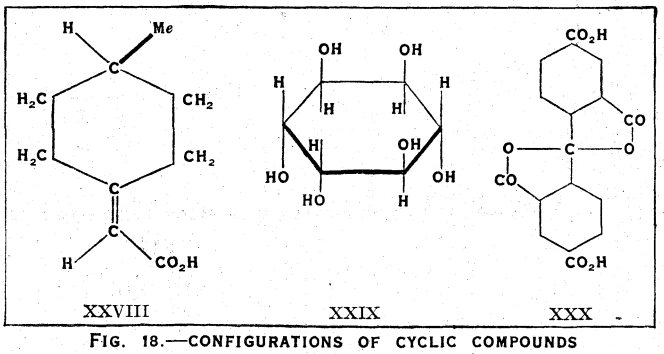

FIG. 18.—CONFIGURATIONS OF CYCLIC COMPOUNDS

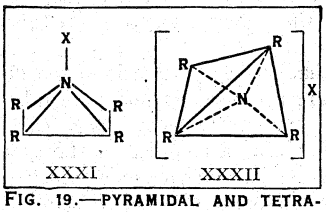
one of the isomers (that of which XXIX. represents one of the antimeric components) is molecularly dissymmetric.

The ketodilactone of benzophenonetetracarboxylic acid, XXX., resolved by Mills and Nodder (1921) is of the type

Its optical activity demonstrates the molecular dissymmetry that on the tetrahedral theory such spirocyclic compounds, in spite of the symmetry of their structural formulae, should possess. They have an axis of symmetry and the two forms correspond with the right- and left-handed forms of a two-bladed screw-propeller.

## STEREOCHEMISTRY OF ELEMENTS OTHER THAN CARBON

**4-Covalent Elements.**—In all optically active compounds known up to 1899 the molecular dissymmetry was dependent upon the spatial arrangement of the valencies of carbon. In that year a great advance was made through the discovery by Pope and Peachey that quaternary ammonium salts of the type $N(R_1R_2R_3R_4)X$ could be resolved into optical antipodes, for this indicated that the valency configurations of other elements besides carbon could have sufficient permanence to make their stereochemical investigation possible, and thus a wide field of research was opened. Further work on quaternary ammonium salts showed, (1) that molecular dissymmetry could no longer be demonstrated when two of the hydrocarbon radicals were identical, proving that the ion $(NR_1R_2R_3R_3)$ has a plane of symmetry; (2) that different methods of formation of a given salt, such as



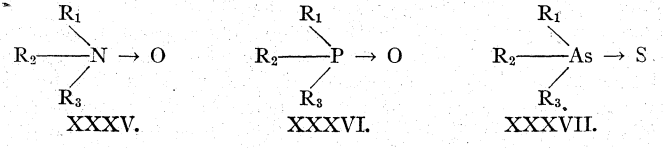


FIG. 19.—PYRAMIDAL AND TETRAHEDRAL CONFIGURATIONS FOR AMINE SALTS

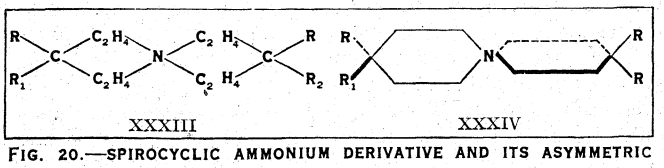
$$NR_1R_2R_3+R_4X\rightarrow NR_1R_2R_3R_4X\leftarrow NR_2R_3R_4+R_1X$$

never yielded isomeric modifications, indicating that the valencies linking the four hydrocarbon radicals to the nitrogen atom are inter-equivalent. Only two configurations of the ammonium ion satisfy these conditions, namely, the pyramidal configuration XXXI. (fig. 19) and the tetrahedral configuration XXXII., and of these the first has been definitely disproved by showing that a spirocyclic ammonium salt of the type XXXIII. (fig. 20) can be resolved into optically active components; for it can easily be seen that, if the two rings in this compound were attached to the base of a square pyramid, the molecule would have a plane of symmetry and the compound would be non-resolvable. In the ammonium ion the nitrogen atom must accordingly have the tetrahedral configuration XXXII. corresponding with the asymmetric configuration XXXIV. of its spirocyclic derivative XXXIII.

The amine-oxides are another class of compounds of 4-covalent nitrogen (*see* VALENCY), and in these also the radicals are tetrahedrally disposed about the nitrogen atom, for amine-oxides of the type XXXV. have been obtained in optically active forms by Meisenheimer (1908).

Phosphorus and arsenic have also been shown to have the tetrahedral configuration when in the 4-covalent state—phosphorus



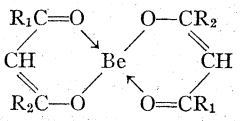


FIG. 20.—SPIROCYCLIC AMMONIUM DERIVATIVE AND ITS ASYMMETRIC CONFIGURATION

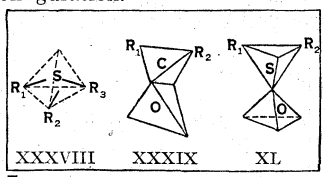
through the optical activity of a phosphine-oxide, XXXVI. (Meisenheimer and Lichtenstadt, 1911), and arsenic through that of an arsine-sulphide, XXXVII. (Mills and Raper, 1925). In the first short period (*see* PERIODIC LAW), besides carbon and nitrogen, the elements beryllium, boron and oxygen can assume the 4-covalent state, and there is evidence that the atoms of each of these elements then have the four radicals tetrahedrally disposed about them. This was proved for beryllium by the pro-

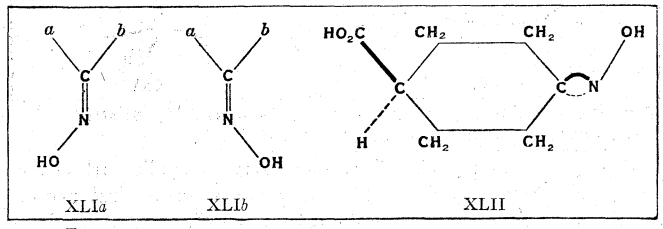
duction of an optically active compound of the type



(Mills and Gotts, 1926), and for boron in a similar way by Böeseken and Meulenhoff (1924), and the tetrahedral symmetry of 4-covalent oxygen is indicated by the work of Morgan and Bragg on basic beryllium acetate (1923). The molecular dissymmetry of silicon compounds of the type $SiR_1R_2R_3R_4$ has been established by Kipping, and the investigation of the configuration of 4-covalent copper and zinc by the method used for 4-covalent beryllium has shown that their valencies are also tetrahedrally distributed.

It thus appears to be the rule that when an atom is linked directly to four other atoms these are arranged around it tetrahedrally. This rule is however not universal: thus, many compounds of 4-covalent platinum containing a complex of the type $[PtA_2B_2]$ occur in two, evidently stereoisomeric, modifications. A and B may be chemically similar, as ammonia and ethylamine, the complex then being a bivalent ion, or chemically diverse, as pyridine and chlorine, when the complex is electrically neutral. This isomerism is clearly incompatible with a tetrahedral arrangement of the radicals about the platinum atom and is to be explained most simply by supposing that 4-covalent platinum has a plane configuration and that the isomers are cis- and trans-modifications of the type

**3-Covalent Elements.**—The stereochemical relationships of 3-co-ordinated elements are clearest in the case of sulphur. Sulphonium salts $[SR_1R_2R_3]X$, in which three groups are covalently linked to the sulphur atom, were shown to be molecularly dissymmetric by Pope and by Smiles (1900); the sulphonium ion therefore has a non-planar configuration (fig. 21).



Other compounds of 3-covalent sulphur are the sulphinic esters, $R{\cdot}S{<}^{O}_{OEt}$, the sulphoxides, $\begin{matrix}R\\R\end{matrix}\!>\!S{\rightarrow}O$, and the sulphilimines, $\begin{matrix}R\\R\end{matrix}\!>\!S{\rightarrow}NR$, and these have each been shown to have a similar non-planar configuration, since optically active representatives of the three classes have been obtained, principally by Phillips and Kenyon (1925–27). The sulphoxides therefore differ from the ketones in configuration, probably as shown in diagrams which are given in fig. 21; the difference assumed in the oxygen linking is indicated by the electronic theory of valency and is confirmed by the parachor (*q.v.*). Optically active selenonium salts were obtained by Pope and Neville (1902); hence 3-covalent selenium also has a non-planar configuration.

XXXVIII XXXIX XL

FIG. 21.—NON-PLANAR CONFIGURATIONS FOR 3-COVALENT ELEMENTS

The configuration of the trivalent nitrogen atom is of special interest on account of the number and importance of the compounds in which the element is present in this state. The numerous attempts made to obtain optically active compounds of the type $NR_1R_2R_3$ have all given negative results, but it is scarcely safe to conclude from this that these compounds have a planar configuration, for it is possible that they are non-planar but racemize rapidly, and the configuration of this important type is still an open question. However, in compounds of trivalent nitrogen of the type $-X{:}N{\cdot}Y-$, where the nitrogen atom is directly linked to two other atoms only, and therefore to one of them by a double bond, the evidence for the non-planar disposition of its valencies is quite definite. Thus, oximes of the type $\begin{matrix}a\\b\end{matrix}\!>\!C{:}NOH$ can generally be prepared in two isomeric modifications, and as the isomerism is repeated in the *O*-methyl ethers, for which only one structure $\begin{matrix}a\\b\end{matrix}\!>\!C{:}NOMe$ is possible, it must be determined by a difference of configuration. The form of the group $\begin{matrix}a\\b\end{matrix}\!>\!C{:}N$ being fixed by the well-established tetrahedral arrangement of the carbon valencies, a configurational difference can only be produced by a lateral displacement of the hydroxyl

XLI*a* XLI*b* XLII

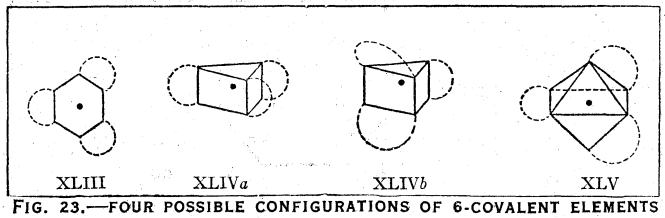


FIG. 22.—POSSIBLE DISPOSITIONS OF CYANIDE RADICALS

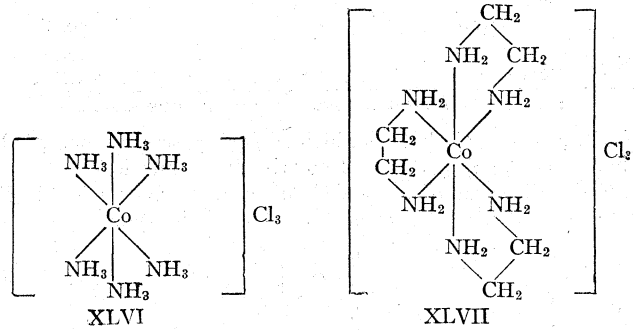
group to bring it nearer to one of the groups *a* or *b*, as indicated by the diagrams (fig. 22), and this requires a non-planar disposition of the nitrogen valencies.

This view, due to Hantzsch and Werner (1890), is confirmed, (1) by the course in the two isomerides of an intra-molecular transformation brought about by acids (*Beckmann transformation*) in which one of the two groups *a* or *b* changes places with the hydroxyl group, for if *a* is thus transposed in the one modification then *b* is transposed in the other; and (2) by the optical activity of the cyclic oxime, demonstrated by Mills and Bain (1910), since the molecule of this compound can only be dissymmetric if the nitrogen valencies do not lie in one plane.



**6-Covalent Elements.**—Werner's proof that substances like the compounds of metallic salts with ammonia, formerly regarded as "molecular compounds," are co-ordination compounds in which a certain number of atoms or groups, most frequently six, are directly attached to the metallic atom ($CoCl_3{\cdot}6NH_3$, for example, having the constitution XLVI.) brought with it the problem of determining how these six groups are disposed about the central atom. If it is assumed that the valencies by which they are attached are inter-equivalent (and this is supported by the absence of the isomerism which should otherwise occur), three arrangements are possible: the plane hexagonal, the prismatic, and the octahedral (fig. 23).

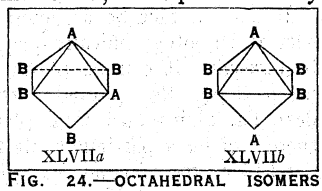
A decision between these was obtained by investigating the compounds formed by linking the co-ordination positions together in pairs through 4-membered chains, as can be done, for example,

XLIII XLIV*a* XLIV*b* XLV

FIG. 23.—FOUR POSSIBLE CONFIGURATIONS OF 6-COVALENT ELEMENTS

XLVI XLVII

by the three-fold replacement of two co-ordinated ammonia molecules by one of ethylenediamine (or of two nitrito-groups by an oxalato-group), so as to produce a complex in which the metallic atom forms a common member of three symmetrical 5-membered rings, XLVII. Since it is evident that only adjacent co-ordination positions can be bridged in this way, the possible configurations for the tricyclic complex are those indicated by the dotted lines in the four different diagrams which are given in fig. 23, and of these the three first are evidently symmetrical and only the last is dissymmetrical, for it possesses only a (trigonal) axis of symmetry. Experimental investigation of the salts of these tricyclic ions has shown that they can be produced in optically active forms. The ions are thus dissymmetric and must consequently have the last configuration. It is therefore to be concluded that in such compounds the six covalencies of the central metallic atom are octahedrally disposed.



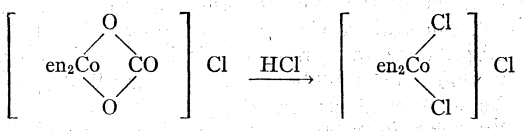


FIG. 24.—OCTAHEDRAL ISOMERS (A) CIS- AND (B) TRANS-

This conclusion is confirmed by the phenomena of geometrical isomerism shown by complexes of the type $[MA_2B_4]$, such as are contained in the diacidotetrammine salts of cobalt and chromium. These compounds should exist in three isomeric forms if their configuration is hexagonal or prismatic, but in two only if it is octahedral, the alternative arrangements then being those in which the two groups A lie at the ends, (1) of an edge (*cis*-compound), and (2) of a diagonal (*trans*-compound) of the octahedron, and the number of isomers actually found is two. Moreover, in dicyclic derivatives of this type like $[en_2CoCl_2]Cl$ ($en = NH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2$), that isomer for which the *cis*-configuration is indicated by its formation from a tricyclic compound

can be obtained optically active, whilst the other, the *trans*-isomer, cannot be resolved in accordance with the following tridimensional formulae, fig. 25, which show the symmetry, on the octahedral representation, of the *trans*- and the dissymmetry of the *cis*-form.

The general result of the stereochemical investigation of the elements has thus been to show that as a rule the valencies of an atom are disposed in space as symmetrically as possible, so that, for example, a 4-covalent atom has the four directly attached atoms arranged tetrahedrally about it, and the six atoms linked to a 6-covalent atom are grouped round it octahedrally; but it has also shown that there are well-marked exceptions to this rule, the most notable being the probable square arrangement of the four groups about 4-covalent platinum and the non-planar disposition of the valencies of 3-covalent sulphur. (W. H. Mi.)

**STEREOCOMPARATOR,** an instrument for comparing two astronomical photographs of the same star-field, commonly combined with a Blink-microscope (*q.v.*).

**STEREOPHOTOGRAMMETRY.** In the earliest applications of photography to surveying, use was made of various simple graphical constructions or calculations in order to determine bearings and angles of elevation or depression from the camera station. In order to simplify these constructions or calculations, the photograph was usually exposed in a vertical plane. Two photographs, taken from the ends of a known base and treated in this manner, thus enabled a complete survey to be made of all visible ground in the area common to the pair. The necessity for avoiding acute graphical intersections in the fixing of points usually meant a long base, with a resulting difficulty in the identification of corresponding features in the two widely dissimilar views. The next step was consequently to return to a comparatively short base and at the same time to eliminate the indetermination of acute graphical intersection by the parallactic measurement of distances.

**The Stereocomparator.**—The first practical application of this method appears to have been in the stereocomparator of Tourcade in 1900. The two photographs were taken in the same vertical plane, although not necessarily at the same height, and were of course placed in the same plane in the comparator. Bearings and elevations were still calculated from the photo-co-ordinates of points on one of the pictures, while the distances from the base were calculated from a stereoscopic measure of parallax. The latter was effected by a lateral shift of one plate relative to the other, until the stereoscopically reconstructed image of the setting feature appeared to lie at the same distance from the observer as the fused image of a pair of floating marks contained in the eye-pieces of a binocular microscope used for the examination of the plates.

The stereocomparator has had an extensive application in the past, and is even now directly applied in one modern method of survey from vertical air photographs. From the practical point of view, however, its initial use suffered from two serious drawbacks, in that it required the computation of space co-ordinates from independent measurements, and that it implied a system of point by point plotting. (See also BINOCULAR INSTRUMENT: *The Stereoscope.*)

*The Thompson Stereoplotter.*—The first of these disadvantages was overcome in the 1908 model of the Thompson stereoplotter, which may consequently be considered as the first example of the true plotting machine. It employed the stereocomparator principle without modification, but by the addition of a lever system.

**The Stereoautograph.**—The disadvantage of point by point plotting remained in the Thompson machine and was overcome by the von Orel stereoautograph of 1909–11. It is interesting to note, however, that Thompson in 1908 had in view the construction of an automatic machine called the "stereoplanigraph." This would no doubt have been on the same general lines as the stereoautograph had it reached maturity. The stereocomparator is again used in the von Orel machine, but the plotting system is based on intersections from the ends of the base rather than on an explicit measure of distances. Reduced to its lowest terms, it consists of two azimuth levers which are coupled to the lateral shift of the two plates. This simple arrangement would, however, introduce mechanical difficulties in the carriage of a drawing pencil at the variable intersection of the two levers, and in the necessity for shifting the pivots of these levers in accordance with variations in base length.

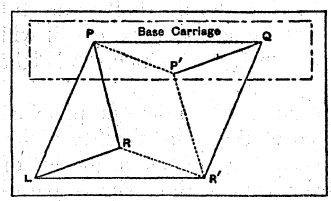

FIG. 1

Suppose, in the first alternative, that LP, RP (fig. 1) were the azimuth levers; P being the plotted point and LR the base. Then if any two parallelograms LPQR′, RPP′R′ are drawn on the rays LP, RP with a common corner at R′, it is clear that P′Q will be equal in magnitude and direction to the base LR, and that LP, R′P′ will still represent the true directions of the azimuth levers. Consequently L, R′ may represent two *fixed* pivots of the azimuth levers, if the base QP′ is set inwards in magnitude and direction from a length PQ equal and parallel to LR′. Moreover the base carriage PP′Q may be moved anywhere parallel to itself by alteration in the lengths and directions of the azimuth levers LP, R′P′. The point P will always represent the position of the plotted point relative to L as left hand camera station. Similarly, P′ will always represent the position of the plotted point relative to R′ as right-hand camera station. Lastly, the actual drawing

pencil will trace a similar plot if it is placed in any fixed position relative to P or P′. It may consequently be rigidly attached anywhere to the base carriage. This simple principle, due originally to von Orel, is sometimes known as the *zeiss parallelogram,* and has been elaborated into several different types. These different types, which find an application in the later plotting machines, are all comprised in the fact that any or all of the three co-ordinates

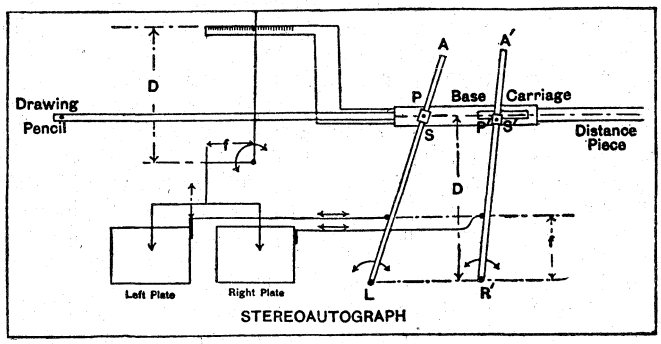

FIG. 2

of one end of the base relative to the other end may be set at any of the corners of the initial parallelogram LPQR′—a statement which is evident from the simplest geometrical considerations.

A diagram of the action of the stereoautograph is given in fig. 2. The azimuth control shifts the carriage of *both* plates, and consequently rotates the two azimuth levers AA′ by an equivalent amount. These levers slide in sleeves SS′ attached to pivots on the base carriage, which is thus moved freely along the distance piece. The sleeve pivots, PP′ correspond to the points PP′ of fig. 1, the base setting being effected on the pivot P′. The distance control moves the distance piece bodily, and parallel to itself, towards or away from the line of pivots LR′ of the azimuth levers. In consequence, the base carriage slides down the left azimuth arm, rotating the right azimuth arm in the process and thus shifting the right-hand plate relative to the left on an upper slide. The parallactic separation of corresponding points is thus altered, so that the floating marks appear successively in stereoscopic coincidence with points whose distance from the base corresponds to the setting of the distance piece. This is of course the unmodified principle of the stereocomparator. The height system is essentially the same as in the Thompson machine, the height scale being carried on an extension of the distance piece.

By combining the movements of the three controls, the apparent movements of the floating mark can be made to follow along the detail of the reconstructed stereoscopic image, the plan of which is thus drawn automatically by a pencil attached to the base carriage. By clamping the height lever to the distance piece, the machine loses a degree of freedom. If then the distance and azimuth controls are moved so that the floating mark still appears to travel along the surface of the ground, the pencil will trace the contour corresponding to the height at which the height lever is clamped.

The stereoautograph is capable of fast automatic plotting, provided that the plates are exposed in the *same vertical plane.* The whole principle of the stereocomparator as a means of determining horizontal distances from a measure of simple parallax otherwise breaks down. Moreover, if the plates are inclined, vertical lines in nature will no longer appear parallel on the photograph, but will converge to the plumb point as vanishing point. The system of plotting azimuths in these early machines, however, obviously requires the image of vertical lines to be parallel, in order that the horizontal distances between points on the plate may be independent of the heights of such points.

Before long, it became essential on the score of accuracy, convenience and economy to expose inclined plates on converging orientations. Even in mountainous country, where photographic survey had hitherto found its exclusive application, it was often desirable to site the cameras on high ground in order to minimize the extent of dead ground not covered stereoscopically. The camera axes had consequently to be depressed in order to include as wide a field as possible. With the World War period of improvements in photography from the air, it became economically possible to survey *flat* country photographically, with the corresponding necessity for exposing horizontal rather than vertical plates. Further, in the case of air photographs, it is as yet impossible so to stabilize the camera or the aeroplane as to ensure that the two plates are exposed in the same plane at all, at any rate to the degree of precision attainable by deliberate exposure on the ground.

It may in fact be assumed that any type of country can be surveyed photographically provided that, in order to secure the best results, it can be photographed on a plate parallel to its mean slope. Precipitous mountain slopes require vertical, and dead flat plains horizontal plates. Between these two extremes there will be a particular tilt for the most efficient survey of a particular type of country, and a corresponding height of station in order to secure the necessary photographic field. The development of air photography has allowed this ideal to be approached, with the consequent demand for a plotting machine with a "universal" range in permissible orientations in space of the camera axes.

The stereoautograph can, as a geometrical proposition, be adapted by certain variations in its plotting mechanism to deal with inclined or converging photographs. *See* O. von Gruber, "Der von Orel-Zeiss'sche Stereoautograph mit Zusatzeinrichtung zur Ausarbeitung von Luftaufnahmen," in *Internationales Archiv für Photogrammetrie* (Vienna, 1923); but a different base setting is in general necessary for each contour. Moreover, corresponding points on the two photographs will, generally speaking, no longer lie at the same distance from the eye base when the photographs are placed in the same plane in the comparator, by reason of the perspective distortion due to tilt. A restricted range in tilt can in these circumstances be tolerated by the eyes without a breakdown of stereoscopic fusion, but the process cannot be continued indefinitely, even if a complicated transverse shift of the plates were introduced.

**The Photogoniometer.**—Attempts were accordingly next made to extend the range of plotting machines by the incorporation of the Porro-Koppe photogoniometer, which uses a theodolite to measure horizontal and vertical angles from a photograph. The photograph is mounted in the plate carrier in relation to a photographic objective, which is in all respects similar to the camera objective, so that the internal perspective conditions are reproduced correctly. This implies two transverse adjustments in the plane of the photograph and a fine focussing rack as the first essentials in design. The external perspective conditions are then re-established by tilting the whole camera body similarly to the field camera at exposure. This implies the possibility of tilting about a horizontal axis in order to set for the magnitude of tilt, and of rotating the photograph in its own plane about the plate perpendicular in order to set for the direction of tilt. Horizontal and vertical angles as from the camera station may then be measured by means of a theodolite whose horizontal and vertical axes are arranged to intersect in or near the centre of the exit pupil of the objective.

Where the photogoniometer is employed as an auxiliary in a plotting machine, rotation in azimuth is usually given to the camera body, while rotation in altitude only is furnished by the telescope of the theodolite. In this form the photogoniometer is mechanically unsuitable for photographs whose axes are vertical or tilted less than about 45° from the vertical; *i.e.,* for the majority of air photographs. Where the instrument is used independently, however, there is no need to accept this limitation. Both altitude and azimuth rotations may, for instance, be imparted to the telescope, leaving the camera body adjustable for tilt only; or, in order to avoid moving the eye into impossible positions where the camera axis approaches the vertical, the altitude movement may be furnished by the rotation of a prism in front of the telescope objective.

**Intersection Photogoniometric Machines.**—The first plotting machine to employ the photogoniometer principle was the

Hugershoff *autocartograph,* the photographs being observed through the goniometer lenses by a binocular telescope. The autocartograph is designed for high obliques, and there is difficulty in dealing with vertical (axis) air photographs, or indeed with any photographs where the camera axis is tilted less than about 45° from the vertical. This is a direct consequence of the design of the photogoniometers, as mentioned above. Moreover the

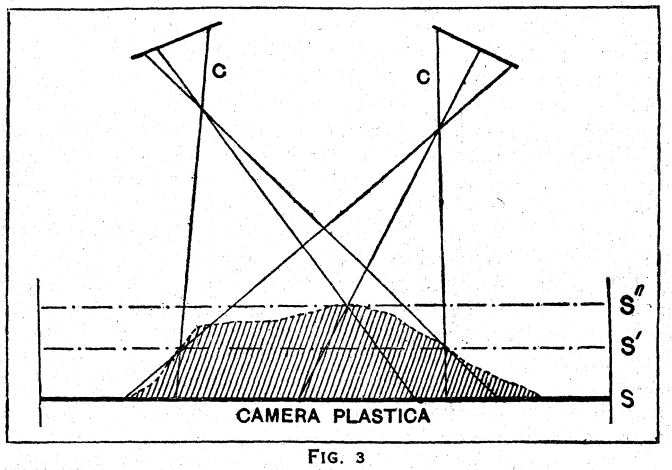

FIG. 3

azimuth levers would need to be capable of all round rotation, and the von Orel plotting system is clearly unsuited to this possibility. It is true that the height and distance controls of the auxiliary drum plot can be interchanged, with the result that an elevation instead of a plan can be drawn on the drum. Consequently, if a pair of vertical (axis) photographs are placed in the position of horizontal (axis) photographs in the goniometers, it is possible to draw a direct plan from them on the drum.

**The Camera Plastica.**—Concurrently with the intersection photogoniometric type, various efforts have been made to develop machines to deal primarily with air photographs on the principle of the *camera plastica.* The latter, usually attributed to Scheimpflug, is shown diagrammatically in fig. 3. Two projection cameras CC are set in the same relation to one another in the scale of the plot as the two positions of the air camera at exposure, and throw real images on a movable screen S representing the ground plane of reference. It is clear that if the screen is moved bodily towards the projection cameras (to S′ or S″) until the coincidence of corresponding images is obtained, this coincident image will represent the true plan position of the point considered, the position of the screen at the same time affording a measure of heights. Coincidence may be estimated by a flicker system which enables the two images to be thrown on the screen alternately in rapid succession, or a stereoscopic image in anaglyphic relief may be obtained by projecting in two colours and viewing through filters of the same colours. In the latter case plotting may be effected according to the movements of a real floating mark in the plane of the screen, the depth movement being effected by bodily translation of the screen towards the projection cameras.

Many applications of this principle have appeared on the market, the best known being perhaps the Nistri *photocartograph.* In this case the two projection cameras are set by trial on control point screens. In order to preserve true perspective conditions the projection lenses are set at the principal distance of the air camera from the photographs, and must consequently be of shorter focus in order to form sharp images on the screen. Coincidence plotting is effected on the flicker system, the movements of a steel pointer over the screen being copied by a pantograph.

The inception of this type of machine was no doubt due to the fact that the whole photograph is seen at once, and that in consequence the systematic trial setting of air photographs on control points is much easier. Up to the present no fully economic method of determining independently the plate constants of the air photograph has been discovered, and the computed or trial setting of photogoniometric machines is apt to be protracted. On the other hand the camera plastica type depends on depth of focus on the plotting screen, and the introduction of considerable tilts and variations in relief is apt to strain this factor beyond its limits of endurance, particularly as the use of a small stop is for various reasons undesirable. With automatic focussing devices and the use of rectified photographs, the range of the camera plastica might possibly be extended.

**The Zeiss Stereoplanigraph.**—This difficulty of preserving focus during movements of the plotting plane has been successfully overcome in the Zeiss stereoplanigraph which works on the same general principle as the camera plastica, by the introduction of an auxiliary tele-objective of variable focus. In this machine two projection cameras are fixed on a cross slide, the internal and external perspective conditions at exposure being reproduced by setting in exactly the same way as for the photogoniometers of the autocartograph. The rear nodes of the projection camera objectives form a Zeiss parallelogram with the two floating marks, any of the corners of which are thus available for setting the magnitude and direction of the base. Actually the projected length of the base is set inwards on the floating marks, while the remaining two co-ordinates defining the orientation of the base in space are set one on each of the camera units. The object of this arrangement is to provide room for the two camera units without an excessive increase in their distance from the floating marks (this being one of the disadvantages of the simple camera plastica), and at the same time to avoid superimposing the two images on a single floating mark, with the consequent necessity for visual separation by colour filters.

The distance and height plotting movements are operative on the cross slide carrying the two camera units, while the direction movement is effected by a lateral shift of the two floating marks together in the direction of the line joining them. The distance and direction, or alternatively height and direction, plotting movements are coupled through gearing to a drawing pencil. This possibility of interchanging the distance and height controls enables direct plotting to be carried out either in plan or in elevation, so that it is possible to deal equally well with horizontal, vertical, or intermediately tilted photographs. In order to preserve focus on the plane of the floating marks, an auxiliary lens system, consisting of bi-convex and bi-concave lenses of equal power, is supported in front of the camera objective, the rear node of the combination coinciding approximately with the rear node of the camera objective. The combination is universally jointed on its rear node and is oriented so that its axis always passes through the floating mark, by means of the taper guide rods.

The visual system is a complicated form of stereoscopic comparator, the object of which is to observe the stereoscopic coincidence of the floating marks with various objects in the landscape during plotting. It thus corresponds essentially to the anaglyph filters of a simple camera plastica. If the original negatives are placed in the projection cameras, a reconstructed space image as in nature is formed near the plane of the floating marks, since the auxiliary lens system introduces no inversion. Since this is viewed in reverse it is necessary to cross the eyepieces of the visual system in order to avoid pseudoscopy. (*See* BINOCULAR INSTRUMENTS; MICROSCOPE.) The eyepieces must for the sake of convenience remain immovable, while the floating marks travel on the direction plotting movement. This is effected by the introduction of scissor-jointed link prisms, which also serve to facilitate the crossing of the eyepieces. Lastly the line of collimation of the instrument must be universally jointed at the floating marks, in order that the movable part between the floating mark and the rear node of the auxiliary lens system may be deflected in a constant direction into the visual system. This is done by means of an optical Cardan link actuated by the taper guide rods. "Leaning" of the image introduced by rotation about the two Cardan axes is, as usual, corrected by the differential rotation of a Dove prism.

**The Wild Autograph.**—The latest complete example of stereophotogrammetric plotting machinery is the Wild "autograph," in which will be recognized the autocartograph and

stereoplanigraph characteristics. The projection cameras are rotatable about horizontal and vertical axes. They are connected to guide rods, which can slide in sleeves attached to universal joints at the ends of the base slide. The centres of these latter joints form a Zeiss parallelogram with the centres of rotation of the projection cameras; the base setting being effected entirely on the two former corners of the parallelogram.

All the three plotting movements act on the base slide B, and are geared to a drawing pencil in exactly the same way as in the stereoplanigraph. Sympathetic movements of the projection cameras follow by reason of their connection to the base slide through the guide rods. In addition the direction plotting movement is shared by two prisms of the visual system rigidly mounted on the vertical axis of the projection cameras. Any tilts may be dealt with by an appropriate initial setting of these prisms or by tilting the whole visual system, and by an interchange of axes as in the stereoplanigraph.

Owing mainly to the absence of heavy moving parts the result is a light, compact machine. This very considerable advantage is however offset by further complication, since, in order to correct the effect of the above plotting movements, it is necessary to introduce a variable rotation of the plates in their own plane; *i.e.*, a rotation which must be varied for each particular tilt of the camera axes at exposure. This variable rotation, which is effected by a system of variable cams, is however entirely automatic, and requires no attention from the observer after the initial setting. There is little in it to go wrong or to require re-adjustment. A practical disadvantage of the machine for air work might lie in the necessity for computing the *relative* orientations of the camera axes in space before the machine can be set. In the case of ground surveys with the Wild phototheodolite, only a few combinations are necessary or possible, and the calculations can be done once and for all.

R. Hinks, "Mr. Wild's Stereoplotting Machine," in *Geographical Journal* (vol. lxx., 1927). (H. HTE.)

**STEREOSCOPE.** An optical instrument used for obtaining from two slightly different pictures (*i.e.*, pictures or photographs of the same object but from a slightly different point of view), the impression of a single picture in relief. *See* BINOCULAR INSTRUMENT.

**STEREOSCOPIC VISION**: *see* VISION.

**STEREOTYPING.** A process of producing duplicate printing plates from a form of type or blocks by pouring molten metal on a matrix made in plaster of paris or papier-mâché. (*See* PRINTING.)

**STERILITY,** the inability to beget living offspring, may be the result of any of the following causes.

*Absence of sexual intercourse* due to the lack of appropriate psychological stimuli leading to coition. This is one factor in the mutual sterility of different species. (*See* HYBRIDISM.)

*Absence or incompleteness of coition* due to gross abnormality of the external or internal organs of reproduction. Hermaphroditism (*see* article, SEX); occlusion of the ducts which convey the gametes from the sex-gland to the site of fertilisation, either congenital or acquired through disease; imperforate hymen and other structural abnormalities fall into this group. The chemical condition of the female passages may be such as to kill the entering spermatozoa.

*Infecundity.*—The inability to produce functional gametes is found in many hybrids (*see* HYBRIDISM) and in certain intersexual forms. In such mammals in which the testes lie normally within a scrotum, the testis if retained within the abdominal cavity does not produce functional spermatozoa. Infecundity may follow upon exposure to X-rays, for these destroy that tissue of the sex-gland which is concerned with the elaboration of the gametes.

*Mutual repugnance on the part of the gametes* resulting in non-fertilisation. Though as yet nothing very definite is known of the physico-chemical requirements of fertilisation there is a considerable body of evidence to show that an attraction between the male and female gametes must exist if fertilisation is to occur.

*Abnormalities in the fertilised egg* which embarrass or prevent cleavage and development bringing these processes to a stop at some stage, death of the individual thereupon resulting. This is the fate of many hybrid embryos. (*See* HYBRIDISM.) Lethal factors (*see* GENETICS and SEX) also operate in this fashion.

*Abnormalities in the medium in which the fertilised eggs find themselves* which prevent or embarrass development. The exact constitution of the sea-water in terms of alkalinity, for example, determines whether or not the fertilised ova of marine organisms shall begin and continue their development. Pathological conditions within the uterus of the mammalian female can prevent proper implantation of the descending egg.

*Disharmonies between the developing offspring and the maternal environment* can lead to difficult labour and death of either or of both mother and young. For example the male cattle×bison hybrid has a prominent crest and this cannot be accommodated by the maternal passages of the cow. Such male hybrids therefore usually are still-born. Contracted pelvis and similar abnormalities of the female birth-canal are common causes of death of both infant and mother. The general well-being of the mother is necessary for the normal development of the infant she bears.

In the case of the human subject there are certain conditions which are essential to fertility. Healthy spermatozoa must be received into a healthy vagina with a normal cervix, uterus, tubes and ovaries. An examination of any case of sterility must therefore begin with an examination of the male. It is estimated that in 25 per cent of childless marriages the man is at fault.

Experimentation with laboratory animals has shown that infecundity may result from deficiency of the reproductive vitamin *E* (Mason, 1925).

**STERLING, JOHN** (1806–1844), British author, was born at Kames Castle in Bute on July 20, 1806. He belonged to a family of Scottish origin which had settled in Ireland during the Cromwellian period. He was the son of Edward Sterling (1773–1847), who was for many years a leader-writer on *The Times*. John Sterling was educated at Glasgow university and at Trinity college and Trinity Hall, Cambridge. At Cambridge he was a member of the famous "Apostles'" Club. With F. D. Maurice he purchased the *Athenaeum* in 1828 from J. Silk Buckingham, which was not a success. In 1834 he was ordained and became curate at Hurstmonceaux, where his old tutor Julius Hare was vicar. Acting on the advice of his physician he resigned his curacy in 1835, but, according to Carlyle, the primary cause was a divergence from the opinions of the Church. He died at Ventnor on Sept. 18, 1844. Sterling owes his fame to the vivid *Life* by Carlyle, to whom, with Hare, his papers were entrusted.

**STERLING,** a term used to denote money of standard weight or quality, especially applied to the English gold sovereign, and hence with the general meaning of recognized worth or authority, genuine, of approved excellence. The word was formerly derived from the name of "Easterlings" given to the north German merchants who came to England in the reign of Edward I and formed a guild in London. Their coins were of uniform weight and excellence, and thus, it was supposed, gave the name of the moneyers to a coinage of recognized fineness. This theory is based on a statement of Walter de Pinchbeck, a monk of the time of Edward I. The word, however, occurs much earlier in the French form *esterlin* (11th or 12th century) and the Latin *libræ sterilensium* (1145); the Latin *sterlingus* occurs in an ordinance of 1184 and in a statute of Edward I (*"denarius Angliæ qui vocatur sterlingus"*). The derivation favoured by the Oxford *Dictionary* is from the late O.E. **steorling*, "coin with a star": some of the

early Norman pennies carry a small star. In early instances the word often occurs in the phrase "pound of sterlings," originally a pound weight of such pennies, 240 of which went to the "pound sterling" of silver of 5,760 grains, 925 fine. "Sterling silver" was originally silver having the same degree of purity as these pennies; later silver of standard quality, and so marked. The word was borrowed by most European languages and is there applied to English money. (*See* MONEY, MEDIAEVAL.)

(W. D. C.)

**STERLING,** a city of Colorado, U.S.A., 128 mi. N.E. of Denver, on the South Platte river and federal highways 6 and 138, served by the Burlington Route and the Union Pacific railway systems; the county seat of Logan county. The population was 6,415 in 1920 (87% native white), 7,195 in 1930 and 7,411 in 1940 by the federal census. The city was founded in 1881 and incorporated in 1883. In 1900 the population was 998.

**STERLING,** a city of Whiteside county, Illinois, U.S.A., on the north bank of Rock river, 110 mi. W. of Chicago. It is on the Lincoln highway and the Hennepin canal feeder, and is served by the Burlington Route and the Chicago and Northwestern railways, and by motor bus lines in all directions. Pop. 8,182 in 1920 (91% was native white) and was 11,363 in 1940 by the federal census. Rock Falls (pop. 4,987 in 1940) is just across the river. The cities have abundant water-power and large manufacturing industries, making agricultural implements. Sterling was chartered as a city in 1857.

**STERN, DANIEL:** *see* AGOULT, MARIE CATHERINE SOPHIE DE FLAVIGNY.

**STERNE, LAURENCE** (1713–1768), English humorist, was the son of Roger Sterne, an English officer, and great-grandson of an archbishop of York. He was born at Clonmel, Ireland, on Nov. 24, 1713, a few days after the arrival of his father's regiment from Dunkirk. For ten years the boy and his mother moved from place to place after the regiment, from England to Ireland, and from one part of Ireland to another. Sterne's early knowledge of garrison life enabled him to draw the portraits of Uncle Toby and Corporal Trim. He was fixed for eight or nine years at a school at Halifax in Yorkshire. His father died when he was in his eighteenth year. He was sent to Jesus College, Cambridge, where he took his degree in 1736. Through the influence of his uncle, precentor and canon of York, he obtained (1738) the living of Sutton-in-the-Forest, near York. Two years after his marriage in 1741 to Elizabeth Lumley he was presented to the neighbouring living of Stillington, and did duty at both places. He was also a prebendary of York Cathedral.

Sutton was Sterne's residence for twenty uneventful years. He kept up an intimacy which had begun at Cambridge with John Hall-Stevenson (1718–1785), a witty and accomplished epicurean, owner of Skelton Hall ("Crazy Castle") in the Cleveland district of Yorkshire. Stevenson's various occasional sallies in verse and prose—his *Fables for Grown Gentlemen* (1761–1770), and his *Crazy Tales* (1762), bear a resemblance in spirit and turn of thought to Sterne's work, inferior as they are in literary genius. In 1759 Sterne wrote a skit on a quarrel between Dean Fountayne and Dr. Topham, a York lawyer, over the bestowal of an office in the gift of the archbishop. This sketch, in which Topham figures as Trim the sexton, and the author as Lorry Slim, gives an earnest of Sterne's powers as a humorist. It was not published until after his death, when it appeared in 1769 under the title of *A Political Romance,* and afterwards the *History of a Warm Watch-Coat.* The first two volumes of *Tristram Shandy* were issued at York in 1759 and advertised in London on Jan. 1, 1760, and at once made a sensation.

For the last eight years of his life after this sudden leap out of obscurity we have a faithful record of Sterne's feelings and movements in letters to various persons, published in 1775 by his only child, Lydia Sterne de Medalle, and in the *Letters from Yorick to Eliza* (1766–1767), also published in 1775. At the end of the sermon in *Tristram* he had intimated that, if this sample of Yorick's pulpit eloquence was liked, "there are now in the possession of the Shandy family as many as will make a handsome volume, at the world's service, and much good may they do it." Accordingly, when a second edition of the first instalment of *Tristram* was called for in three months, two volumes of *Sermons* by Yorick were announced. Although they had little or none of the eccentricity of the history, they proved almost as popular.

Sterne's clerical character was far from being universally injured by his indecorous freaks as a humorist: Lord Fauconberg presented the author of *Tristram Shandy* with the perpetual curacy of Coxwold. To this new residence he went in high spirits with his success, "fully determined to write as hard as could be," seeing no reason why he should not give the public two volumes of Shandyism every year and why this should not go on for forty years. Vols. iii. and iv. appeared in 1761; vols. v. and vi. in January 1762. But he was ordered to the south of France; and he came back after two and a half years very little stronger. He was overjoyed with his reception in Paris. He continued to build up his history of the Shandy family, but the work did not progress as rapidly as it had done. The digressions became extensive. In vol. vii. the work is allowed to stand still while the writer is being transported from Shandy Hall to Languedoc. Vol. viii. begins the long-promised story of Uncle Toby's amours with the Widow Wadman. After seeing to the publication of this instalment of *Tristram* and of another set of sermons—more pronouncedly Shandean in their eccentricity—he quitted England again in the summer of 1765, and travelled in Italy as far as Naples. The ninth and last and shortest volume of *Tristram,* concluding Toby Shandy's amours, appeared in 1767.

This despatched, Sterne turned to a new project, *The Sentimental Journey through France and Italy.* Its plan admitted of any length that the author chose, but, after seeing the first two volumes through the press in the early months of 1768, Sterne's strength failed, and he died in his lodgings, 41 Old Bond Street, London, March 18, three weeks after the publication.

An excellent edition of Sterne's works, edited by Professor George Saintsbury, was issued in six volumes in 1894. *See* also J. J. Texte, *Rousseau et les origines du cosmopolitisme littéraire* (1895); Thayer, *Laurence Sterne in Germany* (1905); Walter Sichel, *Sterne: a Study* (1910); L. Melville, *Life and Letters of Laurence Sterne* (2 vols. 1911); G. Rabizzani, *Sterne in Italia* (1920); W. L. Cross, *The Life and Times of Laurence Sterne,* new ed. (1929).

**STESICHORUS** (*c.* 640–555 B.C.), Greek lyric poet, a native of Himera in Sicily, or of Mataurus a Locrian colony in the south of Italy. The story of his being struck blind for slandering Helen and recovering his sight when he recanted is told by Plato among others. We possess about thirty fragments of his poems, none of them longer than six lines. They are written in the Doric dialect, with epic licences; the metre is dactylico-trochaic. Brief as they are, they show us what Longinus meant by calling Stesichorus "most like Homer"; they are full of epic grandeur, and have a stately sublimity that reminds us of Pindar. This use of lyric for heroic subjects is what Quintilian (*Instit.* x. 1, 62) means by saying that he "sustained the burden of epic poetry with the lyre." Several of his poems sung of the adventures of Heracles; one dealt with the siege of Thebes, another with the sack of Troy. The last is interesting as being the first poem containing that form of the story of Aeneas's flight to which Virgil afterwards gave currency in his *Aeneid.* The popular legends of Sicily also inspired his muse; he was the first to introduce the shepherd Daphnis who came to a miserable end after he had proved faithless to the nymph who loved him. Stesichorus completed the form of the ode by adding the epode to the strophe and antistrophe.

Fragments in T. Bergk, *Poetae lyrici graeci,* iii.

**STETHOSCOPE,** a medical instrument used in auscultation (*q.v.*). The single stethoscope is a straight wooden or metal tube with a small flattened bell, the surface of which is usually covered with ivory or bone at the end, which is placed against the body of the patient, and a large flat disc at the other end, for application to the ear of the observer. In the "binaural" stethoscope, which has the advantage of flexibility, the tube is divided above the bell into two flexible tubes which lead to both ears.

**STETTIN,** capital of the Prussian province of Pomerania, Germany, on the Oder, 17 mi. above its entrance into the Stettiner Haff, 30 mi. from the Baltic, 84 mi. N.E. of Berlin by rail, and at the junction of lines to Stargard-Danzig and Küstrin-

Breslau. Pop. (1939) 268,917. Stettin is said to have existed as a Wendish settlement in the 9th century, but its first authentic appearance in history was in the 12th century, when it was known as Stedyn. From the beginning of the 12th century to 1637 it was the residence of the dukes of Pomerania, one of whom gave it municipal rights in 1243. Already a leading centre of trade it entered the Hanseatic League in 1360. The Pomeranian dynasty became extinct in 1637, and in 1648 Stettin was ceded to Sweden. In 1678 it was taken from Sweden by Frederick William, elector of Brandenburg, but it was restored in 1679, only, however, to be ceded to Prussia in 1720 by the Peace of Stockholm. It was fortified more strongly by Frederick the Great. Stettin was the birthplace of the empress Catherine II. of Russia.

The main part of the town occupies a hilly site on the left bank of the river, and is connected with the suburbs of Lastadie ("lading place" from *lastadium*, "burden,") and Silberwiese, on an island formed by the Parnitz and the Danzig. Until 1874 Stettin was closely girdled by extensive and strong fortifications. The church of St. Peter, founded in 1124 and restored in 1816–17, has the distinction of being the oldest Christian church in Pomerania. Both this and the church of St. James, dating from the 14th century, are remarkable for their size. The old palace, now used as public offices, is a large but unattractive edifice. Two gateways, the Königstor and the Berliner Tor, remains of the old fortifications, are still standing.

Stettin, regarded as the port of Berlin, is one of the principal ship-building centres of Germany and a place of much commercial and industrial activity. There are six floating docks, and four ice breakers keep the port open in winter. A great impulse to its trade was given in 1898 by the opening of a free harbour adjoining the suburb of Lastadie on the east bank of the Oder; this embraces a total area of .2 sq.mi., with two basins containing cranes and storehouses. During World War II Stettin suffered severely from frequent bombing raids.

**STEUBEN, BARON VON, FREDERICK WILLIAM AUGUSTUS HENRY FERDINAND** (1730–1794), German soldier, born at Magdeburg, Prussia, Sept. 17, 1730, was a descendant of a noble family, which for generations had produced soldiers. From his 14th year, Steuben led a soldier's life. Reared in the rigorous military school of Frederick the Great, he took part in many battles of the Seven Years' War, where he so distinguished himself as to attract the attention of King Frederick, who appointed him as his aide-de-camp (1762). After the close of the Seven Years' War, he resigned from the army and became grand-marshal at the court of the Prince of Hohenzollern-Hechingen, and, after a service of ten years, accepted a similar position at the court of the margrave of Baden. In 1777, his old friend the count of St. Germain, then the French minister of war, persuaded him to go to the assistance of the American colonists.

Steuben arrived at Portsmouth (N.H.), on Dec. 1, 1777, and offered his services to Congress as a volunteer. In March 1778 he began drilling the inexperienced soldiers at Valley Forge; and by May he was made inspector-general or drill-master. He trained the soldiers admirably, adapting Prussian military ideas to the needs of his pupils. Results of his work were shown in the next campaign, particularly at Monmouth, where he rallied the disordered, retreating troops of Gen. Charles Lee. His *Regulations for the Order and Discipline of the Troops of the United States* (1779) was of great value to the army. He was a member of the court-martial which tried Maj. John André in 1780, and after Gen. Horatio Gates's defeat at Camden was placed in command of the district of Virginia, with instructions "to collect, organize, discipline and expedite the recruits for the Southern Army."

In April 1781 he was superseded in command of Virginia by La Fayette, and later took part in the siege of Yorktown. Retiring from the service after the war, he passed the last years of his life at Steubenville (N.Y.), where he died on Nov. 28, 1794. New York, Virginia, Pennsylvania and New Jersey gave him grants of land for his services, and Congress passed a vote of thanks and gave him a gold-hilted sword in 1784, and later granted him a pension of $2,500.

*See* Frederick Kapp, *The Life of Frederick William von Steuben* (1859); and George W. Greene, *The German Element in the War of American Independence* (Cambridge, Mass., 1876); Francis Bowen, "Life of Baron Steuben" in J. Sparks's *Library of American Biography*, vol. viii., pp. 119–202 (1902); Rudolf Cronan, "The Army of the American Revolution and its Organizer," *American Historical Review* vol. xxxi. pp. 455–458 (1923).

**STEUBENVILLE,** a city of eastern Ohio, U.S.A., on the Ohio river, 40 mi. W. of Pittsburgh; the county seat of Jefferson county. It is served by the Pennsylvania, the Wheeling and Lake Erie railroads, motorbus and truck lines, river packets and barges. Two highway bridges span the Ohio. Pop. (1940) 37,651. The city lies on a plain 700 ft. above sea level, surrounded by hills rising 300–500 ft. higher, in a beautiful and fertile region containing rich deposits of coal, oil, gas, clay and building stone. The manufacturing industries are large and varied, including iron, steel, paper, glass and clay works. Two air-mail pickups and deliveries make up the daily schedule for Steubenville. Bank clearings in 1940 amounted to $124,387,878.06. Steubenville was planned in 1797, immediately after the erection of the county, on the site of Ft. Steuben (built 1786 and named after Baron von Steuben). It was incorporated in 1805. Steubenville has one radio station WSTV and the *Herald-Star*, one of the oldest newspapers in the tristate district, has served the community since 1806.

**STEVENAGE,** an urban district of Hertfordshire, England, 28½ mi. N. of London by the L.N.E. railway. Pop. (1938) 5,637. Area 7.2 sq.mi. The church of St. Nicholas, with a graceful tower and spire, is mainly Early English, but has Norman and later portions. Alleyne's grammar school was founded in 1558.

**STEVENS, ALFRED** (1818–1875), British sculptor, was born at Blandford in Dorset on Jan. 28, 1818. He was the son of a house painter. In 1833 the rector of his parish sent him to Italy, where he spent nine years in study at Naples, Rome, Florence, Milan and Venice. He had never been at an English school. In 1841 Thorwaldsen employed him for a year in Rome. After this he left Italy for England, and in 1845 he obtained a tutorial position in the School of Design, London, which he held until 1847. In 1850 he became chief artist to a Sheffield firm of workers in bronze and metal. In 1852 he returned to London. To this period belongs his design for the vases on the railings in front of the British Museum, and also the lions on the dwarf posts which were subsequently transferred to the inside of the museum. In 1856 Stevens agreed to execute the Wellington monument for St. Paul's Cathedral for the sum of £20,000.

Stevens died in London on May 1, 1875.

*See* SCULPTURE: *British;* Sir William Armstrong, *Alfred Stevens* (1881); H. Stannus, *Alfred Stevens* (1891).

**STEVENS, ALFRED** (1828–1906), Belgian painter, was born in Brussels on May 11, 1828. His father, an officer in the service of William I., king of the Netherlands, encouraged his son's talent and sent him to draw in the studio of François Navez, director of the Brussels Academy. In 1844 Stevens went to Paris and worked under Camille Roqueplan, a friend of his father's; he also attended the classes at the École des Beaux Arts, where Ingres was then professor. In 1849 he settled in Paris, where he exhibited in the Salons. In 1855 he exhibited at the Antwerp Salon a little picture called "At Home," which showed his genius for depicting ladies of fashion. Henceforth he concentrated on graceful female subjects. At the Historical Exhibition of Belgian Art, Brussels, 1880, he exhibited "The Four Seasons" (in the Palace at Brussels), "The Parisian Sphinx," "The Japanese Mask," "The Japanese Robe," and "The Lady-bird" (Brussels Gallery). He died on Aug. 24, 1906.

*See* J. du Jardin, *L'Art flamand* (6 vols., 1896–1900); Camille Lemonnier, *Histoire des beaux arts en Belgique* (1882; 2nd ed., 1887).

**STEVENS, HENRY** (1819–1886), American bibliographer, was born in Barnet, Vt., on Aug. 24, 1819. He studied at Middlebury college, Vermont, and graduated at Yale in 1843, teaching to pay his way and for a time acting as a Government clerk. In this capacity he won the friendship of Col. Peter Force, who employed him to collect books, pamphlets and manuscripts for the American archives on his return to Yale and during his year

at the Cambridge, Mass., law school. His commissions from Force and other collectors took him abroad, where he ransacked the European capitals for rare Americana for the Smithsonian Institution, the library of Congress, and such private buyers as John Carter Brown and James Lenox. At the suggestion of Sir Anthony Panizzi, the librarian of the British Museum, he also supplied that institution with many American books. He died at Hampstead, London, England, on Feb. 28, 1886.

Perhaps his most notable achievement was his redemption of the Franklin manuscripts, which were finally disposed of to the U.S. Government. He wrote: *Catalogue of the American Books in the Library of the British Museum* (1856); *Historical Nuggets, Bibliotheca Americana* (1862); *Historical and Geographical Notes on the Earliest Discoveries in America* (1869); *Benjamin Franklin's Life and Writings* (1881); *Recollections of Mr. James Lenox . . . and the Formation of His Library* (1886); and *Thomas Hariot* (1900); edited by his son, H. N. Stevens.

**STEVENS, JOHN** (1749–1838), American inventor, was born in New York City in 1749, graduated at Columbia university in 1768, subsequently studied law and was admitted to the New York bar in 1771. In 1776 he became a captain in the Revolutionary army, and later colonel of his own regiment. From 1777 to 1782 he served as treasurer of the State of New Jersey. In 1784 he built a home on what was then the Island of Hoboken, subsequently, when connected with the mainland, known as Stevens Point, where he resided for over half a century until his death March 6, 1838. He purchased the ferry to New York and much of the main New Jersey shore. Along the road leading to the ferry landing he began the development of the city of Hoboken.

The problem of safe and speedy transportation across the Hudson drew his interest early to the possibilities of steam navigation. In 1788 he built the first multitubular boiler on record for use in his marine engines. In a desire to protect this invention he petitioned Congress for a patent law, which he outlined, and which was passed as the Patent Law of 1790 the foundation of the present patent system. He was the first to apply the principle of screw propulsion to navigation, building in 1802 a steamboat with two underwater propellers of screw type in the stern which successfully crossed the Hudson several times and only failed because the inefficient boilers of that day could not generate enough power to make the screw device practical. He turned then toward the development of high pressure steam engines and boilers in which field he was a pioneer. But a few days after Fulton's successful trial of the "Clermont" Stevens launched the "Phoenix," the engine of which was built by Stevens himself, whereas that of the "Clermont" was imported from England. Fulton having received a monopoly grant of navigation rights on the Hudson, Stevens sent the "Phoenix" by sea to Philadelphia, the first voyage of a steamship on ocean waters. Stevens was also interested in railways, writing in 1812 a pamphlet entitled *Documents tending to prove the Superior Advantages of Railways and Steam Carriages over Canal Navigation.* On February 6, 1815, he obtained the first railway charter granted in America for a railway between the Delaware and Raritan rivers, but it was not until 1830 that he formed the Camden and Amboy Railway company, and 1832 that he completed the first railway across New Jersey, operated by his sons Robert L. Stevens (*q.v.*) and Edward A. Stevens.

*See* A. D. Turnbull, *John Stevens: An American Record* (1928).

**STEVENS, ROBERT LIVINGSTON** (1787–1856), American mechanical engineer, was born at New York City on Oct. 18, 1787, the son of John Stevens (*q.v.*) whose mechanical ability he inherited. Whereas the father spent most of his thought on the improvement of motive-power and machinery of steamboats, the son made many advances in construction, strengthening hulls, reducing weight, distributing strain and improving the lines to gain speed. He designed the false bow, which, when first introduced on the "New Philadelphia," enabled that steamer to break previous records and be the first of Hudson river steamers to go from Albany to New York during daylight. With this steamer and the "North America," the Stevens family inaugurated a day line on the Hudson. In 1822 he built the ferryboat "Hoboken" on modern lines and introduced the piled slip which directed the boat's entrance to the landing-place.

In 1830 he was made first president of the Camden and Amboy railway and went to England to inspect equipment already in use there. On the outward voyage he designed the "T" rail with a broad base, long known as the Stevens, or American rail, and now universally used. He contracted in England for 500 tons of such rails, the first made, and also placed an order with the Stephensons for a locomotive made according to his specifications. This was the famous "John Bull" which he brought to America on his return, and which is now in the Smithsonian Institution. He made many improvements on railway locomotives, introducing the pilot truck in 1832, the bogie truck shortly afterwards, and, finally, using eight instead of four or six wheels in order to promote adhesion to the rails and drawing power. When stone blocks could not be furnished fast enough for his road-bed he resorted to logs laid crosswise with broken stone and gravel between and discovered that he had found a bed more serviceable and comfortable than any known previously. He devised spikes "six inches long with heads" to hold the rails in place on the logs. As a recreation Stevens took up yachting, and in 1844 he designed the "Maria," for twenty years the swiftest yacht afloat. Later he designed the "America" for his brother, John Cox Stevens, who with it defeated all English challengers, and founded the America's Cup races. He died at Hoboken, New Jersey, April 20, 1856.

**STEVENS, THADDEUS** (1792–1868), American political leader, was born in Danville, Vt., April 4, 1792. He graduated at Dartmouth college in 1814, removed to York, Pa., was admitted to the bar (in Maryland), and for 15 years practised at Gettysburg, Pa. He frequently appeared in behalf of fugitive slaves before the Pennsylvania courts. He was a Whig representative in Congress in 1849–53, and was leader of the radical Whigs and Free-Soilers, strongly opposing the Compromise Measures of 1850, and being especially bitter in his denunciations of the Fugitive Slave law. In 1855 he took a prominent part in organizing the Republican party in Pennsylvania. He became chairman of the ways and means committee on July 4, 1861, and until his death was, as James G. Blaine said, "the natural leader who assumed his place by common consent." During the Civil War he was instrumental in having necessary revenue measures passed. He was not in harmony with Lincoln, who was far more conservative. He introduced from the joint committee what became the Fourteenth Amendment, and also the Reconstruction Act of Feb. 6, 1867. He advocated the Freedmen's Bureau bills and the Tenure of Office Act, and went beyond Congress in favouring the confiscation of property in Confederate States. He led Congress in the struggle with President Johnson, and reported the impeachment resolution and was chairman of the committee appointed to draft the articles of impeachment. He died at Washington, Aug. 11, 1868.

**STEVENSON, ADLAI EWING** (1835–1914), Vice President of the United States, 1893–97, was born in Christian County, Ky., on Oct. 23, 1835. He studied at Centre College, read law, and commenced practice at Metamora, Illinois. He was a member of the 44th and 46th Congresses and served as First Assistant Postmaster General in Cleveland's first administration. He was given the Democratic nomination for Vice President in 1892 so that the West should be represented on the ticket which Cleveland, an Easterner, headed. In 1897 he was chairman of a commission sent to Europe to work for international bimetallism. He was again nominated for Vice President on the ticket with Bryan in 1900, and in 1908 he was unsuccessful as the Democratic candidate for governor of Illinois. He wrote a pleasant book of reminiscences, *Something of Men I Have Known.*

**STEVENSON, ROBERT** (1772–1850), Scottish engineer, was the only son of Alan Stevenson, partner in a West Indian house in Glasgow, and was born in that city on June 8, 1772. He was educated at Anderson's College, Glasgow, and at Edinburgh University. He assisted his stepfather, Thomas Smith, in lighthouse schemes, and at nineteen was sent to superintend the erection of a lighthouse on the island of Little Cumbrae. Subsequently he succeeded Smith as engineer to the Commissioners of Northern Lighthouses, and from 1797 to 1843, he designed and built a large number of lighthouses, the most important being that on the Bell

Rock, begun in 1807. On his advice an admiralty survey was established, from which the admiralty sailing directions for the coasts of Great Britain and Ireland were prepared. Stevenson published an *Account of the Bell Rock Lighthouse* in 1824, contributed to the *Encyclopædia Britannica,* and wrote various papers read before learned societies. He died at Edinburgh on July 12, 1850.

**STEVENSON, ROBERT LOUIS BALFOUR** (1850–1894), British essayist, novelist and poet, was the only child of Thomas Stevenson, civil engineer, and his wife, Margaret Isabella Balfour. He was born at 8 Howard Place, Edinburgh, on Nov. 13, 1850. He suffered from infancy from great fragility of health, and nearly died in 1858 of gastric fever, which left much constitutional weakness behind it. He went to school, mainly in Edinburgh, from 1858 to 1867. As his health improved it was hoped that he would be able to adopt the family profession of civil engineering, and in 1868 he went to Anstruther and then to Wick as a pupil engineer. In 1871 he had so far advanced as to receive the silver medal of the Edinburgh Society of Arts for a paper suggesting improvements in lighthouse apparatus. His earliest publication, the anonymous pamphlet of *The Pentland Rising,* had appeared in 1866, and *The Charity Bazaar,* a trifle in which his future manner is happily displayed, in 1868. Though he greatly enjoyed the outdoor business of the engineer's life it strained his physical endurance too much, and in 1871 it was reluctantly exchanged for study at the Edinburgh bar, to which he was called in 1875. In 1873 he first met Sidney Colvin, who was to prove the closest of his friends and at last the loyal and admirable editor of his works and his correspondence.

He was now labouring, with extreme assiduity, to ground himself in the forms and habits of literary style. In 1875 appeared, anonymously, his *Appeal to the Clergy of the Church of Scotland,* and in that year he made the first of many visits to the forest of Fontainebleau. Meanwhile at Mentone in the winter of 1873–1874 he had grown in mind under the shadow of extreme physical weakness, and in the following spring began to contribute essays of high originality to one or two periodicals, of which the *Cornhill,* then edited by Leslie Stephen, was at first the most important. Stevenson made no attempt to practise at the bar, and the next years were spent in wanderings in France, Germany and Scotland. Records of these journeys were published as *An Inland Voyage* (1878), and as *Travels with a Donkey in the Cevennes* (1879). During these four years Stevenson's health, which was always bettered by life out of doors, gave him little trouble. At Fontainebleau in 1876 Stevenson had met Mrs. Osbourne, the lady who afterwards became his wife; she returned to her home in California in 1878, and in August of the following year, alarmed at news of her illness, Stevenson hurriedly crossed the Atlantic. He travelled, from lack of means, as a steerage passenger and then as an emigrant, and in December, after hardships which seriously affected his health, he arrived in San Francisco. In May 1880 he married, and moved to the desolate mining-camp which he has described in *The Silverado Squatters.* Some of his most poignant and most enchanting letters were written during this romantic period of his life. In the autumn of 1880 he returned to Scotland, with his wife and stepson, who were received at once into the Edinburgh household of his parents. But the condition of his health continued to be very alarming, and they went almost immediately to Davos, where he remained until the spring of 1881. In this year was published *Virginibus puerisque,* the earliest collection of Stevenson's essays. He spent the summer months in Scotland, writing articles, poems, and above all his first romance, *The Sea-Cook,* afterwards known as *Treasure Island;* but he was driven back to Davos in October. In 1882 appeared *Familiar Studies of Men and Books* and *New Arabian Nights.* His two winters at Davos had done him some good, but his summers in Scotland invariably undid the benefit. He therefore determined to reside wholly in the south of Europe, and in the autumn of 1882 he settled near Marseilles. This did not suit him, but from March 1883 to July 1884 he was at home at a charming house called La Solitude, above Hyères; this was in many ways to be the happiest station in the painful and hurrying pilgrimage of Stevenson's life. *The Silverado Squatters* was published in 1883, and also the more important *Treasure Island,* which made Stevenson for the first time a popular writer. He planned a vast amount of work, but his schemes were all frustrated in January 1884 by the most serious illness from which he had yet suffered. The attack was followed by long prostration and incapacity for work, and by continued relapses. In July he was brought back to England, and from this time until August 1887 Stevenson's home was at Bournemouth. In 1885 he published, after long indecision, his volume of poems, *A Child's Garden of Verses,* an inferior story, *The Body Snatcher,* and that admirable romance, *Prince Otto,* in which the peculiar quality of Stevenson's style was displayed at its highest. He also collaborated with W. E. Henley in some plays, *Beau Austin, Admiral Guinea* and *Robert Macaire.* Early in 1886 he struck the public taste with precision in his wild symbolic tale of *The Strange Case of Dr. Jekyll and Mr. Hyde.* In the summer of the same year he published *Kidnapped,* which had been written at Bournemouth.

Stevenson printed privately as a pamphlet, in June 1887, a brief and touching sketch of his father. In July he published his volume of lyrical poems called *Underwoods.* The ties which bound him to England were now severed, and he determined to remove to another hemisphere. He sailed from London, with his wife, mother and stepson, for New York on Aug. 17, 1887. He never set foot in Europe again. His memoir of his friend Professor Fleeming Jenkin was published soon after his departure. After resting at Newport, he went for the winter to be under the care of a physician at Saranac Lake in the Adirondacks. In this retreat he was very quiet, and steadily active with his pen, writing both the greater part of the *Master of Ballantrae* and many of his finest later essays. He had undertaken to contribute a monthly essay to *Scribner's Magazine,* and these essays, twelve in number, were published continuously throughout the year 1888. Early in that year was begun *The Wrong Box,* a farcical romance in which Mr. Lloyd Osbourne participated; Stevenson also began a romance about the Indian Mutiny, which he abandoned. His attitude about this time to life and experience is reflected in *Pulvis et umbra,* one of the noblest of all his essays. In April 1888 he was at the coast of New Jersey for some weeks, and in June started for San Francisco, where he had ordered a schooner, the "Casco," to be ready to receive him. On the 28th of the month, he started, as Mr. Colvin has said, "on what was only intended to be a pleasure excursion . . . but turned into a voluntary exile prolonged until the hour of his death": he never again left the waters of the Pacific. The "Casco" proceeded first to the Marquesas, and south and east to Tahiti, passing before Christmas northwards to Honolulu, where Stevenson spent six months and finished *The Master of Ballantrae* and *The Wrong Box.* It was during this time that he paid his famous visit to the leper settlement at Molokai. In 1889, "on a certain bright June day," the Stevensons sailed for the Gilbert Islands, and after six months' cruising found themselves at Samoa, where he landed for the first time about Christmas Day 1889. On this occasion, however, though strongly drawn to the beautiful island, he stayed not longer than six weeks, and proceeded to Sydney, where early in 1890, he published, in a blaze of righteous anger, his *Father Damien: an Open Letter to the Rev. Dr. Hyde of Honolulu,* in vindication of the memory of Father Damien and his work among the lepers of the Pacific. Meanwhile his volume of *Ballads* was published in London.

The last four years of his unquiet life were spent at Samoa, in circumstances of such health and vigour as he had never previously enjoyed, and in surroundings singularly picturesque. In November 1890 he made his abode at Vailima, where he took a small barrack of a wooden box 500 ft. above the sea, and began to build himself a large house close by. The natives gave him the name of Tusitala. He took up the cause of the deposed king Mataafa with extreme ardour, and he wrote a book, *A Footnote to History: Eight Years of Trouble in Samoa* (1892), in the endeavour to win over British sympathy to his native friends. In the autumn of this year he received a visit at Vailima from the countess of Jersey, in company with whom and some others

he wrote the burlesque extravagance in prose and verse, called *An Object of Pity,* privately printed in 1893 at Sydney. Whenever the cultivation of his estate and the vigorous championship of his Samoan retainers gave him the leisure, Stevenson was during these years almost wholly occupied in writing romances of Scottish life. *The Wrecker,* an adventurous tale of American life, which mainly belonged to an earlier time, was written in collaboration with Mr. Lloyd Osbourne and finally published in 1892; and towards the close of that very eventful and busy year he began *The Justice Clerk,* afterwards *Weir of Hermiston.* In 1893 Stevenson published the Scottish romance of *Catriona,* written as a sequel to *Kidnapped,* and the three tales illustrative of Pacific Ocean character, *Island Nights' Entertainments.* But in 1893 the uniform good fortune which had attended the Stevensons since their settlement in Samoa began to be disturbed. The whole family at Vailima became ill, and the final subjugation of his protégé Mataafa, and the destruction of his party in Samoan politics, deeply distressed and discouraged Stevenson. In a series of letters to *The Times* he exposed the policy of the chief justice, Mr. Cedercrantz, and the president of the council, Baron Senfft. He so influenced public opinion that both were removed from office. In the autumn of that year he went for a change of scene to the Sandwich Islands, but was taken ill there, and was only too glad to return to Samoa. In 1894 he was greatly cheered by the plan, suggested by friends in England and carried out by them with the greatest energy, of the noble collection of his works in twenty-eight volumes, since known as the Edinburgh edition. In September 1894 was published *The Ebb Tide,* the latest of his books which he saw through the press. Of Stevenson's daily avocations, and of the temper of his mind through these years of romantic exile, a clear idea may be obtained by the posthumous *Vailima Letters,* edited by Mr. Sidney Colvin in 1895. Through 1894 he was engaged in composing two romances, neither of which he lived to complete. He was dictating *Weir of Hermiston,* apparently in his usual health, on the day he died. This was Dec. 3, 1894; he was gaily talking on the verandah of his house at Vailima when he had a stroke of apoplexy, from which he never recovered consciousness, and passed away painlessly in the course of the evening. His body was carried next day by sixty sturdy Samoans, who acknowledged Stevenson as their chief, to the summit of the precipitous peak of Vaea, where he had wished to be buried, with the Pacific Ocean at his feet.

The charm of the personal character of Stevenson and the romantic vicissitudes of his life are so predominant in the minds of all who knew him, or lived within earshot of his legend, that they made the ultimate position which he will take in the history of English literature somewhat difficult to decide. That he was the most attractive figure of a man of letters in his generation is admitted; and the acknowledged fascination of his character was deepened, and was extended over an extremely wide circle of readers, by the publication in 1899 of his *Letters,* which have subdued even those who were rebellious to the entertainment of his books. It is therefore from the point of view of its "charm" that the genius of Stevenson must be approached, and in this respect there was between himself and his books, his manners and his style, his practice and his theory, a very unusual harmony.

The personal appearance of Stevenson has often been described: he was tall, extremely thin, dark-haired, restless, compelling attention with the lustre of his wonderful brown eyes. Whatever may be the ultimate order of reputation among his various books, or whatever posterity may ultimately see fit to ordain as regards the popularity of any of them, it is difficult to believe that the time will ever come in which Stevenson will not be remembered as the most beloved of the writers of that age which he did so much to cheer and stimulate. (E. G.; X.)

R. L. Stevenson's other works include: *Memories and Portraits* (1887); *The Merry Men and other Tales and Fables* (1887); *The Black Arrow* (1888); *Edinburgh: Picturesque Notes* (1889); *Across the Plains, with other Memories and Essays* (1892), and the posthumous works, *Songs of Travel and other Verses* (1896), *St. Ives* (1899), completed by Sir A. T. Quiller Couch; *A Stevenson Medley* (1899); *In the South Seas: experiences . . . on the "Casco" (1888) and the Equator (1889)* (1900). *See* the *Letters of Stevenson to his Family* (1899), with the critical and biographical preface by Mr. Sidney Colvin; *Vailima Letters, to Sidney Colvin* (1895), and the *Life of Robert Louis Stevenson* by Graham Balfour (1901) A complete edition of Stevenson's works was issued at Edinburgh in 1894–98. *Bibliographies* of the works of R. L. Stevenson were published by J. H. Slater (1914) and by W. F. Prideaux (1917).

*See* Prof. Walter Raleigh, *R. L. Stevenson* (1895); Isobel Strong and Lloyd Osbourne, *Memories of Vailima* (1903); F. A. Swinnerton, *R. L. Stevenson: a critical study* (1914); G. Balfour, *The Life of Robert Louis Stevenson* (1918 rev. ed. 1922); G. E. Brown, *A Book of R. L. S. Works, travels, friends and commentators* (1919); R. O. Masson, *Life of R. L. Stevenson* (Edinburgh, 1923); A. St. John Adcock, *Robert Louis Stevenson: his work and his personality* (1924); J. A. Stewart, *R. L. Stevenson, Man and Writer* (2 vols., 1924); G. S. Hellman, *The True Stevenson: A study in clarification* (1925).

**STEVENSON, WILLIAM** (d. 1575), probable author of the English comedy *Gammer Gurton's Needle,* was born at Hunwick, Durham, matriculated in 1546, took his M. A. degree in 1553, and became B.D. in 1560. Stevenson was a fellow of Christ's college, Cambridge, from 1551 to 1554 and from 1559 to 1561. He was made a prebendary of Durham in 1560–61 and died in 1575. *Gammer Gurton's Needle* is the second extant English comedy, properly so-called. William Stevenson is known to have written a play which was acted at Christ's college in 1553–54; and in the accounts of Christ's college for 1559–60 is the entry, "Spent at Mr. Stevenson's plaie, 5s." Contemporary Puritan writers in the Marprelate tracts allude to Dr. John Bridges, dean of Salisbury, author of *A Defence of the Government of the Church of England,* as the reputed author of *Gammer Gurton's Needle,* but he obviously could not be properly described as "Mr. S." He took his M.A. degree at Pembroke college, Cambridge, in 1560. He may possibly have been a coadjutor.

*See* Henry Bradley's essay prefixed to his edition of the play in *Representative English Comedies* (1903). The piece is also reprinted in Dodsley's *Old Plays* (vol. 1., 1744; vol. 2., 1780); in *Ancient British Drama* (1810), vol. 1.; and in J. M. Manley's *Specimens of the Pre-Shakespearean Drama* (Boston, U.S.A., 1897). *See* also H. F. B. Brett-Smith's edition of *Gammer Gurton's Needle* (Percy Reprints, 1920).

**STEVENS POINT,** a city of central Wisconsin, U.S.A., on the Wisconsin river; the county seat of Portage county. It is on Federal highways 10 and 51, and is served by the Green Bay and Western and the Soo Line railways. Pop. (1930) 13,623; in 1940 it was 15,777. The village was incorporated in 1847 and was chartered as a city in 1858.

**STEVENSTON,** manufacturing town and parish of Ayrshire, Scotland. Pop. (1931) 7,879. It is situated about 1 mi. from Saltcoats on the coast of the Firth of Clyde, 29 m. S.W. of Glasgow by the L.M.S. railway. There are coal-mines, large ironworks and foundries, and, along the shore, the works of Nobel's Explosives company. Pop. of civil parish (1931) 11,572.

**STEVINUS, SIMON** (1548–1620), Dutch mathematician, was born in 1548 at Bruges and died in 1620 at The Hague or in Leyden. He was director of the "waterstaet," and afterwards quartermaster-general. Stevinus was known to his contemporaries by his military methods and inventions; he invented defence by a system of sluices which was of great importance in the Netherlands. He also invented a carriage with sails which was used on the seashore and carried 26 passengers.

In his *Statics and Hydrostatics* (Leyden, 1586) he enunciated the important theorem of the triangle of forces. This gave a new impetus to the study of statics, which had previously been founded on the theory of the lever. He discovered the hydrostatic paradox that the downward pressure of a liquid is independent of the shape of the vessel, and depends only on its height and base.

In 1586 he published a pamphlet of a few pages, the French translation of which is entitled *La Disme enseignant facilement expédier par Nombres Entiers sans rompuz tous Comptes se rencontrans aux Affaires des Hommes.* In this he treated decimal fractions. Decimal fractions and fractions had been employed for the extraction of square roots some five centuries before his time, but nobody before Stevinus established their daily use. He declared the universal introduction of decimal coinage, measures and weights to be only a question of time. His notation is rather unwieldy. He printed little circles round the exponents of the different powers of one-tenth. For instance, $237\frac{578}{1000}$ was printed

237 ⓪ 5 ① 7 ② 8 ③; and the fact that Stevinus meant those encircled numerals to denote mere exponents is evident from his employing the same sign for powers of algebraic quantities, *e.g.*, 9 ④ − 14 ③ + 6 ① − 5 to denote $9x^4-14x^3+6x-5$.

A number of his writings were translated into Latin by W. Snellius. There are two complete editions in French of his works (Leyden, 1608 and 1634) by Albert Girard. *See* Steichen, *Vie et travaux de Simon Stevin* (Brussels, 1846); M. Cantor, *Geschichte der Mathematik.*

**STEWART, STUART** or **STEUART,** the surname of a family which inherited the Scottish and ultimately the English crown. Their descent is traced to a Breton immigrant, Alan the son of Flaald, which Flaald was a brother of Alan, steward (or seneschal) of Dol in Brittany. This elder Alan, whose name occurs in Breton documents before 1080, went on crusade in 1097, and was apparently succeeded by his brother Flaald, whose son, the younger Alan, enjoyed the favour of Henry I., who bestowed on him Mileham and its barony in Norfolk, where he founded Sporle Priory. By the daughter of Ernulf de Hesdin (in Picardy), a Domesday baron, he was father of at least three sons: Jordan, who succeeded to the family office of steward of Dol; William, who inherited Mileham and other estates in England, and who founded the great baronial house of Fitz Alan (afterwards earls of Arundel); and Walter, who was made by David I. steward (*dapifer*) or seneschal of Scotland. The Scottish king conferred on Walter various lands in Renfrewshire, including Paisley, where he founded the abbey in 1163. Walter, his grandson, third steward, was appointed by Alexander II. justiciary of Scotland, and, dying in 1246, left four sons and three daughters. The third son, Walter, obtained by marriage the earldom of Menteith, which ultimately came by marriage to Robert, duke of Albany, son of Robert II. Alexander, fourth steward, the eldest son of Walter, third steward, inherited by his marriage with Jean, granddaughter of Somerled, the islands of Bute and Arran, and on Oct. 2, 1263 led the Scots against Haakon IV., king of Norway, at Largs. He had two sons, James and John. The latter, who commanded the men of Bute at the battle of Falkirk in 1298, had seven sons: (1) Sir Alexander, whose grandson George became in 1389 earl of Angus, the title afterwards passing in the female line to the Douglases, and in 1761 to the duke of Hamilton; (2) Sir Alan of Dreghorn, ancestor of the earls and dukes of Lennox, from whom Lord Darnley, husband of Queen Mary, and also Lady Arabella Stuart, were descended; (3) Sir Walter, who obtained the barony of Garlies, Wigtownshire, from his uncle John Randolph, earl of Moray, and was the ancestor of the earls of Galloway, younger branches of the family being the Stewarts of Tonderghie, Wigtownshire, and also those of Physgill and Glenturk in the same county; (4) Sir James, who fell at Dupplin in 1332, ancestor of the lords of Lorn, on whose descendants were conferred at different periods the earldoms of Athole, Buchan and Traquair, and who were also the progenitors of the Stewarts of Appin, Argyllshire, and of Grandtully, Perthshire; (5) Sir John, killed at Halidon Hill in 1333; (6) Sir Hugh, who fought under Edward Bruce in Ireland; and (7) Sir Robert of Daldowie, ancestor of the Stewarts of Allanton and of Coltness. James Stewart, the elder son of Alexander, fourth steward, succeeded his father in 1283, and, after distinguishing himself in the wars of Wallace and of Bruce, died in 1309. His son Walter, sixth steward, who had joint command with Sir James Douglas of the left wing at the battle of Bannockburn, married Marjory, daughter of Robert the Bruce, and during the latter's absence in Ireland was entrusted with the government of the kingdom. He died in 1326, leaving an only son, who as Robert II. ascended the throne of Scotland in 1371. Sir Alexander Stewart, earl of Buchan, fourth son of Robert II., who earned by his ferocity the title of the "Wolf of Badenoch," inherited by his wife the earldom of Ross, but died without legitimate issue, although from his illegitimate offspring were descended the Stewarts of Belladrum, of Athole, of Garth, of Urrard and of St. Fort. On the death of the "Wolf of Badenoch" the earldom of Buchan passed to his brother Robert, duke of Albany, also earl of Fife and earl of Menteith, but these earldoms were forfeited on the execution of his son Murdoch in 1425, the earldom of Buchan again, however, coming to the house of Stewart in the person of James, second son of Sir James Stewart, the black knight of Lorn, by Joan or Joanna, widow of King James I. From Murdoch, duke of Albany, were descended the Stewarts of Ardvoirlich and other families of the name in Perthshire, and also the Stuarts of Inchbreck and Laithers, Aberdeenshire. From a natural son of Robert II. were descended the Steuarts of Dalguise, Perthshire, and from a natural son of Robert III. the Shaw Stewarts of Blackhall and Greenock. The direct male line of the royal family terminated with the death of James V. in 1542, whose daughter Mary was the first to adopt the spelling "Stuart." Mary was succeeded in her lifetime in 1567 by her only son James VI., who through his father Lord Darnley was also head of the second branch, there being no surviving male issue of the family from progenitors later than Robert II. In James V., son of James IV. by Margaret, daughter of Henry VII., the claims of Margaret's descendants became merged in the Scottish line, and on the death of Queen Elizabeth of England, the last surviving descendant of Henry VIII., James VI. of Scotland, lineally the nearest heir, was proclaimed king of England, in accordance with the arrangements made by Lord Burghley and Elizabeth's other advisers. The accession of James was, however, contrary to the will of Henry VIII., which favoured the heirs of his younger sister Mary, wife of Charles Brandon, duke of Suffolk.

By the usurpation of Cromwell the Stuarts were excluded from the throne from the defeat of Charles I. at Naseby in 1645 until the restoration of his son Charles II. on May 8, 1660. On the death of Charles II. without issue in 1685, his brother James, duke of York, ascended the throne as James II., but he so alienated the sympathies of the nation by his unconstitutional efforts to further the Roman Catholic religion that an invitation was sent to the prince of Orange to come "to the rescue of the laws and religion of England." Next to the son of James II., still an infant under his father's control, Mary, princess of Orange, elder daughter of James II., had the strongest claim to the crown; but the claims of the prince of Orange also, even apart from his marriage, were not very remote, since he was the son of Mary, eldest daughter of Charles I. The marriage had strengthened the claims of both, and they were proclaimed joint sovereigns of England on Feb. 12, 1689, Scotland following the example of England on April 11. They left no issue, and the Act of Settlement, passed in 1701, excluding Roman Catholics from the throne, secured the succession to Anne, second daughter of James II., and on her death without issue (1714) to the Protestant house of Hanover, descended from the princess Elizabeth, daughter of James I., wife of Frederick V., count palatine of the Rhine. George, elector of Hanover, eldest son of Sophia (youngest child of the princess Elizabeth), and Ernest, elector of Brunswick-Lüneburg, or Hanover, became sovereign of Great Britain and Ireland. The female issue of James II. ended with the death of Anne. James, called James III. by the Jacobites and the Old Pretender by the Hanoverians, had two sons—Charles Edward, the Young Pretender, who died without legitimate issue in 1780, and Henry Stuart, titular duke of York, commonly called Cardinal York, on whose death in 1807 the male line of James II. came to an end. Henry was also the last descendant in the lineal male line of any of the crowned heads of the race, so far as either England or Scotland was concerned. In the female line, however, there are among the descendants of James I. representatives of the royal Stuarts who are senior to the house of Hanover, for Philip, duke of Orleans (brother of Louis XIV.), married, as his first wife, Henrietta, daughter of Charles I., and, as his second, Charlotte, granddaughter and heiress of the princess Elizabeth (daughter of James I.). By the former, through their daughter, the queen of Sardinia, he was ancestor, among others, of the princess Maria Theresa of Bavaria, who in 1910 was "heir of line" of the house of Stuart, her eldest son, Prince Rupert, being at that time heir to the throne of Bavaria.

The best chart pedigree of the house is that which was prepared for the Stuart Exhibition by W. A. Lindsay.

**STEWART, SIR DONALD MARTIN** (1824–1900), British field marshal, son of Robert Stewart of Forres, Elginshire, was born at Mount Pleasant, near Forres, on March 1, 1824. He entered the Bengal army in 1840, and served in 1854 and 1855 in the frontier expeditions against the Mohmands, and Afridis Aka and Bari Khel (medal and clasp). In the Indian Mutiny in 1857 Stewart, after a famous ride from Agra to Delhi with despatches, served on the staff at the siege and capture of Delhi and Lucknow, and afterwards through the campaign in Rohilkhand. For nine years he was assistant and deputy-adjutant-general of the Bengal army, commanded the Bengal brigade in the Abyssinian expedition in 1867, and became a major-general in 1868. He reorganized the penal settlement of the Andaman Islands, where he was commandant when Lord Mayo was assassinated, and, after holding the Lahore command, was promoted lieutenant-general in 1877, and commanded the Kandahar field force in the Afghan War in 1878. On hearing of the Maiwand disaster he despatched Roberts with a division on his celebrated march from Kabul to Kandahar, and himself led the rest of the army back to India by the Khyber Pass. Promoted general in 1881, he was for five years commander-in-chief in India, and afterwards member of the council of the secretary of state for India until his death. He was promoted to be field marshal in 1894, and appointed governor of Chelsea Hospital in 1895. He died at Algiers on March 26, 1900.

*See* G. R. Elsmie, *Sir Donald Stewart* (1903).

**STEWART, DUGALD** (1753–1828), Scottish philosopher, was born in Edinburgh on Nov. 22, 1753. His father, Matthew Stewart (1715–1785), was professor of mathematics in the university of Edinburgh (1747–1772). Dugald Stewart was educated at Edinburgh and Glasgow. At 19 he acted as substitute for his father in the chair of mathematics at Edinburgh. From 1785 to 1820 he was professor of moral philosophy in the university, though he retired from the active duties of the chair after the death (1809) of his second son, which was a great blow to him. He died at Edinburgh on June 11, 1828.

Stewart's principal work is *Elements of the Philosophy of the Human Mind* (3 vols. 1792, 1814, 1827). He also wrote *Philosophical Essays* (1810), and *The Philosophy of the Active and Moral Powers* (1828). His philosophical views are mainly the reproduction of those of his master Reid.

**STEWART, SIR HERBERT** (1843–1885), British soldier, born on June 30, 1843, at Sparsholt, Hampshire, was educated at Winchester and entered the army in 1863. Returning from service in India in 1873, he entered the staff college and the Inner Temple. He served in South Africa in the Zulu War and against Sikukuni, and was present at Majuba (1881), where he was made prisoner for a month. In Aug. 1882 he was placed on the staff of the cavalry division in Egypt, and took possession of Cairo after Tel-el-Kebir (Sept. 13, 1882). In 1884 he commanded the cavalry under Sir Gerald Graham at Suakin. For his services in Egypt he was made K.C.B., and was assistant adjutant and Q.M.G. in the south-eastern district in England (April–Sept. 1884). He then joined the expedition for the relief of Khartoum, and commanded the relief column sent by Lord Wolseley across the desert of Metemma. On Jan. 17, 1885, he repulsed an enemy charge near Abu Klea. He was promoted major-general, but died on the way back from Khartoum to Korti, on Feb. 16, 1885, and was buried near the wells of Jakdul.

**STEWART, WILLIAM** (*c.* 1480–*c.* 1550), Scottish poet and translator, descendant of one of the illegitimate sons of Alexander Stewart, earl of Buchan, the "Wolf of Badenoch," was a member of the university of St. Andrews. He was in orders, and a hanger-on at the court of James V. Portions of his minor verse are preserved in the Bannatyne and Maitland Folio MSS. His chief work is a metrical translation of Hector Boece's *History*, in obedience to the command of James V., who entrusted Bellenden with its translation into Scots prose.

Stewart's version remained in ms. till 1858, when it was edited by W. Turnbull for the "Rolls Series" (3 vols.). The ms. is now in the library of the university of Cambridge.

**STEWART, SIR WILLIAM** (*c.* 1540–*c.* 1605), Scottish politician, began life as a soldier in the Netherlands, where he became a colonel. In 1582 he was in Scotland, where James VI. made him captain of his guard. Having visited the English court in the king's interest in 1583, Stewart helped to free James from William Ruthven, earl of Gowrie, and to restore James Stewart, earl of Arran, to power; he was made a privy councillor and for a time assisted Arran to govern Scotland. In 1584 he captured Gowrie at Dundee. In 1594 he was knighted and was given lands at Houston. He died before 1606.

**STEWART, WILLIAM DOWNIE** (1878– ), New Zealand politician and publicist, was born at Dunedin on July 29, 1878, his father being a member of the legislative council. In 1914 he entered parliament as member for Dunedin West, holding this seat from 1919 to 1935 after his political career had been interrupted by a period of war service with the Otago regiment in 1916–17. He was minister of customs 1921–28, of internal affairs 1921–24, of industries and commerce 1923–26, of finance 1926–28 and 1931–33, and attorney-general and acting prime minister in 1926. He is joint author (with Professor Le Rossignol) of *State Socialism in New Zealand* (1910).

**STEYN, MARTINUS THEUNIS** (1857–1916), last president of the Orange Free State, was born at Winburg in that State on Oct. 2, 1857. He was a student in Holland and later in England at the Inner Temple, and was called to the English bar in Nov. 1882. After his return to South Africa he practised as a barrister at Bloemfontein, and in 1889 was appointed state attorney of the Free State. A few months afterwards he became second puisne judge, and in 1893 first puisne judge of the high court. His decisions won him a reputation for ability and sound judgment. In 1895, upon the resignation of President F. W. Reitz, Steyn was the candidate of the pan-Dutch party for the vacant post. The election resulted (Feb. 1896) in a decisive victory for Steyn. As president he linked the fortunes of his State with those of the Transvaal, a policy which led to the extinction of the republic. He took part in the peace negotiations at Klerksdorp in April 1902, but was prevented by illness from signing the instrument of surrender at Pretoria on May 31. In 1908–1909 he was vice-president of the Closer Union Convention, where he showed a conciliatory attitude.

**STEYNING** (stĕn'nĭng), town in Sussex, England, 12 mi. W.N.W. of Brighton by a branch of the S.R. Pop. (1931) 1,885. The church of St. Andrew retains a series of Norman pier-arches in the nave. The Anglo-Saxon church of Steyning mentioned in Domesday is attributed to St. Cuthman, who is said to have settled here before the 9th century, and whose shrine became a resort for pilgrims. In 1086 Steyning was a thriving port, with a market, a mint and two churches. Its decay began in the 14th century owing to the recession of the sea, and it received another blow in the suppression of its priory by Henry IV.

**STEYR,** a town in Upper Austria at the junction of the Steyr with the Enns, seized by Germany in 1938. It is an old town, dominated by a 10th century castle. Two important new suburbs, Steyrdorf and Ennsdorf, lie across the streams. Steyr is a centre of the iron and steel industry. Pop. (1939) 44,821.

**STIBNITE,** a mineral consisting of antimony sulphide, $Sb_2S_3$, occurring as bladed or acicular orthorhombic crystals; an important ore of antimony. It was mentioned by Dioscorides and Pliny under the names *stimmi, stibi* and *platyophthalmon* (πλατυόφθαλμον); the last name refers to the use which the ancients made of the powdered mineral for darkening the eyebrows to increase the apparent size of the eyes. The Arabic name *al-kohl* (now strangely corrupted to *alcohol*) had reference to the same use. Antimonite is also a common name for this species.

The crystals are prismatic in habit, deeply furrowed longitudinally, and usually terminated by acute pyramidal planes. There is a perfect cleavage (010) parallel to the length of the crystals, and the basal plane (001) is a plane of gliding; the latter gives rise to very characteristic transverse striations or nicks on the cleavage surfaces of crystals which have been bent. The colour is lead-grey, and the lustre metallic and brilliant; crystals become dull on prolonged exposure to light. Cleavage flakes of extreme thinness transmit a small amount of red light, but are more transparent for heat rays. The mineral is quite soft (H=2), and has a specific gravity of 4·6. Stibnite occurs with quartz in beds and veins in gneisses and schists, or with blende, galena, etc., in metalliferous veins. Magnificent groups of brilliant crystals, up to 20 in. in length, were formerly abundant in the antimony mine of Ichinokawa, on Shikoku island, Japan. Large, but dull, crystals have also been found at Lubilhac in Haute-Loire, France. Prismatic and acicular crystals often penetrating tabular crystals of barytes, are common at Baia Sprie in Rumania (formerly Felsőbánya, Hungary). (L. J. S.)

**STICK-INSECT,** an insect of the family Phasmatidae (*see* ORTHOPTERA), so named because of a resemblance to twigs of trees and shrubs, upon which most phasmids live and feed. The body and legs are long and slender, and the protective resemblance to twigs is enhanced by the usually brown, gray or green coloration and the immobile attitudes assumed. Some species are further protected by an armature of sharp spines. Many are wingless; when winged the tegmina are short, but the hind wings are often large and beautifully coloured, though usually kept folded over the abdomen. As in the leaf-insects (*q.v.*), to which phasmids are closely allied, the eggs closely resemble seeds. Stick-insects attain their largest size and greatest profusion of species in the tropics, one Australian species, *Palophus titan,* reaching a length of 10 in. A few smaller forms occur in southern Europe, and 25 species are known from the United States, among them *Diapheromera femorata,* which sometimes defoliates oak forests. Phasmids freely regenerate amputated legs and antennae; under certain conditions the stump of an antenna will regenerate a leg (*see* REGENERATION IN ANIMALS). (T. H. Hl.)

**STICKLEBACK,** a group of small fishes (*Gasterosteus*) which inhabit the fresh and brackish waters as well as the coasts of the temperate zone of the northern hemisphere. The majority have a compressed well-proportioned body, which in the marine species is of a more elongate form. Their mouth is of moderate width, oblique, and armed with small teeth. The head is protected by hard bone. There are a series of scutes protecting the sides. The first dorsal fin and the ventrals are transformed into pointed formidable spines, and joined to firm bony plates of the endoskeleton. A remarkable degree of variability is shown by many species. Sticklebacks construct a nest for the reception of the spawn, which is jealously guarded by the male until the young are hatched, from ten to eighteen days after oviposition. He also protects them for the first few days of their existence.

Sticklebacks are short-lived animals said to reach an age of three or four years. In spring each male selects a territory, which he fiercely defends and to which he invites all females, until the nest is filled with ova. At this period he assumes a dress of blue and red. The eggs are comparatively large, one female depositing from 50 to 100.

The three-spined stickleback (*G. aculeatus*) is found everywhere in northern and central Europe, northern Asia, and North America. The ten-spined stickleback (*G. pungitius*) is smaller than the three-spined species, rarely exceeding 2 in. in length. Its geographical range nearly coincides with that of the other species. The sea-stickleback (*Spinachia spinachia*) attains a length of 7 in., and is armed with 15 short spines. It is common round the British coasts. At suitable localities which are sheltered from the waves and overgrown with seaweed, especially in rock pools and shallows covered with *Zostera,* one or two males establish themselves with their harems. The elaborate nest is constructed by binding together suitable fronds of seaweed.

**STIGAND** (d. 1072), archbishop of Canterbury, is first mentioned in 1020. He was then chaplain to Canute and afterward to his son, Harold Harefoot, and after the death of Canute appears to have acted as the chief adviser of his widow, Emma. In 1043 he was consecrated bishop of Elmham and in 1047 was translated to Winchester; he supported Earl Godwine in his quarrel with Edward the Confessor, and in 1052 arranged the peace between the earl and the king. In this year the archbishop of Canterbury, Robert of Jumièges, having been outlawed, Stigand was appointed to the archbishopric; but Pope Leo IX. and his two successors refused to recognize him. In 1058, however, Benedict X. gave him the pall, but this pope was deposed in the following year. Stigand is said by Norman writers to have crowned Harold in Jan. 1066; but this ceremony was probably performed by Aldred, archbishop of York. Stigand submitted to William, and assisted at his coronation. But the Conqueror was anxious to get rid of him. In 1070 he was deposed by the papal legates and was imprisoned at Winchester, where he died, probably on Feb. 22, 1072. Stigand was an avaricious man and a great pluralist, holding the bishopric of Winchester after he became archbishop of Canterbury, in addition to several abbeys.

*See* E. A. Freeman, *The Norman Conquest* (1870–76), vols. ii., iii. and iv.; and J. R. Green, *The Conquest of England* (1899), vol. ii.

**STIGMATIZATION,** the impression of *stigmata.* Originally, the process of marking or branding slaves and criminals.

The apostle Paul is the first to speak of stigmata in a religious sense. He reminds the Galatians of the distinctive "marks (*stigmata*) of the Lord Jesus" in opposition to the old mark of circumcision: "I bear the marks of the Lord Jesus in my body" (Gal. 6:17). Paul's stigmata were scars of wounds received during his apostolate from persons opposed to his preaching (II Cor. 11:24 f.).

Specifically, stigmatization is a phenomenon observed in a number of Christian saints and mystics for which no satisfactory natural explanation has been offered as yet. It consists of the appearance, on the body of a living person, of wounds or scars corresponding to those of the crucified Christ.

The first and most celebrated stigmatization of this kind is that of St. Francis of Assisi (1181–1226). His biographers, Thomas of Celano, St. Bonaventure and other contemporaries tell us that early one morning, Sept. 14, 1224, while Francis was praying on mount La Verna, a six-winged seraph appeared to him bearing between his wings the form of one crucified and clearly the figure of Christ. When the apparition vanished, a great love of God was felt in Francis' soul and in his body there appeared an impression of the wounds of the Lord Jesus. The reproduction of a lance-wound, fresh and bleeding, was seen on his side, whence thereafter blood came out, on many occasions staining his garments. His hands and feet seemed perforated in the middle. Pope Alexander IV and many other witnesses declared that they had seen the stigmata both before and after his death.

According to Dr. A. Imbert-Gourbeyre, up to 341 cases of stigmatization have been recorded after the time of St. Francis. In 300 cases, the stigmatized person was a woman. Better known stigmatists of modern times are: Catherine Emmerich of Muenster, (1774–1824); Mary von Möerl of Kaltern, Tyrol, (1812–68); Louise Lateau of Bois de Haine, (1850–83). Two renowned cases of stigmatization belong to the 20th century, those of Gemma Galgani of Lucca, Italy, (1878–1903) and of Theresa Neumann of Konnersreuth, Germany. Gemma is the last stigmatist to be canonised by the Roman Catholic Church (May 2, 1940). However, she was declared a saint not on account of her stigmata but for her heroic virtue. Gemma received the stigmata on June 8, 1899. In addition to the wounds in her hands, feet and side, she experienced also the stigmata of the crown of thorns and those of the flagellation. Her stigmata were not permanent but recurrent, reappearing ordinarily every Friday.

The case of Theresa Neumann attracted the attention of scholars and scientists for several years. Born on Good Friday, April 8, 1898, she received the first stigmata on the upper surface of her hands and feet on Good Friday, April 2, 1926. On this occasion, her eyes began to bleed profusely, a phenomenon that used to occur whenever she meditated on Christ's suffering. Stigmata on the lower surface of her hands and feet appeared on the fol-

lowing Good Friday, April 15, 1927, and in subsequent years those on her side, shoulder and brow became manifest. They were witnessed by thousands within the first decade of their appearance and became an object of study and investigation (*Muenchener medicinische Wochenschrift,* Nov. 18, 1927). It has been often observed that real stigmata cannot be cured, that the wounds remain fresh and show no sign of suppuration even after months and years of exposure.

**STILBENE,** a glistening colourless crystalline hydrocarbon melting at 124° C, and boiling at 306° C, and soluble in alcohol or ether. It is prepared either by the action of sodium on benzylidene (benzal) chloride, $C_6H_5{\cdot}CHCl_2$, or by passing toluene over heated lead oxide. Stilbene is symmetrical diphenylethylene, $C_6H_5{\cdot}CH{:}CH{\cdot}C_6H_5$, and many of its derivatives are known to exist in two structural forms exhibiting stereoisomerism of the type shown by fumaric and maleic acids. It is chiefly of interest as being the basis of several important synthetic dyes. *Stilbene azo-dyes,* 4:4′-Diaminostilbene-2:2′-disulphonic acid, $NH_2{\cdot}C_6H_3(SO_3H)CH{:}CH{\cdot}C_6H_3(SO_3H){\cdot}NH_2$, prepared from *para*-nitrotoluene*ortho*sulphonic acid by successive treatment with aqueous caustic soda and alkaline zinc dust, when diazotised and coupled with β-naphthylamine and its sulphonic acids, furnishes substantive cotton dyes known as Hessian Purples M.

*Stilbene colours.*—Various cotton yellows and oranges are obtained by boiling *p*-nitrotoluene-*o*-sulphonic acid with aqueous caustic soda alone (Chlorazol yellow), in the presence of oxidisable substances such as glycerol, sodium sulphite, or gallic acid (Chlorazol Fast Orange) or with oxidising agents such as sodium hypochlorite (Chlorazol Fast Yellow).

*Diphenylacetylene* or *tolane,* $C_6H_5{\cdot}C{:}C{\cdot}C_6H_5$, colourless crystals melting at 60° C, results from the action of alcoholic potash on stilbene dibromide. (G. T. M.)

**STILBITE,** a mineral of the zeolite group consisting of hydrated calcium aluminium silicate, $CaAl_2(SiO_3)_6{+}6H_2O$. Usually a small proportion of the calcium is replaced by sodium. Crystals are monoclinic, and are invariably twinned, giving rise to complex groups and characteristic sheaf-like aggregates. The colour is usually white, sometimes red, and on the perfect cleavage (parallel to the plane of symmetry) the lustre is markedly pearly; hence the name stilbite (Gr. *στίλβειν,* to shine) given by R. J. Haüy in 1796. After the separation of heulandite from this species in 1818, the name desmine (*δέσμη,* a bundle) was proposed, and this name is now employed in Germany. The hardness is 3·5 and the specific gravity 2·2. Stilbite occurs with other zeolites in the amygdaloidal cavities of basic volcanic rocks; it is sometimes found in granite and gneiss, and exceptionally in metalliferous veins. Beautiful, salmon-pink crystals occur with pale green apophyllite in the Deccan traps near Bombay and Poona; white sheaf-like groups encrust the calcite (Iceland-spar) of Berufjord near Djupivogr, Iceland; and crystals of a brick-red colour are found at Old Kilpatrick, Dumbartonshire.

**STILES, EZRA** (1727–1795), American clergyman and educationalist, seventh president of Yale college, was born on Nov. 29, 1727 in North Haven, a parish of New Haven (Connecticut). He graduated at Yale in 1746; was licensed to preach in 1749 and was a tutor at Yale in 1749–55. He also preached in 1750 to the Indians at Stockbridge, was admitted to the bar in 1753, and practised in New Haven for two years. After pastorates at Newport (R.I.) and Portsmouth (N.H.) he became in 1778 president of Yale college and professor of ecclesiastical history, becoming for a few years after 1780 professor of divinity and lecturing on many subjects. He died in New Haven on May 12, 1795. His wise administration as president made possible the speedy recovery of Yale college after the War of Independence; his intellectual and theological breadth helped to secularize and strengthen the college. He carefully kept thermometric and meteorological statistics; he imported silkworms and books on silk culture; he corresponded with many litterati; he undertook the study of Hebrew at the age of 40 and became an able scholar; in short, his hunger for knowledge was insatiable. On Franklin's recommendation he was made a doctor of divinity by the University of Edinburgh in 1765, and he was awarded other honorary degrees in his own country. Dr. Stiles published a number of sermons, an *Account of the Settlement of Bristol, Rhode Island* (1785); and a *History of Three of the Judges of King Charles I.* (1794). His *Literary Diary* (3 vol., 1901) was edited by F. B. Dexter, who quotes largely from Dr. Stiles's *Itineraries. Extracts from the Itineraries and Other Miscellanies* with selections from Dr. Stiles's correspondence prepared by the same editor appeared in 1916. Both give a valuable picture of New England life and contemporary figures.

*See* the *Life of Ezra Stiles* (1798), by his daughter's husband, Abiel Holmes, the father of Oliver Wendell Holmes, and the life by J. L. Kingsley in Jared Sparks, *American Biography* (ser. 2, vol. vi., 1845).

**STILICHO, FLAVIUS** (?–408), Roman general and statesman, was the son of a Vandal who had served as an officer in the army of the emperor Valens (364–378). He himself entered the imperial army at an early age and speedily attained high promotion. He had already become master of the horse when in 383 he was sent by Theodosius (379–395) at the head of an embassy to the Persian king, Sapor III. His mission was very successful, and soon after his return he was made count of the domestics and received in marriage Serena, the emperor's niece and adopted daughter. In 385 he was appointed master of the soldiery in Thrace, and shortly afterwards directed energetic campaigns in Britain against Picts, Scots and Saxons, and along the Rhine against other barbarians. Stilicho and Serena were named guardians of the youthful Honorius when the latter was created joint emperor in 394. Rivalry had already existed between Stilicho and Rufinus, the praetorian praefect of the East. Consequently in 395, after a successful campaign against the Germans on the Rhine, Stilicho marched east, with the design of displacing Rufinus; and by connivance with the barbarians he procured the assassination of Rufinus at the close of the year, and thereby became virtual master of the empire. In 396 he fought in Greece against the Visigoths, but an arrangement was effected whereby their chieftain Alaric was appointed master of the soldiery in Illyricum (397). In 398 he quelled Gildo's revolt in Africa and married his daughter Maria to Honorius. Two years later he was consul. He thwarted the efforts of Alaric and Radagaisus to seize lands in Italy by his victories on the Danube at Pollentia and Verona in 401–3.

In a second campaign against Radagaisus, who led a large force of various Germanic peoples into Italy in 405, he surrounded the barbarian chieftain on the rocks of Fiesole and starved him into surrender. Early in 408 he married his second daughter Thermantia to Honorius. It was rumoured about this time that Stilicho was plotting with Alaric and with Germans in Gaul and taking other treasonable steps in order to make his own son Eucherius emperor. The facts are doubtful. It is certain, however, that he was suspected by Honorius and abandoned by his own troops, and that he fled to Ravenna, and, having been induced by false promises to quit the church in which he had taken sanctuary, was executed on Aug. 23, 408.

The principal sources for the life of Stilicho are the histories of Zosimus and of Orosius and the flattering verses of Claudian. *See* T. Hodgkin, *Italy and her Invaders,* vols. i. and ii. (Oxford, 1880); E. Gibbon, *Decline and Fall of the Roman Empire,* edited by J. B. Bury, vol. iii. (1902); P. Villari, *The Barbarian Invasions of Italy,* translated by L. Villari, vol. i. (New York, 1902); S. Dill, *Roman Society in the last century of the Western Empire* (1899); Mommsen in *Hermes* xxviii.; and K. Birtin, *Spätrömische Charakterbilder* (Leipzig, 1919).

**STILL, ANDREW T.** (1828–1917), founder of osteopathy, was born in Jonesville, Va., on Aug. 6, 1828. His family moved in 1837 to Macon county, Missouri, and later to the Shawnee

reservation near Kansas City, Kansas. Still took an active part in the slave question in Kansas, and in 1857 was elected to the Kansas Territorial legislature on the Free State ticket. He began searching for other means than medicine to combat disease and formulated his principles of osteopathy in 1874. He underwent a long period of opposition, but finally, in 1892, founded the American School of Osteopathy at Kirksville, Mo., in conjunction with William Smith, a Scottish physician. In 1922 the Andrew T. Still College of Osteopathy and Surgery was founded and merged with the original American school. He was the author of *The Philosophy of Osteopathy* (1899), *Autobiography of Andrew T. Still* (1897) and *Osteopathy, Research and Practice* (1910).

*See* "Andrew T. Still," *Missouri Historical Review*, vol. xix., 1924, by Ray G. Hulburt; E. R. Booth, *History of Osteopathy*.

**STILL, JOHN** (1543?–1608), bishop of Bath and Wells, was born at Grantham, Lincs. He studied at Christ's college, Cambridge. He was appointed in 1570 Lady Margaret professor of divinity, subsequently held livings in Suffolk and Yorkshire, and was master successively of St. John's College (1574) and of Trinity College (1577). Still was vice-chancellor of his university in 1575–76 and again in 1592–93, and was raised to the bishopric of Bath and Wells in 1593. He died on Feb. 26, 1608, leaving a large fortune from lead mines discovered in the Mendip Hills. He was for some time generally believed to be the author of the English comedy *Gammer Gurton's Needle,* which is now ascribed to William Stevenson (*q.v.*)

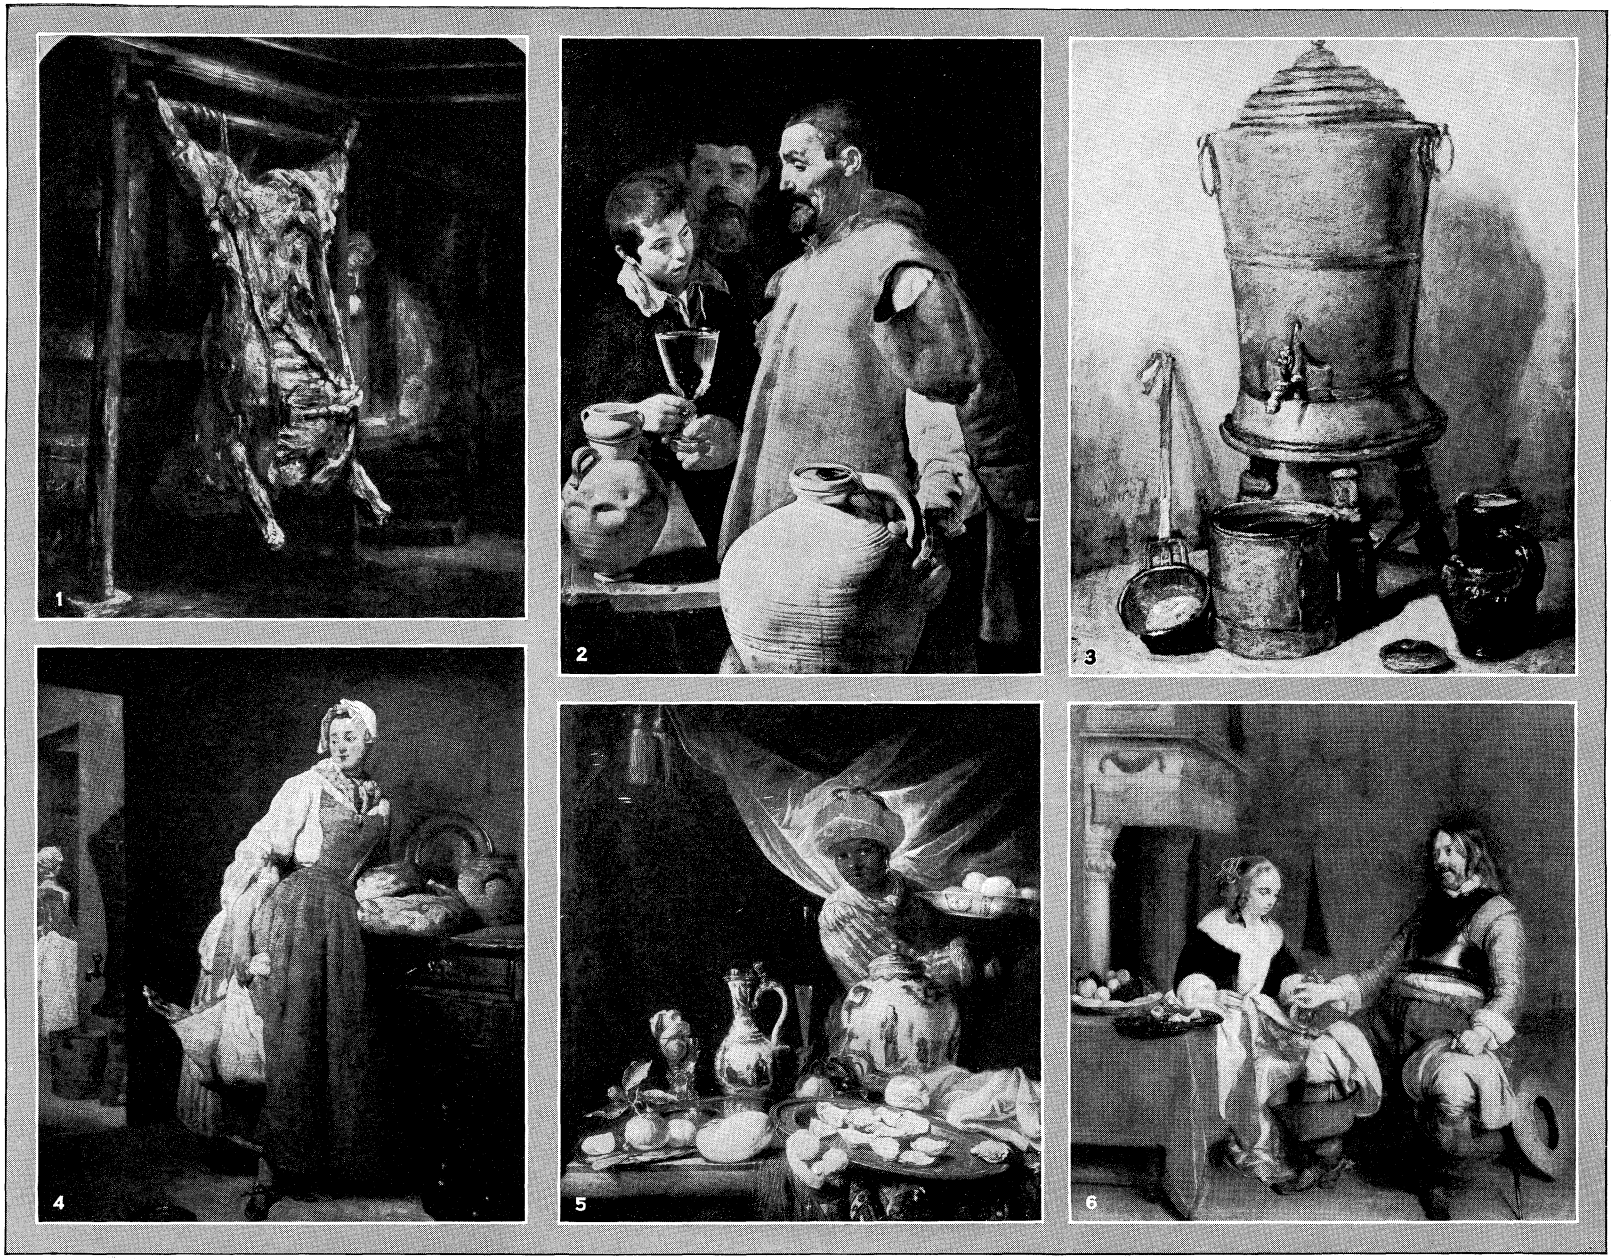
**STILL ENGINE:** *see* INTERNAL COMBUSTION ENGINES.

**STILLINGFLEET, EDWARD** (1635–1699), English divine, was born at Cranborne, Dorset, on April 17, 1635. He graduated from St. John's college, Cambridge, in 1652, and in the following year was elected to a fellowship. At Sutton, Beds., of which he was vicar, he published (1659) his *Irenicum* in which he sought to give expression to the prevailing weariness of the faction between Episcopacy and Presbyterianism, and to find some compromise. He looks upon the form of church government as non-essential, but condemns Nonconformity. Although in 1680 he published his *Unreasonableness of Separation,* his willingness to serve on the ecclesiastical commission of 1689, and the interpretation he then proposed of the damnatory clauses of the Athanasian creed, are proof that to the end he leaned towards toleration. His rapid promotion dates from 1662, when he published *Origines sacrae, or a Rational Account of the Christian Faith as to the Truth and Divine Authority of the Scriptures and the Matters therein contained.* In 1665 the earl of Southampton presented him to St. Andrew's, Holborn, two years later he became prebendary of St. Paul's, in 1668 chaplain to Charles II., in 1670 canon residentiary, and in 1678 dean of St. Paul's. He was also preacher at the Rolls Chapel and reader at the Temple. Finally he was consecrated bishop of Worcester on Oct. 13, 1689. During these years he was ceaselessly engaged in controversy with Nonconformists, Romanists, Deists and Socinians. His various learning, his dialectical expertness, and his massive judgment, rendered him a formidable antagonist; but the respect entertained for him by his opponents was chiefly aroused by his recognized love of truth. The range of his learning is most clearly seen in his *Bishop's Right to Vote in Parliament in Cases Capital.* His *Origines Britannicae, or Antiquities of the British Church* (1685), is a strange mixture of critical and uncritical research. In his closing years he had some controversy with John Locke, whom he considered to have impugned the doctrine of the Trinity. He died at Westminster on March 28, 1699. His manuscripts were bought by Robert Harley, afterwards Earl of Oxford.

A collected edition of his works, with life by Richard Bentley, was published in London, 6 vols. (1710); and a useful edition of *The Doctrines and Practices of the Church of Rome Truly Represented* was published in 1845 by William Cunningham.

**STILL-LIFE PAINTING,** the art of painting inanimate objects for their beauty of colour, line or arrangement. It was first developed as an individual branch of easel painting by the artists of the Netherland school of painters. Families of artists chose this simple line of art for their life's work. Gold and silver cups, flagons and plates of porcelain and delft, oriental rugs and draperies, Venetian and Bohemian glass richly ornamented, and even jewels, scientifically arranged for scintillating effects, were motifs for some of the most brilliant artists. Simple kitchen utensils of brass and copper, with meat, fish and vegetables, made fine subjects for colour and line. The sparkle of metals, the glitter of wet fish, the deep and rich tones of meat and vegetables—what better material could the painter desire!

Exquisite drawing, with painstaking draughtsmanship as a primary factor, resulted in paintings that were sought not only by the rich burghers, but by visiting princes and ambassadors. In every museum may be found these masterpieces, and although not so numerous as the many rows of portraits, *genre* and religious canvases, they, nevertheless, hold their high place in Dutch art.



The Flemish and Dutch artists felt, and so did many true lovers of the fine arts of that time, that the subject of a picture was not the only motif worth while; that an arrangement beautifully composed, either for luxurious abundance or for simplicity in colour, tone, values and line, would make a noble work of art, in spite of what higher thought might find in portraying character in the portrait and deep feeling in the religious picture. They argued that a well painted still-life was a greater art production than a badly painted Madonna, however well conceived.

**Subject-matter.**—Pictures of the life of the people themselves, their houses, gardens, the interior of the splendidly furnished homes of merchants and aristocrats, rich in hangings and elaborate in table service, made beautiful settings for the painter. The everyday life of the people around the artist showed him just what he wanted. Besides, it furnished a subject that was simpler to do than the literary picture, as well as being more straightforward and true. People in silk and velvet, visiting in well-appointed rooms to listen to music or to partake of wine and cake or fruit, served on silver or choice porcelain, were none the better as subjects than a girl scouring a brass kettle in the kitchen.

That greatest part of the painter's knowledge, the observation of values, which means rendering the lights and shadows of a subject regardless of local colour, was first thoroughly understood by these artists, and is the basis of all sound painting. From the work of these men, still-life developed. The principle is the same, the interiors being to a great extent still-life. There is usually very little expression or movement needed for the figures. However well painted the heads, the clothes, even the glass of amber-coloured wine in the lady's hand, seem almost of the same interest as the head. Take the figures out and the pure still-life is the result. The simple composition of a few peaches on a piece of delft with a silver pitcher and an ornamented glass half full of wine is all that a master like Willem Kalf needs to make a supreme painting.

**Technique.**—Often in the galleries and at exhibitions, critical visitors, some of whom are professional painters, ask: "What is still-life?" Reproducing the roundness and firmness of a red apple is not very different from the modelling of a head. Lovers of painting look for something different in a canvas, something that for them means beauty or truth—and not every one sees the same beauty in a picture painted by a master. Take Velázquez' "Aguador" for an example; to the painter, a quiet study of modelling, with remarkable still-life; to one with perhaps no ability as a painter, a thoughtful study of a man's head; to another a beautiful head of a boy. Velázquez had a number of interesting still-life pictures. In "The Steward" and "Old Woman Frying Eggs," each has a single figure in the composition, but the pictures are evidently made for close studies of inanimate life, dead fish, meat, jars and glass, masses of objects, scattered all over the canvas. Rembrandt's "Flayed Ox" in the Louvre is a great example of noble quality, rich in colour, bold in treatment, closely observed in values, and of great simplicity—a masterpiece.

Pieter Aertsen, early 16th century, one of the first absolute still-life painters, although at times introducing figures in the background of some of his pictures, painted pictures of meats, vegetables, etc., in the kitchen or larder. His large canvas in Uppsala, representing a butcher-shop with a calf's head, a side of beef, a pig's head and sausages, fowl, fish and all sorts of gruesome details of what one expects to find in such a place, is typical. The canvas is overfilled, every small place is crowded, and

## STILL-LIFE PAINTINGS

1. "Flayed Ox," by Rembrandt (1606–1669). Bold treatment, rich colour, values closely observed. Now in Louvre. 2. "Aguador de Sevilla" by Velazquez (1599–1660). Quiet study of modelling. In collection of His Grace the Duke of Wellington. 3. "La Fontaine," superb canvas, one of Chardin's favourite works. Chardin (1699–1779) was able to see and reproduce beauty in simple utensils of the kitchen. In the Metropolitan Museum of Art, New York. 4. Chardin's "La Pourvoyeuse," one of the three most famous paintings by this master of still life; light, colour and harmony emphasized. Now in Louvre. 5. Still life by Emil Carlsen (1853–1932), meticulous attention paid to the small details. 6. "Le Gallant Militaire," by Ter Borch (1617–1681). Painted in the adopted style of the Dutch. Values and tonality closely observed. In Louvre

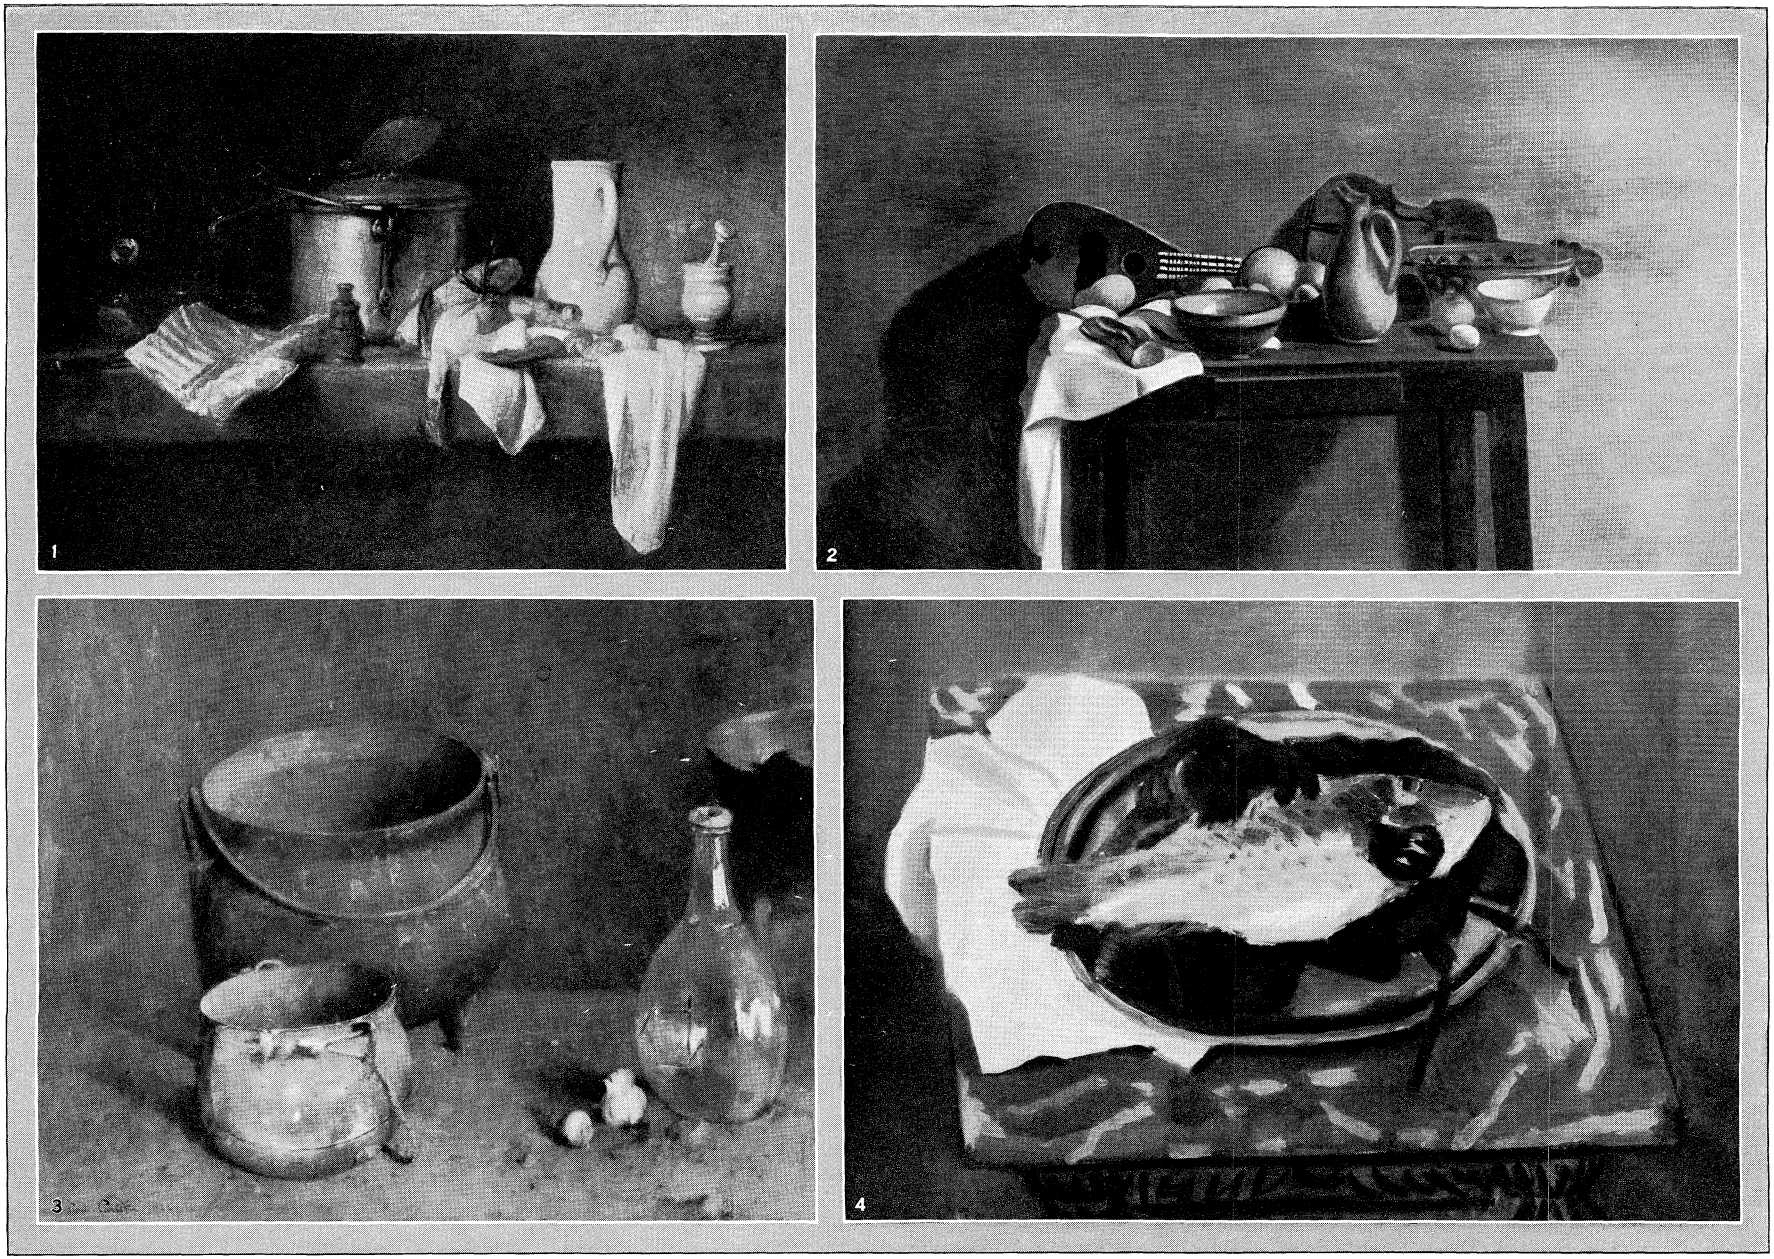
## FISH, FRUIT AND GAME



1. "Still Life" by Willem Kalf (1622–93), who needed only the simple composition of a few peaches, a pitcher and an ornamental wine glass to make a masterpiece. Dutch
2. "Large Still Life With Bird's Nest" by Jan Davidsz van Heem (c. 1600–c. 1683). Dutch. Van Heem's pictures are drawn and coloured exquisitely. His use of chiaroscuro was very effective
3. "Still Life," one of Antoine Vollon's pictures (1833-1900). French. Most of this painter's work was done in one sitting. He painted somewhat after the Dutch manner. In the Louvre
4. "Lobster, Fruit and Flowers" by Cornelius de Heem (1631–95), son of Jan Davidsz van Heem. Dutch
5. "Study of Still Life," by Frans Snyders (1579–1657). Flemish. Snyders painted many typical models of still life during the early part of his career. In the Rijks museum
6. A still life by Jean Baptiste Simeon Chardin (1699–1779) depicting a bowl of fruit and a pitcher. Every colour value is observed. Now in Phillips Memorial gallery, Washington, D.C. French
7. "Fish on a Table," a still life by Alexander Adriassen (1587–1661). German

## EXAMPLES OF STILL-LIFE ART

1. "Fruit and Game" by Jan Weenix (1640–1719), highly decorative, luxurious surroundings, garden background. Dutch. In Rijks museum
2. "Dead Game" by Jan Fyt (1609–61), pupil of Frans Snyders (1579–1657), realistic in quality of the painting of the feathers. In the Metropolitan Museum of Art, New York
3. "The Butcher Shop" by Pieter Aertszen (1507–73). Fine quality, excellent perspective, gruesome details have not been overlooked
4. "Fish," a still-life painting by William Chase (1849–1916), American. In the Metropolitan Museum of Art, New York

## ARTISTIC STILL-LIFE CANVASES

1. "Kitchen Table" by Jean Baptiste Siméon Chardin (1699–1779); splendid handling of white pigment, as shown in treatment of white jug and fowl. French. Museum of Fine Arts, Boston
2. "The Table" by André Derain (1880– ), who combined the influence of Cézanne and Gauguin with the primitive. French
3. "Hearthstone" by Emil Carlsen (1853–1932), characterised by simplicity of treatment and faithful portrayal of homely utensils. American
4. "Fish" by Henri Matisse (1869– ), noted for sureness and simplicity in his drawings. French. In the Tate Gallery, London

although correct in drawing, well coloured and a picture most interesting, it is in questionable taste.

Abraham van Beyeren (1620–75) stands out as one of the foremost painters of fish, producing well composed paintings, glowing with bright colours and glistening surfaces. The painting of wet, sparkling fish gives opportunities to the student for the study of brilliant light against the deep and rich notes in the wet fish, and as the fish very soon deteriorates in colour and form, the canvas must be painted quickly, in the heat of enthusiasm, thus bringing forth the finest results, the most spontaneous work.

Joachim Buckelaer painted fish, as did Alexander Adriassen and, in their late years, Vollon, Manet and Chase.

Jan Davidsz van Heem and his son, Cornelius de Heem, the two most celebrated members of a large family of still-life painters, are separately noticed. Jan was one of the earliest and ablest. The realism of the individual flower or peach was more desired by these painters than the ensemble of the picture. Jan van Huysum (*q.v.*) reached the top as a flower painter whose style was similar to that of the de Heems.

Willem Kalf, like Willem Claasz Heda, had finer perception of tone and envelopment. Both were painters of rich objects that were executed in the adopted style of the Dutch, but with keen observation of values and tonality; they were taught by masters like Vermeer and Terborch.

Frans Snyders' large game compositions are highly decorative, his fruit rich in colour, well drawn and painted, but overfilled with details and without concentration of the motif. No air in them! The pictures of game that his pupil, Jan Fyt, painted are well studied, realistic in the weight of deer and hare, and in the quality of the painting of fur and feathers. Jan Weenix was a highly decorative painter of dead game in luxurious surroundings, garden backgrounds with decorated vases, the implements for the hunt and its spoils.

In all this interesting still-life work it was always the manner that was considered superior to the matter, and it was always the school that called for excellence of craftsmanship. Every master had his pupils who followed his style; father taught son, and the son taught his son; it was a trade that had to be learned.

Without absolute knowledge of his tools and the preparation of the canvas or panel, one did not count for much in the craft. So-called "visions" were not considered in the Netherlands, as they were in Italy. Pictures that could be studied and loved at short range were called for, and the work could not be carelessly done. Therefore, something was often missing, even in this beautiful work. It left no room for imagination. It was only for the eye—charming to look at, but nothing to dream about—and was generally the work of the painter and rarely of the artist.

**Chardin.**—Jean Baptiste Simeon Chardin lifted still-life to a higher plane in art than the Hollanders and Flemings of former years. Understanding their methods, he added to their technique air and light as the aim to search for. His simplicity saw beauty in his daily surroundings; his honesty rendered them with absolute truth. Every utensil in his kitchen we know—the copper water-fountain, the charcoal brazier, the brass kettles, the handsome water-jar, the bread knife, as well as the large loaf of bread, the herrings, cuts of meat, onions and pieces of china. Chardin's living-room we know, with the straight-backed chairs and the bird in its cage on a stand. We know the housewife with her white apron —and how splendid a white! Chardin's whites are miracles of painting. The white jug and the white fowl in the still-life in the Boston museum are unequalled. Few painters of all time have been able to handle white pigment as Chardin could. James McNeill Whistler was among the few.

Among his earliest pictures was the "Skate," now in the Louvre. This was accepted by the academy as his diploma picture, simply painted and freer in treatment than other canvases of his early career. He painted a great many interiors, with one or two figures. Again and again it is the light that predominates, the atmosphere of the room or rooms, for we often look through an open door into another room, and that room full of light. Every figure has its weight, stands soundly on its feet and is well in its distance from the onlooker and from the wall behind. As still-life painting or interior with figure, it has every quality known; every colour value is observed, the drawing is easy, never overdrawn, and still never slighted. Chardin's textures are rendered as only a master could paint them; metal is metal and cloth is cloth; every edge, the despair of the average painter, is firm but well blended; light and air are over and around every figure or object. This is still-life painting, an answer to "What is still-life?"

**Later Still-life Artists.**—Chardin died in 1779, and for nearly a century there were no still-life painters of note; there was practically no interest in *nature morte*. When Courbet started his bold and vigorous manner of painting, he was alone; he painted what he saw and in a manner of his own invention. Whatever in nature looked worth painting he painted—figures, landscape, marines and still-life. His still-life canvases are done truthfully and spontaneously, and are of a flat, well-coloured technique. Several of his pictures have a stag in them, similar in motion to those of Snyders or Weenix, but with more weight and greater originality.

Manet was an artist who painted for excellence, and his still-life work, of which he did a great deal, is always of a high order. Simple and full of light, the canvas is never overfilled. Manet was also an individual who saw with his own eyes and painted in a flat manner, local colour and values being purposely slighted.

Antoine Vollon painted landscapes, but is better known for his still-life, in which he was very prolific. Most of his work was done in one sitting, and in a decorative, well-arranged, somewhat Dutch manner.

Vollon's picture of "Fish" in the Luxembourg is a splendid piece of painting, with its dark shadows, almost monotone, and the wet and slimy fish in brilliant light. His reputation was widespread.

Bonvin and Fantin-Latour were men of well-merited reputation. Fantin-Latour's flower paintings are tastefully arranged and finely executed. Bonvin's work, simple and truthful, is based on Chardin's methods.

Of the American painters, William M. Chase (1849–1916) painted fish, pots and brass kettles, and pictures of great brilliancy. Julian Alden Weir's flowers are noted for their exquisite delicacy and beauty. (*See* also PAINTING; FLOWER PAINTING.)

**STILLMAN, WILLIAM JAMES** (1828–1901), American painter and journalist, was born at Schenectady (N. Y.), June 1, 1828. He graduated at Union college, Schenectady, in 1848. He studied art under Frederick E. Church and early in 1850 went to England, where he fell so much under the influence of Rossetti and Millais that on his return home in the same year he speedily became known as the "American Pre-Raphaelite." He studied art under Yvon in Paris, returned to the United States and devoted himself to landscape painting on Upper Saranac Lake in the Adirondacks and in New York City, where he started the *Crayon*. When it failed for want of funds, Stillman removed to Cambridge, Massachusetts. He returned to England, and afterwards painted with Ruskin in Switzerland. He was in Normandy in 1861 when the American Civil War broke out. His health was too weak for him to serve in the Northern ranks and he was appointed United States consul in Rome. In 1865 he resigned, but immediately afterwards he was appointed to Crete. He was an editor of *Scribner's Magazine* for a short time. When in London lived with D. G. Rossetti. When the insurrection of 1875 broke out in Hercegovina he went there as a correspondent of *The Times,* and his letters from the Balkans aroused so much interest that the British government was induced to lend its countenance to Montenegrin aspirations. In 1877–83 he served as the correspondent of *The Times* at Athens; in 1886–98 at Rome. After his retirement he lived in Surrey, where he died on July 6, 1901. He wrote *The Cretan Insurrection* 1866–1868 (1874), *On the Track of Ulysses* (1888), *Billy and Hans* (1897) and *Francesco Crispi* (1899).

*See* his *Autobiography of a Journalist* (Boston, 1901).

**STILLWATER,** a city of eastern Minnesota, U.S.A., on the St. Croix river, at the head of Lake St. Croix, 20 m. N.E. of Saint Paul; the county seat of Washington county. It is served by the Chicago, Milwaukee, St. Paul and Pacific, the Chicago, St. Paul, Minneapolis and Omaha, and the Northern Pacific railways. Pop. (1930) 7,173; and it was 7,013 in 1940. The city has a picturesque situation on bluffs high above the river. It is the seat of the state prison (established 1851); a shipping point for the agricultural products of the region; and a manufacturing centre of growing importance. Before the exhaustion of the forests, it had a large trade in pine lumber. Stillwater was settled in 1843, laid out in 1848, and chartered in 1854. The "Stillwater Convention" of 1848 was the first step toward the erection of Minnesota Territory.

**STILO PRAECONINUS, LUCIUS AELIUS** (*c.* 154–74 B.C.), of Lanuvium, the earliest Roman philologist, belonged to the equestrian order. His aristocratic sympathies were so strong that he voluntarily accompanied Q. Caecilius Metellus Numidicus into exile. At Rome he divided his time between teaching and literary work. His most famous pupils were Varro and Cicero, and amongst his friends were Coelius Antipater, the historian, and Lucilius, the satirist, who dedicated their works to him. Only a few fragments of his works remain. He wrote commentaries on the hymns of the Salii, and (probably) on the Twelve Tables; and investigated the genuineness of the Plautine comedies, of which he recognized 25, four more than were allowed by Varro. The rhetorical treatise *Ad Herennium* has been attributed to him by some modern scholars.

*See* Cicero, *Brutus,* 205–207, *De legibus,* ii. 23, 59; Suetonius, *De grammaticis,* 2; Gellius iii. 3, 1. 12; Quintilian, *Inst. orat.* x., 1, 99; monographs by J. van Heusde (1839) and F. Mentz (1888); Mommsen, *Hist. of Rome,* bk. iv. ch. 12, 13; J. E. Sandys, *History of Classical Scholarship* (2nd ed. 1906); M. Schanz, *Geschichte der römischen Literatur* (1898), vol. i.; Teuffel, *Hist. of Roman Literature* (Eng. trans., 1900), p. 148.

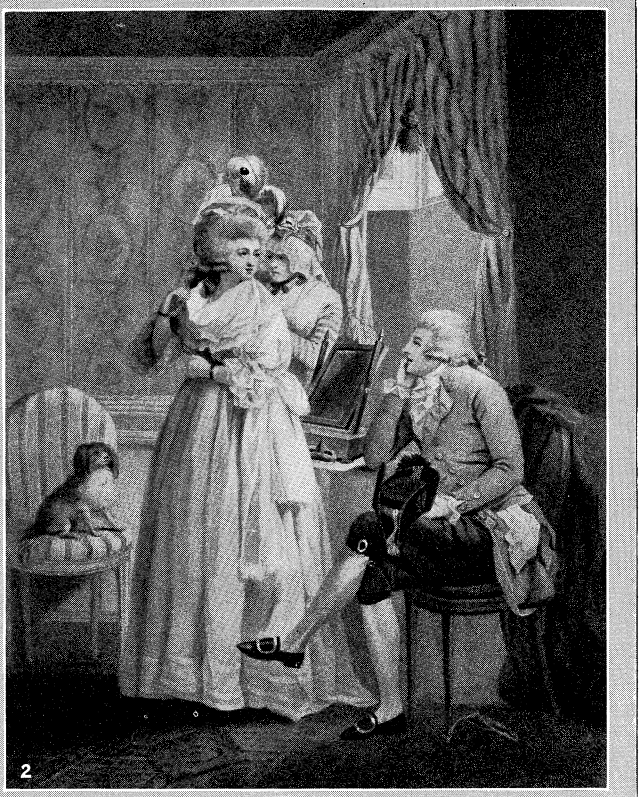
**STILT** (*Himantopus himantopus*), a bird of the plover family (*see* PLOVER), remarkable for the extreme length of its slender legs. The bill is long and straight; the legs red; the wings and back black; the head, neck and lower parts white. The sexes are alike. Its food consists of small arthropods, which it obtains by wading in shallow water. It ranges over Europe and Asia, not breeding northward of the Danube valley. The nest is a slight structure on the margin of a pool or lake, and contains four eggs, which resemble those of the oyster-catcher (*q.v.*). In America, from Oregon southward to Brazil, occurs the black-necked stilt, *H. nigricollis.* Other species occur in South America, Australia and New Zealand. The stilts are allied to the avocets (*q.v.*), and, like them, spend much time wading in shallow water.

THE STILT (HIMANTOPUS HIMANTOPUS)

**STILTS,** poles with footrests fixed at a certain distance above the ground. They were originally designed for use in crossing rivers and marshes. As a means of amusement stilts have been used by all peoples in all ages, as well as by the inhabitants of marshy or flooded districts. The city of Namur in Belgium, which formerly suffered from the overflowing of the rivers Sambre and Meuse, has been celebrated for its stilt-walkers for many centuries. Not only the townspeople but also the soldiers used stilts. The governor of Namur having promised the archduke Albert (about 1600) a company of soldiers that should neither ride nor walk, sent a detachment on stilts, which so pleased the archduke that he conferred upon the city perpetual exemption from the beer-tax, no small privilege at that time.

The home of stilt-walking at the present day is the department of Landes in Gascony, where, owing to the impermeability of the subsoil, all low-lying districts are converted into marshes. Stilts used by children are very long, the upper half being held under the arms; they are not strapped to the leg.

**STIMSON, HENRY LEWIS** (1867– ), American lawyer and statesman, was born in New York city on Sept. 21, 1867, and educated at Yale (A.B., 1888) and Harvard (A.M., 1889) universities. He attended the Harvard Law school and in 1891 was admitted to the New York bar. In 1906 he was appointed U.S. attorney for the southern district of New York state. This position he relinquished in 1910 to become the unsuccessful candidate of the Republican party for governor of New York. In 1911 he was appointed secretary of war by President Taft, in which office he continued from May 1911 to March 1913. He subsequently resumed his law practice, which was interrupted during U.S. participation in World War I by his service in France as colonel of the 31st field artillery. In 1927 he was sent by President Coolidge as a special commissioner to Nicaragua, where he met President Díaz and the rebel leader Moncada and was instrumental in persuading both leaders to lay down their arms on condition that the U.S. would supervise the 1928 election. His success on this mission, together with his study of the Philippine question in 1926, led to his appointment, in Dec. 1927, as governor-general of the Philippine Islands, in which position he succeeded Maj.-Gen. Leonard Wood, whose policies he continued with notable success. As secretary of state in Herbert Hoover's cabinet from 1929 to 1933 he urged international opposition to Japan's aggressions in Manchuria. He led the U.S. delegations to the London naval conference in 1930 and the disarmament conference of 1932. He served again as secretary of war from 1940 to 1945.



**STINKHORN,** the popular name of a group of fungi belonging to the Basidiomycetes, so called because of their carrion-like odour. The young plant (egg) resembles a small puff-ball (*q.v.*) but soon splits open at the apex when a stalk emerges with a conical, slimy, evil-smelling head on which the spores are borne. The spores are dispersed by insects attracted by the odour.

**STINK-WOOD,** a South African tree, known botanically as *Ocotea bullata,* and a member of the family Lauraceae. Other names for it are Cape walnut, stinkhout, Cape laurel and laurel wood. It derives its name from having a strong and unpleasant smell when freshly felled. It is used for building in South Africa and is said to be a substitute for teak and equally durable. The wood is dark walnut or reddish brown to black with a yellow sapwood, and the grain extremely fine, close, dense and smooth.

**STINNES, HUGO** (1870–1924), German industrialist, was born in Mülheim on Feb. 12, 1870. Educated as a mining engineer, he entered his grandfather's firm in 1890, but two years later established a business of his own, with a capital of 50,000 marks. The business expanded steadily and came to include, besides dealing in coal, the ownership of coal mines, barges, river steamers and sea-going vessels. Stinnes organized an international business in coal, including the importation of coal from England. He built up a fleet of steamers trading in the North Sea, the Baltic, the Mediterranean and the Black Sea. He also established iron and steel factories. During the World War he commanded a large share of the industrial work required by the German authorities, and rapidly increased his shipping interests. In 1920 he entered the Reichstag as a member of the German People's Party (the former National Liberal party). He began to buy up newspapers, whose democratic opinions were quickly modified in accordance with his own. In 1921 he was reported to be contemplating the formation of a super-trust to control the whole of German industry. He died in Berlin April 10, 1924. After his death the business, conducted by his son, rapidly shrank. In June 1925 a conference of bankers was called to investigate the financial affairs of the trust; and bit by bit the great organization was liquidated and sold. In Oct. 1925 a new company was registered at Hamburg under the title of Hugo Stinnes Coal Trade and Shipping Co., Ltd., the Stinnes family retaining 40% of the shares.

**STIPPLE AND CRAYON ENGRAVING.** Stipple-engraving was a little art of prettiness and daintiness, particularly well adapted to the translation of anecdotic pictures of a sentimental, mildly romantic, or domestic character, such as were

## ENGLISH STIPPLE ENGRAVINGS OF THE 18TH CENTURY

Stipple engraving consists of a design drawn in a series or group of dots through an etching ground on a copper plate, and bitten with acid, then completed with dots made directly in the copper by a curved stipple-graver and perhaps a toothed wheel called a roulette

1. "Countess Spencer," engraved by Francesco Bartolozzi (1727–1813) after the painting by Sir Joshua Reynolds (1723–92). 2. "Dressing for the Masquerade," engraved by John Raphael Smith (1752–1812) after the painting by George Morland (1763–1804). 3. "Constancy," engraved by William Ward (1766–1826) after the painting by George Morland. 4. "Emma," engraved by John Jones (1745–97) after the painting by George Romney (1734–1802)

turned out in great numbers to supply a vogue in the English market during the reign of George III., many of which, popular in their day, survive only in the colour-prints and, though rarely of much artistic value, are yet now highly valued for their merit in survival. Nevertheless there were in the brief hey-day of the art a few among the multitude of designers and engravers who, realizing its limitations, made the most of its qualities, and these, such as J. R. Smith, William Ward and John Jones, the great mezzotinters Charles Wilkin, Thomas Burke, and whenever he chose to do so, Francesco Bartolozzi, with Peltro William Tomkins, Knight, Cheeseman, Schiavonetti, and others of the school, used the medium with individuality, undeniable charm and some artistic effect.

As a separate method, stipple-engraving came to England from France probably about 1764, by way of the crayon manner and the pastel, and these had evolved originally from the dotted manner, to which Ludwig von Siegen refers, in announcing the wonders of his own invention of mezzotint in 1642, as one of the modes of engraving which it was not. The dotted manner, a process of punching the plate with awl and mallet, called *opus mallei,* was used for its own sake with pictorial effect by Jan Lutma, an Amsterdam goldsmith, and the son of Rembrandt's sitter; but graven dots had been used earlier as accessory to line-engraving by Giulio Campagnola, Ottavio Leoni, and others, while in England the earliest important engraver of portraits, William Rogers, in Queen Elizabeth's reign, had stippled the face of the Queen, while Lucas Vorsterman used dots also to suggest the flesh in his head of Charles I.

But in the 18th century, when the crayon and pastel drawings of Boucher and others were popular in France, the aim of the engravers was to reproduce their texture on the copper-plate. The idea was in the air, so to speak, and several were engaged in the attempt to materialize it. Thus the invention of the crayon manner was claimed separately by Jean Charles François, Gilles Demarteau, who used his own version of it with artistic feeling, and Louis Marin Bonnet, an ingenious engraver to whom we owe at least the "pastel manner." This was a subtle development of the crayon mode admitting colour variety from a series of plates, as we may see in Bonnet's really fine print, *La Tête de Flore,* after Boucher, but François seems to have been actually the first in the field. The means used to imitate crayon drawing resembled soft-ground etching, though to produce the appearance of the chalk lines the etching-ground was perforated by tools of the roulette order, and various kinds of needles, while, after the usual biting by the acid, the finishing touches were given by graver, dry-point and roulette, though one often fancies the methods of soft-ground had been employed. François taught this crayon engraving, and with it the application of colour in printing *à la poupée,* to William Wynn Ryland, a young English line-engraver, who had been studying with Le Bas in Paris, and who, when funds were lacking after his return to London, bethought him of the new manner of engraving he had learnt. Then having called Bartolozzi into collaboration, they both modified and developed it as stipple-engraving.

The new method proved very easy of accomplishment, simple and rapid. The outline was etched in a series of dots, and all the shadows were put in with large or closer dots, or tiny groups of dots. When all the biting was over, the ground was removed, and the finishing was done with dry-point and stipple-graver, a curved tool. Then the printing was done with black, red, or several coloured inks, a rag-stump, or *poupée,* being used, and the plate freshly cleaned for each impression. Beginning by translating the pretty pseudo-classical designs of Angelica Kauffman and Cipriani, which acquired a very popular vogue, Ryland and Bartolozzi found the new method exceedingly profitable. To the ready hand of Bartolozzi it came almost as a fairy gift, with the facilities of the medium linking themselves to his sweet caressing sense of beauty. Indeed, he developed it with richer character in its fine shades than the unfortunate Ryland could do, as we may see in many notable prints after Reynolds and other distinguished painters. All the painters of the day were anxious to share in the profits so readily made by the stipple-prints which were filling the print-sellers' windows, and few native engravers could resist the easy attraction of the new method, while it brought also Italian and French engravers to learn it, and work here for the English market. There was also, up to the war with revolutionary France in 1793, a great trade in English prints on the continent, and Bonnet and other French engravers, adopting the stipple method, tried to get a share in this trade by issuing prints with titles often in misspelt English. Sir Robert Strange, the eminent line-engraver, launched an indignant tirade against stipple, and even denied its claim to be regarded as engraving at all, though there was no denying its efficacy as a medium for colour-printing, the white of the paper, showing between the tinted dots, affording a peculiarly luminous quality, and thus giving it a superiority over the coloured mezzotint, though it must be admitted that rarely was the stipple or the mezzotint of old time completely printed in colours, some portions invariably being left to be coloured by hand. Nevertheless, the popularity of stipple continued as long as the special subjects for which it was used remained in fashion, and as long as the leading 18th century painters and engravers survived the period of their comparatively short though successful collaboration, but it really waned with the advent of colour-lithography. Stipple-engraving is rarely practised nowadays as a separate art, though a recent attempt has been made to revive it for original expression by Dorothy Woollard. As a medium for original colour-printing it has completely given place to aquatint, woodcut or wood engraving, lithography, or relief-etching from several plates.

**STIRES, ERNEST MILMORE** (1866– ), bishop of Long Island, was born in Norfolk, Va., on May 20, 1866. He received the degree of B. Litt. at the University of Virginia in 1888, and from 1889–91 continued his studies at the Episcopal Theological seminary of Virginia, receiving the degree of D.D. at Trinity college in 1901. The degree of LL.D. was conferred upon him at Kenyon college in 1903. He received his first appointment as rector at West Point in 1891, and in 1893 went to the Church of the Good Shepherd in Augusta, Ga. In the same year he was called to Grace church, Chicago, where he remained until 1901. He then accepted a call to St. Thomas's church, New York. Under his pastorate the parish became one of the most important in the country. He was consecrated bishop of Long Island on Nov. 24, 1925.

**STIRLING, WILLIAM ALEXANDER,** EARL OF (*c.* 1567–1640), Scottish poet and statesman, generally known as William Alexander, was born at Menstrie House, near Stirling, about 1567, and probably educated at Stirling Grammar school. He may also have been to the universities of Glasgow and Leyden. He followed James VI. to England, where he became one of the gentlemen-extraordinary of Prince Henry's chamber. For the prince he wrote his *Paraenesis to the Prince . . .* (1604), a poem in eight-lined stanzas on the theme of princely duty. He was knighted in 1609; in 1614 he was appointed master of requests, and in July 1615 to a seat in the Scottish privy council. In 1613 he began a correspondence with Drummond of Hawthornden. In 1621 he received from James I. enormous grants of land in America, including Nova Scotia and New Brunswick, and was appointed lieutenant-governor of the new colony which, however, was ceded to the French in 1632. (*See* NOVA SCOTIA: *History.*) From 1626 till his death he was the king's secretary for Scotland, and in 1630 was created viscount Stirling and Lord Alexander of Tullibody. In 1631 he edited and published a translation of the Psalms said to be by James I. In 1639 he became earl of Donovan. He died on Feb. 12, 1640, in London.

Alexander's poetical miscellanies and minor verse include *Aurora,* containing the first fancies of the author's youth (1604); *An Elegie on the Death of Prince Henrie,* and shorter pieces. He also wrote four tragedies, *Darius* (1603); *Croesus* (1604); *The Alexandrean* (1605), and *Julius Caesar* (1607); the first two of which were published together in 1604 as the *Monarchicke Tragedies;* they are didactic poems or dialogues rather than plays,

but they contain some fine soliloquies. Of Alexander's heroic poem *Jonathan* only the first book was written. *Domesday,* or *The Great Day of the Lord's Judgment* (1614), is a dreary production, in 12 books or "hours," in eight-lined stanzas. A collected edition of his work appeared in 1637, with the title *Recreations with the Muses* (folio), but did not include *Aurora* and the *Elegie.* A complete modern reprint *The Poetical Works,* etc., was published in 3 vols. (Glasgow, 1870).

His *Encouragement to Colonies* was edited for the Bannatyne Club by David Laing (1867), and by Edmund F. Slafter, in *Sir W. Alexander and Amer. Colonization* (Prince Society, Boston, Mass., 1865). *See* also E. F. Slafter, *The Copper Coinage of the Earl of Stirling, 1632* (1874); *The Earl of Stirling's Register of Royal Letters relative to the Affairs of Scotland and Nova Scotia from 1615–1635* (edit. C. Rogers, with biographical introduction 1884–85); C. Rogers, *Memorials of the Earl of Stirling* (1877); the introduction to the *Works* (1870) referred to above; the *Register of the Privy Council of Scotland, passim;* and the bibliography for William Drummond (*q.v.*) of Hawthornden.

**STIRLING, WILLIAM ALEXANDER,** titular EARL OF (1726–1783), American soldier, was born in New York city. He served first as commissary and then as aide-de-camp to Governor William Shirley at the beginning of the French and Indian War, and in 1756 he accompanied Shirley to England, where he prosecuted his claim to the earldom of Stirling. In 1759 an Edinburgh jury declared him to be the nearest heir to the last earl of Stirling, and in 1761 he returned to America and assumed the title of Lord Stirling by which he was afterwards known in America. He became a member of the New Jersey provincial council and surveyor general of the colony. In 1775 he sided with the patriot cause and was appointed colonel of a regiment in New Jersey. In March he became brigadier-general, and for a time was in command at New York, and supervised the fortification of the city and harbour. At the battle of Long Island he was taken prisoner, but was soon afterwards exchanged, and in Feb. 1777 became a major-general. He participated in the battles of Trenton, Princeton, Brandywine and Germantown, and especially distinguished himself at Monmouth. He took an active part in exposing the Conway Cabal, presided over the court-martial of General Charles Lee, and enjoyed the confidence of Washington to an unusual degree. In Oct. 1781 he took command of the northern department at Albany to check an expected invasion from Canada. He died at Albany on Jan. 15, 1783. He was a member of the board of governors of King's college (now Columbia university) and was devoted to the study of mathematics and astronomy.

**STIRLING,** royal, large and parliamentary burgh, river port and county town of Stirlingshire, Scotland. Pop. (1938), 23,552. It is finely situated on the right bank of the Forth, 39¾ mi. N.W. of Edinburgh and 29½ mi. N.E. of Glasgow, being served by the L.N.E. and L.M.S. railways. The old town occupies the slopes of a basaltic hill (420 ft. above the sea) terminating on the north and west in a precipice. The modern quarters have been laid out on the level ground at the base, especially toward the south. Remains of a town wall exist at the south end of the Black walk. Formerly there were two main entrances—the South port and the "auld brig" over the Forth to the north, a high-pitched structure of four arches, now used only by foot-passengers. It dates from the end of the 14th century and was once literally "the key to the Highlands." Just below it is the bridge erected in 1829 from designs by Robert Stevenson, and below this again the railway viaduct. The castle crowning the hill is of unknown age, but from the time that Alexander I died within its walls in 1124 until the union of the crowns in 1603, it was intimately associated with the fortunes of the Scottish monarchs. It is approached from the esplanade, on which stands a colossal statue of Robert Bruce. The main gateway, built by James III, gives access to the lower and then to the upper square, on the south side of which stands the palace, begun by James V (1540) and completed by Mary of Guise. The east side of the quadrangle is occupied by the parliament house, a Gothic building of the time of James III, now used as a barrack-room and stores. On the north side of the square is the chapel royal, founded by Alexander I, rebuilt in the 15th century and again in 1594 by James VI (who was christened in it), and afterwards converted into an armoury and finally a storeroom. In the plain to the southwest were the King's gardens, now under grass, with an octagonal turf-covered mound called the King's Knot in the centre. Farther south lies the King's park. On a hill of lower elevation than the castle and separated from the esplanade by a depression styled the Valley—the tilting-ground of former times—a cemetery has been laid out. Here is the Virgin Martyrs' memorial, in memory of Margaret Maclachlan and Margaret Wilson, who were drowned by the rising tide in Wigtown bay for their fidelity to the Covenant (1685); the large pyramid to the memory of the Covenanters, and the Ladies' rock, from which ladies viewed the jousts in the Valley. Adjoining the cemetery on the south is the parish church, portions of which may have formed part of the first church, founded by David I. Following the Reformation it was divided into two churches, but was restored to its original condition in 1935. The choir (the old East church) was added in 1494 by James IV, and the apse a few years later. At the west stands the stately battlemented square tower. The nave (the former West church) is a transition between Romanesque and Gothic, with pointed windows. The crow-stepped Gothic gable of the south transept afforded the main entrance to both churches. The choir is in the Decorated and Perpendicular styles. Within its walls Mary Queen of Scots was crowned in 1543, when nine months old, and in the same year the earl of Arran, regent of Scotland, abjured Protestantism; in 1544 an assembly of nobles appointed Mary of Guise queen-regent; on July 29, 1567, James VI was crowned, John Knox preaching the sermon, and in Aug. 1571 and June 1578 the general assembly of the Church of Scotland met. James Guthrie (1612–1661), the martyr, and Ebenezer Erskine (1680–1794), founder of the Scottish Secession Church, were two of the most distinguished ministers. To the southwest of the church is Cowane's hospital, founded in 1639 by John Cowane, dean of guild, and now used as a guildhall. Adjoining it is the military prison. Near the principal entrance to the esplanade stands Argyll's Lodging, erected about 1630 by the 1st earl of Stirling, Sir William Alexander, the founder of Nova Scotia. On his death in 1640 it passed to the 1st marquess of Argyll and later was made into a military hospital. It is a fine example of a baronial town house. Broad street contains Mar's Work, the palace built by John Erskine, 1st (or 6th) earl of Mar, about 1570, according to tradition, out of the stones of Cambuskenneth abbey; the old town house, erected in 1701 to replace that in which John Hamilton, the last Roman Catholic archbishop of St. Andrews, was hanged for alleged complicity in the murders of Darnley and the regent Moray; the town cross, restored in 1891, and the house which was, as a mural tablet says, the "nursery of James VI and his son Prince Henry." The Smith institute, founded in 1873 by Thomas Stewart Smith, an artist, contains a picture gallery, museum and reading room. Carpet weaving and woollen spinning and manufactures are the staple industries, and iron-founding, carriage-building and agricultural implement-making are also carried on, in addition to furniture factories, cooperage and rubber works and confectionery works. There is some shipping from the small harbour, which is accessible only at high water.

Stirling, with Falkirk and Grangemouth, returns a member to parliament.

The Abbey craig, an outlying spur of the Ochils, 1½ mi. northeast of Stirling, is a thickly-wooded hill on the top of which stands the Wallace monument (1869), a baronial tower, with a valhalla containing busts of eminent Scotsmen. Cambuskenneth abbey, on the left bank of the Forth, about 1 mi. E.N.E. of Stirling, was founded by David I in 1147 for monks of the order of St. Augustine. Several Scots parliaments met within its walls. At the Reformation Mary Queen of Scots bestowed it on the 1st earl of Mar (1562), who is said to have used the stones for his palace in Stirling. All that remains of the abbey is the massive, four-storied tower, the west doorway and the foundations of some of the walls. The bones of James III and his queen, Margaret of

Denmark, who were buried within the precincts, were discovered in 1864 and reinterred next year under a tomb at the high altar at the expense of Queen Victoria.

Stirling was known also as Snowdoun, which became the official title of the Scots heralds. The Romans probably had a station here. In 1119 it was a royal burgh and under Alexander I. was one of the Court of Four Burghs (superseded under James III. by the Convention of Royal Burghs). In 1174 it was handed over to the English in security for the treaty of Falaise, being restored to the Scots by Richard I. The earliest known charter was that granted in 1226 by Alexander II., who made the castle a royal residence. The fortress was repeatedly besieged during the wars of the Scottish Independence. In 1304 it fell with the town to Edward I. The English held it for ten years, and it was in order to raise the Scottish siege in 1314 that Edward II. risked the battle at Bannockburn. Edward Baliol surrendered it in 1334 in terms of his compact with Edward III., but the Scots regained it in 1339.

From this time till the collapse of Queen Mary's fortunes in 1568, Stirling almost shared with Edinburgh the rank and privileges of capital of the kingdom. It was the birthplace of James II. in 1430 and probably of James III. and James IV. In 1571 an attempt was made to surprise the castle by Mary's adherents, the regent Lennox being slain in the fray, and seven years later it was captured by James Douglas, 4th earl of Morton, after which a reconciliation took place between the Protestants and Roman Catholics. It was occupied in 1584 by the earls of Angus and Mar, the Protestant leaders, who, however, fled to England on the approach of the king. Next year they returned with a strong force and compelled James VI. to open the gates, his personal safety having been guaranteed. In 1594 Prince Henry was baptized in the chapel royal, which had been rebuilt on a larger scale. After the union of the crowns (1603) Stirling ceased to play a prominent part on the national stage. The privy council and court of session met in the town in 1637 on account of the disturbed state of Edinburgh. In 1641 Charles I. gave it its last governing charter, and four years afterwards parliament was held in Stirling on account of the plague in the capital, but the outbreak of the pest in Stirling caused the legislators to remove to Perth. During the Civil War the Covenanters held the town, to which the committees of church and state adjourned after Cromwell's victory at Dunbar (1650), but in August next year the castle was taken by General Monk. In 1715 the 3rd duke of Argyll held it to prevent the passage of the Forth by the Jacobites, and in 1746 it was ineffectually besieged by Prince Charles Edward.

**STIRLING NUMBERS,** in mathematics. In the year 1730 James Stirling, in his *Methodus Differentialis* introduced into analysis two sets of numbers which, because of their uses in various branches of analysis, their properties, and the methods used in their computation, have continued to attract the attention of mathematicians.

One of the latest writers on the subject, Professor Nielsen of Copenhagen has named them "Stirling numbers of the first and second kind" in honour of their discoverer.

**Definitions.**—The Stirling numbers of order $n$ of the first kind may be defined as the co-efficients in the expansion of

$$(1+x)(1+2x)\cdots(1+nx)=1+{}_nS_1x+{}_nS_2x^2+{}_nS_3x^3+\cdots$$

in ascending powers of $x$, while the Stirling numbers of the second kind are found in

$$\frac{1}{(1+x)(1+2x)\cdots(1+nx)}=1-{}_nT_1x+{}_nT_2x^2-{}_nT_3x^3+\cdots,$$

also in ascending powers of $x$.

This definition immediately leads to the following theorems:

(*a*) The $P^{th}$ Stirling number of order $n$ of the first kind is equal to the sum of the products of the first $n$ integers taken $P$ at a time without repetition.

(*b*) The $P^{th}$ Stirling number of the second kind of order $n$ is equal to the sum of the products of the first $n$ integers taken $P$ at a time with repetitions.

Stirling used the numbers now named after him as a tool for expressing $x^n$ as a series of factorials.

$$x^2=x(x-1)+x,$$
$$x^3=x(x-1)(x-2)+3x(x-1)+x,$$
$$x^4=x(x-1)(x-2)(x-3)+6x(x-1)(x-2)+7x(x-1)+x,$$
$$x^5=x(x-1)(x-2)(x-3)(x-4)+10x(x-1)(x-2)(x-3)+25x(x-1)(x-2)+15x(x-1)+x.$$

The coefficients of the various factorials (1·1; 1·3·1; 1·6·7·1; 1·10·25·15·1) are the Stirling numbers of the second kind. For about 150 years mathematicians considered it important to be able to express algebraic expressions in form of sequences of factorials. The result was a rich literature consisting of memoirs dealing with the peculiarities of this method of expression. In the year 1846 Weierstrass proved the general futility of this mode of notation, and since then the subject of "factorial notation" has slowly but surely been eliminated as a topic of discussion in mathematical literature. At present it is used only in certain problems of finite summation, in theories of interpolation, and as an example illustrating some of the uses of the Stirling numbers.

**Applications.**—George Boole in his treatise on the calculus of finite differences calls attention to the "system of numbers expressed by $\Delta^n o^m$ (differences of nothing)" without indicating whether he realized that these numbers were already used by Stirling. The formula given by Boole for $\Delta^n o^m$ may well be used for the calculation of the above mentioned coefficients $T$; *i.e.*, the Stirling numbers of the second kind,

$$\frac{1}{n!}\,{}_nT_{m-n}=n^m-\binom{n}{1}(n-1)^m+\binom{n}{2}(n-2)^m-\binom{n}{3}(n-3)^m+\cdots$$

The Stirling numbers of the second kind ($T$) also appear in the expansion of $(e^x-1)^p$. Thus,

$$\frac{1}{2!}(e^x-1)^2=\frac{x^2}{2!}+\frac{{}_2T_1x^3}{3!}+\frac{{}_2T_2x^4}{4!}+\cdots$$
$$\frac{1}{3!}(e^x-1)^3=\frac{x^3}{3!}+\frac{{}_3T_1}{4!}x^4+\frac{{}_3T_2x^5}{5!}+\cdots$$
$$\frac{1}{p!}(e^x-1)^p=\frac{x^p}{p!}+\frac{{}_pT_1}{(p+1)!}x^{p+1}+\frac{{}_pT_2}{(p+2)!}x^{p+2}+\cdots$$

**Formulas.**—Of the recurring formulas the most important are

$${}_{n+1}S_p={}_nS_p+n\cdot{}_nS_{p-1},$$
$${}_{n+1}T_p={}_nT_p+n\cdot{}_{n+1}T_{p-1}.$$

Of the independent formulas developed by various writers, none is suitable for practical purposes; but theoretically the following formulas which appear in a work by Ettinghausen (1826) are important:

$${}_nS_p=\Sigma\frac{(n+1)!}{a!\,b!\,c!\cdots 1^a\,2^b\,3^c\cdots}$$

for all integral values of $a,b,c\ldots$ satisfying the equations:

$$a+b+c+\cdots=p+1,$$
$$a+2b+3c+\cdots=n+1,$$

and

$${}_nT_p=\Sigma\frac{(n+p)!}{a!b!c!\cdots 1^a(2!)^b(3!)^c\cdots}$$

for all integers satisfying the equations

$$a+b+c+\cdots=p,$$
$$a+2b+3c+\cdots=n+p.$$

Relations between the $S$'s and the $T$'s are given by

$${}_nT_p=\begin{vmatrix} {}_nS_1 & 1 & \cdots & 0\\ {}_nS_2 & {}_nS_1 & \cdots & 0\\ \cdot & \cdot & \cdots & \cdot\\ \cdot & \cdot & \cdots & 1\\ {}_nS_p & {}_nS_{p-1} & \cdots & {}_nS_1 \end{vmatrix},\quad\text{and}\quad {}_nS_p=\begin{vmatrix} {}_nT_1 & 1 & \cdots & 0\\ {}_nT_2 & {}_nT_1 & \cdots & 0\\ \cdot & \cdot & \cdots & 0\\ \cdot & \cdot & \cdots & 1\\ {}_nT_p & {}_nT_{p-1} & \cdots & {}_nT_1 \end{vmatrix}.$$

The second formula is evidently obtained from the first by interchanging the *T's* and the *S's*. It has also been observed (*Amer. Math. Monthly,* 1928) that the Stirling numbers of the first kind can be obtained by performing the algebraic divisions,

$$\frac{2+x}{(1-x)^5}, \frac{6+8x+x^2}{(1-x)^7}, \frac{24+58x+22x^2+x^3}{(1-x)^9} \ldots$$

while the Stirling numbers of the second kind appear in the quotients of

$$\frac{1+2x}{(1-x)^5}, \frac{1+8x+6x^2}{(1-x)^7}, \frac{1+22x+58x^2+24x^3}{(1-x)^9} \ldots$$

The Stirling numbers have many important relationships to the Bernoulli numbers (*q.v.*), Euler numbers (*q.v.*), and the tangential coefficients, and there are numerous formulas connecting them. In fact, there is a way of regarding the Bernoulli numbers as a species of Stirling numbers; that is $(e^x-1)^n$ always gives, when expanded, Stirling numbers; and when we let $n=-1$, we obtain a well-known expansion giving the Bernoulli numbers.

The consideration of $(e^x-1)^{-n}$ leads to what may be called ultra-Stirling numbers, a subject which, like the ultra-Bernoulli and ultra-Euler numbers has been very little studied.

**STIRLINGSHIRE,** midland county, Scotland, bounded north by Perthshire, north-east by Clackmannanshire and the Firth of Forth, south-east by Linlithgowshire, south by Lanarkshire and the detached part of Dumbartonshire and south-west and west by Dumbartonshire; land area 288,332 ac., or 450.5 sq.mi. In the northwest the Grampians end in Ben Lomond (3,192 ft.). The centre is occupied by the Lennox hills. The oldest rocks are the Dalradian schists in the north-west beyond a great fault which runs from near the bottom end of Loch Lomond in a north-easterly direction across Scotland. On the south-eastern side of the fault are the conglomerates and sandstones of Lower Old Red Sandstone age, followed by the Upper Old Red series. Then follows the Carboniferous system occupying the rest of the county. The true coal-measures are well-developed between Grangemouth and Stenhousemuir and about Falkirk. Intrusive sheets of basalt have penetrated the Carboniferous rocks and are quarried for road metal; Abbey Craig and Stirling Castle hill are formed of one of the more important of these intrusions. Much boulder clay covers the older rocks and an interesting blue marine clay is found beneath it in the Endrick valley. The Carse of Stirling is overlaid by the muds and sands of the 50-ft. raised beach; and traces of the 100-ft. beach also are found.

The chief river is the Forth, which forms most of the northern boundary. The other important streams are the Carron, rising in Campsie fells and flowing to the Forth at Grangemouth; the Endrick, which, rising in Fintry hills, empties itself into Loch Lomond; the Kelvin, which, from its source in Kilsyth hills, flows southwest to the Clyde at Glasgow after a run of 22 m.; and the Avon, rising in the detached portion of Dumbartonshire, and flowing to the Forth. The principal lochs include the greater part of the eastern waters of Loch Lomond; a small portion of the upper end of Loch Katrine, and Loch Arklet, in the north-west area, which, like Loch Katrine, provides part of the water supply of Glasgow. The Forth and Clyde canal crosses the south-eastern corner of the county from Grangemouth to Castlecary.

**History and Antiquities.**—The wall of Antonius, built by Lollius Urbicus, in A.D. 142, connecting the Forth and Clyde, passed through the south-east of the county, in which it is locally known as Graham's Dyke. At Castlecary and Camelon many relics have been found. The Camelon causeway ran eastwards from Castlecary and crossed the rampart at Camelon, whence it proceeded northwards to Stirling and the Forth, where there was a station near the present bridge of Drip. Thence it crossed the river to Keir and Dunblane in Perthshire. After the withdrawal of the Romans the county once more fell into the hands of the native inhabitants, who, however, gradually retired before the advance of the Saxons and Scots. By the time of Malcolm Canmore (d. 1093) the lowland area had become settled, but the highland tract remained a disturbed and disturbing region until the pacification following the Jacobite rising of 1745–6. The county played a conspicuous part in the struggle for Scottish independence, being particularly associated with many of the exploits of Sir William Wallace and Robert Bruce. The three great battles of the independence were fought in the shire—Stirling Bridge (1297), Falkirk (1298), Bannockburn (1314). James III. was stabbed to death in a cottage in the village of Milton after the battle of Sauchieburn (1488), but apart from the disastrous defeat of the Covenanters at Kilsyth (1645) and the transitory triumph which Prince Charles Edward won at Falkirk (1746), the history of the shire practically centres in that of the county town.

**Agriculture and Industries.**—The arable soils are of two kinds, locally distinguished as "carse" and "dryfield," the rest of the land being composed of pasture, moor and peat. The "carse" extends along the valley from Buchlyvie to the eastern boundary. The soil consists of the finest clays, without stones, but interspersed with strata of marine shells. It has been largely stripped of the overlying peat, and by draining, subsoil ploughing and the use of lime has been converted into a rich soil, especially adapted for wheat and beans. The "dryfield," which occupies the valleys and the higher ground bordering the carse, is fertile and suited for potatoes and turnips, of which there were 5,880 ac. in 1938. Oats (14,672 ac.) and wheat (2,997 ac.) are the chief grain crops. Beans are also grown. The cattle are comparatively few, but sheep, chiefly Black-faced, are raised. The average size of the 1,511 holdings in 1938 was 70½ ac., but over half were of 50 ac. and under. Birches grow on the lower slopes of the mountains in Buchanan and Drymen, and oaks on the banks of Loch Lomond. Larch and Scots fir are the leading trees in modern plantations.

The coalfield of the south-east supplies the staple industry, and coal is also mined in the east, near the Forth and Clyde canal. Iron ore and fireclay are also obtained, while granite, limestone and sandstone are quarried. The ironworks at Carron near Falkirk are important and nails are made at St. Ninian's and elsewhere. Woollens are manufactured at Stirling, St. Ninian's and Bannockburn; calico-printing and bleaching are established in the south-west, especially at Lennoxtown and Milton, and there are chemical works at Falkirk and Denny. Tanning, iron-founding, paper-making, brewing and distilling are carried on at different places, and shipbuilding at Grangemouth, the chief port. The southern and south-eastern districts are served by the L.N.E.R. from Edinburgh to Glasgow (via Falkirk) and the L.M.S.R. from Glasgow to Stirling (via Larbert), while branches connect Grangemouth, Denny and other places with the through-lines. One L.N.E. line crosses the shire, mostly in the north, from Stirling to Balloch, and another goes from Glasgow to Aberfoyle.

**Population and Administration.**—Pop. (est. 1938) 173,410. In 1931 Gaelic and English were spoken by 1,059 persons. Falkirk (est. 1938 pop. 38,173) and Stirling (23,552) are large burghs, the small burghs being Grangemouth (13,716), Kilsyth (8,703), Denny and Dunipace (5,995), and Bridge-of-Allan (2,899). There are three county districts. The shire returns a member to parliament with Clackmannan, and Stirling, Falkirk and Grangemouth one member. Stirling is the only royal burgh. The shire forms a sheriffdom with the counties of Dumbarton and Clackmannan, but there is a resident sheriff-substitute at Stirling and another at Falkirk. The shire is under school board jurisdiction, and there are high schools at Stirling and Falkirk.

**STJERNHJELM, GEORG** (1598–1672), Swedish poet and scholar, whose original name was Göran Lilja, was born at Wika in Dalecarlia on Aug. 7, 1598. He took his degree at Greifswald, and spent some years in travelling over every quarter of Europe. Gustavus Adolphus gave him a responsible post at Dorpat in 1630, and raised him next year to the nobility. After the king's death, Christina attached him, as a kind of poet laureate, to her

court in Stockholm. His property lay in Livonia, and when the Russians plundered that Province in 1656 the poet, who was in temporary disgrace at the court, was reduced to extreme poverty for two or three years. He subsequently became judge at Trondhjem, member of the council of war (1661) and president (1667) of the College of Antiquities at Stockholm. He died at Stockholm on April 22, 1672. His greatest poem *Hercules* (pr. 1653) is a didactic allegory in hexameters, written in very musical verse, and with almost Oriental splendour of phrase and imagery. *Bröllops-Besvärs Ihugkommelse,* a sort of serio-comic epithalamium in the same measure, is another brilliant work. His masques, *Then fångne Cupido* (Cupid Caught) (1649), *Freds-afl* (The Birth of Peace) (1649), and *Parnassus triumphans* (1651), were written for the entertainment of Queen Christina. He can scarcely be said to have been successful in his attempt, in the first two of these, to introduce unrhymed song-measures.

Stjernhjelm was an active philologist, and left a great number of works on language, of which only a few have been printed. He also wrote on history, mathematics, philosophy and natural science, producing original and valuable work on every subject he attempted. There is a full list of his writings in the *Svenskt biographiskt Lexikon,* vol. xv. (Uppsala, 1848).

**STOA,** a public building of ancient Greece, whose roof is supported by one or more rows of columns, usually placed adjacent to the agora (*q.v.*), and used either for a sheltered promenade or as a market hall. Extensive remains of stoae exist at Assus. At Athens, there are remains of the stoa of Attalus II. (159–138 B.C.); the so-called stoa of Hadrian is, in reality, a part of the great library of Hadrian.

**STOBAEUS, JOANNES,** so called from his native place Stobi in Macedonia, the compiler of a valuable series of extracts from Greek authors. Of his life nothing is known, but he probably belongs to the latter half of the 5th century A.D. From his silence in regard to Christian authors, it is inferred that he was not a Christian.

The extracts were intended by Stobaeus for his son Septimius, and were preceded by a letter briefly explaining the purpose of the work and giving a summary of the contents. From this summary (preserved in Photius's *Bibliotheca*) we learn that Stobaeus divided his work into four books and two volumes. In most of our MSS. the work is divided into three books, of which the first and second are generally called Ἐκλογαὶ φυσικαὶ καὶ ἠθικαί (Physical and Moral Extracts), and the third Ἀνθολόγιον (*Florilegium* or *Sermones*). The differences in arrangement between the work as we have it and the summary in Photius, combined with its fragmentary nature in places, suggests that what we have is a later Byzantine epitome. The first book teaches physics—in the wide Greek sense—by means of extracts. It is often untrustworthy: Stobaeus betrays a tendency to confound the dogmas of the early Ionic philosophers, and he occasionally mixes up Platonism with Pythagoreanism. The third and fourth books, like the larger part of the second, treat of ethics and politics. In all, Stobaeus quotes more than five hundred writers.

Editio princeps (1609); *Eclogae,* ed. T. Gaisford (1822), A. Meineke (1860–64); *Florilegium,* ed. T. Gaisford (1850), A. Meineke (1855–1857), C. Wachsmuth and O. Hense (1884–94, and 1909).

**STOCK.** When money is invested, the investor requires some tangible evidence of his investment and some measure of its size. Moreover, when, as is usually the case, he is one of many investors in the same object, means must exist of defining rigidly and legally the proportion held by each. This is true whether he invests his capital in a loan to a government, municipality or trading concern, or acquires a definite share of the last-named.

This evidence of the existence, nature and size of his holding consists either of "stock" or of "shares." Stock in Great Britain can be issued, bought, sold or redeemed in any odd amount. A share is indivisible and represents, as its name implies, a definite proportion of the total nominal value of the property. This is the vital distinction, which is best clarified by an example.

Stock is always expressed in "so many pounds, shillings and pence face value." Thus "£200 consols" means "£200 face value of British Consolidated Stock." The face value, in conjunction with the rate of interest, determines the dividend. Thus the rate of interest upon consols is 2½ per cent., and so the dividend upon £200 consols is £5 per annum. Face value has no connection with the market value. Thus a sale of £200 consols may fetch no more than £100 in cash. Market value depends simply upon the current price, which is usually quoted in pounds cash per £100 stock. Thus, at a market price of 60, £200 consols could be bought and sold for £120 cash. Stock is always bought and sold in quantities expressed in face value, viz.: a sale of £215.6.8 stock, or a purchase of £350.10.4 stock. Shares are always bought and sold by number, viz.: 352 Courtaulds ordinary shares. (*See* SHARES.)

The chief forms of stock are as follows—(*A*) Government (British, colonial or foreign), municipal (British, colonial or foreign) and debenture stock (railways, shipping, trading, manufacturing, etc.). In every case the stock is evidence of a loan made to the Government, municipality, railway, etc. The stock may be redeemable or it may be irredeemable. The total amount issued is usually limited, but the borrower may have power to issue more at his discretion. It may be issued at par (*i.e.,* £100 stock for £100 cash) or at a premium or a discount, *i.e.,* at more or less than £100 cash. It may be redeemable at par or at a premium. It may have definite, tangible security behind it, such as a lien on the customs revenues or upon the manufacturer's plant, or it may be secured simply by the word of the borrower. The vital point is that it is measured in, bought and sold according to, and its dividends based upon, its face value.

(*B*) Preferred, ordinary and deferred stock. Such stock is evidence of a definite share in the property owned by the issuing company—of which each stockholder is *ipso facto* a member. By virtue of his holding, he is entitled to a share of the net profits, after interest on debentures has been met, and to certain rights, privileges and liabilities, according to his class of holding. His stock comes under the broad heading of capital stock. As a rule, capital is issued in the form of shares and not stock, and so the reader is referred to the article on SHARES for any further description. Two points only need here be mentioned. The first is that dividends are always declared in the form of "so much per cent. on the face value of the stock." The second is that, in case of liquidation, any available assets are divided among the stockholders, class by class, in the same proportion as that borne by the face value of their holding to the total face value of the whole of the outstanding stock in the class to which they belong.

For forms of issue, *see* TRANSFER. (N. E. C.)

### UNITED STATES

The usage of the terms "stocks" and "shares" in the United States is quite different from that in England. In the United States stock signifies the ownership in the business held by the many persons who have bought interest in it and who are known as the stockholders. It does not carry the idea of a loan but indicates always an actual purchase of part ownership. Loans to either private businesses, governments or municipalities are represented by "bonds," except in the case of New York city, which still adheres to the English usage and still has outstanding its "stock," which is to all intents and purposes equivalent to the municipal bonds of other American cities. The aggregate ownership or stock of an American corporation is divided into a large number of units or shares, of which each stockholder may hold one or many. The share, then, is one of the units of ownership. This ownership is represented by "certificates of stock," and when a person buys one or more shares of stock he receives as evidence of this ownership a certificate of stock filled in for the proper number of shares. This is a convenient and practical method of representing ownership, because the ownership can readily be transferred by the transfer of the certificate. (*See* TRANSFER.) Owners of stock in a corporation participate in the prosperity of the company by receiving their proportionate share of any profits that the board of directors sees fit from time to time to divide among them. This division of surplus is generally made annually, semi-

annually or quarterly, and all moneys or other property so divided among the shareholders is called a dividend. (*See* DIVIDEND.)

### CLASSES OF STOCK

Stock of a corporation is a commodity which the corporation must sell in order to raise the funds necessary for the business, and therefore it is incumbent upon the corporation to make this commodity as attractive as possible, this in order not only that it may be disposed of easily but also at an advantageous price. Stocks are issued, therefore, in several classes providing numerous combinations of the three elements, income, control and risk. The average buyer of securities wants as large and as steady an income as possible with the smallest risk, and takes comparatively little interest in the control. The cautious investor will take a smaller income if there be less risk attached, whereas the speculatively inclined will take a greater risk for the chance of greater income. Instances often occur where control of the company is the chief end sought by the stock-buyer and he will practically ignore both present risk and income to get the control. The two great divisions or classifications of stock are "common" and "preferred."

**Common Stock** is simply ownership in the corporation, carrying with it all the usual rights of stockholders (unless otherwise specified) but no special privileges or preferences. These fundamental rights of stockholders are: (1) To proportionate ownership in the undivided assets of the corporation and to a certificate stating this ownership in shares. (2) To transfer ownership of his shares. (3) To receive dividends when earned and declared by the board of directors. (4) To inspect the corporate books. (5) To subscribe, in proportion to his holdings, to any new issue of stock. (6) To proportionate control through voting power. (7) To vote on other questions affecting the corporation property as a whole. (8) To protect the corporation against wrongful acts of a majority. (9) To restrain *ultra vires* acts of the corporation. (10) To share in the proceeds of dissolution.

**Preferred Stock** is stock which, while it possesses the same rights and privileges as common stock (unless otherwise specified), has in addition certain more or less valuable and desirable preferences. It may be preferred as to assets, dividends or both, but in ordinary parlance the term "preferred stock" means preferred as to dividends.

Being preferred as to assets means that in case of dissolution of the company, the holders of the stock will receive their portion of the proceeds of dissolution before holders of other stock not preferred as to assets will participate. This preference is, of course, of no service to the stockholder as long as his company is prosperous and in no danger of dissolution, but in the case of weak companies the preference tends to give his stock a higher market value than stock not so preferred. And in the case of actual dissolution where the assets are not sufficient to satisfy all, the preference will prove to be most valuable.

"Preferred as to dividends" means that this stock is entitled to a specified rate of dividend out of the earnings before any dividend is given to the stock not so preferred. It does not mean that a certain dividend is guaranteed but merely that if any amount of the earnings be declared as a dividend, the amount necessary to pay the specified rate of dividend on the preferred stock, or such part of such dividend as possible, must be used for this purpose before any is allocated to pay a dividend on non-preferred stock. If the entire amount declared as a dividend is absorbed by the dividend on the preferred stock, it means simply that the non-preferred or common stock gets nothing. In prosperous companies, however, it is usually possible to pay the stipulated rate to the preferred stock and still have sufficient moneys left to pay an equal or even larger rate to the common stock. It is ordinarily only fair that the common stock should get more in view of the fact that it takes a risk by permitting the preferred stock to take out its share of dividend first.

It is sometimes deemed advisable to have several issues of preferred stock, one taking precedence over the next, just as ordinary preferred takes precedence over common. These several issues are then usually classified as 1st preferred, 2nd preferred, 3rd preferred and so on, or sometimes as preferred A, preferred B, preferred C.

These two great classes of stock, common and preferred, have not by any means satisfied the wants of investors and speculators, and hence a large number of variations have grown up, particularly in preferred stock, affecting the income, control or risk of the stockholders in various manners. The more important of these various classes will be explained.

**Nonparticipating and Participating.**—Nonparticipating preferred stock is stock which, through the terms of its issue and sale, is to receive a preferential dividend at a stipulated rate, usually about 6%, and nothing whatever beyond that, all other dividend, regardless of its amount, going to the common stock.

Participating preferred stock is that which is to receive first its preferential dividend at the stipulated rate and after that is to participate or share with the other stock in the remainder of the funds declared as dividend. This participation or sharing may be done in one of a number of ways, but regardless of the manner of participation, if the preferred stock shares in any way in the dividend over and above its stipulated rate, it is participating stock. The methods of participation are generally known as "participating simply," "participating immediately" and "participating specially."

*Simple Participating.*—Simple or ordinary participation is an arrangement whereby the preferred stock first gets its dividends up to the specified rate; after that the common stock will be paid dividends as far as possible up to and including the same rate that the preferred has received; if, after having paid both the preferred and the common the same rate of dividend, there be anything left of the total amount declared as dividend, it is shared or participated in by both the preferred and common alike, just as though they were only one class.

The term "participating preferred stock" in itself means that it is simply participating.

*Participating Immediately.*—Preferred stock is said to be immediately participating when the arrangement for apportioning the dividend among the classes of stock provides that the preferred stock first receives dividend up to the specified rate and that immediately thereafter without first giving the common stock a dividend payment at the same rate, all the remainder of the dividend money is allotted to all stock alike, regardless of whether it be preferred or common.

*Participating Specially.*—The above described methods of participation are, however, by no means the only ones. As a matter of fact, the number of methods of participation is limited only by the ingenuity of the company organizers. It is possible, for instance, to have the preferred get 6%, then the common 6%, then the preferred all the remainder; or the preferred 6%, then common 6%, then preferred 4%, then common 2% and the remainder *pro rata;* or preferred 5%, then common 6%, then all the remainder to preferred and common in the proportion of two to one; or any other arrangement whatever that may be provided in the certificate of incorporation, which in this respect constitutes a contract between the company and the stockholder.

**Noncumulative and Cumulative.**—The dividends on preferred stock may be noncumulative or cumulative. Provision is often made in the certificate of incorporation that if sufficient dividends are not declared in any one year to pay the full dividend on the preferred stock, there is no obligation on the part of the corporation to make up the deficiency in any subsequent year. This means that dividends or parts of dividends not paid to preferred stockholders in any given year are lost to them forever. Stock governed by this provision is known as "noncumulative."

Cumulative preferred stock, on the other hand, is stock, the stipulated dividend of which, if not paid in full in one or more years, carries over from year to year till fully paid. When dividends have not been declared, or have been declared in amount insufficient to pay the full specified rate of dividend on this cumulative preferred stock, they are in arrears and as long as they are unpaid they constitute a claim on future earnings prior to any dividend claim of the common stock. In other words, common stockholders are not entitled to receive any dividend as long

as the cumulative preferred stock dividends are in arrears. In case the certificate of incorporation makes no provision concerning whether or not the preferred stock dividend is to be cumulative, it has been held by the courts that the dividend shall be cumulative.

Companies sometimes provide that their preferred stock shall be noncumulative for several years, after which it shall become cumulative. This provision relieves the company of the necessity of paying full dividends on the preferred stock during the early years when earnings are expected to be small or of having the dividend accumulate as a charge against future years, and yet assures the stock almost as good selling power as if it were fully cumulative from the first.

**Redeemable Stock.**—Preferred stock, or certain classes of preferred stock, are occasionally made redeemable. This means that the company has the option under the conditions and on terms specified in the certificate of incorporation, of redeeming or buying back the stock from the stockholders. This redemption right rests, of course, entirely with the company, and stockholders can neither compel nor refuse redemption of their stock. Some advance notice of intended redemption is usually provided for, and a redemption price is generally set at a premium so as to compensate the holder for the loss of his investment and give him an opportunity to seek a reinvestment of his money without suffering loss of income in the interim. Redemption at a premium is not universal, however, many companies having the redemption price set at par. If the redeemable stock has the voting power, its redemption has considerable effect upon the control of the company because of the elimination of all the votes represented by it.

Redeemability also may have a material effect upon the market price of a stock, the tendency being to keep the market price lower than it otherwise might be. If the stock is redeemable at 110 and has an investment value of 140, a buyer would in all probability refuse to pay this much for it, fearing that the corporation might exercise its redemption privilege and deprive him of his stock at 110, thus bringing about a considerable loss. If, on the other hand, the investment value is below the redemption price, the redemption feature would ordinarily have no effect on the market unless to make the stock slightly less attractive because of the fact that there is an upper limit to the possible price rise.

**Convertible Stock.**—One or more classes of stock may be made convertible, that is, exchangeable at the option of the holder, into some other specified security. Conversion, unlike redemption, is always at the option of the holder. The certificate of incorporation may make certain stipulations or set a certain time limit for the conversion, but within these restrictions the stockholder can demand the conversion at his pleasure. The most usual conversion permitted is from preferred to common stock. Convertible stock of this type is quite popular because it enables the holder to receive preference as to dividends when the earnings are small and there is little left for the common dividends, and yet permits him to trade in his stock for common in case the earnings become large and the common is receiving large returns.

The matter of control also frequently enters, as nonvoting preferred stock is often convertible into voting common stock. This feature will sometimes induce stockholders to convert, even at a financial loss. Occasionally, stock is issued which is convertible into bonds. This is rare, however, and is hedged about with various protective stipulations. In the first place, such conversion should be only at the option of the company, for if this were not the case, holders of such stock in a weak or insolvent company could convert their stock into bonds and thus share in the proceeds of dissolution ahead of many creditors and on an equal footing with other bondholders of the company who acquired them through *bona fide* purchase, which is manifestly unfair. The money which stockholders pay into the company for their ownership is a part of the owned capital of the company, and it is upon the strength of this owned capital and the security afforded by it that the company is enabled to obtain its borrowed capital through the sale of bonds. If, therefore, a large number of stockholders are permitted to convert their stock into bonds, thus becoming creditors of the company instead of part owners, it naturally means increase of bonded debt with no increase whatever of assets, and lessens the value of all other bonds.

**Protected Preferred Stock.**—Recently some companies have been making some of their preferred stock especially attractive as an investment by "protecting the dividend." This means simply that after the preferred dividend is paid, a certain amount is placed each year in a reserve or sinking fund, before the dividend is paid to the common stock. This sinking fund is built up to some required size and is to be used to pay the preferred dividends in case of poor years when the current surplus would not be sufficient. When this fund reaches the stipulated size, it is not built up further, but the dividends can then go direct to the common stock without the fund payment coming in ahead. If the fund is depleted, however, by being drawn on to meet a preferred dividend in a poor year, it must be built up to full requirements again as before.

**Debenture Stock.**—This term is very rarely used in the United States. It is an English expression meaning, in reality, not stock at all but a bond, corresponding to the American debenture bond. In American finance, however, the name has been adopted occasionally and applied to a special type of stock conferring rights, superior to both preferred and common, something in the nature of a prior preference stock. The best known example of this use of the term is the 8% debenture stock of the Dennison Manufacturing company.

**Prior Preference Stock.**—Prior preference stock, or prior lien stock, is a term rarely used but indicates usually that, after the issuance of the regular preferred stock, another issue has, with the consent of the old stockholders, been issued having a claim prior to that of all other stocks on dividends or assets. Upon issue, it becomes a first preferred stock and the other names serve merely as convenient descriptions. The prior preferred stock of the Celanese Corporation of America and the prior preferred stock of the Market Street Railway Company of San Francisco are examples.

**Guaranteed Stocks.**—Guaranteed stock is stock whose dividend payments are guaranteed by some other company, usually one which is using the property of the issuing concern. Railway companies frequently lease and operate the property of other companies and, as part of the rental, guarantee the payment of dividends at a certain rate to all the stockholders. Although such operation is most general among railway companies, it is frequently practised among industrials also. Preferred stock is sometimes referred to as guaranteed stock, a term which, of course, is erroneous. A corporation cannot guarantee its own stock and cannot issue a guaranteed stock.

**Voting and Nonvoting Stock.**—All stockholders have the inherent right to participate in the management of the corporation through voting for directors and on other matters. Nonvoting stock may be issued, however, and purchasers of such stock voluntarily surrender their voting rights. It is generally customary to give the vote to the common stock and to withhold it from the preferred. The vote may be apportioned among several classes of stock in any desired manner as long as at least one class of stock is vested with voting power. If stock is issued as voting stock, however, such stock cannot be deprived of the vote without the consent of the holder.

**Vetoing Stock.**—Vetoing is the name given to stock which has not general voting power but is entitled through provision of the certificate of incorporation to vote on certain questions. Thus a certain issue of preferred stock may be voteless except on the question of the issue of additional preferred stock on which question it is given the voting right.

It is quite common to give to nonvoting preferred stock the right to vote after its dividends have not been paid for a certain period of time, and to continue this voting power as long as the dividends are unpaid, or in case of cumulative preferred stock as long as dividends are in arrears. In such cases this stock is sometimes given the right to vote along with the common, sometimes the exclusive voting right, and sometimes the right to elect a given proportion of the board of directors.

**Par Value and Nonpar Value Stock.**—For a great many years each share of stock of a corporation was given a nominal or par value, the common unit being a share with a par value of $100. The sum of all of the $100 shares constitutes the nominal value of all the authorized stock of the company. This par value, however, does

not necessarily represent any real value, though many people are misled by it. A share of stock may have a par value of $100 while the book value may be $80 and its actual market value $60. The nominal or par valuation of stock is, therefore, purely artificial. It furnishes a basis or principal amount upon which to reckon dividends on a percentage basis, but otherwise is no indication of real value.

After 1912 there grew up the practice of issuing shares of stock without any nominal or par value, known variously as nonpar value, or no-par value stock, stock without par value, and unvalued shares. The issuance of nonpar value stock is now permitted by the laws of most states, and this type of stock has been widely adopted in new incorporations and in reorganizations of existing corporations, partly due to tax laws affecting stocks and stock transfers. The statutes usually provide that such stock shall be sold by the company at a price not less than that prescribed in the certificate of incorporation, or the fair market value, or as may be from time to time set by the board of directors provided that the certificate of incorporation confers this authority, or for such consideration as shall be consented to or approved by the holders of the majority of shares at a meeting called to vote on the question. All nonpar value shares sold in accordance with these legal provisions are deemed fully paid and nonassessable and the holder of such shares is not liable to the corporation or to the creditors in respect thereto. Every certificate of stock without par value must show the total number of such shares authorized, as well as the number represented by the certificate, and also the authorized number of par-value shares, if any, and their par value, thus making it possible to determine the proportionate interest in the net assets of a corporation which a given stock certificate represents. Having no par value or base on which to estimate a percentage dividend, the total dividend allotment is divided equally among all the nonpar value shares outstanding, and declared as so many dollars per share.

**Ex-Rights and Rights-on.**—Corporate stockholders often have, either by law or agreement, the privilege to purchase their proportionate parts of any new stock offered by their company before it may be offered to outsiders. This is known as the "privileged subscription right." These rights are represented by warrants and are transferable, hence they are freely dealt in upon the security market. When an issue of "rights" is declared by corporate directors they are announced as issuable to the stockholders of record as of some specified date. After the declaration any stock of the issue entitled to "rights" which is bought, sold, or transferred prior to the "right" issue date is traded in upon a "rights-on" basis, that is the purchaser gets not only title to the stock itself but also acquires the prerogative to receive the rights pertaining thereto "when, as, and if issued." The price of the stock in such a case will cover not only the market value of the shares themselves but also the estimated value of the "rights" to which they are entitled. After the "rights" have been issued the shares of stock and the warrants representing the "rights" are dealt in separately and the stock is said to be sold "ex-rights," that is, having no claim upon the "rights" involved. In such a case the market price of the stock will very closely approximate the former "rights-on" quotation minus the value of the rights.

*See* C. W. Gerstenberg, *Financial Organization and Management of Business* (1944 ed.); Guthmann and Dougall, *Corporate Financial Policy* (1944 ed.); Bonneville and Dewey, *Organizing and Financing Business* (1945 ed.). (J. H. B.)

**STOCKBRIDGE,** a town of Berkshire county, Massachusetts, U.S.A., on the Housatonic river, served by the New York, New Haven and Hartford railroad. Pop. 1940, 1,815 by federal census. It is a summer and autumn resort, and a region of historic interest. Within its area of 24 sq.mi. are Lake Mahkeenac or Stockbridge Bowl, Ice Glen (where caverns are lined with ice even in midsummer), and Monument mountain (1,710 ft.). Most of "Tanglewood," home of the Berkshire Symphonic festival and the Boston Symphony orchestra's Berkshire music centre, is in Stockbridge, overlooking "the Bowl." In 1736 a plantation 6 mi. square (including the present town of Stockbridge) was laid out for the Mohican Indians who had come to the Housatonic valley from the west bank of the Hudson when white settlements began to encroach on their territory, and among whom John Sergeant had established a mission in 1734. In 1739 this "Indian Town" was incorporated as the town of Stockbridge. The Indians had a school and a church with Jonathan Edwards in charge from 1750 to 1758. Many of them fought on the American side during the Revolution. In 1783–88 nearly all of them moved to New York, and by 1829 most of them had gone to Wisconsin.

**STOCKBROKER,** an agent who deals in stocks and shares. He need not be a member of any recognized stock exchange, nor of an association of stock exchanges. He need not confine his energies to dealing in only such securities as those which are quoted in a stock exchange. The broker member of the London stock exchange is an agent for the buying and the selling of stocks and shares of any description, and his status is kept strictly clear from that of a stockjobber, so far as the London stock exchange rules are concerned. The broker, if a stock exchange member, acts as an agent; seldom as a principal. He does not as a rule buy from a client nor sell to a client. He buys or sells on behalf of the client, and takes a certain amount of commission, the extent of which is laid down in stock exchange rules for members of the stock exchange as his remuneration for doing the business. He is not allowed, in the London stock exchange, to buy 100 shares from a client say at £5 and sell them simultaneously to another client at £5 5s. To do this would be acting as a principal, the part assigned to a stockjobber.

The young man who would become a broker in a London stock exchange usually finds that a good way of achieving his end is to obtain a seat in the office of a stock exchange firm, entering either as a junior or a clerk, and gradually working his way through the various stages which stand between the outsider and the full-blown member of the stock exchange. He can become a member without delay, provided he is not less than 21 years of age and is able to obtain three sureties who will guarantee, in the sum of £500 each, the fulfilment of his obligations for four years from the date of his admission. If the candidate has served as a clerk in the stock exchange for four years previously to the lodging of his application form, two sureties, or recommenders, only are required, who must each enter into an obligation as above mentioned, but for £300 apiece. The scale of the London stock exchange charges, both for admission fee and annual subscription, is substantially less in the case of the experienced man. The candidate for membership must obtain with a very small proportion of exceptions, a nomination, the price of which varies considerably. When first created some years before World War I, a nomination reached the value of £700. After that war, nominations became at one time practically valueless. Several are known to have changed hands at £5 apiece. After that an improvement set in, and the price rose to about £2,000, but it fell heavily during World War II.

Strict rules govern the stockbroker in the London stock exchange, and some of the provincial stock exchanges have modelled their rules upon them. He must be a British subject; he has to apply for re-election every year; he must state whether he intends to act as broker or jobber; he must not be a principal in any business other than that of stock exchange, nor must he be member of, or subscriber to, any other institution where dealings in stocks and shares are carried on. His wife, also, must not be engaged in business. His duties bring him into contact with his clients, and with brokers and jobbers alike, and he acts as agent between the public on one side and members of the stock exchange on the other. He is required to have a general knowledge of all the markets in which he is called upon to deal, and he must be prepared to give reasonable answers to the hundreds of questions with which he is plied on all sorts of subjects. The broker's life is more arduous than that of a jobber, involving longer hours and the exercise of unlimited patience, for he has to make allowance for the fact that the majority of his clients do not grasp the intimate details of what is after all a very technical business. His first daily duty, after having digested the financial parts of his newspaper, is to deal with the correspondence that has reached him, and extract from it the orders that he will take into the stock exchange for execution when the markets open. He, the broker, buys or sells War loan in one market, Kaffirs in another, artificial silks in another, going through various parts of the House that have no strict delimitations, one market impinging on the next. The men round the markets who deal in specialized stocks and shares are the jobbers, and to them the broker proceeds, expecting that he will be able to get a double price made to him, at the higher of which he can buy and at the lower of which he can sell without the jobber knowing in advance which of the two courses the broker will take in executing his client's order.

In the spring of 1939, owing to the losses sustained for many previous years by members of the public through the malpractice of what are called "bucket-shops," parliament passed an act to provide for regulating the business of dealing in securities. It is

called the Prevention of Fraud (Investments) act 1939. Section 1 lays down that no person shall, on or after the appointed day, carry on or purport to carry on the business of dealing in securities except under the authority of a principal's licence; that is to say, a licence under this act authorizing him to carry on the business of dealing in securities. The servant or agent of any such person is required to hold a representative's licence authorizing him to deal in securities as a servant or agent of the holder of a principal's licence. These restrictions do not apply, the act lays down, to a member of any recognized stock exchange or recognized association of dealers in securities. The Bank of England, certain other bodies and persons, are exempted from the restrictions imposed by this act. Contravention of its provisions involves liability for heavy penalties. Issue of the licences, the act provides, is in the hands of the board of trade and a prescribed fee, together with a deposit of £500, is required for a principal's licence which will be valid for one year. Fraudulently inducing persons to invest money is an offense that carries liability to penal servitude for a term not exceeding seven years, and restrictions are placed upon the distribution of circulars relating to investments. The restrictions do not apply to prospectuses and other documents permitted by the board of trade. The act was partly suspended after the outbreak of World War II. (W. L.)

**United States.**—A stockbroker is an agent who deals in stocks, bonds and other securities either on or off an organized exchange. Legally, the relationship between the broker and customer is not only that of agent and principal but becomes that of creditor and debtor and that of pledgee and pledgor when the customer purchases on margin and the broker furnishes the required additional funds secured by collateral. The relationships between brokers and their customers are governed by the various and differing state statutes, customs, business policy and the constitutions and rules of the organized exchanges. The New York stock exchange does not permit a corporation to become a member; consequently brokerage houses with memberships on the exchange are partnerships.

The distinction between brokers and jobbers, which obtains in London, does not exist in the United States. On the New York stock exchange all brokers are free to trade with one another and with the public as they choose provided they conform with the constitution and rules of the exchange. Brokers on the New York stock exchange may be divided, according to the special nature of their business, into five groups: (1) commission brokers, those who act for the public at a commission fixed by the exchange; (2) "two-dollar" brokers, who act as agents for other member brokers on the exchange at a rate of $2.50 per 100 shares (the old name still prevailing although the $2 rate has been superseded); (3) floor or room traders, those who buy and sell for themselves and for their own profit; (4) specialists, who specialize in certain securities and may act as commission brokers or floor traders but who ordinarily do not come into contact with the public; and (5) the odd-lot dealers, who supply or buy from commission brokers a sufficient number of odd lots to equal the full 100 shares, which is the minimum amount that may be purchased or sold on the exchange. While very few houses deal in odd lots, they usually have several representatives on the exchange and probably one-fourth of all the business done on the exchange originates in odd lots. The odd-lot dealer enables the small investor to trade in a few stocks or shares within a small fraction above the price at which large lots are bought and sold.

Brokers who are members of the New York stock exchange are controlled rigidly by the constitution, rules and customs of the exchange in an effort to secure fair competition and the proper relationship between the broker and his customer. For example, a broker may not take the side of the market opposite his customer, his charges are regulated, he must report accurately the status of his business to the exchange, he may not advertise securities falsely and the advertising by the firm of itself is regulated explicitly by the exchange. American stock exchanges are modelled after the New York exchange. Brokers are also regulated by the laws of their respective states and by the Securities and Exchange commission created by federal law. (W. E. S.; X.)

**STÖCKER, HELENE** (1869– ), German writer, editor, educator and organizer in the pacifist movement, was born at Elberfeld in 1869. Of a strict Calvinistic family opposed to higher education for women, she eventually went to Berlin in 1892, and was one of the first women to study philosophy, economics, art and literature at the universities of Berlin, Glasgow and Berne. She received a Ph.D. degree from the last named institution in 1901, subsequently settling in Berlin as an adult educator. In 1905 she founded the League for the Protection of Motherhood and Sexual Reform, and edited its publication, *New Generation*. To her intransigence respecting more wholesome sex relations was added her firm pacifism, induced by Bertha von Suttner's story, "Die Waffen nieder." For criticizing the Treaty of Brest-Litovsk she was forbidden by the military authorities, during World War I, to make further public pronouncements. After the war she continued her work for peace as a member of the board of the "Deutsche Friedensgesellschaft" and in 1921 as a member of the International Peace Bureau of Geneva. Some of her proposals, notably one concerning a legal status for the children of unmarried mothers, were incorporated in the constitution of the Weimar republic.

In 1922 she expressed her views on love in a novel entitled *Liebe*, and several collections of her essays appeared in the following years. With Hitler's rise to power she was obliged to flee Germany, going first to Czechoslovakia, then to Switzerland, England, Sweden and eventually to the United States by way of Siberia. She was deprived of her citizenship and her property was confiscated by the National Socialist government.

**STOCK EXCHANGE** or **BOURSE,** a market for the purchase and sale of securities, such as shares, stocks and bonds. Markets for dealing in securities have existed for centuries. They had their beginnings usually in a few men meeting regularly in a certain place, a coffee house or restaurant, who for a commission were prepared to act as intermediaries between buyers and sellers. As their business grew, these men formed themselves into a sort of association, and rules were framed to regulate the conduct of their business. With the growth and wider distribution of wealth, the volume of stock exchange business has steadily expanded, and in the past quarter of a century the growth has been more rapid than in any similar period. Nowadays, practically everyone in highly-civilized countries has dealings with a stock exchange, or bourse as it is called on the continent. The development of joint stock enterprise could never have reached its present stage but for the facilities which the stock exchanges provide for dealing in securities. Their primary function is to liquefy capital by enabling a person who has invested money in, say, a factory or a railway, to convert it into cash by disposing of his share in the enterprise to someone else. Without the stock exchange, capital would become immobilized, for once invested there would be no means of liquefying it.

**London.**—London is the greatest of the world's stock exchanges in the range and volume of its transactions. Although New York has made great progress in recent years, London is by far the most international stock exchange in the world, the range of its business covering every corner of the earth and every class and type of security. It was not until the latter part of the 18th century that the London stockbrokers definitely formed themselves into a stock exchange with premises of their own. They had been in the habit of meeting and doing business in the Royal Exchange and neighbouring places, but in 1773 those who had hitherto met at "Jonathan's" (Coffee House), in Change Alley, moved to a room in Sweeting's Alley to which the name of "The Stock Exchange" was formally given, the building becoming known as "The Stock Exchange Coffee House" or "Tavern." Business grew apace and in 1801 a group of members raised £20,000 of capital in 400 shares of £50 each for the purpose of providing an adequate building and acquired a site in Capel Court, Bartholomew lane, which to-day is one of the entrances to the "house."

The new building of the members was opened in 1802. At that time the members of the stock exchange numbered about 500. Rules were drawn up for the conduct of business and for regu-

lating membership of the "house." It was provided that all future members should be admitted by ballot, and members were required to pay a subscription of 10 guineas each for themselves and 5 guineas for their clerks. It was always the general intention that the shares should be held by members but there was always a large number of members who did not hold shares. The first extension was made in 1823 when the floor space was nearly doubled by the addition of a second room for dealings in foreign stock. In 1854 the two rooms with some small additions were rebuilt as one in the form of a dome with two transepts. Several subsequent extensions of this building have been made, the principal one being in 1885 when another dome was added. The stock exchange building occupies the greater portion of the triangular area formed by Throgmorton street, Bartholomew lane and Old Broad street. Outwardly it is an uninspiring structure, but the interior is both spacious and handsome.

The premises and property of the London stock exchange are owned by an association called "The Stock Exchange," the capital of which is in 20,000 shares of unlimited liability. On each of these shares £36 has been paid up. No one person may hold more than 200 shares, and only members can be registered as shareholders, except in the case of those who acquired their shares from proprietors who held them before Dec. 31, 1875. The new deed of settlement took effect on Jan. 1, 1876, when the number of proprietors was 268. In 1928 the number was 2,712. When a shareholder dies his shares must be sold to a member within two years. There is a ready market for the shares, for the dividends are handsome. Recently they have amounted to £10 per share. The income of the stock exchange (for 1927–28 it amounted to £231,583) is derived from the annual subscriptions of members and their clerks and from entrance fees paid by new members and from rents and investments. The fees have been raised from time to time; members admitted before March 25, 1876, and members admitted with two sureties before March 25, 1879, pay an annual subscription of only £21. The present annual subscription for new members with three sureties, is 100 guineas, and for new members with two sureties—that is to say, a clerk who has served four years in the house—50 guineas. The present entrance fees are 600 guineas for a member with three sureties and 300 guineas for one with two sureties. The present entrance fees for authorized clerks—clerks authorized to deal—are 50 guineas and for unauthorized clerks 15 guineas; and their annual subscriptions amount to 100 guineas and 30 guineas respectively. For clerks admitted to the settling room only, no entrance fee is payable, but an annual subscription of 10 guineas is payable for each clerk. These subscriptions and fees are fixed annually by the trustees and managers.

The property of the stock exchange is under the control and administration of nine trustees and managers, who are appointed by the shareholders. Every five years three retire, and are eligible for re-election. If two vacancies occur they are immediately filled, but in the case of one vacancy it is not filled until the annual meeting. The trustees and managers have no control over business transactions on the stock exchange, which are in the hands of the committee for general purposes, numbering 30 members, who are elected annually. This body regulates the transaction of business on the stock exchange, makes others and repeals rules and regulations for the same, is charged with the admission and discipline of members and their clerks, and is generally responsible for the good order and government of the members. Its work is so heavy that subcommittees are formed to deal with particular matters.

Securities cannot be dealt in on the stock exchange except by permission of the committee, and conditions have to be fulfilled before that permission is granted. This is one of the most important new rules of the stock exchange. Before World War I any security could be dealt in without the permission of the committee, and all that the latter were called upon to do was to fix a special settlement for the completion of the first transactions. Sometimes weeks would elapse before a special settlement was applied for and granted, and sometimes none was applied for or granted. Grave abuses occasionally arose in connection with the marketing of new shares in this way. This licence to deal has been abolished, and the interests of the public are much better protected than they used to be. The discipline of the stock exchange is very strict and the committee deals severely with any members guilty of improper conduct. The committee settles disputes between members and also between members and their clients. It has power to suspend or expel a member. Membership is for 12 months only, and thus everyone who wishes to remain a member must apply to the committee for re-election. The year ends on March 24. An important innovation was made in the year 1904, when it was decided to restrict the growth of membership. Prior to that date it was possible to become a member without the nomination of a retiring member. As a result, in active times membership rapidly increased, and when dull times came the competition for business became extremely keen. The rule passed in that year virtually stopping the growth of membership is the most important rule affecting the stock exchange passed in the present century. In the ordinary way the only method by which a person may become a member is to obtain a nomination (by purchase) from an existing member who must retire in his favour. Nominations may be obtained from a former member, or, if he has not disposed of his nomination, from the legal personal representative of a deceased member. Nominations, which are personal and nontransferable, are usually purchased, and the cost may be as high as £2,000. To-day (1928) the cost is about £1,150. A candidate for membership must be recommended by three members, who become sureties for him during the first four years in £500 each, or £1,500 altogether. A certain number of clerks who have completed four years' service are admitted each year without nomination. The number of such admissions is left to the discretion of the committee; in 1927–28 the number of such new admissions was 20.

The fact that the stock exchange is owned by the shareholders and controlled by their elected trustees and managers, while a separate body, the stock exchange committee, appointed by the members, controls and regulates business, has constituted what is known as dual control. The committee has no funds of its own and cannot initiate or control the expenditure of the money subscribed by the members. While the arrangement has worked remarkably smoothly, it is nevertheless anomalous and various efforts have been made to terminate it. But none of them has succeeded. After Nov. 23, 1904, every member admitted with two sureties has been obliged to become the owner of at least one share and every member with three sureties must hold three shares; under this arrangement the dual control is not likely to be abolished for a long time to come. One of the most interesting innovations on the stock exchange has been the introduction in 1928 of a pension scheme for members' clerks. The scheme was floated by the Clerks' Provident Fund with the blessing of the committee, but it is really unofficial and voluntary. Members, however, have generously supported the scheme, which in time will no doubt be generally adopted.

The London stock exchange contains two notable monuments, the Boer War memorial and the memorial to those who fell in World War I.

By custom, each market has a special place allotted to it; for instance, the space immediately in front of World War I memorial is the market for British government securities and other gilt-edged stocks. Dealers or jobbers in these securities take up their posts in this space every day, and dealers in other classes of securities similarly occupy the floor space allotted to their particular markets. In this way the locality of a market can be readily and easily found by the brokers who go to the house to buy or sell securities for their clients. There is an important distinction between brokers and dealers. Brokers are not allowed to deal on their own account, nor can dealers act as brokers. Their functions are defined by a rule which was last amended in 1908 and took effect as from Feb. 1, 1909. The dealer or jobber occupies a position similar to that of the wholesale dealer in commodities. He keeps a stock of particular securities, say oil shares, and his function is to buy oil shares when they are offered to him and to sell them if they are wanted. He quotes

two prices for a share, a buying price, which is the lower, and a selling price, which is the higher, and the difference represents his profit. A broker acts for the public which desires to buy or sell securities. Ordinarily, both for buying and selling securities, though under certain circumstances only for buying, a commission is charged. On receiving an order to deal in a certain security, a broker goes to a jobber in that market, and asks for a price, mentioning the amount of stock which he desires to deal in, but he does not disclose whether he is a buyer or a seller. The jobber "makes a price," *i.e.,* gives two prices; at one he is prepared to buy and at the other to sell. If the broker is satisfied with the price, or if it conforms with the price limit fixed by his client, he will tell the jobber that he sells or buys as the case may be, at the price quoted. On the other hand, if he is dissatisfied, the broker will ask for a closer price, and if the jobber is anxious to do business, will make a closer price, and the bargain is then made. A jobber's business requires special qualifications. It has been said that a jobber is born, not made. There is much truth in this. The most successful jobbers have a flair for the business. They must be men of good nerve, cool judgment, and ready to deal under any ordinary conditions. They must be men of financial standing, considerable experience, with an understanding of market psychology.

The number of members (1928) is nearly 4,000 and these employ about 2,000 clerks who have the right of entry to the house. The hours of business are nominally from 10.45 A.M. to 4 P.M. No bargains, however, are marked after 3.30 for inclusion in the lists published in the evening of the same day. Late bargains are marked and published the following day. During World War I and for some time after, it was compulsory to mark all bargains, but owing to pressure of business, this excellent rule was abolished. Bargains are to-day recorded at the option of dealers or on request by brokers for their clients. During the period of compulsory marking, the stock exchange had to issue a list of securities which were not included in the official list. This list is known as the supplementary list. Fortunately this continues to be published, though it is not so useful as it might be owing to optional marking. Since the war broke out no sessions have been held on a Saturday, and it seems unlikely that they will ever be resumed unless the public insistently demands it. This is improbable, for the reason that since 1914 Saturday has become to an increasing extent a day of clearing up. The banks have shortened their hours of work on a Saturday by closing at noon instead of at 1 o'clock, and this would have to be altered before the stock exchange would be justified in opening on a Saturday. The movement towards making Saturday more and more a holiday is the result of the increasing intensity of business. The motor car and the telephone make it possible to transact far more business in a day than was possible 30 years ago, and the hustle of modern business life renders more rest essential. Moreover, on the stock exchange great improvements in working practices have been introduced in recent years, and the efficiency of dealers' and brokers' staffs is much higher. The volume of work they transact in a day is far larger than before the war, the population of investors having enormously increased. Except in the gilt-edged market, every bargain a broker executes for his client is "for the account," unless otherwise specified. This means that the bargain will be completed—*i.e.,* the stock handed over and paid for—on the next settling day. The usual period of the account is a fortnight, but there are four 21-day accounts in the course of a year. Settling days are usually fixed for a Thursday, the passing of tickets—ticket day—takes place on a Tuesday, and making-up day is Monday, prices for the settlement of current securities being fixed at 11.30 A.M. Brokers on executing an order for a client send to him a contract note which sets forth the details of the transaction, the price obtained or to be paid, the amount of brokers' commission, of stamp and transfer fee, and the amount of the contract stamp. Later, as settlement day approaches, a further note is sent to a client who has bought stock, requesting him to forward the purchase money. In the case of a speculative transaction the same procedure is adopted, except that the client, if he has bought stock, is required not to pay the total purchase money, but merely the difference between the price which he gave and the price fixed on making-up day if the latter is lower than the former. If, however, the security has risen in price, the client receives a cheque for the difference between the price at which he bought and the making-up price. A rate of interest or contango, is charged for the facilities of buying and holding stock without paying for it. Contangoes vary in accordance with the current rate of interest. Usually they are higher on the more speculative securities than on the investment type. The rate of a contango is also affected by the state of the "open" account, as it is called, in a particular share.

If there is a large "bull" account—*i.e.,* a large number of speculative purchases for a rise—and dealers are anxious to discourage further buying, the contango may rise to 10% or more. Rates are generally lower on the more active shares and higher on the less active, which means that there are fewer people ready to carry the latter type of share. Shares in which the market is narrow and difficult, cannot be contangoed. Some speculators sell for a fall as well as buy for a rise. Facilities for technically lending shares to speculators who have sold them are also provided, and the rate of interest charged for lending stock is called "backwardation." This varies with the size of the "bear" account, as a speculative sale is called. If the "bull" account open in a stock is larger than the "bear," there will be a contango rate and no backwardation rate, and *vice versa.* Since World War I the facilities for carrying over bargains from account to account have been greatly reduced, but speculation has not diminished. The speculators have merely changed their methods. The banks, instead of lending money to members of the stock exchange as largely as formerly, for relending to their clients, now lend freely to their own customers on stock exchange collateral. This is a safer method, for a bank rarely allows its client to borrow more than he can repay. Another popular device of speculators is to gamble during one account only. If markets are rising, a speculator will buy at the beginning of an account and sell towards the end, and *vice versa.* Speculation is cheaper in this form, for by completing his operation in one account, the operator pays only one commission. During one of the periods of stock exchange depression before the war a movement was started and carried to a successful conclusion for fixing a scale of minimum commissions. It was fixed on a generous scale, for after the war little change was made in spite of the great increase in all other prices and costs. The inflation of capital values, of course, helped to swell considerably the volume of business.

(C. J. Mt.)

**New York.**—The New York Stock exchange is the principal organized securities market of the United States. It came into existence in 1792 and closely parallels, in its history, almost the entire course of the life of that country.

It was in the third year of George Washington's first administration that a few business men who traded in the securities of the day decided to appoint a place and a regular time for their meetings. New York city was then a small city, by today's standards. It had 40,000 people and occupied 5 sq.mi.
